The common names for PCB varied from country to country. In the United States they were called Aroclors, in France, Phenechlor, in Japan, Kaneclor, and in Russia, Sovol.⁴ PCB is the acronym for polychlorinated biphenyl. This name accurately depicts its chemical structure. Biphenyl is a compound consisting of two benzene (phenyl) rings connected by a single carbon-to-carbon bond. The polychlorinated modifier signifies that there is at least one or several chlorine atoms substituted at one or more of the ten carbons of the biphenyl backbone. The substitution of chlorine

on the biphenyl backbone leads to the nomenclature that is typical for the more than 100 congeners that are widely described in the literature (Figure 18.1).

There are actually 209 congeners that are theoretically possible from the base structure (Figure 18.1[a], Table 18.1). The congeners are designated individually with separate BZ numbers that were assigned by Ballschmitter and Zell in 1978.⁵ These congener assignments are broadly accepted today with only slight modification by the International Union of Pure and Applied Chemists.⁶

Of the possible 209 compounds, only about 100 to 150 are represented in formulations that have been used and are now widely dispersed in the environment. Besides the great numbers of different chemistries resulting from the varying chlorine substitutions (amounts and positions) that are shown in Table 18.1, there are also configurational variations, or atropisomers, within selected single congeners (nine unique pairs are possible). These configurational differences occur because of restricted rotations of the two phenyl groups when three or more *ortho*-substituted (two or six positions) chlorines are present. Each of the congeners having this property therefore exists in an enantiomeric pair. A prominent example of one of these atropisomers is BZ# 174 (Figure 18.1[b]). As they were synthesized, commercial PCBs had equal quantities of each member of the pair of these atropisomers; however, biological processes will usually degrade one form in preference to the other. Environmental chemists have begun to use measurements of PCB atropisomers in attempts to distinguish chemical from biological processing and to track environmental weathering.^{7,8,9}

18.1.2 PCDDs and PCDFs

Polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) are two related classes of aromatic heterocyclic compounds (Figure 18.2). In contrast to PCBs, PCDFs and PCDDs have no commercial use and are released into the environment as contaminants of chemical and combustion processes. The number of chlorine atoms can vary between one and eight, which allows for 75 PCDD and 135 PCDF positional isomers, respectively. The toxicity of PCDD/PCDF compounds is associated with substitution at the lateral (2,3,7, and 8) positions, and

Figure 18.2 Generalized structures for PCDDs and PCDFs.

the two compounds with all of these positions occupied — 2,3,7,8-TCDD and 2,3,7,8-TCDF — are extremely toxic to certain species of laboratory animals, particularly guinea pigs (LD_{50} approx. $1 \mu\text{g}/\text{kg}$).¹⁰ However, other species are considerably less sensitive to the two compounds, and consequently there is no clear consensus in the scientific community on the human toxicity of PCDD/PCDF compounds.¹¹

PCDD/PCDF compounds are thermally very stable, and extensive decomposition of 2,3,7,8-TCDD, the most toxic PCDD/PCDF compound, does not occur until temperatures exceed 750°C .¹² However, PCDDs and PCDFs do undergo electrophilic substitution reactions,¹³ and photochemical degradation occurs in both organic solvents¹⁴ and water.¹⁵ In the gas phase, reactions can occur between photochemically generated hydroxyl (OH) radicals and PCDDs/PCDFs.¹⁶ Since atmospheric PCDDs/PCDFs with six or fewer chlorines exist primarily in the vapor phase, the OH radical reactions could reduce the atmospheric concentrations of all PCDDs/PCDFs except for the hepta- and octaisomers. The 2,3,7,8-TCDD isomer has very low solubility in water, with a value of $20 \text{ ng}/\text{g}$ reported for dissolution from a thin film,¹⁷ and $483 \text{ ng}/\text{g}$ reported from generator column studies.¹⁸ As a consequence of its low water solubility, 2,3,7,8-TCDD has a very high carbon-based sediment partition coefficient, with a $\log K_{oc}$ value near 7.¹⁹

18.2 SOURCES AND PATHWAYS OF PCBs IN THE ENVIRONMENT

Important concerns for PCBs are their extensive release to the environment and their aquatic and terrestrial fates after release. PCBs are distributed throughout the world, a fact largely resulting from their considerable aquatic and atmospheric mobility. There is a great deal of literature on the environmental fate and properties of PCBs, including numerous books and special reports.^{4,20–26} Much of the concern about this group of chemicals arises from their extensive environmental occurrence and from numerous data indicating that members of this group of compounds may be carcinogenic²⁷ or may cause adverse endocrine and general reproductive effects.²⁸

Manufacturing sites that made extended use of the Aroclors as hydraulic fluids or that used them to manufacture electrical devices, especially transformers or fluorescent light ballasts, became the most common sites for environmental buildup. For example, die-casting equipment used great quantities of hydraulic fluids in the pressing out of metal parts for automobiles and related industries. Also, the electrical industries, especially those assembling capacitors and transformers, employed large amounts of the Aroclors as an insulating fluid. Therefore, areas where these facilities occurred, e.g., the Northeast and heavy manufacturing regions in Michigan, Wisconsin, and Illinois, became regions for major PCB buildup. Examples of documented hotspots are the General Electric Plant in Glens Falls, NY;²⁹ a die-casting operation on the North Branch of the Shiawasee River;³⁰ electronic manufacturing facilities in New Bedford Harbor;³¹ and an automobile foundry and an aluminum manufacturing plant on the St. Lawrence River.³² There also were specialized uses for PCBs that led to localized buildups. One of these uses was for carbonless paper, and buildups occurred at locations where these papers were deinked and recycled for reuse, e.g., Kalamazoo River, Kalamazoo, MI had several plants in the city and downstream,³³ and there were also plants along the lower Fox River in Wisconsin.³⁴ As further evidence for this manufacturing localization

for PCB contamination, it is noteworthy that even 20 years after cessation of their use, these same areas are now recognized as regions for PCB fishing advisories across the United States³⁵ — the Northeast, the upper Midwest, and coastal regions near population centers.

With the 1979 U.S. ban, it can now be safely said that most direct sources of PCB releases to surface waters and air have ceased, except for the occasional spills or the increasingly less frequent acts of illegal disposal or dumping.

18.2.1 Release of PCBs into the Environment

The primary emission of PCBs into the environment occurs through release to water, with maximum wildlife and human exposure occurring directly or indirectly through aqueous systems. Atmospheric processes are secondary in terms of immediate exposure, even though geographic dispersion through the atmosphere is most likely greater.

18.2.1.1 Emission of PCBs into Water

Past discharge into rivers and streams has led to significant dispersion of, and exposure to, PCBs. Fortunately, however, most of these direct discharges have ceased, and exposures in aquatic systems generally center around past deposits that reside in sediments. Many of the sites identified in the Great Lakes as “areas of concern” by the U.S./Canadian Great Lakes Water Quality Agreement³⁶ have this designation because of PCB buildup in their sediments (more than 70% of the 42 sites). Considerable debate continues on the relative merits/costs of dredging these and other areas to reduce exposure from these deposits. Two notable examples of high sediment buildup of PCBs are the Hudson River³⁷ and New Bedford Harbor.³⁸ The high level of PCBs in the sediment of the Upper Hudson River site remains from earlier industrial practices that, at the time, were considered acceptable.³⁹ There are several case studies that could be presented to describe the environmental fate and distribution of PCBs in aqueous systems. One of the most extensively documented is indeed the Hudson River PCB problem.^{39,40} Among areas, the PCB spill in Duwamish Harbor in Seattle is of historical interest, as it has long since been corrected.⁴¹ Another more recent focus is an effort underway⁴² to define the extent of PCB contamination in Baltimore Harbor.

Some areas have undergone dredging as a mitigative strategy, with sampling built in as a check for improvement in the systems.^{30,43} New Bedford Harbor is an estuary severely contaminated with PCBs. It has undergone a multistage Superfund remediation involving a long-term monitoring program. Based on this monitoring, it was found that the major redistributions of contaminated sediments were confined to the immediate vicinity of remedial activities; however, there was evidence that low-molecular-weight PCBs were transported farther.^{34,44} In another study by Bremle and co-workers,⁴⁵ in which suction dredging was performed on a small Swedish lake, it was determined that 97% of the PCB-contaminated sediment was removed, and little excess PCB was released as a result of the dredging. This may have been aided by the use of a geotextile silt curtain that reduced leakage of PCB to the river downstream. In the early assessment process to determine options to remediate the PCB buildup in the Hudson River, separate sediment transport and resuspension studies were carried out to determine the degree of remobilization of PCBs that might take place during dredging (Tofflemire 1984, as cited in Final Environmental Impact Statement on the Hudson River PCB Reclamation Demonstration Project⁴⁶). Losses were found to be negligible.

18.2.1.2 Emissions of PCBs into the Atmosphere

While the quantities mobilized through the air are likely similar to losses to aqueous systems, dispersion and dilution into the atmosphere are much more extensive and rapid. The impacts from air dispersion, however, are less obvious than in the aqueous situation. Atmospheric processes are clearly responsible for significant dispersion of PCBs to large isolated waterbodies like the Great

Lakes,⁴⁷⁻⁵⁰ Lake Baikal,^{51,52} and most of the marine portions of the Arctic.^{53,54} Furthermore, it has been repeatedly documented that there is a general trend of atmospheric movement of the more volatile components of the Aroclor mixes to colder areas of the world.⁵⁵

Rather than atmospheric emissions emitting directly from source areas, as was the case in the 1960s and 1970s, today's atmospheric levels originate predominantly from recycling of past atmospheric deposits. This recycling tends to maintain higher concentrations in these areas, preventing levels from declining as quickly as was observed right after sources were cut off in the late 1960s.⁵⁶ Studies of current atmospheric emission have concluded that reprocessing of soil-sorbed PCBs is a major contributor to loading in urban/industrial areas. Local hot spots will also contribute to these loads; however, estimates using known hot spots vs. general recycling have been carried out in London, and these hot-spot contributions were determined to be rather insignificant.⁵⁷

Indoor levels of PCBs are generally much higher ($0.3 \mu\text{g}/\text{m}^3$) than levels measured in outdoor air ($0.004 \mu\text{g}/\text{m}^3$).⁵⁸ PCB concentrations were measured in the indoor air of several public buildings in Bloomington, IN.⁵⁹ The concentrations were 5 to 300 times higher than outdoor concentrations, and the indoor-air PCB levels were highest in buildings having the earliest construction dates. Indoor air ventilation systems were found to be a short-range source, governed by factors such as the building ventilation rate, and it was hypothesized that this building release even constituted a principal source of tri- and tetrachlorinated PCBs at a Birmingham sampling site.⁶⁰ Much of the explanation for higher levels in indoor air appears to be linked to the extensive use of fluorescent light ballasts in the past, especially in schools, office buildings, and institutional building, such as hospitals. Each of these ballasts contains approximately 1.6 kg of PCBs. Many of these ballasts can still be found in use even today.⁶¹

18.2.2 Aquatic and Terrestrial Fate of PCBs

18.2.2.1 Biaccumulation Pathways of PCBs

PCBs are noted for their tendency to bioaccumulate in aquatic and terrestrial organisms. This characteristic can be depicted by characterizing processes involved in the pharmacokinetics of exposed experimental animals.⁶² Matthews and Dedrick⁶² reviewed this subject and reported their findings for one study in which specific congeners were applied to rats, and the exact chemistry of the compounds and their distribution were carefully followed (Table 18.2). Other rodent studies have shown similar trends for intrabody distribution of PCBs. Notice in Table 18.2 that the more

lipophilic 5/6-chlorobiphenyls tend to preferentially bioconcentrate in fatty tissues (adipose tissue and skin), whereas the more polar members, especially the polar metabolites, tend to show up in the hydrophilic cell tissues/compartments. Note also that the size of the clearance rate constant (K_m) is structure-dependent; e.g., the K_m for CB-1 is 10, while the values decrease as the chlorine content increases.

In addition to the gross structural character of the molecule that is established by chlorine content, position of the chlorines on the ring also affects distribution and persistence within organisms. For example among the four hexachlorobiphenyls 2,2',3,3',5,5'-; 2,2',3,3',6,6'-; 2,2',4,4',5,5'-; and 2,2',4,4',6,6', the 2,2',3,3',6,6' was eliminated and metabolized more rapidly than were the other three. This was due to the fact that the 4,5 unsubstituted carbons of this congener were not present in the others. In another set of tests, a group of 6-CBs with no *ortho* and only one *ortho* (2 position) was administered. Levels tested after 29 days showed that there were marked differences in retention of these compounds depending on the animal species (fat levels were higher in the mammalian species than in trout and quail): 8.27, 6.84, and 4.74 in the rat, rabbit, and guinea pig, respectively, vs. 3.02 and 2.15, respectively, in trout and Japanese quail. Furthermore, structure also contributed to variations in retention. The quail retained only the non*ortho* congeners; this was true even when low levels were tested. Rabbits retained the highest levels of the di-*ortho* and mono-*ortho* compounds. Fish retained fairly even amounts of all the components and at lower levels of all of the congeners than for the other organisms.

18.2.2.1.1 Aquatic Bioaccumulative Processes of PCBs

The aquatic bioaccumulative fate of PCBs has been studied in several ecosystem types and over numerous food-chain pathways. Several examples to support bioaccumulation can be cited. All of these, however, suffer from lack of control of all of the input parameters and also control as the tiers increase. A dramatic example was described by Safe⁶³ for the Lake Ontario ecosystem. The chain was depicted to start with water at 0.05 ng/g PCB, then progressing through sediment (150 ng/g) to plankton (1880 ng/g) to catfish at 11,580 ng/g to finally the herring gull at 3,530,000 ng/g. Laboratory studies can overcome the lack of input accountability in environmental examples; however, transferring these findings to the field situation is difficult. Eisler⁶⁴ provided a relevant review of information on how the sublethal effects of PCBs on aquatic organisms are linked to their high bioaccumulation potential. Briefly, he demonstrated that the high potential for bioaccumulation of PCBs by aquatic organisms is due to their intimate exposure to these compounds and to the highly lipophilic nature of PCBs, causing them to accumulate in the fatty tissues of these organisms.

Bioconcentration factors are used to express this bioaccumulation tendency. Gobas⁶⁵ provides an excellent treatise on distinguishing bioaccumulation factors (BAFs) from bioconcentration factors (BCFs) for PCBs based on 1984 data that he and his co-workers generated for individual PCB congeners.⁶⁶ The typical values increase by a factor of 10- to 100-fold when ascending major consumption levels in a food chain, i.e., from algae to fish to birds. Depuration of accumulated PCBs is slow. In fish, egg maturation and spawning can, however, result in significant reduction in the body burden of persistent PCBs such as 2,5,2',5'-tetrachloro-biphenyl.⁶⁷

It is largely the bioaccumulative property of PCBs that has caused them to be identified as ubiquitous contaminants. The chemicals tend to concentrate in fatty organisms that often reside at the peak of food chains. Such food chains are especially common in arctic climates, where fats are the most efficient and common means of energy storage. PCBs are found in nearly all marine plant and animal species, fish, mammals, birds (especially fish-eating birds), and, of course humans. Wassermann and co-workers⁶⁸ published an extensive review of PCBs in animals that, with the exception of the highest values, is still generally valid today. Specifically, they reported that for marine food webs, zooplankton range from < 0.003 µg/g to 1 µg/g, whereas top consumers, such as seals and fish, had ranges of PCB from 0.03 to 212 µg/g. Moessner and Ballschmiter⁶⁹ monitored

seven indicator congeners of the polychlorinated biphenyls (PCB # 28, 52, 101, 118, 138, 153, and 180) in marine mammals that differed in their geographic distributions. They found that animals from the western North Atlantic were contaminated at levels that were about 15 times higher than for animals from the eastern North Pacific and the Bering Sea/Arctic Ocean.

18.2.2.1.2 Terrestrial Biaccumulative Processes of PCBs

The terrestrial biaccumulative fate of PCBs is less studied, largely because levels tend to be lower and concern for exposure is less than for aquatic organisms. The lower accumulation in terrestrial organisms is believed to be a function of food chains that are shorter than those in aquatic environments.⁵⁴ Levels in terrestrial biota can reach high levels in organisms near PCB landfill sites⁷⁰ or in terrestrial communities neighboring regions of high aqueous buildup. For example, for eagles were studied in the Great Lakes region; those nearest the lakes had notably higher levels than those farther inland.⁷¹ Also, tree swallows living near the shores of the Hudson River had higher PCB levels than those from river sites more distant from known PCB pollution.⁷²

The most extensive and detailed studies of terrestrial transfer of PCBs exist for the Arctic⁷³ (several studies were summarized in the AMAP, Assessment Report, Arctic Pollution Issues⁵⁴). Extensive study of caribou and reindeer revealed that, even though concentrations of the PCBs were substantially lower in tissues of these terrestrial herbivores than in marine mammals collected from nearby areas, the importance of these herbivores to the native diets in the Arctic makes this route for human exposure one for concern.⁵⁴ Levels of PCBs were higher (~twofold) in Russian reindeer (20 ng/g wet weight) than in Canadian caribou. Elkin and co-workers⁷⁴ provided an example of a food-chain transfer by way of caribou in the Northwest Territory of Canada; the transfer was from lichens to caribou to wolves. The pattern of congeners changed as the mixture of PCBs was transferred. The food-chain buildup is obvious, with levels reaching a maximum of about 50 ng/g lipid weight in the wolf, after starting around 0.4 ng/g dry weight for the lichens. The congener shift observed with caribou was similar to that observed by Muir and co-workers⁷⁵ in marine organisms — fish to seal to polar bear.

Accumulation of PCBs by dairy cows has been studied by several investigators.^{76–79} Thomas and co-workers⁷⁸ described the distribution fate of PCBs in cows with a concern for terrestrial exposure through forage and consumption. They developed a model that incorporates degradation, especially for the readily metabolized congeners (e.g., BZ#33). Calamari and co-workers⁸⁰ studied plant uptake of PCBs and used this as a measure of the geographic distribution of PCBs. Hermanson and Hites⁸¹ looked at uptake by bark as a means of describing geographic distribution of PCBs and other hydrophobic pollutants.

18.2.2.2 Abiotic Dispersal of PCBs

The fate and dispersion of PCBs is greatly influenced by abiotic dispersion processes, volatility, solubility, particle sorption, etc. and these are all important and interactive processes ongoing in the atmospheric and aquatic systems that are the major reservoirs for the world's inventory of PCBs. The concept of inventories is important for an understanding of where likely exposure will occur. One such inventory was conducted by the National Academy of Science in the early 1980s.²¹ The accessible PCBs were defined as residing in the mobile environmental reservoir (MER). A major objective of these early assessments was to attempt to balance what was produced with where it had come to rest and to determine how much was still available to contaminate the environment. Much of the existing PCBs at that time (1977) were still in commerce, in storage awaiting destruction, or in reservoirs that were considered inaccessible (landfills, deep sediment, or degraded). Tanabe,⁸² using updated information (1987 data), performed a similar exercise and calculated the global distribution of available PCB. Despite the passage of 10 years between the two estimates, there was remarkable similarity between them (Figure 18.3). Tanabe further indi-

Figure 18.3 Global distribution of environmentally available PCB, as estimated by Tanabe.⁸²

cated the need for increased concern for the marine mammals that would be receiving the greatest exposure according to these predictions. Most recent inventories for PCBs have been developed for specific regions of the country. Harrad and co-workers⁵⁷ describe the present United Kingdom environmental levels of PCBs. Only 1% of the amount of PCBs sold in the United Kingdom since 1954 was found to still be present in the U.K. environment. Across the range of congeners, persistence increased with increasing chlorination. The major loss mechanism for PCBs was advection, atmospheric or pelagic, transport from the United Kingdom. There was a dramatic fall in levels in archived soils and vegetation between the mid-1960s and the present. Ninety-three percent of the contemporary U.K. burden is associated with soils, with 3.5% in seawater and 2.1% in marine sediment. Freshwater sediments, vegetation, humans, and sewage sludge combined to account for only 1.4% of the present burden, and PCB loadings in air and freshwater were insignificant. The major loss pathway from the United Kingdom is atmospheric, with sources feeding this atmospheric advection as follows: volatilization from soils (88.1%), leaks from large capacitors (8.5%), production of refuse-derived fuel (RDF) (2.2%), leaks from transformers (0.6%), recovery of contaminated scrap metal (0.5%), and volatilization from sewage sludge-amended land (0.2%).⁵⁷

18.2.2.2.1 Atmospheric Dispersal of PCBs

The air concentrations of PCBs and other chemicals play an important role in the deposition of these chemicals in terrestrial ecosystems (on leaves/needles, grass, soil).^{57,83} Long-range overland transport of PCBs is critically linked to atmospheric routes of exposure; this mechanism was clearly demonstrated for transport of PCBs in Canadian lakes by Muir and co-workers.⁸⁴ The conclusion from this study was that atmospheric movement northward, and subsequent fractionation by volatility, led to selective changes in the PCB profile in the liver of burbot that inhabited these lakes. The PCB profiles progressed from a preponderance of heavier (less volatile) to lighter (more volatile) PCB homologs in the burbot livers in lakes dispersed with increasing latitudes north.

The importance of atmospheric processes for dispersal of PCBs has been established on a global scale.^{56,85,80} Higher levels occur downwind of known sources, e.g., the Chicago plume⁸⁶ and landfill

sources.⁸⁷ Considerable data, especially on the Great Lakes, have been recorded to indicate that PCBs will exchange across the air/water interface^{88,89} and that this process is controlled by temperature, mass balance levels in the air and water, and wind speed.⁹⁰ Actually, realization of this process has helped greatly towards reconciling the amount of PCB that could be accounted for by measurements in sediment and water column of the Great Lakes with the predicted amounts based on loadings. Realization of a reverse flux, i.e., gaseous losses out of the water column, has allowed researchers to account for the imbalance in their previous estimates and provided a means for mass balance estimates that include dynamic exchange of PCBs as gases across the air/water interface.

The best predictive chemical constant for describing these fluxes is the compounds' Henry's Law constant (air–water partition coefficient); H-values have been calculated for a considerable number of PCB congeners. Typical values for the estimated Henry's Law constants for Aroclors indicate that water-to-air degassing can be a significant environmental transport process for PCBs when they are in disequilibrium in water vs. overlying air, especially when water temperatures are high and air concentrations are low, e.g., during autumn over the Great Lakes.⁹⁰ Reported H-values for the Aroclor mixtures 1242 and 1260, respectively, were 58.5 and 731 Pa m³/mol.⁹¹ Burkhard and co-workers⁹² developed a method by which to estimate H-values for the congeners; their estimated values compared favorably with the limited measured values that were available previously. A recent review of H-values for all 209 of the PCB congeners⁹³ indicates that there is wide range in values (varying from 160 Pa m³/mol for BZ#9, a dichlorobiphenyl, to 1.00 Pa m³/mol for BZ#199, which is an octochlorobiphenyl). Bamford and co-workers⁹⁴ recently generated measured H-values for 26 congeners, including direct measurements for their changing values as functions of temperature (–3 to 31°C). This is an important property to consider, especially for environmental modeling.

Wania and Mackay⁵⁵ described the relative mobility of PCB homologs on a global scale by using vapor pressure and log octanol–air partition coefficients of PCBs. They grouped PCBs into four categories based on the relative mobilities of the PCBs to move away from sources and toward the poles. These groupings were: 0 to 1 Cl (highly mobile worldwide/no deposition), 1 to 4 Cl (relatively high mobility/deposition in polar latitudes), 4 to 8 Cl (relatively low mobility/deposition in mid-latitudes), and 8 to 9 Cl (low mobility/deposition close to source).

Model predictions of the concentration of PCBs in air can be made by knowing the slope of the log vapor pressure vs. inverse temperature curve (Antoine equation) as well as the expected air concentrations of particulate matter.⁹⁵ It has been shown by other researchers that atmospheric PCB concentrations, which are only weakly dependent on transport paths, are strongly dependent on temperature because of the vapor pressures of the compound.⁹⁶

The major source of PCBs to vegetation is transfer of vapor-phase PCBs from air to the aerial aboveground portions of the plants.⁹⁷ Harner and co-workers⁹⁸ measured atmospheric PCBs near hazardous waste sites that were greater than background. Their conclusion was that PCBs were being emitted from the soils near these sites where previous deposition had occurred. Also, losses from moist soil are greater than from dry soil, due to stronger soil binding in the absence of water.⁹⁹

18.2.2.2.2 Aquatic Dispersal of PCBs

Abiotic-mediated movement and fate of PCBs in aquatic systems has been monitored extensively and in every conceivable situation: open ocean,^{100,101} rivers (see numerous references cited throughout text), large lakes (Lake Baikal,^{56,102,51} Great Lakes⁴⁸), small arctic lakes,¹⁰³ and embayments and estuaries.^{41,104,44}

In water, adsorption to sediment or other organic matter is a major PCB removal process. Experimental and monitoring data have shown that PCB concentrations are higher in sediment and suspended matter than in the associated water column. The low water solubility and, therefore, resulting high octanol–water partition coefficients (expressed by the log K_{ow}) range from 4.5 to 8.1 for individual PCB congeners¹⁰⁵ and result in a strong adsorption to soils and sediments, suggesting that leaching should not occur in soil under most conditions. If leaching does occur, it will be

Table 18.3 Ranges of Physicochemical Properties of Polychlorobiphenyls (C₁₂H_{10-n}Cl_n)

Homolog Group	Molecular Weight (µg/L)	Solubility (Pa) 20°	Vapor Pressure	Log K _{ow}
Monochloro-	188.7	1.3×10^3 – 7×10^3	2.2×10^3 – 9.2×10^2	4.6–4.7
Dichloro-	223.1	0.6×10^2 – 7.9×10^2	3.7×10^2 – 7.5×10	5.2–5.3
Trichloro-	257.6	0.1×10^2 – 6.4×10^2	1.1×10^2 – 1.3×10	5.7–6.1
Tetrachloro-	292.0	0.2×10^2 – 1.7×10^2	1.8–4	5.9–6.7
Pentachloro-	326.4	4.5–12	5.3–0.88	6.4–7.5
Hexachloro-	360.9	0.4–0.9	1.9–0.2	6.4–7.6
Heptachloro-	395.3	0.5	0.53 – 4.8×10^{-2}	7.0–7.7
Octachloro-	429.8	0.2–0.3	7.8×10^{-2} – 9×10^{-3}	7.0–7.6
Nonachloro-	464.2	0.1	3.2×10^{-2} – 1.1×10^{-2}	7.7–7.9
Decachloro-	498.7	0.02	5.6×10^{-3}	8.4

Source: Ballschmiter, K. et al., in *Halogenated Biphenyls, Terphenyls, Naphthalenes, Dibenzodioxins and Related Products*, Kimbrough, R.D. and Jensen, A.A., Eds., Elsevier, Amsterdam, 1989. With permission.

greatest for the least-chlorinated congeners. These trends in physical properties are apparent in Table 18.3.

Although adsorption and subsequent sedimentation may immobilize PCBs for relatively long periods of time in aquatic systems, redissolution into the water column has been shown to occur. The substantial quantities of PCBs contained in aquatic sediments can therefore act as a reservoir from which PCBs may be released over long periods of time. Since sorption to soil is proportional to the soil's organic carbon content,^{107,108} leaching or loss is expected to be greatest from soils with low organic carbon.

An interesting discovery in remote pristine lakes in the arctic was the differentiation of atmospheric loading from biotransported PCBs. Grayling were monitored to measure background levels in the water. One grayling population was in a salmon-spawning lake, and the other in a nearby lake without salmon and receiving pollutants only via atmospheric deposition. The grayling in the salmon-spawning lake had concentrations of PCBs more than twofold higher than those in the grayling in the salmon-free lake, and the pollutant composition resembled that found in salmon.¹⁰³

18.2.3 PCB Removal Processes

Significant removal of PCBs from the MER can occur through natural processes. One process in the aquatic system is simple physical removal due to sediment burial. However, permanent removal by degradation is the preferred method for ultimate protection of the environment. Chemical degradation in natural systems is minimal,¹⁰⁹ except for photolysis. Anderson and Hites¹¹⁰ measured hydroxyl radical degradation as it occurs during photolytic exposure. They estimated half-lives ranging from 2 to 34 days for several PCB congeners. Atkinson¹¹¹ reviewed the literature on the atmospheric chemistry of PCBs and verified that losses due to photolysis can be high. Tropospheric half-lives due to hydroxyl radical removal were listed as follows: mono-, 3.5 to 7.6 days; di-, 5.5 to 11.8 days; tri-, 9.7 to 20.8 days; tetra-, 17.3 to 41.6 days; and penta-, 41.6 to 83.2 days.

Biological degradation is slow, according to most studies performed over a wide range of organisms including higher animals, plants, and several microbial systems. PCBs are very resistant to biological transformation — one of the very features of the group that made them useful in commerce. In spite of the abundant evidence for PCBs' ability to resist biological degradation, much study has gone into attempting to isolate a "bug" or consortium of bugs that will magically clean up the numerous hot spots of PCB known to exist in the environment.^{112, 113}

18.2.3.1 Biological Degradation of PCBs

Metabolism of PCBs by biological systems has been studied extensively. Several reviews of this subject are available.^{62,114–116} Invariably, the phenolic products are the major PCB metabolites,

although sulfur-containing metabolites (sulfones), *trans* dihydrols, polyhydroxylated PCBs, and their methyl–ether derivatives and ring-degraded microbial oxidation products have been identified. The effects of chlorine substitution patterns on oxidative breakdown seem to fall into the following patterns:¹¹⁴

1. Hydroxylation is favored at the *para* position in the least-chlorinated phenyl ring, unless this site is sterically hindered.
2. In the less-chlorinated biphenyls, the *para* position of both biphenyl rings and the carbon that is *para* to the chlorine are all readily hydroxylated.
3. The availability of two vicinal unsubstituted carbon atoms (particularly C-5 and C-4 in the biphenyl nucleus) also facilitates oxidative metabolism of the PCB substrate, but it is not a necessary requirement for metabolism.
4. As the degree of chlorination increases on both phenyl rings, the rate of oxidative metabolism decreases.
5. The metabolism of specific PCB isomers by different species can result in considerable variations in metabolite distribution. Most PCB congeners, particularly those lacking adjacent unsubstituted positions on the biphenyl rings (2,4,5-, 2,3,5-, or 2,3,6- substituted on both rings), are extremely persistent in the environment.

Harner and co-workers⁹⁸ have suggested that microbial degradation half-lives on the order of 10 years are possible; however, the actual values are likely congener-specific and are also a function of concentration and microbial condition in the soil. Biodegradation of PCBs in sediment can occur under both aerobic¹¹⁷ and anaerobic¹¹⁸ conditions. Biodegradation rates are highly variable because they depend on a number of factors, including the amount of chlorination, concentration, type of microbial population, available nutrients, and temperature. Results show, however, that under aerobic conditions, mono-, di-, and trichlorinated biphenyls generally biodegrade relatively fast; tetrachlorinated biphenyls generally biodegrade slowly; and the more highly chlorinated biphenyls generally resist biodegradation.

Studies of subsurface anaerobic biodegradation of aquatic sediment show that the pattern of congener reactivity is determined by two main factors — reductive potential of the system and molecular shape of the PCBs. PCBs containing chlorines in the *para* positions are preferentially biodegraded, compared to PCBs containing chlorines in other ring positions,¹¹⁹ and meta chlorines appear to be preferentially lost. Studies from spill sites also show that the highly chlorinated congeners are biotransformed by a reductive dechlorination to less-chlorinated PCBs, which are biodegradable by aerobic processes.^{120,121} For highly chlorinated PCBs that have been shown to dechlorinate naturally in anaerobic sediments, there appears to be a concentration threshold (10 µg/g dry weight) below which this anaerobic process will not start.^{118,119}

Biodegradation is probably the ultimate loss process for PCBs in sediments (at least in surficial zones); however, diagenesis experiments in deeper sediments need to be carried out in order to assess the lifetime of PCBs that are deeply buried. Biodegradation in soils with high organic carbon content is slower than in less organic-carbon-enriched soils.¹²²

18.3 SOURCES AND PATHWAYS OF PCDDs AND PCDFs IN THE ENVIRONMENT

18.3.1 Release of PCDDs and PCDFs into the Environment

18.3.1.1 Emission of PCDDs and PCDFs into Water

PCDDs and PCDFs are formed as by-products in several chemical manufacturing processes. In the case of PCBs, a PCDF molecule can be formed by ring closure of a PCB molecule in the

presence of oxygen. While industrialized countries ceased producing PCBs in the 1970s, PCDF concentrations in commercial PCB formulations used prior to that time were reported to range from less than 1 mg/kg to more than 10 mg/kg.¹²³⁻¹²⁵ PCBs were used primarily as dielectric fluids in transformers and capacitors (see section on PCBs above), and additional formation of PCDFs has been found to occur in catastrophic events such as arcs and electrical fires, with concentrations of total PCDFs as high as 2000 mg/kg on soot particles from PCB fires.¹²⁶ Certain dielectric fluids also contain chlorobenzenes (CBs) in addition to PCBs. While the CBs can also be converted to PCDDs by catastrophic events, the reaction is bimolecular, and therefore the PCDD concentrations are two orders of magnitude lower than the PCDF concentrations.

Emissions into the aquatic environment from PCB fires can be controlled, and any contamination is usually confined to a small area. In contrast, operations associated with the manufacturing and servicing of electrical equipment or with the improper disposal of capacitors and transformers have resulted in more widespread contamination of the aquatic environment by both PCDFs and PCBs.

Chlorophenols (CPs) are contaminated with PCDDs/PCDFs, and the manufacture and utilization of these compounds have resulted in the release of PCDDs/PCDFs into the aquatic environment. Pentachlorophenol (PCP) has been widely used as a fungicide and insecticide in the wood-products industry, and 2,4,5-trichlorophenol (TCP) was used as the precursor of the herbicide 2,4,5-T. At one time, 2,4,5-T was used extensively in the United States and other industrialized countries as a herbicide on grasslands where cattle and sheep were grazed, on rice-growing fields, in the control of deciduous species in conifer forests, and along roadsides. The toxic 2,3,7,8-TCDD is the major PCDD/PCDF contaminant in 2,4,5-T, and concentrations exceeding 10 mg/kg were found in certain 2,4,5-T formulations produced between 1966 and 1970.¹²⁷ However, these were unusually high concentrations, since most 2,4,5-T formulations produced in the 1960s did not contain 2,3,7,8-TCDD concentrations greater than 0.2 mg/kg.^{128,129}

The production of PCP in the United States was 20 million kg in 1976 and 14.5 million kg in Japan in 1966.¹³⁰ After 1971, production ceased in Japan, but the compound is still produced at one plant in the United States. There are no production figures available for Europe. Results from a number of studies have shown that mg/kg concentrations of hexa-, hepta- and octa-CDDs and CDFs are present in commercial formulations of PCP, with reported concentrations varying over several orders of magnitude.¹³¹ One manufacturer produced a purified PCP formulation that contained less than 25 mg/kg of total PCDD/PCDF compounds.¹³² The toxic properties of the PCDD/PCDF compounds in PCP can be attributed to the presence of 1,2,3,6,7,8-hexa CDD. This isomer accounts for nearly 50% of the total hexa CDD concentration in some PCP formulations.¹³²

The PCDD/PCDF compounds associated with CPs can be released into water either during manufacturing operations or during the use of the products. Sediments in the vicinity of many chlorophenol-manufacturing plants in the United States and Europe have become contaminated with PCDD/PCDF compounds. A plant situated on the Passaic River 3 km upstream from Newark Bay produced approximately 15 million tons of 2,4,5-T between 1948 and 1969. Sediment samples collected from different locations were dated by radiochemical methods and were analyzed for tetra-, hepta- and octa-CDDs and CDFs.¹⁴ Immediately outside the plant a sediment core section from the mid-1960s was contaminated with 7600 pg/g of 2,3,7,8-TCDD, whereas a 1985 section from the same core had a 2,3,7,8-TCDD concentration of 730 pg/g (all sediment concentrations of PCDDs/PCDFs reported in this subsection are expressed on a dry-weight basis). Samples taken further downstream in Newark Bay and in New York Harbor had considerably lower concentrations of 2,3,7,8-TCDD but were contaminated with PCDDs/PCDFs whose patterns were statistically associated with other sources of contamination.¹³⁴

While the utilization of 2,4,5-T has undoubtedly contributed to 2,3,7,8-TCDD contamination in the aquatic environment, it is generally not possible to determine the point sources for this contamination. However, it is possible to determine aquatic contamination by PCDD/PCDF compounds from facilities where wood is treated with PCP. In a wood treatment plant in Pensacola, Florida, that was closed in 1981, it was found in 1984 that sludge and sediments from wastewater

impoundments were contaminated with total hexa- to octa-CDD concentrations of 49 and 105 mg/kg, respectively.¹³⁵ It was found by taking soil samples at 0.3 and 0.6 m depths that subsurface migration had occurred, with total PCDD concentrations decreasing from 1.1 mg/kg near the impoundment site to 9.9 ng/g at a distance of 275 m from the site. Sediments collected in the harbor of Thunder Bay, Ontario, near a wood-treatment plant also showed evidence of PCDD/PCDF contamination, with a maximum level of 1.3 ng/g.¹³⁶

In 1985, during the course of the U.S. EPA National Dioxin Study, a comprehensive study on PCDD/PCDF contamination in the United States, it was discovered that fish collected downstream from pulp and paper mills that used the kraft process were contaminated with 2,3,7,8-TCDD.¹³⁷

Subsequent investigations showed that the PCDD/PCDF compounds were primarily formed during the chlorination stage of the pulp-bleaching process.^{138,139} Only a small number of isomers were formed, with 2,3,7,8-TCDF as the dominant isomer, followed by either 2,3,7,8-TCDD or octa CDD.^{140,141} These results are consistent with a mechanism of direct chlorination of dibenzo-*p*-dioxin (DD) and dibenzofuran (DF). It was shown that both DD and DF were present at ng/g levels in petroleum-based defoaming agents formerly used in pulp processing.¹⁴² However, the PCDD/PCDF compounds must also have been formed by other reaction mechanisms, since lignin from which all low-molecular-weight compounds had been removed by methanol extraction formed the PCDD/PCDF compounds in the presence of chlorine.¹³⁹ Based on a study of 104 pulp and paper mills in the United States, it was found that the average export of 2,3,7,8-TCDD from a mill site was uniformly distributed in three media: pulp 38%, effluent 29%, and sludge 33%.¹⁴³ For the kraft mills involved in the study, mean concentrations of 2,3,7,8-TCDF in softwood pulp, effluent, and sludge were 137, 0.5, and 806 pg/g, respectively, and mean concentrations of 2,3,7,8-TCDD in the same media were 12, 0.06, and 95 pg/g, respectively. Comparable concentrations of the two analytes were found in the effluents of Canadian pulp and paper mills.¹⁴¹ In the 1990s, defoaming agents containing PCDD/PCDF precursors were eliminated, and steps were taken to replace chlorine as a bleaching agent by other products, primarily chlorine dioxide. Studies conducted in Canada have shown that these process changes have resulted in > 90% reduction in the levels of 2,3,7,8-TCDF and 2,3,7,8-TCDD discharged to the environment from pulp and paper mills.^{144–146}

The sludges from pulp and paper mills are frequently used for the fertilization of agricultural lands and therefore can serve as a source of PCDD/PCDF contamination for both terrestrial and aquatic environments. Sludge from sewage treatment plants is frequently used for the same purpose, and results from several investigations have shown that the sewage sludges from industrialized countries are contaminated with PCDD/PCDF compounds, primarily hepta-CDDs and octa-CDD.^{147,148} There has been a trend toward decreasing concentrations over time, with current mean PCDD/PCDF concentration in sewage sludges from Catalonia, Spain of 55 pg I-TEQ/g (International Toxic Equivalents¹⁴⁹), compared to 620 pg I-TEQ/g in the period from 1979 to 1987.¹⁴⁷ For a full discussion of TEQ (dioxin-like toxicity, toxicity equivalency factors and toxicity equivalents), see Section 18.6, Effects of PCBs, PCDDs, and PCDFs.

A predominant source of the PCDD/PCDF compounds in sewage sludge has not been identified. However, there is evidence from the United Kingdom to suggest that combustion and PCP may be major sources of PCDDs/PCDFs in sewage sludges.¹⁴⁸ Furthermore, a study conducted in Germany showed that household wastewater from the washing of PCP-treated textiles contributed between 27 and 94% of the PCDDs/PCDFs in sewage sludge from a nonindustrial area.¹⁴⁷ Additional sources of PCDDs/PCDFs in sewage sludge are textile dyes and formation from precursors during sludge digestion.

Precursor compounds with structures closely related to PCDD/PCDF compounds are present in the chemical processes described above. However, virtually every chemical process in which there is a source of carbon and chlorine has the potential to produce PCDD/PCDF compounds, with the concentrations decreasing as the structures of the precursor compounds deviate from PCDD/PCDF structures. It was found in 1974 that commercial preparations of hexachlorobenzene were contaminated with octa-CDF (0.4–58 mg/kg) and octa-CDD (0.05–212 mg/kg).¹⁵⁰ Only traces

(pg/g) of PCDD/PCDF compounds were found in commercial preparations of short-chain chlorinated hydrocarbons.¹⁵¹ However, these compounds have low boiling points, and high PCDD/PCDF concentrations were found in sediments near waste-discharge points from a vinyl chloride monomer plant in Finland.¹⁵²

18.3.1.2 Emissions of PCDDs and PCDFs into the Atmosphere

It was originally considered that PCDD/PCDF compounds were only formed as by-products in the manufacture of chlorinated aromatic chemicals. However, in 1977, PCDD/PCDF compounds were found in the flue gases from several municipal incinerators in the Netherlands.¹⁵³ A study carried out in 1978 showed that PCDD/PCDF compounds were present in cigarette smoke and in particulate matter from chemical and municipal waste incinerators, automobile and diesel truck mufflers, charcoal-broiled steaks, and fireplaces.¹⁵⁴ Based on these results, it was concluded that PCDD/PCDF compounds were ubiquitous by-products of combustion processes.

Municipal waste incinerators (MWIs) are generally considered to be a major combustion source of PCDD/PCDF compounds, and there are numerous reports in the literature on the determination of PCDDs/PCDFs in both ash by-products (fly-ash and bottom ash) and stack gas emissions. There is considerable variability in the patterns of PCDD/PCDF compounds found in MWI samples, but in general the PCDDs are dominated by octa-CDD, with concentrations of the other congener groups decreasing as the number of chlorine atoms is reduced. In contrast, the PCDFs, which are generally present at higher concentrations than the PCDDs, are dominated by less-highly-chlorinated congeners — usually either penta- or hexa-CDF congeners.¹⁵⁵ The absolute amounts of PCDD/PCDF compounds in stack gas emissions from 32 MWIs in industrialized countries varied from < 1 to 33,047 ng/dry standard cubic meter (ng/DSCM).¹⁵⁶ Data compiled by the WHO Regional Office for Europe also showed that there were large differences in the concentrations of 2,3,7,8-substituted PCDD/PCDF compounds emitted by different municipal MWIs.^{157,158} The higher concentrations were often associated with abnormal operating conditions during the sampling program. Older incinerators and incinerators with inadequate emission-control equipment also had higher PCDD/PCDF emissions. The stack gas emissions of most MWIs in industrial countries are now close to the desired limit (0.1 ng I-TEQ/m³).¹⁵⁹

In comparison to MWIs, hazardous waste incinerators (HWIs) consume a much smaller quantity of waste. However, the concentrations and the patterns of PCDD/PCDF compounds emitted by state-of-the-art HWIs are similar to those found for municipal incinerators, although the waste stream in the former often contains large quantities of chlorinated chemicals.¹⁵⁸ While hospital incinerators also consume a relatively small quantity of waste, emissions of PCDD/PCDF compounds from these incinerators can be high.^{160,161} In Denmark, it was estimated that 1,750,000 and 16,800 tons of waste were burned annually in MWIs and in hospital incinerators, respectively.¹⁶² However, the total amounts of PCDD/PCDF compounds produced were 2200 g and 900 g, respectively. The high concentrations of PCDD/PCDF compounds in hospital incinerator emissions have been attributed to the presence of a high percentage of plastics in hospital wastes.¹⁶³ Also, these incinerators were often poorly designed, and it is now agreed that incinerators of advanced design should be used for the destruction of hospital waste.

Metal-processing plants are also a source of atmospheric PCDD/PCDF compounds. In Sweden in 1992, it was reported that steel mills were the single largest source of PCDD/PCDF compounds.¹⁶⁴ In the case of scrap-metal-reclamation plants, the presence of chlorine-containing plastics, such as polyvinyl chloride (PVC), in the feedstock would appear to be one of the factors responsible for the increased PCDD/PCDF production.¹⁶⁵ However, other factors, such as furnace design, also are important in controlling PCDD/PCDF emissions.¹⁶⁶

Studies conducted in Sweden¹⁶⁷ and New Zealand¹⁶⁸ showed that automobiles represented an additional source of PCDD/PCDF compounds in the atmosphere when leaded gasoline was used as a fuel, with TCDFs as the major congener group in the emissions. However, no PCDDs/PCDFs

were identified in emissions from automobiles using unleaded gasoline, suggesting that the lead scavenger dichloroethane was the source of the PCDDs/PCDFs. While diesel-powered vehicles are still a source of PCDD/PCDF emissions, data from stationary engine tests¹⁶⁹ in Europe and from on-road sampling¹⁷⁰ in the U.S. suggest that these emissions contribute less than 10% of the total atmospheric emissions of PCDDs/PCDFs.

As PCDD/PCDF emissions from incinerators are being reduced by the introduction of new technology, diffuse burning sources, including domestic heating, are making a larger contribution to the total load of atmospheric PCDDs/PCDFs. Based on tests conducted at the U.S. EPA's Open Burning Test facility, it was estimated that between 2 and 40 households burning their trash daily in barrels could produce PCDD/PCDF emissions comparable to a 182,000 kg/day MWI.¹⁷¹ Bonfires are customarily lit in the United Kingdom during a November festival, and it was determined that PCDD/PCDF emissions during the festival amounted to ~5 to 14% of the United Kingdom's total annual emissions from primary sources.¹⁷²

18.3.2 Aquatic and Terrestrial Fate of PCDDs and PCDFs

18.3.2.1 Bioaccumulation Pathways of PCDDs and PCDFs

18.3.2.1.1 Aquatic Bioaccumulation Pathways of PCDDs and PCDFs

There are three potential reservoirs of PCDDs/PCDFs available to aquatic organisms: water, sediment (suspended and bottom), and food. The importance of each reservoir as a source of PCDDs/PCDFs for fish was studied in a laboratory investigation of 2,3,7,8-TCDD bioaccumulation in Lake Ontario. It was found, using various combinations of contaminated food, sediment, and water, that food was the major source of 2,3,7,8-TCDD for lake trout (*Salvelinus namaycush*).¹⁷³ Only 22 to 30% of the 2,3,7,8-TCDD residue in the lake trout was derived from the sediment, and insignificant quantities of 2,3,7,8-TCDD were bioaccumulated from water.

However, the lake trout is a piscivorous species, and results from laboratory experiments conducted with a planktivorous species, guppy (*Poecilia reticulata*), and fly-ash extracts as a PCDD/PCDF source showed that the contribution of food residues to the body burdens of five PCDDs/PCDFs was less than 5% of the contribution from water.¹⁷⁴ A direct comparison with the Lake Ontario study is not possible, since 2,3,7,8-TCDD was not detected in the guppies. An additional bioaccumulation study was carried out with guppies in which one group of fish was exposed to the PCDD/PCDF fly-ash extract dissolved in water and another group was exposed to the same water solution that had been equilibrated with sediment prior to addition to the exposure tanks.¹⁷⁵ While the PCDD/PCDF concentrations in the water were the same in both experimental groups, fish exposed to the sediment-equilibrated water had lower PCDD/PCDF concentrations. It was suggested that PCDD/PCDF compounds in the sediment-equilibrated water were associated with dissolved or colloidal matter and that this association hindered the uptake of the compound across the cell membrane.

For the fish exposed to the sediment-equilibrated water, the bioaccumulation potential for different PCDD/PCDF compounds was evaluated by calculating biota-sediment accumulation factors (BSAFs). The BSAF is defined as the ratio of the concentration of a chemical in tissue lipid to the concentration in sediment organic carbon. This is a very useful parameter since sediment is the major reservoir of PCDDs/PCDFs in the aquatic environment. Also, these hydrophobic compounds associate with organic carbon in sediment and with lipid in biota; therefore, it is possible to compare data from studies in which there are differences in tissue lipid content and organic carbon content. If the affinities of the PCDDs/PCDFs were equal in lipid and in sediment, the BSAFs should approach one and should be independent of a compound's hydrophobicity. However, the BSAFs were all found to be less than one, and they decreased with increasing chlorine content, e.g., from 0.15 for 2,3,7,8-TCDD to 0.003 for OCDD. While the exposures were carried out for

the comparatively short period of 30 days, the results could not be attributed to a failure to reach equilibrium, since comparable BSAFs were found when carp (*Cyprinus carpio*) were exposed for 205 days to contaminated Wisconsin River sediments.¹⁷⁶

In practice, PCDDs/PCDFs may have different affinities for organic carbon and lipids, and these affinities could be influenced by hydrophobicity. Reductions in water solubility or diffusion across biological membranes are other factors that could explain the decrease in BSAF values as molecular weights increase. Sediments in the marine environment can also be a source of PCDDs/PCDFs for aquatic organisms. Sandworms (*Nereis virens*), clams (*Macoma nasuta*), and grass shrimp (*Palaemonetes pugio*) were found to bioaccumulate 2,3,7,8-TCDD, 2,3,7,8-TCDF, and PCBs when exposed to sediments from the Passaic River in New Jersey.¹⁷⁷ While clams rapidly accumulated and depurated the compounds, the highest concentrations were found in the worms, which had slower rates of accumulation and depuration.

In their larval stages, aquatic insects are in intimate contact with sediments; it has been found that the emerging insects can serve as a means of transporting contaminants into aquatic and terrestrial food chains. When small areas of Canadian lakes were isolated as mesocosms by polyethylene barriers, it was determined that up to 2% of a dose of tritiated 2,3,7,8-TCDF in the sediment could be exported annually by emerging insects.¹⁷⁸

Fly ash from incinerators represents a major atmospheric source of PCDDs/PCDFs (see below), and fly-ash particles are undoubtedly present in many sediment-deposition layers of the Industrial Age. Results from a study on the bioavailability of 2,3,7,8-TCDD from municipal incinerator fly ash to carp suggest that PCDD/PCDF bioavailability from fly ash in the aquatic environment can vary over a wide range, depending on the source of the fly ash and on its organic carbon content.¹⁷⁹ It was found that carp exposed to a fly ash from the East Coast with a high organic carbon content (4%) had lower 2,3,7,8-TCDD residues than did carp exposed to fly ash from the Midwest with a lower organic carbon content (1%), even though the East Coast fly ash had 12 times as much 2,3,7,8-TCDD. In a follow-up study with the Midwest fly ash, BSAF values were determined for selected PCDDs/PCDFs.¹⁸⁰ The BSAFs for tetra- to hepta-CDDs decreased from 7.4×10^{-4} to 7.8×10^{-5} , and for tetra- to hepta-CDFs from 5.7×10^{-4} to 9.2×10^{-5} . These BSAFs are considerably lower than the BSAFs reported for sediments. However, certain fly ashes are highly contaminated with PCDDs/PCDFs and therefore could contribute more strongly to PCDD/PCDF body burdens found in fish.

There are also several field investigations of the food-chain bioaccumulation of PCDDs/PCDFs in aquatic birds. In the first study, PCDD/PCDF concentrations in the livers of Dutch fish-eating birds, primarily of cormorants (*Phalacrocorax carbo*), were compared to PCDD/PCDF concentrations in eels (*Anquilla anquilla*), an important food source for cormorants.¹⁸¹ The major contaminant in the cormorant liver tissue was 2,3,4,7,8-penta-CDF, followed by 2,3,7,8-TCDD and 1,2,3,7,8-hexa-CDD. These compounds were also found at lower concentrations in the eel tissue. Significant correlations (r values from 0.8 to 0.95, $p < 0.05$) were found between the congener concentrations in the cormorants. It was proposed that this pattern was a result of exposure to a relatively constant mixture of PCDDs/PCDFs via a food source such as the eels. Direct uptake from sediments was considered an unlikely bioaccumulation route since sediment PCDD/PCDF concentrations in the Netherlands are highly variable.

In the second study, concentrations of PCDDs/PCDFs, PCBs, and organochlorine pesticides in the eggs, livers, and whole-body tissues of Lake Ontario herring gulls were compared to the PCDD/PCDF concentrations in alewife (*Alosa pseudoharengus*).¹⁸² The alewife and the rainbow smelt (*Osmerus mordax*) constitute the major fish species in the gulls' diet, and both species contain nearly identical concentrations of organochlorine contaminants. Biomagnification factors (BMFs) are ratios of the PCDD/PCDF concentrations in biota at one trophic level and the PCDD/PCDF concentrations in their food from a lower trophic level.

By using BMFs based on wet-tissue weight rather than lipid weight, we can compare results from the Dutch study with the herring gull study. The BMFs for 2,3,7,8-TCDD, 1,2,3,6,7,8-hexa

CDD, and 2,3,4,7,8-penta CDF in the livers of the cormorants were 12, 29, and 340, respectively, compared to 12, 30, and 9, respectively, in the livers of the Lake Ontario herring gulls. The BMFs for the two PCDDs are in close agreement, whereas there is a large discrepancy in the values for 2,3,4,7,8-penta-CDF. The discrepancy could be due to species differences in liver retention, elimination rates, or unidentified food sources. In the herring gull study, liver concentrations were compared to whole-body concentrations. On a lipid-adjusted basis, the liver/whole-body ratios for the PCDDs/PCDFs exceeded those found for other organochlorine compounds and varied from 1.4 for 2,3,7,8-TCDD to 12 for octa-CDD. It has been found in rats that 2,3,4,7,8-penta CDF binds to nonmetabolizing sites on the protein of the microsomal oxidase cytochrome P-448.¹⁸³ This was considered a plausible explanation for the increase in liver retention of the PCDDs/PCDFs in the herring gulls as the degree of chlorination increased.

It is now understood that if the tissue levels of certain PCB congeners that share structural similarities with PCDDs/PCDFs ("dioxin-like" PCBs) are high enough, the TEQ contributions of these congeners may be much more significant than those of the PCDDs/PCDFs. The importance of PCBs in contributing to toxicity can be illustrated by results from a study conducted in the western Mediterranean. In this study, eggs were collected from nests of the Audouin's Gull (*Larus audouinii*), a protected piscivorous species, and the yellow-legged gull (*Larus cachinnans*), a scavenging species that feeds mainly at refuse dumps¹⁸⁴. The total I-TEQs from PCBs and PCDDs/PCDFs were 2955 and 126 pg/g dry weight in the Audouin's gull eggs and in yellow-legged-gull eggs, respectively. However, the PCDD/PCDF contributions to these total TEQ values were less than 3%. The presence of higher total TEQs in Audouin's gulls can be explained by the higher trophic level occupied by this species relative to yellow-legged gulls.

Aquatic biota are exposed to both 2,3,7,8-substituted- and non-2,3,7,8-substituted PCDDs/PCDFs. However, only 2,3,7,8-substituted PCDD/PCDF isomers are bioaccumulated/bio-magnified in vertebrates, although in certain cases non-2,3,7,8-substituted PCDDs/PCDFs can be found in invertebrates. The preferential bioaccumulation of 2,3,7,8-substituted PCDDs/PCDFs in vertebrates has been confirmed by a large number of both field and laboratory studies. Metabolism or selective absorption and retention are possible explanations for this effect.

18.3.2.1.2 Terrestrial Bioaccumulation Pathways of PCDDs and PCDFs

There is a much wider dispersion of PCDD/PCDF compounds in the terrestrial environment than in the aquatic environment, and the potential for terrestrial bioaccumulation is generally considered low. However, industrial accidents have occurred that have resulted in localized contamination by PCDDs/PCDFs. After an explosion at a trichlorophenol manufacturing facility at Seveso near Milan in 1976, severe mortality was found in domestic rabbits raised in areas near the chemical plant. In the group of 341 samples that had positive signals for 2,3,7,8-TCDD, liver concentrations for the analyte ranged from 0.25 ng/g to 1025 ng/g.¹⁸⁵ A fire at a pentachlorophenol wood-treatment facility at Oroville, California, in 1987 contaminated the soil of surrounding farmland with PCDD/PCDF compounds, which were subsequently bioaccumulated by farm animals. There was some suggestion that livestock had been exposed to PCDD/PCDF compounds prior to the fire since a cow slaughtered prior to the fire had the same concentration of PCDD/PCDF compounds as a cow slaughtered after the fire.¹⁸⁶ A controlled laboratory study was carried out in which chickens were fed a formulated diet containing 10% contaminated soil from the area. Approximately 20–50% of the 2,3,7,8-substituted tetra- through hexa-compounds and 50–90% of the hepta-CDD/CDF compounds present in the feed was eliminated in the feces, and 7–54% of all 2,3,7,8-substituted PCDDs/PCDFs was excreted in the eggs.¹⁸⁷ Adipose tissue was the major deposition site for the PCDDs/PCDFs, with less than 0.5% in the liver. BMFs between the soil and the adipose tissue ranged from ~8 for penta-CDDs/CDFs to 0.3 for octa-CDD/CDF.

Several studies have been conducted in which rodent or other small mammals were fed 2,3,7,8-TCDD-contaminated soil or extracts from soil. When results from these studies were compared,

large differences in 2,3,7,8-TCDD bioavailability were found. Soil obtained from two areas in Missouri — Times Beach and Minker Stout — was contaminated with approximately 800 ng/g 2,3,7,8-TCDD as a result of the improper use of waste oils for dust control. When the soil was administered to guinea pigs by gavage as an aqueous suspension, severe mortality occurred, with LD₅₀ values close to the value for positive controls (1.75 µg/kg body weight).¹⁸⁸ Based on a comparison of liver concentrations in the positive controls and in the soil-treated animals, it can be calculated that ~85% of the 2,3,7,8-TCDD in the soils was bioavailable. In contrast, when guinea pigs were administered soil from a former 2,4,5-T manufacturing site in New Jersey, typical signs of PCDD toxicity were not found, and the calculated bioavailability was only 0.5%.¹⁸⁹ The soil for this study was contaminated with 2200 ng/g 2,3,7,8-TCDD and several other PCDD/PCDF compounds. Two explanations were offered for the observed differences in bioavailability. First, the nature of the soil could alter the bioavailability. The fill at the New Jersey site contained asphalt, and the carbonaceous nature of this matrix could enhance binding of PCDDs/PCDFs. Second, the soil at New Jersey was contaminated over a long period of time, with a generally aqueous medium, whereas the Missouri soils were contaminated with an oil mixture. The presence of oil would tend to reduce the binding of PCDDs/PCDFs to the soil and make them more bioavailable.

The potential for PCDD/PCDF bioaccumulation in ruminants in the wild may be assessed from results of a study on 2,3,7,8-TCDD bioaccumulation in beef cattle.¹⁹⁰ In this study, seven animals were fed a standard cattle ration containing 24 pg/g 2,3,7,8-TCDD for 28 days. Three animals were then sacrificed for tissue analysis, while 2,3,7,8-TCDD elimination in the remaining animals was monitored over a 36-week period by taking fat biopsies at 4-week intervals. The data were examined using a one-compartment kinetic model, and it was extrapolated that a steady-state level would be reached in 500 days, at which time the fat-tissue concentration would be 594 pg/g (all tissue concentrations of PCDDs/PCDFs reported in this subsection are expressed on a wet-weight basis unless noted otherwise). Therefore, a BMF of 25 could be expected for ruminant species in the wild such as deer. This value would be considerably reduced for does with fawns since the carry-over from feed to milk for cows was found to vary from 40% for 2,3,4,7,8-PeCDF to 0.68% for OCDD.¹⁹¹ The excreted PCDDs/PCDFs would, however, increase the PCDD/PCDF body burden of the fawns.

18.3.2.2 Abiotic Dispersal of PCDDs and PCDFs

18.3.2.2.1 Atmospheric Dispersal of PCDDs and PCDFs

Studies carried out to determine the sources of PCDDs/PCDFs in the environment have revealed that the atmosphere is a very important medium for the transport of PCDD/PCDF compounds. With the exception of sediments collected from Lake Ontario, remarkable similarities were found between PCDD/PCDF patterns in urban-air particulates and in sediments from different locations in the Great Lakes.¹⁹² The generalized pattern was dominated by octa-CDD, and it was suggested that atmospheric transport of combustion-derived PCDDs/PCDFs was the common source for each location. By invocation of photolysis as a plausible degradation pathway with the less-chlorinated PCDD/PCDF compounds, the PCDD/PCDF patterns found for municipal incinerators could be transformed into the patterns found in the sediments and the air particulates. In the case of the Lake Ontario sample, which had elevated concentrations of both octa-CDD and octa-CDF, a pattern-recognition technique showed that the sample had a PCDD/PCDF pattern very similar to the PCDD/PCDF pattern in pentachlorophenol. It is, in fact, known that chemical wastes have been transported from the Niagara River into Lake Ontario and that some of these wastes could have included pentachlorophenol and associated PCDDs/PCDFs. In another study of PCDD/PCDF deposition in sediment cores from the Great Lakes, it was determined that the most isolated Great Lake, Lake Superior, receives only 20% of its current input of PCDDs/PCDFs from local sources by atmospheric and aquatic routes. In contrast, Lake Ontario receives >90% of its input from local sources.¹⁹³

A small lake from which sediments were collected, Siskiwit Lake, is situated on a remote island in Lake Superior; it therefore could receive contaminants only via atmospheric transport. By use of radiochemical techniques for dating sediment core sections, annual PCDD/PCDF fluxes to Siskiwit Lake could be plotted against time from 1920 to 1998.¹⁹⁴ It was found that the annual fluxes to the lake were low (< 1 pg/cm²/year) before 1935 and then increased to a maximum of 9.5 pg/cm²/year in the period 1975–1980. Since this increase parallels the increase in production of chlorinated aromatic compounds in the 1940s, it was concluded that combustion of wastes containing these compounds was the most significant source of atmospheric PCDDs/PCDFs. The decline in PCDD/PCDF concentrations that occurred after the 1970s was attributed to a reduction of particulate emissions following the passage of environmental legislation. However, the total decline for the period 1987–1995 was estimated to be 20%, whereas the U.S. EPA has calculated that emissions from combustion sources declined by 75% during the same time period. The lower-than-expected rate of decline of PCDDs/PCDFs in the sediments was attributed to the photochemical conversion of PCP to OCDD and HpCDDs in condensed atmospheric water (see below). Additional studies conducted on sediment cores collected from remote lakes in North America¹⁹⁵ and Europe^{196–198} support the pattern of current and historical loading of PCDD/PCDF compounds described for Siskiwit Lake.

It is generally accepted that combustion processes are a major source of PCDDs/PCDFs in the environment. In contrast, a study conducted in 1995 found that, on a global scale, deposition estimates exceeded emission estimates by a factor of approximately four.¹⁹⁹ In this study, depositional fluxes were determined from the PCDD/PCDF concentrations in 107 soil samples. Total global deposition was estimated to be $13,100 \pm 2,000$ kg/yr. Data from air sampling conducted in the North Atlantic suggested that less than 10% of this total deposition was occurring over the oceans.²⁰⁰ The deposition estimate was then improved by collection of 63 additional soil samples from areas that had been inadequately sampled in the first study.²⁰¹ Since NO_x emissions were highly correlated with PCDD/PCDF fluxes, available NO_x data were used to estimate PCDD/PCDF emissions in areas where no soil samples had been collected. The database for emissions estimates was further expanded after PCDD/PCDF emissions were found to be well correlated with both CO₂ emissions and Gross Domestic Product (GDP) of the country. Only 23 countries did not report data for either CO₂ or GDP, and these countries were at any rate considered to have very low dioxin emissions.²⁰² Through the use of all of these additional data, it was determined that global PCDD/PCDF emissions were in the range of 1800 kg/year, compared to a deposition estimate of 3,000–10,000 kg/year.²⁰² Therefore, although the more recent data show that the mass balance discrepancy may be closer to a factor of two, the findings still point to a deposition rate that exceeds the emissions rate.

Experiments conducted in the laboratory have shown that 1,2,3,4-TCDD can react in the gas phase with OH radicals generated from either the photolysis of ozone (O₃) in the presence of water or from the photolysis of hydrogen peroxide.¹⁶ The 1,2,3,4-TCDD-OH reaction rate constant was calculated from experimental data, and the average OH reaction rate constants for PCDD/PCDF congener groups with four to eight chlorines were then calculated from structure–activity considerations. When these average OH rate constants were applied to source data via a simple model incorporating gas/particle partitioning, a reduction in concentrations of lower chlorinated congeners was found, but OCDD and HpCDD were not found to be as predominant as they are in sinks.²⁰²

In order to reconcile the mass balance data and the congener profile data for sources and sinks, Baker and Hites²⁰² have suggested that PCP is converted into OCDD and HpCDD by a photochemical reaction in condensed atmospheric water. In support of this hypothesis, it was found that aqueous solutions of PCP could be converted in a photochemical reactor into OCDD, HpCDD, and HxCDD at respective approximate yields of 0.1, 0.01, and 0.003%. Based on current measurements of PCP concentrations in rain, these yields would be sufficient to close the mass balance gap. While the experiments were conducted at environmentally relevant pH (5.5) and irradiation wavelengths

(> 290 nm), the authors have pointed out that the laboratory conditions do not mimic all of the conditions existing in condensed atmospheric water.

18.3.2.2.2 *Aquatic Dispersal of PCDDs and PCDFs*

The subject of aquatic dispersal of PCDDs/PCDFs has received considerably less attention than that of atmospheric dispersion. Tyler and co-workers²⁰³ found that PCDD/PCDF concentrations in sediments from the Clyde Estuary decreased with distance downstream from Glasgow. The concentration at a 1-km distance was 6000 pg/g, decreasing to 322 pg/g at a distance of 22 km. Since organic pollutants favor fine sediments with high surface area and high organic carbon content, it was suggested that these fine sediments were being filtered out in their movement downstream, thereby resulting in a decrease in the PCDD/PCDF sediment concentration. However, there was also a decrease in the relative proportion of octa-CDD, suggesting that other physicochemical processes were occurring.

18.3.3 PCDD and PCDF Removal Processes in Aquatic Systems

Laboratory studies have shown that PCDDs/PCDFs dissolved in water can be photodegraded on exposure to either sunlight or UV light at wavelengths that are environmentally relevant (> 290 nm).^{204,205} The process follows first-order kinetics, and the rates in sunlight are quite rapid for congeners dissolved in pure water (half-lives of 6.4 h and 8.3 h for 1,2,7,8-TCDD and 1,2,7,8-TCDF, respectively). When the PCDDs/PCDFs were dissolved in natural water from streams and lakes, they were photosensitized by humic acids and other organic compounds, increasing the photolysis rates by a factor of two.^{15,204} While dechlorination occurs during these reactions to form lower-chlorinated PCDDs/PCDFs, the dechlorination process makes only a minor contribution to the total loss of the parent PCDD/PCDF.

Anaerobic microbial metabolism is another degradation process that has been shown to dechlorinate PCDDs/PCDFs in sediments.²⁰⁶ In contrast to photodegradation reactions, in which the lateral positions are preferentially dechlorinated, peri positions (the position closest to the ether bridge) are frequently selected for dechlorination by anaerobic microorganisms. This could potentially increase toxicity by leading to the formation of 2,3,7,8-substituted congeners. However, over time, the 2,3,7,8-substituted congeners are subject to degradation by consortia with the capability of removing chlorine atoms from both lateral and peri positions. Studies carried out using sediment inocula from polluted rivers in the United States and Germany suggest that 20 to 30% of PCDDs/PCDFs are dechlorinated over periods varying from 7 months to 2 years during incubations at temperatures varying from 20°C to 30°C.^{206–208} There is also evidence that PCDDs/PCDFs can be dechlorinated by abiotic processes involving electron transfer from inorganic (zerovalent iron and zinc) and organic (hydroquinone/quinone and vitamin B12) molecules.²⁰⁹ Additional data show that peridechlorination may be enhanced by the synergistic actions of the abiotic and microbial dechlorination processes.²¹⁰

While these laboratory studies indicate that PCDDs/PCDFs can be degraded by sunlight, anaerobic microorganisms, or abiotic dechlorination, it is not clear whether any of these degradation processes has a significant impact on the levels of PCDDs/PCDFs in the aquatic environment. Since PCDDs/PCDFs are hydrophobic compounds, they are primarily associated with sediment particles; this association would limit the dissolved concentrations of the compounds available for photodegradation. In the case of anaerobic metabolism, dechlorination rates for OCDD in sediment systems were considerably lower than those found using spiked sediment-free elutriates.²¹¹ Therefore, bioavailability to microorganisms from sediments could be a limiting factor in the anaerobic metabolism of PCDDs/PCDFs. Finally, the anaerobic incubations were carried out in the presence of cosubstrates and nutrients and at temperatures exceeding those generally found in the aquatic environment.

18.4 AMBIENT LEVELS OF PCBs

18.4.1 Ambient Levels of PCBs in Aquatic Biota

One of the first reports of the environmental persistence of PCB congeners came from the observation of a Swedish chemist, Sören Jensen, who noted their presence in fish. He was looking for evidence of DDT contamination in biological tissues and discovered, in addition to DDT and its metabolites, several other chlorinated hydrocarbons, which were later verified to be chlorinated biphenyls.²¹² As accumulators of PCBs, many organisms are among the best monitors of PCB, especially for conducting trend analyses. They integrate exposure over extended time periods, and, since they magnify levels, their concentrations will build up to levels much higher than in their external media, allowing for ease of measurement. Several nations have monitoring programs underway involving analyses of PCBs in sentinel species, usually fish,²⁹ but also aquatic birds (herring gulls),³⁶ marine mammals,²¹³ and shellfish.²¹⁴ In the Great Lakes, lake trout have been routinely monitored since 1979; in them, a continuing decline in PCBs has been reported.³⁶ NOAA Status and Trends data exist for PCBs in coastal areas also showing downward trends of PCBs in mussels.²¹⁴ European data, especially from Sweden, have been discussed in several publications, and both terrestrial and aquatic species have been studied.²¹⁵ Especially high levels have been reported in porpoises and seals, and several long-term studies have been done on polar bears.²¹⁵

18.4.2 Ambient Levels of PCBs in Sediments

Much of the PCBs released into the environment over time are believed to reside in sediment. As clean sediment is delivered (now that external loadings have decreased) these deposited sediments are being buried, and eventually, in the absence of scouring or resuspension, they will be removed from the MER of PCBs. Deviations from this gradual burial process have been documented. In a Lake Erie study of PCBs in biota, investigators found that unusually high wind speeds from 1996 to 1997 led to increased PCB concentrations in biota that reside above the sediment due to resuspension of previously buried sediment deposit.²¹⁷ Therefore, deep scouring during flooding in rivers or heavy-storm-induced resuspension in lakes can lead to renewed exposure of PCBs from sediment deposits.

Other additional natural losses such as microbial degradation are also possible, but the rates of such processes in deeper sediments are very slow. Historical assessments of PCB deposition into sediments rely on dating the deposition layers within sediment cores that are removed from the deposit areas and relating the layers with their respective PCB concentrations. The chronology of past depositions of the PCB into undisturbed sediments has been documented for the Hudson River estuary, Great Lakes, and the Baltic.^{217–220} Several sediment profiles have provided evidence for anaerobic dechlorination losses, for example, in the Hudson River¹²¹ and in the tributary basin of the Thames River in England.²²¹ These researchers' evidence for dechlorination was expressed as a change in the ratios of less highly chlorinated (tri- and tetra-) congeners relative to congeners with five or more substituted chlorine atoms. In one of their cores samples, they²²¹ reported an average ratio of 0.23 from the surface of this core to ratios increasing to 0.32 at 2.3 m depth and finally to 0.62 by 5.8 m below the surface. As long as contaminated sediments reside in place in deposit zones they are subject to remobilization. Careful stewardship of these deposit zones is the preferred option. This stewardship is best provided by careful removal and placement in secure upland disposal facilities. While choosing this option has to be done on a case-by-case basis, it is the most frequently chosen option when costs are not a concern.³⁹

18.4.3 Ambient Levels of PCBs in Soils

There are few data on the levels of PCBs in soil. The general rule is that ambient air levels of PCBs are greatly affected by soil/air partitioning and that soils and other exposed surfaces in urban

communities generally receive influx of atmospheric PCBs. However, now that ambient background levels of PCBs in air are declining, soils in rural areas are releasing more PCBs than they are receiving. Thus, the congener ratios of PCBs in rural soils and at remote sites tend to reflect depletion of the more volatile congeners and enrichment of more highly chlorinated congeners.⁹⁶ In tests of several soil types by Ayris and Harrad,¹⁰⁷ the most important influences on the rate constant for soil partitioning were from the log $K_{\text{octanol/air}}$ (adjusted for soil temperature) and soil organic carbon.

One of the more careful and complete studies of soil interactions with PCBs has been conducted by Kevin Jones' research group in the United Kingdom.^{56,98,222,223} Most of the soils that were the centerpiece of their work came from agricultural plots. The levels of total PCBs ranged from 10 to 670 $\mu\text{g}/\text{kg}$ (median 30 $\mu\text{g}/\text{kg}$).²²² Twenty-six congeners were routinely monitored and quantitated in each of the samples. The soils included contemporary samples and historical samples dating back to 1944. All of the contemporary samples had levels similar to those in early 1940s samples; however, there tended to be a higher proportion of more highly chlorinated congeners in the contemporary samples. The soil levels of PCBs increase when atmospheric levels are high by gas-to-soil exchange. Then, as source releases are depleted, the exchange from surface soils is reversed, buffering the levels in the atmosphere.⁹⁸ There appears to be a delay (10 years' time lag was observed by Harner and co-workers⁹⁸), and there is a slower release of those accumulated PCBs having half-lives of 10–20 years, an effect that tends to prolong background levels for longer periods of time. Numerous investigators have noted that hotspot buildup often occurred in soils near transformer spills; these remain for long periods of time.

18.4.4 Ambient Levels of PCBs in Air

Air concentrations of total PCBs in metropolitan centers generally run about five to ten times higher than background levels and correlate closely with the higher particle concentrations in cities. The total gaseous PCB concentrations at an overlake site 15 km from Chicago ranged from 132 to 1120 pg/m^3 ,³ with higher concentrations occurring in warm periods and when wind directions were from the city. Therefore, Chicago was determined to be a major source of PCBs for Lake Michigan.⁸⁶ Because of concern for elevated concentrations of PCBs in the Great Lakes region and because of the sensitivity of this area to PCBs, there is currently an air-monitoring network analyzing PCBs on a regular basis (IADN Network-Integrated Atmospheric Deposition Network).^{224,225} Data now available from these collections show that mean yearly values for PCBs range from 89 to 370 pg/m^3 . Concentrations at an urban site near Lake Erie were about two times higher than concentrations at the two more remote sites near Lake Superior.²²⁶

Five years of data, from 1992 to 1997, were summarized for PCBs measured in air at a site in northwest England. PCB levels declined, with specific half-lives ranging from 2 to 6 years for all of the congeners that were modeled; the decline was fastest for congener 52.⁵⁶ Schreitmüller and Ballschmiter⁸⁵ measured PCBs in air over the North Atlantic. Values for total PCBs ranged between 48 pg/m^3 in 1992 in the eastern North Atlantic and 22 pg/m^3 in the central South Atlantic for this year. Several papers confirm that PCB air concentrations vary with season (high concentrations when air temperatures are high and low PCB concentrations when the temperatures are lower). PCB concentrations in air vary with latitude, i.e., they are higher at mid latitudes (most industrial sources exist here) and lower at higher latitudes that are closer to polar regions.⁵⁵

18.5 AMBIENT LEVELS OF PCDDs AND PCDFs

18.5.1 Ambient Levels of PCDDs and PCDFs in Aquatic Biota

When the first efforts to monitor PCDDs/PCDFs were undertaken in the 1980s, major emphasis was placed on the determination of 2,3,7,8-TCDD in fish from aquatic environments that receive

wastes from industrial processes. In 1983, O'Keefe and co-workers²²⁷ found that 2,3,7,8-TCDD was present in fish from all of the Great Lakes. However, the most heavily contaminated fish were found in Lake Ontario and in the Saginaw Bay area of Lake Huron, where concentrations varied from 2 to 162 pg/g and from 2.5 to 29 pg/g, respectively. Fish from the other Great Lakes (Lake Erie, Lake Michigan, and Lake Superior) had < 3pg/g. Later studies²²⁸⁻²³⁰ confirmed these results. Norstrom and co-workers²³¹ also found that herring gull eggs collected from colonies in Lake Ontario and the Saginaw Bay area of Lake Huron had higher 2,3,7,8-TCDD concentrations (43 to 86 pg/g) than did eggs from colonies in Lakes Erie, Michigan, and Superior (9 to 11 pg/g). PCDDs/PCDFs containing from four to eight chlorine atoms were determined in Great Lakes fish by Stalling and co-workers²³² in 1982 and Zacharewski and co-workers²³³ in 1989. Both studies showed that PCDFs were more widely distributed in the Great Lakes than were PCDDs, which suggests that the PCDFs are entering the lakes from other sources, including commercial Aroclors. The major PCDD/PCDF congener in most samples was 2,3,7,8-TCDF, with the exception of samples from Lake Ontario, where 2,3,7,8-TCDD was the major congener, and samples from Saginaw Bay, Lake Huron, where there were significant quantities (> 30 pg/g) of tetra-, penta-, and hexa-CDDs and CDFs.²³² While fish collected from Lake Michigan generally have low concentrations of PCDDs/PCDFs, higher concentrations have been found in biota collected around Green Bay, WI, an area contaminated by effluents from pulp and paper mills and other industrial wastes. Eggs from colonies of Forster's terns located in this area were found by Kubiak and co-workers²³⁴ to contain median 2,3,7,8-TCDD and total PCDD concentrations of 37 and 102 pg/g, respectively.

A national survey conducted by the U.S. EPA demonstrated that contamination of aquatic biota in the U.S. by PCDD/PCDF compounds was not confined to the Great Lakes. In this study, bottom-feeding and predator fish were collected from almost 400 sites including the Great Lakes. It was found that 2,3,7,8-TCDD could be detected in fish from 112 of the 395 sites (28%), with concentrations below 5 pg/g from 74 sites (67%), between 5 and 25 pg/g from 34 sites (32%), and between 25 and 85 pg/g from 4 sites (1%).¹³⁷

Aquatic biota, other than fish and birds, bioaccumulate PCDDs/PCDFs. Bullfrogs (*Rana catesbeiana*) collected near a chemical plant at Jacksonville, Arkansas, that formerly manufactured the herbicide 2,4,5-T had concentrations of 2,3,7,8-TCDD in their fat tissues as high as 68,000 pg/g.²³⁵ For females, concentrations were also elevated in ovaries and oviducts. Snapping turtles (*Chelydra serpentina*) are long-lived organisms consuming both plants and animals, including fish; they therefore tend to bioaccumulate high concentrations of organochlorine compounds. Ryan and co-workers²³⁶ analyzed PCDD/PCDF compounds in fat and liver samples from three snapping turtles from the upper St. Lawrence River. Concentrations of 2,3,7,8-TCDD in the fat tissue varied from 232 to 474 pg/g. It is conceivable that this PCDD congener was transported into the upper St. Lawrence from its source, Lake Ontario. One of the three samples was collected near industrial sites at Massena, New York; this sample contained 3 ng/g 2,3,4,7,8-penta CDF in addition to 2,3,7,8-TCDD. It is now known that this area is heavily contaminated with PCBs and PCDFs.

The aquatic species described above accumulate predominantly 2,3,7,8-substituted isomers. However, crustaceans discriminate to a lesser extent between 2,3,7,8-substituted and non-2,3,7,8-substituted isomers, as was shown in a study conducted by Rappe and co-workers²³⁷ in the New York Bight and the Newark Bay area of New York Harbor. When tissues of blue crabs (*Callinectes sapidus*) and American lobsters (*Homarus americanus*) were analyzed, concentrations were considerably higher in the hepatopancreas than in the meat, with a concentration of over 6000 pg/g 2,3,7,8-TCDD in the hepatopancreas from one crab. While 2,3,7,8-TCDD was the major TCDD isomer, the 2,3,7,8-substituted isomers constituted less than 30% of the total congener group concentrations for the penta- and hexa-CDDs and the tetra- to hexa-CDFs. In general, similar isomer patterns were found in the hepatopancreas and the meat tissue.

In Europe, studies to monitor PCDDs/PCDFs in aquatic biota have focused on major rivers, such as the Rhine and the Elbe, and on the Baltic Sea. In the Elbe, bream (*Abramis brama*)

collected in the Hamburg Harbor area near a pesticide manufacturing plant had total 2,3,7,8-substituted PCDD/PCDF concentrations and 2,3,7,8 TCDD concentrations as high as 308 and 102 pg/g, respectively.²³⁸ Lower PCDD/PCDF concentrations (< 50 pg/g) were generally found in bream collected at other locations in Hamburg Harbor and at sampling points from the river mouth to a point 200 km upstream.²³⁹ In all of the samples in this study, the PCDF concentrations exceeded those of PCDD, with 2,3,7,8-TCDF/2,3,7,8-TCDD ratios exceeding 10. Also, comparable levels of 1,2,3,7,8- and 2,3,4,7,8-penta CDF were detected, whereas in both North American and Scandinavian studies the 2,3,4,7,8 isomer has been found to predominate. However, it was also apparent that the capillary gas chromatography column was not capable of separating 1,2,3,7,8- and 2,3,4,7,8-penta CDF standards. Concentrations and isomer patterns of PCDDs/PCDFs in fish from the upper reaches of the Rhine and its tributary, the Neckar, were comparable to those found in the River Elbe fish. The more usual pattern of higher 2,3,4,7,8-penta CDF than 1,2,3,7,8-penta CDF concentrations was found in the Rhine/Neckar samples.²⁴⁰ Eel samples, however, had quite different patterns that were dominated by octa-CDD, suggesting a more direct influence from sediments.

In 1989, Rappe and co-workers²⁴¹ summarized their investigations of PCDD/PCDF concentrations in fish collected from the Baltic Sea and from Lake Vattern in Sweden. Composites of herring from various locations in the Baltic and a control site on the Atlantic coast of Sweden had very similar PCDD/PCDF patterns that were dominated by 2,3,4,7,8-penta CDF (3–19 pg/g), with lower amounts of 2,3,7,8-TCDF (1.7–6.2 pg/g) and no detectable levels of 2,3,7,8-TCDD. Total congener group concentrations varied from 7 pg/g for the Atlantic Coast sample to over 30 pg/g for a sample collected near Stockholm, with intermediate levels for samples from the Gulf of Bothnia, an area in which several pulp and paper mills are located. As salmon are predators, it was not unexpected to find higher PCDD/PCDF concentrations in these fish than in either herrings or hatchery-raised salmon receiving synthetic food. Wild salmon from the Gulf of Bothnia had PCDD/PCDF concentrations approximately five to ten times higher than either the herrings or the hatchery salmon. In samples collected close to pulp and paper mills, the dominant PCDD/PCDF congener was either 2,3,7,8-TCDD, as in the case of perch from Norrsundet in the Gulf of Bothnia (13–19 pg/g), or 2,3,7,8-TCDF for Artic Char from Lake Vattern (20–75 pg/g). For the Artic Char, there was a direct relationship between fish weight and contaminant levels.

Monitoring data are now available showing the time trend of PCDD/PCDF concentrations in aquatic biota. For herring gull eggs from the Great Lakes, concentrations declined between 1981 and 1984.²⁴² However, there were no obvious temporal trends between 1984 and 1991. In a review of a database on TCDD concentrations in fish and shellfish collected from U.S. waterways between 1979 and 1994, Firestone and co-workers found that there had been a steady decline during the study period.²⁴³ This decline was most apparent at contaminated sites on the Great Lakes. From 1981 to 1982, five of ten fish collected in Lake Ontario had TCDD concentrations exceeding 11 pg/g, whereas in 1994, TCDD was not detected in any of nine fish (≤ 1 –2 pg/g). Significant declines in PCDD/PCDF levels in wildlife have also occurred in British Columbia, Canada as a result of the replacement of chlorine by chlorine dioxide as a bleaching agent for wood pulp and the introduction of regulations to control the use of chlorophenols as antisapstaining agents for undried lumber. In a study of PCDDs/PCDFs in osprey eggs collected in the drainage systems of the Columbia and Fraser Rivers, reductions between four- and tenfold were found in the PCDD/PCDF concentrations in the eggs over the period from 1991 to 1997. These reductions were mainly attributed to regulatory controls on PCDD/PCDF releases from pulp and paper mills introduced between 1991 and 1993.^{146,244} However, in many recently industrialized countries and in Central and Eastern European countries, reports published between 1995 and 1997 show that there are locations where wildlife are still contaminated with high concentrations of PCDDs/PCDFs. Fish taken from the Er Jen River in Taiwan, near metal-reclamation plants, had PCDD/PCDF TEQs as high as 2084 pg/g.²⁴⁵ Blubber tissue from one juvenile and two adult female Baikal seals (*Phoca sibirica*) collected from Lake Baikal in Russia had PCDD/PCDF TEQs of 28, 73, and 93 pg/g,

respectively — levels comparable to those found for ringed seals (*Phoca hispida*) in contaminated areas of the Baltic Sea.²⁴⁶

18.5.2 Ambient Levels of PCDDs and PCDFs in Sediments

Current background PCDD/PCDF concentrations in sediments from various countries in the Northern Hemisphere have been determined from analysis of the top sections of sediment cores from remote lakes. Between 1993 and 1998, it was reported that Siskiwit Lake in the United States,¹⁹⁴ Loch Coire nan Arr in northwest Scotland,¹⁹⁶ and three lakes in Subarctic Finland¹⁹⁷ had recent total PCDD/PCDF sediment concentrations of 382, 488, and 202 ± 92 pg/g, respectively. These data are in remarkable agreement and demonstrate that long-range atmospheric transport can distribute PCDDs/PCDFs over wide areas. Lakes in the Black Forest in Germany, where the prevailing winds can transport PCDDs/PCDFs directly from emission sources in industrial areas, have higher sediment PCDD/PCDF concentrations (8.9–18 ng/g).¹⁹⁸ The highest sediment PCDD/PCDF concentrations occur where there is direct loading to water from point sources. Norwood and co-workers²⁴⁷ analyzed surface sediments from a number of contaminated coastal areas in the United States and found the highest PCDD/PCDF concentration (44 ng/g) in sediment from Eagle Harbor, Washington, a location that had been contaminated with PCP wastes.

18.5.3 Ambient Levels of PCDDs and PCDFs in Soils

Comprehensive studies of PCDD/PCDF contamination in soil samples have been carried out in England. The first study involved the collection of 77 rural soil samples at the intersection points of a 50-km grid.²⁴⁸ When 12 samples contaminated by local point sources were eliminated from the data set, it was found that the mean concentrations of PCDDs and PCDFs were 311 and 132 pg/g, respectively. Mean concentrations of the PCDDs/PCDFs were considerably higher in soil samples collected from 19 urban areas (11 ng/g for PCDDs and 0.9 ng/g for PCDFs).²⁴⁹ Principal-components analysis suggested that combustion processes, such as coal burning and municipal incinerators, were the principal sources of PCDD/PCDF compounds in the urban soils. In an investigation of PCDDs/PCDFs in soil samples collected in rural Germany, samples collected from cultivated land and grassland had total PCDD/PCDF concentrations slightly lower than those found in the English study (mean values of 123 pg/g and 170 pg/g for cultivated land and grassland, respectively).²⁵⁰ However, elevated PCDD/PCDF concentrations were found in soil samples collected from forested areas (mean values of 2.3 ng/g and 6.5 ng/g for deciduous and coniferous forest soils, respectively). It is known that leaves and needles can take up PCDDs/PCDFs, primarily by dry gaseous deposition, and subsequently the falling needles/leaves increase PCDD/PCDF concentrations in the surrounding soil.²⁵¹

18.5.4 Ambient Levels of PCDDs and PCDFs in Air

Measurements of PCDD/PCDF compounds in ambient air have been carried out at several locations in Europe, North America, New Zealand, and Japan. In rural areas,^{168,252} total PCDD/PCDF concentrations in ambient air generally do not exceed 1 pg/m^3 and are often lower ($< 0.5 \text{ pg/m}^3$).²⁵³ In suburban locations, where there is no impact from point sources, PCDD/PCDF concentrations range from 1 to 5 pg/m^3 .²⁵⁴ Urban-air concentrations of PCDDs/PCDFs range from 5 to 20 pg/m^3 ,³ but concentrations can exceed 100 pg/m^3 where there is a direct impact from industrial emissions.²⁵² PCDD/PCDF patterns in ambient-air samples from different locations are usually quite similar, with equal amounts of PCDDs and PCDFs. The congener profiles are dominated by 2,3,7,8-TCDF and octa-CDD. The decline in deposition fluxes following the introduction of pollution-control

regulations has been discussed previously in this chapter. This decline has also been reflected in ambient-air PCDD/PCDF concentrations, particularly in urban areas. In the German cities of Köln, Duisburg, Dortmund, and Essen, ambient PCDD/PCDF concentrations were in the range of 6.5–17.4 pg/m³ in 1987/1988; these levels had declined to 3.2–9.9 pg/m³ by 1993/1994.²⁵⁴

18.6 EFFECTS OF PCBs, PCDDs, AND PCDFs

Most of the data describing the ecological effects of PCBs, PCDDs, and PCDFs in the environment deal with direct aquatic exposures (sediments/particulates, food, and water) and, thus, their related aquatic-based foodchains. Over time, especially in the last 20 years, additional toxicological and exposure information has been generated on aquatic species, especially predators, including other aquatic species, terrestrial and marine mammals, and avian species. Before the advent of improved analytical capabilities and availability of standards of the specific congeners of the PCBs, data on toxicity were only available for the commercial mixtures.

Evaluation of the health effects of PCBs is complicated by several factors. Worldwide, each of the commercial PCBs is a mixture of fewer than the possible 209 congeners, and toxicity depends on the precise congener makeup of each of these mixtures that accumulate in the tissues of organisms and the metabolites that arise from these residues. Also, the degree of contamination of commercial PCB mixtures with PCDFs complicates the situation, since PCDFs are considerably more toxic, especially to fish. Furthermore, direct transfer of the unaltered manufactured PCB mixtures to a target organism seldom occurs, except in a laboratory situation. Even then, congener and mixture homolog group patterns change following assimilation due to differential metabolism in various test species. This holds true in the ambient environment as well, where multiple processes change composition and relative proportions of congeners. Of the PCDDs and PCDFs, those that are bioaccumulated and biomagnified are primarily 2,3,7,8-substituted. For PCBs, both dioxin-like and nondioxin-like congeners bioaccumulate and biomagnify in organisms and produce acute and chronic effects.

The earliest tests were done with Aroclor mixtures. Table 18.4, compiled from ATSDR's Toxicological Profile for Polychlorinated Biphenyls,²⁷ provides an example of these mixture tests, predominantly done for human-health purposes. The lethal dose decreases with length of exposure, and the most serious damage to these organisms occurs through reproductive effects. Reproductive effects occur at doses much lower than mortality levels.

Regulations for PCBs are based on total PCB concentrations (e.g., a sum of the mixed congeners), while PCDD/PCDF regulatory guidelines require individual congener identification and quantification. Mechanistically, this has resulted in an interpretation gap between the PCBs and PCDDs/PCDFs. While specific isomer information has always been available for assessing exposure and toxic dose for PCDD/PCDFs, concentration data for PCBs has always been more complicated to deal with, e.g., even with the congener-specific data for PCBs there is currently no unified and accepted way to integrate all of the multiple congener exposures.

18.6.1 Toxicological and Structural Similarities

The general consensus about the mode of action of TCDD is that it involves the activation of the TCDD-receptor complex, and the subsequent translocation of this complex into the cell nucleus is a necessary, but not sufficient, prerequisite for any TCDD-related effect.²⁵⁵ It is also generally agreed that: (1) animals that possess an aryl hydrocarbon (Ah) receptor respond to TCDD similarly; (2) multiple effects, including enzyme induction, immunotoxicity, reproductive toxicity, developmental toxicity and carcinogenicity, occur in all susceptible species; and (3) chemicals that are

Table 18.4 Most Sensitive Laboratory Animal Species Tested with Mixed Aroclors

Response	Species	Route ^b	Exposure Duration/ Frequency	NOAEL ^c (mg/kg/day)	LOAEL (effect) ^d (mg/kg/day)	Form

isostereomers of TCDD (i.e., polychlorinated and polybrominated dibenzo-*p*-dioxins, dibenzofurans, and coplanar biphenyls) act through the same mode of toxic action. This final point is used to justify discussing the mammalian and nonmammalian vertebrate effects of 2,3,7,8-substituted PCDDs and PCDFs together with the effect of coplanar PCBs.

Species-specific factors, such as uptake, disposition, and metabolism of TCDD, as well as interspecies differences in concentration, tissue distribution, and ligand affinity of the Ah receptor, all likely play roles in determining the relative sensitivity of an organism to TCDD. However, the presence of the Ah receptor clearly appears to be a necessary prerequisite for TCDD (and related compounds) to exhibit toxicity. The presence of the Ah receptor in fishes and the lack of the receptor in aquatic invertebrates are consistent with the relative sensitivities of the two groups of species to TCDD and structurally similar compounds. For example, TCDD has been shown to be lethal to a number of fish species when administered through the diet or the water, or by injection (egg or whole organism). Conversely, long-term exposures of a number of different species to TCDD (snails [*Physa* sp.], worms [*Paranis* sp.], and mosquito larvae [*Aedes aegypti*]) failed to result in discernible toxicity.²⁵⁶

Congener-specific chemistry advances and toxicological interpretation considerations have consistently driven the need for a normalization protocol based on common mechanisms of action. Today, this protocol is termed Toxicity Equivalency and is now commonly used in risk assessment. However, it is not yet a uniform regulatory requirement, at least in the United States.

For those congeners belonging to this group (all PCDDs, PCDFs and selected planar PCB congeners, Table 18.5), relative toxicity of a congener can be normalized to the potency 2,3,7,8-

TCDD, the prototype, and the most toxic compound of this group of stereoisomers. This normalized value is referred to as the TCDD toxicity equivalent concentration. Considered within a generally accepted model of additivity, these congeners' individual toxicity equivalent concentrations (actual concentration \times Toxicity Equivalency Factor, or TEF) are summed to derive a total value of exposure in an organism of interest or in the foods that it consumes.

Table 18.5 World Health Organization Toxic Equivalency Factors (TEFs) for Humans Mammals, Fish, and Birds²⁶⁰

The mechanism of action of all planar halogenated hydrocarbons (another designation for the group to which PCDDs and PCDFs and selected PCB congeners belong) is of great importance because the cumulative risks are much greater than their individual toxicities in many instances. Support for this approach was most recently documented by van den Berg and co-workers²⁵⁷ under the auspices of the World Health Organization. This group reviewed previous work regarding TEFs

derived from mammalian species^{258, 259} and recommended the establishment of animal-class-specific TEFs for humans/mammals, fish, and birds. The WHO database used to develop these TEFs is available from a U.S. Fish and Wildlife website²⁶⁰ by clicking on dioxin_information.xls on the cited webpage. Table 18.5 provides a summary of these TEFs.

Most of the effort to isolate these more toxic components has focused on the dioxin-like response from PCBs. This similarity in effect to dioxin, i.e., mixed-function oxidase (MFO) induction, subcutaneous edema, reproductive impairment, weight loss, immune suppression, and hormonal alterations, has now further been narrowed to those compounds in the PCB mix that have a three-dimensional similarity in their structure. The potency and specificity for binding to the Ah receptor, followed by MFO induction (and correlatively, for potential toxicity) of individual PCB congeners can be directly related to how closely they approach the molecular spatial configuration and distribution of forces of 2,3,7,8-TCDD. The most toxicologically active PCB congeners are those having chlorine substitution at the *para* (4 and 4') positions and at least two *meta* (3,3',5,5') substitutions on the biphenyl nucleus, but no *ortho* (2,2',6, and 6') substitutions. The PCB congeners that have no *ortho* substitutions can assume a coplanar configuration, because the *ortho* chlorines are absent that would otherwise prevent rotation of the two opposing phenyl rings from assuming a planar configuration. Because the potential toxicity is enhanced by coplanarity, this rule limits the number of such PCB congeners to four: 77, 81, 126, and 169 (3,3',4,4'-, 3,4,4',5-, 3,3',4,4',5-, 3,3',4,4',5,5'). With the exception of number 81, the non*ortho*-coplanar congeners are potent inducers of aryl hydrocarbon hydroxylase AHH and 7-ethoxyresorufin O-deethylase EROD in *in vitro* rat hepatoma cell preparations. The 81 congener is a very potent avian *in ovo* EROD inducer (see Table 18.5). Virtually no toxicity data are available for this congener. The *in vitro* inductions are correlated with *in vivo* demonstrations of mammalian, avian, and fish toxicity such as thymic atrophy and inhibition of body weight gain.²⁶¹ The 81 congener has what is called a "mixed" type response in that it induces both methyl cholanthrene (3-MC)-type reactions and also phenobarbital (PB)-type enzyme systems. From the data of Tillitt and co-workers²⁶² regarding mink accumulation and *in vitro* data, PCB 81 appears to be rapidly hydroxylated and is not biomagnified in mammals, but it is present in fish and birds as well as in their egg yolks, which contain lipids. It has not been reported or assessed in terms of human exposures.²⁶³

The second group of congeners having enzyme-inducing potencies and potential toxicities of high concern are analogs of the four non*ortho*-coplanar congeners that are still relatively coplanar but have a single *ortho*-chloro substitution. These are congeners 105, 114, 118, 123, 156, 157, 167, and 189. This group of congeners has demonstrated mixed phenobarbital (PB)- and 3-methyl cholanthrene (3-MC)-type-inducing properties. Most of the more highly chlorinated dioxins and furans have received relatively little toxicity testing relative to 2,3,7,8-TCDD. Even the TEFs for the pentachloro dioxin and furan analogs are not based on whole-organism toxicity testing but on *in vivo* or *in vitro* MFO induction or quantitative structure-activity relationships (see footnotes in Table 18.5). In fish and birds, most PCDDs and PCDFs have not been reported in the primary literature with *in ovo* data for toxicity, and again the listed TEFs rely more on MFO induction data rather than data sets involving more thorough toxicity screening. However, older data on lethality and developmental anomalies for other PCDDs and PCDFs from the U.S. Food and Drug Administration (FDA) (reported by Verret,²⁶⁴ and a Verret personal communication cited in Goldstein²⁶⁵) are generally consistent with the WHO TEFs for birds. This pioneering work by the FDA is now viewed as having been crucial to stimulating and refining scientific understanding of toxicity effects in birds and other oviparous vertebrates. For instance, the derivation of the WHO TEFs for birds and fish is *in ovo* tissue/residue-based, when such information is available. This stands in contrast to the situation for mammalian TEFs, which are derived from studies of adult dosing with concurrent partial metabolic elimination — despite the acknowledgment that body-burden-based toxicity information is preferable.

18.6.2 Structural and Toxicological Dissimilarities

Environmental exposures to PCB congeners and their metabolites that are not mechanistically identical to the PCDDs and PCDFs should still be considered. At a minimum, use of total PCB measurements in the assessment of the compounds' nondioxin-like effects is still prudent until similar equivalency approaches for other PCB congener groups having other modes of action are developed. This approach also provides a framework for interpreting long-term trends in environmental matrices. Giesy and Kannan²⁶⁶ recently provided a perspective on the relative risks of dioxin-like vs. nondioxin-like PCBs using mink as a model species. Besides this example, little work has been done to assess the effects of the complex mix of dioxin-like and nondioxin-like congeners with their metabolites and across multiple animal classes.

Certain PCB metabolites have been found that may be operating via non-Ah receptor mechanisms or that may provide additional physiologically significant interactions with parent congeners. This fact is a caveat against pursuing only one approach,^{268–271} despite the current evidence supporting the dominant toxicological importance of those congeners that act through the Ah-receptor. Conversely, it would be scientifically unsound to disregard the power of the TEF/TEQ approach and not to use it for ecological risk assessment. Based on what is known today, the uncertainties of continuing the present practice of assessing TCDD alone, or using TEQs for the PCDDs and PCDFs when considering total PCBs separately, would be greater than the uncertainty of adopting a TEF/TEQ approach that integrates PCDDs and PCDFs with the dioxin-like PCBs.²⁷² Given the additional known effects and accompanying uncertainties associated with the remaining PCB congeners, dual-track total PCB-based and TEF/TEQ-based assessments are recommended. More information is being generated and summarized for PCBs that are nondioxin-like.^{273,274} Alternative methods for assessing these congeners in functional groups, as is being done for those that act through the Ah receptor, may be forthcoming and may be proposed for consensus adoption.

The primary consideration regarding the nondioxin-like congeners is the need to establish ecological relevance. For this, environmental exposure–effect relationships must be documented. The effects must be demonstrated in a toxicological significance range in which the exposure–effect is equal to or greater than for the dioxin-like congeners in the same species/life stage being assessed. More work with various animal classes will determine whether nondioxin-like congeners are as toxicologically significant as those that are dioxin-like. Invertebrates appear particularly attractive to study because they lack the Ah receptor. Aquatic organisms (fish, amphibians, and reptiles), in particular, require comparative study.

18.6.3 Effects Categories

Usually, the earliest sign of general toxicity from exposure to PCBs or PCDDs/PCDFs in controlled laboratory studies is weight loss. Female animals are more sensitive than males, and young animals are more sensitive than adults. Poultry, guinea pigs, mink, and nonhuman primates are the most sensitive.^{275–277} Weight loss in chickens — “chicken edema disease” — is accompanied by increased bloating, which is actually an extracellular accumulation of body fluids and not real weight gain.^{278,279} Terminally, rodents, mink, and especially birds show hemorrhage in the gastrointestinal tract.

18.6.3.1 Acute Signs of Poisoning

Acute signs of poisoning that are common include binding to the nuclear Ah receptor and resulting MFO induction of AHH and EROD. Following initial binding, induction or inhibition of other MFOs as well as hormonal and vitamin alterations can occur. Pathologically, subcutaneous, pericardial, and peritoneal edema, eyelid edema, hemorrhage, weight loss or reduced weight gain (termed “wasting” when accompanied by mortality), immune suppression, fatty infiltration of the

liver, hepatomegaly, and thymic (lymphoid) and gonadal atrophy have been demonstrated in numerous test species. All of the planar congeners show a degree of toxicity that relates to both the number and the locations of the halogen atoms. Lesser amounts of all of these planar compounds are needed to cause toxicity as the length of exposure increases. As an example, the single oral LD₅₀ for 2,3,7,8-TCDD in monkeys was found to be 50 µg/kg, but if 500 ng/kg was administered over 6 months, then the cumulative LD₅₀ was 2 µg/kg. Of the polychlorinated dioxins, 2,3,7,8-TCDD is the most studied because of its extreme toxicity to many organisms. Species information reveals the following rank order for adult LD₅₀ TCDD sensitivity: guinea pig 1 µg/kg;²⁷⁵ mink 4.2 µg/kg;²⁸⁰ rabbit 115 µg/kg; chicken 25–50 µg/kg;²⁷⁸ male and female rat 22 µg/kg and 45 µg/kg, respectively;²⁷⁵ mouse 114 µg/kg;²⁸¹ bullfrog > 500;²⁸² and hamster 5000 µg/kg.²⁸³ Comparably, Aulerich and associates reported interperitoneally injected newborn mink mortalities of 62 to 100% with a 1 ng/g TCDD daily dose for 12 days, and a dietary 135-day LC₅₀ for mink of 0.05 µg/g for PCB 169.^{284,285}

18.6.3.2 Chronic Signs of Poisoning

Chronic signs of poisoning in laboratory species include ligand binding, MFO induction, and other biochemical alterations, immunotoxicity, developmental defects, chloracne, cancer, and death.^{286,287} Reviews by various authors indicate that the dioxin-like congeners correlatively manifest similar effects in a given species when dosages are adjusted to compensate for their lesser potencies relative to 2,3,7,8-TCDD. Interspecies sensitivity is variable, and not all acute and chronic symptoms of poisoning occur in every species. It is also very clear from the literature that life-stage sensitivity is exceedingly important in the full assessment of the effects of these compounds. For instance, the embryonic LD₅₀ of 140 pg/g for TCDD in the chicken egg is 140–280 times higher than the LD₅₀ in the adult.^{278,288} For virtually all species tested, reproductive, developmental, and endocrine-related effects are the most sensitive endpoint indicators.

18.6.3.3 Endocrine and Mixed-Function Oxidase Effects

Available information suggests that dioxin-like exposures have the potential to compromise basic reproductive and developmental processes that can impair a population through modifying embryonic set points that are normally programmed for future survival and recruitment. The most responsive adverse effects are on the developing immune, nervous, and reproductive systems. In mammals, these effects have been observed at maternal body burdens of 2,3,7,8-TCDD in the range 30–80 pg/g for both nonhuman primates and rodents. While there is a 5000-fold acute adult lethality difference among guinea pigs, rats, mice, and hamsters, the doses associated with fetotoxicity are similar.²⁸⁷ Among the most striking results of recent ecotoxicological relevant are those involving rats. Prenatal TCDD exposure toward the end of organogenesis produces permanent adverse effects in both male and female rat pups. Males exhibit delayed puberty, altered mating behavior, and decreased spermatogenesis, while females have a unique genital malformation that is characterized by a vaginal thread and cleft phallus, as well as premature reproductive senescence.^{289–295} These effects occur at an estimated body burden of 28 pg/g over the background body burden of 4 pg/g of TCDD typically measured in rats and mice.²⁷¹

There is a general relationship between the amount and timing of the dose for these compounds, not unlike “timing windows” for hormones. Lower dosage levels applied over longer periods of time can result in an identical toxic response of a single high dose. Developing embryos and early-life-stage compromise of basic maturation processes are known targets of these compounds. In this context, therefore, these endocrine effects can threaten maintenance of healthy ecological communities by compromising the ability of individuals to survive, breed, and recruit in a population. Because many of these congeners are persistent in the environment and magnify into higher trophic-level biota, full life-cycle exposures in laboratory testing are important for analyses of population effects.

Other noncancer endpoints have been researched and appear associated with endocrine disruption; these have been recently summarized by Birnbaum and Tuomisto.²⁸⁷ Those with potential ecotoxicological significance that have been found in laboratory species exposed to TCDD and related compounds include: alterations of Leydig cells and normal dentition; induction of cleft palate and hydronephrosis; permanent lowering of core body temperature; onset of hearing deficits associated with circulating T4; learning deficits and impairments possibly associated with brain damage; locomotor and rearing behavior changes; promotion of endometriosis; thymic atrophy and decreases in thymic cellularity and depletion of all four subsets of T-cells; splenic atrophy; thyroid follicular cell hyperplasia; and changes in levels of androgens, estradiol, leutinizing hormone (LH), follicle stimulating hormone (FSH), vitamin A, thyroxine (T4), melatonin, insulin, glucose, serum gastrin, and glucocorticoids. Tissue-specific alterations of several glucocorticoid and estrogen receptor levels have been reported for doses as low as 0.1 of LD₅₀s. Alteration of nuclear retinoid receptor expression has been suggested as well as expression of mitogenic growth factors, such as epidermal growth factor (EGF). Many of these effects appear as direct or indirect divergences from hormonal homeostasis.

The most common sublethal biological effect of PCBs, PCDDs, and PCDFs across all vertebrate classes is increased activity in the hepatic microsomal MFO system. Many enzymes are induced or inhibited by exposures either *in vitro* or in the whole organisms. Typical environmental concentrations of TCDD and TCDD-equivalent tissue concentrations are less than 1.0 ng/g. Therefore, most typical effects on organisms will be through sublethal and chronic effects, as adult LD₅₀ and LC₅₀ values for the species known to be most sensitive are seldom approached in the environment, except at waste sites and in accidental poisoning episodes.

Physiological functions that are controlled by steroid hormones may be altered by exposure of organisms to PCBs, PCDDs, and PCDFs. Growth, molting, and reproduction are primary functions that can be affected by exposure of aquatic organisms to PCBs in numerous laboratory investigations. The ability of organisms to eliminate foreign organic compounds or endogenous waste products also may be affected. Steroid biosynthesis and the degradation and biotransformation of foreign compounds are metabolic activities in both fish and higher vertebrates that are strongly influenced by terminal oxidase activities of the microsomal cytochrome P450 system (or MFO system). Some, though not all, PCB congeners are MFO inducers in fish, mammals, and birds and to a lesser extent in aquatic invertebrates. There are excellent historical reviews on this topic, covering mammals, birds, and, more recently, fish.^{265,276,277,296,297,299-301}

PCB metabolites can be more toxic than the parent compound.²⁶¹ Similarly, some steroids associated with reproduction may be oxidized or altered as a result of the metabolic process used by organisms in the attempt to deplete PCBs and PCDD/PCDFs.³⁰²⁻³⁰⁴ Effects on reproduction in fish may occur prior to spawning, at spawning and egg deposition, or during egg and larval development. Steroid alteration can affect oogenesis, and the production of toxic metabolites can influence oocyte maturation.³⁰⁴ Again, the difficulties in isolating these effects in the environment are severely compounded by the fact that they are very likely indirect, complicated by the interaction with nonchemically related environmental variables that also contribute to these responses. Some examples include deficiency syndromes associated with thiamine, vitamin D, or iodine that may be independent of, or interactive with, toxic effects from these compounds.³⁰⁵⁻³⁰⁷ The increased sensitivity of organisms to PCBs, PCDDs, and PCDFs when challenged with exposure-independent and exposure-dependent deficiencies needs further elucidation.

18.6.4 Wildlife

Generally, the research to date on the effects of the mixed PCBs on mammalian wildlife agree with the data found for traditional laboratory animals. This is partly because few in-depth studies have been carried out on nontraditional laboratory animals, and thus our understanding is far from complete, especially with regard to full-life-cycle testing. For other nonmammalian species, several different types of responses have been observed.

18.6.4.1 Fish

18.6.4.1.1 Acute Effects of Poisoning

Laboratory studies indicate that fish vary in their acute response to PCBs. Eisler,⁶⁴ summarizing the LC₅₀ responses of fishes, showed quite a considerable range depending on the Aroclor type, the species, and whether the species was marine or freshwater. The general level that produced lethality was in the 10- to 300- $\mu\text{g/g}$ range (the exceptions were two marine fish that tested at 0.1 to 0.9 for long-term lab studies of 12 to 38 days). The longer the exposure period, the lower the LC₅₀ value needed to kill the fish species. Early research found PCB toxicities in the range of 8 to 234 $\mu\text{g/L}$ in various fish for 96-hour LC₅₀ tests.^{308,309} Trout species were found to require 1 to 62 mg/L to show LC₅₀ values in 96-hour tests.³¹⁰

In fish, the general characteristic of TCDD-induced toxicity is similar to that observed for mammalian species, i.e., there is a slow wasting-away syndrome leading to mortality. Furthermore, other symptoms are similar, i.e., reproductive toxicity, histopathologic alterations, and possibly immunosuppression and induction of cytochrome-P450-dependent monooxygenases.²⁵⁶ Generally, concentrations causing observable effects were as follows: for rainbow trout, concentrations as low as 0.038 ng/L in flow-through systems caused mortality,²⁵⁶ and adult carp (*Cyprinus carpio*) showed mortality after 71 days on 0.06 ng/L in the same study. Exposure of eggs caused the most dramatic effects: some residues as low as 40 pg/g in eggs caused mortality in lake trout (*Salvelinus namaycush*).³¹² Other species were not as sensitive, e.g., rainbow trout exhibited mortality at 230 to 488 pg/g .³¹³ Later stages of growth were also less sensitive. Intraperitoneal injections of juveniles caused 80-day LD₅₀s at 5 ng/g in bullheads³¹⁴ and 3 ng/g in carp, whereas 16 ng/g of an intraperitoneal dose was required to produce mortality in bluegills (*Lepomis macrochirus*), and 11 ng/g were required in largemouth bass (*Micropterus salmoides*).

18.6.4.1.2 Chronic Effects of Poisoning

For PCBs, long-term toxicity tests on fish indicated little or no effect, even when high water concentrations or dietary exposures were tested. Salmon fingerlings fed 480 mg/kg Aroclor 1254 died after 260 days, while no effect was observed when catfish were fed 2.4–24 mg/kg of four Aroclors for 193 days.³¹⁰ Similarly, adult catfish fed 20 mg/kg Aroclor 1242 for 196 days showed no effect.³¹⁵ Day-old fathead minnows exposed to 0.9 to 5 $\mu\text{g/L}$ Aroclor 1242 and 0.2 to 5 $\mu\text{g/L}$ of Aroclor 1254 for 260 days showed no effects.³⁰⁹ However, 10% lower growth of trout was observed when 17-day-old trout were exposed to 0.2 to 2.9 $\mu\text{g/L}$ Aroclors 1254:1260 (1:2) for 90 days.³¹¹

Oviparous fish appear to show a wide range of reproductive sensitivities. Cold-water species such as lake trout, brook trout, and rainbow trout (*Onchorrhynchus mykiss*) are more sensitive than certain cool-/warm-water species, specifically the fathead minnow (*Pimephales promelas*), channel catfish (*Ictalurus punctatus*), lake herring (*Coregonus artedii*), Japanese medaka (*Oryzias latipes*), white sucker (*Catostomus commersoni*), Northern pike (*Esox lucius*), and zebrafish (*Danio rerio*).³¹⁶ The lake trout is the most sensitive (LC₅₀ 65 pg/g_{egg}), while the least sensitive is the zebrafish (LC₅₀ 2610 pg/g_{egg}). Thus, tested cool-/warm-water species are 8- to 38-fold less sensitive than lake trout. At the present time, hatching and early-life-stage studies have not been extended to partial and full life-cycle testing, which prolongs exposure, determines long-term survival, and looks for additional functional problems demonstrated in other animal classes. Much like the *in utero* effects in mammals, *in ovo* TCDD exposures in fish result in facial/jaw deformities, blue sac disease (yolk sac and pericardial edema), cranial edema, subcutaneous hemorrhaging, spinal deformities, and MFO induction — developmental symptoms similar to those seen in birds. The species differences in sensitivity may be due to variations in the length of time needed for fry to reach swim-up stage and fill their air bladders, in Ah-receptor toxicodynamics, and in toxicokinetics. Readers are urged to consult the underlying references in the WHO TEF scheme;²⁵⁷ these references constitute the

basis for our understanding of the similarity of chronic effects of related congeners. They also document the diminished potency of the PCBs needed to produce these effects in fish relative to mammals and birds.

Toxicologically, it is important to consider the absorption/absorptive exposure in fish, rather than relying on water exposures. In a series of studies with the brook trout with natural accumulation of TCDD via contaminated food pellets, an adult whole-body concentration of 300 pg/g was sufficient to achieve egg concentrations associated with significant adverse effects on embryo survival and delay in time to initial spawning, suggesting that ovulation was affected. In a high-dose (1200 pg/g) treatment, the hepatosomatic index increases were dose-dependent in both sexes.³¹⁸ Companion study results³¹⁹ produced an $LC_{50\text{egg}}$ of 138 pg/g wet weight at swim-up stage. Eggs constituted 39% of the adult whole-body concentration. Exophthalmia, cranial deformities, and generalized edema and hemorrhaging were observed, consistent with previous egg-injection studies in salmonids. Results from natural deposition of TCDD into the eggs resulted in a lower $LC_{50\text{egg}}$ of 138 pg/g, compared to injection concentration of 200 pg/g in a previous study.³¹⁹ Threshold $LC_{10\text{egg}}$ and $LC_{90\text{egg}}$ values were 88 and 184 pg/g.

A physiologically based toxicokinetic model was also produced in the third paper of this series.³²⁰ While affected individuals have not been raised to adulthood, it would obviously be beneficial to have observed these effects in older individuals. This is especially crucial for comparative purposes when wild fish observations are documented. For instance, striped bass (*Morone saxatilis*) have been characterized as having morphological abnormalities. Upon retrospective review of this study, these abnormalities qualitatively resemble certain dioxin-like induced effects (pugheadedness and skeletal) seen in the lower Hudson River and along coastal Long Island in New York during the mid-1970s.³²¹ Similar symptoms of bone-development abnormalities were seen in brook trout tested with Aroclor 1254; in these, backbone phosphorus and hydroxyproline as well as fry survival were reduced, and calcium backbone levels were increased, at fry whole-body concentrations ranging from 17 to 284 $\mu\text{g/g}$.³²²

Integration of abiotic and biotic exposure compartments is needed to address risk and to remediate excessive environmental pollution with these compounds. In a modeling paper discussing retrospective analysis of dioxin-like compounds using biota sediment accumulation factors (BSAFs) and dated sediment cores, lake trout from Lake Ontario were assessed. Effects on reproductive impairment were based on egg TEFs and toxicity equivalence concentration (TECs), defined as the sum of the products of the TEFs and the concentration of each congener in a mixture. In this case study based on egg TECs, lake trout suffered some early-life-stage mortality from approximately 1940 to 1990; for three of these five decades, they suffered total mortality. Eggs were contaminated by multiple dioxin-like congeners, with TCDD and PCB 126 exerting the predominant effects. Ecoepidemiological information confirmed this relationship through monitoring of feral, contaminated eggs under laboratory conditions and the appearance of naturally produced 1- to 2-year-old fish in 1994 when the level of the contaminants had declined.³²³

Atlantic salmon have been tested with a complex mixture of Aroclors 1016, 1221, 1254, and 1260. Tissue concentrations that were 5.6 $\mu\text{g/g}$ from the 48-hour water exposure to this mixture produced reduced wet weight and length after 6 months. A higher tissue concentration (14.2 $\mu\text{g/g}$) was accompanied by altered behavior and reduced predation behavior by the fish.³²⁴

18.6.4.1.3 Endocrine and Mixed-Function Oxidase Effects

Endocrine and MFO effects of exposures have been investigated for several decades in fish, but with less firm results than for other animal classes. In early investigations, only thyroid effects were observed at very high-dose (0.4 to 650 mg/kg) Aroclor diets.³¹⁰ MFO activity in fish, however, is a major site of response to PCB exposure. Although increased activity of this system alone does not represent a toxicological threat,^{325–327} it could have some negative aspects through the formation

and function of secondary products and downstream cascade effects from Ah-receptor binding. Thus, reexamination of old data may be warranted.

Reproductive toxicities have been documented in certain species of fish. Baltic flounder (*Platichthys flesus*) exhibited toxicity when ovary concentrations exceeded 0.12 mg/kg fresh weight.³⁰⁹ Eisler cites several examples in his review chapter on PCBs:⁶⁴ among these, rainbow trout at 0.4 mg/kg Aroclor 1242 produced eggs with low survival and numerous fry deformities, rainbow trout at 0.33 mg/kg 1254 had 10 to 28% mortality, and Atlantic salmon at 0.6 to 1.9 mg/kg had 46 to 100% mortality. However, other studies on trout indicated that eggs with residue levels of 1.6 mg/kg did not have diminished survival.³¹⁷ Eggs exposed to water with 0.4 to 13 $\mu\text{g/L}$ Aroclor 1254 had 21 to 100% fry mortality.³²² Thyroid hyperplasia has been observed in Great Lakes salmonids, and some attention has been given to this response in laboratory testing with PCBs. However, other than higher thyroid activity, no harmful effects have yet to be documented.^{303,309,310}

2,3,4,7,8-pentachlorodibenzofuran, TCDD, and 2,3,7,8-tetrachlorodibenzofuran as well as β -naphthoflavone inhibited vitellogenin synthesis in 17 β -estradiol-treated rainbow trout liver cells.³³¹ Potency of inhibition was directly related to strength as an inducer of CYP1A1 protein. PCB congeners 77, 126, and 156 did not inhibit vitellogenin synthesis and induced no levels or only moderate levels of CYP1A1 protein or EROD activity at molar concentrations that did produce vitellogenin effects from the tested furans and dioxin.

The pineal hormone melatonin, an important regulator of endocrine function and circadian rhythms in vertebrates, was investigated in rainbow trout primary hepatocytes. Treatment with 2,3,7,8-TCDD increased the major oxidative metabolite, 6-hydroxymelatonin, about 2.5-fold after 24 h and 1.2-fold after 48 h exposure, relative to the control cultures.³³²

Schmitt and co-workers³³³ provided a description of the complexity of relationships in the environment for fish exposures to multiple contaminants, including PCBs, PCDDs, and PCDFs from various regions of the United States, specifically the Mississippi, Columbia, and Rio Grande River watersheds. The yolk protein, vitellogenin, occurrence in plasma and ovarian cells in the testes of male fish from several sites, along with abnormal ratios of sex steroids, suggesting that fish from some sites are exposed to endocrine-modulating substances. Because of the antiestrogenic activity of dioxin-like PCBs, PCDDs, and PCDFs, it is difficult for these compounds to be clearly implicated in male fish vitellogenin induction (a hallmark of an estrogenic substance). However, the abnormal sex steroid ratios might be implicated. Hydroxylated PCBs, which are not dioxin-like, may be important in vitellogenin induction and feminization of male fish; they require further male-specific investigation.

Aroclor 1254 disrupted reproductive/endocrine function in Atlantic croaker (*Micropogonias undulatus*) when they were fed a dietary concentration of 0.5 mg/100g body weight for 17 days. Ovarian growth was impaired, and vitellogenesis decline was associated with a decline in plasma estradiol. *In vitro* spontaneous secretion of gonadotropin from pituitary glands of PCB-treated fish was also demonstrated.³³⁴ More recent work in this species, again with exposure to Aroclor 1254 (dietary dose 1 $\mu\text{g/g}$ for 30 days), demonstrated reduced serotonin, dopamine, testosterone and 11-ketotestosterone, testicular growth inhibition, and reduced testicular gonadal somatic index.^{335,336}

Endocrine stress response and abnormal development were demonstrated in carp that were water-exposed to PCB 126.³³⁷ At 10^{-10} and 10^{-11} mol L⁻¹, PCB 126 altered the levels of stress hormones, adrenocorticotrophic hormone (ACTH), α -melanocyte-stimulating hormone (MSH), and cortisol in whole-body measurements. Swelling of the yolk sac and pericardium occurred, indicating that edema was induced, as well as PCB-stimulated body pigmentation thought to be mediated by elevated α -MSH at all PCB 126 test concentrations.

TCDD, PCB 126, β -naphthoflavone, benzo(a)pyrene, and diindolylmethane caused a concentration-dependent suppression of the secretion of vitellogenin, which was related to the response observed with E2-treated cultured female carp hepatocytes. The order of potency for suppression of vitellogenin secretion was comparable to the order of potency for CYP1A induction. These

investigators suggested that the antiestrogenicity of these compounds, while AhR-mediated does not involve CYP1A. This could be relevant for feral fish populations, as they are frequently exposed to Ah-receptor agonists at levels at which AhR-mediated effects are observed.³³⁸

Study of multiple exposures exemplifies the difficulty in establishing cause-and-effect relationships without complementary laboratory and combined field/laboratory study designs. The joint toxicity of tributyl tin (TBT) and PCB in the diets of Japanese medaka demonstrated additive effects on spawning success but antagonistic effects on embryological success of eggs and swim-up success of larvae.³³⁹

In a study of zebrafish,³⁴⁰ 17 β -estradiol; 2,3,3',4,4',5,6-HpCB (PCB-190); 2,3,4,4'-TeCB (PCB-60); and 2,2',4,6,6'-PeCB (PCB-104), which are PCBs considered to be nondioxin-like, increased embryo and larval mortality. The most severe effects on viability were observed following treatment with 17 β -estradiol or the weakly estrogenic PCB-104. Delayed embryo development and hatching were seen. PCB-190 showed only moderate effects on early-life-stage mortality. The fish were reared until sexual maturation, after which they were subjected to gross morphological and histological analyses. Changes in morphology were observed following PCB-104 and PCB-190 treatment. Both substances produced craniofacial malformations, while PCB-104 induced lordosis in females and scoliosis in fish of both sexes. From histological analysis it was found that PCB-104 and 17 β -estradiol resulted in karyorrhexis and karyolysis in the kidney. Ovaries showed atresia and limited failure of testicular spermatogenesis in fish treated with 17 β -estradiol, PCB-104, or PCB-60. This study demonstrated that xenoestrogenic substances are embryotoxic and manifest certain characteristic symptoms in common with the dioxin-like effects, although obviously through a different primary mechanism.

PCB 81 was tested in juvenile rainbow trout and was found to be 0.004-fold as potent as TCDD in the induction of AHH activity.³⁴¹ When investigated in medaka embryos in this study, PCB 81 was more toxic than PCB 77, and TEFs of 0.0014 and 0.006 were determined for mortality and for swim bladder inflation, respectively.

Detailed reviews that address PCBs and dioxins have recently covered the effects on the immune, MFO, and endocrine systems in fish.^{301,342-346}

18.6.4.2 Birds

18.6.4.2.1 Acute Effects of Poisoning

As noted by Eisler,⁶⁴ birds are more resistant to acutely toxic effects of PCBs than are mammals. LD₅₀s ranged from the 60s to > 6000 mg/kg diet for several birds tested in laboratory studies.⁶² Little field mortality can be ascribed to PCBs. In southern Ontario, high PCB exposure, as indicated by levels in the brain in excess of 310 μ g/g, were believed to have caused mortality in ring-billed gulls in late summer and early autumn 1973.³⁴⁷ This mortality may also have been caused by high PCDF and PCDD contamination, which is well documented in the Lake Ontario ecosystem.

Birds that forage within aquatic-based foodchains, such as gulls, terns, herons, and mergansers, can accumulate relatively high concentrations of PCBs and PCDD/PCDFs. They differ from true terrestrial species, such as passerine and gallinaceous birds, which generally have lower concentrations of PCBs and PCDD/PCDFs. However, for eagles, falcons, hawks, and owls, which are at the top of their respective food chains, there is a potential for high exposure due to their high biomagnification potentials (i.e., 10,000 and higher) and their unique feeding habits. Those individual species that possess feeding strategies in which they hunt other birds (or their eggs) and mammals — which already may be exposed and also have biomagnified these contaminants — will have the highest exposures and will possibly move past an effects threshold. Additionally, for birds that are scavenger feeders, e.g., foragers at municipal dumps or dead carcasses of seals, the potential for exposure is high, though dependent on the frequency of such behavior.

Laboratory Species — There are considerable data for PCB toxicity and more limited data for PCDD toxicity to chickens. This species appears to be unusually sensitive to PCBs and dioxin-like compounds in general. The term “chick edema disease” was first used during investigative studies of unintentional poisonings in young chickens (reviewed in Firestone³⁴⁸). Chick edema disease was caused by 1,2,3,7,8,9-HpCDD, which was discovered in chicken feed that was contaminated with a “toxic fat” food supplement. The toxic fat was linked to the degreasing of cattle hides with pentachlorophenol, the ultimate source. More interpretive PCB and PCDD studies have been conducted with chicken (*Gallus gallus*) than with any other bird species.

Pen and Laboratory Studies — Adult and juvenile birds of precocial species exhibit varying sensitivities to ingestion of Aroclor and PCB mixtures. In 5-day feeding trials, dietary median lethal concentrations (8-day $\mu\text{g/g-LC}_{50\text{s}}$) were 604 with Aroclor 1254 for northern bobwhite (*Colinus virginianus*), 1091 for ring-necked pheasants (*Phasianus colchicus*), 2697 for mallards (*Anas platyrhynchos*), and 2895 for Japanese quail (*Coturnix japonica*).³⁴⁹ In a related publication on this same Aroclor toxicity study, Heath and co-workers²⁷⁹ documented the complete absence of fat and the presence of pericardial edema in lethally poisoned bobwhite chicks — characteristics of chick edema disease. This early study also tested the joint lethality of Aroclor 1254 and p,p'-DDE to Japanese quail chicks, using three different but wide-ranging ratios; it found that all combinations “proved to be essentially additive” in the joint action of the two compounds. This has implications for causal determinations of reproductive impairment in the wild where multiple contaminant exposures are common and where statistical significance alone, on a chemical-by-chemical basis, may not account for combined causal associations that are biologically significant.

Dahlgren and co-workers³⁵⁰ administered capsules daily containing 10, 20, or 210 mg of Aroclor 1254 to 11-week-old hen pheasants until death or sacrifice. PCB ingestion, at all levels in a dose-dependent fashion, killed birds, with those receiving the least PCB taking longer to die. The authors concluded that a brain residue level of 300 to 400 $\mu\text{g/g}$ was indicative of death due to PCB toxicosis. Further studies by these authors³⁵¹ revealed that periodic food deprivation increased brain residues, leading to more rapid death.

Young cockerels (day-old at start) that died on dosage of 600 $\mu\text{g/g}$ Aroclor 1260 contained 270 to 420 $\mu\text{g/g}$ of PCBs in the brain.³⁵² Dosage with phenochlor and chlophen (60% chlorine mixtures) resulted in more variable residues, and these two formulations were more toxic than Aroclor 1260 and produced pathological signs. However, both of these formulations proved to be contaminated with chlorinated dibenzofurans.³⁵³ Pathological examination of these chickens revealed severe edema and lesions.

Wildlife Species — Studies conducted with altricial species of birds have included observations with cormorants, herons, finches, and blackbirds. Great cormorants (*Phalacrocorax carbo*) dosed experimentally with clophen A 60 died with brain residues of 76–180 $\mu\text{g/g}$ (mean, 130) whereas herons that died on clophen dosage contained 420–445 $\mu\text{g/g}$, suggesting that cormorants were more sensitive than herons.³⁵⁴ These authors concluded that survival time in cormorants was related to the capacity of the birds to store the PCBs in adipose and other tissues, apart from brain, indicating that total-body content is not a good criterion by which to assess mortality.

As observed above, lethality in birds appears to be correlated with brain residue levels. Stickel and co-workers³⁵⁵ conducted one of the most comprehensive studies designed to establish lethal brain residues of PCBs, using Aroclor 1254, in passerine species. These species included immature male common grackles (*Quiscalus quiscula*), immature female red-winged blackbirds (*Agelaius phoeniceus*), adult male brown-headed cowbirds (*Molothrus ater*), and immature female starlings (*Sturnus vulgaris*). PCB residues in brains of birds that died were distinctly higher than those in sacrificed survivors, providing suitable diagnostic criteria. PCB residues varied from 349 to 763 $\mu\text{g/g}$ wet weight in brains of dead birds and from 54 to 301 $\mu\text{g/g}$ in sacrificed birds. The authors considered a threshold of 310 $\mu\text{g/g}$ to be diagnostic of PCB-induced mortality. PCBs in brains of

dead birds for three species did not differ significantly from one another, but residues in starlings (mean 439 $\mu\text{g/g}$) averaged significantly lower than for red-winged blackbirds and grackles.

18.6.4.2.2 *Chronic Effects of Poisoning*

Egg Injection Studies — Most chronic-effects studies have focused on the reproductive outcomes of embryonic exposure to PCBs and PCDD/PCDFs. Egg-injection studies have been successfully utilized to mimic natural deposition of these lipophilic contaminants from a laying hen, either by introduction into the air sac or direct yolk-sac injection. Additionally, several methods have been used to observe the reproductive effects of chronic adult exposure, including dietary, water, and injected exposures of the hen to the toxicant, as well as allowing for natural deposition into the egg, in which yolk is the toxicant reservoir. As in other experiments, it appears that (1) the longer the exposure, the greater the effect, and that (2) the earlier in development the compounds are administered (day-zero exposure in an egg), the greater the toxic effect. This makes it difficult to separate out general chronic toxicity from that mediated indirectly through endocrine system disruption. All of the above effects appear to be related for these (PCBs and PCDD/PCDF) compounds.

Laboratory Species — In a white leghorn study, hens received diets containing 0 to 80 $\mu\text{g/g}$ Aroclor 1242 for 6 weeks.³⁵⁶ Egg production, egg weight, shell thickness, and shell weight were not affected, but hatchability was affected within 2 weeks for hens fed as little as 20 $\mu\text{g/g}$ dry weight. Yolks contained 2.4 $\mu\text{g/g}$ (expected whole-egg concentration of 0.87 $\mu\text{g/g}$). This conversion is based on the chicken yolk comprising 0.364 of the whole-egg content mass.³⁵⁷ Even 10 $\mu\text{g/g}$ dry weight in the diet caused a small reduction in hatching at the end of 6 weeks (yolk concentration of 3.7 $\mu\text{g/g}$, or expected whole-egg concentration of 1.3 $\mu\text{g/g}$). Scott³⁵⁸ reported that hatchability was decreased after 4 weeks of Aroclor 1248 at 10 $\mu\text{g/g}$ dry weight in the diet, with egg residues of 22.7 $\mu\text{g/g}$.

Numerous egg-injection studies have been conducted with PCBs in the chicken egg. Blazak and Marcum³⁵⁹ injected Aroclor 1242 into the air cell of fertile white leghorn eggs. Both 10 and 20 $\mu\text{g/g}$ caused 64 to 67% mortality but did not result in chromosomal breakage, as had been reported in ringed-turtle doves by Peakall and co-workers.³⁶⁰ Srebocan and co-workers³⁶¹ injected Aroclor 1254 into chicken egg air cells and noted decreased activity in key gluconeogenic enzymes. Brunstrom and Orberg³⁶² injected white leghorn eggs, after 4 days of incubation, into the yolk sacs to attain egg concentrations of 0, 1, 5, and 25 $\mu\text{g/g}$ of Aroclor 1248. Hatchability was 96, 92, 17, and 0%, respectively, with mortality occurring the earliest in the 25 $\mu\text{g/g}$ group (days 6–12). A great number of egg-injection studies have been conducted with specific PCB congeners studying the effects in chickens and other species. Rifkind and co-workers³⁶³ injected chicken eggs at 10 days of incubation with 5 to 1000 nmol/egg for each of three PCB congeners (77, 169, and 2,2',3,3',6,6'-HCB (PCB 136)). PCB 77 caused dose-related decreases in survival from day 10 through 19 days of exposure at 100 to 1000 nmol/egg, and PCB 169 at 500 to 1000 nmol/egg. These decreases in survival were accompanied by decreased thymus weight and increased pericardial and subcutaneous edema in surviving embryos. Another study by these authors revealed that hepatocyte swelling, the major histopathologic change, was apparent within 24 h, after doses as low as 5 nmol/egg for PCB 77.

Wildlife Species — Effects of PCB congeners 126 and 77 in chickens, common terns (*Sterna hirundo*), and American kestrels (*Falco sparverius*) were studied through hatching, following air-cell injections on day 4 of incubation.³⁶⁴ In the chicken, kestrel, and common tern, the LD_{50} s for PCB 126 were, respectively, ~0.4 ng/g_{egg}, 65 ng/g_{egg}, and 104 ng/g_{egg}. This study also demonstrated that PCB 77 was about fivefold less toxic than PCB 126 in the chicken model (LD_{50} 2.6 ng/g_{egg}). In the kestrel, the LD_{50} for PCB 77 was 316 ng/g_{egg}. In common terns, deformities occurred at egg concentrations at which hatching success was affected, whereas malformations occurred below those concentrations affecting hatching success in the chicken and kestrel. Hatching success,

malformations, and edema in this study were consistent with the reproductive problems identified in other recent laboratory studies of chickens^{288,365} as well as Great Lakes species (Forster's tern, common tern, Caspian tern, double-crested cormorant, bald eagle, and herring gull).^{366–369}

Probably the most important finding of the study was on kestrels, considered as a surrogate species for interpreting effects on the bald eagle in the Great Lakes and elsewhere. Eagle eggs from New Jersey³⁷⁰ and the Great Lakes,^{371,372} areas where reproductive impairment including malformations³⁷³ have been documented, contained elevated PCB 126 concentrations at 2–4 ng/g egg to 42 ng/g egg fresh wet weight. PCB 126 is always the largest contributor to TCDD TEQs in birds having significant PCB exposure. In kestrels, malformations begin occurring at 0.23 ng/g_{egg}, combined malformations and edema are statistically different from controls at 2.3 ng/g_{egg}, and malformations alone are statistically different at 23 ng/g_{egg}. These findings present a plausible explanation for the occurrence of bill defects in Great Lakes eaglet nestlings. Growth retardation indicators of toxicity measured in exposed kestrels (hatch weight, liver weight, and femur length) were statistically significant at 0.23 ng/g_{egg}. Although these effects have not been studied directly in bald eagles because of their protected status, it seems reasonable to expect growth retardation in more highly exposed individual hatchlings, leading to reduced productivity and reduced survival from other chronic stressors. Kestrel chick developmental toxicity was shown to be lower than for embryos and higher than for adults.³⁷⁴

In an exposure study using carp from Saginaw Bay, Lake Huron as a weathered, environmentally relevant source, white leghorn hens were administered between 0.3 (control (0%) carp) and 6.6 (high-dose [35%] carp) mg/kg/day total PCBs, yielding time- and dose-dependent reproductive toxicity.³⁷⁵ Embryos displayed typical embryo mortality and reduced hatchability, as well as classic deformities including head, neck, and abdominal edema, hemorrhaging, and foot, leg, skull, brain, and yolk-sac deformities. Organ weights were significantly affected including livers, spleens, and bursas. Hatched chicks showed significant effects on body, brain, liver, heart, and bursa weights. These effects are all consistent with the establishment of Koch's fifth postulate, which requires the hypothesized putative factor to be introduced into the test organism and to reproduce symptomatic adverse effects. In this case, the sensitive model species was utilized as a surrogate for fish-eating birds that have demonstrated historical symptoms of PCB and dioxin-like reproductive toxicity.^{366–368}

Comparative avian egg-injection studies by Brunstrom and co-workers have shown that chickens are more sensitive than turkeys (*Meleagris gallopavo*), pheasants, ducks (mallards and goldeneyes (*Bucephala clangula*), domestic geese (*Anser anser*), herring gulls, and black-headed gulls (*Larus ridibundus*).³⁷⁶

Reproductive impairment has been reported in at least five species of birds that were experimentally dosed with PCBs including chickens, ringed-turtle doves (*Streptopelia risoria*), Japanese quail, mourning doves (*Zenaida macroura*), and ring-necked pheasants. Egg production was reduced with 5 µg/g in the diet, but hatchability was unaffected. However, after 14 weeks, fertility was lower. Hatchability of fertile eggs was only affected when the PCB concentration exceeded 15 µg/g in eggs; at such levels, embryonic mortality was high and occurred at earlier stages. In contrast, Cecil and co-workers³⁷⁷ reported that dietary levels of 20 µg/g for Aroclor 1254 did not affect hatching success of chickens at the end of 5 weeks with egg residues of 13.2 µg/g. Tumasonis and co-workers³⁷⁸ exposed white leghorn hens for 6 weeks to 50 mg/L Aroclor 1254 in drinking water. Within 2 weeks, hatching success dropped to 34%. The authors concluded that yolk concentrations > 10–15 µg/g (whole egg concentrations above 4 µg/g) were required to cause this effect. Peakall and Peakall³⁷⁹ found that 10 µg/g of Aroclor 1254 caused increases in embryonic mortality of ringed-turtle doves; this effect was greatly increased when the eggs were incubated by the parents, but it was decreased by artificial incubation. Monitoring of egg temperatures suggested that mortality increased with decreased parental attentiveness. Further studies with Aroclor 1254 in this species revealed depletions of brain dopamine and norepinephrine that were inversely correlated with brain residues.³⁸⁰ Other species appear to be less reproductively sensitive to PCB exposure.

Neither Aroclor 1254 nor Aroclor 1242 affected reproductive success of mallards. Other tests showed screech owls (*Otus asio*) and Atlantic puffins (*Fratercula arctica*) to be unresponsive.

In a more recent iteration of the determination of relative species sensitivity to PCB 126,³⁶⁵ a comparative investigation of yolk-sac-injected eggs demonstrated marked differences in relative embryo mortality sensitivity in the following rank order (most sensitive to least): white leghorn, turkey, common tern, and Japanese quail. For the common tern, the results are consistent with findings by Hoffman and co-workers,³⁶⁴ although the two studies used different dosage methods. The bobwhite is much more sensitive to PCB 126, based on the reported LD₅₀ of 24 ng/g_{egg},³⁶⁴ than is the Japanese quail, with a no-effect concentration on mortality of 240 ng/g_{egg}.³⁶⁵ For the former, the divergence is consistent with early feeding studies of these species in which bobwhites were three to four times more sensitive in dietary acute exposures with various Aroclors.²⁷⁹ In contrast, the piscivorous double-crested cormorant is intermediate in sensitivity, with an LD_{50egg} for PCB 126 of 158 ng/g.³⁸¹

Among the various bird species that have been tested with 2,3,7,8-TCDD, the ring-necked pheasant was the most sensitive besides the chicken, with egg injections of 2.1 ng/g producing LD₅₀s and 25 ng/g i.p. for 80% mortality in the adult hen after 77 days. Other studies³⁸² with ring-necked pheasant determined that the delayed onset of mortality occurred at a single injection of 25 µg/kg. With repeated injections, the cumulative level of 10 µg/kg over 10 weeks caused similar symptoms. Egg-injection studies of ring-necked pheasant eggs demonstrated LD₅₀s of 1.35 and 2.2 pg/g, respectively, for albumen and yolk injections.³⁸³ Bobwhite were sensitive to an LD₅₀ dose of 15 ng/g in their feed,³⁸⁴ but mallards and ringed-turtle doves showed no response at concentrations greater than 108 and 810 ng/g of feed (single dose), respectively.

Among the most compelling case histories available to document the reproductive problems caused by PCBs is for Green Bay Forster's terns (*Sterna forsteri*) in the 1980s. Egg-intrinsic and adult behavioral nest-attentiveness problems lead to a variety of measurement endpoints, including wasting syndrome, as documented in a followup³⁸⁵ to the original study, and provide convincing ecoepidemiological evidence for total PCBs as well as TCDD equivalents as the putative causative factors, as measured in study eggs.³⁸⁶⁻³⁹⁰ The above findings did not determine DDT/DDE to be important to Forster's tern reproductive impairment. Additional work on this species, subsequently conducted in Texas, showed that total PCB egg residues were low and that DDT/DDE residues were greater than those at Green Bay; however, reproductive success was normal.³⁹¹ This study represents an independent confirmation of the importance of the PCBs in Green Bay, conducted by other investigators in a different time and ecosystem.

Wasting syndrome has been documented to various degrees in fish-eating colonial waterbirds, in at least three Great Lakes species investigations, for Forster's terns,³⁸⁵ Caspian terns,³⁹² and herring gulls.³⁹³ A comprehensive review by Hoffman and co-workers³⁶⁸ should be consulted for historical toxicity information from both the laboratory and field study of birds with these compounds.

18.6.4.2.3 Endocrine and Mixed-Function Oxidase Effects

Histological and Biochemical — Comparison of the toxicities of PCB congeners injected into the yolk sac of chicken eggs at an early stage of development (4 days of incubation) revealed that PCB 126 was the most toxic and also the most potent inducer of MFO (EROD) in chick embryo liver.³⁹⁴ The EROD-inducing potencies correlated well with the embryo-lethalities. When injections were administered at the earlier stage of incubation (day 4) via the yolk sac and eggs were incubated until day 18, the congeners were even more toxic. Nonortho chlorinated congeners were more potent inhibitors than were mono-ortho-chlorinated congeners of lymphoid development in the embryonic bursa of *Fabricius*.³⁹⁵ The most immunotoxic of the mono-ortho-chlorinated analogs of PCB 77 and PCB 126 were about 1000 times less potent than PCB 126.

18.6.4.2.4 Other Effects

Specific congeners have been tested as inducers of porphyria in Japanese quail and American kestrels.^{396,397} Liver residue levels for PCB 105 of 2.6 ± 1.7 mg/kg, and for PCB 126 of only 0.091 ± 0.08 mg/kg were found to cause porphyria after 2 weeks in Japanese quail.³⁹⁸ PCB 153 at 52.6 mg/kg in the liver had minimal effects. PCB 126 caused a decrease in thymus weight. All three congeners induced MFO activity as detected by the EROD assay. In American kestrels, residue levels in pooled adipose tissue of 182 mg/kg for PCB 105, of 119 mg/kg for PCB 153, and of 3.3 μ g/kg for PCB 126 did not cause porphyria but did induce hepatic MFO activities.³⁹⁷

Studies have examined the effects of specific PCB congeners on growth. The effects of feeding 400 μ g/g of five hexachlorobiphenyl congeners, including 2,2',4,4',6,6'-HCB (PCB 155), 2,2',3,3',6,6'-HCB (PCB 136), 2,2',4,4',5,5'-HCB (PCB 153), 2,2',3,3',4,4'-HCB (PCB 128), and 3,3',4,4',5,5'-HCB (PCB 169), were examined in growing chicks for 21 days.³⁹⁸ PCB 169 was the most toxic, causing complete mortality, and it produced the highest accumulation (mean of 203 μ g/g) of all congeners in the liver. Growth was reduced by all congeners except PCB 155. Liver-to-body weight ratio was increased by all congeners, with the largest increase produced by PCB 155 and the smallest by PCB 136. Another study examined the effects of PCB congeners 126, 77, and 105 on growth and development of American kestrel nestlings.³⁷⁴ Dosing with 50 ng/g resulted in pronounced liver enlargement and some mild coagulative necrosis of the liver. Increasing the dose to 250 ng/g resulted in intensification of the above effects as well as lesions of the thyroid, decreased spleen weight, and lymphoid depletion of the spleen and bursa.

In testing of PCB 126 in primary immune organ development,³⁹⁹ thymus mass decreased at doses between 0.13 and 0.32 ng/g_{egg} and thymic lymphoid cell numbers dropped sharply at doses between 0.051 and 0.13 ng/g_{egg} when injected into chicken egg air cells. Similarly, bursa mass began to decrease at the lowest dose (0.051 ng/g_{egg}). The number of viable cells decreased across the dose range and reached a minimum at 0.13 ng/g_{egg}. The study concluded that (1) lymphoid cell numbers were more sensitive than organ mass, (2) bursa was more sensitive than the thymus, and (3) the doses to reduce the quantity of viable cells were at least an order of magnitude lower with full-term embryo exposure (day 0–7 injection before incubation, and day-20 egg opening, in a normal 21-day incubation) than with late-stage exposure only. In a related study,⁴⁰⁰ thymocyte phenotype TCR- β^+ decreased with dose as a function of the declines in TCR- β^+ percentages and total thymocyte numbers. The number of viable lymphoid cells in the bursa decreased to 45% lower than in controls at 0.13 ng/g_{egg} and fell to 76% lower than the controls at 0.8 ng/g_{egg}. The authors also calculated that these immunological effects were comparable to those found in Great Lakes herring gull eggs, after correction for interspecies differences in sensitivity to PCB 126. Other related studies on Saginaw Bay Caspian terns have suggested a biologically significant effect on immune function by PHA (phytohemagglutinin), which measures T lymphocyte response.⁴⁰¹ PCB concentrations correlated with reduced immune function to a greater extent than did those of DDE, although both types of compounds were significantly correlated in plasma and eggs. These authors also observed that these and other immune-function tests^{393,402} suggest an association with the reduced recruitment of young terns into the contaminated Saginaw Bay ecosystem that has been characterized through studies of breeding reproduction and population dynamics.⁴⁰³

Environmental Extract Egg-Injection Studies and Vitamin D — In another approach to understanding relative sensitivity, extracts obtained from Great Lakes double-crested cormorants were injected into chicken eggs. One egg-equivalent of cormorant extract injected into chicken eggs produced 77% embryo mortality.⁴⁰⁴ Yet at these levels, no malformations occurred, which is unusual, whereas body weight and relative bursa weights were reduced, while relative brain weights were increased.

Egg-injection studies with extracts from wild bird eggs have failed to produce statistically significant increases in deformities in cormorants,³⁸¹ chickens,⁴⁰⁴ or herring gulls,⁴⁰⁵ suggesting that

another factor or factors (such as vitamin D deficiency³⁰⁶) may be altered during egg development and that this cannot be duplicated in “clean” test eggs. One possibility that has received little attention in ecotoxicological or laboratory studies is that PCBs may alter deposition, in either form or amount, of vitamin D in egg yolks. Vitamin D is lipid-soluble and is critical to proper bone development. Vitamin D is twice hydroxylated, once by hepatic 25-hydroxylase and a second time by renal hydroxylase, to produce the hormone-like activity of $1\alpha,25$ -dihydroxycholecalciferol that is used for calcium regulation and bone deposition. Additionally in the Great Lakes, where bill defects in cormorant nestlings⁴⁰⁶ and dead embryos⁴⁰⁷ are relatively common, altered vitamin D deposition into the yolk could be influenced by exposure of cormorant hens to dioxin-like congeners prior to egg laying. This could be a cofactor in the incidence and prevalence of bill defects, along with dioxin-like congener exposure *in ovo*. Under the combined influence of altered enzyme activity and *in ovo* dioxin-like congener contamination, there could be a deficiency, excess, or altered availability of $1\alpha,25$ -dihydroxycholecalciferol that could be related to bill and skeletal defects or even embryonic mortality.⁴⁰⁸

Embryonic exposure, together with effects in the environment, could result in an enhanced sensitivity of embryos that are simultaneously deficient in available vitamin D and that have altered egg proteins that are associated with reduced vitellogenin synthesis caused by antiestrogenic, dioxin-like congeners. Ascertaining whether such a relationship exists would help to resolve outstanding inconsistencies between extract-based egg injection studies and adult feeding protocols.³⁷⁵ Investigations along these lines may also help explain the puzzling observation that cormorants exposed to low PCB levels developed bill malformations only after hatching and in conjunction with vitamin D-deficient diets (frozen fish) and sunlight deprivation (resulting from indoor zoological captivity).³⁰⁶

Several lines of evidence suggest that during embryonic development, vitamin D, calcium requirements, and vitellogenin formation can be linked to embryotoxic and teratogenic effects caused by certain dioxin-like compounds. Basic bird research on vitamin D has demonstrated that $1\alpha,25$ -dihydroxycholecalciferol-deficient Japanese quail embryos die of calcium deficiency at day 15 of development when hens produce vitamin D-deficient eggs. Single doses of 125 ng cholecalciferol, 600 ng $24,25$ -dihydrocholecalciferol, or 100 ng $1\alpha,25$ -dihydroxycholecalciferol increased hatchability when injected into eggs prior to incubation, but they were toxic when injected into eggs on days 11 and 12. *In vitro* formation of vitellogenin by liver slices of vitamin D-deficient hens is reduced to less than 30% of that occurring in vitamin D-sufficient controls, and vitamin D-deficient hens have lowered Ca^{2+} in blood plasma.⁴⁰⁹ It is not known whether any yolk-related proteins or binding proteins are altered in vitamin D-deficient adult birds. In a review of the primary literature on comparative avian nutrition,⁴¹⁰ Klasing’s discussion of vitamins A and D, among others, provides additional evidence for a potential relationship between embryotoxic and teratogenic effects that are consistent with certain dioxin-like effects. For instance, vitamin D-deficient embryos can develop deformed mandibles and beaks and problems pipping the shell due to overall weakness, and they can have poor bone calcification.

Summary Information — Besides the studies addressed above, recommended resources on the following selected topics are: MFO effects in birds,^{300,411,412} and in-depth development and documentation on TEFs (www.who.nl).

18.6.4.3 Mammals

18.6.4.3.1 Acute Signs of Poisoning

The hallmark responses of MFO induction — wasting and edema — are common to most tested species. In addition, there are species-specific signs of acute toxicity that have been documented. In the monkey, alopecia and swollen eyelids have been demonstrated. In mink, lethargy, anorexia,

hemorrhaging, and hemorrhagic gastric ulcers are symptomatic, along with a dose-dependent decrease in feed consumption with corresponding body weight loss. Gross necropsy revealed mottling and discoloration of the liver, spleen, and kidneys. In mink that are exposed to high doses of TCDD, brain, kidneys, heart, and thyroid and adrenal glands all become enlarged relative to the organism's body weight.²⁸⁰ Fatty infiltration of the liver may or may not occur, depending on the length of the acute exposure. In the European ferret, which is less sensitive than the mink, claws become markedly curled, with an appearance similar to deformed bills in birds.⁴¹³ Similarly, hooves of horses that curled upward was a documented effect observed in horses exposed to horse-arena soil that was contaminated by TCDD from a 2,4,5-T manufacturing facility. The episodic horse exposure is not common in the general environment, whereas acute exposures of mink to TCDD and dioxin-like chemicals in contaminated ecosystems are still possible.

18.6.4.3.2 Chronic Signs of Poisoning

General Indicators — Skin lesions are generally observed in various species. The specific class of compounds first ascribed to causing this response was the chlorinated naphthalenes that caused the hyperkeratotic disease of cattle in the United States labeled “X-disease.” Later an “X-disease-like symptom” was associated with chlorinated dioxins and chlorinated dibenzofurans;¹⁰ PBBs caused skin lesions like the X-disease in cattle in Michigan,⁴¹⁴ and Old World monkeys developed chloracne and a thickened condition of the eyelids.⁴¹⁵ McConnell¹⁰ listed the following chronic features associated with poisoning by these agents. Chloracne-like lesions are not usually observed in rodents. Internal lesions are quite common with these classes of compounds; such lesions vary with duration of exposure and depend especially on the age of the organism being tested. In all experiments involving immature animals, the size and weight of the thymus are markedly less than in the controls. Chronic effects in blood are quite variable; however, the one common component observed in most long-term studies is a dose-time-related anemia that is postulated to be due to the toxic effects on erythropoiesis from all of these types of compounds. The carcinogenic potential of PCBs and dioxins has been studied, but information on dibenzofurans is not available. Dioxins, specifically TCDD and HxCDD, have been shown to be carcinogenic in rats and mice by several investigators. The reproductive effects from intoxication with PCBs and dioxins have been studied in depth.

The first reported reproductive dysfunction that was suggested to be a result of intoxication with the general class of compounds to which PCBs, dioxins, and dibenzofurans belong was observed in a study of women exposed during 1968 to PCBs in Yusho, Japan. These women exhibited irregularities in their menstrual cycles. As stated earlier, the likely components causing these problems were dibenzofurans and dioxin impurities in the PCBs. TCDD has been reported to affect the testes and accessory male reproductive organs. TCDD also adversely affects spermatogenesis and testosterone levels.⁴¹⁶ Many reports of TCDD developmental toxicity are available. TCDD causes cleft palate in mice and other manifestations of developmental toxicity in other species. Furans also induce cleft palate and hydronephrosis in responsive mice. Additional studies of the effects of TCDD on palate and kidney development have been reported. There are considerable differences in toxicity among members of the chemical classes that make up the dioxins and the furan series of compounds.

Metabolism and excretion are assumed to be important modes of detoxification of these chemicals. Exposure of target tissues is to a great extent closely related to chemical solubility and lipophilicity of the particular compounds. Solubility tends to decrease with increasing degree of halogenation, as do the extent and rate of metabolism (and therefore elimination). Thus, highly halogenated members of the groups tend to be more persistent and to have greater potential for bioaccumulation. Those halogenated dioxins, and furans with adjacent unsubstituted carbon atoms, are more readily metabolized than are those without this feature. The symmetrical tetrachlorinated dibenzo-*p*-dioxins and dibenzofurans have no adjacent unsubstituted carbon atoms and are the most toxic members of their respective classes, including developmental toxicity.

Regarding relative species and strain sensitivities, clear differences among species in susceptibility to developmental toxicity have been reported that are relatable to inherent genetic susceptibility, differences in tissue disposition of the chemical, and perhaps other factors that are currently not understood or appreciated. In general, adverse reproductive effects have been caused in multiple species by 2,3,7,8-substituted dioxins. Greater species differences are noted for developmental toxicity than for adverse reproductive effects. Mice are generally more likely to demonstrate malformations, with or without effects on size of pups or litters. In contrast, rats are more likely to have resorption or decreased fetal weight than malformations. Nonhuman primates are more likely to show an effect on fertility and *in utero* survival than abnormalities of structural development. Observations on humans exposed accidentally to dioxins suggest that humans are not more sensitive to adverse reproductive developmental effects than laboratory animals.⁴¹⁶ Additionally, the recent WHO reevaluation of the “tolerable daily intake” for humans estimated the body burdens of laboratory animals at their respective lowest observed adverse effect levels (LOAELs). Those body burdens were transformed into estimated daily human intakes that on a chronic basis would be expected to lead to similar body burdens in humans. The reevaluation noted that “the estimated human daily intakes are related to the body burdens in animals where adverse effects have been reported.”²⁷¹

Mink — Hochstein and co-workers⁴¹⁷ determined the LC₅₀ dietary concentration in adult female mink fed TCDD for 28 or 125 days. Based on feed consumption of control mink, LC₅₀ concentrations approximated 0.264 and 0.047 µg TCDD/kg body weight/day, respectively, for the two lengths of dosing.

In adult female mink exposed to 5 ng/g TCDD for 6 months, the maxilla and mandible were grossly unremarkable, but histologically they had nests of squamous epithelium within the periodontal ligament. There was osteolysis of the adjacent alveolar bone.⁴¹⁸ In a study of 12-week-old male mink fed 24 ng/g PCB 126 for 31–69 days, similar symptoms developed, including thickened gingiva and loose teeth. Squamous cells proliferated into bone and caused jaw osteoporosis.⁴¹⁹ Rhesus macaques (*Macaca mulatta*) also showed these symptoms.⁴²⁰ This study was one of the first to address equitoxic doses of congeners and Aroclor mixtures that produced similar effects at different doses, including Aroclors 1242, 1248, PCB 77, PCB126, TCDD, 2,3,7,8-TCDF, and 2,3,4,6,7,8-hexachlorodibenzo-*p*-dioxin. The importance of 1,25-dihydroxy-vitamin D3 in the control of tooth development was linked to vitamin D deficiency in rats; it was concluded that the tooth is a target organ for 1,25-dihydroxyvitamin D3.⁴²¹ Calcitonin, estrogen, and parathyroid hormone all interact with vitamin D in the control and deposition of bone and for maintaining tooth health. Aroclor 1254 resulted in smaller body weight and increased urinary alkaline phosphatase and lactate dehydrogenase, serum calcium, nephrotoxicity, and abnormal bone morphometry in young, growing male Fisher 344 rats, but serum PTH, phosphorus, alkaline phosphatase, LDH, and 1,25-dihydroxy vitamin D3 were unchanged at any dose.⁴²² The influence of the dioxin-like congeners on MFO induction/inhibition, and availability of the above hormones, as well as their effect on carrier and other proteins that direct calcium metabolism and toxic effect in general need further elucidation.

A study of multigenerational effects was conducted on mink in which they consumed PCB-contaminated carp from Saginaw Bay, Lake Huron.⁴²³ The adult mink were fed diets formulated to provide 0 (control), 0.25, 0.5, or 1.0 µg/g PCBs through substitution of Saginaw Bay carp for ocean fish in the diet. Continuous F1 exposures to = 0.25 µg/g of PCBs delayed the onset of estrus (as determined by vulvar swelling and time of mating) and lessened the whelping rate. Litters whelped by females continuously exposed to = 0.5 µg/g of PCBs had greater mortality and lower body weights than did controls. Continuous exposure to 1.0 µg/g PCBs had a variable effect on serum thyroxin (T4) and triiodothyronine (T3) concentrations. There were significant differences in kidney, liver, brain, spleen, heart, and thyroid gland weights of the mink continuously exposed to 1.0 µg/g PCBs.

Plasma and liver PCB concentrations of the adult and kit mink were, in general, directly related to the dietary concentration of PCBs and the duration and time of exposure. Short-term parental exposure to PCBs had detrimental effects on survival of subsequent generations of mink, conceived months after the parents were placed on “clean” feed. The LOAEL for use of an environmentally weathered PCB diet in this study was 0.25 µg/g. Using a similar Saginaw Bay carp feeding protocol in a one-generation test, Tillitt and co-workers²⁶² estimated a total TCDD toxicity equivalent concentration threshold dietary dose of 1.9 pg/g and 60 pg/g_{liver} for adult mink that had been exposed and chemically analyzed. According to earlier WHO mammalian TEFs,^{258,259} PCBs contributed approximately 76 to 82% of dietary total TCDD equivalents, while in livers of adult mink, PCBs accounted for 61 to 65% of total TCDD equivalents. Since absorbed concentrations are more relevant in assessment of target organ and reproductive effects, liver concentrations of the latter are more ecotoxicologically important. Rank-ordered contributors to total TCDD equivalent concentrations, from highest to lowest, were PCB 126, 2,3,7,8-TCDD, 2,3,7,8-TCDF, 2,3,4,7,8-PeCDF, and PCB 118.

Across dosage groups, PCB 126 was at least fivefold more potent as a contributor to total TEQ concentrations in mink liver than either 2,3,7,8-TCDD or 2,3,7,8-TCDF. These relative importance rankings will vary because ecosystems, on a site-specific scale, have been polluted with different congener ratios from different sources. The new WHO TEFs²⁵⁷ would increase the overall importance of the PCDDs in this study slightly due to the change of TEF for 1,2,3,7,8-PCDD from 0.5 to 1.0. Chronic effects in adult mink dosed in this study are addressed in a companion paper⁴²⁴ and are consistent with previous work using known quantities of commercial PCB mixtures. In a study of the risk to Great Lakes fish contaminated with PCBs, virtually every fish species potentially consumed by mink offered some measure of risk.⁴²⁵

Other Mammals — Common seal populations in the Wadden Sea in The Netherlands appear to have declined due to PCBs.^{426,427} Effects on the uteri of Baltic ringed seals have been noted when levels of DDT and PCB are higher than in normal females. The same effect was observed in Baltic grey seals (*Halichoerus grypus*) when concentrations of PCB were > 70 µg/g in blubber fat, and they were not fertile at these concentrations. High PCDD and PCDF levels were also correlated with the high PCBs in these species, suggesting that these compounds may actually be responsible for these reproductive problems.

It has been suggested that PCBs may affect bats.^{428,429} Reinhold and associates⁴³⁰ studied the pond bat (*Myotis dasycneme*) and its major food source, chironomids. They found that PCBs measured in chironomids did not exceed “safe” dietary levels for mammals. Nonetheless, some bats had PCB concentrations of 9, 33, or 76 mg kg⁻¹ lipid weight, which exceed the concentration levels that cause reproductive effects in mink. Further work on bats appear mandatory since several bat species are federally listed species in the United States.

For additional information on the exposure to and the effects of PCBs, PCDDs, and PCDFs on aquatic and marine mammals, some excellent recent reviews can be consulted.^{431–433} Another recent review provided analysis of tissue and dietary thresholds for various aquatic mammals.⁴³⁴ Threshold PCB or TCDD-equivalent concentrations in livers of aquatic mammals that elicited physiological effects ranged from 6.6 to 11 µg PCBs/g (geometric mean: 8.7 µg/g) and 160 to 1400 pg TCDD equivalents (geometric mean: 520 pg/g) for lipid weight, respectively. Biomagnification factors for PCBs and TCDD equivalents varied by species of marine mammal. The dietary threshold concentration ranges for these marine mammals were 10 to 150 ng PCBs/g and 1.4 to 1.9 pg TEQs/g wet weight.

18.6.4.4 Endocrine and Mixed Function Oxidase Effects

There is a dearth of information on wild mammals concerning MFO induction, and little more information is available concerning their immune systems. Controlled studies are extremely difficult

to conduct, especially for large marine mammals. Concern over the use of larger mammals in testing is also evident from this paucity of information. As with the preceding discussion on chronic effects, key reviews should be consulted to assess what is available.⁴³¹⁻⁴³³

Seals — Harbor seals fed fish from the Wadden Sea (high-level PCB contamination) had significantly lower concentrations of plasma retinol, total thyroxin (TT4) and free thyroxin (FT4), and total triiodothyronine (TT3). The PCB-induced reduction in plasma retinol levels disappeared when seals on a diet of Wadden Sea fish were subsequently fed low-PCB-containing Atlantic Ocean fish. The authors suggested that an increased susceptibility to microbial infections, reproductive disorders, and other pathological alterations were related to reproductive disorders and to the lethal viral infections in seals and other marine mammal populations in the Baltic Sea, North Sea, and Wadden Sea. The reduced plasma retinol and thyroid hormone levels were implicated.⁴³⁵ Subsequently, a comprehensive review of the seal problem and concerns for their protection was produced in 1992, which included a suggestion to perform feeding experiments with mink as a surrogate species for studying the problem.⁴³⁶

In an additional report on these harbor seals, impairment of T-cell-mediated immune responses became apparent during the second year on the Wadden Sea/Atlantic Ocean fish diets used earlier and correlated significantly with TCDD equivalent levels in blubber biopsies taken from the seals after 2 years. Humoral immune responses remained largely unaffected. The authors concluded that cellular immune system suppression response in seals fed a third diet of Baltic herring was induced by the chronic exposure to immunotoxic environmental contaminants accumulated through the food chain and could be of crucial importance in the clearance of morbillivirus (canine distemper virus) infections. Environmental-pollution-related immunosuppression may have contributed to the severity and extent of recent morbillivirus-related mass mortalities among marine mammals.⁴³⁷ More recently, total PCBs in the blubber and liver of harbor seals were correlated with P450, P420, and MFO activity levels.⁴³⁸

Harbor seals assessed from southern San Francisco Bay had a mean whole-blood PCB concentration of 50 ng/mL, about three times the average level reported for blood of captive seals fed exclusively on fish from the Baltic's PCB-contaminated Wadden Sea. These findings support concerns about the ecological effects of PCB contamination in San Francisco Bay.⁴³⁹ Four-week-old harbor seal pups from coastal California had mean PCB concentrations in blubber of 3.3 µg/g on a lipid basis.⁴⁴⁰ This study demonstrated that contaminated pups exhibited relatively strong lymphocyte proliferative response to conconavalin A and moderate responses to poke weed mitogen and phytohemagglutinin. Serum thyroid hormone levels in the pups were typical for levels reported in neonatal seals. Regression analysis revealed associations between reduced immune responses and increasing levels of TCDD equivalents (non-ortho PCBs were 46% of the total), suggesting an effect of planar PCBs on T-cell function. Reduced thyroid hormone levels were associated with increasing levels of TCDD equivalents, suggesting the involvement of planar and nonplanar congeners. The estimated threshold for immune- and endocrine-disrupting effects of bioactive PCB congeners was 3 µg/g on a lipid basis for neonatal harbor seals.

The situation for the Baltic grey seal was recently reviewed. It has seen general improvement in reproductive and other parameters between 1977 and 1996, but there is an increase in colonic ulcers in young grey seals, suggesting the possibility of another new contaminant in this ecosystem.⁴⁴¹ The disease complex comprised lesions of claws, skull bone, intestine (colonic ulcers), kidneys (glomerulopathy, tubular cell proliferations), arteries (sclerosis) and adrenal glands (cortical hyperplasia, cortical adenomas). Besides occlusions and stenoses, tumors (leiomyomas) were common in the uterus. A time trend of improving gynecological health with decreasing PCBs and DDT was confirmed.

Mink — In a study of mink from the Frazer and Columbia River systems in the Pacific Northwest of North America, juvenile mink demonstrated a significant negative correlation between total PCB

concentrations in the liver and baculum length. The association of juvenile baculum length with eventual reproductive success is unknown at the present time.⁴⁴² There is supportive evidence for these types of responses occurring in other mammals as follows: dosing of adult rats with PCB 169 produced male offspring that had reduced ventral prostate, seminal vesicles, testes weights, epididymides, and sperm counts and were in general considered to be slow in all maturation events including time to puberty. Delayed development in this sense was not considered an antiandrogenic response because hallmark effects of reduced anogenital distance, male hypospadias, or induction of areolas or nipples did not occur.⁴⁴³ However, as 600-day-old adults, these PCB 169-exposed offspring had ventral prostates, caudal sperm counts, and ejaculated sperm counts that were all significantly reduced, and there was a significant increase in dorsolateral lobe prostatitis.

Polar Bear — In a recent comprehensive review from Canada, the species with the most significant risk of exposure to PCBs and organochlorine (OC) pesticides appeared to be the polar bear (*Ursus maritimus*). In this study, the measured EROD function in the polar bear appeared to have elevated CYP1A-mediated activity, relative to beluga whale (*Delphinapterus leucas*) and ringed seal. The MFO enzyme data for polar bear, beluga, and seal suggest that even the relatively low levels of contaminants present in Arctic animals may not be without biological effects, especially during years of poor feeding.⁴⁴⁴ The PCDD/PCDF congener pattern in polar bear milk from Svalbard, Norway was different from that found in polar bear fat from the Canadian Arctic, although non-ortho-substituted PCBs in polar bear milk were similar to those found in polar bear fat from the Canadian North.⁴⁴⁵ In 1996, two yearling polar bears at Svalbard, Norway were captured that were found to have a normal vaginal opening and a 20-mm penis containing a baculum. The penis was located caudal to the location in a normal male and was concealed within the vaginal opening by a single pair of labia. Neither of the yearlings showed signs of a Y chromosome, so both bears were regarded as female pseudohermaphrodites. Two additional bears with aberrant genital morphology and a high degree of clitoral hypertrophy at Svalbard were also classified as female pseudohermaphrodites. The observed rate of female pseudohermaphroditism in this area was 1.5% (4/269). Pseudohermaphroditism in this polar bear population could result from excessive androgen excretion by the mother, be caused by a tumor, or be the result of endocrine disruption from environmental contaminants.⁴⁴⁶ A recent compilation of contamination and effects has been produced covering the Svalbard area.⁴⁴⁷

Whales and Dolphins — The Gulf of St. Lawrence beluga whales have received considerable attention as a population of which approximately 500 individuals remain. It is not expanding, suggesting reduced reproduction and survival of juveniles. Of all of the tumors reported in cetaceans, 37% were observed in these whales. An adult hermaphrodite beluga has been documented, with two ovaries, two testes, and complete genital tracts of both sexes, with the exception of cervix, vagina, and vulva. Belugas are contaminated with a wide mix of endocrine-disruptive and carcinogenic contaminants. So far no attempts have been made to identify any likely causative agents from the large family of pollutants to which the belugas are exposed.⁴⁴⁸ Bottlenose dolphins (*Tursiops truncatus*) have a reduced *in vitro* mitogen response to Con A and PHA that is associated with increased levels of PCBs and DDT in peripheral blood.⁴⁴⁹

18.6.4.5 Invertebrates and Other Aquatic Organisms

18.6.4.5.1 Invertebrates

Barber and co-workers⁴⁵⁰ found no indication of 2,3,7,8-TCDD toxicity to survival or growth in the amphipod (*Ampelisca abdita*), using spiked sediments from coastal New Jersey waters with a range of 2,3,7,8-TCDD concentrations (0–25 µg/kg dry weight). The maximum 2,3,7,8-TCDD concentration in ambient sediment was 0.62 µg/kg. Ashley and co-workers⁴⁵¹ reported a 2,3,7,8-

TCDD LD₅₀ of 30–100 µg/kg for freshwater crayfish (*Pacifastacus leniusculus*), with a delayed mortality of typically 15–40 days after dosing, and anergia. These authors reported that treatment of crayfish with 3 µg/kg of TCDD significantly induced cytochrome P450, as measured spectrally, and that induction and delayed onset of mortality suggested the presence of a receptor-mediated mechanism of TCDD toxicity in crayfish. Hahn and co-workers⁴⁵² and Powell and co-workers⁴⁵³ provide useful information on, respectively, the possible evolutionary precursor of the Ah receptor in invertebrates and the discovery of an ortholog Ah receptor in the invertebrate nematode *Caenorhabditis elegans*.

Acute PCB doses vary by organism, ranging from 10,000 µg/g for hydra⁴⁵⁴ to 1.3 µg/L for 121-day exposure of *Daphnia magna*.⁴⁵⁵ Crayfish, damselfly, glass shrimp, and stonefly were also tested.⁶⁴ Marine invertebrates have been tested; shrimp (Grass, Brown, and Pink) had LD₅₀s of 6.1 to 12.5 µg/g.^{328,456}

Several reports of decreased growth of aquatic organisms during exposure to PCBs can be found in the literature. For example, diatoms were affected at 0.1 µg/L Aroclor 1254, and oysters were affected at 10 µg/L Aroclor 1016. These concentrations are much higher than are usually encountered in the environment today. When sediment is chemically characterized, various comparative “effects thresholds” have been assessed for invertebrate toxicity.⁴⁵⁶ A consensus-based probable effects threshold was calculated to be 676 µg/kg sediment, expressed on a dry-weight basis. This value is relevant for invertebrate species that have been tested and do not apply to other animal classes in which PCBs and related compounds bioaccumulate and biomagnify to higher trophic levels.

18.6.4.5.2 Other Aquatic Organisms

There is little definitive information on reptiles and amphibians. Snapping turtles have received considerable attention. Studies on the Northern leopard frog have not found the species to be sensitive to dioxin-like exposures; effects studied include PCB 126 MFO induction,⁴⁵⁷ EROD activity and feral carcass PCB concentration,⁴⁵⁸ PCB 126 weight loss, and growth rate.⁴⁵⁹ These results are consistent with the resistance of the bullfrog to TCDD.^{235,282} Contaminant reviews that have addressed reptiles and amphibians should be consulted.^{460,461}

18.7 SUMMARY

PCBs, PCDDs, and PCDFs are all similar in their chemistry, i.e., aromatic rings with varying degrees of chlorination. The dioxins and dibenzofurans differ in the fact that they all have a bridge oxygen substituted across adjoining phenyl rings. The chemistry, fate, and effects of these compounds are very complex. This complexity arises primarily from the fact that these compounds exist as complex mixtures. PCBs are composed of a large number of compounds (usually 100–150 separate congeners) that require specialized methods of analysis. In the dioxin and dibenzofuran class of compounds, there are fewer isomers. However, there is the added problem of the extreme toxicity of these compounds, requiring methods for analysis and detection down to levels of picogram-per-gram concentration.

PCBs are universally distributed throughout the world, a fact largely resulting from their considerable aquatic and atmospheric mobility. Much of the release of these chemicals occurred over the span of their industrial use, from 1930 until the late 1970s, primarily as electrical insulating compounds and as hydraulic fluids. Numerous hot spots exist even today, over 20 years after the compounds were banned by the United States in 1977. Because of the extensive use of PCBs in electrical devices, indoor air levels of PCBs still exceed their levels in most outside air. Initial releases most often occurred into aqueous systems; however, atmospheric losses, especially from aquatic systems, are important for the dispersal of PCBs to remote systems such as the Arctic.

Levels in the air have begun to stabilize, to the point where ambient concentrations in Great Lakes water now degas into the atmosphere rather than continually load from the air, as was the situation in earlier times.

PCBs are noted for their tendency to bioaccumulate in aquatic and terrestrial organisms. This accumulation is a function of the compounds' partitioning behaviors, with increasing buildup accompanying greater chlorine substitution. Empirical data for terrestrial accumulation show the importance of diet and location, especially for caribou in the Arctic. Models for accumulation by dairy cows show the importance of atmospheric accumulation into forage crops and how lipid association and metabolism can be used to explain accumulation levels and possible human exposure. Abiotic dispersal of PCBs is sufficient to explain most of what we know about the existing placement of the world's supply of PCBs. The mobile environmental reservoir for PCBs is largely in the oceans (87%), followed by freshwater sediments, water, and biota (9.9%). How the compounds have distributed themselves in these compartments depends mostly on their physicochemical properties.

The air-water exchange behavior of PCBs has helped modelers to better explain existing levels in large bodies of water, particularly the Great Lakes. The soil reservoir and soil-to-air transfer have been widely recognized as important in maintaining existing levels in rural and metropolitan areas, especially in the United Kingdom. Long-term monitoring of PCBs in air is being used in the Great Lakes and other areas to identify sources. In water, adsorption to sediment or other organic matter is an important fate process for PCBs. Several sites with high-PCB sediment concentrations are being considered for mitigation; one of the most extensively contaminated sites is the upper Hudson River in New York State. Decreasing concentrations of PCBs in biota are beginning to be observed at locations throughout the world. Both aerobic and anaerobic degradation of PCBs have been described. Generally, the overall changes in levels due to degradation are slight, except for processes involving atmospheric photolysis.

During the late 1960s and early 1970s, it was recognized that PCDDs and PCDFs could be formed as by-products during the manufacture of various classes of chlorinated organic chemicals e.g., PCDFs from PCBs and PCDDs/PCDFs from chlorophenols. Since in most industrialized countries the manufacture and use of PCBs have been terminated and chlorophenol use has been severely restricted, emissions from the combustion of municipal wastes are currently the most important sources of PCDDs/PCDFs in the environment. However, diffuse sources such as domestic heating and outdoor trash burning are assuming greater relative importance, as controls are being implemented on municipal incinerators.

On a global scale, estimates of the quantity of deposited PCDDs/PCDFs exceed emissions estimates from combustion by a factor of two to three. Recently it has been proposed that the discrepancy could be accounted for by the photochemical formation of the two major atmospheric PCDDs/PCDFs, heptaCDD and OCDD, from pentachlorophenol in cloud water. While the photochemical process is an alternate pathway for the formation of PCDDs/PCDFs, controls that have been placed on chemical manufacturing and combustion emissions have resulted in significant declines in PCDDs/PCDFs in aquatic, atmospheric, and terrestrial environments. In the 1980s, it was found that biota in large bodies of water receiving industrial discharges, such as the Great Lakes and the Baltic Sea, were contaminated with PCDDs and PCDFs. Concentrations of 2,3,7,8-TCDD in fish from Lake Ontario varied from 2 pg/g for brown bullhead, a planktivorous fish species, to 162 pg/g for brown trout, a piscivorous species. In 1994, no 2,3,7,8-TCDD was detected at limits of detection of 1–2 pg/g in nine fish collected from Lake Ontario, including salmon, walleye, and perch. Similar improvements have been found for other aquatic species. During the same time period, ambient atmospheric concentrations of PCDDs/PCDFs declined by a factor of two in major European cities; current levels generally do not exceed 10 pg/m.³

The ability to address the effects of these three structurally and toxicologically related groupings of halogenated organics has greatly improved, especially over the last 10 years. Exposures of test organisms have demonstrated that, for classic measurement endpoints, a given species will respond

identically to different dioxin-like congeners when exposure is adjusted to compensate for their different toxic potencies. Use of a combination of relative toxic potency to produce a multitude of measurement endpoints and an additive model of toxicity for the dioxin-like components of the PCBs, PCDDs, and PCDFs have dramatically improved our ability to interpret environmental residues along with representative biological and toxicological responses to a variety of organisms.

Across animal taxa and on a number of levels, there are differences in relative sensitivity to these exposures. Mammal, bird, and fish species may be either highly sensitive or highly resistant to dioxin-like adverse effects, especially chronic reproductive and developmental/endocrine effects. Aquatic food chain species (seals, dolphins, polar bears, piscivorous birds, and cold-water fish species) with high exposure potential through biomagnification are particularly vulnerable to such effects. Invertebrates are relatively insensitive because they lack an Ah receptor. Ecological effects of PCDDs, PCDFs, and PCBs have manifested and continue to manifest in areas where such compounds have been documented historically at high concentrations. Environmental effects can remain for long periods because of ecosystem dynamics and the persistence of these chemicals. Continued study of nondioxin-like congeners, especially with PCBs, is needed across animal taxa. The reporting of total PCBs from the summation of congener-specific analyses, as well as the reporting of individual congeners, is also important because of the large abundance of nondioxin-like PCB congeners in the original commercial mixtures and in environmental samples.

19.1 INTRODUCTION

The main purpose of treating stormwater is to reduce its adverse impacts on the beneficial uses of receiving waters. Therefore, it is important in any urban stormwater study to assess the detrimental effects that runoff is actually having on a receiving water. Urban receiving waters may have many beneficial-use goals, including:

- stormwater conveyance (flood prevention)
- biological uses (warm water fishery, biological integrity, etc.)
- noncontact recreation (linear parks, aesthetics, boating, etc.)
- contact recreation (swimming)
- water supply

Two joint research projects recently funded by the U.S. Environmental Protection Agency (EPA^{145,146}) examined the historical development of stormwater management programs and modifications that should be incorporated into future design procedures. The projects found that, with full development in an urban watershed and with no stormwater controls, it is unlikely that any of the above listed uses can be fully obtained. With less development and with the application of stormwater controls, some uses may be possible. It is important that unreasonable expectations not be placed on urban waters, as the cost to obtain these uses may be prohibitive. With full-scale development and lack of adequate stormwater controls, severely degraded streams will be common. However, stormwater conveyance and aesthetics should be the basic beneficial-use goals for all urban waters. Biological integrity should also be a goal, but with the realization that the natural stream ecosystem will be severely modified with urbanization. Certain basic controls, installed at the time of development, plus protection of stream habitat, may enable partial use of some of these basic goals in urbanized watersheds. Careful planning and optimal utilization of stormwater controls are necessary to achieve these basic goals in most watersheds. Water contact recreation, consumptive fisheries, and water supplies are not appropriate goals for most urbanized watersheds. However, these higher uses may be possible in urban areas where the receiving waters are large and drain mostly undeveloped areas.

*Water Environment & Technology*¹ reported that a recent National Water Quality Inventory released by the EPA only showed a slight improvement in the attainment of beneficial uses in the nation's waters. Urban runoff was cited as the leading source of problems in estuaries, with nutrients and bacteria as the leading problems. Problems in rivers and lakes were caused mostly by agricultural runoff, with urban runoff the third ranked source for lakes and the fourth ranked source for rivers. Bacteria, siltation, and nutrients were the leading problems in the nation's rivers and lakes. Borchardt and Statzner² stressed that many conditions may affect receiving waters from stormwater, specifically physical factors (such as shear stress) and chemical factors (such as oxygen depletion and/or nonionized ammonia).

In general, monitoring of urban stormwater runoff has indicated that the biological beneficial uses of urban receiving waters are most likely affected by habitat destruction and long-term exposures to contaminants (especially to macroinvertebrates via contaminated sediment), while documented effects associated with acute exposures of toxicants in the water column are rare.³⁻⁵ Receiving water contaminant concentrations resulting from runoff events and typical laboratory bioassay test results have not indicated many significant short-term receiving-water problems. As an example, Lee and Jones-Lee⁶ state that the existence of a beneficial-use impairment is not necessarily implied if numeric criteria are exceeded by short-term discharges. Many toxicologists and water-quality experts have concluded that the relatively short periods of exposures to the toxicant concentrations in stormwater are not sufficient to produce the receiving-water effects that are evident in urban receiving waters, especially considering the relatively large portion of the toxicants that are associated with particulates.⁷ Lee and Jones-Lee⁷ conclude that the biological problems evident in urban receiving waters are mostly associated with illegal discharges and that the sediment-bound toxicants are of little risk. Mancini and Plummer⁸ have long been advocates of numeric water-quality standards for stormwater that reflect the partitioning of the toxicants and the short periods of exposure during rains. Unfortunately, this approach attempts to isolate individual runoff events and does not consider the cumulative adverse effects caused by the frequent exposures of receiving-water organisms to stormwater.⁹⁻¹¹ Recent investigations have identified acute toxicity problems associated with moderate-term (about 10 to 20 days) exposures to adverse toxicant

concentrations in urban receiving streams.¹² However, the most severe receiving-water problems are likely associated with chronic exposures to contaminated sediment and to habitat destruction.

Pathogens in stormwater are also a significant concern potentially affecting human health. The use of indicator bacteria is controversial for stormwater, as is the assumed time of typical exposure of swimmers to contaminated receiving waters. However, recent epidemiological studies have shown significant health effects associated with stormwater-contaminated marine swimming areas. Protozoa pathogens, especially associated with likely sewage-contaminated stormwater, is also a public-health concern.

Evaluating a receiving water and understanding the potential role that urban wet-weather flows may have on its beneficial uses is a complex and time-consuming activity. Burton and Pitt¹³ have produced a comprehensive book describing the development of effective monitoring strategies including selection of parameters, development of the experimental design, and detailed guidance on sampling, analyses, and data interpretation.

Urban runoff has been found to cause significant receiving water impacts on aquatic life.^{3,4,13} The effects are obviously most severe for receiving waters draining heavily urbanized watersheds. However, some studies have shown important aquatic life impacts for streams in watersheds that are less than 10% urbanized.^{19,22}

To best identify and understand these impacts, it is necessary to include biological monitoring, using a variety of techniques, and sediment-quality analyses, in a monitoring program. Water-column testing alone has been shown to be very misleading. Most aquatic life impacts associated with urbanization are probably related to long-term problems caused by polluted sediments and food-web disruption. Transient water-column-quality conditions associated with urban runoff probably rarely cause significant aquatic-life impacts.

The underlying theme of these researchers is that an adequate analysis of receiving-water biological impacts must include investigations of a number of biological organism groups (fish, benthic macroinvertebrates, algae, rooted macrophytes, etc.) in addition to studies of water and sediment quality.¹³ Simple studies of water quality alone, even with possible comparisons with water-quality criteria for the protection of aquatic life, are usually inadequate to predict biological impacts associated with urban runoff.

Duda et al.¹⁴ presented a discussion on why traditional approaches to assessing water quality — and selecting control options — in urban areas have failed. The main difficulties of traditional approaches when used with urban runoff are: the complexity of contaminant sources, wet-weather monitoring problems, and limitations when using water-quality standards to evaluate the severity of wet-weather receiving-water problems. They also discuss the difficulty of meeting water-quality goals in urban areas that were promulgated in the Water Pollution Control Act.

Relationships between observed receiving-water biological effects and possible causes have been especially difficult to identify, let alone quantify. The studies reported in this paper have identified a wide variety of possible causative agents, including sediment contamination, poor water quality (low dissolved oxygen, high toxicants, etc.), and factors affecting the physical habitat of the stream (high flows, unstable streambeds, absence of refuge areas, etc.). It is expected that all of these factors are problems, but their relative importance varies greatly depending on the watershed and receiving-water conditions. For example, Horner¹⁵ notes that many watershed-, site-, and organism-specific factors must be determined before the best combination of runoff-control practices to protect aquatic life can be determined.

The time scale of biological impacts in receiving waters affected by stormwater must also be considered. Snodgrass et al.¹⁶ reported that ecological responses to watershed changes may take between 5 and 10 years to equilibrate. Therefore, receiving-water investigations conducted soon after disturbances or mitigation may not accurately reflect the long-term conditions that will eventually occur. They found that the first changes due to urbanization will be to stream and groundwater hydrology, followed by fluvial morphology, then water quality, and finally the aquatic ecosystem. They also reported that it is not possible to predict biological responses from in-stream

habitat changes or conditions, although they, along with many other researchers,^{26,62-67,77,80-82,85-88,99,102,103,105-108} have found that habitat changes are among the most serious causes of the aquatic biological problems associated with urbanization of a watershed.

This chapter contains numerous citations and summaries of many research activities conducted throughout the world concerning receiving-water effects associated with urban wet-weather flows, specifically stormwater. The purpose of these discussions is to demonstrate the widespread nature of the various problems that may occur. During the last few years, the number of technical publications addressing stormwater-quality issues has risen dramatically. The annual literature review issues of *Water Environment Research*¹⁴⁸⁻¹⁵² contain a growing section on urban wet-weather flows. In 1996, about 250 international references were cited in this review, growing to more than 500 in the 2000 review. Many of these references addressed receiving-water impacts and are summarized in this chapter. Obviously, many other interesting papers may exist but have been unintentionally left out of this review.

19.2 GROSS INDICATORS OF ACUTE AQUATIC ORGANISM STRESS IN URBAN RECEIVING WATERS

19.2.1 Dissolved-Oxygen-Depletion Investigations

Dissolved-oxygen (DO) stream levels have historically been used to indicate receiving-water problems associated with point-source contaminant discharges and with combined sewer overflows. Therefore, early investigations of the effects of stormwater discharges mostly focused on in-stream dissolved oxygen conditions downstream from outfalls. Of course, DO levels are also being evaluated in most current receiving water investigations also, but the emphasis has shifted more toward elevated nutrient and toxicant concentrations, plus numerous other indicators of aquatic organism stress, as described later.

An early study of DO in urban streams affected only by stormwater was conducted by Ketchum¹⁷ in Indiana. Sampling was conducted at nine cities, and the project was designed to detect significant DO deficits in streams during periods of rainfall and runoff. The results of this study indicated that wet-weather DO levels generally appeared to be similar or higher than those observed during dry-weather conditions in the same streams. They found that significant wet-weather DO depletions were not observed, and due to the screening nature of the sampling program, more subtle impacts could not be measured. Heaney et al.,¹⁸ during their review of studies that examined continuous DO monitoring stations downstream from urbanized areas, indicated that the worst DO levels occurred after rainstorms in about one third of the cases studied. This lowered DO could be due to urban runoff moving downstream, combined sewer overflows, or resuspension of benthic deposits. Resuspended benthic deposits could have been previously settled urban runoff settleable solids. They also found that worst-case conditions do not always occur during the low flow periods following storms. As noted below, adverse DO conditions associated with urban runoff are likely to occur a substantial time after the runoff event and downstream from the discharge locations.

Figure 19.1 illustrates a problem that may be common to DO predictions in urban receiving waters. Pitt¹⁹ conducted three long-term biochemical oxygen demand (BOD) experiments with stormwater collected from a residential area in San Jose, California. These were conventional BOD tests, using approved procedures published in the then current version of *Standard Methods*. Basically, many BOD bottles were prepared for each sample, representing replicates for each day for the observations, and for several different dilutions. The bottles were seeded with activated sludge to provide a starting microbial population. As the figure shows, the observed BOD curves do not have a conventional shape. The BOD₅ values are about 25 mg/L, typical of what is commonly reported for most stormwater. However, the BOD curves are seen to rapidly increase throughout the 20-day test period, instead of leveling off at about 7 to 10 days, as expected for municipal

Figure 19.1 Long-term BOD tests for stormwater.¹⁹

wastewaters. These curves illustrate the common problem of acclimation of a wastewater to the microorganisms that are present in the test solution. Stormwater has relatively low levels of nutrients and easily assimilated organic material, but moderate levels of toxicants. It is possible that the activated sludge seed requires extra time for the microbial population to shift to a population dominated by organisms capable of effectively degrading the organics in stormwater. Alternatively (or in addition), the more refractory organics in stormwater may simply require a longer period of time for degradation. In any case, the ultimate BOD/BOD₅ ratio for stormwater is much greater than for conventional municipal wastewaters, making simple use of observed BOD₅ values in receiving water models problematic. Urban-stream sediments are commonly anaerobic, likely caused by the deposition of the slowly decaying stormwater organic compounds. Stormwater effects on short-term stream DO levels may be minimal, but sediment interaction (including scour) with the water can have adverse effects long after the stormwater event that discharged the decaying material. Therefore, the misuse of the classical BOD₅ test for stormwater can lead to poor conclusions concerning urban DO conditions, one of the more commonly used indicators of ecological health.

19.2.2 Urban Runoff Effects on Receiving Water Contaminant Concentrations

Numerous data are available characterizing stormwater chemical characteristics. This discussion summarizes a few example cases where in-stream measurements found significant changes in quality as a function of land use. These studies usually sampled streams as they passed through urban areas, from upstream relatively uncontaminated areas through and past urban areas. Both wet- and dry-weather sampling was also usually conducted.

In the southeast, many urban lakes in developing areas are typically characterized by high turbidity levels caused by high erosion rates of fine-grained clays. There has been conflicting evidence on the role of these elevated turbidity levels on eutrophication processes and resulting highly fluctuating DO levels. Because of the high sediment loads, these urban lakes are quite different compared to most studied impoundments. Burkholder et al.²⁰ described a series of enclosure experiments they conducted in Durant Reservoir, near Raleigh, North Carolina. The experimental design allowed investigating the effects of different levels of sediment and nutrients on algal productivity. They found that the effects (reduction of light reduction and coflocculation of clay and phosphate) of low (about 5 mg/L) and moderately high clay (about 15 mg/L) loadings added every 7 to 14 days did not significantly reduce the algal productivity simulation caused by high phosphate loadings. However, they noted that other investigators using higher clay loadings (about

25 mg/L added every 2 days) did see depressed effects of phosphorus enrichment on the test lake. They concluded that dynamically turbid systems, such as represented in southeastern urban lakes, have complex interacting mechanisms between discharged clay and nutrients that make simple predictions of the effects of eutrophication much more difficult than in the more commonly studied clear lakes. In general, they concluded that increased turbidity will either have no effect, or a mitigating effect, on the cultural eutrophication process.

Field and Cibik²¹ summarized some potential urban-runoff effects reported in other studies. Two studies of a reservoir near Knoxville, Tennessee, showed that the quality of the contributing streams were degraded to a small extent by urban runoff and that the reservoir itself experienced a significant change in DO, pH, BOD₅, conductivity, temperature, total solids, and total coliform bacteria during short storm events. In another study at the Christina River in Newark, Delaware, cadmium and lead concentrations several miles below the urban area remained at elevated values up to 48 h after storm periods. The quality of runoff from similar nonurbanized watersheds was compared with this urbanized area's runoff. They found that concentrations of nitrates, phosphorus, heavy metals, and pesticides were considerably higher in the urbanized areas than in the forested regions. Field and Cibik²¹ also reported on a study conducted in Virginia, where water, sediment, detritus, caddisflies, snails, and crayfish were analyzed for iron, manganese, nickel, lead, cadmium, zinc, chromium, and copper. The sampling areas were exposed to wastewater effluent and urban runoff. They found that concentrations increased immediately below stormwater-discharge locations. They also reported on a study from Hawaii that indicated that receiving-water conditions were designated as hazardous because of very high concentrations of suspended solids, heavy metals, and bacterial pathogens.

During the Coyote Creek, San Jose, California study, dry-weather concentrations of many constituents exceeded expected wet-weather concentrations by factors of two to five times.²² During dry weather, many of the major constituents (e.g., major ions, total solids, etc.) were significantly greater in both the urban and nonurban reaches. These constituents were all found in substantially lower concentrations in the urban runoff and in the rain. The rain and the resultant runoff apparently diluted the concentrations of these constituents in the creek during wet weather. Within the urban area, many constituents were found in greater concentrations during wet weather than during dry weather (chemical oxygen demand, organic nitrogen, and especially heavy metals — lead, zinc, copper, cadmium, mercury, iron, and nickel). Lead concentrations were found to be more than seven times greater in the urban reach than in the nonurban reach during dry weather, with a confidence level of 75%. Other significant increases in urban-area concentrations occurred for nitrogen, chloride, orthophosphate, chemical oxygen demand (COD), specific conductance, sulfate, and zinc. The DO measurements were about 20% less in the urban reach than in the nonurban reach of the creek.

Bolstad and Swank²³ examined the in-stream water quality at five sampling stations in Cowetta Creek in western North Carolina over a 3-year period. The watershed is 4350 ha and is relatively undeveloped (forested) in the area above the most upstream sampling station and becomes more urbanized at the downstream sampling station. Baseflow water quality was good, while most constituents increased during wet weather. Bacteria values increased substantially during wet weather, with total and fecal coliforms and fecal streptococci increasing by two to three times during storms. Water quality was compared to building density for the different monitoring stations, with increasing stormwater contaminant concentrations (especially for turbidity, bacteria, and some inorganic solutes) with increasing building densities. Baseflow concentrations also typically increased with increasing urban density, but at a much lower rate. In addition, the highest concentrations observed during individual events corresponded to the highest flow rates.

19.2.3 Reported Fish Kill Information

Urban-runoff impacts are sometimes difficult for many people to appreciate in urban areas. Fish kills are the most obvious indication of water-quality problems for many people. However,

because urban receiving-water quality is usually so poor, the aquatic life in typical urban receiving waters is usually limited in abundance and diversity and quite resistant to poor water quality. Sensitive native organisms have typically been displaced, or killed, long ago. It is also quite difficult to identify the specific cause of a fish kill in an urban stream. Ray and White,²⁴ for example, stated that one of the complicating factors in determining fish kills related to heavy metals is that the fish mortality may lag behind the first toxic exposure by several days and is usually detected many miles downstream from the discharge location. The actual concentrations of the water-quality constituents that may have caused the kill could then be diluted beyond detection limits, making probable sources of the toxic materials impossible to determine in many cases.

Heaney et al.¹⁸ reviewed fish-kill information reported to government agencies from 1970 to 1979. They found that less than 3% of the reported 10,000 fish kills were identified as having been caused by urban runoff. This is less than 30 fish kills per year nationwide. A substantial number of these 10,000 fish kills were not identified as having any direct cause. They concluded that many of these fish kills were likely caused by urban runoff or by a combination of problems that could have been worsened by urban runoff.

During the Bellevue, Washington, receiving-water studies, some fish kills were noted in the unusually clean urban streams.²⁵ The fish kills were usually associated with inappropriate discharges to the storm drainage system (such as cleaning materials and industrial chemical spills) and not from “typical” urban runoff. However, as noted later, the composition of the fish in the urban stream was quite different, as compared to the control stream.²⁶

Fish-kill data have therefore not been found to be a good indication of receiving water problems caused by urban runoff. However, the composition of the fisheries and other aquatic-life taxonomic indicators are sensitive indicators of receiving-water problems in urban streams.

19.2.4 Toxicological Effects of Stormwater

Even though acute toxicity of stormwater on most aquatic organisms has been relatively rare, short-term toxicity tests are still commonly conducted as part of some whole-effluent-toxicity (WET) tests required by some state regulatory agencies and by some stormwater researchers.¹⁴⁷

The need for endpoints for toxicological assessments using multiple stressors was discussed by Marcy and Gerritsen.²⁷ They used five watershed-level ecological risk assessments to develop appropriate endpoints based on specific project objectives. Dyer and White^{28a} also examined the problem of multiple stressors affecting toxicity assessments. They felt that field surveys can rarely be used to verify simple single-parameter laboratory experiments. They developed a watershed approach integrating numerous databases in conjunction with *in situ* biological observations to help examine the effects of many possible causative factors. Toxic-effect endpoints are additive for compounds having the same “mode of toxic action,” enabling predictions of complex chemical mixtures in water, as reported by *Environmental Science & Technology*.^{28b} They reported that EPA researchers at the Environmental Research Laboratory in Duluth, Minnesota, identified about five or six major action groups that contain almost all of the compounds of interest in the aquatic environment. Much work still needs to be done, but these new analytical methods may enable the in-stream toxic effects of stormwater to be better predicted.

Ireland et al.²⁹ found that exposure to UV radiation (natural sunlight) increased the toxicity of polycyclic aromatic hydrocarbon (PAH)-contaminated urban sediments to *C. dubia*. The toxicity was removed when the UV wavelengths did not penetrate the water column to the exposed organisms. Toxicity was also reduced significantly in the presence of UV when the organic fraction of the stormwater was removed. Photo-induced toxicity occurred frequently during low-flow conditions and wet weather but was reduced during turbid conditions.

Johnson et al.³⁰ and Herricks et al.^{10,11} describe a structured tier testing protocol to assess both short-term and long-term wet-weather discharge toxicity that they developed and tested. The protocol recognizes that the test systems must be appropriate to the time scale of exposure during

the discharge. Therefore, three time-scale protocols were developed — for intraevent, event, and long-term exposures. The use of standard WET tests was found to overestimate the potential toxicity of stormwater discharges.

The effects of stormwater on Lincoln Creek, near Milwaukee, Wisconsin, were described by Crunkilton et al.¹² Lincoln Creek drains a heavily urbanized watershed of 19 mi² that is about 9 mi long. On-site toxicity testing was conducted with side-stream flow-through aquaria using fathead minnows, plus in-stream biological assessments, along with water and sediment chemical measurements. In the basic tests, Lincoln Creek water was continuously pumped through the test tanks, reflecting the natural changes in water quality during both dry- and wet-weather conditions. The continuous flow-through mortality tests indicated no toxicity until after about 14 days of exposure, with more than 80% mortality after about 25 days, indicating that the shorter-term toxicity tests likely underestimate stormwater toxicity. The biological and physical habitat assessments also supported a definitive relationship between degraded-stream ecology and urban runoff.

Rainbow³¹ presented a detailed overview of heavy metals in aquatic invertebrates. He concluded that the presence of a metal in an organism could not indicate directly whether that metal is poisoning the organism. However, if compared to concentrations in a suite of well-researched biomonitors, it is possible to determine if the accumulated concentrations are atypically high, with the possible presence of toxic effects. Allen³² also presented an overview of metal-contaminated aquatic sediments. Allen's book presents many topics that would enable the user to better interpret measured heavy-metal concentrations in urban-stream sediments.

One of the key objectives of the Chesapeake Bay restoration effort is to reduce the impacts of toxicants, of which stormwater is a recognized major source for the area. Hall et al.³³ describe the *Toxics Reduction Strategy*, based on water-column and sediment-chemical analyses, benthic-community health, and fish-body burdens. More than 40% of the sites have displayed some degree of water-column toxicity, and about 70% of the sites have displayed sediment toxicity. Garries et al.³⁴ further describe how the list of *Toxics of Concern* is developed for Chesapeake Bay.

Sediment contaminated by stormwater discharges has a detrimental effect on the receiving-water biological community. Schueler³⁵ summarized *in situ* assessment methods of stormwater-impacted sediments. The use of *in situ* test chambers, using *C. dubia*, eliminates many of the sample-disruption problems associated with conducting sediment toxicity tests in the laboratory. Love and Woolley³⁶ found that stormwater was alarmingly more toxic than treated sewage and that treatment before reuse of residential-area stormwater may be needed.

Pitt³⁷ reported a series of laboratory toxicity tests using 20 stormwater and CSO samples. He found that the most promising results are associated with using several complementary tests, instead of any one test method. However, simple screening toxicity tests (such as the Azur Microtox[®] test) are useful during preliminary assessments or for treatability tests.

Huber and Quigley³⁸ studied highway construction and repair materials (e.g., deck sealers, wood preservatives, waste-amended pavement, etc.) for their chemical and toxicological properties and leaching characteristics. *Daphnia magna* (a water flea) and the algae *Selenastrum capricornutum* were used for the toxicity tests. Leaching was evaluated as a function of time using batch tests, flat-plate tests, and column tests, as appropriate for the end-use of the highway material. These comprehensive tests identified a number of maintenance and construction materials that should be avoided for use near aquatic environments due to their elevated toxicity.

Kosmala et al.⁴⁰ used *C. dubia* in laboratory toxicity tests in combination with field analysis of the *Hydropsychid* life cycle to assess the impact of both the wastewater-treatment-plant effluent and the stormwater overflow on the receiving water. They found that the results seen in the laboratory toxicity tests and in the *in situ* biological measurements were due to nutrient and micropollutant loadings. Marsalek et al.⁴¹ used several different toxicity tests to assess the various types of toxicity in typical urban runoff and in runoff from a multilane highway. The tests included traditional toxicity analysis using *Daphnia magna*, the Microtox toxicity test, submitochondrial particles, and

the SOS Chromotest for genotoxicity. Marsalek and Rochfort⁴² also investigated the toxicity of urban stormwater and CSO. Acute toxicity, chronic toxicity, and genotoxicity of stormwater and CSO were studied at 19 urban sampling sites in Ontario, Canada, using a battery of seven bioassays. The most frequent responses of severe toxicity were found in stormwater samples (in 14% of all samples), particularly those collected on freeways during the winter months. Compared to stormwater, CSO displayed lower acute toxicity (7% of the samples were moderately toxic, and none of the samples was severely toxic).

Skinner et al.⁴³ showed that stormwater runoff produced significant toxicity in the early life stages of medaka (*Oryzias latipes*) and inland silverside (*Menidia beryllina*). Developmental problems and toxicity were strongly correlated with the total metal content of the runoff and corresponded with exceedences of water-quality criteria of Cd, Cu, W, and Zn.

Tucker and Burton⁴⁴ compared *in situ* vs. laboratory conditions for toxicity testing of nonpoint-source runoff. They found that NPS runoff from urban areas was more toxic to the organisms in the laboratory, while agricultural runoff was more toxic to the organisms exposed *in situ*. The differences seen between the two types of toxicity tests demonstrated the importance of *in situ* assays in examining the effects of NPS runoff. Hatch and Burton,⁴⁵ using field and laboratory bioassays, demonstrated the impact of the urban stormwater runoff on *Hyalella azteca*, *Daphnia magna*, and *Pimephales promelas* survival after 48 h of exposure. The significant toxicity seen at the outfall site was attributed to the contaminant accumulation in the sediments and the mobilization of the top layers of sediment during storm events.

Bickford et al.⁴⁶ described the methodology developed and implemented by Sydney Water in Australia to assess the risk to humans and aquatic organisms in creeks, rivers, estuaries, and ocean waters from wet-weather flows (WWFs). The model used in this study was designed to predict concentrations of various chemicals in WWFs and compare the values to toxicity reference values. Brent and Herricks⁴⁷ proposed a methodology for predicting and quantifying the toxic response of aquatic systems to brief exposures to pollutants such as the contaminants contained in stormwater runoff. The method contains an event-focused toxicity method, a test metric (event toxicity unit, or ETU) to represent the toxicity of intermittent events, and an event-based index that would describe the acute toxicity of this brief exposure. The toxicity metric proposed (PE-LET₅₀ [post-exposure lethal exposure time]) was the exposure duration required to kill 50% of the population during a prespecified, postexposure monitoring period. Colford et al.⁴⁸ proposed three methods of analytically evaluating the impact of storm-sewer and combined-sewer outflows on public health.

19.3 SUBTLE (CHRONIC) EFFECTS OF STORMWATER DISCHARGES ON AQUATIC LIFE

Many studies have shown the severe detrimental effects of urban runoff on receiving-water organisms. These studies have generally either examined receiving-water conditions above and below a city or compared two parallel streams, one urbanized and the other nonurbanized. The researchers usually carefully selected the urbanized streams to minimize contaminant sources other than urban runoff. However, few studies have examined direct cause-and-effect relationships of urban runoff for receiving-water aquatic organisms.⁴⁹ The following paragraphs briefly describe a variety of urban receiving-water investigations.

Klein⁵⁰ studied 27 small watersheds having similar physical characteristics but varying land uses in the Piedmont region of Maryland. During an initial phase of the study, they found definite relationships between water quality and land use. Subsequent study phases examined aquatic-life relationships in the watersheds. The principal finding was that stream aquatic-life problems were first identified with watersheds having imperviousness areas comprising at least 12% of the watershed. Severe problems were noted after the imperviousness quantities reached 30%.

Receiving-water impact studies were also conducted in North Carolina.⁵¹⁻⁵³ The benthic fauna occurred mainly on rocks. As sedimentation increased, the amount of exposed rocks decreased, with a decreasing density of benthic macroinvertebrates. Data from 1978 and 1979 in five cities showed that urban streams were grossly polluted by a combination of toxicants and sediment. Chemical analyses, without biological analyses, would have underestimated the severity of the problems because the water-column quality varied rapidly, while the major problems were associated with sediment quality and effects on macroinvertebrates. Macroinvertebrate diversities were severely reduced in the urban streams compared to the control streams. The biotic indices indicated very poor conditions for all urban streams. Occasionally, high populations of pollutant-tolerant organisms were found in the urban streams but abruptly disappeared before subsequent sampling efforts. This was probably caused by intermittent discharges of spills or illegal dumpings of toxicants. Although the cities studied were located in different geographic areas of North Carolina, the results were remarkably uniform.

During the early Coyote Creek, San Jose, California, receiving-water study, 41 stations were sampled in both urban and nonurban perennial-flow stretches of the creek over 3 years. Short- and long-term sampling techniques were used to evaluate the effects of urban runoff on water quality, sediment properties, fish, macroinvertebrates, attached algae, and rooted aquatic vegetation.²² These investigations found distinct differences in the taxonomic composition and relative abundance of the aquatic biota present. The nonurban sections of the creek supported a comparatively diverse assemblage of aquatic organisms including an abundance of native fishes and numerous benthic macroinvertebrate taxa. In contrast, however, the urban portions of the creek (less than 5% urbanized), affected only by urban runoff discharges and not industrial or municipal discharges, had an aquatic community generally lacking in diversity and was dominated by pollution-tolerant organisms such as mosquitofish and tubificid worms.

A major nonpoint-runoff receiving-water-impact research program was conducted in Georgia (U.S.).⁵⁴ Several groups of researchers examined streams in major areas of the state. Benke et al.⁵⁵ studied 21 stream ecosystems near Atlanta having watersheds of 1 to 3 square mi each and land uses ranging from 0 to 98% urbanization. They measured stream-water quality but found little relationship between water quality and degree of urbanization. The water-quality parameters also did not identify a major degree of pollution. In contrast, there were major correlations between urbanization and the number of species found. They had problems applying diversity indices to their study because the individual organisms varied greatly in size (biomass). CTA⁵⁶ also examined receiving-water aquatic biota impacts associated with urban runoff sources in Georgia. They studied habitat composition, water quality, macroinvertebrates, periphyton, fish, and toxicant concentrations in the water, sediment, and fish. They found that the impacts of land use were the greatest in the urban basins. Beneficial uses were impaired or denied in all three urban basins studied. Fish were absent in two of the basins and severely restricted in the third. The native macroinvertebrates were replaced with pollution-tolerant organisms. The periphyton in the urban streams were very different from those found in the control streams and were dominated by species known to create taste and odor problems.

Pratt et al.⁵⁷ used basket artificial substrates to compare benthic population trends along urban and nonurban areas of the Green River in Massachusetts. The benthic community became increasingly disrupted as urbanization increased. The problems were not associated only with times of heavy rain but seemed to be present at all times. The stress was greatest during summer low-flow periods and was probably localized near the streambed. They concluded that the high degree of correspondence between the known sources of urban runoff and the observed effects on the benthic community was a forceful argument that urban runoff was the causal agent of the disruption observed.

Cedar swamps in the New Jersey Pine Barrens were studied by Ehrenfeld and Schneider.⁵⁸ They examined 19 wetlands subjected to varying amounts of urbanization. Typical plant species were lost and replaced by weeds and exotic plants in urban-runoff-affected wetlands. Increased uptakes of phosphorus and lead in the plants were found. It was concluded that the presence of stormwater

runoff to the cedar swamps caused marked changes in community structure, vegetation dynamics, and plant-tissue-element concentrations.

Medeiros and Coler⁵⁹ and Medeiros et al.⁶⁰ used a combination of laboratory and field studies to investigate the effects of urban runoff on fathead minnows. Hatchability, survival, and growth were assessed in the laboratory in flow-through and static bioassay tests. Growth was reduced to one half of the control growth rates at 60% dilutions of urban runoff. The observed effects were believed to be associated with a combination of toxicants.

The University of Washington^{25,61-67} conducted a series of studies to contrast the biological and chemical conditions in urban Kelsey Creek with rural Bear Creek in Bellevue, Washington. The urban creek was significantly degraded when compared to the rural creek but still supported a productive, albeit limited and unhealthy, salmonid fishery. Many of the fish in the urban creek had respiratory anomalies. The urban creek was not grossly polluted, but flooding from urban developments had increased dramatically in recent years. These increased flows dramatically changed the urban stream's channel by causing unstable conditions with increased streambed movement and by altering the availability of food for the aquatic organisms. The aquatic organisms were very dependent on the few relatively undisturbed reaches. DO concentrations in the sediments depressed embryo salmon survival in the urban creek. Various organic and metallic priority pollutants were discharged to the urban creek, but most of them were apparently carried through the creek system by the high storm flows to Lake Washington. The urbanized Kelsey Creek also had higher water temperatures (probably due to reduced shading) than Bear Creek. This probably caused the faster fish growth in Kelsey Creek.

The fish population in the urbanized Kelsey Creek had adapted to its degrading environment by shifting the species composition from Coho salmon to less sensitive cutthroat trout and by making extensive use of less disturbed refuge areas. Studies of damaged gills found that up to three fourths of the fish in Kelsey Creek were affected with respiratory anomalies, while no cutthroat trout and only two of the Coho salmon sampled in the forested Bear Creek had damaged gills. Massive fish kills in Kelsey Creek and its tributaries were also observed on several occasions during the project due to the dumping of toxic materials down the storm drains.

There were also significant differences in the numbers and types of benthic organisms found in urban and forested creeks during the Bellevue research. Mayflies, stoneflies, caddisflies, and beetles were rarely observed in the urban Kelsey Creek but were quite abundant in the forested Bear Creek. These organisms are commonly regarded as sensitive indicators of environmental degradation. One example of degraded conditions in Kelsey Creek was shown by a species of clams (*Unionidae*) that was not found in Kelsey Creek but was commonly found in Bear Creek. These clams are very sensitive to heavy siltation and unstable sediments. Empty clamshells, however, were found buried in the Kelsey Creek sediments, indicating their previous presence in the creek and their inability to adjust to the changing conditions. The benthic-organism composition in Kelsey Creek varied radically with time and place, while the organisms were much more stable in Bear Creek.

Urban-runoff-impact studies were conducted in the Hillsborough River near Tampa Bay, Florida, as part of the U.S. EPA's Nationwide Urban Runoff Program (NURP).⁶⁸ Plants, animals, sediment, and water quality were all studied in the field and supplemented by laboratory bioassay tests. Effects of saltwater intrusion and urban runoff were both measured because of the estuarine environment. During wet weather, freshwater species were found closer to the Bay than during dry weather. In coastal areas, these additional natural factors made it even more difficult to identify the cause-and-effect relationships for aquatic-life problems. During another NURP project, Striegl⁶⁹ found that the effects of accumulated contaminants in Lake Ellyn (Glen Ellyn, Illinois) inhibited desirable benthic invertebrates and fish and increased undesirable phytoplankton blooms.

The number of benthic-organism taxa in Shabakunk Creek in Mercer County, New Jersey declined from 13 in relatively undeveloped areas to four below heavily urbanized areas.^{70,71} Periphyton samples were also analyzed for heavy metals with significantly higher metal concentrations found below the heavily urbanized area than above.

Stewart et al.⁷² collected diatoms (*Bacillariophyta*) and water-quality samples from three streams that drain the Great Marsh in the Indiana Dunes National Lakeshore. They found that diatom species diversity could be used as indicators of water quality, which could then be linked to land use in a watershed. Diatom species diversity was most variable in areas with poorer water quality and was directly correlated to the total alkalinity, total hardness, and specific conductance of the water in the stream.

A number of papers presented at the 7th International Conference on Urban Storm Drainage, held in Hannover, Germany, described receiving-water studies that investigated organic and heavy metal toxicants. Handová et al.⁷³ examined the bioavailability of metals from CSOs near Prague. They compared these results with biomonitoring. The metals were ranked according to their mobility as: Cd (95%), Zn (87%), Ni (64%), Cr (59%), Pb (48%), and Cu (45%). The mobile fraction was defined as the metal content that was exchangeable, bound to carbonates, bound to iron and manganese oxides, and bound to organic matter. Boudries et al.⁷⁴ and Estèbe et al.⁷⁵ investigated heavy metals and organics bound to particulates in the River Seine near Paris. The Paris CSOs caused a significant increase in the aliphatic and aromatic hydrocarbons bound to river sediments. The high flows during the winter were associated with lower heavy metal associations with the sediment, compared to the lower summer flow conditions. These differences were found to be due to dilution of the CSOs in the river and to the changing contributions of rural vs. urban suspended solids during the different seasons.

The Northeastern Illinois Planning Commission⁷⁶ compared comprehensive fish survey information from over 40 northeastern Illinois small- to moderate-sized streams and rivers to demographic data for the contributing watershed areas. The streams had watershed areas ranging from about 12 to 222 square mi and had population densities ranging from about 30 to more than 4500 people per square mile. The fish data was used in the index of biotic integrity (IBI) to identify the quality of the fish populations. Table 19.1 lists the fish data that are used in the IBI, and Table 19.2 shows the different scores for the quality categories. Factors necessary for good- and excellent-quality fish communities include the presence of diverse and reproducing fish and other aquatic organisms, including a significant percentage of intolerant species (such as darters and smallmouth bass).

The more commonly used imperviousness-based indicator of development was not used due to a lack of available data and the difficulty of acquiring good-quality current imperviousness data, let alone estimating historical imperviousness data. In contrast, population data was readily available and thought to be an adequate indicator of the extent and density of urbanization in the watersheds. They found that nearly all streams in urban and suburban watersheds having population densities greater than about 300 people per square mile showed signs of considerable impairment to their fish communities (being in fair to very poor condition). In contrast, nearly all rural streams supported fish communities that were rated good or excellent. They identified both point and nonpoint sources

Table 19.1 Index of Biotic Integrity (IBI) Metrics⁷⁶

Category	Metric
Species richness and composition	Total number of fish species
	Number and identity of darter species
	Number and identity of sunfish species
	Number and identity of sucker species
	Number and identity of intolerant species
Trophic composition	Proportion of individuals as green sunfish
	Proportion of individuals as omnivores
	Proportion of individuals as hybrids
Fish abundance and condition	Proportion of individuals as piscivores
	Number of individuals in sample
	Proportion of individuals as hybrids
	Proportion of individuals with disease, tumors, fin damage, and skeletal anomalies

Table 19.2 Illinois Environmental Protection Agency (IEPA) Biological Stream Characterization (BSC) and Index of Biotic Integrity (IBI) Classifications and Criteria⁷⁶

IBI Score	Stream Class	BSC Category	Biotic Resource Quality
51–60	A	Unique	Excellent
41–50	B	Highly valued	Good
31–40	C	Moderate	Fair
21–30	D	Limited	Poor
≤ 20	E	Restricted	Very poor

as major contributors to these impairments. However, the point-source discharges and CSO discharges have substantially decreased over the past 20 years, while the nonpoint-source discharges have increased significantly with increased development, and the fisheries are still declining in many areas. In stable areas that were mostly affected by point sources and CSOs, documented dramatic improvements in some water-quality indicators (especially DO and ammonia) and the fish populations have occurred. In areas that are similar but that have continued urban development, the fisheries have continued to decline.

The researchers concluded that although rural watersheds have known water-quality problems (especially agricultural chemicals and erosion, plus manure runoff), these issues did not prevent the attainment of mostly high-quality fisheries in these areas. Similar conclusions were noted in the comparison study by the USGS in North Carolina⁷⁷ of forested, agricultural, and urban streams. Although the forested streams were of the best quality, the streams in the agricultural areas were of intermediate quality and had significantly better biological conditions than the urban stream (which had poor macroinvertebrate and fish conditions, poor sediment and temperature conditions, and fair substrate and nutrient conditions).

19.4 HABITAT EFFECTS CAUSED BY STORMWATER DISCHARGES

Some of the most serious effects of urban runoff are on the aquatic habitat of the receiving waters. These habitat effects are in addition to the pollutant-concentration effects. Numerous papers already referenced found significant sedimentation problems in urban receiving waters. The major effects of urban sediment on the aquatic habitat include silting of spawning and food production areas and unstable bed conditions.⁷⁸ Other major habitat-destruction problems include rapidly changing flows and the absence of refuge areas to protect the biota during these flow changes. Removal of riparian vegetation can increase water temperatures and a major source of large organic debris that are important refuge areas. The major references on stream geomorphology that many of the following researchers based their work on were by Leopold et al.,⁷⁹ Brookes,⁸⁰ and Rosgen.⁸¹ These fundamental references should be consulted for excellent descriptions of the many natural processes affecting streams in transition. Brookes also specifically examines urbanization effects on stream morphology. Knowledge of these basic processes will better enable an understanding of local stream changes occurring with watershed urbanization. This understanding will, in turn, enable more efficient rehabilitation efforts of degraded streams and the use of watershed controls to minimize these effects.

Brookes⁸⁰ has documented many cases in the United States and Great Britain of stream-morphology changes associated with urbanization. These changes are mostly responsible for habitat destruction, which is usually the most significant detriment to aquatic life. In many cases, water-quality improvement would result in very little aquatic-life benefits if the physical habitat is grossly modified. The most obvious habitat problems are associated with stream “improvement” projects, ranging from debris removal and stream straightening to channelization projects. Brookes^{80,82} presents a number of ways to minimize habitat problems associated with stream-channel projects, including stream restoration.

In Maryland streams affected by urban construction activities, Wolman and Schick⁸³ observed deposition of channel bars, erosion of channel banks, obstruction of flows, increased flooding, and shifting of channel bottoms, along with concomitant changes in the aquatic life.

Pess and Bilby⁸⁴ identified Coho salmon (*Oncorhynchus kisutch*) distribution and abundance in Puget Sound rivers and explained the distribution by using both stream-reach and watershed-scale habitat characteristics, including the influence of urban areas on the habitat. In the Puget Sound region of the U.S. Pacific Northwest, Greenberg et al.⁸⁵ developed and evaluated the Urban Stream Baseline Evaluation Method to characterize baseline habitat conditions for salmonids. The methodology, based on assessment of geomorphic suitability, fish distribution, and habitat alteration, was recommended for use to prioritize recovery actions.

Bragg and Kershner⁸⁶ investigated the impact on the habitats of aquatic life and they found that coarse woody debris in riparian zones could be used successfully to maintain the integrity of these ecosystems. Larson⁸⁷ evaluated the effectiveness in urban areas of these habitat-restoration activities using large woody debris and found that in urban areas, the success of restoration may be hindered by the high sediment loads and increased flow associated with urbanization. Markowitz et al.⁸⁸ documented the CSO Long Term Control Plan implemented by the City of Akron, Ohio, which focused on habitat preservation and aquatic-life use of the receiving waters. The plan included these nontraditional alternatives: riparian setbacks in undeveloped areas, stream restoration, linear parks or greenways, and artificial riffles for stream aeration; these alternative approaches were found to cost less than 5% of the typical cost of controlling CSO flows. A methodology to investigate the chronic and cumulative degradation of the river Orne due to CSO and urban runoff was presented by Zobrist et al.,⁸⁹ with the results being used to evaluate management activities. Xu et al.⁹¹ reported on the improvement plan being used for a river passing through the downtown area of a city in Western Japan and the problems inherent in developing a compromise strategy between flood control and mitigation and the desire to have an attractive waterway running through the city. The final improvement plan recommended construction of a new flood drain tunnel and a new underground flood-control reservoir.

Cianfrani et al.⁹² used a GIS system to document the results of a comprehensive inventory of the natural resources of the Fairmount Park (Philadelphia, Pennsylvania) stream system including vegetation communities, fish, aquatic and terrestrial insects, birds, mollusks, amphibians, reptiles, and streams. The stream assessment also included the characterization of stream reaches by in-stream habitat, geomorphology, and riparian zone. This GIS inventory then was used in planning the restoration of sites in the Fairmount Park system. Derry et al.⁹³ reported on the habitat management strategies implemented by the City of Olympia, Washington, to control the degradation of aquatic habitats by urban stormwater runoff. These management strategies provided a basis for resolving the conflict between growth and the protection of aquatic resources. Ishikawa et al.⁹⁴ reported on the efforts to restore the hydrological cycle in the Izumi River Basin in Yokohama, Japan, while Saeki et al.⁹⁵ have documented the efforts of the Tokyo Metropolitan Government and its Basin Committee to restore the natural water cycle in the Kanda River. Kennen⁹⁶ investigated the relationship between selected basin and water-quality characteristics in New Jersey streams and the impact on the macroinvertebrate community and stream habitat. He found that urban areas had the greatest probability of having impacted stream areas, with the amount of urban land and the total flow of treated sewage effluent being the strongest explanatory variables for the impact. He also found that levels of impairment were significantly different between the Atlantic Coastal Rivers drainage area and the Lower Delaware River drainage area.

19.4.1 Increased Flows from Urbanization

Increased flows are the probably the best known example of impacts associated with urbanization. Most of the recognition has, of course, focused on increased flooding and associated damages. This has led to numerous attempts to control peak flows from new urban areas through the use of

regulations that limit postdevelopment peak flows to predevelopment levels for relatively large design storms. The typical response has been to use dry detention ponds. This approach is limited and may actually increase downstream flows. In addition to the serious issue of flooding, high flows also cause detrimental ecological problems in receiving waters. The following discussion presents several case studies where increased flows were found to have serious effects on stream habitat conditions.

The aquatic organism differences in urbanized and control streams found during the Bellevue Urban Runoff Program were probably most associated with the increased peak flows. The increased flows in the urbanized Kelsey Creek resulted in increases in sediment carrying capacity and channel instability of the creek.⁶¹⁻⁶⁵ Kelsey Creek had much lower flows than the control Bear Creek during periods between storms. About 30% less water was available in Kelsey Creek during the summers. These low flows may also have significantly affected the aquatic habitat and the ability of the urban creek to flush toxic spills or other dry-weather contaminants from the creek system.^{66,67} Kelsey Creek had extreme hydrologic responses to storm. Flooding substantially increased in Kelsey Creek during the period of urban development; the peak annual discharges almost doubled in 30 years, and the flooding frequency also increased due to urbanization.^{66,67} These increased flows in urbanized Kelsey Creek resulted in greatly increased sediment transport and channel instability.

Bhaduri et al.⁹⁷ also quantified the changes in streamflow and associated decreases in groundwater recharge associated with urbanization. They point out that the most widely addressed hydrologic effect of urbanization is the peak discharge increases that cause local flooding. However, the increase in surface runoff volume also represents a net loss in groundwater recharge. They point out that urbanization is linked to increased variability in volume of water available for wetlands and small streams, causing “flashy” or “flood-and-drought” conditions. In northern Ohio, urbanization at a study area was found to cause a 195% increase in the annual volume of runoff, while the expected increase in the peak flow for the local 100-year event was only 26% for the same site. Although any increase in severe flooding is problematic and cause for concern, the much larger increase in annual runoff volume, and associated decrease in groundwater recharge, likely has a much greater effect on in-stream biological conditions.

Snodgrass et al.¹⁶ reported that in the Toronto, Ontario area, flows causing bankfull conditions occur with a return frequency of about 1.5 years. Storms with this frequency are in general equilibrium with resisting forces that tend to stabilize the channel (such as vegetation and tree root mats), with increased flows overcoming these resisting forces, causing channel enlargement. Infrequent flows can therefore be highly erosive. With urbanization, the flows that were bankfull flows during historical times now occur much more frequently (about every 0.4 years in Toronto). The channel cross-sectional area, therefore, greatly increases to accommodate the increased stream discharges and power associated with the “new” 1.5-year flows that are trying to reestablish equilibrium.

Booth and Jackson⁹⁸ examined numerous data from lowland streams in western Washington and concluded that development having about 10% imperviousness caused a readily apparent degradation of aquatic life in the receiving waters. They linked the association between increased imperviousness and biological degradation to increases in flows and sediment discharges. They concluded that conventional methods to size stormwater mitigation measures (especially detention ponds) were seriously inadequate. They felt that without a better understanding of the critical processes that lead to degradation, some downstream damage to the aquatic ecosystem is likely inevitable, without unpopular restrictions to the extent of development in the watershed corresponding to < 10% imperviousness. The stream channels were generally stable if the effective impervious areas remained below 10% of the complete watershed. This level of development corresponds to a 2-year developed condition flow being less than the historical 10-year predeveloped flow condition. They found that the classical goal of detention ponds to maintain predevelopment flows was seriously inadequate because there is no control on the duration of the peak flows. They showed that a duration standard to maintain post development flow durations for all sediment-transporting discharges to predevelopment durations will avoid many receiving water habitat problems associated with stream instability. Without infiltration, the amount of runoff will obviously still increase with

urbanization, but the increased water could be discharged from detention facilities at flow rates below the critical threshold, causing sediment transport. The identification of the threshold discharge below which sediment transport does not occur, unfortunately, is difficult and very site-specific. A presumed threshold discharge of about one half of the predevelopment 2-year flow was recommended for gravel-bedded streams. Sand-bedded channels have sediment transport thresholds that are very small, with inevitable bed load transport likely to occur for most levels of urbanization.

19.4.2 Channel Modifications Due to Urban Wet Weather Flow Discharges

Changes in physical stream channel characteristics can have a significant effect on the biological health of the stream. These changes in urban streams have been mostly related to changes in the flow regime of the stream, specifically increases in peak flow rates, increased frequencies and durations of erosive flows, and channel modifications made in an attempt to accommodate increased stormwater discharges.

Schueler⁹⁹ stated that channel geometric stability can be a good indicator of the effectiveness of stormwater control practices. He also found that once a watershed area has more than about 10 to 15% effective impervious cover, noticeable changes in channel morphology occur, along with quantifiable impacts on water quality and biological conditions. Stephenson¹⁰⁰ studied changes in streamflow volumes in South Africa during urbanization. He found increased stormwater runoff, decreases in the groundwater table, and dramatically decreased times of concentration. The peak flow rates increased by about twofold, about half caused by increased pavement (in an area having about only 5% effective impervious cover), with the remainder caused by decreased times of concentration (related to the increased drainage efficiency of artificial conveyances).

Richey⁶⁴ made some observations about bank stabilities in Kelsey and Bear Creeks as part of the Bellevue, Washington, NURP project.²⁵ She notes that the Kelsey Creek channel width had been constrained during urban development. In addition, 35% of the urbanized Kelsey Creek channel mapped during these projects was modified by the addition of some type of stabilization structure. Only 8% of nonurbanized Bear Creek's length was stabilized. Most of the stabilization structures in Bear Creek were low walls in disrepair, while more than half of the structures observed along Kelsey Creek were large riprap or concrete retention walls. The necessity of the stabilization structures was evident from the extent and severity of erosion cuts and the number of deposition bars observed along the Kelsey Creek stream banks. Bridges and culverts were also frequently found along Kelsey Creek; these structures further act to constrict the channel. As discharges increased and the channel width is constrained, the velocity increases, causing increases in erosion and sediment transport.

The use of heavy riprap along the creek seemed to worsen the flood problems. Storm flows are unable to spread out onto the flood plain, and the increased velocities are evident downstream along with increased sediment loads. This rapidly moving water has enough energy to erode unprotected banks downstream of riprap. Many erosion cuts along Kelsey Creek downstream of these riprap structures were found. Similar erosion of the banks did not occur in Bear Creek. Much of the Bear Creek channel had a wide flood plain with many side sloughs and back eddies. High flows in Bear Creek could spread onto the flood plains and drop much of their sediment load as the water velocities decreased.

The University of Washington studies also examined sediment transport in urbanized Kelsey and nonurbanized Bear Creeks. Richey⁶⁴ found that the relative lack of debris dams and off-channel storage areas and sloughs in Kelsey Creek contributed to the rapid downstream transit of water and materials. Both the small size of the riparian vegetation and the increased stream power probably contributed to the lack of debris in the channel. It is also possible that the channel debris may have been cleared from the stream to facilitate rapid drainage. The high flows from high velocities caused the sediments to be relatively coarse. The finer materials were more easily

Table 19.3 Hours of Exceedence of Developed Conditions with Zero Runoff Increase Controls Compared to Predevelopment Conditions¹⁰²

Recurrence Interval (years)	Existing Flowrate (m ³ /s)	Exceedence for Predevelopment Conditions (hours per 5 yrs)	Exceedence for Existing Development Conditions, with ZRI Controls (hours per 5 yrs)	Exceedence for Ultimate Development Conditions, with ZRI Controls (hours per 5 yrs)
1.01 (critical mid-bankfull conditions)	1.24	90	380	900
1.5 (bankfull conditions)	2.1	30	34	120

transported downstream. Larger boulders were also found in the sediment but were probably from failed riprap or gabion structures.

Maxted¹⁰¹ examined stream problems in Delaware associated with urbanization. He found an apparent strong correlation between habitat score and biology score from 40 stream study locations. He found that it is not possible to have acceptable biological conditions if the habitat is degraded. The leading contributor to habitat degradation was found to be urban runoff, especially the associated high flows and sediment accumulations.

A number of presentations concerning aquatic habitat effects from urbanization were made at the *Effects of Watershed Development and Management on Aquatic Ecosystems* conference held in Snowbird, Utah, in August 1996, sponsored by the Engineering Foundation and the ASCE. MacRae¹⁰² presented a review of the development of the common zero-runoff-increase (ZRI) discharge criterion, referring to peak discharges before and after development. This criterion is commonly met using detention ponds for the 2-year storm. MacRae shows how this criterion has not effectively protected the receiving-water habitat. He found that streambed and bank erosion is controlled by the frequency and duration of the mid-depth flows (generally occurring more often than once a year), not the bankfull condition (approximated by the 2-year event). During monitoring near Toronto, he found that the duration of the geomorphically significant predevelopment mid-bankfull flows increased by a factor of 4.2 times after 34% of the basin had been urbanized compared to flow conditions before development. The channel had responded by increasing in cross-sectional area by as much as three times in some areas, and was still expanding. Table 19.3 shows the modeled durations of critical discharges for predevelopment conditions, compared to current and ultimate levels of development with “zero-runoff-increase” controls in place. At full development and even with full ZRI compliance in this watershed, the hours exceeding the critical mid-bankfull conditions will increase by a factor of ten, with resulting significant effects on channel stability and the physical habitat.

MacRae¹⁰² also reported other studies that found that channel cross-sectional areas began to enlarge after about 20 to 25% of the watershed was developed, corresponding to about a 5% impervious cover in the watershed. When the watersheds are completely developed, the channel enlargements were about five to seven times the original cross-sectional areas. Changes from stable streambed conditions to unstable conditions appear to occur with basin imperviousness of about 10%, similar to the value reported previously for serious biological degradation. He also summarized a study conducted in British Columbia that examined 30 stream reaches in natural areas, in urbanized areas having peak-flow attenuation ponds, and in urbanized areas not having any stormwater controls. The channel widths in the uncontrolled urban streams were about 1.7 times the widths of the natural streams. The streams having the ponds also showed widening, but at a reduced amount compared to the uncontrolled urban streams. He concluded that an effective criterion to protect stream stability (a major component of habitat protection) must address mid-bankfull events, especially by requiring similar durations and frequencies of stream power (the product of shear stress and flow velocity, not just flow velocity alone) at these depths, compared to satisfactory reference conditions.

Much research on habitat changes and rehabilitation attempts in urban streams has occurred in the Seattle area of western Washington over the past 20 years. Sovern and Washington¹⁰³ described the in-stream processes associated with urbanization in this area, as part of a paper describing a recommended approach for the rehabilitation of urban streams. They were concerned that many attempts to “restore” urban streams were destined to failure because of a lack of understanding of the actual changes occurring in streams as the watersheds changed from forested to urban land uses. They presented a concept of the “new urban stream” that attempts to correct several of the most important changes to better accommodate the native Pacific Northwest fish, instead of the unrealistic goal of trying to totally restore the streams to predevelopment conditions. The important factors that affect the direction and magnitude of the changes in a stream’s physical characteristics due to urbanization include:

- The depths and widths of the dominant discharge channel will increase directly proportional to the water discharge. The width is also directly proportional to the sediment discharge. The channel width divided by the depth (the channel shape) is also directly related to sediment discharge.
- The channel gradient is inversely proportional to the water discharge rate and directly proportional to the sediment discharge rate and the sediment grain size.
- The sinuosity of the stream is directly proportional to the stream’s valley gradient and inversely proportional to the sediment discharge.
- Bed load transport is directly related to the stream power and the concentration of fine material and inversely proportional to the fall diameter of the bed material.

In their natural state, small streams in forested watersheds in western Washington have small low-flow channels (the aquatic habitat channel) with little meandering.¹⁰³ The stream banks are nearly vertical because of clayey bank soils and heavy root structures, and the streams have numerous debris jams from fallen timber. The stream widths are also narrow, generally from 3 to 6 feet wide. Stable forested watersheds also support about 250 aquatic plant and animal species along the stream corridor. In contrast, fewer than 50 aquatic plant and animal species are usually found along urban streams. Pool/riffle habitat is dominant along streams having gradients less than about 2% slope, while pool/drop habitat is dominant along streams having gradients from 4 to 10%. The pools form behind large organic debris (LOD) or rocks. The salmon and trout in western Washington have evolved to take advantage of these stream characteristics. Sovern and Washington¹⁰³ point out that less athletic fish species (such as chum and pink salmon) cannot utilize the steeper gradient and upper reaches of the streams. Coho, steelhead, and cutthroat can use these upper areas, however.

Urbanization radically affects many of these natural stream characteristics. Pitt and Bissonnette²⁵ reported that the Coho salmon and cutthroat trout were affected by the increased nutrients and elevated temperatures of the urbanized streams in Bellevue, as studied by the University of Washington under the U.S. EPA’s NURP project.¹⁰⁴ These conditions were probably responsible for accelerated growth of the fry that were observed to migrate to Puget Sound and the Pacific Ocean sooner than their counterparts in the control forested watershed that was also studied. However, the degradation of sediments, mainly the decreased particle sizes, adversely affected their spawning areas in streams that had become urbanized.

Sovern and Washington¹⁰³ reported that in western Washington frequent high flow rates can be 10 to 100 times the predevelopment flows in urbanized areas, but that the low flows in the urban streams are commonly lower than the predevelopment low flows. They have concluded that the effects of urbanization on western Washington streams are dramatic, in most cases permanently changing the stream hydrologic balance by increasing the annual water volume in the stream, increasing the volume and rate of storm flows, decreasing the low flows during dry periods, and increasing the sediment and contaminant discharges from the watershed. With urbanization, the streams increase in cross-sectional area to accommodate these increased flows, and headwater downcutting occurs to decrease the channel gradient. The gradients of stable urban streams are often only about 1 to 2%, compared to 2 to 10% gradients in natural areas. These changes in width

and the downcutting result in very different and changing stream conditions. The common pool/drop habitats are generally replaced by pool/riffle habitats, and the streambed material is comprised of much finer material, for example. The researchers have concluded that once urbanization begins, the effects on stream shape are not completely reversible. Developing and maintaining quality aquatic-life habitat, however, is possible under urban conditions, but it requires human intervention and will not be the same as for forested watersheds.

Other Seattle area researchers have specifically examined the role that large woody debris (LWD) has in stabilizing the habitat in urban streams. Booth et al.¹⁰⁵ found that LWD performs key functions in undisturbed streams that drain lowland forested watersheds in western Washington. These important functions include energy dissipation of the flow energy, channel bank and bed stabilization, sediment trapping, and pool formation. Urbanization typically results in the almost complete removal of this material. They point out that logs and other debris have long been removed from channels in urban areas for many reasons, especially because such debris has the potential to block culverts or to form jams at bridges and can increase bank scour, and many residents favor “neat” stream-bank areas (a lack of woody debris in and near the water and even with mowed grass to the waters edge). Booth et al.¹⁰⁵ present and modify the stream classification system originally developed by Montgomery and Buffington¹⁰⁶ that recognizes LWD as an important component of Pacific Northwest streams that are being severely affected by urbanization.

The role of LWD varies in each channel type, and the effects of its removal also vary. The channel types are described as follows. The upper colluvial channels are wholly surrounded by colluvium (sediment transported by creep or landsliding, and not by stream transport) and generally lie at the top of the channel network. The cascade channels are the steepest of the alluvial channels and are characterized by their tumbling flows around individual boulders that dissipate most of the energy of the flowing water. Only very small pools are in cascade channels. The step-pool channels have accumulations of debris that form a series of steps that are one to four channel widths apart. The steps separate small pools that accumulate fine sediment. The fine sediment can be periodically flushed downstream during rare events.

“Free” step-pool channels are characterized by steps that are made of alluvium that can be periodically transported downstream during high flows, while “forced” step-pool channels are characterized by steps that are made of immovable obstructions (large logs or bedrock). The removal of LWD from a forced step-pool stream in the Cascade Range could be naturally compensated by the common occurrence of large boulders that also form forced steps. However, in the lowlands near Puget Sound, the available sand and gravel stream deposits are too small to form stable steps, and the removal of LWD would have a much more severe effect on the channel stability. Plane-bed channels have long and channel-wide reaches of uniform riffles and do not have pronounced meanders and associated pools. Pool-riffle channels are the most common lowland stream channels in western Washington. These streams have pronounced meanders with pools at the outside of the bends and corresponding bars on the inside of the bends. Riffles form in the relatively straight stretch between the pools. There are also “free” and “forced” pool-riffle channels. Forced riffle-pool channels are typically formed with obstructions, such as LWD, and their removal would generally lead to a plane-bed channel characteristic. Forced riffle-pool channels form due to natural meanders and the inertial forces of the water. Dune-ripple channels have beds mostly made of sand where the character of the bed material changes in response to the flows.

The role of LWD is also highly dependent on the width of the stream. In narrow channels (high gradient colluvial and cascade channels), much of the LWD can be suspended above the flows, rarely being submerged and not available as a fish refuge or sediment trap or to dissipate the water’s energy. In wide channels (dune-ripple channels), the LWD may be significantly shorter than the channel width, with minimal stable opportunities to provide steps in the channel. Therefore, LWD plays a much more important role in channels having medium widths (lowland streams having plane-bed and pool-riffle channels), where the timber can become tightly lodged in the common flow channel. The removal of the LWD in these streams, especially in streams having few boulder

steps, would have significant effects. Fish populations decline rapidly and precipitously following the removal of LWD in these critical streams.¹⁰⁵

Horner et al.¹⁰⁷ described an extensive study in the Pacific Northwest where 31 stream reaches were examined beginning in 1994 for a variety of in-stream and watershed characteristics. They concluded that the most severe in-stream biological changes were most likely associated with changes in habitat, especially increased frequencies and magnitudes of high flows. These flow changes were therefore thought to be most related to watershed factors affecting runoff, especially the amount of impervious areas in the watershed. They felt that the most rapid changes in ecological conditions were most likely to occur for urbanizing streams at relatively low levels of development, conditions representing most of the selected study sites.

Horner et al.¹⁰⁷ found a rapid decline in biological conditions as total imperviousness area increases to about 8% in the watershed. The rate of decline is less for higher levels of urbanization. Eight study areas had better biological conditions than expected and were associated with higher amounts of intact wetlands along the riparian corridors than other sites, indicating a possible significant moderating effect associated with preserving stream corridors in their natural condition. The less tolerant Coho salmon is much more abundant than the more tolerant cutthroat trout only for very low levels of urbanization. Stormwater concentrations of zinc were also seen to increase steadily with increasing impervious areas. However, the concentrations are well below the critical water-quality criteria until the impervious cover reaches about 40%, a level much greater than when significant biological effects are noted.

Similar conclusions were made with other metal concentrations and contaminant concentrations in the sediment. They interpreted these findings to imply that contaminant conditions were much less important than habitat destruction when it comes to affecting in-stream biological conditions. They concluded that the preponderance of physical and biological evidence indicated rapid in-stream degradation of biological conditions at early stages of urbanization. However, chemical contaminants did not appear to significantly affect biological conditions in the early stages of urbanization but may have at very high levels of urbanization. Based on their results, they developed a preliminary summary of the conditions that would allow high levels of biological functions in the Puget Sound area:

- Total impervious areas less than 5% of the watershed area, unless mitigated by extensive riparian protection, management efforts, or both;
- 2-year peak flow/winter baseflow ratio of <20;
- Greater than 60% of the upstream buffer should be greater than 30 m wide; and
- Less than 15% of the sediment in the stream bed should be less than 0.85 mm.

Habitat evaluations are commonly and justifiably recognized as critical components of stream and watershed studies. However, Poole et al.¹⁰⁸ caution users concerning their use to quantify aquatic habitat or channel morphology in an attempt to measure the response of individual streams to human activities. Their concern is the subjectivity of habitat surveys and the lack of repeatability, precision, and transferability of the measurement techniques. The measurement parameters are also assigned relatively arbitrary nominal values that are not easily statistically evaluated. According to them, the typical use of habitat unit classifications encourages the focus on direct manipulation or replacement of habitat structures (such as in-stream “restoration” activities) while neglecting the long-term maintenance of habitat-forming biophysical processes (such as controlling the energy distribution of stream discharges and the discharges of sediment into the streams).

Therefore, the use of habitat unit classifications as an indicator of watershed health may be most appropriately used for only very large differences or changes, when conducted over a large portion of a watershed being studied, and only if a sufficiently large number of observations and replicates are made to compensate for the high inherent measurement variations. Many current habitat surveys are being conducted on small scales within a short period of time, with few observations, and without adequate statistical evaluations of the data. The results of these surveys

are, therefore, of questionable value. As for all indicators, it is important that methods be developed and tested to improve the accuracy of the tool and that additional supplemental measurement methods also be used to confirm observations and conclusions, especially when evaluating cause-and-effect relationships in watersheds.

19.5 STORMWATER CONTAMINATION OF SEDIMENTS AND INCREASED SEDIMENT DISCHARGES IN URBAN STREAMS

Many of the observed biological effects associated with urban runoff may be caused by polluted sediments and associated benthic-organism impacts. There has been a tremendous amount of research focusing on sediment toxicity. The following paragraphs only briefly describe several cases where sediment toxicity was examined in some detail in urban environments in which the major contaminant sources originated from stormwater alone. Burton and Pitt,¹³ Allen,³² Hatch and Burton,⁴⁵ among others, provide reviews of other urban-stream-sediment toxicity studies.

The EPA¹⁰⁹ prepared a four-volume report to Congress on the incidence and severity of sediment contamination in the surface waters of the United States. This report was required by the Water Resources Development Act of 1992. This Act defines contaminated sediment as “sediment containing chemical substances in excess of appropriate geochemical, toxicological, or sediment quality criteria or measures; or otherwise considered to pose a threat to human health or the environment.” In the national quality survey, the EPA examined data from 65% of the 2111 watersheds in the United States and identified 96 watersheds that contain areas of probable concern. In portions of these waters, benthic organisms and fish may contain chemicals at levels unsafe for regular consumption. Areas of probable concern are located in regions affected by urban and agricultural runoff, municipal and industrial waste discharges, and other contaminant sources. When the fourth volume is completed, much more detailed information will become available concerning the relative role that urban stormwater contributes to national contaminated sediment problems. The development of sediment-quality criteria is an emerging area, with slowly emerging general guidance available to compare locally observed conditions to “standards.” In most cases, local reference conditions have been most effectively used to indicate if the observed conditions constitute a problem.¹³

Examples of elevated heavy-metal and nutrient accumulations in urban sediments are numerous. DePinto et al.¹¹⁰ found that the cadmium content of river sediments can be more than 1000 times greater than the overlying water concentrations, and the accumulation factors in sediments are closely correlated with sediment organic content. They reported that sediments were also able to adsorb phosphorus in proportion to the phosphorus concentrations in the overlying waters during aerobic periods, but that the sediments released phosphorus during anaerobic periods. Heaney¹¹¹ found that long-term impacts of urban runoff related to the resuspension of previously deposited polluted benthos material may be more important than short-term discharges of contaminants from potential “first-flushes.”

Another comprehensive study on polluted sediment was conducted by Wilber and Hunter¹¹² along the Saddle River in New Jersey, where they found significant increases in sediment contamination with increasing urbanization. They found large variations in metal concentrations for different sediment particle sizes in the urban river. The sediment particle-size distribution was the predominant influencing factor for total metal concentrations in the sediments. Areas having fine sediments had a substantially greater concentration of heavy metals than those areas having coarse sediments.

In another study, Pitt and Bozeman²² observed concentrations for many contaminants in the urban-area sediments of Coyote Creek (San Jose, California) that were much greater than those from the nonurban area. Orthophosphates, TOC, BOD₅, sulfates, sulfur, and lead were all found in higher concentrations in the sediments from the urban-area stations, as compared with those from the upstream, nonurban-area stations. The median sediment particle sizes were also found to be significantly smaller at the urban-area stations, reflecting a higher silt content.

Several of the University of Washington projects as well as the Seattle METRO project investigated physical and chemical characteristics of the Kelsey and Bear Creeks sediments as part of the Bellevue, Washington, NURP projects.²⁵ Perkins⁶³ found that the size and composition of the sediments near the water interface tended to be more variable and of a larger median size in Kelsey Creek than in Bear Creek. These particle sizes varied in both streams on an annual cycle in response to runoff events. Larger particle sizes were more common during the winter months, when the larger flows were probably more efficient in flushing through the finer materials. Pedersen⁶¹ also states that Kelsey Creek demonstrated a much greater accumulation of sandy sediments in the early spring. This decreases the suitability of the stream substrates for benthic colonization. Scott et al.²⁶ state that the level of fines in the sediment samples appears to be a more sensitive measure of substrate quality than the geometric mean of the particle-size distribution. Fines were defined as all material less than about 840 μm in diameter. METRO¹¹³ also analyzed organic priority pollutants in 17 creek sediments including several in Kelsey and Bear Creeks. Very few organic compounds were detected in either stream, with the most notable trend being the much more common occurrence of various PAHs in Kelsey Creek, while none were detected in Bear Creek.

The University of Washington project and the Seattle METRO project analyzed interstitial water for various constituents. These samples were obtained by inserting perforated aluminum standpipes into the creek sediment. This water is most affected by the sediment quality and in turn affects the benthic organisms much more than the creek water column. Scott et al.⁶⁵ found that the interstitial water pH ranged from 6.5 to 7.6 and did not significantly differ between the two streams but did tend to decrease during the spring months. The lower fall temperatures and pH levels contributed to reductions in ammonium concentrations. The total ammonia and nonionized ammonia concentrations were significantly greater in Kelsey Creek than in Bear Creek. They also found that the interstitial DO concentrations in Kelsey Creek were much below those concentrations considered normal for undisturbed watersheds. These decreased interstitial oxygen concentrations were much less than the water-column concentrations and indicated the possible impact of urban development. The DO concentrations in the interstitial waters and in Bear Creek were also lower than expected, potentially suggesting deteriorating fish spawning conditions. During the winter and spring months, the interstitial oxygen concentrations appeared to be intermediate between those characteristic of disturbed and undisturbed watersheds.

The University of Washington⁶⁴ also analyzed heavy metals in the interstitial waters, focusing mostly on the more readily detected lead and zinc measurements compared to the low, or undetectable, copper and chromium concentrations. The urban Kelsey Creek interstitial water had concentrations of heavy metals approximately twice those found in the rural Bear Creek interstitial water. They expect that most of the metals were loosely bound to fine sediment particles. Most of the lead found was associated with the particulates, with very little soluble lead found in the interstitial waters. The interstitial samples taken from the standpipe samplers were full of sediment particles, which could be expected to release lead into solution following the mild acid digestion for exchangeable lead analyses. They also found that the metal concentrations in Kelsey Creek interstitial water decreased in a downstream direction. They thought that this might be caused by stream scouring of the benthic material in that part of the creek. The downstream Kelsey Creek sites were more prone to erosion and channel scouring, while the uppermost stream station was relatively stable.

Variable interstitial water quality may cause variations in sediment toxicity with time and location. Seattle METRO¹¹³ monitored heavy metals in the interstitial waters in Kelsey and Bear Creeks. They found large variations in heavy-metal concentrations, depending on whether the sample was obtained during the wet or the dry season. During storm periods, the interstitial water and creek water heavy-metal concentrations approached the stormwater values (200 $\mu\text{g/L}$ for lead). During nonstorm periods, the interstitial lead concentrations were typically about only 1 $\mu\text{g/L}$. They also analyzed priority pollutant organics in interstitial waters. Only benzene was found and only in the urban stream. The observed benzene concentrations in two Kelsey Creek samples were

22 and 24 $\mu\text{g/L}$, while the reported concentrations were less than 1 $\mu\text{g/L}$ in all other interstitial water samples analyzed for benzene.

A number of recent investigations have examined sediment quality in conjunction with biological conditions in urban receiving waters in attempts to identify causative agents affecting the biological community. Arhelger et al.¹¹⁴ examined conditions in the upper Houston Ship Channel, which receives drainage from the metropolitan Houston area. The channel has been dredged to allow large vessels access to the upper reaches of what used to be a relatively small channel. The dredging has increased the cross-sectional area by about 20 times, with attendant significant decreases in flushing flows. This has caused increased sedimentation of suspended material discharged from the 500-square-mile urban watershed. The sediments have undergone extensive chemical, physical, and toxicity testing, with frequent indications of toxicity. The tests have indicated that the toxicity is most likely caused by the high sediment oxygen demand and associated low DO conditions. Toxicity testing of *Ampelisca* under varied DO conditions showed significant decreases in survival when the bottom DO is less than 3 mg/L, for example. Even though the point-source BOD loads have been reduced by more than 90% since the 1970s, receiving-water and sediment oxygen levels are very low. Arhelger et al.¹¹⁴ concluded that this remaining DO problem was caused by uncontrolled stormwater discharges.

Previous studies near Auckland, New Zealand have shown that sediment concentrations of many constituents near stormwater outfalls, especially in industrial areas, often exceed guidelines intended to protect bottom-dwelling animals. Guidelines used were as presented by Long et al.¹¹⁵ and were as follows (along with sediment concentrations from two locations near Auckland):

mg/kg	Copper	Lead	Zinc
Effects range — low	34	47	150
Effects range — median	270	218	410
Hellyers/Kaipatiki	17–36	13–95	58–192
Pakuranga	14–65	22–112	108–345

Lead, zinc, and organochlorine were the most widespread potential problems. Field surveys and laboratory toxicity tests had shown circumstantial evidence of chronic toxicity associated with stormwater. Detailed field surveys by Morrissey et al.¹¹⁶ were therefore conducted to better understand actual toxicity problems in the local marine estuaries that are influenced by complex natural factors. These complicating factors include strong gradients in salinity, sediment texture, currents, and wave action, all radically affecting the natural distribution of benthic fauna. In slowly growing areas or in relatively low-density urban areas, the relatively small rate of accumulation of contaminated sediments from nonpoint-sources could take many years to accumulate to levels that might produce detectable impacts in the receiving waters. In addition, changing urban conditions and changing weather from year to year make the rate of accumulation highly variable. These factors all make it difficult to conduct many types of field experiments that rely on before and after observations or other short-term observations that assume steady conditions. They therefore relied on a “weight-of-evidence” approach that considers many different and reinforcing/confirming procedures (such as the sediment-quality-triad and the effects-range tests, both of which rely on distribution of contaminants and organisms in the field and from laboratory toxicity tests). They also applied their results to the Abundance Biomass Comparison index proposed by Warwick.¹¹⁷ This index is a relative measure of biomass vs. abundance and has been shown to work well for individual sites when control sites are difficult to identify and study, especially if available “control” sites are already impacted. Pore-water chemistry, sediment quality, and benthic-community composition were included in the field analyses. Statistical analyses identified the strongest correlations between pH and iron content of the pore water and between the sediment texture and benthic composition. The pH and iron pore-water conditions may affect the bioavailability of the sediment

heavy metals. Current and future work includes similar studies in nonurbanized estuaries, the development of chronic toxicity tests using local indigenous organisms, and studies of recolonization of heavily impacted sites.

Watzin et al.¹¹⁸ examined sediment contamination in Lake Champlain near Burlington, Vermont, to compare several toxicity endpoints with sediment characteristics. They measured sediment pore-water toxicity using *Ceriodaphnia dubia*, *Chironomus tentans*, and *Pimephales promelas*, benthic-community composition, and many physical and chemical characteristics at 19 locations. Four major storm drains and the secondary sewage treatment plant all discharged to the harbor. Boat traffic and historical petroleum-handling facilities also affected some of the sampling locations. They found variable levels of toxicity at the different sites, but no correlation was observed between acid-volatile sulfides (AVS), heavy-metal concentrations, and sediment toxicity. However, they did find strong associations between increasing levels of organics and lowering toxicity levels, indicating that possible metal–organic-matter complexation was reducing the metal availability. The sediment toxicity tests did indicate a moderate level of concern, but the macroinvertebrate community was apparently not significantly affected during these tests. They proposed the use of a weight-of-evidence approach that uses multiple indicators of problems and possible sources of the problems, plus repeated observations over seasonal cycles, before management recommendations are developed.

Rhoads and Cahill¹²⁰ studied the elevated concentrations of chromium, copper, lead, nickel, and zinc that were found in sediments near storm-sewer outfalls. They noted that copper and zinc concentrations were greater in the bedload compared to the bed material and therefore were more likely to be mobilized during runoff events.

Crabill et al.¹²¹ presented their analysis of the water and sediment in Oak Creek in Arizona, which showed that the sediment fecal coliform counts were on average 2200 times greater than those in the water column. Water-quality standards for fecal coliforms were regularly violated during the summer due to the high recreational activity and animal activity in the watershed as well as the storm surges due to the summer storm season.

Vollertsen et al.¹²² characterized the biodegradability of combined-sewer organic matter based on settling velocity. Fast-settling organic matter, which represents the largest fraction of the organic material, was found to be rather slowly biodegradable compared to the slow-settling organic fraction. They stressed that the biodegradability of sewer sediments should be taken into account when evaluating CSO impacts. Vollertsen and Hvitved-Jacobsen¹²³ studied the stoichiometric and kinetic model parameters for predicting microbial transformations of suspended solids in combined sewer systems.

The effects of large discharges of relatively uncontaminated sediment on the receiving-water aquatic environment were summarized by Schueler.¹²⁴ These large discharges are mostly associated with poorly controlled construction sites, where 30 to 300 tons of sediment per acre per year of exposure may be lost. These high rates can be 20 to 2000 times the unit area rates associated with other land uses. Unfortunately, much of this sediment reaches urban receiving waters, where massive impacts on the aquatic environment can result. Unfortunately, high rates of sediment loss can also be associated with later phases of urbanization, where receiving-water channel banks widen to accommodate the increased runoff volume and frequency of high erosive flow rates. Sediment is typically listed as one of the most important pollutants causing receiving water problems in the nation's waters. Schueler¹²⁴ listed the impacts that can be associated with suspended sediment:

- Abrades and damages fish gills, increasing risk of infection and disease
- Scours periphyton from streams (plants attached to rocks)
- Causes loss of sensitive or threatened fish species when turbidity exceeds 25 NTU
- Leads to shifts in fish communities toward more sediment tolerant species
- Causes decline in sunfish, bass, chub, and catfish when monthly turbidity exceeds 100 NTU
- Reduces sight distance for trout, with reduction in feeding efficiency
- Reduces light penetration, which causes reduction in plankton and aquatic plant growth

- Reduces filtration efficiency of zooplankton in lakes and estuaries
- Adversely impacts aquatic insects, which are the base of the food chain
- Slightly increases stream temperature in summer
- Carries significant amounts of nutrients and metals
- Increases probability of boating, swimming, and diving accidents resulting from high turbidity
- Increases water treatment to meet drinking water standards
- Increases wear and tear on hydroelectric and water-intake equipment
- Reduces anglers' chances of catching fish
- Diminishes direct and indirect recreational experience of receiving waters

He also listed the impacts that can be associated with deposited sediment:

- Physical smothering of benthic aquatic insect community
- Reduced survival rates for fish eggs
- Destruction of fish spawning areas and redds
- Reduces fish and macroinvertebrate habitat value from 'Imbedding' of stream bottom
- Loss of trout habitat when fine sediments are deposited in spawning or riffle-runs
- Possible elimination of sensitive or threatened darters and dace from fish community
- Depleted DO in lakes or streams due to increases in sediment oxygen demand
- Alarming decline of freshwater mussels
- Reduced channel capacity, exacerbating downstream bank erosion and flooding
- Reduced flood transport capacity under bridges and through culverts
- Loss of storage and lower design life for reservoirs, impoundments, and ponds
- Dredging costs for maintaining navigable channels and reservoir capacity
- Spoiling of sand beaches
- Diminished scenic and recreational value of waterways

19.5.1 Sediment Contamination Effects

There is much concern and discussion about contaminated sediments in urban receiving waters. Many historical discussions downplayed the significance of contaminated sediments, based on their assumed "low-availability" to aquatic organisms. However, many of the previously described receiving-water studies found greatly affected benthic-organism populations at sites with contaminated urban sediments, compared to uncontaminated control sites. More specifically, *in situ* sediment toxicity tests in urban receiving waters (such as those conducted by Burton and Stemmer¹²⁵; Burton^{126, 128-129}; Burton et al.¹²⁷; Burton and Scott¹³⁰; and Crunkilton et al.¹²) have illustrated the direct toxic effects associated with exposure to contaminated urban sediments, to problems associated with their scour, and to decreases in toxicity associated with their removal from stormwater.

The fate of contaminated sediments, and especially mechanisms that expose contaminants to sensitive organisms, can determine the overall and varied effects that the sediments may have. Scour of fine-grained sediments during periods of high flows in streams and rivers, or due to turbulence from watercraft in shallow waterbodies, has frequently been encountered. In addition, contaminant remobilization may also occur through bioturbation from sediment-dwelling organisms or from nest-building fish. These mechanisms may resuspend contaminants, making them more available to organisms. Burrowing organisms can also transport deeply buried contaminants to surface layers, thereby increasing surface contamination levels, while the surface-scouring mechanisms tend to decrease the concentrations in the surface sediment. Bioturbation has been reported to strongly influence the fate of contaminants and sediment-bound contaminants can be remobilized by this biological activity.¹³¹

Lee and Jones-Lee⁶ reviewed the significance of chemically contaminated sediments and associated impacts. They are especially concerned about the development of sediment-contamination criteria based on simple chemical tests. They concluded that there has been sufficiently demonstrated evidence that the toxic-available form of chemical constituents present in the sediment is the

dissolved form present in the interstitial waters. Historically, the EPA assumed that the dissolved form of certain organic toxicants could be estimated based on an equilibrium partitioning model based on the particulate organic carbon present. Likewise, the dissolved forms of heavy metals were assumed to be controlled by metal sulfide precipitates. Lee and Jones-Lee hold that the EPA's overly simplistic two-component-box model used to predict dissolved forms of toxicants should never be used alone without concurrent well-established toxicity measurements. They are also concerned about the use of databases to relate measured sediment chemical conditions with observed biological conditions that are also sometimes used to establish sediment criteria. These databases have not considered some of the most important possible causes of toxicity at the test sites, namely, low DO and high ammonia and hydrogen sulfide concentrations. They outlined the components of sediment toxicity tests they believe are necessary:

- Nonchemically based "toxicity" can be caused by factors such as sediment grain size.
- Natural vs. anthropogenic sediment toxicity also needs to be separated. They mention several instances where sediments are naturally toxic according to laboratory toxicity tests but still support healthy and high-quality sport fisheries in overlying waters. The most obvious natural cause of sediment toxicity is low oxygen levels in the interstitial water. High levels of ammonia and hydrogen sulfide may also then occur. They state that "the presence of highly toxic conditions in sediments from natural causes, which decimates the benthic-organism populations for a considerable part of the year, does not preclude the presence of an outstanding sports fishery."
- The sensitivity of the test organisms to ammonia toxicity should be considered. Several commonly used toxicity test organisms are much less sensitive to ammonia than many naturally occurring aquatic life forms of interest. Some researchers also strip ammonia from sediments before testing, treating ammonia as a test interference. They believe that nutrient-derived toxicity (algal decomposition effects on sediment oxygen demand and the resulting reducing conditions, low DO levels, and high ammonia and hydrogen sulfide levels) may be the most important cause of toxicity in aquatic sediments. An appropriate toxicity investigation evaluation (TIE) should be conducted to identify the cause of any identified toxicity problems. The use of acid-volatile sulfide and heavy-metal concentrations and TOC normalized sediment organic concentrations can be used as part of a TIE to rule out metals or certain organics as the potential cause of toxicity, but the reverse is not reliable (these methods cannot predict toxicity).
- Selecting reference sites is critical. A suite of test toxicity organisms (at least two or three) must be used, along with a suite of reference sites. Multiple reference sites is needed to help understand the role of natural causes of toxicity. In addition, investigations should be conducted at least twice in a year during important times for the aquatic organisms.

Many researchers contend that the best approach in developing sediment-quality evaluations would use a best-professional-judgment (BPJ), weight-of-evidence approach. This approach involves an integrated assessment of the aquatic-life-toxicity test results, assessment of the bioaccumulations of hazardous chemicals in edible portions of aquatic life, knowledge of chemical characteristics of the sediments and associated waters, and investigations of the aquatic-life assemblages in the sediments of concern compared to appropriate reference sites.

19.6 BIOASSESSMENTS AND OTHER WATERSHED INDICATORS AS COMPONENTS OF RECEIVING WATER EVALUATIONS

Kuehne¹³² studied the usefulness of using various aquatic organisms during stream taxonomic surveys as indicators of pollution. He found that invertebrates can reveal pollution for some time after a water pollution event, but they cannot give accurate indications of the nature of the contaminants. He stated that in-stream fish studies had not been employed as biological indicators much before 1975 but that they are comparable in many ways to invertebrates as quality indicators

and can be more easily identified. However, because of better information pertaining to invertebrates and due to their limited mobility, certain species may be useful as sensitive indicators of minor changes in water quality. Fish can be highly mobile and cover large sections of a stream as long as their passage is not totally blocked by adverse conditions. Fish-disease surveys were also used during the Bellevue, Washington, urban-runoff studies as an indicator of water-quality problems.^{25,65} McHardy et al.¹³³ also examined heavy-metal uptake in green algae (*Cladophora glomerata*) from urban runoff for use as a biological monitor of specific metals.

Burton et al.,¹²⁷ during tests conducted at polluted stream and landfill sites, found that a battery of laboratory and *in situ* bioassay tests were most useful when determining aquatic biota problems. The test series included microbial activity tests, along with exposures of microfaunal organisms, zooplankton, amphipods, and fathead minnows to the test water. The newly developed microbial tests correlated well with *in situ* biological test results. Bascombe et al.¹³⁴ also reported on the use of *in situ* biological tests, using an amphipod exposed for 5 to 6 weeks in urban streams, to examine urban-runoff receiving-water effects. Ellis et al.¹³⁵ examined bioassay procedures for evaluating urban-runoff effects on receiving-water biota. They concluded that an acceptable criterion for protecting receiving-water organisms should not only provide information on concentration and exposure relationships for *in situ* bioassays but also consider body burdens, recovery rates, and sediment-related effects.

A number of stormwater researchers have recently presented bioassessment and other “watershed indicators” that they have found to be useful tools for quantifying local receiving-water problems. Many of these schemes were presented at the conference *Assessing the Cumulative Impacts of Watershed Development in Aquatic Ecosystems and Water Quality* held in Chicago in March 1996, sponsored by the Northeastern Illinois Planning Commission, and at the conference *Effects of Watershed Development and Management on Aquatic Ecosystems* held in Snowbird, Utah, in August 1996, sponsored by the Engineering Foundation and the ASCE. Several papers from those conferences are summarized by location below.

19.6.1 U.S. National Perspective of Bioassessments

Barbour¹³⁶ reviewed many of the state programs throughout the United States that are using biological assessments as part of their water-resources programs. Most of the active state bioassessment programs started after 1990, following the publication of the EPA’s *Rapid Bioassessment Protocols*¹³⁷ and the *Program Guidance for Biocriteria*¹³⁸ manuals. By 1996, numeric biocriteria were in place in Ohio and Florida (and promulgated in Maine) and under development in 13 other states. Although the majority of the states had not used biocriteria, nearly three fourths had used bioassessment data to measure the attainment of their aquatic uses. Almost all states were using benthic macroinvertebrates (47 states) and fish (36 states). Seven states were also using algae in their bioassessment programs.

An important aspect of the biocriteria approach is that local and regional expectations be considered in setting specific objectives. In addition, local reference sites representing specific ecoregions are also used to calibrate observations. The basic components of a bioassessment include:

- Study objectives (typically the determination of biological conditions for different watershed characteristics)
- Site classification (identification of homogeneous areas within a watershed, typically using various biological metrics)
- Reference condition (relatively undisturbed areas for comparison and calibration of the metrics)
- Standardized protocols (training and the use of consistent methods)
- Data analysis (selection of several complementary metrics based on local relevancy)
- Habitat assessment (physical habitat structure evaluations, generally a visual technique)
- Quality assurance (assign responsibility, establish protocols, etc. to ensure repeatability)

19.6.2 Watershed Indicators of Receiving Water Problems

The EPA¹³⁹ published a list of 18 indicators to track the health of the nation's aquatic ecosystems. These indicators are intended to supplement conventional water-quality analyses in compliance-monitoring activities. The use of broader indicators of environmental health is increasing. As an example, 12 states are currently using biological indicators, and 27 states are developing local biological indicators, according to Pelley.¹⁴⁰ Because of the broad nature of the nation's potential receiving-water problems, this list is more general than typically used for specific stormwater issues. These 18 indicators are:¹³⁹

1. Population served by drinking water systems violating health-based requirements.
2. Population served by unfiltered surface water systems at risk from microbiological contamination.
3. Population served by communities by community drinking water systems exceeding lead action levels.
4. Drinking water systems with source-water-protection programs.
5. Fish consumption advisories.
6. Shellfish-growing waters approved for harvest for human consumption.
7. Biological integrity of rivers and estuaries.
8. Species at risk of extinction.
9. Rate of wetland acreage loss.
10. Designated uses: drinking water supply, fish and shellfish consumption, recreation, aquatic like.
11. Groundwater pollutants (nitrate).
12. Surface-water pollutants.
13. Selected coastal surface water pollutants in shellfish.
14. Estuarine eutrophication conditions.
15. Contaminated sediments.
16. Selected point-source loadings to surface water and groundwater.
17. Nonpoint-source sediment loadings from cropland.
18. Marine debris.

These environmental indicators cover a wide range of problems and many are for specific local uses. Most, however, are applicable to stormwater problems in urban areas.

Claytor^{141,142} summarized the approach developed by the Center for Watershed Protection as part of their EPA-sponsored research on identifying watershed indicators that can be used to assess the effectiveness of stormwater-management programs.¹⁴³ The indicators selected are direct or indirect measurements of conditions or elements that indicate trends or responses of watershed conditions to stormwater-management activities. Categories of these environmental indicators are shown in Table 19.4, ranging from conventional water-quality measurements to citizen surveys. Biological and habitat categories are also represented. Table 19.5 lists the 26 indicators by category. It is recommended that appropriate indicators be selected from each category for a specific area under study. This will enable a better understanding of the linkage of what is done on the land, how the sources are regulated or managed, and the associated receiving-water problems. The indicators were selected to: (1) measure stress or the activities that lead to impacts on receiving waters, (2) assess the resources themselves, and (3) measure the regulatory compliance or program initiatives. Claytor¹⁴² presented a framework for using stormwater indicators, as shown below.

Level 1 (problem identification):

1. Establish management sphere (who is responsible, other regulatory agencies involved, etc.).
2. Gather and review historical data.
3. Identify local uses that may be impacted by stormwater (flooding/drainage, biological integrity, noncontact recreation, drinking-water supply, contact recreation, and aquaculture).
4. Inventory resources and identify constraints (time frame, expertise, funding, and labor limitations)
5. Assess baseline conditions (use rapid assessment methods).

Table 19.4 Stormwater Indicator Categories¹⁴²

Category	Description	Principal Element Being Assessed
Water quality	Specific water-quality characteristics	Receiving-water quality
Physical/hydrological	Measure changes to, or impacts on, the physical environment	Receiving-water quality
Biological	Use of biological communities to measure changes to, or impacts on, biological parameters	Receiving-water quality
Social	Responses to surveys or questionnaires to assess social concerns	Human activity on the land surface
Programmatic	Quantify various nonaquatic parameters for measuring program activities	Regulatory compliance or program initiatives
Site	Indicators adapted for assessing specific conditions at the site level	Human activity on the land surface

Table 19.5 Environmental Indicators¹⁴²

Indicator Category	Indicator Name
Water quality indicators	Water-quality pollutant-constituent monitoring Toxicity testing Nonpoint source loadings Exceedence frequencies of water-quality standards Sediment contamination Human health criteria
Physical and hydrological indicators	Stream widening/downcutting Physical habitat monitoring Impacted dry-weather flows Increased flooding frequency Stream temperature monitoring
Biological indicators	Fish assemblage Macroinvertebrate assemblage Single species indicator Composite indicators Other biological indicators
Social indicators	Public attitude surveys Industrial/commercial pollution prevention Public involvement and monitoring User perception
Programmatic indicators	Illicit connections identified/corrected BMPs installed, inspected, and maintained Permitting and compliance Growth and development
Site indicators	BMP performance monitoring Industrial-site-compliance monitoring

The selection of the indicators to assess the baseline conditions should be based on the local uses of concern, as shown in Table 19.6. Most of the anticipated important uses are shown to require indicators selected for each of the categories.

The Level 2 assessment strategy is for examining the local management program and is outlined below:

1. State goals for program (based on baseline conditions, resources, and constraints).
2. Inventory prior and ongoing efforts (including evaluating the success of ongoing efforts).
3. Develop and implement management program.
4. Develop and implement monitoring program (more quantitative indicators than typically used for the Level 1 evaluations above).

Table 19.6 Selection of Indicators for Evaluating Baseline Conditions by Receiving-Water Use¹⁴²

	Water Quality	Physical/ Hydrological	Biological Indicators	Social Indicators	Programmatic Indicators	Site Indicators
Flooding/drainage		x		x	x	x
Biological integrity	x		x	x	x	x
Noncontact recreation	x	x	x	x	x	x
Water supply	x		x	x	x	x
Contact recreation	x	x	x	x	x	x
Aquaculture	x	x	x	x	x	x

5. Assess indicator results. (Does the stormwater indicator monitoring program measure the overall watershed health?)
6. Reevaluate management program (update and revise management program based on measured successes and failures).

Cave¹⁴⁴ described how environmental indicators are being used to summarize the massive amounts of data being generated by the Rouge River National Wet Weather Demonstration Project in Wayne County (Detroit area), Michigan. This massive project is examining existing receiving-water problems, the performance of stormwater and CSO management practices, and receiving-water responses in a 438-square-mile watershed having more than 1.5 million people in 48 separate communities. The baseline monitoring program now has more than 4 years of continuous monitoring of flow, pH, temperature, conductivity, and DO, supplemented by automatic sampling for other water-quality constituents, at 18 river stations. More than 60 projects are examining the effectiveness of stormwater-management practices, and 20 projects are examining the effectiveness of CSO controls, each also generating large amounts of data. Toxicants are also being monitored in sediment, water, and fish tissue and with semipermeable membranes to help evaluate human-health and aquatic-life effects. Habitat surveys were conducted at 83 locations along more than 200 mi of waterway. Algal diversity and benthic macroinvertebrate assessments were also conducted at these survey locations. Electro-fishing surveys were conducted at 36 locations along the main river and in tributaries. Several computer models were also used to predict sources, loadings, and wet-weather flow-management options for the receiving waters and for the drainage systems. A geographic information system was used to manage and provide spatial analyses of the massive amounts of data collected. However, there was still a great need to simply present the data and findings, especially for public presentations. Cave described how they developed a short list of 35 indicators, based on the list of 18 from the EPA and with discussions with state and national regulatory personnel. They then developed seven indices that could be color-coded and placed on maps to indicate areas of existing problems and projected conditions based on alternative management scenarios. These indices are described as follows:

Condition quality indicators:

1. Dissolved oxygen. Concentration and percent saturation values (ecologically important).
2. Fish consumption index. Based on advisories from the Michigan Dept. of Public Health.
3. River flow. Significant for aquatic habitat and fish communities.
4. Bacteria count. *E. coli* counts based on Michigan Water Quality Standards, distinguished for wet and dry conditions.

Multifactor indices:

1. Aquatic biology index. Composite index based on fish and macroinvertebrate community assessments (populations and individuals).
2. Aquatic habitat index. Habitat suitability index, based on substrate, cover, channel morphology, riparian/bank condition, and water quality.
3. Aesthetic index. Based on water clarity, color, odor, and visible debris.

These seven indicators represent 30 physical, chemical, and biological conditions that directly impact the local receiving-water uses (water contact recreation, warmwater fishery, and general aesthetics). Cave presented specific descriptions for each of the indices and gave examples of how they are color-coded for map presentation.

The use of reference sites is common to many bioassessment approaches. As indicated above, reference sites typically are selected as representing as close to natural conditions as possible. However, it is not possible to identify such pristine locations representing varied habitat conditions in most areas of the country. Ohio, for example, has numerous reference sites throughout the state representing a broad range of conditions, but few are completely unimpacted by modifications or human activity in the watersheds. Schueler⁷⁷ reviewed a USGS report prepared by Crawford and Leant that examined the differences between streams located in forested, agricultural, and urban watersheds in North Carolina. He points out that in many cases, a completely natural forested area is not a suitable benchmark for current conditions before urbanization. In many areas of the country, agricultural land is being converted to urban land, and the in-stream changes expected may be better compared to agricultural conditions. The USGS study found that the stream impacted by agricultural operations was intermediate in quality, with higher nutrient and worse substrate conditions than the urban stream, but better macroinvertebrate and fish conditions. The forested watershed had the best conditions (good-quality conditions for all categories), except for somewhat higher sediment heavy-metal concentrations than expected. Even though the agricultural watershed had little impervious area, it had high sediment and nutrient discharges, plus some impacted stream corridors. The urban stream had poor macroinvertebrate and fish conditions, poor sediment and temperature conditions, and fair substrate and nutrient conditions.

19.6.3 Summary of Assessment Tools

Almost all states using bioassessment tools have relied on the EPA reference documents as the basis for their programs. Common components of these bioassessment programs (in general order of popularity) include:

- Macroinvertebrate surveys (almost all programs, but with varying identification and sampling efforts)
- Habitat surveys (almost all programs)
- Some simple water-quality analyses
- Some watershed characterizations
- Few fish surveys
- Limited sediment-quality analyses
- Limited stream-flow analyses
- Hardly any toxicity testing
- Hardly any comprehensive water quality analyses

Normally, numerous metrics are used, typically only based on macroinvertebrate survey results, which are then assembled into a composite index. Many researchers have identified correlations between these composite index values and habitat conditions. Water-quality analyses in many of these assessments are seldom comprehensive, a possible overreaction to conventional very costly programs that have typically resulted in minimally worthwhile information. Burton and Pitt¹³ have recommended a more balanced assessment approach, using toxicity testing and carefully selected water and sediment analyses to supplement the needed biological monitoring activities. A multicomponent assessment enables a more complete evaluation of causative factors and potential mitigation approaches.

19.7 SUMMARY OF URBAN-RUNOFF EFFECTS ON RECEIVING WATERS

The effects of urban runoff on receiving-water aquatic organisms or other beneficial uses is very site-specific. Different land-development practices create substantially different runoff-flow

characteristics. Different rain patterns cause different particulate washoff, transport, and dilution conditions. Local attitudes also define specific beneficial uses and, therefore, current problems. There is also a wide variety of water types receiving urban runoff, and these waters all have watersheds that are urbanized to various degrees. Therefore, it is not surprising that urban-runoff effects, though generally dramatic, are also quite variable and site-specific.

Previous attempts to identify urban-runoff problems using existing water-quality data have not been conclusive because of differences in sampling procedures and the common practice of pooling data from various sites or conditions.⁴ It is therefore necessary to carefully design comprehensive, long-term studies to investigate urban-runoff problems on a site-specific basis.¹³ Sediment transport, deposition, and chemistry play key roles in urban receiving waters and need additional research. Receiving-water aquatic biological conditions, especially compared to unaffected receiving waters, should be studied as a supplement to laboratory bioassays. In-stream taxonomic surveys are sensitive to natural variations of pollutant concentrations, flows, and other habitat affects. However, laboratory studies are necessary to help understand potential cause-and-effect relationships because of their ability to better control exposure variables.

These specific studies need to examine beneficial uses directly and not rely on published water-quality criteria and water-column measurements alone. Published criteria are usually not applicable to urban runoff because of the highly variable nature of urban runoff and the unique chemical speciation of its components. Typical natural water-pollutant characteristics (especially chemical mixtures and exposure pulses) are difficult to interpret, compared to simpler artificial systems having continuous discharges of more uniform characteristics.

The long-term aquatic-life effects of urban runoff are probably more important than short-term effects associated with specific events and are related to site-specific conditions associated with dilution, watershed size, and stream size. The long-term effects are probably related to habitat degradation, deposition and accumulation of toxic sediments, or the inability of the aquatic organisms to adjust to repeated exposures to high concentrations of toxic materials or high flow rates.

20.1 INTRODUCTION

Assessing the radiological and physical impact of nuclear-energy-related activities on natural environments is important for the protection of natural systems and their species components. Impacts of nuclear power facilities on the environment result from routine and accidental releases of radionuclides to terrestrial and aquatic ecosystems and the interaction of condenser cooling systems with aquatic ecosystems. Sources of release of radionuclides to the environment include normal operation of nuclear power plants and plutonium-production reactors, nuclear plant accidents, past nuclear weapons testing, and leakage from radioactive waste storage sites. Several excellent reviews of radioecology and radiation effects on the environment have been published.¹⁻⁶

Few conclusions can be drawn about the effects of chronic, low-level doses of radiation on natural populations, communities, and ecosystems. Routine, chronic releases from nuclear reactors are controlled to keep human exposures below specified limits. As a result, natural populations of biota are likely protected.⁷⁻⁹ However, exposures may be greater as the result of accidents, weapons testing, and habitation at terrestrial and aquatic waste-disposal sites. Numerous studies have documented uptake of radionuclides in field situations without examining potential adverse effects. Discussion in this chapter is focused on studies conducted in the field, with supporting information from relevant laboratory studies. Although radiation doses experienced in the field are difficult to estimate, the selected examples attempt to relate estimated doses or tissue levels of radionuclides to effects.

Power plant condenser cooling systems at both nuclear and fossil-fueled sites may withdraw and discharge large quantities of surface waters. The removal of aquatic organisms by impingement or entrainment and the added load of warm water and chemicals may impact the receiving aquatic ecosystem. These potential impacts have been studied for years¹⁰⁻¹⁷ with no apparent long-term effects observed.¹⁸ Potential problems have been mitigated by redesigning intake structures, regulating intake flow and temperature changes, and building cooling towers or closed-system cooling lakes. The impact of several power plants on the biota of the Hudson River is presented as a case study.

20.2 BASIC RADIOLOGICAL CONCEPTS

In order to facilitate a discussion of the effects of radioactivity on the environment, important radiological concepts are briefly presented. In-depth discussions of the chemistry, physics, and acute biological effects of radiation can be found in appropriate textbooks.

Radioactivity is the property of isotopes of elements, termed radionuclides, that spontaneously emit radiation by disintegration (decay) of their unstable nuclei. The radiation can be in the form of particles or electromagnetic waves; the most important of these are alpha (α) and beta (β) particles, neutrons, and gamma (γ) and related x-rays. Because these types of radiation have sufficient energy to penetrate matter and eject electrons (protons in the case of neutrons) from atoms, thereby producing positively and negatively charged ion pairs, they are referred to as ionizing radiation. Another decay process is electron capture in which the parent nucleus captures an orbital electron and subsequently emits radiation.

20.2.1 Types of Ionizing Radiation

The five types of ionizing radiation differ in energy and ability to penetrate living tissues. Penetration ability increases with increasing energy of the radiation. Alpha particles are composed

of two protons and two neutrons with a charge of plus two. They are emitted from heavy elements with unstable nuclei such as uranium, plutonium, and radium. Because of their double charge and large mass, they interact strongly with matter, producing many ions; however, they possess a low penetrating ability. For example, alpha particles can be stopped by a sheet of paper; in tissues their penetration is measured in micrometers.

Beta particles are negatively charged electrons ejected from the nuclei of radioactive atoms during the conversion of a neutron to a proton. Energy levels of beta particles are continuous, but maximum energy levels are specific for specific isotopes. Positively charged beta particles, termed positrons (β^+), are less frequently emitted. Shielding from beta particles can be effected by 3 mm of metal or 6 mm of wood.

Neutrons consist of an electron and a proton. They are released from elements that decay by spontaneous fission. In nuclear reactors, bombardment of elements with high fission probabilities, such as uranium-235 (^{235}U), with slow neutrons results in fission products and additional neutrons, which in turn cause a fission "chain reaction." In tissues, neutrons produce ionization indirectly by ejection of protons from the nuclei of hydrogen atoms and by activation of elements via neutron capture, the latter resulting in the release of gamma rays. Due to their large mass and chargeless state, neutrons have great kinetic energy and penetration capacity.

Gamma and x-rays have no mass or electrical charge. Gamma rays are emitted by nuclei, usually in combination with alpha or beta emission, whereas x-rays arise from the electron shells. Both have very short wavelengths and great penetrating ability. Gamma rays can be stopped by 5 to 10 cm of lead or 30 to 60 cm of concrete.

20.2.2 Half-Life

By definition, a parent radionuclide is unstable, undergoing spontaneous disintegration or decay by the emission of one or more alpha or beta particles and forming a decay or daughter product. The daughter radionuclide may be stable or radioactive. Very heavy elements such as ^{238}U and plutonium-238 and 239 ($^{239-240}\text{Pu}$) tend to decay by emission of alpha particles; for lighter elements, beta emission is the most frequent decay process. The time required for half of a given number of atoms to decay is defined as the physical half-life. For example, with the loss of beta particles, half of a given mass of strontium-90 (^{90}Sr) decays to its radioactive daughter, yttrium-90 (^{90}Y), in approximately 28 years.

20.2.3 Units of Measurement

Originally, units of radioactivity and radioactivity measurement were expressed in curies (Ci), Roentgens (R), rads, and rems. Presently, the International System (SI) of Units (Becquerel [Bq], Gray [Gy], and Sievert [Sv]) has been adopted for standard usage. In order to change systems, the following conversion factors are routinely used: 1 Bq = 27 pCi (1 pCi = 0.037 Bq), 1 mGy = 100 mrad, and 10 mSv = 1 rem.

The Gray and Sievert (rad and rem, respectively) apply to all types of ionizing radiations; however, the Sievert takes into consideration the linear energy transfer of the radiation. The Sievert is equal to the absorbed dose in rads multiplied by a quality factor or the relative biological effectiveness of the radiation and other modifying factors. The quality factor for gamma and x-rays and electrons and positrons is approximately 1. A quality factor of ten is used for alpha particles and fast neutrons.

A confounding factor in applying dose measurements is that the external radiation exposure from gamma or x-rays in air cannot be directly translated to absorbed dose. However, for soft tissue, a crude approximation is that a dose of approximately 0.01 Gy will result from exposure to

Table 20.1 Average Annual Terrestrial Radiation Dose from Natural Sources^a

Source	Dose Rate (mGy/year)
Cosmic radiation	0.4
Terrestrial gamma rays	0.4
Internal radioactivity	0.2

^a From Biological Effects of Ionizing Radiation (BEIR) Advisory Committee Report: *The Effects on Populations of Exposure to Low Levels of Ionizing Radiation*, National Academy of Sciences, National Research Council, Washington, D.C., 1972.

1 R (2.58×10^{-4} Coulomb (C)/kg of air from x-rays or gamma rays¹²). The energy deposition in tissue for a dose of 1 R has also been estimated as about 0.0096 J/kg.

20.3 SOURCES OF IONIZING RADIATION

Exposure to ionizing radiation may result from background sources as well as radionuclides released during fuel fabrication, the normal operation of nuclear power reactors, nuclear accidents, waste storage sites, and past weapons testing.

20.3.1 Background Radiation

To put radiation from anthropogenic sources into perspective, it is important to consider the amount of naturally occurring background radioactivity that all organisms are unavoidably exposed to. Natural background radiation is due to cosmic radiation, terrestrial gamma rays from naturally occurring radionuclides, and internal radioactivity, primarily potassium-40 (⁴⁰K), which occurs naturally in foods. The total dose to man and large terrestrial vertebrates from natural background radiation varies geographically but has been estimated at 1 mGy/year (Table 20.1). The total dose has also been expressed as absorbed dose equivalent: 1 mSv/year. For comparison, global fallout from past nuclear weapons testing adds an additional 0.04 mSv; the contribution of nuclear power is minor, 0.003 μ Sv/yr.¹⁹ Estimates of background doses received by marine and freshwater biota are presented in Table 20.2. As can be seen from the data, annual doses to aquatic organisms from natural sources are generally less than 5 mGy/year.^{2,20}

20.3.2 Fuel Fabrication and Production Facilities

The primary fuels for nuclear reactors are uranium dioxide (UO₂) enriched in ²³⁵U to 2 to 3% and, to a lesser extent, thorium-232 (²³²Th). The primary enrichment process has been gaseous diffusion, using UF₆ gas. Enrichment plants are presently located at Paducah, Kentucky, and Piketon, Ohio;²¹ a third plant in Oak Ridge, Tennessee, was put on standby in 1985 and shut down in 1987. Enrichment by gaseous diffusion is expensive and requires considerable amounts of energy. More efficient enrichment processes, including gas centrifugation and enrichment by lasers, are being developed. Most nuclear reactors utilize UO₂ fuel sintered into rods, or the fuel may be in the form of small pellets, clad with a thin metallic coating. Gaseous and liquid releases from such fuel fabrication facilities contain a small amount of U radioisotopes and ²³⁴Th.^{22,23} In addition to the gaseous diffusion plants, there are eight additional major uranium fuel fabrication and uranium hexafluoride production facilities licensed to operate in seven states.²¹ There are 17 other facilities in the United States that possess or process significant quantities of special nuclear material.

Table 20.2 Estimates of Annual Doses Received by Marine and Freshwater Organisms from Natural Sources of Radiation (mGy/year)^a

	Phytoplankton	Zooplankton	Mollusca	Crustacea	Fish

20.3.3 Nuclear Power Reactors

As of 1999, there were 104 commercial nuclear power reactors licensed to operate in 31 states.²¹ Reactors employed for electric power generation in the United States are light-water reactors, using water as moderator and coolant. Light-water reactors are of two types: pressurized-water reactors and boiling-water reactors. During normal operation of the reactor, new radionuclides are formed by fission of the nuclear fuel and neutron activation of structural materials. Despite containment within the reactor system, small amounts of radionuclides escape through the fuel cladding into the coolant system; from there they are released into liquid and gaseous effluents. Under normal operations, the principal radionuclides present in coolant water of light-water-cooled reactors are tritium (³H); sodium-24 (²⁴Na); silicon-31 (³¹Si); phosphorus-32 (³²P); scandium-46 (⁴⁶Sc); chromium-51 (⁵¹Cr); manganese-56 (⁵⁶Mn); cobalt-58 and cobalt-60 (⁵⁸Co and ⁶⁰Co); copper-64 (⁶⁴Cu); arsenic-76 (⁷⁶As); krypton-85 (⁸⁵Kr); strontium-85, strontium-90, and strontium-91 (⁸⁵Sr, ⁹⁰Sr, and ⁹¹Sr); yttrium-90, yttrium-92, and yttrium-93 (⁹⁰Y, ⁹²Y, and ⁹³Y); zirconium-97 (⁹⁷Zr); molybdenum-99 (⁹⁹Mo); technetium-99m (^{99m}Tc); rhodium-105 (¹⁰⁵Rh); iodine-130, iodine-131, iodine-133, and iodine-135 (¹³⁰I, ¹³¹I, ¹³³I, and ¹³⁵I); xenon-131 and xenon-133 (¹³¹Xe and ¹³³Xe); cesium-134 and cesium-137 (¹³⁴Cs and ¹³⁷Cs); cerium-143 (¹⁴³Ce); barium-140 (¹⁴⁰Ba); and neptunium-239 (²³⁹Np).^{24–26} Many of the more than 200 fission products produced are short lived and of no environmental consequence. Each reactor releases an average of 2.22×10^{11} Bq/year of mixed fission and neutron-activation products in liquid effluents; greater amounts of ³H and noble gases (⁸⁵Kr, ¹³¹Xe, and ¹³³Xe) are released in gaseous effluents. Biologically important fission and neutron-activation products, based on concentration, half-life, chemical properties, and solubility, are listed in Table 20.3. Also listed are the types of radiation emitted and half-lives of the radionuclides. Of primary concern in environmental studies are ⁹⁰Sr and ¹³⁷Cs.

Routine emissions from power plant operation do not contribute significantly to detectable levels in the environment. For example, an off-site survey at the Rancho Seco nuclear plant found primarily ¹³⁷Cs and ¹³⁴Cs, with lesser amounts of ⁶⁰Co and ⁵⁸Co along streams receiving liquid effluent and in fields irrigated with water from these streams.²⁷ Gamma radiation exposures along the creek and in irrigated fields ranged from 8 microrentgen (μ R)/hour (background) to 14 μ R/hour.

Table 20.3 Radionuclides of Potential Environmental Concern Produced by Nuclear Reactors^a

Radionuclide	Half-life	Radiation	Source	Element Analog
³ H	12.3 years	β	Fission product, neutron activation	H
¹⁴ C	5568 years	β	Neutron activation	C
²⁴ Na	15 h	β, γ	Neutron activation	Na
³² P	14 days	β	Neutron activation	P
³⁵ S	87 days	β	Neutron activation	S
⁴¹ Ar	110 min	β, γ	Neutron activation	—
⁴⁵ Ca	164 days	β	Neutron activation	Ca
⁵⁴ Mn	291 days	γ	Neutron activation	Mn

^a From Whicker, F. W. and Schultz, V., *Radioecology: Nuclear Energy and the Environment*, Vol. II, CRC Press, Boca Raton, FL, 1982.

In addition to commercial power reactors, there are 37 nonpower reactors licensed to operate in 24 states.²¹ These reactors are designed and utilized for research, testing, and educational purposes.

20.3.4 Weapons Production

Three U.S. Department of Energy sites have been engaged in the production of weapons-grade plutonium and tritium: the Savannah River Plant, Aiken, South Carolina; the Hanford Reservation, Hanford, Washington; and the Idaho National Engineering Laboratory, Idaho Falls, Idaho. Cooling water for the five reactors at the Savannah River Plant was released to two major aquatic habitats: cooling ponds and natural streams that drain into swamp forest and, ultimately, the Savannah River.¹⁰ At least two of the reactors are no longer in operation. From 1944 to 1971 the Columbia River served as a source of single-pass cooling water for the plutonium production reactors at Hanford. Complete inventories of these releases are not available.

20.3.5 Reprocessing Plants

After partial burn-up of the contained fissile material in the reactor, the spent fuel assemblies are withdrawn, stored for 90 days or longer to allow decay of most of the short-lived radioactivity and, in the past, shipped to reprocessing plants.²² Reprocessing plants in the United States were licensed or scheduled for licensing at West Valley, New York; Morris, Illinois; and Barnwell, South Carolina. Because these sites are not in operation at present, spent fuel is being stored in the United States. Reprocessing in connection with production of plutonium for weapons has taken place at the three U.S. Department of Energy weapons production sites. As an example of the amount of radioactivity that may be released to the environment from such activities, reprocessing in connection with the Windscale uranium-fueled reactor in England (now called Sellafield) has released 3.7×10^{14} to 5.6×10^{15} Bq of ^{137}Cs to the Irish Sea annually.²³ Since 1976, discharges have been decreasing as a result of changes in operating procedures. Figures were not available for U.S. plants.

The Mayak Production Association is a nuclear fuel reprocessing facility located in the southern Urals of Russia, approximately 2000 km from Moscow. This facility processed weapons-grade plutonium during 1949 to 1952. Water from the adjacent Techa River was used as a coolant and subsequently discharged to the river. Although large quantities of wastes associated with plutonium production were buried near the facility, the greatest impact to the environment was from discharges to the river. During this period, approximately 10^{17} Bq were released into the river. Predominant radionuclides included ^{89}Sr , ^{90}Sr , ^{137}Cs , ^{95}Zr - ^{95}Nb , ^{103}Ru , and isotopes of rare-earth elements. Beta-activity in the river has decreased over time, but ^{90}Sr and ^{137}Cs remain the major contributors to the radioactivity present.²⁸

20.3.6 Reactor Accidents

The most serious accident at a U.S.-licensed commercial power plant occurred at Three Mile Island Unit 2 on March 28, 1979. Noble gases and ^{131}I were released to the atmosphere, but other fission products were not released in measurable quantities. Detectable levels of radioiodine were found in milk samples of domestic animals and in thyroids of voles (*Microtus pennsylvanicus*) in the immediate area.^{18,29}

Several other major accidents — one at Windscale, England, one at Kysym in the Ural Mountains, Russia, and one at Chernobyl in Ukraine — have occurred. Windscale is a plutonium production reactor located on the northwest coast of England. In October 1957, one of the two air-cooled, graphite-moderated natural-uranium reactors was damaged by fire, resulting in the release of fission products to the surrounding countryside and the Irish Sea. Radioactivity from the principal isotopes released during the fire (^{131}I , ^{137}Cs , ^{89}Sr , and ^{90}Sr) was estimated at 6.5 to 7.7×10^{14} Bq.²³

In 1957, a thermal explosion of a tank containing liquid radioactive waste at the Mayak nuclear materials production complex in Russia released 7.4×10^{17} Bq, which contaminated the surrounding area.^{30,31} Many of the radionuclides were short-lived, but release of ^{90}Sr and ^{90}Y has resulted in long-term contamination of a 23,000-km² area. Contributing to the radiation contamination in this region are the direct discharge of radioactive contaminants into the Techa River from 1949 to 1959 and the current discharge and release of radionuclides into the environment by the Mayak Production Association.³¹

In the early morning of April 26, 1986, the 1000-MW water-cooled, pressure-tube, graphite-moderated reactor at the Chernobyl power station in the U.S.S.R. was destroyed by an accident, resulting in heavy local contamination and fallout on an extensive worldwide level. By May 6, 1986, an estimated 8×10^{19} Bq of radioactivity from ^{133}Xe , ^{85}Kr , ^{131}I , ^{132}Te , ^{134}Cs , ^{137}Cs , ^{99}Mo , ^{95}Zr , ^{103}Ru , ^{106}Ru , ^{140}Be , ^{141}Ce , ^{144}Ce , ^{89}Sr , ^{90}Sr , ^{238}Pu , ^{239}Pu , ^{240}Pu , ^{241}Pu , ^{242}Pu , ^{242}Cm , and ^{234}Np had been released.²³ The fire carried radioactive gases and particulates to relatively high altitudes, resulting in worldwide dispersion. Cesium-137 was the most important contaminant because of its high concentration in the fallout. Fallout over Europe was nonuniform and dependent on rainfall.

For example, from May 5 to 7, ground beta and gamma activity in West Germany, a distance of 1200 km from Chernobyl, ranged from less than 15,000 to more than 240,000 Bq/m².³² In Greece, levels ranged from 10 to 137,000 Bq/m².³³

20.3.7 Low-Level Waste Burial Sites

Low-level waste materials consist of solid trash, laundry wastes, and concentrates from liquid wastes. In the United States, most low-level radioactive wastes have been treated and disposed of by shallow land burial with or without concrete vaults.²¹ In addition, liquid wastes at some sites have been discharged to surface ponds. The major federal low-level waste burial sites operated by the U.S. Department of Energy are located at Oak Ridge National Laboratory, Oak Ridge, Tennessee, the Savannah River Plant, Aiken, South Carolina, the Hanford Reservation, Hanford, Washington, Los Alamos Scientific Laboratory, Los Alamos, New Mexico, and the Idaho National Engineering Laboratory, Idaho Falls, Idaho. Environmental contamination from radionuclides has occurred at four of these sites as a result of infiltration into groundwater and surface-water runoff.¹ At some sites, rodents have come into contact with surface contamination or burrowed into the trenches and spread small amounts of radioactivity.³⁴⁻³⁷

In 2000, there were three commercial sites licensed by states under agreements with the Nuclear Regulatory Commission or by the Nuclear Regulatory Commission itself to store radioactive wastes.²¹ These sites are located at Barnwell, South Carolina, Hanford, Washington, and Clive, Utah. The sites at West Valley, New York, Maxey Flats, Kentucky, Sheffield, Illinois, and Beatty, Nevada are closed.

High-level wastes, primarily from reprocessing plants, are stored in steel tanks awaiting treatment or development of storage facilities. At West Valley, New York, a high-level waste-vitrification demonstration project has been underway since 1980.²¹ The West Valley Demonstration Project began converting liquid high-level waste into glass logs in July 1996. Under the U.S. Department of Energy, a waste-solidification facility project is underway in Hanford, Washington.

20.3.8 Weapons Testing

Nuclear testing in the atmosphere was carried out from 1945 until the test moratorium in 1963. The first nuclear detonation took place at the Trinity Site in New Mexico on July 16, 1945. Testing began in the Pacific Ocean in 1946. Fission products and products of neutron activation from materials used for bomb construction are released as radioactive fallout. Some of these are ⁸⁹Sr, ⁹⁰Sr, ⁹⁵Zr, ¹⁰⁶Ru, ¹³¹I, ¹³⁷Cs, ¹⁴¹Ce, ¹⁴⁴Ce, and ²³⁹Pu.²⁶ Radioactive material introduced into the troposphere was distributed locally, while that introduced into the stratosphere was deposited worldwide. Small amounts continue to be deposited from the stratosphere;¹ the yearly dose to humans is 0.04 mSv.¹⁹ Both of the fission products ⁹⁰Sr and ¹³⁷Cs are of ecological concern; ¹³⁷Cs has a high yield from nuclear fission and is one of the major dose-contributing radionuclides in the environment.

20.4 BEHAVIOR OF RADIONUCLIDES IN THE ENVIRONMENT

Radionuclides introduced into the environment become diluted and distributed according to highly complex interactions of physical, chemical, and biological factors.^{1,2} The chemical behavior of radionuclides is the same as the stable form of the element and is similar to other elements in the same groupings (vertical columns) of the periodic table of elements. This results in their distribution in various components of the food chain in a manner similar to their stable chemical analogs (Table 20.3). For example, radionuclides such as ⁸⁹Sr, ⁹⁰Sr, ¹⁴⁰Ba, ²²⁶Ra, and ⁴⁵Ca will behave like calcium, and ⁴⁰K, ⁸⁶Rb, and ¹³⁷Cs will have properties similar to potassium. In biota,

^{137}Cs will be distributed throughout the soft tissue of the body, whereas ^{90}Sr will be deposited primarily in bone, shells, or exoskeletons. Tritium (^3H) will behave like hydrogen, and ^{131}I will behave like stable iodine. Some radionuclides, such as ^{239}Pu , lack nutrient analogs, but plutonium accumulates in bone. Inert gases such as ^{85}Kr tend to stay in the atmosphere until they decay; iodine and radon emitted to the atmosphere also tend to stay in the gaseous phase.¹

Uptake or concentration ratios of radionuclides, such as strontium and cesium, are dependent on the biota, specific tissues, mode of uptake, environmental source, and the properties of the radionuclide itself. Terrestrial plants tend to discriminate against strontium in favor of calcium; plant/soil concentration ratios average 0.017.²² Tissue concentrations of strontium do not increase with trophic level, as evidenced by concentration ratios through successive trophic levels of less than 1.0. Turnover is slow, as strontium concentrates in hard tissue such as bone, shell, and exoskeleton. In addition to uptake by ingestion, aquatic organisms adsorb and concentrate radionuclides directly from the water. Because of larger dilution factors and the abundance of competing nutrient elements in seawater, marine organisms do not concentrate radionuclides to the same degree as do freshwater organisms. In freshwater aquatic systems, concentration ratios (concentration in organism/concentration in water) of strontium in algae, mollusks, crustaceans, and fish average 500, 300, 300, and 30, respectively. In marine systems, the respective ratios are 20, 1, 1, and 1.^{22,38,39}

Cesium-137 binds very firmly to clay particles in both soil and sediments. Although there is little uptake by plants, with plant/soil concentration ratios of 0.01, cesium does accumulate through food chains in terrestrial systems.² In an aquatic system, ^{137}Cs will move from the water compartment to the sediments, where it is available to detritivores and bottom feeders. From there, cesium moves through the food chain to sessile vegetation and phytoplankton, to herbivorous consumers, to primary consumers such as small fish and carnivorous invertebrates, and finally to secondary consumers (large fish).⁴⁰ Successive trophic-level concentration factors may approach 3.0;² the biological half-life is weeks to months. Cesium concentration factors for freshwater algae, mollusks, crustaceans, and fish typically average 500, 100, 100, and 2000, respectively; respective values for marine species are 10, 10, 50, and 30.^{22,38,39}

Food-chain accumulation of ^{137}Cs has been followed in the environment because of uptake by large herbivores such as mule deer (*Odocoileus hemionus*) and reindeer (*Rangifer tarandus*), which serve as food for humans. Cesium-137 from fallout is deposited on and accumulated over soil levels by fungi and lichens, which serve as food for these species. Following the Chernobyl accident, lichens (*Cladonia stellaris*) contained 30,000 to 50,000 Bq/kg dry weight; various species of fungi contained 500 to 445,000 Bq/kg dry weight.⁴¹ In mountain pastures of Norway, fresh-weight ^{137}Cs concentrations in reindeer, which feed primarily on lichens, ranged up to 90,000 Bq/kg of meat.^{41,42} Deposition of $^{134,137}\text{Cs}$ in soil ranged from less than 5 to 200 Bq/m².

20.5 BIOLOGICAL EFFECTS OF RADIATION

Many factors, both intrinsic and extrinsic, may modify the response of living organisms to radiation. In plants, sensitivity to radiation is dependent on chromosome number, volume, and duplication; length and stage of the mitotic cycle; percentage of cells dividing; type of cell or tissue; stage of cell differentiation; stature and structure of organism; age of organism; stage of growth cycle; nutritional condition; concentrations of sensitizing or protective substances; and species.²

Depending on total dose, dose rate, type of radiation, and exposure period, exposure to radiation can lead to no observable effects; genetic changes; physiological changes such as effects on the hemopoietic and reproductive systems; effects on growth and development; or life shortening, including cancer or death. In the laboratory, where most studies have focused on response to acute doses, total dose and dose rates can be closely estimated. In natural situations, however, where dose rates are not uniform and where total dose is due to both external and internal irradiation from absorption, ingestion, and inhalation, dose is at best a crude estimate.

Relative sensitivities of plants, animals, and bacteria to acute lethal doses have been summarized by Whicker and Schultz.² Although sensitivities vary widely within taxonomic groups, mammals appear more sensitive to radiation than birds, reptiles, amphibians, fish, insects, plants, and microorganisms with acute lethal exposures in mammals ranging from 2 to 13 Gy. Direct mortality is not significant for any taxa until a dose of approximately 2 Gy is reached; disruption of the ecological community would occur at 10 Gy or more. These doses are unlikely to occur except in the event of a catastrophic nuclear accident or nuclear warfare.²

Studies have also been conducted using longer-term exposures at much lower doses with observations made on effects other than mortality. Effects on the blood were often studied because acute doses revealed the hemopoietic system as one of the most radiosensitive systems in the body. From the standpoint of survival of the population, reproduction is the most sensitive indicator of radiation impairment.⁴³ Minimum acute doses required to depress reproduction and growth rates may be less than 10 to 100% of those required to produce direct mortality.² According to the National Council on Radiation Protection and Measurements (NCRPM),⁸ chronic exposures of ≤ 10 mGy are very unlikely to produce measurable deleterious changes in populations or communities of aquatic plants or animals. Studies reviewed by French et al.⁴⁴ indicated that a dose rate of 10 mGy/day was the approximate threshold at which effects became apparent in irradiated natural mammalian populations. The IAEA⁹ concluded that limiting the chronic radiation dose rate to 1 mGy/day would be protective of terrestrial plants and animals.

Another sensitive indicator of radiation exposure in vertebrates is the frequency of chromosomal aberrations in bone marrow cells or peripheral lymphocytes. This type of genetic damage appears when the animals are exposed to a dose of 0.25 Gy or more.⁴⁵ Observation of chromosome aberrations must be interpreted with care, however, because other agents are capable of causing genetic damage. In addition, DNA repair mechanisms and cellular recovery processes serve to reduce radiation damage. However, even when effects are not observable, there is a possibility of increased risk of cancer or life shortening.⁴⁵ The use of stable chromosome translocations as a biosimetric tool is currently being explored as a method to assess both exposure to radiation and potential risk to biota in the field.⁴⁶

When considering the effects of radiation on humans, concern is focused on individuals, and a mutation or cancer is perceived as a deleterious event. When considering the effects of radiation on nonhuman animals, however, concern is usually not focused on individual animals but on whether the population remains viable and successful. Thus, an increase in the mutation rate or an increase in cancer will have little influence on the population because most organisms serve as food for others, and sick or damaged animals would be rapidly removed.²⁰ Furthermore, subcellular and cellular lesions that do not result in mortality are not manifested in measurable attributes of populations and communities.²

20.6 EFFECTS OF RADIATION ON TERRESTRIAL POPULATIONS AND COMMUNITIES

Reviews of responses of populations and communities of terrestrial plants⁴⁷ and terrestrial animals⁴⁸ to chronic irradiation have been published. In most contaminated areas, levels of radioactivity are too low to detect population- and community-level effects.² Experimental field studies using ¹³⁷Cs or ⁶⁰Co as large sources of short-term and chronic gamma radiation have provided data on effects on natural communities of plants. For example, Woodwell's studies⁴⁹ with chronic gamma irradiation of an oak-pine forest demonstrated a relationship between plant physiognomy and radiosensitivity. Pine trees were the most sensitive, followed by shrubs and then herbaceous forms. Low and crustose forms such as lichens were the most resistant. A reduction in species diversity was observed at 100 R/day (1 Gy/day).

The use of large gamma sources, such as those used to show changes in plant communities, is not a good method for demonstrating changes in animal populations and communities because many animals, such as invertebrates, are dependent on the presence of vegetation, which may be destroyed by the radiation. In addition, other animals, because of their natural mobility and shielding by vegetation or burrows, do not receive uniform doses.⁴⁸ Moreover, radiation doses are difficult to estimate, as dose rate decreases as a power function with distance from the source. In the field, animals confined to enclosures have been irradiated chronically.^{2,48} In the laboratory, the acute response of animals is usually measured in terms of acute lethal doses, usually LD₅₀₍₃₀₎ values, the dose lethal to 50% of organisms within 30 days; few laboratory studies involve chronic irradiation.

Many studies conducted in the area of nuclear facilities or testing have documented the uptake of radionuclides by natural biota. No appreciable radiation exposures to natural populations of terrestrial animals has occurred from normal operation of the reactors at nuclear power plant sites in the United States.¹⁸ Higher levels of radiation, either acute or chronic, are necessary to show effects on populations of plants and animals. However, information is available for several other contaminated terrestrial sites where estimated doses were calculated and effects on natural populations studied. These sites include areas contaminated by reactor accidents, several national laboratories, and waste sites. Where applicable, supporting evidence from relevant laboratory studies is included. The most highly radiation-contaminated terrestrial site is the area surrounding the Chernobyl nuclear reactor accident; these studies are noted here and reviewed in Chapter 24 by Eisler.

Effects of the Chernobyl accident on the flora and fauna in the surrounding contaminated area have been reviewed.⁵⁰⁻⁵³ Following the accident, the human population was evacuated from a highly contaminated area within a 30-km radius around the damaged reactor. Wildlife populations have become established in the absence of humans. This area, divided into a 10-km inner zone and an outer zone, now serves as a unique natural ecosystem of enormous radiological interest.^{53,54}

Within three months of the Chernobyl accident, Russian scientists began studying the effects of radiation on plants and animals within the highly contaminated zones surrounding the plant and comparing the results with biota from reference areas. Because of the uneven distribution of radiation around the plant, doses to biota were often difficult to estimate. When studies were continued over a 3-year period, 1986 to 1989, recovery of the exposed populations took place, either by immigration of animals into the area or by a decrease in mortality and lethal genetic effects with time. Many of the studies address accumulation of genetic changes in the resident populations, the consequence of which are presently unknown.

20.6.1 Plant Populations and Communities

Of the flora in the area surrounding the damaged Chernobyl reactor, the pine and spruce (*Pinus silvestris* and *Picea excelsa*) in the nearby forest were the most radio-sensitive species, and by late summer of 1986, trees in a 4400-ha area were dead or dying. Doses to the trees were estimated at 80 to 100 Gy.⁵⁰⁻⁵³ Doses of 8 to 10 Gy killed younger trees and young shoots. Trees that received sublethal doses, 3 to 4 Gy, lost needles and developed morphological variations such as shortened and curved shoots. At the edge of the 30-km zone, where doses were estimated at 1 to 1.5 Gy, growth was temporarily suppressed. During 1987 to 1989, regenerative processes took over, and damaged trees formed gigantic needles. Mass flowering was observed. The deciduous forest, represented by birch (*Betula tremula*), aspen (*Populus tremula*), alder (*Alnus glutinosa*), and oak (*Quercus robur*), was more radioresistant, although foliage turned yellow and growth was temporarily suppressed in the area that was sublethal to the pine forest. The deciduous species are considered ten times more radioresistant than pines.

Although no visible damage to herbaceous plants was reported in some studies, Savchenko reported increased phenotypic diversity and genetic modifications in several species, including *Plantago lanceolata* (Plantaginaceae) and *Hieracium umbellatum* (Compositae), found throughout

the contaminated area.⁵³ Doses were not estimated. The following changes in plants were additionally reported in the contaminated area: an increase in chlorophyll mutation frequency, a decrease in seed viability, mass gall formation, and the appearance of leaf deformation/asymmetry and abnormal stem branching.

Two species were chosen for genetic toxicity studies. Chromosome aberrations were observed in root meristem cells of *Crepis tectorum* (Compositae), where gamma exposure rates ranged from 0.02 to 20 mR/hour.⁵⁵ Beta exposure rates were estimated at ten times higher. For *Arabidopsis thaliana* (Cruciferae), there was a correlation between the radioactive contamination level, which ranged from 0.01 to 240 mR/hour, and frequency of plants with mutations,⁵⁶ although there was no effect of these exposures on the germination rate of the plants.⁵⁰

20.6.2 Invertebrate Populations and Communities

Species presence and population numbers of pine-forest-litter and soil fauna, such as mites, springtails, beetles, earthworms, and spiders within a 3-km radius of the Chernobyl reactor, were impacted by the fallout.⁵⁷ Because of shielding by the soil, soil animals were affected to a lesser degree than pine-litter animals. Also, adult animals were less affected by 30-Gy doses (estimated by thermoluminescent dosimeters distributed on the soil surface) than were eggs and juveniles. Among soil microfauna, first instar nymphs and larvae were absent in the soil following the accident; populations of young earthworms were decreased.⁵⁰ The authors estimated that an absorbed dose of about 29 Gy devastated the soil microfauna, while a dose of about 8 Gy led to minor changes. In previously plowed soil, a surface dose of 4000 rad did not affect soil dwellers due to the shielding effect of the soil. Several specific studies were reviewed by Sokolov et al.⁵⁰ The soil worm *Aporectodea caliginose*, a diploid species, suffered genetic damage in its male germ cells (chromosome fragments in 20% of the cells), and the population size was smaller in the contaminated zone than in a reference area. In contrast, the hexaploid parthenogenetic species *Dendrobaena octaedra*, which lives in the pine litter, had increased its population size over that of a reference area by 1988. The relative radioresistance of the latter species was attributed to the polyploid genome and the lack of predators.

Following the Chernobyl accident, changes involving greater phenotypic diversity and an increased frequency of rare phenotypes were observed in several species of dragonflies.⁵³ Fruit flies (*Drosophila melanogaster*), which are known to be radioresistant, showed little difference in mutation frequency following the accident.⁵⁸ However, in another study, an increase in dominant lethal mutations in fruit flies collected from an area with a radiation dose of 80.6 mR/hour compared with a reference area was reported.⁵⁰

20.6.3 Small-Mammal Populations

Mammals are considered more radiosensitive than other taxonomic groups, with acute lethal doses ranging from 2 to 11 Gy.² The mammal population in the Chernobyl area could not be compared pre- and postaccident, as the area was heavily inhabited by humans prior to the accident.⁵⁰ But a 90% mortality of small mammals as a consequence of the accident was predicted, based on comparisons with reference plots and given the external radiation doses of up to 6000 R (approximately 60 Gy). By spring of 1987, the populations appeared to increase due to migration from adjacent noncontaminated areas⁵⁰ and trapping of small mammals within the contaminated zone 8 years after the accident yielded greater success rates than in uncontaminated areas.⁵⁹ Bank voles (*Clethrionomys glareolus*) captured in 1986 showed an increased number of corpora lutea but also an increase in embryonic mortality.⁵⁰

An extensive study of genetic damage to small mammals at the Chernobyl site was carried out with the house mouse, *Mus musculus*.^{50,51,60} House mice were captured at three plots with average

external radiation doses of 0.1 to 1.5 mR/hour, 1 to 2 mR/hour, and 60 to 100 mR/hour (the latter approximately 0.6 to 1.0 mGy/hour). These animals did not show any signs of radiation sickness. When males were mated with female laboratory mice, only two males (from the maximally contaminated area) of 122 were irreversibly sterile. For the rest of the males caught in this area, only temporary sterility was observed. In both males collected from this area and male progeny of pregnant laboratory female mice caged in the radioactive area, the frequency of chromosome aberrations as indicated by reciprocal translocations in spermatocytes was increased. The frequency of reciprocal translocations in spermatocytes increased linearly with increasing absorbed dose to the testes, which was estimated at 0.1 to 25 Gy for mice caught at the site.⁶⁰

In 1994 and 1995, a study was undertaken to describe the diversity, distribution, and karyotypes of small mammals that live in the most radioactive sites within the exclusion zone near Chernobyl.⁵⁹ An examination of karyotypes of 11 species of small mammals from the 30-km exclusion zone with species obtained from outside of the exclusion zone did not document gross chromosomal rearrangements. The diversity and abundance of small-mammal fauna was not reduced at the most radioactive sites, and the trapped specimens did not demonstrate aberrant gross morphological features other than enlargement of the spleen. The most commonly collected species were voles and shrews: *Microtus arvalis*, *M. oeconomus*, *M. rossiaemeridionalis*, and *Sorex araneus*. An examination of the mitochondrial cytochrome b gene of voles from Chernobyl did not reveal an increased mutation rate over that of voles from a reference area.^{61,62} In addition to enlargement of the spleen observed in some individuals collected at the site, physiological responses to radiation-induced stress may involve enlarged livers and thymus glands.⁶³

Following the Chernobyl accident, several studies documented the genetic impact of radiation on small mammals. Bank voles (*Clethrionomys glareolus*) were extensively studied because they are common inhabitants of the area and have the highest levels of cesium and strontium. Through 1991, Goncharova and Ryabokon found elevated incidences of chromosome aberrations and polyploid cells in voles in the Chernobyl area.⁶⁴ In Sweden, bank voles in a Chernobyl-contaminated area were found to have increased numbers of micronucleated polychromatic erythrocytes.⁶⁵ However, bank voles collected in 1997 from the most contaminated area at Chernobyl did not have increased frequencies of micronuclei⁶⁶ and did not have reduced genetic variation.⁶⁷ A possible explanation for these observations is the radioresistance or radioadaptation of bank voles.^{68,69} Bank voles trapped in the Chernobyl area and further irradiated with ⁶⁰Co had increased life spans several generations after irradiation. The LD_{50/30} for this species is 966 R.⁷⁰ Continuing monitoring studies of voles in the Chernobyl area will help to clarify the long-term genetic effects of radioactive contamination on natural populations.

Compared with Chernobyl, radioactive waste storage sites are minimally contaminated. Following the partial draining of White Oak Lake, a settling basin for low-level radioactive wastes from the Oak Ridge National Laboratory, Dunaway and colleagues⁷¹⁻⁷⁴ studied the rodent populations utilizing the site. Doses to cotton rats (*Sigmodon hispidus*) were estimated by placing dosimeters 1 m above ground level and subcutaneously within the animals. It was estimated that the rats were exposed to 0.004 Gy/week internally and 0.025 Gy/week externally based on free-air exposures of 15 mR/hr. The total dose was estimated at 0.03 Gy/week, and lifetime doses were probably less than 2 to 3 Gy. No effects on size, sex ratio, fertility, litter size, blood cell counts, or tissue lesions attributable to radiation were found. In the laboratory, an acute dose of 2 Gy resulted in no blood changes except a transient leucopenia in both cotton rats and rice rats (*Oryzomys palustris*).⁷⁵ A dose of 6 Gy was lethal to rice rats but not to cotton rats. Chronic irradiation studies were not conducted with either species.

Since 1952, approximately 3×10^{17} Bq of solid radioactive waste has been buried at a 36-ha subsurface disposal site at the Idaho National Engineering Laboratory. Small mammals have burrowed into the site and dispersed some of the radioactivity.^{36,76} Radiation dosimeters implanted in deer mice (*Peromyscus maniculatus*) inhabiting the disposal area indicated radiation dose rates

of 0.004 to 418 mGy/day (median, 0.02 mGy/day); the dose at a reference site was 0.004 mGy/day.⁷⁶ Comparisons with dosimeters placed 15 cm above the ground showed that the doses were primarily external from the buried waste and not from internal emitters (¹³⁷Cs, ⁶⁰Co, and ⁹⁵Nb). The doses depended to a large degree on radioactivity in the area of capture and season, which in turn reflected animal movement outside the burrow. Implications of the dose were not assessed, but it was noted that the population density within the burial area was not significantly different from the density in an adjacent area. It is likely that the few animals that received the maximum dose rate of 418 mGy/day did not survive. Radiation dose rates received by Ord's kangaroo rats (*Dipodomys ordii*) were much less than those received by deer mice. Doses to either species were less than those received by cotton and rice rats at the Oak Ridge site, where chronic exposure to 0.03 Gy/day did not result in significant effects on fertility.

A concurrent study concluded that radiation doses received by the deer mice inhabiting the area had no effect on body or organ weights and caused no increase in chromosomal aberrations.⁷⁷ However, these observations were made two weeks after the mice were transported to an uncontaminated site. Deer mice that were trapped near a radioactive leaching pond and that received dose rates of up to 0.01 Gy/day failed to exhibit any blood changes or pathologic lesions such as tumors.⁷⁸ Using a shielded ¹³⁷Cs radiation source to provide a uniform dose rate, French et al.⁴⁴ exposed a population of pocket mice (*Perognathus formosus*) enclosed in a desert area to chronic yearly dose rates of 2.11 to 3.60 Gy/year (5.8 to 10 mGy/day). These dose rates were sufficient to increase the death rate of this species.

20.6.4 Avian Populations

The early literature on ionizing radiation and wild birds was reviewed by Mellinger and Schultz.⁷⁹ Monitoring studies at radioactive sites did not reveal any apparent gross effects on birds. Lethal doses (LD_{50/30}) for various species are presented. Birds are only slightly less radiosensitive than mammals, with a range of acute lethal doses of 4.5 to 15 Gy.²

Ellegren et al. found an increased frequency of partial albinism among adult and nestling barn swallows (*Hirundo rustica*) captured close to Chernobyl compared to swallows captured in an uncontaminated reference area.⁸⁰ As high as 15% of birds captured near Chernobyl in 1996 displayed partial albinism compared with < 2% in reference areas. Aberrant coloration, such as partial albinism, may be associated with increased risk of predation and reduced mating success; this genotoxic effect appears to have resulted in a loss of fitness in the breeding population that may be associated with a significant decline in breeding population size between 1986 and 1996. The authors proposed that the mutation was associated with germ cells and thus was heritable. The level of radiation in the area of capture at Chernobyl was 300 to 500 µR.

Bird populations were studied at the Idaho National Engineering Laboratory. Populations of barn swallows (*H. rustica*) that nested near the Test Reactor Area radioactive leaching ponds utilized leaching-pond arthropods as a food source and contaminated mud for nest construction.⁸¹ Adult birds contained primarily ⁵¹Cr (16.1 Bq/g), but 72% of the internal dose rate was due to ²⁴Na (0.22 mGy/day). Thermoluminescent dosimeters placed in the nests indicated average external dose rates of 0.84 mGy/day for eggs and 2.20 mGy/day for nestlings, for a total of 54 mGy during the nesting period. Mortality rates for this population did not differ from that of a reference population. The mean growth rate of first-clutch swallows and mean asymptotic weights of immature birds were significantly different ($p < 0.05$) compared with the reference group, but they were within the normal range reported in the literature.

In a related laboratory-field study at the above site, freshly-hatched tree swallows (*Tachycineta bicolor*) acutely exposed to 0.9 Gy showed a normal growth rate, whereas those exposed to 2.7 or 4.5 Gy showed pronounced growth depression by the end of the nestling stage.⁸² Earlier, the authors had located a single tree-swallow nest with five eggs chronically exposed to 1.0 Gy/day throughout the nesting period. Fledglings from this nest showed severe growth depression.

20.7 EFFECTS OF RADIATION ON AQUATIC POPULATIONS AND COMMUNITIES

Radionuclides have entered aquatic environments from natural sources, nuclear weapons testing, nuclear waste disposal, and accidental releases from nuclear power plants and via runoff from contaminated terrestrial environments. Associated with the presence of radioactive contaminants in aquatic systems is the potential for effects on aquatic biota. Exposure of such organisms may occur externally due to (1) radiation present in water and sediment and (2) the absorption of radionuclides onto the surface of biota, and internally as a consequence of absorption or ingestion. As indicated in Table 20.2, annual doses received by marine and freshwater biota from natural sources of radiation are generally less than 5 mGy/year.²⁰

Radiation-induced somatic and genetic effects have been observed in individual organisms following acute exposures in the laboratory.^{8,20,83-85} Several general conclusions have been drawn from acute and chronic laboratory investigations on aquatic organisms.⁸ Adult fish have radiation sensitivities similar to terrestrial mammals, provided sufficient time is allowed for temperature adjustments in the poikilothermic animals. Aquatic invertebrates tend to be more resistant to effects of radiation than vertebrates. Sensitivities of fish to radiation are dependent on the age of the fish and stage of embryological development. As pointed out by Blaylock and Witherspoon⁸⁶ and the NCRP,⁸ such studies are often conducted at doses many times greater than that expected in aquatic environments associated with nuclear activities. Surveys of the literature indicate a lack of data on chronic exposures in the environment, especially at the population and community level of organization.^{2,8,85}

Included among the freshwater environments that have been studied for radiation effects are three U.S. Department of Energy sites: White Oak Lake at Oak Ridge National Laboratory, seepage basins and a reactor cooling reservoir at the Savannah River Plant, and ponds and streams at the Hanford Site; also studied are aquatic environments adjacent to the Chernobyl accident site and the Mayak plutonium reprocessing facility in Russia as well as marine atolls that have undergone nuclear testing activities. Each of these environments contains radionuclides at above-background concentrations. In some cases, effects have been noted in individual organisms; however, adverse effects have not been observed at the population or community level.^{8,20} For the most part, these studies have shown the resilience of populations of freshwater biota to doses of less than 10 mGy/day.

Field studies on the effects of radiation on the marine environment are primarily limited to those that have been conducted near Bikini and Eniwetok atolls and in the North Irish Sea. In both instances, contamination of the marine environment was associated with nuclear-weapons-related activities. Long-term studies conducted in these areas have shown no impact on populations of aquatic biota. Comparisons of freshwater and marine ecosystems indicate that radiation effects on marine systems may be less than those expected in freshwater systems based on the larger size of marine systems and therefore greater potential for contaminants to disperse, and on the greater number of species usually present in marine environments as compared to freshwater ecosystems.²⁰ The studies discussed below support the resilience of marine ecosystems to low-level ionizing radiation.

20.7.1 Plant Populations

The first large-scale introduction of radionuclides into the marine environment as a result of human activities occurred in 1946 on Bikini atoll. Both Bikini atoll and Eniwetok were used as the "Pacific Proving Ground" for test detonations of nuclear and thermonuclear devices. The biological studies that have been conducted in these areas have been summarized by Templeton et al.⁸³ Intensive studies were conducted from 1950 through the 1960s to determine what effects radiation had on the marine environment. The studies concluded that, although individual organisms perished as a result of nuclear testing, the marine environment became repopulated with the impacted species over time. A few examples of effects on individual organisms from the area have

been found. Physiological functions of sessile algae were not noticeably altered one year after an explosion when algae were exposed to 5 to 20 to 30 mR/day.⁸⁷ Abnormalities in plant growth have also been noted on Bikini and Eniwetok atolls. Chronic dose rates of gamma radiation of 0.13 to 0.37 Gy/day for 2 to 4 months (total dose 7.8 to 55 Gy) can result in abnormalities similar to those found on these atolls. Abnormalities in plant growth observed in the field at these sites include tumors and changes from vine growth to stalk growth in one plant.⁸⁸

20.7.2 Invertebrate Populations

Located on the Oak Ridge National Laboratory's Reservation is a 7-ha impounded embayment known as White Oak Lake, which has been used since 1943 as a settling basin for low-level radioactive waste and nonradioactive contaminants. Most of the radioactivity within the lake is contributed by ¹³⁷Cesium, ⁶⁰Co, ⁹⁰Sr, and ³H. Transuranic and ¹⁰⁶Ruthenium radionuclides are also present in the lake.^{89,90} Radioactivity within the lake water and sediment has varied over the years. Several species of fish, turtles, aquatic invertebrates, and plants have been reported in the eutrophic lake. Among them, chironomid larvae, snails, mosquitofish, and pond slider and snapping turtles have been studied for possible effects of chronic exposure to low-level radiation on the individuals and populations that reside in the lake. Although genetic effects and reproductive differences were observed between animals from the lake and animals from the reference sites as observed in the following discussions, adverse impacts at the population level were not expected to occur. Populations of aquatic organisms have been present since impoundment of the lake.

Larvae of the midge, *Chironomus tentans*, were collected from White Oak Lake on two separate occasions and examined for chromosome aberrations.^{91,92} Chironomids collected from the lake in 1960 received a daily dose of 6.24 mGy, approximately 1000 times normal background level.⁹³ Comparisons of chromosomes within the salivary gland of these benthic aquatic invertebrates from White Oak Lake and reference populations indicated an increased number of chromosomal aberrations in animals from the contaminated site. The frequency of endemic inversions was, however, similar between the areas. The author attributed the lack of difference to the possible elimination of inversion through natural selection or to genetic drift within the White Oak Lake populations. In a follow-up study conducted 10 years later, when the dose rate received by chironomids was 0.3 mGy/day, no chromosomal aberrations were detected.⁹⁴ A laboratory study with a related species, *Chironomus riparius*, revealed that 360 mGy/day was the lowest dose rate at which an increased frequency of chromosome aberrations could be detected in the larval and pupal stages of chironomids reared in tritiated water.⁹⁵ A comparative study of chromosomal aberrations induced by chronic gamma radiation from an external ⁶⁰Co source and beta radiation from incorporated tritium revealed similarities in the frequency of aberrations.⁹⁶

Chromosomal abnormalities have also been measured in chironomids from the water reservoirs of the Chernobyl atomic power plant.⁵³ In 1998, two years following the accident, all individuals of *Chironomus balatonicus* had chromosomal abnormalities, with 85.7% having heterozygous inversions, 85.7% with homozygous inversions, and 3.6% of the individuals with "B-chromosomes." The radiation dose to these organisms was not estimated.

A field experiment conducted in the early 1970s examined the effects of chronic irradiation on the population of an aquatic snail, *Physa heterostropha*.⁹⁷ White Oak Lake snails, receiving a dose of 6.5 mGy/day, were found to have a significantly lower number of egg capsules per snail than did snails from the control population; however, snails from the contaminated site contained a significantly greater number of eggs per egg capsule. As a consequence, egg production was found to be similar in both populations. Laboratory populations of *Physa heterostropha* receiving a chronic dose of 10 mGy/hour (240 mGy/day) showed no significant differences from the control population in the number of egg capsules per snail, number of eggs per capsule, percent of eggs hatched, mortality, or snail size.⁹⁸ A dose rate of 100 mGy/hour (2400 mGy/day), however, significantly decreased each of the population parameters.

Snails have been shown to be good biomonitors of radio-strontium in aquatic environments and to be relatively tolerant of elevated doses of radiation. Mollusks were collected from the Dnieper drainage area and throughout the Kiev administrative region following the Chernobyl nuclear accident.⁹⁹ Radioactivity in shells and soft tissue were found to exceed pre-Chernobyl concentrations by factors as great as three orders of magnitude. The highest recorded concentrations were 4 to 5 MBq/kg in shells of *Lymnaea* and *Plorbarius*. Abnormalities and impacts on snail populations were not recorded in the investigation. Gene frequencies at four polymorphic loci were examined in seven populations of the snail *Dreissena polymorphs* adjacent to the Chernobyl atomic power station.¹⁰⁰ Recorded differences were attributed to conditions of the breeding site, such as substrate characteristics and water flow rate, and not to radiation or thermal differences.

20.7.3 Fish Populations

Studies have been conducted that examined the effects of chronic low-level radiation on mosquitofish (*Gambusia affinis*) populations in White Oak Lake.^{101,102} Fish collected from the lake in 1965 were found to have significantly larger brood sizes (when adjustments were made to correct for differences in maternal size) than did fish from the reference population. In addition, an increased number of dead and deformed embryos were noted in the White Oak Lake population. The fitness of White Oak Lake mosquitofish was further investigated in 1973 by the rearing of field-collected fish from the lake and from four reference sites.¹⁰² Significant differences were not found in the brood sizes of the F₁ generations of the laboratory-reared fish from the five locations. It was therefore concluded that the larger brood size originally observed in White Oak Lake mosquitofish populations was likely attributable to the eutrophic conditions of the lake and not to genetic adaptation as a response to radiation. The increased incidence of dead and deformed embryos did, however, persist in the White Oak Lake stock reared in the laboratory. Measurements of other characteristics revealed differences in the size and variability in the size of female fish and differences in the variability and mean critical thermal maximum of male mosquitofish from the White Oak Lake stock. Although these findings were used to support the explanation of the presence of radiation-induced recessive mutations in the gene pool of White Oak Lake, no significant negative impact on the overall fitness of mosquitofish from the lake was expected.¹⁰²

As an added note, the dose rate to mosquitofish in White Oak Lake was 0.59 mGy/day in 1975 and 3.6 mGy/day in 1965. Both rates were considerably lower than the dose rate found to decrease brood size and increase sterility in the guppy, *Poecilia reticulata*, following chronic exposure in the laboratory.¹⁰³ DNA strand breakage was also evaluated in mosquitofish (*Gambusia affinis*) from two sites associated with this facility.¹⁰⁴ Fecundity was found to be negatively correlated with the amount of double-stranded breaks at one radioactively contaminated site. In addition, a higher proportion of strand breaks was found in females with broods containing deformed embryos than in females with normal broods. These data indicate a link between DNA strand breaks and potential population-level effects.

Fish from regions near Chernobyl have been examined for both genetic and morphological abnormalities. Chromosomal aberrations in the corneal epithelium were examined in carp from the cooling reservoir of the Chernobyl Atomic Power Station during 1987. The rate of mutagenesis between carp from the cooling pond and a site 60 km from Chernobyl were not interpreted as significantly different.⁵⁰ DNA strand breaks and micronuclei were examined in channel catfish (*Ictalurus punctatus*) from the Chernobyl cooling pond and a fish hatchery 30 km from the Chernobyl site.¹⁰⁵ Catfish from the cooling pond were found with a higher incidence of DNA damage; however, no difference in the number of micronuclei was detected. Radiocesium concentrations in the cooling pond were at least 50% greater than at the U.S. Department of Energy Savannah River Site, where DNA damage was also detected in largemouth bass (*Micropterus salmoides*).¹⁰⁶ The ability of catfish populations within the cooling ponds to withstand sediment exposures of up to approximately 3 Gy/day was attributed to possible acclimation and adaptation

over time.¹⁰⁵ This may be supported by the lack of anomalous abnormalities in fish breeding near Chernobyl one year following the nuclear reactor accident.⁵⁰

Activities of the Windscale reprocessing plant were responsible for the release of radionuclides into the marine environment as a consequence of the discharge of low-level radioactive effluent and a nuclear reactor accident in 1957. Fish in the North Irish Sea have been exposed to low-level radiation for over 20 years. Plaice (*Pleuronectes platessa*), a commercial fish species collected from the area in 1968 to 1970, showed no differences in average body length when compared to fish from other areas.²⁰ In addition, laboratory studies conducted on plaice embryos revealed that a radiation dose rate of 0.05 mGy/day (measured in the area from 1967 to 1969)⁸⁵ would not be sufficient to induce a discernible effect on individual plaice or on populations of the fish.¹⁰⁷

Nuclear testing in the Pacific has also resulted in observable effects in marine fish. Thyroid tissue damage was observed in fish collected from Eniwetok for a period of 8 months following a nuclear detonation. The damage was attributed to the radiation from iodine, despite the absence of radioiodine from the fish thyroids.¹⁰⁸

20.7.4 Turtle Populations

In the late 1980s, two species of turtles were collected from White Oak Lake and a reference site and examined for single-stranded DNA breaks, a nonspecific indicator of possible exposure to genotoxic agents in the environment.¹⁰⁹ Both the pond slider (*Trachemys scripta*) and common snapping turtle (*Chelydra serpentina*) from the lake were found to contain a significantly greater amount of DNA damage than turtles from the reference site. Differences between species were not found. Turtles from White Oak Lake also contained significantly higher tissue concentrations of ¹³⁷Cs, ⁹⁰Sr, ⁶⁰Co, and mercury. Because turtles in the lake were exposed to agents other than radiation that may have induced the DNA damage, radiation could not be singled out as the cause of the damage. The dose received by turtles in the lake was not determined, and comparative laboratory studies have not been conducted to ascertain whether radiation could induce the single-stranded DNA breaks observed in the field.

As with White Oak Lake, the Savannah River Plant is located on a U.S. Department of Energy facility. On the approximately 80,000 ha in South Carolina are five nuclear reactor facilities, two chemical separation plants, a heavy-water separating plant, small test-reactor facilities, and the Savannah River laboratory.¹¹⁰ Seepage basins on site have received radioactive and nonradioactive wastes from the plant in the past. A reactor cooling pond, designated Pond B, received fission products from a nuclear reactor between 1961 and 1964.¹¹¹ A flow cytometric assay was utilized to assess the impact of low-level radiation on the DNA of turtles and ducks from contaminated aquatic environments on the Savannah River Plant. Bickham et al.¹¹² collected slider turtles from two seepage basin complexes containing primarily ¹³⁴Cs, ¹³⁷Cs, ⁸⁹Sr, ⁹⁰Sr, and ³H. Chromium, mercury, and nitrate were also contaminants within the basins. Turtles from the seepage basins were found to possess significantly greater DNA content in red blood cells than turtles from the reference site. In addition, four turtles from the contaminated basins contained mosaic DNA. The enhanced amount of variation in DNA content was attributed to chromosomal rearrangements in the DNA, which can result in deletions and duplications of genetic material.

The presence of mosaic DNA is related to the proliferation of such cell lines. A correlation was found between the plastron length of the turtle, which is a rough estimate of age, and the amount of variation in cellular DNA. The dose rate to turtles was not determined, and the specific cause of the genetic damage in the Savannah River Plant turtles could not be ascertained. To determine whether low-level radiation could induce genetic damage as observed in the turtles from the seepage basins, slider turtles were collected from Pond B and cellular DNA content in red blood cells measured.¹¹³ As with the turtles from the seepage basins, a significantly greater variation in DNA content was found in turtles from the radioactive site than in turtles from the reference site. DNA from two of the turtles from Pond B showed evidence of aneuploid mosaicism. Although the

radiation dose received by the turtles was not determined, Pond B sliders were noted as containing average total body burdens of ^{137}Cs and ^{90}Sr of 842 Bq and 1879 Bq, respectively. Body burdens of the White Oak Lake pond sliders were, incidentally, within the range of that measured in the Savannah River turtles.¹¹⁴ Impacts of the variation in DNA content and presence of mosaicism on the turtle populations are unknown.

20.7.5 Waterfowl Populations

The same flow cytometric assay used on the Savannah River turtles was used to detect DNA abnormalities in ducks exposed to radionuclides in Pond B.¹¹¹ Cesium-137 constituted 99% of the activity present in the reservoir. Game-farm-reared male mallards were released onto Pond B and allowed to roam free during the daylight hours for 12 months. Flow cytometric measurements were conducted on a regular basis by the extraction of blood from exposed and control mallards. Differences were found between the Pond B mallards and the control groups' only after the ^{137}Cs concentration in the exposed ducks had reached steady-state equilibrium (mean of 2.52 Bq/g at 8 months). After 9 months, the coefficient of variation in DNA content was significantly greater in the Pond B mallards, with aneuploid mosaicism detected in 2 of the 14 pond ducks. Again, the impacts of these findings on the population level are unknown.

20.7.6 Aquatic Communities

The Hanford site near Richland, Washington, contains several aquatic systems with origins that date back to the Manhattan Project in 1943. Hanford ponds and streams were maintained to receive wastewater from nuclear reactor, reprocessing, and laboratory operations. The aquatic systems on site contain a variety of contaminants. Most contain radioactive waste in the form of mixed-fission and activation products with actinides including transuranics in some locations. Chemical waste was also released into some of the systems. In the mid-1970s, several of the aquatic ecosystems on site were studied to determine whether the presence of radioactive wastes could impact the community structure in terms of diversity and productivity.¹¹⁵ The study characterized limnological and radiological conditions in several ponds, ditches, and a trench. Although some differences in population parameters for algae, macrophytes, and invertebrates were found among the Hanford sites and between the Hanford sites and off-site systems, they could not be correlated with radiological differences. Comparisons of doses from ionizing radiation to aquatic biota in the Hanford ponds and streams to doses reported in the literature to cause minor to intermediate damage in aquatic organisms revealed that dose rates of 50 to 100 R/day in 100-N Trench may have been sufficient to induce limited damage to algae, invertebrates, and amphibians.

Aquatic environments were impacted by the Chernobyl atomic power plant (CAPP) accident in 1986. Many species formerly associated with the CAPP cooling ponds have returned to the ponds.⁵¹ A colony of beaver (*Castor fiber*) storks has returned to the ponds. Bivalve mollusk populations of *Anodonata cygnea* appear to be recovering and are actively growing following the radiation insult; however, populations of *Dreissena* continue to be depressed. Model estimates indicate an external radiation dose to aquatic biota of 2 to 3 mGy/day shortly after the accident. Fish within these ponds also appeared to breed and grow successfully.

20.8 RADIOLOGICAL DOSE MODELS

Simplistic models are often used in screening level risk assessments to estimate exposure and risk to ecological receptors. A variety of radiation dose models have been developed to estimate dose to terrestrial¹¹⁶⁻¹¹⁹ and aquatic biota.¹²⁰⁻¹²² Recently, dose models have been developed that allow for a comparison of radionuclide concentrations with screening benchmark values intended

to be protective of the ecosystems of concerns. Such models provide guidance on how ecological risks can be assessed by using environmental monitoring data to estimate dose to specific ecological receptors, followed by a comparison of the calculated dose against acceptable dose limits for aquatic^{123–126} and terrestrial biota.^{123,126,127}

The most comprehensive and user-friendly of these ecological risk-related radiation dose models is that developed by the U.S. Department of Energy.¹²³ A graded approach, which includes methods for both screening and detailed analyses, was developed as a technical standard to evaluate compliance with specific radiation dose limits to populations of aquatic and terrestrial biota exposed to anthropogenic sources of radiation at U.S. Department of Energy sites. The dose limits used in the analysis of risk are those recommended by the IAEA⁹ of 10 mGy/day for aquatic biota, 10 mGy/day for terrestrial plants, and 1 mGy/day for terrestrial animals. A companion tool to the standard is the RAD-BCG Calculator. This tool contains a series of electronic spreadsheets that facilitate the calculation of total radiation dose to each receptor.

Strengths and weaknesses of predictive models in assessing exposure, dose, and effects have been reviewed by radioecologists.^{128–131} Basic conclusions are:

- Existing exposure/dose models are often simplistic and utilize generalized default parameters that can result in either over- or underestimation of potential risk to the receptor. Selection of default values is also highly dependent upon professional judgment, which can vary among modelers.
- Existing models should be tested and calibrated with actual data from the field or laboratory.
- Models in the past have been primarily deterministic. Greater technical value would be achieved through stochastic models that incorporate error propagation and probability distributions of specific parameter values.

Existing radiation dose models are, however, useful tools in predicting potential doses and effects to ecological receptors in the absence of site-specific information, as in a screening-level ecological risk assessment.

20.9 EFFECTS OF POWER PLANT COOLING SYSTEMS

Over half of the nuclear power plants in the United States use once-through cooling systems. Receiving-water bodies include rivers, lakes and reservoirs, cooling ponds, the Great Lakes, and estuaries and coastal areas.¹⁸ Other units have closed-cycle cooling, primarily mechanical or natural-draft-cooling towers, which results in little water withdrawal. With cooling towers, most of the heat is dissipated to the atmosphere. The number of fossil-fueled plants is considerably greater than the number of nuclear plants.

Operation of once-through cooling systems at power plants, whether nuclear or fossil-fueled, primarily affects the aquatic environment. The impacts on terrestrial resources — construction changes, transmission-line maintenance, and drift from cooling towers — are few and are limited to the immediate area, particularly when considering population-, community-, and ecosystem-level effects.¹⁸ The following discussion concerns both nuclear and fossil-fueled power plants; nuclear plants require larger amounts of cooling water than do fossil-fueled plants. Although the effects of cooling systems on the aquatic environment are site specific, some generalizations can be made.

Once-through condenser cooling systems require large amounts of water that are withdrawn directly from surface waters and returned to the receiving water body with an increased heat and chemical load. During operation of the cooling system, intake screens bar debris and large organisms from entering the plant. Impingement occurs when aquatic organisms are caught on the screens. Impingement results in mortality if the organisms are held against the screens for long periods of time. Entrainment — the pumped passage of small organisms, including eggs and larvae, through the condenser cooling system where they are subjected to heat, mechanical, and pressure stresses

— may also result in mortality. Entrained organisms may suffer heat shock as a result of abrupt exposure to the elevated temperature of the cooling water. On the other hand, organisms acclimated to the temperature of the receiving water may suffer cold shock during winter months when plant shutdowns occur. Periodic condenser chlorination to control fouling also results in mortality of entrained organisms. These impacts of power plant cooling systems on the aquatic environment have been monitored for years,^{10–17} with no long-range problems.^{18,132,133}

Initially, the concern regarding the impacts of cooling systems on the aquatic environment centered on heated discharges (“thermal effects”), which were regulated under the Clean Water Act (CWA) 316(a) requirements. Depending on the flow, use of biocides, and type or placement of the outlet in the water column, scouring and the absence of benthic invertebrates in the immediate area have been observed. At some plants, seasonal changes in river phytoplankton were amplified in the heated area, with disappearance of some taxa in summer and replacement of green algae with the more heat-tolerant blue-green algae.¹³⁴ The response of fish to thermal effluents is seasonal and depends on the thermal preference and temperature tolerance of the individual species.¹³⁵ Available data show that thermal plumes in rivers do not usually affect anadromous or resident fish migration; migrating fish have been shown to avoid areas of maximum temperature by passing around or under the plume.^{132,136} In some cases, temperatures of 32 to 35°C have not presented a barrier to the presence¹³⁷ or movement¹³⁸ of fish. A review of the response of fish to heated discharges indicates that some species avoid heated areas, whereas some warm-water species have been observed feeding in thermal plumes at temperatures as high as 41°C.¹³⁹ Thus, there have been changes in the distribution of organisms, with replacement of heat-sensitive species of fish, invertebrates, and algae by more resistant species in the immediate vicinity of the discharge; however, none of the changes regarding thermal effluents have impacted the entire ecosystem.

In addition to the direct effects on organisms, there is concern about the impact on fish populations resulting from mortality of fish eggs and larvae carried by the cooling waters through the plant and from impingement of juvenile fish colliding with the intake screens.^{14,16} Neither entrainment of early life stages of fish or impingement of fish and shellfish has been found to be a problem at most power plants.¹⁸ Several studies conducted at power plants on the Hudson River indicated that entrainment mortalities are less than 50% for some fish species, and the combined effects of entrainment and impingement would result in 10 to 20% loss of a year class of several fish species.¹⁴⁰ The problem may become significant, however, when many plants are sited on the same river or estuarine system, cooling water intake is considerable compared to natural flow, and early life stages of commercially important anadromous fish are involved.

Five electricity-generating plants with once-through cooling systems are located on the Hudson River estuary between river kilometers 60 and 107. The only nuclear plant among these is the Indian Point power plant located at kilometer 69. In the 1960s, construction of two additional units, both with once-through cooling, was proposed for the Indian Point site. In addition, a proposed pumped-storage hydroelectric plant was proposed for the Cornwall area (kilometer 93). Both of these facilities would draw large volumes of water from an area of the Hudson River estuary that served as a spawning and nursery habitat for several species of commercially and recreationally important fish. It was feared that entrainment and impingement would result in the decline of the striped bass (*Morone saxatilis*) population.

Between 1963 and 1980, an intensive environmental research and assessment program was undertaken, documenting the characteristics of the estuary including geography, hydrology, and physicochemistry of the river; biological productivity; abundance, distribution, and life histories of the fish fauna; and potential impact of additional power plants.^{140,141} Mathematical population models were developed to calculate potential impacts. These studies supported a series of legal proceedings (regarding licenses and discharge permits) among scientists, conservationists, and utility companies that ended in an out-of-court settlement in December 1980. As an alternative to building cooling towers, three key measures were agreed upon for mitigating entrainment and impingement loss: flow reductions and power outages at several of the plants during periods of

peak entrainment, a barrier net to mitigate fish impingement at one plant, and a program of stocking of hatchery-reared striped bass by the utility companies.

In the late 1990s, concern for the potential adverse environmental effects of power plants focused less on thermal discharges and more on cooling-water intake structures, as the U.S. Environmental Protection Agency revisited the CWA 316(b) requirements for new and existing facilities. The last 30 years of research on impingement and entrainment, i.e., 316(b) issues, were recently summarized.¹³³ Early assessments of the impacts of cooling-water intakes used models to predict losses to key fish populations. Using worst possible scenarios, these models predicted high annual exploitation rates. However, monitoring of fish populations in the Hudson River (mentioned previously) and the Delaware estuaries has failed to show adverse population-level impacts.¹⁴² A variety of fish-protection technologies have been employed to mitigate impingement and entrainment: fish collection systems, fish diversion systems, physical barriers, and behavioral barriers.¹⁴³ Nevertheless, compensation, or the ability of fish populations to offset losses, remains an area of active research. Phytoplankton and zooplankton are less impacted than fish populations.

20.10 SUMMARY

This chapter addresses man-made sources of ionizing radiation, the movement of radionuclides in the environment, and potential effects on natural populations and communities of plants and animals. In addition to natural background radiation, irradiation occurs from the normal operation of nuclear power plants and plutonium-production reactors, nuclear plant accidents, nuclear weapons testing, and contact with or leakage from radioactive waste storage sites. No studies of plants or animals exposed chronically to the low doses found in the environment demonstrated a detrimental effect on populations, although some biological effects have been observed. Aquatic organisms associated with environments contaminated by activities at the Mayak Production Association facility in the southern Urals of Russia have been exposed to unusually high levels of radiation for extended periods. Impacts on snail populations have been noted following doses of 2 to 3 Gy/day; however, recovery of some populations over time has also been noted. More common are acute doses at high exposure levels, which are not expected to occur except in the event of a catastrophic nuclear accident — nuclear warfare.

Radiation effects in this chapter focus on field studies, with supporting information from relevant laboratory investigations. Selected examples attempted to relate estimated doses or tissue levels to potential effects; however, dose estimates in the field are often imprecise, and observations are further confounded by the presence of other contaminants or stressors.

Very few studies address the effects of exposure of natural populations of terrestrial plants and animals to chronic, low-level irradiation. Chronic exposure of a population of cotton rats to 0.03 Gy/day at one radioactive site did not result in significant effects on fertility or blood parameters. Results of laboratory studies indicate that adverse effects are not expected at doses below 1 to 2 Gy. Chronic dose rates below 1 mGy/day should be protective of natural terrestrial populations.

Adverse effects of radiation on natural aquatic populations have been demonstrated only in severely contaminated areas. While genetic and reproductive changes have been measured in aquatic biota from areas contaminated with radiation, the overall fecundity of the populations did not appear to be adversely impacted. Changes in DNA have been observed in field-collected turtles and waterfowl, but for the purpose of evaluating the effects of radiation at the population level, these studies are lacking because dose rates were not determined for comparison with laboratory acute radiation data. In addition, impacts on survival, fertility, or fecundity were not measured. In some instances, as with the White Oak Lake, Savannah River Plant, and Hanford studies, observed effects in the field could not be exclusively attributed to radiation because of the presence of chemical contaminants or potential impacts of other environmental stressors.

Responses of aquatic organisms to radiation can be modified by salinity, temperature, and water chemistry in addition to the biological factors such as life stage and metabolic rate. In addition, competition between chemically similar stable elements and radionuclides, such as calcium and ^{90}Sr or potassium and ^{137}Cs , can have an impact on the exposure of aquatic biota to radiation. In cases where dose rates received by organisms in natural aquatic environments have been measured, it appears that chronic dose rates of ≤ 10 mGy/day do not result in deleterious effects on natural populations of aquatic organisms. Snail populations in adjacent aquatic environments associated with the Mayak nuclear fuel reprocessing plant in Russia, may, however, be an exception. Further field investigations of these chronically exposed aquatic populations are warranted. The general resilience of aquatic species to exposure to low-level radiation are perhaps best illustrated with the marine environments of Bikini and Eniwetok atolls, where populations and communities have survived decades of nuclear weapons testing.

The impacts of power plant cooling systems — impingement, entrainment, elevated water temperatures, heat shock, and cold shock — on aquatic populations and communities have been intensively studied for more than 20 years. Local effects have been observed, but there have been no long-range problems. Procedures such as siting considerations, modifications of intake structures, cooling water flow reductions, and the greater use of cooling towers have helped to mitigate potential environmental impacts. Stocking programs can be used to replenish populations of important fish species.

21.1 INTRODUCTION

For most of the last 10,000 years, since the development of settled agriculture, the environmental effects of deforestation have been scattered in time and space. Large areas of forest were cleared long ago in Mesoamerica, Europe, and parts of Asia and Africa, some of these clearings lasting to the present and others returning to forests as empires declined.¹ In the last few centuries, however, and particularly in the last several decades, the effects of deforestation have become global, not only in

the sense that they occur almost everywhere on the earth, but in the sense that they contribute to global changes in climate through emissions of greenhouse gases. Changes in climate affect all peoples of the planet, whether or not they contributed to the changes. In this sense, the effects are similar to other forms of ecotoxicology: the unintended consequences are often borne by communities that did not benefit from the intended consequences. The consequences of deforestation extend far beyond the borders of forests and thus affect the global commons or, in other words, the public interest.² As with other elements of globalization, the balance of private and public rights needs attention.

Deforestation has always had consequences at local and regional scales. Locally, deforestation often increases the frequency and severity of floods and mudslides, increases the day-night range of temperature, reduces the capacity of soils to hold water, and may lead to soil erosion and the silting-in of downstream reservoirs, thus shortening the lifetime of hydroelectric dams. In addition, deforestation results in a loss of fuel, shelter, and other resources for local inhabitants. These effects are particularly troublesome for the people of developing nations, a great number of whom depend directly on the land for their survival. The major cause of deforestation, ironically, is the clearing of new agricultural land for greater production of food. One of the tragedies of deforestation in the tropics is that much of the agricultural land carved from forests is abandoned from production after a few years, having lost its fertility. In many locations, abandoned land may return to forest, but the worldwide increase in degraded lands shows that such reforestation is generally not taking place. Instead, these abandoned agricultural lands often remain degraded, eroded, or waterlogged, with an impoverished, low-statured vegetation of woody shrubs. The net effect of deforestation, with subsequent overuse of the land, is a reduction in the capacity of the earth to support human populations.

Regionally, the effects of deforestation include changes in temperature and moisture. For example, deforestation in the tropics leads to reduced rainfall and elevated temperatures within the region,³ while deforestation in mid-latitudes leads to cooler temperatures.⁴ The changes in surface energy and water budgets may extend beyond the regions deforested and thus have global effects,⁵ similar, qualitatively at least, to El Niño and its equivalent in northern mid-latitudes, the North Atlantic Oscillation.

Other effects of deforestation are more clearly global. They include not only the conversion of potentially productive land to land with diminished capacity to support either crops, forests, or people, but also the irreplaceable loss of species, and emissions to the atmosphere of chemically active and heat-trapping trace gases, such as carbon dioxide, methane, nitrous oxide, and carbon monoxide. The last of these global effects is considered here — the effect of deforestation on the emissions of trace gases and, hence, on the earth's atmosphere and climate.

When forests are cleared and replaced with agricultural lands, the carbon originally held in the trees is released as carbon dioxide to the atmosphere, either immediately, if the forests are burned, or more slowly, as the unburned organic matter decays. Cultivation of forest soil also oxidizes organic carbon held in soil and releases it to the atmosphere as carbon dioxide. Reforestation reverses these fluxes of carbon. While forests are regrowing, they withdraw carbon from the atmosphere and accumulate it in trees and soil. Although deforestation itself may not release significant quantities of methane or nitrous oxide to the atmosphere, subsequent use of the land for cattle or other ruminant livestock, for paddy rice, or for agricultural production enhanced by nitrogen fertilizers does release these other heat-trapping gases.

This paper will review the contribution of deforestation and subsequent land use to the increasing concentrations of greenhouse gases in the atmosphere. It will also consider the reverse process: How might forests be managed so as to withdraw carbon from the atmosphere? And how much carbon might be accumulated if forests were reestablished on suitable lands?

21.2 GLOBAL WARMING

The scientific community is in agreement about most aspects of global warming. Two scientific assessments of climatic change, involving more than 400 scientists from 26 countries, have been

Table 21.1 Characteristics of Greenhouse Gases and Their Relative Contributions to Global Warming over a 100-Year Time Horizon

Gas	1990 Emissions (Tg)	Warming Effect of an Emission of 1 kg Relative to that of CO ₂	Atmospheric Lifetime (Years)	Relative Contribution over 100 Years
Carbon dioxide	26,000 ^a	1	50–200 ^b	61%
Methane	300	21 ^c	10	15%
Nitrous oxide	6	290	130	4%
CFCs and HCFCs ^d	1	1000's	10's to 100's	11%
Others ^e				9%

^a 26,000 Tg CO₂ = 7 Pg C.

^b The broad range in lifetime for CO₂ results from uncertainties in the global carbon cycle and from the fact that the removal of CO₂ from the atmosphere depends not only on the amount but on the rate at which CO₂ is emitted to the atmosphere.

^c Includes the indirect effects to concentrations of other greenhouse gases through chemical interactions in the atmosphere.

^d The radiative properties and atmospheric lifetimes of specific CFCs and HCFCs are known precisely. Only order-of-magnitude averages for the more abundant gases are shown here.

^e Principally tropospheric ozone, indirectly generated in the atmosphere as a result of other emissions.

carried out by the Intergovernmental Panel on Climatic Change (IPCC),^{6,7} and a third assessment was published in 2001.^{7a} The IPCC was established by the World Meteorological Organization and the United Nations Environmental Programme. According to these IPCC assessments of climate change, scientists are certain, first, that there is a natural greenhouse effect, and, second, that emissions of carbon dioxide (CO₂), methane (CH₄), nitrous oxide (N₂O), and chlorofluorocarbons (CFCs) from human activities are increasing the concentrations of these greenhouse gases in the atmosphere. "There is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities."^{7a}

Evidence of the natural greenhouse effect comes from understanding the characteristics of greenhouse gases (Table 21.1), from satellite measurements of radiation at different levels within the earth's atmosphere, and from the high correlation between concentrations of CO₂ (and CH₄) and the surface temperature of the earth over the last 420,000 years. Without the natural greenhouse effect, the average temperature of the surface of the earth would be 33°C cooler, and life would be very different if it didn't exist at all. Evidence for the increased concentrations of greenhouse gases in the atmosphere comes from direct measurements in the atmosphere over recent decades and, over the last centuries, from measurements of air trapped in the ice of polar glaciers.

Evidence that the 30% increase in atmospheric CO₂ since preindustrial times is from human activities comes from several sources. First, the concentration of CO₂ fluctuated less than 10 parts per million by volume (ppmv) over the 1000 years preceding 1750. In less than 250 years the concentration has increased from about 285 ppmv to 363 ppmv (in 1997). Nowhere in the last 420,000 years has the concentration been as high as it is now. Second, the releases of CO₂ from combustion of fossil fuel and from changes in land use parallel the rise in atmospheric concentrations. Third, the north-south gradient in CO₂ concentrations is consistent with the distribution of emissions, predominantly in the northern mid-latitudes. And fourth, the observed changes in isotopes of atmospheric carbon are consistent with the known sources of CO₂ and with the global circulation of carbon as described by global carbon models.

The global warming potential of a gas can be calculated from three factors: the amount of gas emitted annually to the atmosphere, the radiative properties of the gas, and its average atmospheric lifetime. Table 21.1 gives these characteristics for the most important greenhouse gases and shows their expected contributions to global warming in the next century if current trends in emissions

continue (the IPCC business-as-usual scenario).⁶ Over the next 100 years, the relative contributions to a global warming are calculated to be 61% for CO₂, 15% for CH₄, 4% for N₂O, and 11% for CFCs. Other gases, principally tropospheric ozone, are expected to contribute about 9%.

Those greenhouse gases with long atmospheric lifetimes will continue to have a radiative effect for centuries after they are emitted to the atmosphere. The longer the emission rates continue to increase at present rates, the greater will be the reductions in emissions required to obtain a given atmospheric concentration. Reductions of more than 60% in emissions of CO₂, N₂O, and CFCs will be required immediately to stabilize atmospheric concentrations at today's levels.

This last point bears emphasis. It provides the strongest example of the existing gap between science and public affairs. The Kyoto Protocol calls for developed countries to reduce 1990 levels of emissions by an average of 5% by 2010. For the United States, the reduction is 7%. In fact, emissions in the United States were 11.2% higher in 1998 than they had been in 1990, so the reduction required for compliance with the Kyoto Protocol is no longer 7%, but 18.2%. In contrast to the emissions reductions agreed to in the Kyoto Protocol, however, the reductions required for stabilization of atmospheric concentrations at today's levels are greater than 60%. If CO₂ emissions were to stay constant at current levels, they would lead to a nearly constant rate of increase in atmospheric concentrations for at least two centuries, reaching about 500 ppmv by the end of the 21st century.⁷

The mean global surface temperature has increased by 0.3 to 0.6°C since the late nineteenth century, with an acceleration in the warming since 1980. The warmest years to date have been 1998 and 1997. The magnitude of this warming is consistent with the results of global climate models when they include the cooling effect of aerosols, but it is also consistent with natural variability. Nevertheless, the IPCC's latest assessment recognizes a discernible human influence on global climate.⁷

Scientists predict on the basis of General Circulation Models (GCMs) that in the business-as-usual scenario, the mean global temperature will increase by about 2°C (range 1–3.5°C) by the year 2100 (0.2°C per decade). This rate of warming is greater than experienced in the last 10,000 years. However, the rate will vary regionally and seasonally. More of the warming will occur at higher latitudes and in winter. Sea level is predicted to rise about 50 cm by the year 2100 (5 cm per decade with an uncertainty of 1.5 to 9.5 cm per decade). Under alternative scenarios that include some degree of control on emissions, rates of warming are predicted to be one half to one third the rate predicted on the basis of current trends. There are numerous uncertainties in the above predictions. The major ones are the sources and sinks of greenhouse gases, the role of clouds in affecting climate, the role of the oceans in delaying the timing of the warming, and the role of polar ice in affecting sea level and in amplifying the warming.

The prospects of a climatic change associated with business-as-usual may be described qualitatively as follows: the warming will be rapid, 10 to 60 times more rapid than the warming associated with the last retreat of the glaciers, about 10,000 years ago. The warming will be continuous; it will not stop unless deliberate steps are taken to halt it. The combination of a rapid and continuous change will make coping strategies difficult; adjustments will always lag behind the latest climate. The climate will not equilibrate at a doubled CO₂ concentration, as modeling experiments suggest, but will keep on changing. The reserves of fossil fuels are sufficiently large to release to the atmosphere on the order of 10 times more carbon than is currently in the atmosphere. Finally, an enhanced greenhouse warming will be irreversible within a human lifetime. The irreversibility results from the long atmospheric residence times of most of the greenhouse gases, on the order of a century or more, and from the thermal lag of the oceans, which commits the earth to a warming of about twice that realized at any point in time. There is no way to remove these gases rapidly from the atmosphere. Although the oceans will eventually absorb the excess CO₂ and processes in the atmosphere will eventually consume N₂O and CFCs, reductions in atmospheric concentrations will require centuries.

21.3 EFFECTS OF DEFORESTATION ON SOURCES AND SINKS OF GREENHOUSE GASES

21.3.1 CARBON

21.3.1.1 *Carbon Stored in Vegetation and Soils*

The amount of carbon stored in the living plants of the earth is of the same order as the amount held in the earth's atmosphere. In the eighteenth century, 700–800 Pg (1 Pg = 1×10^{15} g) carbon were held in the earth's vegetation, and about 600 PgC were in the atmosphere. Today, trees, grasses, and herbs are believed to hold about 500 PgC, and the atmosphere about 760 Pg. The increase in atmospheric CO₂ is accurately known; the decrease in terrestrial biomass is not as well known. The amount of organic carbon stored in the soils of the earth has also decreased (by about 3%) over the last 150 years as a result of cultivation and remains at 1100–1500 PgC. Terrestrial ecosystems (including both the living plants and soils) hold almost three times as much carbon as the atmosphere. Most of this terrestrial carbon is stored in forests. Forests cover about 30% of the land surface and hold almost half of the world's terrestrial carbon. If only vegetation is considered (soils ignored), forests hold about 75% of the living carbon.

In area, tropical forests account for slightly less than half of the world's forests, yet they hold about as much carbon in their vegetation and soils as temperate-zone and boreal forests combined. Considering only vegetation, undisturbed tropical forests hold, on average, about 65% more carbon per unit area than forests outside the tropics. When the carbon in soils is included, temperate zone and tropical forests are more nearly equal. Nevertheless, equivalent rates of deforestation in the two regions will cause considerably more carbon to be released from the tropics than from regions outside the tropics because only a fraction of the soil carbon is lost with cultivation.

The biomass of temperate zone and boreal forests is reasonably well known because foresters have been conducting forest inventories in northern countries for decades. Such inventories are rare in tropical countries, and the distribution of biomass throughout the tropics is poorly known. A recent comparison in the Brazilian Amazon showed that estimates of biomass for the entire region varied by more than a factor of two.⁸ Uncertainties result from limited data on belowground biomass and variability in the biomass of trees smaller than those routinely sampled, in vines, in nontree components, in palms, in the shape and density of tree boles, and in the amount of woody debris on the forest floor. There is also considerable uncertainty in the spatial distribution of biomass over large areas. None of the five estimates compared in the Brazilian Amazon showed similar distributions of high- and low-biomass forests.⁸

Per unit area, forests hold 20 to 50 times more carbon in trees than the ecosystems that generally replace them (Table 21.2), and this carbon is released to the atmosphere as forests are transformed to other uses. In the tropics, much of the carbon is released immediately through burning. Afterwards, decay of soil organic matter and woody debris continues to release carbon to the atmosphere, but at lower rates. If croplands are abandoned, regrowth of live vegetation and redevelopment of soil organic matter withdraw carbon from the atmosphere and accumulate it again on land. To calculate the net flux of carbon from deforestation and reforestation, ecologists have documented the changes in carbon associated with different types of land use and different types of ecosystems in different regions of the world. Annual changes in the different reservoirs of carbon (live vegetation, soils, debris, and wood products) determine the annual net flux of carbon between the land and the atmosphere. Because of the variety of ecosystems and land uses, and because the calculations require accounting for cohorts of different ages, bookkeeping models have been developed for the calculations.^{9–13}

Table 21.2 compares the relative losses of carbon as a result of converting forests to other uses. The losses in biomass range from 100% for permanently cleared land to 0% for nondestructive

Table 21.2 Percent of Initial Carbon Stocks Lost to the Atmosphere when Tropical Forests are Converted to Different Kinds of Land Use

Land Use	Carbon Lost to the Atmosphere Expressed as % of Initial Carbon Stocks	
	Vegetation	Soil
Cultivated land	90–100	25
Pasture	90–100	12
Degraded croplands and pastures ^a	60–90	12–25
Shifting cultivation	60	10
Degraded forests	25–50	<10
Logging ^b	10–50	<10
Plantations ^c	30–50	<10
Extractive reserves	0	0

Note: For soils, the stocks are to a depth of 1 m. The loss of carbon may occur within 1 year, with burning, or over 100 years or more, with some wood products. Values are from Houghton et al.⁹ unless otherwise indicated.

^a Croplands and pastures, abandoned because of reduced fertility, may accumulate carbon, but their stocks remain lower than the initial forests.

^b Based on current estimates of aboveground biomass in undisturbed and logged tropical forests.⁶¹ When logged forests are colonized by settlers, the losses are equivalent to those associated with one of the agricultural uses of land.

^c Plantations may hold as much or more carbon than natural forests, but a managed plantation will hold, on average, 1/3 to 1/2 as much carbon as an undisturbed forest because it is generally regrowing from harvest.⁶²

harvest of fruits, nuts, and latex (extractive reserves). Losses of carbon from soil may also occur, especially if the soils are cultivated.

21.3.1.2 The Global Extent of Deforestation

21.3.1.2.1 Temperate and Boreal Forests

According to the latest Forest Resources Assessment published by the Food and Agriculture Organization (FAO) of the United Nations,¹⁴ the area of forest in developed countries (largely outside the tropics) increased by an average of 1.76×10^6 ha/year during the first half of the 1990s. This increase does not include the Russian Federation because the FAO could not determine a reliable estimate. Reported increases in forest area of 2.4×10^6 ha between 1988 and 1993 are largely a result of reclassifications and definition: forest lands in Russia are defined as lands that trees can grow on and that are not used for other purposes. One estimate finds that the area actually covered by closed canopy forests (more than 30–40% canopy cover) declined by 7.6×10^6 ha between 1988 and 1993.¹⁵ However, in the 10 years between 1983 and 1993, only about 30% of the forests in Siberia were inventoried, and few of these areas were inventoried twice, so estimates of change are unreliable for the country with the largest share of the world's forests.

The average annual change of 1.76×10^6 ha included increases of 0.39, 0.76, 0.05, and 0.56×10^6 ha/year in the developed countries of Europe, North America, Oceania, and countries of the former Soviet Union (not including Russia), respectively, during the period 1990–1995.¹⁴ In China, forest area experienced a net loss of 0.087×10^6 ha/year. Despite this net loss of forests, China has established the largest area of forest plantations: 34×10^6 ha by 1995. As mentioned above, it is not clear whether changes in Russian forests would have increased or decreased the average increase of 1.76×10^6 ha/year in developed (largely temperate-zone and boreal) countries.

Table 21.3 Average Annual Rates of Deforestation (10^6 ha yr⁻¹) in Developing (Largely Tropical) Regions

	1980–1990	1990–1995
Africa	4.28	3.75
Asia-Oceania	4.41	4.17
Latin America and Caribbean	<u>6.77</u>	<u>5.81</u>
Developing world	15.46	13.73

Source: From FAO, *State of the World's Forests 1997*, FAO, Rome, 1997.

21.3.1.2.2 Tropical Forests

In contrast to the modest increase in developed countries, the average rate of deforestation in developing (largely tropical) countries was 13.7×10^6 ha/year during the first half of the 1990s (Table 21.3), down somewhat from the 15.5×10^6 ha/year rate for the 1980s. The recent rate is equivalent to clearing an area about the size of Georgia or Wisconsin each year. The highest rates (in 10^6 ha/yr) were reported in Brazil (2.554), Indonesia (1.084), Zaire (0.740), Bolivia (0.581), Mexico (0.508), and Venezuela (0.503). For all developing countries, the annual rate of forest loss was about 0.65% of forest area. Relative rates of loss are somewhat smaller in tropical Latin America (0.62%/year) and largest in tropical Asia (0.98%/year). The rates of deforestation in developing countries were offset to some extent by the establishment of forest plantations. Tropical countries reporting the largest areas of plantations in 1995 were India, Indonesia, and Brazil, with 15, 6, and 5×10^6 ha, respectively. Natural forests and plantations are not readily distinguished in developed countries, and so were combined in the discussion of developed countries above.

The errors in the rates of deforestation reported by the FAO are unknown. The most recent assessment by the FAO¹⁴ revised the 1990 estimate of deforestation from 16.3 to 15.5×10^6 ha/year (5%) as a result of new estimates of forest cover in 1980 and 1990. At the other extreme, preliminary national communications from Bolivia and Zimbabwe reported rates of deforestation six times less than reported by the FAO.¹⁶ Other countries were more similar to, or used, the FAO estimate. Mexico reported credible rates that varied between 0.370 and 0.858×10^6 ha/year, a range that is approximately 80% of the mean. It is possible to lower the uncertainty in average rates of deforestation with the use of high-spatial-resolution data from satellites, such as Landsat. However, two estimates of the total area deforested in the Brazilian Amazon, both based on data from Landsat, differed by 25%.¹⁷ The reasons for the difference have not been fully resolved.

One fate of land in the tropics bears special attention from the perspective of deforestation. Most deforestation is thought to be for agriculture. The expansion of human settlements involves relatively little area, and logged areas, if the logging has not been too destructive and if the area is not colonized by farmers, generally return to forests. However, despite the fact that most deforestation is for some form of agriculture, the annual net expansion of agricultural lands is considerably less than the annual net reduction in forest area.¹⁸ For the entire tropics, for example, the expansion of croplands accounted for only 27% of total deforestation. Adding the increase in pasture area accounted for an additional 18% of deforestation. Fully 55% of the deforestation between 1980 and 1985 was explained by an increase in “other land.”¹⁹ Although some of this “other land” is urban land, roads, and other settled lands, these uses are unlikely to have accounted for more than a few percent of the area deforested. Most of the increase in “other land” seems likely to be abandoned, degraded croplands and pastures, lands that no longer support crop or livestock production but that do not revert readily to forest, either.

Forests are not converted directly to degraded areas, of course. The transformation of land is from forest to agriculture and, subsequently, to degraded land. The important point is that only about one half of the area of tropical forest lost each year actually expands the area in agriculture. The other half is only temporarily useful. After a few years it is lost, neither agriculturally productive nor forested. If these estimates are correct, making agriculture sustainable, so that agricultural lands

can be farmed continuously, may be as effective in halting deforestation as increasing the yields of crops.

The fraction of deforestation used to expand the area in agriculture, as opposed to replacing worn-out land, varies among tropical regions. In Africa, the expansion of croplands accounted for only about 12% of the net area deforested. Eighty-eight percent of the decrease in forest area was matched by the expansion of "other land." In tropical Asia, 40% of the net reduction in forests appeared as an expansion of agricultural lands. In Latin America, about two thirds of the reduction in forests could be accounted for by the expansion of croplands and pastures. If agriculture could be made sustainable throughout the tropics, rates of deforestation could be reduced by about 50% without reducing the expansion of agricultural lands, and large areas of marginal or degraded lands might be reforested

21.3.1.3 A Broader Definition of Deforestation: Land-Use Change

Because this review is concerned with the effects of forests and forest management on emissions of greenhouse gases, particularly carbon dioxide, it is important to consider changes in the carbon content, or stature, of forests and not just changes in their area. The carbon content of forests, in MgC/ha (1 Mg = 10^6 g), varies geographically as a function of climate and soil fertility. It also varies temporally as a result of disturbances, including those attributable to human activities, such as logging or shifting cultivation, and as forests respond to management, for example, silviculture or fire suppression (Table 21.2).

21.3.1.3.1 Temperate and Boreal Forests

In temperate and boreal forests, the small net changes in area do not reflect the changes in carbon stocks. Estimates of recent changes in the carbon content of temperate and boreal zone forests suggest that forests were accumulating 0.7 to 0.8 PgC/yr (1 Pg = 10^{15} g) during the 1980s and 1990s.²⁰⁻²² The factors responsible for this net accumulation are uncertain. Changes in land use are not thought to have been responsible because releases of carbon from decay of logging debris and wood products approximately balanced accumulations of carbon in growing forests.^{9,23} Thus, the accumulation of carbon measured in forest inventories has been attributed largely to changing environmental factors or to recovery from past natural disturbances rather than from human activity (land-use change).

A more recent analysis of the United States alone estimated a net uptake (sink) of 0.15 to 0.35 PgC/year,²⁴ but less than half of this sink was in forests, and only 25% of the forest sink was attributed to past changes in land use or management. Although forests in the eastern U.S. were accumulating carbon as a result of fire suppression and the abandonment of agricultural lands, increased rates of logging in the northwest were responsible for a net release of carbon in that region. Another recent analysis of forests in the U.S. found that almost all of the carbon accumulating could be attributed to the age structure of the forests, that is, to past disturbances or management rather than to enhanced growth rates.²⁵ Understanding the reasons for the accumulation of carbon is more than academic. If the present accumulation of carbon is the result of environmental changes (for example, increased concentrations of CO₂ in the atmosphere, deposition of nitrogen, changes in climate), then the sink may be expected to continue until other factors limit forest growth. On the other hand, if the current sink is the result of past land-use and management practices, a continuation of this sink into the future is limited, because, once regrown, forests no longer accumulate carbon.

There are other reasons to suspect that the current terrestrial sink may not continue in the future. Indeed, reductions in forest area could be self-amplifying. One of the effects of a global warming, for example, is likely to be an increased rate of respiration (including decomposition of soil organic matter).^{26,27} Increased emissions of respiratory CO₂ and CH₄, in turn, would increase the warming,

and the warming might then be beyond human control. Perhaps relatedly, the areas burned annually in Canadian and U.S. forests have increased in recent years. Earlier fire suppression allowed carbon to accumulate in both live and dead plant material, but in the last decades, the frequency of fires in Canada seems to have increased dramatically.²⁸ The year 2000 was also a year in which an unusually large area of forest burned in the U.S. Whether the change is related to global warming and whether it will continue in the future are unknown at present. The net effect of numerous other global changes currently underway is difficult to predict. The danger, of course, is that the changes will reduce the capacity of the earth to support life and, further, that the changes will initiate processes in the earth's climate system that are irreversible for generations. For the present, the net flux of carbon into or out of northern forests is small relative to the emissions of carbon from deforestation in the tropics. However, these possible feedbacks are not included in any of the models used to predict future climatic change.

21.3.1.3.2 Tropical Forests

There is considerable evidence that carbon is being lost from tropical forests in addition to the losses resulting from outright deforestation. Selective logging, shifting cultivation, and grazing are widespread within tropical forests, and the increasing practice of these activities for both subsistence and economic interests is reducing the standing stock of carbon in trees.²⁹⁻³⁵

Whether the carbon content is changing in response to factors other than direct human activity is as uncertain in tropical forests as it is in temperate-zone and boreal forests. In fact, changes are more difficult to evaluate in the tropics. In contrast to the national forest inventories of temperate-zone countries, tropical forests have rarely been inventoried. Direct measurement of change is limited to small areas where permanent plots are repeatedly sampled. An analysis of these plots suggests that growth rates may have increased in South America but not in tropical Africa or Asia.³⁶ The finding may be artificial, however, and related more to methods of measurement than to real change.³⁷ Evidence for an accumulation of carbon in undisturbed forests also comes from a small number of sites where the flux of CO₂ has been measured over a forest. Measurements suggest that undisturbed tropical forests are indeed a sink for carbon.^{38,39} However, the method is sensitive to atmospheric conditions, which differ day and night. Because the fluxes also vary day and night, the possibility for a systematic bias in measurement is strong. Indeed, a positive correlation between nighttime respiration and wind speed seems to confirm a methodological, rather than a physiological, basis for variations in respiration and, hence, net uptake. If only those nights with a high wind speed are considered, the calculated net flux of carbon is a source, rather than a large sink (M. Goulden, personal communication).

21.3.1.4 Emissions of Carbon to the Atmosphere Caused by Land-Use Change

The net flux of carbon to the atmosphere from deforestation and reforestation (in the broad sense, including activities affecting biomass within forests) are calculated from two types of information: historic and current reconstructions of land-use change (for example, annual rates of forest conversion to croplands and annual rates of wood harvest) and a knowledge of the per-hectare stocks of carbon in vegetation and soils and changes in these stocks as a result of land-use change. Between 1850 and 1990, about 120 PgC are calculated to have been released globally into the atmosphere from changes in land use.⁴⁰ This value is a net flux; it includes the uptake of carbon in forest growth following harvests as well as the releases of carbon from burning and decay. The total net flux from changes in land use is approximately half of the amount of carbon emitted from combustion of fossil fuels over this period. Before the first part of the twentieth century, the annual net flux from land-use change was greater than annual emissions from fossil fuels. Almost two thirds of the carbon released from terrestrial ecosystems has come from tropical lands; one third has come from temperate and boreal lands. About 90% of the net flux has been from forests, most of the rest arising from cultivation of mid-latitude prairies.

Table 21.4 Relative Contribution of Deforestation to the Anthropogenic Radiative Effect in the 1980s Relative to Preindustrial Times

Gas	Contribution of the Gas to Radiative Forcing ^a	Annual Emissions	Deforestation as Percentage of Total Emissions	Deforestation as Percentage of Radiative Forcing

^b 1 Tg = 10¹² g.

^c 1 Gg = 10⁹ g.

Estimates of the current (1980–1995) net flux from land-use change range between 1.6 and 2.4 PgC/year.^{17,24,40,41} Outside the tropics, estimates of the current net flux of carbon from land-use change are near zero, or slightly negative (carbon accumulating on land). The areas deforested or reforested are relatively small, and most of the flux results from earlier abandonment of croplands, fire suppression, and logging, with associated regrowth. More than 90% of the global flux of carbon is currently from deforestation in the tropics, especially in Asia and Latin America.^{40,41} The countries with the largest sources of carbon are those with the highest rates of deforestation: Brazil, Indonesia, Zaire, Bolivia, Mexico, and Venezuela. Deforestation, in the strict sense, accounts for about 75% of the net flux from the tropics, but reductions in the carbon content of forests (through unsustainable logging and shifting cultivation) are estimated to account for more than 50% of the net carbon loss in some regions of Africa.³⁵

If the net release of carbon from deforestation (the broader definition) was 2.0 PgC/yr (midpoint of the range of estimates), deforestation accounted for about 25% of total carbon emissions and about 15% of the enhanced greenhouse effect during the 1980s (Table 21.4). Notice that the relative contributions of different greenhouse gases in Table 21.4 are not the same as those in Table 21.1. Table 21.1 is a prediction for the next 100 years; Table 21.4 is for the 1980s.

Will the management of forests contribute significantly to averting climatic change, or will the next decades see an increase in the rate of deforestation and higher emissions of carbon? It is impossible to know, but one can ask how much carbon might be released into the atmosphere if current trends continue, or how much carbon might be withdrawn from the atmosphere and accumulated on land if incentives favored a reverse of current trends in land use.

On the assumption that current rates of deforestation would continue (or increase), the release of carbon over the next 100 years would range between 120 PgC and 335 PgC.⁴² In fact, forests will have been eliminated before 2100 in many countries if today's rates continue. These emissions are equivalent to, and about three times greater than, the amount of carbon estimated to have been released from worldwide deforestation in the last 135 years.

On the other hand, if forests were to be reestablished in areas now degraded, and if woody plants were to be introduced into agricultural lands (agro-forestry), tropical lands might be managed to remove 60 to 160 PgC from the atmosphere over the next 50 to 100 years.⁴³⁻⁴⁵ Peak annual accumulations might reach as much as 1.5 to 3 PgC/year for a few years. Allowing secondary forests to recover to full biomass would also contribute to removing carbon from the atmosphere.

The accumulation of carbon through reforestation, although useful in the short term to withdraw carbon from the atmosphere, does not represent a permanent solution. Once forests have grown to maturity, they are essentially in balance with respect to carbon. They continue to hold the carbon they have accumulated, but the rate of accumulation is low. The most effective use of forests from the perspective of atmospheric carbon dioxide is to substitute wood energy for fossil fuel energy. Gross emissions of carbon will be similar, but as long as next year's wood supply is accumulating in growing forests, the emissions of carbon from combustion of wood will be balanced by these accumulations. Fossil fuels, of course, accumulate much too slowly to be used sustainably in this way.

Future projections can be summarized by the six strategies shown in Table 21.5. The strategies are shown for comparative purposes; all six assume that emissions of carbon from fossil fuels will remain constant at 1990 rates (6.0 PgC/year). In fact, emissions have increased over the 1990s. The first strategy represents the current rate of deforestation and fossil fuel use. A total of 8 PgC are being released each year to the atmosphere, mostly as CO₂. The second strategy shows the

Table 21.5 Potential Annual Fluxes of Carbon (PgC/yr) to or from the Atmosphere from Human Activities

Strategy	Fossil Fuel	Deforestation	Reforestation*	Sustainable Harvest of Fuel	Total	Potential Reduction from Present
I	6.0	2.0	<0.1	0	8	0%
II	6.0	2.0	-1 to -2	0	6 to 7	12 to 25%
III	6.0	0.0	<0.1	0	6	25%
IV	6.0	0.0	-1 to -2	0	4 to 5	35 to 50%
V	0	0	0	0	0	100%
VI	0	0	-1 to -2	0	-1 to -2	112 to 125%

Note: Positive values indicate emissions; negative values indicate a removal of carbon from the atmosphere.

- I This strategy represents current (1990) emissions of carbon.
- II Reforestation: 100 to 200 PgC might be stored in new plantations, in forests protected from further logging and shifting cultivation, and in agroforestry. The accumulations of carbon are assumed to take place over 100 years.
- III No deforestation.
- IV Massive reforestation and a halt to deforestation.
- V Replacing fossil fuels with wood-based fuels grown sustainably (this assumes the world energy consumption will not increase substantially above 1990 rates). Combustion of wood fuels emits as much or more carbon to the atmosphere as combustion of fossil fuels. The emissions from wood, however, are balanced by accumulations of carbon in the forests growing to provide the next years' fuel.
- IV All options are put into effect at once. It is very unlikely in this case, where fuelwood plantations are supplying the world's energy needs, that there will be additional land available to accumulate carbon in new forests.
- This annual accumulation of carbon in growing forests persists only while the forests are growing or while new lands are being reforested. Once forests have matured, in 15 to 100 years, they continue to hold carbon, but they no longer withdraw it from the atmosphere.

effect of massive reforestation: an average of about 1.5 PgC/year might be withdrawn from the atmosphere over the next 100 years and accumulated on land, thereby reducing total annual carbon emissions by 12 to 25%. Halting deforestation (strategy III) has a larger effect; it would reduce total annual emissions by 25%. Halting deforestation and increasing the area of forests through reforestation would reduce current emissions by 35 to 50% (strategies II and III together = strategy IV). Both the efforts together still do not reduce emissions by the 60% necessary for stabilization of atmospheric CO₂ concentrations at today's levels. Furthermore, as mentioned above, reforestation is a temporary solution for reducing atmospheric concentrations of CO₂. Reductions of emissions by 60% or more require halting deforestation and substituting wood-derived fuels for fossil fuels (strategy V). If massive reforestation were to occur as well (strategy VI), worldwide emissions of carbon would be negative. Only strategies V and VI will halt the rise in atmospheric CO₂, and these estimates are wildly optimistic. Clearly, the major reductions in emissions will have to come from a reduced use of fossil fuels.

21.3.2 Methane, Nitrous Oxide, and Carbon Monoxide

The major emissions of CH₄, N₂O, and CO from deforestation do not necessarily occur with the deforestation itself but with subsequent use of the land. For example, paddy rice, cattle, and biomass burning account for 20, 15, and 8%, respectively, of the total annual emissions of CH₄, and the burning associated with deforestation releases little of this CH₄. Similarly, most N₂O is released from land in the months and years following deforestation, especially if nitrogen fertilizers are applied to enhance or maintain productivity.

Part of the carbon emitted to the atmosphere as a result of deforestation is released through burning, but the majority is released through decay.³² Biomass burning, on the other hand, is a major source of atmospheric CH₄, CO, and other chemically reactive gases that are important because they contribute either directly or indirectly to the heat balance of the earth. The accumulation of CH₄ in the atmosphere contributed about 20% of the enhanced radiative forcing in the decade of the 1980s; the contribution from N₂O was about 4% (Table 21.4). While CO is not radiatively important itself, it reacts chemically with hydroxyl radicals (OH) in the atmosphere, thereby affecting the concentration of CH₄.

21.3.2.1 Methane

A small fraction (0.5 to 1.5%) of the carbon released into the atmosphere during biomass burning is CH₄. The radiative effect of a molecule of CH₄, however, is 25 times that of a CO₂ molecule, so if as much as 4% of the carbon were emitted as CH₄, the radiative effects of the CO₂ and CH₄ emissions would be equal in the short term. Because the average residence time of CH₄ in the atmosphere is only about 10 years, while that of CO₂ is 50 to 200 years, the long-term radiative forcing of CO₂ is larger than that for CH₄.

If the ratio of CH₄/CO₂ emitted in fires associated with deforestation is 1%, and if 40% of the emissions from deforestation results from burning,⁴⁶ then only about 10 Tg (1 Tg = 10¹² g) of CH₄ were emitted to the atmosphere directly from deforestation. But this flux is based on the net flux of CO₂. Gross burning is estimated to release about 40 Tg CH₄ annually from burning of pastures, grasslands, and fuelwood.⁴⁷ In addition, about 80 Tg CH₄ are released from cattle ranching, and about 60 Tg are released from rice cultivation. Because some of these releases are from lands never forested, the contribution from deforestation is somewhat less than the total release of 260 Tg CH₄. Overall, about half of the global emissions of CH₄ results directly and indirectly from deforestation. More than half of this flux is a result of tropical deforestation and land use, with a lesser fraction released from outside the tropics. The expansion of wetlands through flooding of forests for hydroelectric dams could become a significant new source of CH₄ in the future.

21.3.2.2 Nitrous Oxide

Nitrous oxide (N_2O) is also a biogenic gas emitted to the atmosphere following deforestation. Small amounts of N_2O are released during burning, but most of the release occurs in the months following a fire, especially in new pastures. Fire affects the chemical form of nitrogen in soils and, as a result, favors a different kind of microbial activity (nitrification). One of the by-products of nitrification is the production of NO and N_2O .

Estimates of the global emissions of N_2O are uncertain. Industrial sources are thought to contribute about 1.3 Tg N_2O -N per year as a result of fossil fuel combustion and the production of adipic acid (nylon) and nitric acid. Biomass burning is estimated to release 0.2 to 1.0 Tg N_2O -N per year, and cultivated soils are estimated to release between 0.03 and 3.0 Tg. The role of soils is very uncertain. They may be both a major sink and a major source of atmospheric N_2O . Fertilized soils may release ten times more N_2O per unit area than undisturbed soils, and the soils of new pastures may release even higher amounts. Deforestation may be responsible for about 20% of the global increase in N_2O concentrations (Table 21.4).

21.3.2.3 Carbon Monoxide

Carbon monoxide (CO) is not a greenhouse gas, but it affects the oxidizing capacity of the atmosphere through interaction with OH and thus indirectly affects the concentrations of other greenhouse gases such as CH_4 . Increased concentrations of CO in the atmosphere will deplete the concentrations of OH, leave less of the radical available to break down CH_4 , and thereby increase the concentration and atmospheric lifetime of CH_4 . Carbon monoxide emissions are generally 5 to 15% of CO_2 emissions from burning, depending on the intensity of the burn. More CO is released during smoldering fires than during rapid burning or flaming. The burning associated with deforestation may thus release 40 to 170 Tg C as CO. In addition, the repeated burning of pastures and savannas in the tropics is estimated to release 200 Tg C, as CO .⁴⁸ Together, these emissions from the tropics are as large as industrial emissions.

The emissions of CO_2 , CH_4 , and N_2O from tropical deforestation and from subsequent use of the land are shown in Table 21.4. Summing the emissions and taking into account their relative contributions to radiative forcing in the decade of the 1980s⁶ shows that deforestation directly and indirectly accounts for about 25% of the radiatively active emissions globally. Most of the emissions of CO_2 from deforestation are from the tropics, but significant emissions of CH_4 and N_2O result from land use outside the tropics.

21.4 OPTIONS FOR INCREASING TERRESTRIAL CARBON STORAGE

About 84 nations have signed (although not ratified) the Kyoto Protocol, which stipulates that industrial countries are to reduce their emissions of greenhouse gases by an average of 5% below their 1990 emissions by the first commitment period, 2008–2012. The Protocol specifically recognizes that sources and sinks of carbon attributable to afforestation, reforestation, and deforestation (ARD) are to be counted in achieving these emissions reductions. It also recognizes that sources and sinks of carbon from other activities besides ARD may be counted but does not specify which ones.

The recognition by the Kyoto Protocol that certain terrestrial carbon sinks may be counted in meeting industrialized countries' emissions reductions has met with considerable criticism. Many European nations and some environmentalists argue that counting terrestrial sinks will take the pressure off the more critical need to reduce emissions of carbon from fossil fuels. The United States, Canada, and others, on the other hand, do not want sinks limited to afforestation and reforestation because there are many other activities and management options that may be used to

sequester carbon. The recently published IPCC Special Report on Land Use, Land-Use Change, and Forestry⁴⁹ provides detailed scientific and technical advice on the feasibility and consequences of defining, counting, and measuring sources and sinks of carbon resulting from ARD and other activities. The issues are complex, both scientifically and politically. The Sixth Conference of the Parties in The Hague in November 2000 failed to reach agreement on how to include terrestrial sinks.

In answer to the question of which sources and sinks should be counted, there are almost as many answers as there are parties to the UN Framework Convention on Climate Change (UNFCCC). The final section of this review addresses this question from the perspective of what is known about the global carbon cycle. The emphasis is on carbon because carbon dioxide has been and is expected to be the most important of the greenhouse gases resulting from human activities. Furthermore, carbon dioxide is the only greenhouse gas that can be accumulated on land and, therefore, withheld, at least temporarily, from the atmosphere. Five broad options are considered:

- Count only those sources and sinks of carbon that result from human activity
- Count only those resulting directly from human activity
- Count only those resulting from afforestation, reforestation, and deforestation
- Count all terrestrial sources and sinks, whatever the cause
- Count no terrestrial sources and sinks of carbon at all

21.4.1 Count Only Those Sources and Sinks of Carbon that Result from Human Activity

The first option considered is to include all sources and sinks of carbon that are the result of human activity. This option appears ideal because the UNFCCC and Kyoto Protocol are concerned with reporting and counting anthropogenic sources and sinks. Anthropogenic sources and sinks are defined as those “that are a direct result of human activities or are the result of natural processes that have been affected by human activities.”⁵⁰ The latter category may also be called “indirect” anthropogenic effects. Sources and sinks not the result of human activity are, by definition, outside of human control and thus not to be penalized or rewarded.

The difficulty with this option is that distinguishing anthropogenic from nonanthropogenic sources and sinks is scientifically difficult. There are at present no direct methods at any scale that enable the net uptake of carbon in forests to be divided between anthropogenic and nonanthropogenic causes. The difficulty in distinguishing anthropogenic and nonanthropogenic factors pertains to almost all measurements of net carbon balance, whether through direct measurement of wood volumes in forest inventories, through direct measurement of CO₂ flux over a forest,^{38,39} or through model inversions based on atmospheric CO₂ concentrations and simulated atmospheric transport.^{51–53} If logging or agricultural abandonment were the only activities that led to forest growth, measured growth could be attributed to human activity. But the regrowth of forests may also result from natural disturbances (fire, insects, disease) that are not attributable to human influence, and rates of growth may vary in response to both human-induced and natural variations in the environment (atmospheric CO₂, nitrogen deposition, climate).

The global carbon cycle may be summarized by the following equation, where sources (+) and sinks (–) of carbon, in PgC year⁻¹, are annual averages for the period 1980–1989:

$$\begin{array}{rcccccc} \text{Atmospheric} & & \text{Fossil} & & \text{Net source} & & \text{Oceanic} & & \text{Residual} \\ \text{increase} & = & \text{fuel} & + & \text{from changes} & - & \text{sink} & - & \text{terrestrial} \\ & & \text{source} & & \text{in land use} & & & & \text{sink} \end{array}$$

$$3.3(\pm 0.2) = 5.5(\pm 0.5) + 2.0(\pm 0.8) - 2.0(\pm 0.8) - 2.2(\pm 1.3) \quad (21.1)$$

The net terrestrial sink is only 0.2 PgC year⁻¹, resulting from a 2.0 PgC year⁻¹ source directly attributable to human activity (deforestation in the broad sense) and a 2.2 PgC year⁻¹ (residual)

sink attributable to either indirect anthropogenic effects or nonanthropogenic effects. The magnitude of the sink is large — as large as the source attributed to land-use change. Some countries would like to be able to claim credit for this sink, but others insist that credit should only result from anthropogenic-induced changes, in other words, from deliberate management.

The distinction between anthropogenically induced and nonanthropogenically induced carbon storage might be demonstrated with controlled experiments for some processes, such as the accumulation of carbon in soils under alternative management practices. For forest growth, however, controlled experiments would be difficult to carry out and interpret. A recent analysis used successive measurements of wood in U.S. forests to show that the accumulation of carbon could be attributed to the age structure of the forests rather than to changing environmental conditions that may have enhanced growth.²⁵ But the age structure results from both natural disturbances and management — for example, agricultural abandonment or fire suppression — so a direct anthropogenic cause is not clear from the analysis. Distinctions between the factors responsible for accumulations of carbon might be determined in the future with process-based ecosystem models, but the current variability in the predictions of such models suggests that their use is not yet reliable enough for attribution.

The distinction between anthropogenic and nonanthropogenic sinks can be made politically, of course, and because of the incentives, countries will want to claim all sinks as anthropogenic. The accumulation of carbon in a forest, for whatever reason, can be defined as anthropogenic simply by declaring the forest is managed. Management is a direct anthropogenic activity, and the decision to do nothing (for example, the decision not to suppress fires) is a management decision. Credit might even be claimed for terrestrial sinks resulting from CO₂ fertilization, i.e., from fossil fuel CO₂ emissions. While there is a certain logic to this claim (higher concentrations of CO₂ enhance forest growth and thus store more carbon), again, it is difficult, at present, to determine the fraction of observed growth attributable to elevated CO₂. To avoid a bias in counting sinks, and not sources, policies might require that all lands counted as sinks be counted in subsequent commitment periods, whether or not they are still functioning as sinks.

Overall, although this option may be logically the most appealing in terms of counting the appropriate sources and sinks, it is also the most difficult to implement scientifically (that is, it contains the largest number of uncertainties). All or none of the 2.2 PgC/year residual sink might be anthropogenic and, by this option, countable (Table 21.6).

It is worth recognizing that sources and sinks of carbon need not be debited and credited to the countries in which they occur. If reliable methods are eventually developed for distinguishing anthropogenic and nonanthropogenic changes in carbon storage, nonanthropogenic changes might be added to a global pool to be divided proportionally among all participating countries. During periods when atmospheric concentrations increase more than expected, anthropogenic emissions might have to be reduced more than anticipated. Conversely, during periods when the growth rate of atmospheric CO₂ is lower than expected, emissions might be allowed to increase. Such an approach would shift the “costs” of nonanthropogenic emissions to the entire community and not penalize (or reward) an individual country. Although such an approach seems worth exploring, balancing incentives for carbon storage within countries with issues of equity among countries will be complex.

21.4.2 Count Only Those Resulting Directly from Human Activity

A modification of the first option, that is, including only those terrestrial sources and sinks that result directly from anthropogenic activities, fares little better in terms of attribution. The global flux of carbon attributed to changes in land use, including forestry, averaged about 2.0 PgC year⁻¹, or 35% of fossil fuel emissions during the 1980s.⁴⁰ But this global perspective hides variation among countries. Almost all of this source was emitted from tropical countries as a result of deforestation. In temperate-zone and boreal countries, carbon sources from decay of wood products

Table 21.6 Global Terrestrial Sources (+) and Sinks (–) of Carbon (PgC yr⁻¹) Counted and Not Counted for the Five Options Discussed in the Text

Terrestrial Sources and Sinks	Counted	Not Counted ^a
1. Changes in carbon directly and indirectly attributable to human activity	–0.2 to 2.0 ^b	0 to –2.2
2. Changes in carbon directly attributable to human activity	2.0	–2.2
3. Changes in carbon resulting from afforestation, reforestation, and deforestation	1.7	–1.9
4. All changes in carbon	–0.2	0
5. No changes counted	0	–0.2

^a The total net flux of carbon always sums to –0.2 PgC year⁻¹ (Equation 21.2). This global net sink is composed of a source of 2.0 PgC year⁻¹ from changes in land use (directly human induced) and a sink of –2.2 PgC year⁻¹ that may have been caused either indirectly from human activity, from non-anthropogenic factors, or from some combination of the two.

^b The range results from not knowing whether the residual terrestrial sink is human-induced or not. If all terrestrial sources and sinks of carbon result either directly or indirectly from human activity (assuming that methods exist for distinguishing human-induced from non-human-induced changes), then human activity accounts for a net sink of 0.2 PgC year⁻¹. At the other extreme, if none of the residual sink results from human activity, then the effect of human activity is equivalent to the source of carbon from land-use change (2.0 PgC year⁻¹).

were approximately offset by sinks in regrowing forests.⁴⁰ In contrast, the geographic distribution of the residual terrestrial sink is uncertain, as are the mechanisms responsible for it. Under this option, no countries would receive credit for the residual sink of 2.2 PgC year⁻¹ (Table 21.6).

To avoid endless discussions of whether sources and sinks of carbon are anthropogenic or not, or direct rather than indirect, there are at least three other options. First, credit might be limited to the sinks resulting from specific activities (option 3, below). Option 4 is to count all changes in terrestrial carbon, ignoring the distinction between anthropogenic and nonanthropogenic causes. And the last option (5) is to ignore terrestrial sources and sinks altogether and consider only changes in fossil fuel emissions.

21.4.3 Count Only Those Resulting from Afforestation, Reforestation, and Deforestation

In the current formulation of the Kyoto Protocol, sources and sinks of carbon from afforestation, reforestation, and deforestation (ARD) are to be counted (Article 3.3). These activities are a subset of the changes in land use considered in option 2 above; changes in carbon within existing forests (for example, as a result of logging) do not count. Counting ARD activities creates an incentive to reduce emissions. The elimination of deforestation would reduce global emissions by an estimated 1.7 PgC year⁻¹ (Table 21.6). Increased afforestation and reforestation have the potential to reduce emissions (increase the storage of carbon on land) by as much as 1.5 to 2.2 PgC year⁻¹.^{43,54,55}

Under most definitions of deforestation, this option does not include forestry, that is, the harvest and subsequent regrowth of forests. At a global level, not much is lost in ignoring harvests of wood. Deforestation (conversion of forests to croplands and pastures) accounted for about 85% of the net changes in carbon attributable to land-use change in the 1980s⁴⁰ (Table 21.6). Wood harvest, including the fate of harvested products as well as subsequent regrowth of harvested forests, contributed only 15% of the terrestrial source from land-use change. Again, one disadvantage of ignoring harvests is that they may account for much more than 15% of the terrestrial source of

carbon in individual countries, while in other countries, such as those in the northern mid-latitudes, past harvests (as well as management) may be a major cause of the current sink.^{20,21,24} Limiting the counting of terrestrial sources and sinks to ARD alone reduces the incentive for forestry practices that sequester carbon. It also reduces the incentive to substitute wood-based fuels and products for fossil-based fuels and products, a practice that could reduce emissions of carbon significantly.⁵⁶

On the other hand, there are advantages to limiting the counting of sources and sinks to ARD activities. The advantages result from the magnitude of the changes, their unambiguous nature, and, hence, the ease of measurement. As pointed out above, ARD activities account for 85% of the net emissions from changes in land use. Fossil fuels and ARD together account for more than 95% of the global carbon emissions resulting directly from human activity. Second, because ARD activities involve the replacement of open lands with forests and vice versa, the per-hectare changes in aboveground carbon are large and readily measured. Third, the areas affected by ARD activities can be reasonably well defined through national surveys and remote sensing techniques. And finally, most of the changes in carbon resulting from ARD can be attributed to direct anthropogenic activity. On any particular hectare, some fraction of the observed increase in carbon storage may result from elevated CO₂ or N deposition, but the fraction is probably small relative to the increased storage resulting from afforestation or reforestation of that hectare in the first place. In contrast, the environmental enhancement of growth in existing (grown) forests may be large relative to an average accumulation of nearly zero, while at the same time the mechanisms responsible for such an enhancement are difficult to demonstrate (see next option).

21.4.4 Count All Terrestrial Sources and Sinks, Whatever the Cause

The fourth option is to ignore the distinction between anthropogenic and nonanthropogenic fluxes and, instead, to measure and count all changes in terrestrial carbon (full carbon accounting).⁵⁷ From one perspective, counting all terrestrial sources and sinks of carbon is consistent with the intent of the UNFCCC: stabilization of atmospheric concentrations of greenhouse gases at a level that would prevent dangerous anthropogenic interference with the climate system. Atmospheric concentrations are determined by the sum of all sources and sinks, not just anthropogenic ones. Why not count all? The major obstacle to full carbon accounting is the technical challenge (and cost) of measuring changes in carbon over the entire earth. At present, global analyses based on atmospheric data and models infer a net change in terrestrial carbon storage that, if correct, implies errors as large as 500% in the forest inventories of northern mid-latitudes: 0.6 PgC year⁻¹ (see Reference 21) vs. 3.5 PgC year⁻¹ (see Reference 51). Recent analyses demonstrate the same relative discrepancy in North America.^{24,58} Full carbon accounting offers the potential to resolve the discrepancy, but the methods will have to have an accuracy much higher than the techniques used to date if the resolution is to be successful.

21.4.5 Count No Terrestrial Sources and Sinks of Carbon at All

The last option considered here is to ignore terrestrial sources and sinks of carbon altogether. The arguments for ignoring these fluxes are that they are uncertain, small relative to the emissions from fossil fuels, and not worth the effort of measurement, verification, and international negotiation. From the global perspective, the net annual flux of carbon between terrestrial ecosystems and the atmosphere is small and, arguably, not worth measuring or counting for the Kyoto Protocol.

$$\text{Atmospheric increase} = \text{Fossil fuel source} - \text{Oceanic sink} - \text{Terrestrial sink}$$

$$3.3(\pm 0.2) = 5.5(\pm 0.5) - 2.0(\pm 0.8) - 0.2(\pm 1.3) \quad (21.2)$$

The equation shows that terrestrial ecosystems were a small net sink during the 1980s, accumulating less than 5% of the fossil fuel source. The fraction may have increased during the 1990s. Recent estimates include net terrestrial sinks of 1.8 PgC for a single year (1992),⁵¹ 0.7 PgC year⁻¹ for the interval 1980–1995,⁵² and 1.3 PgC year⁻¹ for the period 1985–1995.⁵³ These three estimates include only atmospheric exchanges, and if an additional 0.4 to 0.7 PgC is transferred each year from land to ocean through rivers,⁵⁹ estimates of the net increase in terrestrial carbon storage range between about 0 and 1.4 PgC year⁻¹. The latitudinal distribution of this net terrestrial sink is uncertain.

Given the uncertainty, the year-to-year variability, and the small magnitude of this net flux, one might conclude that omitting it from the Kyoto Protocol would be justified. Consideration of fossil fuels alone addresses 75 to 100% of the net anthropogenic emissions of carbon to the atmosphere. Attention to terrestrial sources and sinks dilutes the attention that should be focused on the reduction of fossil fuel use. The counter argument is that there ought to be incentives to halt deforestation and increase the area of forests, thereby reducing net emissions of carbon to the atmosphere. Furthermore, even if the net change in terrestrial carbon storage is small, globally, it is not small for individual countries. In many tropical countries, for example, the emissions of carbon by terrestrial ecosystems are large relative to emissions from fossil fuels.⁶⁰ And in countries of the temperate zone, terrestrial sinks may help reduce net emissions significantly. Regardless of the arguments, ignoring terrestrial sinks is not currently an option under the Kyoto Protocol.

21.5 SUMMARY AND CONCLUSION

Deforestation releases carbon, principally as CO₂, to the atmosphere as the organic carbon stored in trees and soil is oxidized through burning and decay. Emissions of other greenhouse gases, such as CH₄ and N₂O, are also increased as a result of the conversion of forests to agricultural lands. Current emissions of greenhouse gases from deforestation account for about 25% of the global warming calculated to result from all anthropogenic emissions of greenhouse gases. The greatest rates of deforestation are currently in the tropics, but the greatest emissions of greenhouse gases from all sources, including fossil fuels, are from industrialized countries in the northern mid-latitudes. If current trends continue, tropical forests will be eliminated over the next 100 years or so, and in the process about as much carbon will be released into the atmosphere as was emitted from worldwide combustion of fossil fuels since the start of the industrial revolution. Continued emissions of greenhouse gases from both deforestation and industrial sources will raise global mean temperature by an estimated 1 to 3.5°C by the end of this century.

To avert such a warming, the concentrations of greenhouse gases in the atmosphere must be stabilized. The steps needed for stabilization include (1) a large (= 60%) reduction in the use of fossil fuels, through increased efficiency of energy use and a much expanded use of renewable energy sources; (2) the elimination of deforestation; and (3) reforestation of large areas of land, either to store carbon or to provide renewable fuels to replace fossil fuels. These steps required to curb global warming are good for a host of reasons independent of climatic change. The initial steps may even have negative costs. Eventually, the realization of these steps will be difficult and expensive, but the costs of coping with rapid, continuous, irreversible climatic change will also be expensive.

One of the issues that the nations of the world need to resolve for reducing emissions of greenhouse gases is the accounting of terrestrial sources and sinks of carbon. The ideal option for counting terrestrial sources and sinks of carbon (including only those sources and sinks resulting from human activity) is also the most difficult to implement. Methods cannot yet distinguish between anthropogenic and nonanthropogenic changes in carbon storage. The least expensive option for counting terrestrial sources and sinks is to ignore them altogether. Emissions of carbon from fossil fuels accounted for about 75% of global emissions in the 1980s, and the percentage has increased since then. However, an important incentive is lost in not considering terrestrial sinks. Furthermore, in a world with reduced fossil fuel emissions, the emissions from land-use

change may become more important unless they too are reduced. Although counting all sources and sinks would contribute dramatically to scientific understanding of the carbon cycle and thereby increase the confidence of predictions of future atmospheric concentrations from alternative emissions scenarios, the more straightforward (and less expensive) option seems at present to be the one that the Kyoto Protocol initially recognized (ARD), perhaps expanded to include a few other well documented activities that lead to unambiguous changes in carbon storage. Despite numerous arguments to the contrary, the Kyoto Protocol seems to have selected the most feasible, cost-effective, and appropriate option.

Less than full carbon accounting is consistent with the purpose of the UNFCCC, which is to reduce emissions of greenhouse gases so as to avoid dangerous changes in climate. The counting need not be complete, but for precautionary reasons, it must not overestimate sinks (or underestimate sources). In this respect, limiting the counting to a few unambiguous activities is safer than full carbon accounting. The precautionary bias is especially important because of the difference between the common (global) good and the individual (national) good (the tragedy of the commons). Mechanisms for protecting the common good include symmetry and permanence. Symmetry suggests that sinks from reforestation cannot be counted unless sources from prior deforestation are also counted, even if deforestation is accidental and reforestation deliberate. Permanence suggests that parcels of land counted (and thus identified) as sinks must be counted in all subsequent commitment periods. Some forests may switch from sinks to sources in the future (for example, as a result of fire or warming-enhanced respiration), and those sources need to be counted. It is neither consistent with the intention of the UNFCCC nor logical to count sinks (deposits) and not sources (debits). It is important to note, however, that even if some forests change from sinks to sources of carbon, they still hold more carbon than lands without forests.

22.1 INTRODUCTION

Pathogenic organisms are normal components of all ecosystems. Simply defined, pathogenic organisms are life forms that cause disease in other life forms. Most are parasites that live at the expense of their host. Some are free-living but cause disease indirectly, such as by producing toxins to which other life forms become exposed. Ecotoxicology is generally considered to be the study of chemical pollutants in ecosystems. However, pathogenic organisms and the diseases they cause are relevant in this context in several different ways. Pathogens can be regarded as pollutants when they are released by humans into ecosystems for the first time or when they are concentrated in certain areas by human activity. Human activities also can alter ecosystems in ways that change the relationships among pathogens and their hosts and, thus, the occurrence of diseases. The transportation of plants, animals, and human beings around the world has created many new associations of potential pathogens, hosts, vectors, and environments out of which a substantial number of new or newly important diseases have recently emerged. The technology of genetic engineering has made possible the creation of whole new strains of pathogens that are indeed man-made.

This chapter begins with a brief discussion of the nature of pathogenic organisms and the factors that influence the occurrence of the diseases they cause. Four situations in which human activities can alter the occurrence of diseases in the environment are then considered: (1) translocation of pathogens, host species, and vectors to new environments; (2) concentration of pathogens or host species in particular areas; (3) changes in the environment that can alter host-pathogen relationships;

and (4) creation of new pathogens by intentional genetic modification of organisms. While most of the examples used are of diseases in vertebrate animals, the principles exemplified apply to all life forms.

22.2 PATHOGENS AND DISEASES

The relationships among pathogens, their hosts, their biological vectors where such exist, and the occurrence of disease are complex.¹ Infection and disease are not synonyms. Infection is entry and growth of a parasitic organism in the body of a host organism, while disease is some departure from a normal state of health. Whether or not infection of a host organism with a pathogen will result in disease usually depends on interactions among specific aspects of the biology of both the host and the pathogen and on environmental factors that interact with both. For example, in vertebrates, many pathogenic bacteria and viruses readily cause disease when they infect individuals for the first time. However, subsequent infections with the same organisms often cause no disease at all. This is the usual situation with the common diseases of childhood, for example, and results from a change in host physiology after the first encounter with the pathogens such that immune defenses against those specific pathogens are greatly enhanced. The eminent ecologist Paul Erington studied the occurrence of epidemic mortality in muskrats due to infection with the bacterium *Clostridium piliforme* and found that, while the causal bacterium appeared to be a constant presence in the muskrats' environment, it caused epidemic disease only under conditions of inadequate food supply, drought, or very high muskrat population densities.²⁻⁴ These examples illustrate that the occurrence of infectious disease can be influenced by many factors; infection with a pathogen is not the only important variable. Rudolph Virchow, a father of modern medicine, recognized this with startling insight in 1848 when he pronounced that the cause of epidemic typhus, then raging in rural Prussia, was poverty, and that it could be prevented by education, liberty and prosperity.⁵

For any particular pathogen, there can be considerable variation in the ability of individual pathogenic organisms to cause disease. Most readers will be aware that, in humans, some strains of influenza virus cause more severe disease than do others. Similarly, there are many strains of the Newcastle Disease virus, an important pathogen of domestic chickens. Some cause rapidly-lethal disease, while others cause no disease at all in chickens but may cause serious disease in other species of birds.⁶⁻⁷ Examples of eukaryotic pathogens that show great variation in ability to cause disease, include the protozoans *Trichomonas gallinae* in doves and *Trypanosoma brucei* in humans and other African mammals.⁸⁻⁹

Many organisms we consider to be pathogens are, in fact, rather benign parasites of their normal host species. This is a common, though not universal, theme among infectious diseases: severe disease may be uncommon in the infected normal host but common when unusual hosts are infected. For example, *Yersinia pestis*, the bacterium that causes Bubonic Plague, is a normal parasite of certain wild rodents and their fleas. In this natural setting, infection is widespread, but lethal disease is rare and even mild disease is unusual. Large outbreaks of severe disease occur when the bacterium is introduced into abnormal but susceptible hosts living at high density such as prairie dogs, urban rats, and urban humans.¹⁰⁻¹¹ Dutch elm disease in American Elms, and Lassa fever and Lyme disease in humans are all examples of diseases in which parasites that are relatively benign in their normal hosts cause severe disease when they infect new hosts.¹²⁻¹⁴ These relationships between pathogens and hosts are not fixed, however. Sometimes there can be coevolution of parasites and hosts that often leads to a degree of mutual adaptation. The pathogen may lose some of its pathogenicity for the new host, while the host may develop some resistance to the pathogen.¹⁵

There are some similarities between pathogenic organisms and chemical poisons as causes of disease. The effects that both may have on their hosts can vary over a continuum from no detectable effect to rapid death and includes chronic debility and impaired reproduction that can persist indefinitely. Also, for many pathogens, there is a positive relationship between dose and

response such that the occurrence and severity of disease are proportional to the number of pathogenic organisms to which a host organism is exposed. Like polluting chemicals, pathogens exert their effects on populations, communities, and ecosystems through their effects on individual host organisms.

However, there also are important differences between chemicals and pathogenic organisms as causes of disease. Pathogenic organisms are alive. They reproduce, pass from host to host, often by intricately complex methods, and they evolve and change over time as do other living things. A pathogenic organism, released in a new environment in which it can survive, cannot be controlled simply by ceasing the practice that led to its release. The ecosystem itself has been infected, and the pathogen is there for good. Furthermore, pathogenic organisms are normal constituents of ecosystems. They play important roles in the population dynamics of their host species and should be regarded, in general, as components of ecosystems that contribute to stability and resilience.^{3,16-17} Thus, pathogenic organisms can be viewed in several different ways in the context of ecology. The emphasis here is on situations in which human activity can increase the negative impact of pathogenic organisms on host species.

22.3 TRANSLOCATION OF PATHOGENS, HOSTS, AND VECTORS

Movement of people, plants, animals, and products around the world now occurs rapidly and on a vast scale.¹⁸ This movement, or translocation, has the potential to introduce pathogens into ecosystems, to place species of animals and plants into ecosystems that contain pathogens to which the introduced organisms are susceptible, or to introduce into ecosystems species (vectors) that can transmit pathogens from one host to another in new ways. In each scenario, there is potential for a negative impact on populations, communities, and ecosystems, on conservation programs, on human health, and on human economies. Several examples will serve to illustrate these points.

Two parasitic fungi introduced into North America in the 1900s have had major impacts on their host species and associated ecosystems. *Ceratocystis ulmi*, the fungus that causes Dutch elm disease, probably evolved in Asia in elm species with which it had a stable relationship. The fungus arrived in North America with logs imported for veneer manufacture, and the disease was first recognized in American elms (*Ulmus americana*) in Ohio in 1931. Within a few decades, most American elms were dead. The death of the American chestnut (*Castanea dentata*) due to the fungus *Endothia parasitica*, the pathogen of Chestnut blight, also is attributed to importation of a new pathogen from Asia, where it had a stable host-parasite relationship with Asian chestnuts. The American chestnut was the dominant forest tree over much of its former range in eastern North America, and the forest ecosystem it dominated was altered abruptly and completely by the blight; nothing like the primeval forest of eastern North America now exists.¹⁹

Human populations have been directly and severely affected from time to time by introductions of new pathogens. Aboriginal Americans were overwhelmed and severely depopulated by European diseases, particularly smallpox, well in advance of any military or economic conquests.²⁰⁻²¹ Bubonic plague, caused by the bacterium *Yersinia pestis* and introduced to new human populations through trade routes with Asia, may have killed as many as 100 million people during the first recognized pandemic (wide-spread epidemic) that began in 542 A.D. and killed millions more in two subsequent pandemics and numerous regional epidemics in subsequent years.¹¹ The current epidemic of Acquired Immunodeficiency Syndrome (AIDS) is an example of pathogens (Human Immunodeficiency Viruses 1 and 2) spreading from their sites of origin in Africa to new populations on that continent and elsewhere. This process appears to be driven by recent and profound alterations in human ecology including urbanization, improved medical care, and travel.²²

Translocation of human pathogens may have major economic impacts, even if the pathogens' direct effects on human health are small. For example, the epidemic of rabies in raccoons (*Procyon lotor*) that has spread up the east coast of the United States and into Canada over the past 20 years

was initiated by translocation of rabid raccoons from a distant endemic area to the state of West Virginia; it has required vast expenditure of public-health funds on postexposure treatments of people bitten by raccoons and on vaccination of wildlife.²³⁻²⁴ Similarly, the introduction of West Nile virus to the New York City area in the summer of 1999 and its subsequent centrifugal spread evoked massive public expenditure on disease surveillance and mosquito control, severely taxing federal, provincial, state, and municipal resources.²⁵⁻²⁶

Outbreaks of new diseases are most often documented and studied in terms of their effects on a particular affected species rather than in terms of ecosystem-level effects. However, some data are available regarding effects of newly introduced pathogens beyond those on the host species itself. Myxomatosis in England is a case in point. The poxvirus that causes myxomatosis is a New World parasite of rabbits of the genus *Sylvilagus*. It causes severe, lethal disease in 90 to 99% of infected European rabbits (*Oryctolagus cuniculus*) and has been introduced around the world to control rabbit populations. It reached England in 1954 and exterminated rabbits over large areas.²⁷ An intensive study of the vegetation of several areas affected by myxomatosis was undertaken from 1954–1957 and documented major alterations as a result of the absence of grazing by rabbits. In general, grassland species declined in density and diversity, while woody plants, such as gorse and brambles, grew and multiplied.²⁸ These effects of rabbit removal are not surprising, but they emphasize the potential ecological effects that new pathogens can have as a result of their effect on their own host species.

Animals or plants translocated to new environments may themselves be at risk from pathogens already present in these environments. This situation can have tragic impacts on conservation efforts such as recovery programs for endangered species. For example, efforts to reintroduce caribou (*Rangifer tarandus*) to Cape Breton Highlands National Park in Nova Scotia (Canada) and to parts of the State of Maine (U.S.), where caribou once were native, have failed because of the presence of a nematode parasite, *Parelaphostrongylus tenuis*, which causes fatal infection in caribou. This parasite had become endemic in both reintroduction sites through expansion of the range of the white-tailed deer (*Odocoileus virginianus*), its normal host.²⁹⁻³¹ Similarly, the recovery program for the endangered whooping crane (*Grus americana*) included establishment of a captive breeding population in the eastern United States, outside of the normal geographic range of the species. In this new environment, the cranes encountered an endemic pathogen, eastern equine encephalitis virus, which is not present in their native habitat and which caused fatal disease.³²

Some pathogens require a living organism to transmit them efficiently among susceptible hosts. Organisms that carry pathogens from host to host are called vectors; blood-feeding arthropods, such as ticks and mosquitoes, often serve as such vectors. The presence or absence of vectors and the efficiency of the various vectors present as transmitters of a particular pathogen can influence greatly the occurrence of infection and disease among susceptible host species in an ecosystem. Thus, the introduction or elimination of the vector of a pathogen in an ecosystem has the potential to alter the effects of that pathogen on host populations. For example, infection with *Borrelia burgdorferi*, the agent of Lyme disease, occurs in animals only in ecosystems that support the few species of ticks that transmit the disease.³³⁻³⁴ Similarly, the fungus that causes Dutch elm disease is spread from tree to tree by a bark-dwelling beetle and does not spread in the absence of the beetle. Thus, introduction and establishment of new vector species in ecosystems has the potential to radically alter host-pathogen relationships or to create conditions under which a pathogen introduced from elsewhere may successfully establish in a new ecosystem because a vector necessary for its survival is now present.

The effect of introductions of new pathogens and of vectors on native birds of the Hawaiian Islands is an instructive example.³⁵ Over half of the native land bird species of these islands became extinct between about 1800 and 1940.³⁶ There were many causal factors associated with these extinctions, beginning with the arrival of human beings, and, subsequently, of rats, pigs, cats, and mongooses.³⁶⁻³⁸ Two introduced diseases, avian malaria and avian pox, appear to have played very significant roles as well, but their introduction was itself a multistep process. The causal pathogens

of both diseases — a protozoan and a virus, respectively — are transmitted from bird to bird by mosquitoes that act as vectors. Until 1826, there were no mosquitoes on the Hawaiian Islands. In that year, the crew of the ship *Wellington* dumped the mosquito-laden remnants of their water kegs into a Hawaiian stream preparatory to filling them with fresh water. Thus, *Culex quinquefasciatus* from Mexico was introduced and a suitable vector for both pox and malaria was established. The pathogens themselves were introduced later, almost certainly with one or more of the many nonnative species of birds brought to the islands for various purposes by settlers. The poxvirus arrived in the late 1800s, while *Plasmodium relictum*, the agent of avian malaria in Hawaii, probably did not affect native birds on a large scale until around 1920. Van Riper et al. (1986) estimated that 16 species of birds became extinct in the late 1800s and early 1900s, while a further nine became extinct after introduction of malaria.³⁷ Malaria continues to have a negative impact on the native birds of Hawaii, restricting their abundance and distribution while giving a competitive advantage to introduced species that are resistant to the disease.³⁵

22.4 CONCENTRATION OF PATHOGENS

As noted above, for many pathogens, the dose to which a potential host organism is exposed can determine whether or not infection will occur and, sometimes, whether infection will be unimportant or lead to disease. Thus, human acts that result in the concentration of pathogens within a geographic area can alter the normal ecology of host and parasite in favor of disease. Several well-described diseases caused by bacteria illustrate this point.

Salmonella sp. is a genus of bacteria with many different species; it has the ability to infect most vertebrates. Various members of these species cause important diseases in humans and in domestic and wild animals. Two widely different human activities have resulted in increases in prevalence of disease in wild birds due to *Salmonella* sp.: discharge of urban sewage and creation of bird-feeding stations. *Salmonella* sp. thrives in sewage. Muller (1965) found a striking inverse correlation between the prevalence of infection with pathogenic *Salmonella* sp. in gulls and distance from the municipal sewage discharge area of Hamburg, Germany.³⁹ Lethal infection with *Salmonella* occurs quite commonly among passerine birds clustered around bird feeders in winter.^{40–41} The bacterium appears to be carried by certain species, particularly House Sparrows.^{42–43} Many birds can become infected when the feeders are contaminated by the carrier birds. The catalyst for such outbreaks appears to be the feeders themselves, which serve as focal points for contamination with bacteria and infection of many individuals.

Concentration of animals around feed sources has resulted in serious disease problems in other species as well. Winter feeding of wild elk (wapiti: *Cervus elaphus*) in western Wyoming (U.S.) is considered responsible for the maintenance of brucellosis in these populations; in the absence of artificial concentrations of animals in winter and spring around feed sources, the disease does not appear to persist in wild elk populations.^{44–47} Similarly, infection of wild white-tailed deer with bovine tuberculosis, recently found to be widespread in the State of Michigan (U.S.), has occurred in association with maintenance of very high population densities through provision of food in winter; elsewhere this disease is not maintained in wild white-tail populations.⁴⁸ Both these diseases are of major economic importance to agriculture and can be severe diseases in people.

Small wells and ponds created as sources of drinking water for wild or domestic animals also can act as foci of concentration for pathogens and sources of infection for large numbers of animals. Particularly under drought conditions, animals become concentrated around water sources, and the water and surrounding environment can become heavily contaminated with pathogens. In this manner, outbreaks of anthrax (*Bacillus anthracis*) in African wildlife and of necrobacillosis (*Fusibacterium necrophorum*) in elk, deer, and pronghorn (*Antilocapra americana*) in North America have occurred in association with both natural and man-made water sources as well as with feeding stations.^{49–52}

22.5 DISEASE ASSOCIATED WITH CHANGED ENVIRONMENTS

Since, in general, disease occurs through interactions among a pathogen, its host, and their joint environment, it follows that the prevalence or severity of a disease can be influenced as much by environmental changes as by changes in parameters of pathogen or host. This statement says no more than that alterations made to environments by humans can have indirect and unexpected ramifications throughout the ecosystem. The point made here is that diseases are components of ecosystems that can be affected by such environmental changes.

One instructive example of a disease responding to a changed environment is Sacramento River Chinook Disease.⁵³ This disease caused extensive losses of juvenile Chinook salmon in the Sacramento and Mokelumne rivers of California beginning in the 1960s. The emergence of this disease as a serious problem in wild and hatchery salmon was associated with the construction of dams on major Sacramento tributaries. Outbreaks of the disease killed up to 80% of young salmon in hatcheries, and a reduction in the annual spawning run of chinook salmon by 60% was attributed, in part, to this disease. The virus that causes the disease is very sensitive to temperature; it replicates at relatively cold temperatures (7–13°C) and does not produce disease in fish held at 15°C or higher. Dams changed the annual temperature regime of the river system from one in which waters passed through the range of 7–13°C in 2 to 3 weeks each spring to one in which this critical temperature range was maintained for 3 to 4 months each year. Thus, dams led to epizootic virus disease by way of altered environmental temperature.

Recent outbreaks of debilitating and lethal disease in balsam fir (*Abies balsamea*) and white spruce (*Picea glauca*) in eastern Canada and the adjacent United States caused by the spruce budworm (*Choristoneura fumiferana*) are another case in point.⁵⁴ The increase in frequency, extent, and severity of outbreaks of disease caused by this pathogenic insect have been attributed to major changes in forest ecology as a result of human activities. Over the past 200 years, specific logging practices, suppression of forest fires, and spraying of forests with insecticides all have resulted in huge increases in the land area covered with mature fir and spruce. The spruce budworm is a parasite of mature Balsam Fir and White Spruce, and the size and severity of outbreaks correlate well with the size of stands of mature trees. These are the climax species of normal succession in much of the affected region, but the extent of climax forest is normally greatly restricted by fire and, to a lesser extent, by the budworm. Outbreaks of budworm disease that formerly were small, isolated, and self-limiting now involve vast contiguous areas (for example, 55,000,000 ha in the outbreak that began in 1970). Intervals between outbreaks have become much smaller, and the duration of outbreaks has increased; an outbreak in New Brunswick (Canada), which began in 1949, was still underway in 1983 despite heavy application of insecticides for 30 years.

There is mounting evidence that infectious disease can occur as a result of environmental contaminants causing suppression of normal resistance to infection. This is inherently difficult to document because of the complexity of disease causation under natural conditions. Nonetheless, there is experimental evidence that immune function can be reduced as a toxicological effect of exposure to chemical poisons,⁵⁵ and there is also an increasing body of evidence for ecologically significant changes in patterns of disease occurrence as a result of exposure to contaminants. An epidemic of a new virus disease in harbor seals, now called phocine distemper, in northern Europe in 1988 was most severe in seals from the highly-polluted Baltic Sea.^{56–57} This observation led to studies in immune function in seals fed contaminant-rich fish from the Baltic and contaminant-poor fish from the Atlantic. Seals fed contaminant-rich fish had distinctly reduced immune function, as assessed by laboratory measures.⁵⁸ Additional examples of occurrences of infectious diseases attributed to reduced resistance caused by environmental contaminants are adult mortality and destruction of eggs by protozoan and fungal pathogens observed in crayfish associated with acidification of the aquatic environment and the increased susceptibility to bark beetle damage in ponderosa pines associated with exposure to photochemical air pollutants.^{59–60} It should be noted that effects on resistance to infection caused by exposure to environmental pollutants or other

environmental disturbances can be very difficult to identify or attribute to the primary cause. A primary reduction in resistance to disease will usually appear to be a problem of a particular infectious disease itself; the pollutant or disturbance that reduced the normal resistance to infection may not be suspected of contributing to the occurrence of disease.

Avian botulism can serve as a final example of a disease that can change in importance when environments are altered.⁶¹ Botulism is a form of food poisoning that occurs when the bacterium *Clostridium botulinum* grows and produces toxins in food material that is subsequently eaten by animals. Botulism is an especially important disease in waterbirds. For these species, the usual source of botulinum toxin is maggots that develop in rotting carcasses of animals that have died for any reason. In most marshes or other wetland areas, resident animals will have spores of the bacterium in their digestive tracts. When such animals die, the bacterium multiplies, spreads within the carcass, and produces toxin. Maggots growing in the same carcasses absorb and concentrate the toxin but are not affected by it. Waterbirds readily feed on maggots and are subsequently killed by the toxin the maggots contain. These birds, in turn, become additional dead carcasses in which more toxin and maggots can develop and, thus, are sources of poisoning for yet more birds.

Many environmental factors can influence whether or not avian botulism will kill large numbers of birds in a wetland. Any cause of animal mortality in a marsh can increase the probability of botulism. For example, construction of electrical power transmission lines across a marsh has resulted in new annual botulism outbreaks because birds killed by collision with lines or towers dropped into the marsh and served as sources of toxin and maggots.⁶² An increase in the density of waterbirds on a marsh can increase the likelihood of botulism simply because it will increase the likelihood that maggots from carcasses will be found and eaten. An increase in density of waterbirds on wetlands is a continent-wide phenomenon as the quantity of wetland habitat continues to shrink due to drainage and diversion of water, and birds are crowded onto the residual wetland areas. Large populations of scavengers can reduce the probability of botulism by rapid removal of carcasses, while reduction of scavenger populations can have the opposite effect.⁶³ Changes in these environmental factors can alter radically the magnitude of mortality from botulism on any particular wetland, resulting in annual fluctuations over several orders of magnitude.

Human actions that fundamentally change ecological relationships also can have unexpected consequences with respect to disease. Bovine spongiform encephalopathy (BSE), also called “mad cow disease,” is a case in point. The epidemic of BSE that devastated the British cattle industry in the 1990s and has had major economic and public health ramifications throughout Europe and much of the rest of the world arose from human imposition of carnivorous and cannibalistic feeding on a normally herbivorous animal. It was through feeding cattle with meat and bone meal derived from rendered cattle and sheep that the disease was created and spread, an industrial practice that struck down natural ecological barriers that previously had precluded such an epidemic.⁶⁴⁻⁶⁶

22.6 GENETICALLY MODIFIED ORGANISMS

It is now possible to alter the genetic makeup of organisms by direct alteration of the genome. The resultant organisms often are called genetically modified organisms (GMOs) or genetically engineered organisms (GEOs). The ecological effects of release of GMO into ecosystems have not yet been evaluated, and more will be learned over the next several decades.⁶⁷ Here, it can only be noted that pathogens are among the biota that have been, and certainly will be, subjected to genetic engineering. Already, a poxvirus genetically modified to contain a gene from the very different virus that causes rabies has been developed and widely distributed in nature in baits used for the field vaccination of foxes and raccoons against rabies.⁶⁸ This GMO was evaluated extensively prior to use, and no negative impact on the environment has been associated with its use other than the intended reduction or elimination of rabies virus from fox populations and the attendant ecological changes.⁶⁹ However, genetic modification of many potential pathogens has been conceived for a

wide range of purposes: to use as agents for immuno-contraception, to carry drugs to cancerous cells, to implant normal genes in genetically deficient individuals, and to vaccinate against any of a number of diseases important to people or animals. It seems likely that, in the near future, GMOs derived from pathogens or that are themselves potentially new pathogens will enter the biosphere with increasing frequency. Regulatory processes will identify and prevent dissemination of the most hazardous of these modified pathogens, but some small proportion of GMO released into the environment in the future may create ecological changes by causing disease in various plants or animals in a manner analogous to the translocation of an existing pathogen into a new ecosystem.⁷⁰

22.7 PREVENTION AND REMEDIATION

It is immensely more practical, feasible, and affordable to prevent the introduction of new pathogens into ecosystems or to take measures to avoid activities that alter disease occurrence in ecosystems in undesirable ways than it is to pursue remediation after the event. The principal methods of prevention are forethought and risk analysis. It is entirely feasible, for example, to carry out analysis of the risks of disease occurrence prior to taking decisions on translocations of animals and plants or on actions that alter environments in substantial ways. Regulatory procedures that incorporate health risk analysis already are in place in many jurisdictions. Tools and guidelines are available that make such risk analysis readily achievable.⁷¹

Remediation, on the other hand, is unlikely to succeed. Living pathogens, once established in an ecosystem, are very difficult to eliminate or to control in any substantive way. Small pox was eliminated through unprecedented international effort and massive cost.⁷² Rabies has been eliminated from fox populations over large geographic areas by oral vaccine distributed in baits, again at massive cost.⁷³ But most attempts to eradicate or control living pathogens fail. For most pathogens, neither the technology nor the necessary epidemiological information required for control or eradication programs will exist when they are needed, and each will take years to acquire.

Wobeser (1994) has provided a comprehensive discussion of the options and approaches that may be taken to control or eradicate pathogens in animal populations.⁷⁴ While elimination of pathogens from ecosystems often is impossible, specific and modest objectives to reduce specified undesirable effects of pathogens sometimes can be achieved. Measures to achieve these objectives may be directed at the pathogen itself, vector organisms required in the pathogen's life cycle, the host population, the environment, or at human activities and behavior. Success in remediation usually is, at best, modest and limited in scope.

22.8 CONCLUSION

From the foregoing, it is clear that human activities can affect the occurrence and significance of many diseases in a variety of ways. This is a lesson only lately learned, but it is a lesson with important implications. The introduction of a pathogen or an environmental change that disturbs the balanced relationships between hosts and parasites can have widespread and unexpected effects. Thus, disease must be included among the many factors to be considered when the environmental impact of human activities is assessed and when regulations to channel or limit these activities are developed.

23.1 INTRODUCTION

Physical and natural factors have long been known to influence the toxicity of environmental contaminants to vertebrates. The majority of data that address this topic have been derived from studies on fish, highly inbred laboratory rodents, and man.¹⁻³ The degree to which these factors modify toxicity has principally been elucidated by controlled laboratory experiments. Until recently, the significance of such effects to free-ranging vertebrates (Figure 23.1) was frequently overlooked in ecological risk assessments.⁴ Drawing upon controlled experiments and observational science, we overview environmental factors that influence pollutant toxicity in fish and wildlife, and present some perspective on their ecotoxicological significance.

Figure 23.1 Physical and natural factor interactions with contaminants in an aquatic ecosystem. (Modified from Foran, J.A. and Ferenc, S.A., Eds., *Multiple Stressors in Ecological Risk and Impact Assessment*, SETAC Press, Pensacola, FL, 1997.)

23.2 ENVIRONMENTAL FACTORS AFFECTING CONTAMINANT TOXICITY

23.2.1 Temperature

Of all environmental variables that affect contaminant toxicity to vertebrates, temperature has received more attention than any other. For example, a 1972 bibliography on the effects of temperature on fish compiled by Raney et al.⁵ contains more than 4000 references, and the present number is at least an order of magnitude greater. Guidelines for deriving temperature criteria for freshwater fish were prepared by Brungs and Jones⁶ and Houston.⁷ The latter reference also addresses the interactions of temperature and chemical toxicity, a subject reviewed in detail by Cairns et al.⁸ and Sprague.⁹ Information available for terrestrial vertebrates focuses more on effects of drugs than environmental contaminants.² Our current understanding indicates that generalizations cannot be made across classes of contaminants. In part, this is because temperature can be both a lethal factor and a controlling factor, acting on a variety of biological processes such as metabolism.

23.2.1.1 Aquatic and Amphibious Forms

All fish, except large tuna and some sharks, are poikilothermic (ectothermic). Thus, body temperature tracks the environmental temperature rather precisely with little lag, even when temperature changes rapidly.^{10,11} The temperature tolerance zone varies greatly among species and to a lesser degree with the age, physiological condition, and temperature to which the fish has been acclimated.^{7,12} Exposure to sublethal concentrations of toxicants may reduce the upper and raise the lower lethal temperature thresholds of fish, thereby constricting the tolerance zone.^{13–17} Since fish show reduced growth and impaired swimming ability when subjected to the extremes of their temperature tolerance zone, sublethal concentrations of toxicants could have greater effects on these functions at these extremes.¹⁸

Because body temperature of a fish tracks that of the environment, many metabolic processes exhibit a direct relationship to environmental temperature. As a general rule, energy metabolism increases about twofold with every 10°C rise in temperature. This requires gill ventilation to rise proportionately to meet increased metabolic demands.¹⁹ A rise in water flow over the gills results in more rapid uptake of toxic chemicals through the gills, the major uptake route of waterborne

chemicals in freshwater fish and to a lesser extent in marine species.^{20,21} It thus could be assumed that higher temperatures would result in greater toxicity at a constant chemical concentration in the water. However, this assumption is unwarranted. Although there are numerous examples of acute toxicity being directly proportional to temperature, there are also cases (especially with chronic exposure) where the opposite occurs, or where temperature has no effect on contaminant toxicity.²² This is because detoxication and excretion processes also increase with temperature, sometimes at rates equal to or exceeding contaminant uptake. It is important to note that rapid temperature changes coupled with toxicant exposure have more profound effects than responses observed when fish are first acclimated to the extreme temperature and then challenged with the toxicant.^{7,20} However, due to limited data on rapid temperature changes, in the discussion that follows, nearly all studies reviewed utilize thermally acclimated fish.

23.2.1.1.1 Acid

Although literature on acid toxicity to fish is extensive, information on the modulating effect of temperature is relatively scarce.²³ In general, the higher the temperature, the shorter the survival time in a lethal pH for common carp (*Cyprinus carpio*) and brook trout (*Salvelinus fontinalis*).^{24,25} Elevated temperature had the same effect on survival when the median lethal pH was estimated for rainbow trout (*Oncorhynchus mykiss*) fingerlings.²⁶ However, embryos of trout in this study exhibited the opposite response to temperature extremes (i.e., acidity was more harmful at low temperatures). This was attributed to prolonged incubation time at lower temperature, and thus there was more opportunity for the acid to exert effects on the developing embryo.

23.2.1.1.2 Ammonia

The toxicity of ammonia to fish is influenced greatly by pH and temperature because both factors affect ammonia ionization. Ionized ammonia (NH_4^+) has relatively little toxicity (however, see Section 23.2.2.1. on pH effects), whereas the unionized form (NH_3) is highly toxic. A 10°C rise in temperature at any given pH results in a threefold increase in formation of unionized ammonia.²⁷

In most ammonia toxicity studies, however, the unionized ammonia concentration is the only value reported. Under these circumstances, there is little effect on toxicity at temperatures above 10°C in freshwater fish, but at lower temperatures ammonia is actually more toxic.²⁸ Hazel et al.²⁹ found no temperature effect of ammonia on three-spined sticklebacks (*Gasterosteus aculeatus*) in freshwater, but when this euryhaline species was tested in brackish water or seawater, unionized ammonia was much more toxic at the higher temperature. However, in this same report, temperature had no effect on ammonia toxicity at any salinity to another euryhaline species, the striped bass (*Morone saxatilis*), so test species differences appear critical.²⁹

23.2.1.1.3 Chlorine

Chlorine is used extensively as a biocide to prevent fouling of industrial and electric-power-generating cooling systems and as a disinfectant for municipal sewage discharges. In general, it is more toxic at higher temperatures during continuous exposure.³⁰ However, many electric-power-generating facilities chlorinate intermittently (two or three times each day), thereby exposing the nontarget organisms to pulses of chlorine. Heath,³¹ using a laboratory simulation of this regime, found that temperature had little effect on chlorine toxicity for a wide variety of cold- and warmwater fish species. Instead, the fish species and form of chlorine (i.e., free chlorine vs. monochloramine) were much more critical in determining relative toxicity.

23.2.1.1.4 Cyanide

This highly toxic chemical appears to kill fish more rapidly at high temperatures, but only when acutely lethal concentrations are tested.⁸ Death occurs more rapidly at high temperatures because

uptake is rapid and metabolic demand is accelerated, while aerobic metabolism is blocked by cyanide. At acutely toxic cyanide concentrations, detoxication mechanisms are probably overwhelmed. At lower concentrations, temperature may have no effect on time to death. Fish are able to tolerate moderate concentrations of cyanide at high temperatures, probably because detoxication mechanisms (e.g., rhodanase enzyme activity) are also highly temperature-dependent. Rainbow trout are an important exception; cyanide toxicity (96-hour LC_{50} estimate) decreases at elevated temperatures.³²

23.2.1.1.5 Metals

Despite the abundance of information on the toxicity of metals to fishes, relatively little work has been conducted on interactions with temperature. Arsenic can exist in waterways in several forms, but the most stable form is arsenate. Rainbow trout are more sensitive to acute doses of this metalloid at 5°C than at 15°C, but the reverse occurs with chronic arsenate exposure.³³ Evidently, a critical body burden of arsenate must be achieved to cause death, which occurs more rapidly at warmer temperatures because of enhanced uptake rate. At lower exposure concentrations (when detoxication mechanisms are not overwhelmed), elevated temperature facilitates detoxication and excretion processes, thereby delaying or preventing accumulation of the lethal body burden.³³

Zinc toxicity increases or is unaffected at high temperatures.⁸ The definitive study by Hodson and Sprague³⁴ provides the probable explanation for the variety of responses reported in earlier papers. Using Atlantic salmon (*Salmo salar*) as a model, they concluded that fish were more sensitive to zinc at high temperatures, when exposures were at high concentrations and of short duration. As exposure duration was extended, temperature effects were progressively reduced until, at 2-week exposures, the LC_{50} was higher (less toxic) in warm water, a phenomenon similar to that seen with cyanide and arsenate. The mechanisms for the temperature effect may not be the same, however. Zinc causes death by destroying gill tissue. It was found that cold-acclimated fish experienced more gill damage from low doses of zinc than did warm-acclimated fish, even though the latter had greater concentrations of zinc in the gills.³⁴

Whereas fish are more sensitive to arsenate and zinc at cold temperatures, cold-acclimated (6°C) trout exhibited a threefold greater 10-day lethal threshold for cadmium compared with fish at 18°C.³⁵ The elevated toxicity of cadmium at the higher temperature was correlated with enhanced plasma calcium suppression by cadmium. Hypocalcemia is a key mechanism of cadmium toxicity to fish.²¹ In addition, Eisler reported a threefold increase in toxicity of cadmium at 20°C compared to 5°C for mummichog (*Fundulus heteroclitus*).³⁶

Because cadmium appears to be more toxic at higher temperatures, one might expect that fish would seek cooler water when exposed to cadmium. Contrary to expectations, brown bullhead (*Ictalurus nebulosus*) actually moved to a markedly higher temperature following cadmium exposure.³⁷ The investigators hypothesized this response to be a mechanism compensating for cadmium-induced suppression of ventilation. Whereas most metals, including cadmium, cause an elevation in gill ventilation, such a response in the bullhead may be an exception.²¹

The effect of temperature on cadmium toxicity in tadpoles (*Bufo* spp.) would appear to be the reverse of that in fish. Ferrari et al.³⁸ found that a mere 5°C rise in temperature (20–25°C) caused an approximate doubling of the cadmium LC_{50} . This was attributed to enhanced detoxication mechanisms in the higher temperature, although no data were presented to test this hypothesis.

Despite the large amount of data available on copper toxicity, there is little information on interactions with temperature. Based on 96-hour LC_{50} estimates, copper-temperature interactions are insignificant for several species of teleosts.³⁹ However, Dixon and Hilton⁴⁰ observed that a high carbohydrate diet in trout increased the chronic toxicity of waterborne copper and that reduced temperature exacerbated this effect.⁴⁰ In another study, Felts and Heath⁴¹ found that sublethal copper exposure of bluegills (*Lepomis macrochirus*) delayed metabolic acclimation to temperature change.⁴¹ Further study of copper-temperature interactions in fishes are warranted.

Mercury and lead exhibit elevated toxicity at higher temperatures, apparently due to a direct relation between metal accumulation and temperature.^{42,43} Mercury accumulates twice as fast with a 10°C rise in temperature.⁴⁴ Metabolism (and therefore gill ventilation) show a similar rate of increase with temperature, which probably facilitates the uptake; however, excretory processes for mercury and lead may fail to rise at a comparable rate. Part of the detoxication process involves binding of the metal to metallothionein.²¹ Most measures of tissue accumulation do not differentiate between metal bound to metallothionein and that free in the cells, and thus there may not be a direct correlation between body burden and lethality. The greater accumulation of lead and mercury at high temperatures has relevance for predatory animals, including humans, that consume contaminated fish.

23.2.1.1.6 Organics

Polychlorinated biphenyl (PCB) accumulation rates are enhanced by increased temperature. Spigarelli et al.⁴⁵ explored this relation in adult brown trout (*Salmo trutta*) in both constant temperatures and a diel temperature cycle. About 90% of the PCB was taken in by ingestion of food and the remainder via gills. The accumulation rate followed the growth rate, and both responded to temperature as if the fish had been acclimated to the peak of the diel cycle. Such a finding would be interesting to test with other contaminants, including metals, because diel cycles are common in nature.

Among organic pesticides, organochlorine compounds are generally more toxic to fish than organophosphorus compounds.⁴⁶ DDT has been reported to be more toxic at low temperatures in the laboratory. Decreased water temperature in streams two or three months after application can result in delayed mortality of trout.^{47,48} DDT also causes trout to choose warmer temperatures, although at high concentrations they may actually prefer cooler temperatures.⁴⁹ Eisler⁵⁰ found that the 96-hour mortality of *Fundulus heteroclitus* at a given DDT dose was least at 20°C and rose at temperatures above and below 20°C, suggesting the existence of a temperature optimum for minimal toxicity in that species.

Methoxychlor is also more toxic to fish in cold water.⁵¹ Such an interaction with temperature may be limited to salmonids. In tests with lindane, Johnson and Finley report a 2.3-fold decrease in toxicity to rainbow trout with increasing temperature from 2 to 18°C, but the opposite occurred in bluegills (a warmwater centrarchid) over a temperature range of 7 to 29°C.⁵² Macek et al.⁵¹ tested effects of four other organochlorine insecticides on bluegills and trout, and found that all the compounds to be more toxic (96-hour LC₅₀ estimates) at high temperatures. In European eels (*Anguilla anguilla*), the highest LC₅₀ estimate for lindane was at 22°C, while greater lindane toxicity was observed at 15 and 29°C.⁵³ Thus, temperature effects on organochlorine pesticide toxicity are highly dependent on the species of fish and compound tested.

Although some organochlorine compounds are more toxic at cold temperatures, the opposite occurs for organophosphorus compounds.^{47,52,54,55} This is also true for carbaryl (a carbamate), although there are also marked species differences in temperature modulation of its toxicity.⁵² The time-course of temperature acclimation may be an important factor because the action of organophosphorus and carbamate insecticides is to inhibit acetylcholinesterase in nervous tissue, and the activity of this enzyme changes during the temperature-acclimation process in fish.⁵⁶

Pyrethroid exposure studies in fish have demonstrated increased toxicity with reduced water temperature.^{57,58} One of the most pronounced thermal effects was seen with permethrin (a synthetic pyrethroid) exposure of rainbow trout wherein the 96-hour LC₅₀ rose tenfold over a temperature range of 5 to 20°C.⁵⁸ Thus, higher temperatures are clearly protective for this compound in trout. Similar types of studies in amphibians have yielded somewhat inconsistent findings. Lethality of several pyrethroids in adult *Rana pipiens* was noted to be dramatically enhanced by cold temperature (4 vs. 20°C).⁵⁹ Using behavioral endpoints, recovery of newly hatched *Rana clamitans* and *Rana pipiens* tadpoles following sublethal exposures to permethrin and fenvalerate was slower at 15 vs. 20°C.⁶⁰ In contrast, a moderately cool temperature (18 vs. 22°C) actually lowered lethality of esfenvalerate in tadpoles (*Rana* spp.).⁶¹

The cytochrome P450A enzymes are an important detoxication mechanism for organic contaminants in fish, and these enzymes are inducible by the presence of many toxic substances.⁶² Strong induction was detected in both winter- and summer-acclimated arctic char (*Salvelinus alpinus*); however, the response was delayed and longer-lasting in the cold.⁶³ It should be noted that species differences may be very important here, for Machala et al.⁶⁴ found that acclimating carp (a warmwater species) to winter temperatures caused a “highly significant inhibition” of the induction process.

23.2.1.2 Terrestrial Forms

Ambient temperature influences the toxicity of contaminants in homeotherms by affecting metabolic rate, energetics, neural control of thermoregulatory function, and contaminant uptake, transformation, and detoxication. For many pollutants, toxicity is lowest within the thermoneutral zone and tends to increase outside this range, thereby exhibiting a “U-shaped” response curve.

23.2.1.2.1 Petroleum Crude Oil

Spillage of oil during transportation and discharge of petroleum hydrocarbons as industrial effluent frequently result in the exposure of birds externally, by the oiling of plumage, and internally, through the ingestion of oil while feeding or preening. Direct external exposure is probably the most important toxic effect because oiling of feathers causes insulating air to escape, resulting in loss of body heat and increased metabolic rate.^{65–68} Under such physiological conditions, birds exposed to low ambient temperatures (e.g., cold water or air) rapidly deplete their energy reserves and become hypothermic, which can lead to death. Ingestion of oil may alter metabolic rate in seabirds⁶⁷ but does not seem to affect metabolic rate in domestic ducks (*Anas* spp.).⁶⁹ Nonetheless, mild cold exposure seems to exacerbate the toxicity of chronically ingested crude oil in mallards (*Anas platyrhynchos*).⁷⁰ Studies in England have revealed that avian mortality associated with oil pollution rises from a minimum in the summer to a peak in late winter.⁷¹

External oiling of wild mammals (e.g., sea otter, *Enhydra lutris*; polar bear, *Urus maritimus*) increases thermal conductance across the insulating fur layer, resulting in substantial heat loss; this is compensated by an elevated metabolic rate.⁷² Thermal effects have been predicted to be substantially greater upon exposure to cold air or water, although polar bears have exhibited a marked increase in core temperature following external oil exposure that might reflect a febrile response.

23.2.1.2.2 Organochlorine Contaminants

In Columbiformes and gulls (*Larus fuscus*), ingestion of DDT and PCB were associated with reduced metabolic rates, whereas elevated metabolic rates were reported when these compounds were fed to northern bobwhite (*Colinus virginianus*).^{73–76} Cold exposure following ingestion of 100 parts per million (ppm) DDT significantly decreased survival of quail.⁷⁶ This response was attributed to the mobilization of stored DDT and its metabolites. Based upon egg loss in a ruffed grouse (*Bonasa umbellus*) population following a DDT spray, cool weather has been suggested to act synergistically on DDT toxicity.⁷⁷ A retrospective study of the relationship between organochlorine contaminant concentration in herring gull eggs (*Larus argentatus*) and cold weather in the Great Lakes between 1962 and 1995 indicated that PCB levels were positively correlated with winter severity.⁷⁸ This relation appears to reflect altered migratory and feeding behavior, as gulls move to more highly contaminated southerly Great Lakes locations during severe winters and apparently ingest larger quantities of fish.

23.2.1.2.3 Organophosphorus and Carbamate Pesticides

Studies with laboratory rodents show that the toxicity of cholinesterase-inhibiting pesticides are enhanced several fold at reduced and elevated ambient temperature.^{79,80} Considerable evidence

indicates that this effect is due to disruption of central cholinergic and monoaminergic thermoregulatory function, endocrine dysfunction, and altered pesticide absorption.⁸¹ Furthermore, ambient temperature has long been recognized to affect the environmental half-life of these pesticides when sprayed on crops.⁸²

Juvenile northern bobwhite (*C. virginianus*) and mallard ducklings (*A. platyrhynchos*) acutely or subchronically exposed to anticholinesterase compounds (e.g., carbofuran, chlorpyrifos, temephos) exhibit decreased survival rates when maintained at low ambient temperatures compared with thermoneutral controls.^{83–85} A twofold increase in parathion lethality has been observed in northern bobwhite (*C. virginianus*) and Japanese quail (*Coturnix japonica*) maintained within environmental chambers at ambient temperatures below or above the thermoneutral zone.^{81,86} At sublethal parathion dosages, heat-exposed quail exhibited greater brain acetylcholinesterase inhibition than similarly dosed quail exposed to cold or maintained at thermoneutral temperatures. In contrast, recovery of brain acetylcholinesterase activity in brown-headed cowbirds (*Molothrus ater*) receiving dimethoate was actually slower in cold-exposed birds compared to thermoneutral controls.⁸³ These alterations in toxicity are attributed to disruption of thermoregulatory function, as evidenced by hypothermia, and other metabolic and endocrine responses to heat and cold but not to effects on the activities of hepatic enzymes involved in anticholinesterase activation or detoxication (e.g., parathion oxidase, paraoxonase, and paraoxon deethylase).^{81,85,87,88} The circannual toxicity of parathion was investigated in European starlings (*Sturnus vulgaris*) housed in outdoor pens encountering a wide-range of temperatures during winter, spring, summer and fall.⁸⁹ Based upon the acute LD₅₀ of parathion, toxicity was greater during hot summer weather compared with cool winter weather (LD₅₀ of 118 vs. 160 mg/kg).

In a field setting, low temperatures contributed to the poisoning of about 1500 geese (*Anser anser* and *A. brachyrhynchos*) that fed upon carbophenothion-treated winter wheat, and elevated ambient temperature was suggested to have been an exacerbating component in a sage grouse (*Centrocercus urophasianus*) die-off following dimethoate treatment of alfalfa in Idaho.^{90–92}

Temperature-contaminant interaction studies in wild mammals are quite limited. Acute oral exposure to parathion has been demonstrated to evoke hypothermia in white-footed mice (*Peromyscus leucopus*); however, parathion toxicity was not affected in mice maintained at 10°C, possibly because of their ability to undergo facultative torpor.⁹³

23.2.1.2.4 Lead Shot

Lead poisoning from ingested shot is a major cause of waterfowl mortality throughout the world. In North America, most waterfowl that die from ingested lead shot succumb during the cold weather that accompanies the hunting season. Harsh winter weather is generally thought to exacerbate lead toxicity in birds. This has been confirmed in part by studies of Kendall and Scanlon⁹⁴ with ringed turtle doves (*Streptopelia risoria*); marked mortality and greater blood and liver lead concentrations were observed in doves exposed to 6°C compared with birds maintained at 21°C. Comparison of lead-shot toxicity (mortality and body weight change) to mallards (*A. platyrhynchos*) and black ducks (*Anas rubripes*) housed outdoors in winter- and summer-dosing trials suggest that shot toxicity was greater in winter.⁹⁵ Ambient temperature does not seem to affect the toxicity of alternative shot (e.g., bismuth, tungsten, tin) used for hunting of waterfowl in North America.

23.2.1.2.5 Other Contaminants

Temperature influences the toxicity of sodium monofluoroacetate (compound 1080), a commonly used rodenticide. When compared to thermoneutral controls, acute toxicity was greater at low ambient temperatures for brushtail possums (*Trichosurus vulpecula*) and also greater at high ambient temperatures for raccoons (*Procyon lotor*).^{96,97} It was suggested that target-animal control strategies should include scaling of dosage at various ambient temperatures to minimize impacts on nontarget animals while maintaining overall efficacy.⁹⁷

23.2.2 Salinity, Water Hardness, and pH

23.2.2.1 Aquatic and Amphibious Forms

Although the ionic environment is markedly different between the ocean and freshwater, salinity has relatively little influence on acute toxicity of most chemicals.^{9,98} Limited data suggest that chronic responses to toxicants are more readily modulated by salinity than acute responses to toxicants. An important caveat is that tests must be conducted at a salinity to which the species is adapted; lack of ionic acclimation can enhance sensitivity to the chemical.⁹⁹ Furthermore, when the same species is acclimated to either seawater or freshwater, sublethal effects on variables such as blood electrolyte concentrations may be far greater in fish acclimated to freshwater.¹⁰⁰ A potential complicating factor related to the toxicity of metals is the enhanced bioavailability of free metal ions (toxic form) at low salinities. This explains why nearly all metals are more toxic at low salinities.¹⁰¹

Euryhaline species, such as mummichog (*F. heteroclitus*) and rainbow trout (*O. mykiss*), tend to be most sensitive to toxicants in low salinities; many contaminants are least harmful at intermediate salinity near the isosmotic range of 11 to 15 parts per thousand.^{101–104} Because acute doses of a wide variety of chemicals cause ionoregulatory dysfunction, this is not unexpected.²¹ For example, Wilson and Taylor¹⁰⁵ found that exposure of freshwater-acclimated rainbow trout to copper at a concentration of 4.9 mmol caused 100% mortality within 24 h due to severe ionoregulatory and respiratory failure. But when trout were acclimated to full strength seawater and exposed to 6.3 mmol copper for 24 h, there were no alterations in ionoregulatory or respiratory function. Note that full strength seawater is actually hypertonic to fish blood; however, the high calcium concentration in the seawater may provide more competition for external binding sites with copper.¹⁰⁶ Even in a freshwater environment, a low level (4 meq/L) of sodium chloride has been found to reduce the ionoregulatory stress (and thus toxicity) of aluminum.¹⁰⁷

Responses to silver appear to differ in that seawater-acclimated rainbow trout are more sensitive to this metal at higher salinities than at lower ones.¹⁰⁸ The investigators attributed this to the incomplete hypoosmoregulatory ability of the rainbow trout. It is noteworthy that alterations in salinity apparently caused no change in silver speciation.

In their extensive review, Hall and Anderson¹⁰¹ found no consistent trend of salinity on the toxicity of organic chemicals. Some possible exceptions are the organophosphorus insecticides, which appear to be more toxic as salinity increases.

Water hardness, usually expressed as mg/L CaCO₃, substantially affects metal toxicity but seemingly has little effect on the toxicity of organic chemicals.^{9,22,109} Where hardness affects toxicity of organics, it can often be attributed to the effect of pH differences (discussed elsewhere in this chapter). The toxicity of common water pollutants, such as ammonia, surfactants, and phenols, are not greatly affected by water salinity and hardness.⁹

The relation of water hardness to metal toxicity has produced extensive literature including the classic 1968 paper by Brown.¹¹⁰ The almost universal observation is that metals are less toxic in hard water, provided the pH is constant. The effect of hardness varies with the metal, being most dramatic with cadmium, due in part to its precipitation in hard water. Hardness has an almost negligible effect on dissolved lead toxicity.¹¹¹

Copper, zinc, and nickel toxicity are only moderately affected by water hardness.^{110,112,113} In the case of zinc, the effect of hardness seems to be due to changes in the fish gills rather than with metal speciation. Increasing hardness reduces the uptake rate of zinc by gill tissue, the prime target organ for zinc lethality.¹¹⁴ Even at lower doses of zinc, where gill damage is minimal, increased hardness impedes metal uptake into the fish and may facilitate its excretion as well.¹¹⁵

The situation is more complex in the case of copper because water pH greatly affects copper speciation.¹¹⁶ Playle et al.¹¹⁷ found that calcium (but not CaCO₃) reduced gill accumulation of copper at pH 4.8 but not at pH 6.3. Apparently, both calcium and hydrogen ions compete with copper for binding sites on gills.

There has been considerable debate as to whether total hardness or alkalinity are more important in copper toxicity in fish.¹¹⁸ In part the uncertainty exists because alkalinity and hardness tend to track each other, and copper complexes with both carbonate and hydroxide ions. Furthermore, calcium and magnesium reduce copper complex formation.

Consideration should briefly be given to acid pollution, a topic discussed in the first edition of this text.¹¹⁹ The calcium content of water (i.e., hardness) has long been known to be protective of the effects of low pH.¹²⁰ The lakes and streams most sensitive to acid pollution are those that are poorly buffered and, therefore, almost always characterized by low water hardness. Extensive studies on lakes in northern Norway have shown that those with calcium-to-hydrogen ratios of less than 3:1 are usually devoid of fish, whereas those with calcium-to-hydrogen ratios greater than 4:1 support good fisheries.¹²⁰

An interesting complex-formation phenomenon occurs with silicon. Much of the toxicity from acid pollution is due to the presence of aluminum, which is leached from aluminosilicates of rocks and soils by low pH precipitation.^{23,121} The resulting silicic acid in the waters has been shown to greatly reduce or even eliminate the toxicity of aluminum in acid water if excess silicon is present.¹²²

It has been claimed that pH has a greater modifying effect on contaminant toxicity to aquatic animals than any other physical factor.²² This is seen dramatically with ammonia, where a rise of one pH unit in the midrange of that found in surface waters increases the level of NH_3 , the toxic form, about sixfold over NH_4^+ , the ionized and less toxic form. Cyanide also becomes more ionized, and thus less toxic, as pH rises, but the effect is less dramatic than that seen with ammonia.⁹

The effect of pH on metal toxicity is complicated because the form of the metal changes greatly with the pH,¹¹⁶ and the respective toxicities of these forms are quite different. This results in unusual toxicity curves. For example, rainbow trout are most sensitive to copper at pH 6, and this sensitivity decreases as one raises the pH to 7 or lowers it below 6. However, the toxicity increases again as the pH is lowered below 5 or raised above 8.¹²³ The toxicological interactions among copper and dissolved organic carbon, calcium, and pH have been extensively explored by Welsh and coworkers.¹²⁴

In general, zinc is less toxic at a lower pH presumably due to less accumulation in the gills.¹¹³ This is also true of cadmium and nickel,¹²⁵ but at pHs below 5 to 6 (depending on the fish species), acid toxicity alone may be an important factor.

Organic contaminants in the unionized form are more toxic because they more readily penetrate membranes than in the ionic form,⁹ and water pH is the major factor influencing ionization.²² Toxicity of the organophosphorus pesticide chlorpyrifos increased when pH was increased from 7.5 to 9,⁵² and the same was seen with trichlorfon over this pH range.⁵⁵ However, the pesticide terbufos was least toxic at pH 7.5, with toxicity increasing above and below this point.⁵⁵

23.2.2.2 Terrestrial Forms

Ingestion of hyperosmotic water from alkaline lakes, prairie potholes, and estuarine and marine environments constitutes one stressor frequently encountered by endemic and migratory birds. Regulation of fluid and electrolyte balance under these circumstances is facilitated by the salt gland. Contaminant-induced disruption of osmoregulation by the inhibition of $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity has been observed in birds.

Friend and Abel¹²⁶ reported increased mortality rates in mallard ducklings maintained on 0.5% salt water and challenged with an osmotic stress following dietary exposure to the organophosphorus insecticides bidrin and parathion. Increasing the concentration of NaCl in drinking water also enhances the toxicity of malathion and EPN (alone and in combination). However, other studies failed to confirm this observation in adult birds and even suggested that saltwater may have blunted adverse effects by reducing ingestion rates of test diets containing the organophosphorus insecticide fenthion.¹²⁷

Several studies suggest that salt gland $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity and salt gland excretory function of birds may be depressed by organochlorine and cholinesterase-inhibiting pesticides.^{128–130} Large die-offs and severe population declines of some seabird species were at one time attributed to osmoregulatory failure due to mobilization of organochlorine pesticides and their metabolites during starvation. However, other studies demonstrated that this was unlikely.¹³¹

The effects of acidity on amphibious forms have recently been reviewed in detail.¹³² There is considerable inter- and intraspecific variation in pH tolerance among amphibians. Low pH in amphibian embryos can lead to embryonic mortality by impairing development and by inhibiting enzymes necessary for the expansion of the perivitelline membrane for hatching, causing embryos to curl.^{133–137} Acidity can cause the concentration of sodium to drop in larval amphibians, resulting in mortality.^{138–139} The toxicity of low pH is ameliorated for embryos of some species (*Ambystoma jeffersonianum*, *Rana pipiens*, *Bufo americanus*) by the presence of Ca cation and in larvae by high concentrations of cations such as Ca, Mg, and Na.¹³⁷ Little research has been conducted on the effects of pH on adult amphibians. Chronically lethal soil pH for red-backed salamanders (*Plethodon cinereus*) was between 3 and 4, and free-ranging populations were reduced at soil pH 3.7.¹⁴⁰ Sublethal effects of low pH that could reduce long-term survival of amphibians include alteration of time to hatch, abnormal or deformed embryos and hatchlings, altered behavior after hatching, decreased growth rate of larvae, and delayed metamorphosis.¹³²

Aluminum (Al) and low pH can act independently or synergistically, and in some species Al can ameliorate the effects of low pH (similar to the effects of Ca cations).^{137,141–145} Increasing pH can increase toxicity of Cd and Al to *Rana temporaria* larvae,¹⁴⁶ as Cu can for *R. sylvatica* and *A. jeffersonianum*.¹⁴⁷ Addition of Ca and Mg ameliorated the effects for only *R. sylvatica*. Survival of *A. jeffersonianum* larvae at pH 4.5 and 5.5 was dramatically reduced upon chronic exposure to high concentrations of Al, Cu, Fe, Pb, and Zn in combination.¹⁴⁸

In contrast to aquatic vertebrates that reside directly in media whose pH can vary dramatically, effects of pH on contaminant toxicity in terrestrial vertebrates are of less concern. Nonetheless, it is well documented that acid precipitation and poor buffering capacity in some habitats can evoke pH-related effects on the bioavailability of several heavy metals and aluminum to birds and mammals. These indirect effects of pH on contaminant toxicity in higher vertebrates have been reviewed in some detail.^{119,149}

23.2.3 Oxygen Tension

23.2.3.1 Aquatic Forms

The dissolved oxygen (DO) content of water is quite variable, even under so-called “natural” conditions (e.g., the hypolimnion of thermally stratified lakes is usually low in oxygen). The term *hypoxia* refers to any condition in which oxygen content is below saturation; *anoxia* means no oxygen. Anthropogenic inputs of organic wastes result in algal and microbial blooms, which may cause marked oxygen depletion, especially at night in the absence of photosynthesis. Waters that contain contaminants are often low in oxygen, which can influence their toxicity.

Although the influences of DO on toxicity were of substantial interest in the 1960s and early 1970s, surprisingly little research has been conducted on it until recently. Lloyd¹⁵⁰ found that as DO diminished, acute toxicity of zinc, copper, lead, and phenols increased almost linearly by up to a factor of two. Hydrogen sulfide toxicity to goldfish was increased by 1.4 times by lowering the DO to 10% of saturation, a level of oxygen most species of fish could probably not tolerate.^{151,152} Whole pulp mill effluent was about 1.5 times more toxic at 38% oxygen saturation than at 79% saturation.¹⁵³ Ammonia was 1.5- to 2-fold more toxic when DO was lowered to 30% saturation.^{150,154} Bluegills exposed to 22% oxygen saturation were 1.7 times more sensitive to the surfactant linear alkylate sulfonate (LAS) compared with controls in oxygen saturated water, provided the fish were first acclimated to the low DO.¹⁵⁵

Acclimation to the low DO could be an important factor deserving more attention. Hokanson and Smith¹⁵⁵ found that the toxicity of LAS increased by an order of magnitude if fish were not acclimated to low DO before exposure. Fish increase their gill ventilation when exposed to hypoxia, which enhances toxicant contact and uptake by gills, a hypothesis first proposed by Lloyd.^{21,150} Acclimation to hypoxia reduces ventilation volume and causes other physiological adjustments that facilitate functioning in low DO.²¹ Whether acclimation would be relevant to field situations depends on local circumstances. A diurnal DO depletion in a highly eutrophic pond would permit little time for acclimation, whereas acclimation may occur during seasonal cycles.

These data suggest that hypoxia has a relatively small effect on acute toxicity of contaminants in fish. However, Gupta et al.¹⁵⁶ reported that various mixtures of three phenolic compounds exhibited markedly different toxicities when tested with the bronze featherback (*Notopterus notopterus*) maintained at differing DO concentrations. Over a rather limited DO range of 6 to 7.8 ppm, the 96-hour LC₅₀s estimates for the mixtures differed by as much as 15-fold.

An unusual interaction between DO with acute anthracene toxicity has been observed in bluegills.¹⁵⁷ The toxicity of this polycyclic aromatic hydrocarbon is induced by ultraviolet light, and this process is oxygen dependent. In this instance, the relation of DO and toxicity is not linear. Instead, a bimodal curve results in which anthracene is least toxic at low and high DO levels. The heightened toxicity at the intermediate DO may, as McCloskey and Oris hypothesize, be due to a complex interaction between ventilation volume and oxygen-dependent toxicity.¹⁵⁷ Ventilation volume of fish increases as DO is lowered, and this brings more toxicant in contact with the gills. At the highest DO, ventilation volume is at its lowest so the gills are exposed to less anthracene.¹⁵⁷

Studies involving prolonged chemical exposure are even less numerous than those devoted to acute toxicity. In 32-day tests in which fathead minnow (*Pimephales promelas*) embryos and larvae were exposed to 1,2,3-trichlorobenzene, Carlson¹⁵⁸ observed that reducing the DO to 4.5 ppm caused greater effects on survival and weight gain. However, these responses were observed only at a concentration above the toxicity threshold. There did not appear to be any influence of DO on the toxicity threshold of 1,2,3-trichlorobenzene. However, Chapman and Shumway observed that hypoxia caused both a decrease in survival time in lethal concentrations and a lowering of the threshold concentration in steelhead trout embryos and larvae exposed to pentachlorophenol.¹⁵⁹

The inhibition of acetylcholinesterase in the nervous system of fish can be used to detect organophosphorus and carbamate pesticide poisoning, although other contaminants (e.g., mercury) may also inhibit this enzyme.¹⁶⁰ Hoy et al.¹⁶¹ found that fish treated with dichlorvos (an organophosphorus compound used to treat for ectoparasite infestation) experienced a severe inhibition of acetylcholinesterase. Enzyme inhibition was greater when the water had low DO. The mechanism may involve rapid uptake of the pesticide due to hyperventilation by the fish in hypoxic water.

The herbicide paraquat causes increased superoxide dismutase (SOD) in cells as a mechanism to remove free radicals during its metabolism. Vig and Nemcsok exposed carp to severe hypoxia (< 1 ppm DO) and found SOD stimulation in the gills, liver, and brain.¹⁶² Paraquat alone stimulated SOD activity only in gill tissue.¹⁶² Combining hypoxia and paraquat produced an additive effect in the gills but no additional enhancement of SOD activity in the other tissues.

Hypoxia can itself be a lethal factor. In combination with sublethal quantities of a toxicant, there is some evidence of exacerbation of the harmful effects of hypoxia. Nitrite causes methemoglobin formation, which effectively reduces the ability of hemoglobin to transport oxygen. It is not surprising that channel catfish (*Ictalurus punctatus*) exposed to nitrite are less able to tolerate low levels of dissolved oxygen.¹⁶³ Another mechanism by which a toxic chemical may reduce tolerance to hypoxia is illustrated by the work of Hlohowskyj and Chagnon,¹⁶⁴ who found that phenol, which causes histological damage to the gill tissue, reduces hypoxic tolerance in the stoneroller minnow (*Capostoma anomalum*). Since a wide variety of chemicals damage gill tissue, this phenomenon of reduced hypoxic tolerance resulting from chemical exposure deserves further study.²¹

23.2.3.2 Terrestrial Forms

Although two reviews have addressed air-quality effects on wildlife, no information is available on the effects of oxygen tension on contaminant toxicity in terrestrial animals.^{165,166} This is a fertile research area because some species of birds have been observed at altitudes up to 11,300 m,¹⁶⁷ and many mammals may be exposed to moderate hypoxia in their burrows or during torpor.

23.2.4 Nonionizing Radiation

In the past two decades, there has been increased interest in the effects of nonionizing radiation (frequency: 0–300 GHz; wavelength: 10,000 m to 1 mm) on birds with its expanding use by man (e.g., radionavigation; radio, television, and satellite communication; and weather radar). Its pervasiveness has been suggested to result in direct irradiation of birds and their eggs.¹⁶⁸ Direct effects on embryonic development, growth, reproduction, and behavior have been documented in passerines and mallards.¹⁶⁸ Although the potential for interaction with environmental contaminants is great, it has yet to be investigated in free-ranging birds. Because much of the spectrum of nonionizing radiation is rapidly attenuated in the water column, its interaction with contaminants is of limited concern to aquatic vertebrates.

23.2.5 Photoperiod and Season

Photoperiod and season are interrelated because the natural cause of photoperiod difference is the change of season. Temperature, which has a profound effect on physiological systems, changes with season. Thus, there is some application of studies on temperature effects to season. Although information is quite limited, photoperiod *per se* appears to have little effect on toxicant threshold concentrations.¹⁶⁹ However, exposure to ultraviolet light, which is affected by photoperiod and season, has pronounced effects on toxicity of polynuclear aromatic hydrocarbons, carbamates, and some other contaminants through photoactivation mechanisms.^{170,171}

There is considerable interest in the use of biochemical, histological, morphological, and physiological biomarkers for evaluating environmental health.^{172–174} It must be appreciated that nearly all such parameters change to a greater or lesser degree with season.^{175–177} This is not a serious problem provided that the populations under investigation are compared with nearby reference populations sampled at the same time. Unless seasonal fluctuations of parameters are understood in a given species, “baseline” values are difficult to interpret.

23.2.5.1 Aquatic Forms

Many species of fish are seasonal spawners and thus exhibit marked changes in steroid hormone concentrations and energy stores associated with both temperature and photoperiod. These changes are reflected in alterations in the enzyme systems that metabolize xenobiotic chemicals in fish collected from the field.^{178–180} Current data does not permit generalizations as to whether spawning stimulates or inhibits a particular enzyme activity; conflicting results may be due to interspecific differences. Liver metallothionein concentration also appears to be greatly modulated by spawning season, independent of metal exposure.¹⁸¹ It seems probable that the ability of fish to sequester, transform, and excrete toxic chemicals is affected by season, and these effects are due in part to spawning activity.

23.2.5.2 Terrestrial Forms

In dosing studies with the avicide 3-chloro-*p*-toluidine hydrochloride, starlings were found to be more sensitive during daylight hours.¹⁸² Reduction of the light cycle in chronic Kepone feeding

studies evoked a dramatic increase in toxicity to immature Japanese quail but not adults.¹⁸³ Serum B esterases, a key target for cholinesterase-inhibiting pesticides, exhibit diurnal variation, although such changes do not seem to have biologically significant effects on tolerance to anticholinesterase pesticides.^{184,185}

Wild birds and mammals exhibit pronounced fluctuations in body mass and composition associated with seasonal changes in diet and physiological condition as well as reproductive and migratory components of their annual cycle. Dramatic alterations in organic and inorganic contaminant tissue burdens have been documented to accompany these changes.¹⁸⁶⁻¹⁹⁴ Furthermore, seasonal variation in enzyme activities (e.g., acetylcholinesterase and monooxygenase activity) have been detected in several species of amphibians, birds, and mammals.^{185,195,196} The toxicological significance of these circannual changes remain poorly understood.

23.3 CONCLUSIONS

In contrast to toxicity studies conducted in a controlled laboratory setting, free-ranging animals simultaneously encounter a combination of environmental variables that may influence, and even act synergistically to alter, contaminant toxicity. It is not possible to rank these factors, particularly since they are often interrelated (e.g., temperature and seasonal rhythms). Moreover, species differences in toxic chemical sensitivity are often greater than the modulatory effects of environmental variables. However, it is clear that environmental factors (particularly temperature) may alter contaminant exposure and toxicity (accumulation, sublethal effects, and lethality) by more than an order of magnitude in some species. Accordingly, effects of abiotic environmental variables should be considered and factored into ecological risk assessments of anthropogenic pollutants.

24.1 INTRODUCTION

The partial meltdown of the 1000 MW reactor at Chernobyl, Ukraine on April 26, 1986 released large amounts of radiocesium and other radionuclides into the environment, causing widespread radioactive contamination of Europe and the former Soviet Union.¹⁻⁸ Among the reactors operating in the former Soviet Union, 13 are identical to the one in Chernobyl, Ukraine, including units in Chernobyl, Leningrad, Kursk, and Smolensk.⁷⁰ Of the three remaining reactors in Chernobyl, one was closed in 1991 after a fire swept through the turbine hall, causing extensive damage, though not to the reactor.¹⁶⁸ A second unit was closed in 1994 by the Russian president after pledges were received from the Group of Seven to help finance an overall plan to decommission the Chernobyl complex. And the last unit was closed in late 2000.¹⁶⁸

At least 3,000,000 trillion becquerels (TBq) were released from the fuel during the April 1986 accident, dwarfing — by orders of magnitude — radiation releases from other highly publicized reactor accidents at Windscale (U.K.) and Three-Mile Island (U.S.).^{3,9,159} (Note: 1 Bq = 1 disintegration/sec; about 0.037 Bq = 1 picroCurie.) The Chernobyl accident happened while a test was

being conducted during a normal scheduled shutdown and is attributed mainly to human error.³ About 25% of the released radioactive materials escaped during the first day of the accident; the rest over a 9-day period.³ The initial explosions and heat from the fire carried some of the radioactive materials to an altitude of 1500 m, where they were transported by prevailing winds. Long-range atmospheric transport spread the radioactivity through the northern hemisphere, where it was initially detected in Japan on May 2, in China on May 4, in India on May 5, and in Canada and the United States on May 5–6, 1986. Airborne activity was also detected in Turkey, Kuwait, and Israel in early May. No airborne activity from Chernobyl has been reported south of the equator.³

Effective dose equivalents from the Chernobyl accident in various regions of the world were highest in southeastern Europe (1.2 milliSieverts [mSv]), northern Europe (0.97 mSv), and central Europe (0.93 mSv).^{3,4} (Note: 1 mSv = 0.1 rem.) In the first year after the accident, whole-body effective dose equivalents were highest in Bulgaria, Austria, Greece, and Romania (0.5–0.8 mSv); Finland, Yugoslavia, Czechoslovakia, and Italy (0.3–0.5 mSv); Switzerland, Poland, U.S.S.R, Hungary, Norway, Germany, and Turkey (0.2–0.3 mSv); and elsewhere (< 0.2 mSv).^{3,4} This value was 0.81 mSv in the former Soviet Union, < 0.2 mSv in southwest Asia and western Europe, and < 0.1 mSv elsewhere.^{3,4} By comparison, the recommended whole-body annual effective dose equivalent for the general public is < 5 mSv.³ Thyroid dose equivalents were significantly higher than whole-body effective dose equivalents because of significant amounts of ¹³¹I in the released materials. Thyroid dose equivalents were as high as 25 mSv to infants in Bulgaria, 20 mSv in Greece, and 20 mSv in Romania; the adult thyroid dose equivalents were usually 80% lower than the infant dose equivalents.³

This account briefly summarizes ecological and toxicological aspects of the Chernobyl accident with an emphasis on natural resources; it complements and supplements previous reviews.^{8,74,75,121,123,147,149,165,166,172}

24.2 LOCAL EFFECTS

The initial contamination rate in the 30-km exclusion zone surrounding the site of the nuclear accident was estimated at 37,000,000 Bq/km² (1,000 Ci/km²); isotopes included iodine-131, tellurium 127+132, barium-140, lanthanum-140, cerium-141+144, zirconium-95, niobium-95, ruthenium-103+106, praseodymium-144, cesium-134+137, molybdenum-99, strontium-89+90, plutonium-238+239+240+241, silver-110, antimony-125, and others.⁸⁹ About 28,000 km² of land and 2225 settlements in Belarus, Russia, and Ukraine were officially declared contaminated with radiocesium, i.e., levels were > 185,000 Bq ¹³⁴⁺¹³⁷Cs/m² (> 5 Ci/km²).¹⁶⁵ Approximately 850,000 people are still living in these contaminated areas. About 105,000 km² were contaminated with 37,000 Bq/m² (1 Ci/km²) or more. In the first years of the catastrophe, 144,000 ha of agricultural land and 492,000 ha of forest were withdrawn from use. More than 4 million people in these three countries were affected by the accident. Current estimates of the eventual toll from cancer deaths as a direct result of Chernobyl range from a minimum of 14,000 to a maximum of 475,000.¹⁶⁵

24.2.1 Acute Effects

At Chernobyl, at least 115 humans received acute bone marrow doses > 1 Grey (Gy), as judged by lymphocyte aberrations. (Note: 1 Gy = 100 rad.) The death toll within 3 months from the accident was at least 30 individuals, usually from groups receiving > 4 Gy, especially the reactor's operating staff and the fire-fighting crew.³ Humans from highly contaminated areas within 30 km of Chernobyl received mean thyroid doses from radioiodines of 1.6 Gy for adults, 2.1 Gy for those age 7–17 years, and 4.7 Gy for infants.¹⁴³ Residents were evacuated from a 30-km exclusion zone surrounding the reactor because of increasing radiation levels; more than 115,000 people, including 27,000 children, were evacuated from the Kiev region, Belarus, and Ukraine.³ Children evacuated

from the contaminated areas showed — in July 1986 — significantly elevated levels of dicentric chromosomal aberrations when compared to resident children of noncontaminated areas.¹¹⁶ Vitamin E and A deficiencies observed in some children were correlated with high Chernobyl radiation loads of their mothers.¹⁴² Tens of thousands of cattle were also removed from the contaminated area, and consumption of locally produced milk and other foods was banned. Agricultural activities were halted and large-scale decontamination was undertaken.³ Humans residing in areas where topsoil contamination exceeded 555,000 Bq/m² were cautioned against inclusion of forest products in their diets and to avoid cattle grazing on wet floodplain meadows without remediation.¹⁴⁶ The forced evacuation and health concerns contributed to severe sociopsychological impacts in all age groups of the displaced population.¹²⁶

The most sensitive ecosystems affected at Chernobyl were the soil fauna and pine forest communities; the majority of the terrestrial vertebrate communities were not adversely affected by released ionizing radiation.¹⁰ Pine forests seemed to be the most sensitive ecosystem. One 400-ha stand of *Pinus silvestris* died and probably received a dose of 80–100 Gy. Other stands experienced heavy mortality of 10- to 12-year-old trees and as much as 95% necrotization of young shoots; these pines received an estimated dose of 8–10 Gy. Abnormal top shoots developed in some *Pinus*, and these probably received 3–4 Gy. In contrast, leafed trees in the Chernobyl Atomic Power Station zone, such as birch, oak, and aspen, survived undamaged, probably because they are about ten times more radioresistant than pines.¹⁰ Extremely high radioresistance was documented in genetically adapted strains of the filamentous fungus *Alternaria alternata* isolated from the reactor of the Chernobyl power plant; other strains of this species are supersensitive to radiation.¹⁶⁷ There was no increase in mutation rate of spiderwort (*Arabidopsis thaliana*), a radiosensitive plant, suggesting that the dose rate was < 0.05 Gy/h in the Chernobyl locale.¹⁰

Populations of soil mites were reduced in the Chernobyl area, but no population showed a catastrophic drop in numbers. By 1987, soil microfauna — even in the most heavily contaminated plots — was comparable to controls.¹⁰ Flies (*Drosophila* spp.) collected at various distances from the accident site and bred in the laboratory had highest incidences of dominant lethal mutations (14.7%, estimated dose of 0.8 mGy/h) at sites nearest the accident and higher incidences than controls (4.2%).¹⁰

The most contaminated water body in the Chernobyl emergency zone was the Chernobyl cooling pond ecosystem, an area of about 30 km².^{71,99} On May 30, 1986, the total amount of radioactivity in the water of this system was estimated at 806 TBq and in sediments 5657 TBq.⁷¹ In water, ¹³¹I contributed about 31% of the total radioactivity, ¹⁴⁰Ba–¹⁴⁰La 25%, ⁹⁵Zr–⁹⁵Nb 15%, ¹³⁴Cs and ¹³⁷Cs 11%, ¹⁴¹Ce and ¹⁴⁴Ce 10%, ¹⁰³Ru and ¹⁰⁶Ru 7%, and ⁹⁰Sr < 1%. The distribution pattern in sediments was significantly different: about 41% of the total radioactivity was contributed by ⁹⁵Zr–⁹⁵Nb, 27% by ¹⁴¹Ce and ¹⁴⁴Ce, 16% by ¹⁰³Ru and ¹⁰⁶Ru, 12% by ¹⁴⁰Ba–¹⁴⁰La, 3% by ¹³⁴Cs and ¹³⁷Cs, 1% by ⁹⁰Sr, and 0.5% by ¹³¹I.⁷¹

Fish populations seemed unaffected in July–August 1987, and no grossly deformed individuals were found; however, ¹³⁴⁺¹³⁷Cs levels were elevated in young fish. The most heavily contaminated teleost in May 1987 was the carp (*Carassius carassius*). But carp showed no evidence of mutagenesis, as judged by incidence of chromosomal aberrations in cells from the corneal epithelium of carp as far as 60 km from Chernobyl.¹⁰

In 1986, total radioactivity in muscle of birds near Chernobyl after the accident exceeded the temporarily permitted limits for human food consumption (598 Bq/kg FW) by about 100 times.⁸⁹ In 1987, radionuclide concentrations in bird muscle had decreased by a factor of about 7, due in part to physical decay of short-lived isotopes.⁸⁹

Several rodent species comprised the most widely distributed and numerous mammals in the Chernobyl vicinity. It was estimated that about 90% of rodents died in an area receiving 60 Gy and 50% in areas receiving 6 to 60 Gy. Rodent populations seemed normal in spring 1987, and this was attributed to migration from adjacent nonpolluted areas. The most sensitive small mammal was the bank vole (*Clethrionomys glareolus*), which experienced embryonic mortality of 34%. The

house mouse (*Mus musculus*) was one of the more radioresistant species. *Mus* from plots receiving 0.6–1.0 mGy/h did not show signs of radiation sickness, were fertile with normal sperm, bred actively, and produced normal young. Some chromosomal aberrations, namely, an increased frequency of reciprocal translocations, were evident.¹⁰ New data on the house mouse suggests that fertility was dramatically reduced in the 30-km zone around the Chernobyl nuclear power plant station in 1986–1987 and that survivors had high frequencies of abnormal spermatozoa heads and dominant lethal mutations.⁷⁶ Elevated incidences of germ line mutations were observed in four species of *Apodemus* mice from the vicinity of Chernobyl when compared to control areas; however, variability between species was large.¹⁷⁰

During the early period after the accident, there was no evidence of increasing mortality, decline in fecundity, or migration of vertebrates as a result of the direct action of ionizing radiation. The numbers and distribution of wildlife species were somewhat affected by the death of the pine stand, the evacuation of people, termination of cultivation of soils (the crop of 1986 remained standing), and the forced transfer of domestic livestock. There were no recorded changes in survival or species composition of game animals and birds. In fact, because humans had evacuated and hunting pressure was negligible, many game species — including fox, hare, deer, moose, wolf, and waterfowl — moved into the zone in autumn 1986–winter 1987 from the adjacent areas in a 50- to 60-km radius.¹⁰

24.2.2 Latent Effects: Humans

The frequency of childhood thyroid cancer in areas of Belarus and Ukraine most affected by the Chernobyl accident is significantly higher than any other region of the world.^{114,155–158} Thyroid cancers in children were induced by ¹³¹⁺¹³²I, although the mechanisms of action are imperfectly understood.¹²⁷ During the period 1985–1995, childhood thyroid cancer rates in Belarus were higher after a minimum latent period of 3 years, higher in children under age 10 years than those age 10 to 15 years, and higher in females than males.¹¹⁴ Between 1990 and 1997, the group most affected were those younger than 5 years old in 1986; the largest number of cases occurred in patients living in areas of thyroid radiation doses > 0.5 Gy.^{156,157} The post-Chernobyl thyroid carcinomas were usually papillary, more aggressive at presentation, and frequently associated with thyroid autoimmunity.^{155–157} Gene mutations involving the receptor tyrosine kinase (RET) protooncogene were the causative agents specific to papillary cancer.^{155,157,158}

Cutaneous radiation syndrome was the primary cause of death in most of the 32 adult patients who died shortly after the accident. Excessive cutaneous fibrosis in eight survivors who participated in the Chernobyl cleanup was treated successfully with interferon over a period of 36 months.¹²⁵ There is general agreement that cleanup workers and populations residing in heavily-contaminated areas (> 555,000 Bq ¹³⁷Cs/m²) had an increased frequency of thyroid cancers in the period 1986–1993, but current epidemiological evidence does not conclusively support an increased incidence of other types of cancers.¹²⁶

Increased frequencies of chromosome breakage were evident in plants and small mammals from the Chernobyl-contaminated zone in the period 1986–1991.¹⁶⁴ For humans, chromosome and chromatid aberration frequencies in lymphocytes of Chernobyl evacuees (receiving 330–420 mGy) and cleanup personnel (receiving a maximum of 940 mGy) 1 year after the accident were three to four times higher than in controls.¹⁶⁴ By 1994–1995, aberration frequency in evacuees receiving <250 mGy was the same as the controls; however, this value was 1.7 times higher than controls in cleanup personnel, 1.95 times higher in evacuees receiving 250 mGy, and 2.37 times higher in evacuees receiving > 250 mGy in 1986. In some patients, the increased level of chromosome breakage was associated with high cancer susceptibility.¹⁶⁴

Russian adult males who participated in Chernobyl cleanup activities (n = 126) received an estimated 0.14–0.15 Gy (maximum of 0.56–0.95 Gy, depending on the statistical model); however, dose estimates could be overestimated if age and smoking status were ignored, particularly for older subjects who smoke.¹¹² This group had a significantly increased frequency of chromosomal

translocations when compared to Russian controls ($n = 53$).¹¹² Cancer incidence between 1986 and 1996 for cleanup workers ($n = 114,504$) with no known oncology before arrival in 1986 at the 30-km zone increased significantly for solid tumors and malignant neoplasms of the digestive tract (but not of the respiratory system) when compared to controls.¹¹⁰ By 1996, Chernobyl cleanup workers experienced a variety of eye pathologies that seemed to increase in frequency with increasing time postaccident and with high initial doses of absorbed radiation.¹⁴⁰ Eye-pathology patterns are still developing because the latency period for irradiation cataract can exceed 10 years.¹⁴⁰ The incidence of urinary bladder cancer in Ukraine increased from 26.2 per 100,000 population in 1986 to 36.1 in 1997.¹³⁹ Individuals from the most severely radiocontaminated areas showed the greatest incidence of early malignant transformation of bladder epithelium.¹³⁹ In 1995, the endocrine status and spermatogenesis of Chernobyl cleanup workers were normal except for lower cortisol and higher testosterone.¹³⁵ A woman resident of Kiev during the period 1986–1992 who subsequently emigrated to the United States was diagnosed in 1996 with radiation-induced cancer of the ovaries, kidneys, and bile duct.¹⁴⁸

In certain rural portions of Russia receiving Chernobyl contamination on April 28–29, 1986, ¹³⁷Cs concentrations in the human body in 1986–1987 were positively correlated with consumption of meat and dairy products.¹⁶⁰ Domestic livestock were fed clean feed as much as possible for milk production and were fed clean feed for 40 to 120 days before slaughter.¹⁶⁵ Beginning in 1993, however, and persisting to at least 1996, the content of ¹³⁷Cs in whole humans correlated positively with the levels of consumption of naturally occurring foodstuffs, such as mushrooms, wild berries, fish, and game.¹⁶⁰

24.2.3 Latent Effects: Plants and Animals

Total radiocesium-137 deposited in soils at Chernobyl sites 2 to 15 km from the reactor was estimated at 1,660,000 Bq/m², mainly as insoluble fuel particles.¹⁰⁶ The half-time persistence of ¹³⁷Cs in surface soils 0–2 cm in depth decreased from 9 years in 1987 to 3 years in 1994; but the residence time of this isotope increased with increasing depth over time. This increase in deeper layers is attributed to the progressive fixation of radiocesium by clay minerals of the soil.¹⁰⁶

In 1992, bacteria were isolated from soils within 30 km of the power plant. Spore-forming bacilli collected nearest the power plant were more resistant to x-radiation, ultraviolet radiation, and 4-nitroquinoline 1-oxide than were isolates of the same species from control sites.¹⁴¹ In 1993–1995, populations of cellulolytic, nitrifying, and sulfate-reducing bacteria collected within the 10-km zone from contaminated soils (11,000–629,000 Bq/kg DW soil) were 10 to 100 times lower in abundance and diversity than were populations from control soils (< 222 Bq/kg DW soil).¹⁶⁹

On heavily contaminated agricultural lands — about 2.4 million ha — about 388,000 ha were withdrawn from use, and the remainder planted with crops of low coefficients of radionuclide transfer from soil, such as grains, potatoes, and corn.¹⁶⁵ In addition, the upper polluted layer of soil (5–6 cm) was ploughed to a depth of 40–50 cm to inhibit transfer to root systems, especially those of grasses. Application of potassium and phosphorus fertilizers in combination with liming further reduced uptake of ⁹⁰Sr and ¹³⁷Cs by plants.¹⁶⁵ From autumn 1986 to 1991, ¹³⁷Cs in vegetable and animal agricultural products from various contaminated areas of Russia decreased at an observed half-time persistence of 0.7 to 1.5 years.¹¹⁵ Beginning in 1991 and extending through 1995, the average values of transfer factors for ¹³⁷Cs from all sources from soil to milk and potatoes were similar to those of the pre-Chernobyl period.¹¹⁵ Dose rates from soil to the house mouse between 1986 and 1993 ranged from 0.0002 to 2 mGy/h, and these were positively correlated with the frequency of reciprocal translocations in mouse spermatocytes. The frequency of mice heterozygous for recessive lethal mutations decreased over time after the accident.^{76,150}

In 1991, pine forests (*Pinus silvestris*) within 10 km of Chernobyl exposed initially to doses of 10–60 Gy had low survival and no regeneration since 1987; mortality was exacerbated by pathogenic insect invaders.⁹² Samples of wood and bark from these trees had significant histological

changes in resin ducts and radial rays, and this was correlated with radionuclide content of bark.⁹⁶ Stands exposed initially to 0.1–1.0 Gy had reduced growth; trees receiving initial doses of less than 0.1 Gy seemed outwardly normal.⁹² Between 1986 and 1996, radiocesium-137 concentrated in the bark of pine trees grown in the exclusion zone from about 10,000 Bq/kg DW in 1986 to 37,000 Bq/kg DW in 1996; the high ¹³⁷Cs concentrations were associated with growth suppression.¹¹¹ In the period 1986–1994, ¹³⁷Cs dynamics in forests within the 30-km zone around the Chernobyl reactor were influenced mainly by the size of radioactive particles in the fallout, humidity, soil type, and tree age.¹⁰³ In June 1996, abnormal development in three species of plants (black locust tree, *Robinia pseudoacacia*; rowan, *Sorbus aucuparia*; camomile, *Matricaria perforata*) was observed between Chernobyl and an uncontaminated area 225 km to the southeast.¹²⁸ Abnormalities, including leaf or flower asymmetry, were three to four times more frequent near Chernobyl than more distant sites and were directly related to ¹³⁷Cs concentrations in soils.¹²⁸ In 1993–1994, about 55% of all young (2- to 9-year-old) plants of pine and spruce growing within 10 km of Chernobyl had abnormal needles, due in part to radiation-induced alterations in protein composition.¹⁴⁴ In 1993–1995, timber products within 30 km of Chernobyl were sufficiently contaminated with radiocesium and other isotopes as to preclude human use, as was the case for berries and mushrooms.¹⁵¹ Economic damage to forest products within the 30-km exclusion zone is estimated at U.S.\$278 million annually with a total estimated loss between 1986 and 2015 of U.S.\$8.4 billion.¹⁵¹

Concentrations of radioactivity in water, sediments, and biota of the Chernobyl cooling pond ecosystem declined between 1986 and 1990, as judged by ¹³⁷Cs concentrations (Table 24.1). Carp and other fish species held in Chernobyl cooling pond waters had reproductive-system anomalies that were more pronounced in males than females.^{98,99} Silver carp (*Hypophthalmichthys molitrix*) survivors from the cooling pond of the Chernobyl nuclear power station received 7–11 Gy between 1989 and 1992 and displayed reproductive-system disorders that included sterility, changes in gonadal morphology, and degeneration of reproductive cells.⁹⁹ Silver carp born in 1989 from parents reared in Chernobyl cooling pond waters had a marked increase of 17 to 26% above controls in reproductive-system anomalies in 1989–1992.⁷² Anomalies included degenerative changes in oocytes, spermatogonia, and spermatocytes, and the appearance of bisexual and sterile fish. The gonadal abnormalities are attributed to the high radiation dose of 7–10 Gy received by the parent fish during gonad formation and the continuing exposure of 0.2 Gy annually to this generation.⁷² Mature silver carp dwarf individuals age 4+, descendants of fish irradiated in 1986, were observed in 1991.¹⁰⁰ In 1992, second-generation fish hatched from 3-year-old fish of the first generation. Female reproductive systems were not significantly different from controls; however, males had decreased ejaculate volume and concentration and destructive changes in testes caused by irradiation.¹⁰¹ Silver carp from this ecosystem also had a dose-dependent decrease in hormonal control over the Na⁺, K⁺-pump in erythrocytes, with increased passive permeability of the erythrocyte membrane to radioactive analogs of sodium and potassium.⁷³

Radionuclide levels in soil invertebrates, soil, litter, and terrestrial insects within the 30-km exclusion zone declined sharply between 1986 and 1987, usually by a factor of ten or more.¹⁶⁵ Radionuclide concentrations in muscle of fishes from the Kiev Reservoir decreased significantly during the period 1986–1997.¹⁰⁵ Female northern pike, *Esox lucius*, of the 1986 year class from this locale had gonadal abnormalities during the period 1987–1997. Abnormality frequency rate was about 34% and included asymmetry, histopathology, and roe resorption. The internal radiation dose from ¹³⁴⁺¹³⁷Cs decreased from about 0.1–0.2 Gy in 1986 to 0.001–0.002 Gy during 1993–1997.¹⁰⁵ In the 5-year period following the accident, amphibians and reptiles within the 30-km exclusion zone, had gamma radiation levels that remained stable and sometimes increased due to accumulation of radionuclides.¹⁶⁵ One year after the accident, terrestrial birds within the 30-km exclusion zone had gamma radiation levels five to seven times higher than did conspecifics from uncontaminated areas. Waterfowl, however, during the summer of 1987, had radiation levels that were two to five times higher than a year previously, with highest levels in young and females.¹⁶⁵

Table 24.1 Radionuclide Concentrations in Organisms and Abiotic Materials near Chernobyl

Locale, Radionuclide, Sample, and Other Variables	Concentration ^a and Reference
Chernobyl cooling pond ecosystem; ¹³⁷Cs; 1986 (postaccident) vs. 1990	
Water	210 FW vs. 14 FW ⁷¹
Sediments	170,000 FW vs. 140,000 FW ⁷¹
Algae	90,000 FW vs. 19,000 FW ⁷¹
Fishes; 5 spp.; muscle	30,000–180,000 FW vs. 8000–80,000 FW ⁷¹
Various ponds; 20–40 km from Chernobyl; ¹³⁷Cs; September 9–19, 1992	
Sediments	Usually < 1000 DW; Max. 11,000 DW ¹⁷¹
Crucian carp, <i>Carassius carassius</i> ; muscle	< 1000–8200 DW ¹⁷¹
Terrestrial Invertebrates	
Within 30-km exclusion zone, 1986 (postaccident)	
Soil invertebrates; gamma vs. beta radiation levels	21,800–34,800 DW vs. 48,100–166,700 DW ¹⁶⁵
Insects; gamma vs. beta radiation levels	4,800–218,300 DW vs. 200–37,000 DW ¹⁶⁵
Pine forest 80 km from Chernobyl; 1988; ¹³⁴⁺¹³⁷Cs	
Forest workers, human ^b	205 FW ¹⁶²
Soil, up to 5 cm deep	296 DW ¹⁶²
Pine needles	2040 DW ¹⁶²
Forest substrate	151,700 DW ¹⁶²
Mosses	161,000 DW ¹⁶²
Vegetation	
July–August 1988; 6–18 km from power plant

Voles, <i>Microtus</i> spp., 3 spp.	469,400–695,000 DW vs. 780–1000 DW ¹⁴⁵
Bank vole, <i>Clethrionomys glareolus</i>	5,062,200 (Max. 73,090,000) DW vs. 1800 (max. 3000) DW ¹⁴⁵
Common shrew, <i>Sorex araneus</i>	632,300 (45,800–2,910,000) DW vs. 800 (300–1400) DW ¹⁴⁵

Note: All concentrations are in Bq/kg fresh weight (FW), dry weight (DW), or ash weight (AW) unless indicated otherwise.

^a Concentrations are shown as mean, range in parentheses, maximum (Max.), and nondetectable (ND).

^b 65 kg person.

In June 1991, male barn swallows (*Hirundo rustica*) collected within 50 km of Chernobyl — when compared to control areas 100 km distant and with museum samples from both areas — had significant differences in length of tail feathers between the right and left side (fluctuating asymmetry) and in morphology of feathers. The degree of fluctuating asymmetry in male tail length and the frequency of deviant morphology in the tails of male barn swallows were associated with a delay in the start of the breeding season.¹¹⁷ In 1996, barn swallows near Chernobyl, when compared to conspecifics from distant sites, had decreased lymphocyte and immunoglobulin concentrations, reduced spleen size, and reduced intensity of carotenoid-based coloration.¹³⁷ Length of outermost tail feathers of males — important secondary sexual characteristics — was positively related to coloration in controls but not in the Chernobyl population, and this may affect breeding success of Chernobyl swallow populations.¹³⁷ In 1994, mallard tissues collected within 10 km of Chernobyl had 8000 to 30,000 Bq/kg FW (Table 24.1). Conspecifics collected 45 km from the reactor in 1994 had tissue concentrations that were 40 to 100 times lower.⁸⁹ Population numbers of mallards and teals decreased in the 30-km zone in 1994, perhaps due to decreased food sources of farmlands, and invasion of nest areas by plant communities not used in agriculture.⁸⁹ In 1994, there were no cases of radiation-induced pathology in any bird examined.⁸⁹ Also in 1994, there were increased sightings of rarely seen species of egrets, cranes, and eagles.⁸⁹

In 1991, 5 years after the accident, a female root vole (*Microtus oeconomus*) with an abnormal karyotype (reciprocal translocation) was found within the 30-km radius of the Chernobyl nuclear power plant. These chromosomal aberrations were probably inherited and did not affect the viability of vole populations.⁷⁷ Population density of Chernobyl rodents in 1988–1989 was about twice that predicted from previous cycles and was attributed, in part, to increasing radioresistance and abundance of food supplies.¹⁵⁴

In 1994–1995, the diversity and abundance of the small mammal population (12 species of rodents) at the most radioactive sites at Chernobyl were the same as reference sites.⁷⁸ Rodents from the most radioactive areas did not show gross morphological features other than enlargement of the spleen. There were no gross chromosomal arrangements, as judged by examination of the karyotypes. Also observed within the most heavily contaminated site were red fox (*Vulpes vulpes*), gray wolf (*Canis lupus*), moose (*Alces alces*), river otter (*Lutra lutra*), roe deer (*Capreolus capre-*

olus), Russian wild boar (*Sus scrofa*), brown hare (*Lepus europaeus*), and feral dogs.⁷⁸ The rich biodiversity and abundance of individuals in the 10-km exclusion zone is attributed, in part, to the absence of human habitation.¹⁶³

In 1994–1996, small mammals collected within 8 km of the Chernobyl reactor were experiencing substantial radiation dose rates from ¹³⁴⁺¹³⁷Cs in muscle and ⁹⁰Sr in bone.¹⁴⁵ Radiocesium concentrations averaged 3,200,000 Bq/kg muscle DW and for ⁹⁰Sr in bone 297,000 Bq/kg ash weight. Dose rates from radiocesium averaged 2.4 mGy daily (maximum 60 mGy/day) and from radiostrontium 1.0 mGy daily. Conspecifics captured 30 km southeast of the reactor averaged only 2000 Bq/kg muscle DW and were receiving 0.014 mGy daily from internal radiocesium. Estimated dose rates in certain areas of the Chernobyl region now exceed those reported to interfere with mammalian reproduction.¹⁴⁵

24.3 NONLOCAL EFFECTS

Radioactive material from the Chernobyl accident became widely dispersed throughout Europe and the northern hemisphere (Table 24.2). In Europe alone, about 80,000 TBq of ¹³⁷Cs was deposited as follows: Belarus 33.5%, Russia 24%, Ukraine 20%, Sweden 4.4%, Finland 4.3%, Bulgaria 2.8%, Austria 2.7%, Norway 2.3%, Romania 2%, and Germany 1.1%.¹⁷³ It is probable that the full impact of the Chernobyl reactor accident on natural resources will not be known for several decades, primarily because of data gaps on long-term genetic and reproductive effects and on radiocesium cycling and toxicokinetics.

24.3.1 Soil and Vegetation

The radiocesium fallout in Sweden was among the highest in western Europe — exceeding 60,000 Bq/m² on Sweden's Baltic coast — and involved mainly upland pastures and forests.^{5–7} In Norway, radiocesium deposition from the Chernobyl accident ranged from < 5000 to > 200,000 Bq/m², and greatly exceeded deposition from prior nuclear weapons tests.¹¹ In Italy, heavy rainfall coincided with the passage of the Chernobyl radioactive cloud and caused local high deposition of radionuclides in soil, grass, and plants.¹² The Chernobyl plume reached Greece on May 1, 1986. A total of 14 gamma emitters were identified in Greek soil and vegetation in May 1986, and three (¹³⁴Cs, ¹³⁷Cs, ¹³¹I) were also detected in milk of free-grazing animals in the area.¹³ Radiocesium-134 and ¹³⁷Cs intake by humans in Germany during the period 1986–1987 was mainly from rye, wheat, milk, and beef.¹⁴ In the United Kingdom, elevated concentrations of radionuclides of iodine, cesium, ruthenium, and other nuclides were measured in air and rainwater during May 2–5, 1986.¹ The background activity concentrations were about three times normal levels in early May, and those of ¹³¹I approached the derived emergency reference level (DERL) of drinking water of 5 mSv ¹³¹I (equivalent to a thyroid dose of 50 mSv); however, ¹³¹I levels were not elevated in foodstuffs or cow's milk.¹ Syria — 1800 km from Chernobyl — had measurable atmospheric concentrations of ¹³⁷Cs and ¹³¹I and near detection-limit concentrations of ¹⁴⁴Ce, ¹³⁴Cs, ¹⁴⁰La, and ¹⁰⁶Ru.¹⁵ The maximum ¹³¹I thyroid dose equivalent received by Syrians was 116 μSv in adults and 210 μSv in children. One year later, these values were 25 μSv in adults and 70 μSv in a 10 year old.¹⁵

The amount of fallout radioactivity deposited on plant surfaces depends on the exposed surface area, the developmental season of the plants, and the external morphology. Mosses, which have a comparatively large surface area, showed highest concentrations of radiocesium (Table 24.2). In northern Sweden, most of the radiocesium fallout was deposited on plant surfaces in the forest ecosystem and was readily incorporated into living systems because of browsing by herbivores and cesium's chemical similarity to potassium.⁷ In August 1992, the distribution of ¹³⁷Cs fallout from Chernobyl in a Swedish forest was 87% in soils, 6% in the bryophyte layer, and 7% in standing biomass of trees; the mean deposition of ¹³⁷Cs was estimated at 54,000 Bq/m².¹³⁸ The mean ¹³⁷Cs

Locale, Sample, Radionuclide, and Other Variables	Concentration ^a and Reference
Bog whortleberry, <i>Vaccinium uliginosum</i>	5900 DW ¹⁶
Cowberry, <i>Vaccinium vitisidiae</i>	7500 DW ¹⁶
Boreal coniferous forest in Hille, Sweden; average total deposit of 220,000 Bq ¹³⁷ Cs/m ² in 1986; ¹³⁷ Cs; 1991	
Fungi	(120,000–230,000) DW, (3,000–950,000) DW ¹²⁴
Lichens	36,000 (29,000–69,000) DW ¹²⁴
Mosses, ferns, angiosperms	8000–19,000 DW (600–37,000) DW ¹²⁴
Cow's milk; ¹³⁷ Cs	
July 1986	Mostly < 250 FW; Max. 375 FW ⁶⁸
1987	Usually < 70 FW; Max. 120 FW ⁵
Lichen, <i>Bryoria fuscescens</i> ; ¹³⁷ Cs; 4 June 1986	(34,000–120,000) DW ⁶⁷
Roe deer, <i>Capreolus</i> sp.; muscle; ¹³⁷ Cs; 1986, post-accident	(20–12,000) FW ⁵
Lichen, <i>Cladina</i> spp.; ¹³⁷ Cs; 1986, postaccident	Max. 40,000 DW ⁶⁷
Bank vole, <i>Clethrionomys glareolus</i> , collected from soil containing various concentrations of ¹³⁴ + ¹³⁷ Cs; voles analyzed less skull and digestive organs	
1800 Bq/m ² soil (control)	Voles had 9 Bq ¹³⁴ Cs/kg FW, and 39 of ¹³⁷ Cs; mutation frequency 1.3; total daily irradiation of 4.2 μGy ⁴³
22,000 Bq/m ² soil	In Bq/kg FW, voles had 279 ¹³⁴ Cs, and 1031 ¹³⁷ Cs; mutation frequency 1.5; daily dose rate of 8.8 μGy ⁴³
90,000 Bq/m ² soil	Voles had 1356 Bq ¹³⁴ Cs/kg FW and 5119 of ¹³⁷ Cs; mutation frequency 1.9; daily dose of 26.8 μGy ⁴³
145,000 Bq/m ² soil	Voles had 2151 Bq ¹³⁴ Cs/kg FW and 7784 ¹³⁷ Cs; mutation frequency 2.6; daily dose of 39.4 μGy ⁴³
Northern pike, <i>Esox lucius</i> ; Lake Störvindeln; muscle ¹³⁷ Cs vs. ¹³⁴ Cs	
Preaccident	Max. 27 FW vs. < 1.2 FW ¹⁰⁸
May 12–16, 1986	Max. 19 FW vs. < 2.4 FW ¹⁰⁸
May 21–27, 1987	460 FW, Max. 567 FW vs. 156 FW, Max. 199 FW ¹⁰⁸
Buckbean, <i>Menyanthes trifoliata</i> ; ¹³⁷ Cs; 1985 vs. 1987	1000 DW vs. 3880 DW ⁶⁷
Reindeer dietary lichens; ¹³⁷ Cs; April 1986	Usually 40,000–60,000 DW; Max. 120,000 DW ³²
Reindeer	
Moved in November 1986 from a highly contaminated area (> 20,000 Bq ¹³⁷ Cs/m ²) to a less-contaminated area (< 3000 Bq/m ²) of natural pasture	¹³⁷ Cs content in muscle declined from 12,000 FW in November 1986 to about 3000 FW in April 1987 ²⁵
Muscle; ¹³⁷ Cs; 1986, post-Chernobyl	(100–40,000) FW ⁵
Muscle; ¹³⁷ Cs; 1987;	Max. 96,000 FW ¹³⁶
Muscle; Ottsjolagret; October 16, 1987; ¹³⁷ Cs vs. ¹³⁴ Cs	5300 (2970–8955) FW vs. 2024 (1100–3482) FW ¹⁰⁸
Muscle; Ammarnis; ¹³⁷ Cs vs. ¹³⁴ Cs	
Pre-Chernobyl	Max. 140 FW vs. < 3 FW ¹⁰⁸
September 1986	1670 FW, Max. 2460 FW vs. 610 FW, Max. 930 FW ¹⁰⁸
September 1987	950 FW, Max. 2884 FW vs. 338 FW, Max. 1020 FW ¹⁰⁸
August 1989	251 FW, Max. 541 FW vs. no data ¹⁰⁸
Common shrew, <i>Sorex araneus</i> ; July–August 1986; ¹³⁷ Cs; whole less skull, stomach, and viscera	.
From soil containing 1,800 Bq/m ²	48 FW ⁶⁹
From soil containing 22,000 Bq/m ²	751 FW ⁶⁹
From soil containing 90,000 Bq/m ²	3233 FW ⁶⁹
From soil containing 145,000 Bq/m ²	6289 FW ⁶⁹
Syria

Lambs	17 FW vs. < 8 FW ⁵³
Diet (rye grass and vegetation); ^{110m} Ag; 1986 vs. 1987	32 DW vs. 10–30 DW ⁵³
Red fox, <i>Vulpes vulpes</i> ; muscle; November 1986–February 1987; vixen	
¹³⁴ Cs	176 FW ³⁸
¹³⁷ Cs	(461–643) FW ³⁸

Note: All concentrations are in Bq/kg fresh weight (FW) or dry weight (DW) unless noted otherwise.

^a Concentrations are shown as mean, range in parentheses, maximum (Max.), and nondetectable (ND).

concentration in muscle samples from moose shot within a 10,000-ha area around the forest in October 1992 was 810 (51–2133) Bq/kg FW; for roe deer muscle from this area in autumn 1992, it was 4200 (500–12,000) Bq/kg FW.¹³⁸

Forest plants seemed to show less decrease than agricultural crops in ¹³⁷Cs activity over time.¹⁶ For example, the effective retention half-time of ¹³⁷Cs from Chernobyl was 10 to 20 days in herbaceous plants and 180 days in chestnut trees, *Castanea* spp.¹⁷ In Finland during summer 1986, pine-tree needles lost about 50% of their accumulated ¹³⁷Cs activity in 72 days; washout by through-fall accounted for 79% of the decrease and shedding of older needles most of the remainder.¹⁰² The radioactive fallout from the Chernobyl accident also resulted in high ¹³⁷Cs levels in Swedish pasture grass and other forage, although levels in grain were relatively low.¹⁸ Radiocesium isotopes were still easily measurable in grass silage harvested in June 1986 and used as fodder for dairy cows in 1988.¹⁹ The rejection of the first harvests of radiocesium-contaminated perennial pasture and in particular of rye grass (*Lolium perenne*) does not constitute a safe practice because later harvests — even 1 year after the contamination of the field — may contain very high values, as in Greece.²⁰

24.3.2 Aquatic Life

After Chernobyl, the consumption of freshwater fishes by Europeans declined, fishing license sales dropped by 25%, and the sale of fish from radiocesium-contaminated lakes was prohibited.⁶ Many remedial measures have been attempted to reduce radiocesium loadings in fish, but none has proven effective.²¹

Bioconcentration factors (BCF) of ^{137}Cs (Bq/kg FW/Bq/L seawater) measured in plankton and soft-bottom benthos during 1989–1990 in the Adriatic Sea ranged from 29 to 152 for plankton and 100 to 229 for benthos.⁸⁶ Radiocesium BCFs in muscle of fishes from the southern Baltic Sea increased three to four times after Chernobyl,²² and $^{134+137}\text{Cs}$ and ^{106}Ru in fishes in the Danube River increased by a factor of five. However, these levels posed negligible risk to human consumers.²³ BCFs of ^{137}Cs in fishes from Lake Paijanne, Finland — a comparatively contaminated area — ranged between 1250 and 3800; the highest BCF values were measured in the predatory northern pike (*Esox lucius*) a full 3 years after Chernobyl; consumption of these fishes was prohibited.²⁴ Chernobyl radioactivity, in particular ^{141}Ce and ^{144}Ce , entering the Mediterranean as a single pulse, was rapidly removed from surface waters and transported to 200 m in a few days, primarily in fecal pellets of grazing zooplankton.⁷⁹

After the Chernobyl accident, radiocesium isotopes were also elevated in trees and lichens bordering an alpine lake in Scandinavia and in lake sediments, invertebrates, and fishes (Table 24.2). Radiocesium levels in muscle of resident brown trout (*Salmo trutta*) remained elevated for at least 2 years.⁶ People consuming food near this alpine lake derived about 90% of their effective dose equivalent from the consumption of freshwater fish, reindeer meat, and milk. The average effective dose equivalent of this group during the next 50 years is estimated at 6–9 mSv with a changed diet and 8–12 mSv without any dietary changes.⁶

Between 1988 and 1992, ^{137}Cs levels declined in sediments from 52 lakes in southern Finland by 27% and in fish tissues by 26 to 39%.¹²⁰ Radiocesium-137 concentrations in whole freshwater fishes from Norwegian lakes contaminated by Chernobyl fallout were quite variable. Major sources of ^{137}Cs variations included the fish weight and growth rate, and these were related to fish age and diet.⁸⁵ Change over time in dissolved-phase ^{137}Cs concentrations of lake water is significantly related to water residence time and mean lake depth; these variables have been incorporated into models to predict estimates of ^{137}Cs decline in freshwater systems.⁹⁷ Radiocesium-137 activity in muscle of brown trout (*Salmo trutta*) and Arctic char (*Salvelinus alpinus*) from six lakes in Cumbria, England between June 1986 and October 1988 were highest between December 1986 and March 1987, with maximum values of about 1200 Bq/kg FW in trout and 350 in char.¹⁰⁷ Maximum ^{137}Cs values were related to the initial concentration of ^{137}Cs in both water and sediments and the maximum monthly geometric mean ^{137}Cs values obtained from the routine water samples; no similar relationships were found with mean calcium or potassium levels in lake water. Ecological half-life for ^{137}Cs in fish flesh from Cumbrian lakes was 132 days in char and 180 to 240 days in trout.¹⁰⁷

24.3.3 Wildlife

Reindeer (*Rangifer tarandus*) — also known as caribou in North America — are recognized as a key species in the transfer of radioactivity from the environment to humans because 1) the transfer factor of radioactivity from reindeer feed to reindeer muscle is high; 2) lichens — which constitute a substantial portion of the reindeer diet — are efficient accumulators of strontium, cesium, and actinide radioisotopes; and 3) reindeer feed is not significantly supplemented with grain or other feeds low in contamination.^{25–27,29,30,95,136} During the period 1986–1987, about 75% of all reindeer meat produced in Sweden was unfit for human consumption because ^{137}Cs exceeded 300 Bq/kg fresh weight (FW). In May 1987, the maximum permissible level of ^{137}Cs in Swedish reindeer and other game was raised to 1500 Bq/kg FW; however, about 25% of slaughtered reindeer in 1987 to 1989 still exceeded this limit.²⁸ Concentrations in excess of 100,000 Bq $^{134+137}\text{Cs}$ /kg FW in lichens have been recorded in the most contaminated areas and in the 1986–1987 season was reflected in reindeer muscle concentrations of > 50,000 Bq/kg FW from the most contaminated areas of central Norway.³¹ Norwegian reindeer containing 60,000–70,000 Bq ^{137}Cs /kg FW in muscle receive an estimated yearly dose of 500 mSv.³² The maximum radiation dose to reindeer in Sweden after Chernobyl was about 200 mSv/year, with a daily dose rate of about 1 mSv during the winter

period of maximum tissue concentrations.²⁵ In general, reindeer calves had higher ¹³⁷Cs levels in muscle than adult females (4700 vs. 2700 Bq/kg FW) during September 1988, suggesting translocation to the fetus.²⁹ Two reindeer herds in Norway that were heavily contaminated with radiocesium had a 25% decline in survival of calves; survival was normal in a herd with low exposure.²⁷

Several compounds inhibit uptake and reduce retention of ¹³⁷Cs in reindeer muscle from contaminated diets, but the mechanisms of the action are largely unknown. These compounds include zeolite — a group of tectosilicate minerals — when fed at 25–50 g daily;³³ ammonium hexacyanoferrate — also known as Prussian Blue or Giese salt — at 0.3–1.5 g daily;^{34–36} bentonite — a montmorillonite clay — when fed at 2% of diet;³³ and high intakes of potassium.³³ In Sweden, radiocesium concentrations in domestic reindeer meat were reduced by early slaughter (to avoid grazing on pastures abundant in fungi and lichens), feeding uncontaminated diets for 8 to 12 weeks prior to slaughter, and adding cesium binders to the feed.¹³⁶ Much additional work seems needed on chemical and other processes that will hasten excretion and prevent uptake and accumulation of radionuclides in livestock and wildlife.⁹⁵

Reindeer herding is, at present, the most important occupation in Finnish Lapland and portions of Sweden.²⁶ Swedish Lapland reindeer herders have experienced a variety of sociocultural problems as a result of the Chernobyl accident. The variability of contamination has been compounded by the variability of expert statements about risk, the change in national limits of Bq concentrations set for marketability of meat, and the variability of the compensation policy for slaughtered reindeer. These concerns may result in fewer Lapps becoming herders and in a general decline in reindeer husbandry.³⁷

Caribou in northern Quebec contained up to 1129 Bq ¹³⁷Cs/kg muscle FW in 1986–1987, but only 10 to 15% of this amount originated from Chernobyl; the remainder is attributed to fallout from earlier atmospheric nuclear tests.³⁹ The maximum concentration of ¹³⁷Cs in meat of caribou (*Rangifer tarandus granti*) from the Alaskan Porcupine herd after Chernobyl did not exceed 232 Bq/kg FW, and this is substantially below the recommended level of 2260 Bq ¹³⁷Cs/kg FW.⁴⁰ Radiocesium transfer in an Alaskan lichen-reindeer-wolf (*Canis lupus*) food chain has been estimated. If reindeer forage contained 100 Bq/kg dry weight (DW) lichens and 5 Bq/kg DW in vascular plants, the maximum winter concentrations — at an effective half-life of 8.2 years in lichens and 2.0 years in vascular plants — were estimated at 20 Bq/kg FW in reindeer-caribou skeletal muscle and 24 Bq/kg FW in wolf muscle.⁴¹ The radioactive body burden in exposed reindeer and the character of chromosomal aberrations — which was different in exposed and nonexposed reindeer — indicate a genetic effect of radiation from the Chernobyl accident.³¹ Chromosomal aberrations in Norwegian female reindeer positively correlated with increasing radiocesium concentrations in flesh.²⁷ The frequency of chromosomal aberrations in reindeer calves from central Norway were greatest in those born in 1987, when tissue loadings were equivalent to fetal doses of 70–80 mSv and lower in 1988 (50–60 mSv) and 1989 (40–50 mSv), strongly suggesting a dose-dependent induction.³¹

For many households in Sweden, moose (*Alces alces*) are an important source of meat.⁷ Radiocesium concentrations in moose foreleg muscle in Sweden during 1987–1988 were highest in autumn, when the daily dietary intake of the animals was about 25,000 Bq ¹³⁷Cs and lowest during the rest of the year, when mean daily intake was about 800 Bq.¹⁶ Cesium-137 levels in moose flesh did not decrease significantly for about 2 years after the Chernobyl accident.⁵ Nine years after the accident many moose in Sweden from areas receiving high deposition still showed ¹³⁷Cs activity concentrations that exceed the limit for human consumption.⁸⁸

The selection of food by moose is paramount to the uptake of environmental contaminants and the changes in tissue levels over time. Increased foraging on highly contaminated plant species, such as bilberry (*Vaccinium myrtillus*), aquatic plants, and mushrooms, might account for the increased ¹³⁷Cs radioactivity in moose.^{7,88} Habitat is a useful indicator of ¹³⁷Cs radioactivity in moose muscle; radioactivity was highest in moose captured in swamp and marsh habitats and lowest in farmlands.^{80,88} For reasons that are not yet clear, transfer coefficients of ¹³⁷Cs from diet to muscle were about the same in moose (0.03) and beef cattle (0.02), but were significantly higher in sheep (0.24).¹⁶

Consumption of game or wildlife in Great Britain after the Chernobyl accident probably does not exceed the annual limits of intake (ALI) based on $^{134+137}\text{Cs}$ concentrations in game and the numbers of animals that can be eaten in 1 year before the ALI is exceeded.³⁸ For example, a person who eats hares containing 3114 Bq $^{134+137}\text{Cs}/\text{kg}$ FW in muscle would have to consume 99 hares before exceeding the ALI. For the consumption of red grouse (3022 Bq/kg), this number is 441 grouse; and for the consumption of woodcock (55 Bq/kg), it is 45,455 woodcocks.³⁸ Rabbits (*Oryctolagus* sp.) from northeastern Italy that were fed Chernobyl-contaminated alfalfa meal (1215 Bq $^{134+137}\text{Cs}/\text{kg}$ diet) had a maximum of 156 Bq/kg muscle FW of $^{134+137}\text{Cs}$, a value much lower than the current Italian guideline of 370 Bq/kg FW for milk and children's food and 600 Bq/kg FW for other food.¹² More than 85% of the ingested radiocesium was excreted by rabbits in their feces and urine; about 3% was retained.¹²

Radiocesium-137 contamination of muscle of roe deer in 1986–1987 in Germany was lowest in March and highest in October and is attributed to increased food intake and the high concentrations in food plants such as ferns and mushrooms consumed at this time of the year.¹¹³ Cesium radioactivity in tissues and organs of the wolverine (*Gulo gulo*), lynx (*Felis lynx*), and Arctic fox (*Alopex lagopus*) in central Norway after the Chernobyl accident was highly variable. In general, cesium-137 levels were substantially lower in these carnivores than in lower trophic levels,⁴⁵ suggesting little or no food-chain biomagnification, and at variance with results of studies of the omnivore and herbivore food chain.

Mutagenicity tests were used successfully with feral rodents to evaluate the biological effects of the radiation exposure from the Chernobyl accident. Increased mutagenicity in mice (*Mus musculus domesticus*) was evident, as judged by the bone marrow micronucleus test, at 6 months and 1 year after the accident. Rodents with increased chromosomal aberrations also had ^{137}Cs burdens that were 70% higher 6 months after the accident and 55% higher after 1 year, but elevated radiocesium body burdens alone were not sufficient to account for the increase in mutagenicity.⁴² In bank voles, however, mutagenicity (micronucleated polychromatic erythrocytes) correlated well with the ^{137}Cs content in muscle and in the soil of the collection locale.⁴³ The estimated daily absorbed doses of 4.2–39.4 μGy were far lower than those required to produce the same effect in the laboratory.⁴³

Migratory waterfowl could serve as potential vectors of contamination to the human food chain. For example, cooked meat from migratory waterfowl harvested on their wintering grounds as much as 3000 km from the Chernobyl site may exceed the maximum level of radiocesium generally permitted for human consumption (600 Bq/kg FW), depending on deposition rate.⁹¹ Migratory species of game birds in northern Ireland during the period 1986–1988 were contaminated by radiocesium of Chernobyl origin.⁸⁷ The songthrush (*Turdus philomelos*) collected in Spain in November 1986 had elevated concentrations of ^{134}Cs , ^{137}Cs , and ^{90}Sr . The contamination probably occurred in central and northern Europe before the birds' migration to Spain.⁴⁴ In 1994, concentrations in songthrush tissues remained elevated.⁹⁴ However, Spaniards who ate songthrushes contaminated with radiocesium isotopes usually received about 58 μSv yearly, which is well below current international guidelines.⁴⁴ In 1987–1988, ptarmigans (*Lagopus* spp.) from alpine ecosystems in central Norway receiving 20,000–60,000 Bq $^{137}\text{Cs}/\text{m}^2$ in 1986 usually had < 350 Bq $^{137}\text{Cs}/\text{kg}$ FW muscle.¹⁵³ Concentrations of ^{137}Cs in ptarmigan muscle were higher in juveniles than in adults, higher in summer than in winter, and correlated with radiocesium concentrations in food plants.¹⁵³

24.3.4 Domestic Animals

Radiocesium isotopes from the Chernobyl accident transferred easily to grazing farm animals.¹¹ Both ^{134}Cs and ^{137}Cs were rapidly distributed throughout the soft tissues of animals after dietary ingestion and were most highly concentrated in muscle.^{46,47} Radiocesium activity in milk and flesh

of Norwegian sheep and goats, for example, increased three- to fivefold 2 years after the accident and coincided with an abundant growth and availability of fungal fruit bodies with $^{134+137}\text{Cs}$ levels as much as 100 times greater than green vegetation.¹¹ Norway — almost 2000 km from Chernobyl — condemned \$70.9 million (U.S.) of domestic animal products in the period 1986–1995 as a result of the accident.¹⁶¹ In 1986 alone, large amounts of mutton, reindeer meat, and goat's cheese exceeded the radiocesium content set by Norwegian authorities and was destroyed at an estimated loss of \$24 million. Economic loss in 1995 was about \$2.1 million. In 1996, after 10 years of expensive countermeasures (changes of pasturing areas, special feeding, cesium binders, change in slaughtering time), there was some decline in the size of the areas the numbers of animals involved; however, countermeasures are still required.¹⁶¹

In cattle, coefficients of radiocesium transfer from diet to muscle were about 2.5% in adults and 16% in calves. The higher value in calves was probably due to a high availability of cesium from the gastrointestinal tract and to daily uptake of potassium in growing animal muscle.⁴⁸ There was no correlation between retention of ^{137}Cs and pregnancy stage in cattle.⁴⁹ Radiocesium concentrations in pork in Czechoslovakia did not decline between 1986 and 1987 because the feed of pigs during this period contained milk by-products contaminated with $^{134+137}\text{Cs}$.⁵⁰

Sheep farming is the main form of husbandry in the uplands of west Cumbria and north Wales, a region that received high levels of radiocesium fallout during the Chernobyl accident. Afterward, typical vegetation activity concentrations were ~6000 Bq/kg (down to ~1000 Bq/kg in January 1989). But sheep muscle concentrations exceeded 1000 Bq ^{137}Cs /kg FW, which is the United Kingdom's dietary limit for human health protection.⁵¹ Contaminated lambs — which usually had higher concentrations of ^{137}Cs than ewes³⁸ — that were removed to lowland pastures (< 50 Bq/kg vegetation) rapidly excreted radiocesium in feces and urine, and cesium body burdens had an effective half-life of 11 days.⁵¹ This practice should not significantly increase radiocesium levels in soil and vegetation of lowland pastures.⁵¹ The absorption and retention of radiocesium by suckling lambs is highly efficient, about 66%. Fecal excretion was an important pathway after termination of ^{137}Cs ingestion. In weaned animals, the absorption of added ionic cesium was about twice that of cesium fallout after the accident at Chernobyl.⁵² Silver-110m was also detected in the brains and livers of ewes and lambs in the United Kingdom. The transfer of $^{110\text{m}}\text{Ag}$ was associated with perennial rye grass harvested soon after deposition in 1986. Silver-110m was taken up to a greater extent than ^{137}Cs in liver; but unlike ^{137}Cs , the $^{110\text{m}}\text{Ag}$ was not readily translocated to other tissues. Other than cesium isotopes and ^{131}I , $^{110\text{m}}\text{Ag}$ was the only detected nuclide in sheep tissues.⁵³

Atmospheric deposition of ^{137}Cs from Chernobyl to vegetation and eventually to the milk of sheep, cows, and goats on contaminated silage was reported in Italy, The Netherlands, Japan, and the United Kingdom.^{40,54–58} The effective half-life of ^{137}Cs was 6.7 days in silage and 13.6 days in milk.⁵⁹ The average daily transfer coefficient of $^{134+137}\text{Cs}$ from Chernobyl from a 70% grass silage diet to milk of Dutch dairy cows was about 0.25%/liter.¹⁹ In goats (*Capra* sp.), about 12% of orally administered ^{137}Cs was collected in milk within 7 days after dosing.⁴⁶

Iodine-131 was one of the most hazardous radionuclides released in the Chernobyl accident because it is easily transferred through the pasture-animal-milk pathway and rapidly concentrated in the thyroid gland to an extent unparalleled by any other organ. Because of its high specific activity, ^{131}I can transmit a high dose of radiation to the thyroid.⁶¹ Iodine-131 levels of 618,000 Bq/kg FW in sheep thyroids from northwestern Greece on July 3, 1986 are similar to maximal ^{131}I concentrations in sheep thyroids in Tennessee in 1957 after global atmospheric fallout from military weapons tests and in London after the Windscale accident.⁶¹ Iodine-131 has an effective whole-body half-life of about 24 h and is rapidly excreted from sheep and cows.¹³ The effective half-life of ^{131}I in pasture grass was 3.9 days and 5 days in cow's milk.⁵⁹ The daily transfer coefficient of ^{131}I from vegetation to cow's milk was 0.007%/L milk. This value was 57 times higher (0.4) in sheep,⁵⁸ but the mechanism that accounts for this large interspecies difference is not clear.

24.4 SUMMARY

The accident at the Chernobyl, Ukraine nuclear reactor on April 26, 1986 released large amounts of radiocesium and other radionuclides into the environment, contaminating much of the northern hemisphere, especially Europe. In the vicinity of Chernobyl, at least 30 people died, more than 115,000 others were evacuated, and consumption of milk and other foods was banned because of radiocontamination. At least 14,000 human cancer deaths are expected in Russia, Belarus, and Ukraine as a direct result of Chernobyl. The most sensitive local ecosystems, as judged by survival, were the soil fauna, pine forest communities, and certain populations of rodents. Elsewhere, fallout from Chernobyl significantly contaminated freshwater and terrestrial ecosystems and flesh and milk of domestic livestock; in many cases, radionuclide concentrations in biological samples exceeded current radiation protection guidelines. Reindeer (*Rangifer tarandus*) in Scandinavia were among the most seriously afflicted by Chernobyl fallout, probably because their main food during winter (lichens) is an efficient absorber of airborne particles containing radiocesium. Some reindeer calves contaminated with ^{137}Cs from Chernobyl showed ^{137}Cs -dependent decreases in survival and increases in frequency of chromosomal aberrations. Although radiation levels in the biosphere are declining with time, latent effects of initial exposure — including an increased frequency of thyroid and other cancers — are now measurable. The full effect of the Chernobyl nuclear reactor accident on natural resources will probably not be known for at least several decades because of gaps in data on long-term genetic and reproductive effects and on radiocesium cycling and toxicokinetics.

25.1 INTRODUCTION

Since the first occurrences of avian mortality from arsenicals and rodenticides in the early 20th century, concerns over pesticide effects on wildlife have led to the development of regulatory guidelines in many countries. In the United States, the Environmental Protection Agency (U.S. EPA), under the Federal Insecticide, Fungicide and Rodenticide Act of 1947 and its amendments (FIFRA), establishes the criteria for the testing and regulation of pesticides. Under FIFRA, pesticides that pose an unreasonable risk to wildlife should either be restricted in their use or banned altogether. In the face of mounting regulatory requirements, producers have sometimes chosen to withdraw pesticides from the market when the cost of meeting testing requirements exceeds the anticipated value of the product or when the ability of the pesticide to meet environmental safety requirements is doubtful.

Because many countries lack the resources to fully develop pesticide regulatory infrastructures of their own, they frequently rely on decisions made by the U.S. EPA, or equivalent regulatory bodies in other countries, to aid in their own internal decision-making. Restricted-use requirements

* Portions of text from Hooper, M.J., Mineau, P., Zaccagnini, M.E., Winegrad, G.W., and Woodbridge, B., *Pesticide Outlook*, 10(3), 97–102, 1999 have been used, unmodified or modified in this chapter with permission from the Royal Society of Chemistry (<http://www.rsc.org/po/>).

and outright banning of pesticides are actions that appear in the administrative record and are useful in developing regulatory criteria. Withdrawal of a pesticide, however, leaves a gap in the record and provides little useful data upon which decisions can be made in countries where the chemical is still available. This scenario is precisely what happened in the mid-1980s when the organophosphorus (OP) pesticide monocrotophos (dimethyl (E)-1-methyl-2-(methylcarbamoyl)vinyl phosphate; CAS No. 2157-98-4) was withdrawn from the market in the United States. In the subsequent 10 years, monocrotophos went on to become the second-highest-volume OP pesticide used in the world.¹ Ironically, monocrotophos is one of the most acutely toxic pesticides to birds. It took the death of an estimated 20,000 Swainson's hawks (*Buteo swainsoni*) in Argentina to reawaken the world's interest in monocrotophos. What's been learned since, as demonstrated by the risks that face many transborder avian migrants, has clarified the need for greater international cooperation in confronting pesticide impacts.

25.2 THE SWAINSON'S HAWK

A spring and summer inhabitant of western North America, the Swainson's hawk is a medium-sized broad-winged hawk of grassland, sparse shrub, and open woodlands, reaching its highest present-day nesting densities in areas of mixed agriculture and native habitat. During its summer breeding season, the Swainson's hawk nests in solitary trees, shrubs, or groves of trees along streams or agricultural areas, feeding rodents, small birds, reptiles, and insects to its young. The generally monogamous pairs will often return annually to within several km of previous breeding sites. Common farming practices, such as disking, cultivating, flooding, burning, and harvesting, provide hunting opportunities, as prey are disrupted by these actions.²

Gregarious by nature, Swainson's hawks can be seen in mixed adult and juvenile groups as large as 100 birds searching for food in the late summer. Flocks of 5000 to 25,000 birds were observed historically in the vicinity of San Antonio, Texas. Such North American assemblages of hawks are now found only in Mexico and Central America, where flocks containing hundreds of thousands of birds pass over known flyways on their southern migration.² Though overall population levels are relatively stable, if not increasing slightly, it is generally felt that Swainson's hawk numbers fell with the settling of the west. While populations in some areas remain low and the species is considered threatened (California) or in decline (Nevada, Utah, Oregon, and the prairie provinces of Canada), other areas support relatively abundant and stable populations (Idaho, Montana, Washington, and Colorado).^{2,3}

Though scattered banding and field reports document the hawk's presence in Argentina during the northern winter (the southern hemisphere or "austral" summer), the details of their migration weren't well established until 1994, when satellite-transmitter-carrying Swainson's hawks were tracked from their summer territories across western North America to the grasslands, or pampas, of Argentina (Figure 25.1). Hawks from across the western United States and Canada converge in eastern Mexico on the Gulf of Mexico coast. From there they follow a narrow, well-defined path through Central America, cross the Andes Mountains in Columbia, and travel south to Argentina along the eastern slopes of the Andes, moving an average of 188 km/day.^{4,5}

The pampas of Argentina comprise about a quarter of the country's area. With slowed beef exports in the latter 20th century, agricultural crop production increased on the pampas, leading to a rise in cultivated acreage, particularly for oil seed such as soybean, corn (maize), and sunflower that provide export crops for the country. Accompanying this production came a general intensification of farming practices including a lower tolerance of pest infestations and greater use of pesticides. Rather than the mammalian, avian, or reptilian prey chosen during the breeding season, the hawk's diet on the pampas is primarily insectivorous, feeding on grasshoppers, dragonflies, grubs, and other invertebrates.^{4,6-9}

The first transmitter-fitted birds migrated to La Pampa province in 1994, where large flocks of Swainson's hawks numbering from 2000 to 7000 individuals were found inhabiting the region.

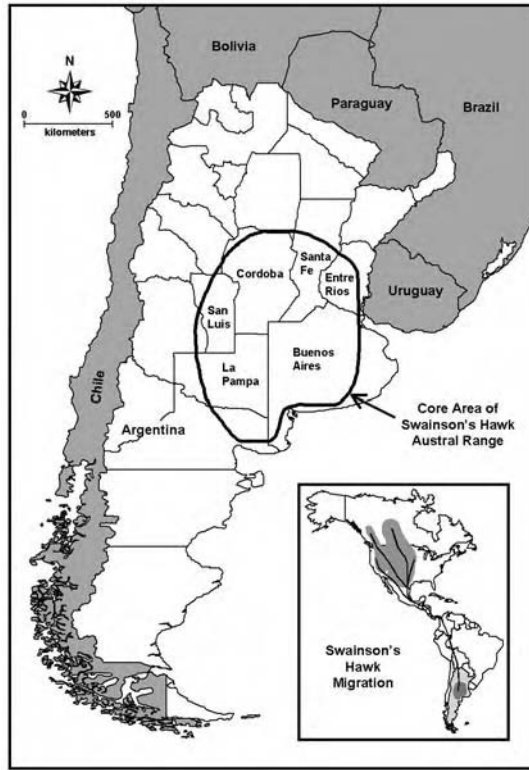

Figure 25.1 North and South American ranges, migratory pathway and core austral range of Swainson's hawks. (Based on Hooper, M. J. et al., *Pest. Outlook*, 10, 97, 1999. With permission.)

“Aguiluchos langosteros” (translated “locust-eating hawks”) foraged on agricultural fields and in the air during the day and roosted in eucalyptus groves (or “montes”) that provide windbreaks for local ranches and farms. In early morning, the hawks would glide to nearby fields, waiting for thermals that came with the sun’s heat and chasing and consuming “tucuras” (*Dichroplus* sp.), a small grasshopper, in the fields. The first evidence of mortality came with the discovery of over 700 dead hawks under one of the montes.⁴ According to the local farmer, hawks died after a neighbor sprayed sunflowers with a pesticide to kill grasshoppers in the young crop. As the carcasses were quite decomposed, no physical data were collected to determine the cause of the deaths. The pesticide used was thought to be monocrotophos. This insecticide would prove to be responsible for the vast majority, if not all, of the Swainson’s hawk mortality recorded in Argentina.

25.3 MONOCROTOPHOS

Of the pesticides used in U.S. agriculture today, excluding herbicides, the cholinesterase (ChE)-inhibiting OPs and carbamates are the most widely applied.¹⁰ In developing countries, where fewer herbicides are used than in developed ones, cholinesterase-inhibiting insecticides can make up a very high proportion of total pesticide use. Initially developed as military nerve agents in the 1930s, anticholinesterases were put to use as insecticides in the 1940s, competing with the newly discovered DDT and other organochlorines. By the late 1970s, OPs and carbamates had, for the most part, replaced the more persistent organochlorines as the insecticides of choice. Following uptake of a lethal OP dose, the pesticide inhibits the enzyme, acetylcholinesterase (AChE), in the nervous system and its target tissues, eventually causing death by respiratory failure or other direct physi-

^a LD₅₀ values are in mg active ingredient/kg body weight.

ological consequences of AChE inhibition.¹¹ Birds are particularly sensitive to OP pesticides, as they have a reduced ability to metabolize and excrete these toxicants from the body.¹²

Monocrotophos was developed in the early 1960s and was introduced in 1965 by Shell and Ciba under the trademarks Azodrin[®] and Nuvacron,[®] respectively. It is a broad-spectrum OP with systemic, residual, and contact toxicity to chewing and sucking insects. It has a high water solubility and breaks down relatively quickly in the environment.¹³ The avian toxicity of monocrotophos, however, places it among the most toxic pesticides to birds, with LD₅₀ values ranging from 0.2 mg active ingredient (a.i.)/kg body weight (b.w.) in the golden eagle (*Aquila chrysaetos*) to 14 mg a.i./kg b.w. in the house finch (*Carpodacus mexicanus*) (Table 25.1).

Because of the U.S. EPA's new avian field testing requirements for pesticides in the mid-1980s, Azodrin,[®] the commercial monocrotophos product available in the United States, was withdrawn from the market in 1989 by DuPont, who had obtained the U.S. rights to the chemical from Shell 3 years earlier (the international rights being purchased by American Cyanamid and currently retained by BASF). Due to its withdrawal, no official action was taken to further regulate or restrict the use of monocrotophos in the U.S. except to ensure compliance with residue tolerances in imported foodstuffs. In spite of its withdrawal from the United States, monocrotophos remained the second-highest-use OP in the world through the mid-1990s, with production continuing by at least 15 manufacturers worldwide (Figure 25.2).¹

The U.S. EPA's avian field-testing requirement for monocrotophos was not without cause. Case histories of monocrotophos field trials, posttreatment monitoring efforts, and mortality incidents are numerous.¹⁴ General trends from more than 25 field reports and publications on cotton, sugar cane, sunflower and maize, grain and forage crops, wide-row vegetable crops, and orchards and vineyards suggested that: (1) when monocrotophos was used above 1 kg a.i./ha, avian mortality was readily and predictably seen and (2) mortality occurred frequently below 1 kg a.i./ha, partic-

Monocrotophos use, in tons of technical product, averaged for 1994 to 1996

Figure 25.2 Global monocrotophos use statistics. (From Hooper, M. J. et al., *Pest. Outlook*, 10, 97, 1999. With permission.)

ularly if there were birds present in or near the field or if avian food items (i.e., weed seeds, fruits, or insect prey) or water sources were in or adjacent to the treated field. This meant that the insecticide had the potential to be causing avian mortality — often at rates of application that were no longer efficacious. Few of these reports are available in the open literature. It is only with the recent publication of Australia's National Registration Authority (NRA) monocrotophos risk assessment that the results of many of these studies have become accessible.¹⁴

It is noteworthy that many of these studies were conducted days to weeks after application and consisted of only quick searches of field perimeters as opposed to formal field studies meeting regulatory requirements for pesticide registration. This both draws into question the validity of negative findings in a few of the studies (notably in orchards) and at the same time demonstrates the obvious magnitude of many of the incidents, given the numbers and ease with which birds were found under the most rudimentary monitoring conditions.

Of particular interest in the list of incidents is the occurrence of a mass mortality of resident, wintering, and migratory raptors that occurred beginning in 1975, when monocrotophos was used to control levant vole (*Microtus guentheri*) populations infesting alfalfa fields in Israel's Hula Valley.^{15,16} The voles' disinterest in rodenticide baits in the face of abundant alfalfa crops had led farmers to turn to monocrotophos spray applications. The raptors, already attracted to the vole outbreak, found the dead and dying rodents on the surface of the fields easy prey. By the time authorities finished counting the bodies and collecting and treating the survivors, 150 raptors were dead and 69 were being treated in wildlife care centers. Based on carcass recoveries and census numbers before and after the incident, it was estimated that 300 to 400 raptors were killed in this incident. Species affected in greatest numbers included spotted eagles, common buzzards, black kites, kestrels, and barn owls (Table 25.2). These deaths were particularly significant, as wintering assemblages of several species in the area were decimated to levels from which their numbers did not recover during the winter season.

Israeli agriculture regulators subsequently banned the use of monocrotophos for vole control in alfalfa. The lack of a suitable control agent to replace monocrotophos, however, led to continued unprosecuted use of the compound.¹⁷ By the end of winter 1979, 365 raptors had been documented killed and another 258 treated for OP toxicosis. The barn owl, kestrel, black kite, common buzzard, and spotted eagle made up nearly 80% of the birds affected throughout the four seasons of monocrotophos use (Table 25.2). Numbers decreased during the latter 2 years as decreased alfalfa plantings (due to vole losses) led to decreased area sprayed. Unfortunately, monocrotophos-induced mortality did not end with the raptor deaths of the 1970s. As recently as 1997, applications of monocrotophos to fields in Israel's Bet She'an Valley led to the death or incapacitation of 59 black

kites (*Milvus migrans*), 11 kestrels (*Falco tinnunculus*), and 19 barn owls (*Tyto alba*) as well as many nonraptor migrants such as 168 red-throated pipits (*Anthus cervinus*) and 65 sky larks (*Alauda arvensis*).¹⁸ Ironically, many of the barn owls and kestrels that were killed had been attracted to the area with an extensive nest-box program aimed specifically at controlling local rodent populations.

25.4 ARGENTINE MORTALITY INCIDENTS

25.4.1 The 1995/1996 Austral Summer

In a follow-up study to the 1994/1995 Swainson's hawk incident, researchers traveled to Argentina, where they worked with the same local farmer and Argentine government wildlife researchers from INTA (Instituto Nacional de Tecnología Agropecuaria) to document the extent of the problem. They discovered four large mortality incidents, totaling over 4100 birds.^{19,20} Argentine researchers documented 14 additional mortality incidents from January through March 1996, bringing the estimated total to 5093 dead Swainson's hawks (Table 25.3). In the majority of the incidents, monocrotophos was implicated as the pesticide responsible for the mortalities.^{20,21} Preliminary estimates, based on a crude area extrapolation, suggested a total kill of up to 20,000 birds.

Forensic evaluation of the Argentine mortalities used landowner and applicator interviews, analyses of chemical residues from hawk stomach contents, and evaluation of ChE activity in tissues from the dead and incapacitated hawks. Landowner and applicator interviews implicated monocrotophos use (16 of 18 interviews), primarily in alfalfa and sunflowers, for control of the tucura grasshoppers.²¹ Though not specifically registered for this use, monocrotophos was registered for use in alfalfa against a number of insect pests. As this type of off-label use was not specifically prohibited in Argentina, farmers were not violating pesticide-use regulations.²²

Monocrotophos was confirmed in 31 of 45 samples from the sites with recoverable tissues, averaging 0.20 ppm (fresh wt.) in gastrointestinal (GI) tract contents. Monocrotophos is different from most OPs used in agriculture because it is applied in its active form, known as an oxon,

Note: Known abuses and cases where chemical or biochemical investigation gave negative results are excluded.

^a Range reflects estimate from one or several observers or different accounts of same incident.

^b CYP-cypermethrin; DIM-dimethoate; DEL-deltamethrin; CPF-chlorpyrifos; FIP-fipronil; LAM- lambda-cyhalothrin; MCP-monocrotophos.

^c Determination based on (1) pesticide residues and ChE evidence; (2) residues and circumstances indicative of poisoning; (3) ChE evidence and circumstances indicative of poisoning; (4) ChE evidence; (5) circumstances indicative of poisoning; (6) circumstances indicative of poisoning as related in an interview. Modified from Mineau, P. et al., *J. Raptor Res.*, 33, 1, 1999.

^d Described as two separate incidents in one reference²⁰ and as two estimates (from two different individuals) relating to the same incident, by another.²¹

^e The identity of the pesticide or crop was very tentative. Although the nearest known pesticide treatment to the kill site was a mixture of chlorpyrifos and cypermethrin, this was 3 km from the kill site. The field is described as both wheat²⁰ and oats.²¹

^f In this case, the involvement of chlorpyrifos is considered more likely than in the other case reported above. All birds were found on the treated field.

^g Bird incapacitated only. Held and released. Low cholinesterase values indicative of exposure. Clinical signs in second case. Identity of pesticide unknown but both birds found in zone where MCP was supposed to be excluded.

^h Zaccagnini, M.E., Unpublished data, 2000.

ⁱ Another 5 individuals of the following species also found: *Myiopsitta monachus*, *Colaptes melanochloros*, *Zenaida auriculata*, *Polyborus plancus*.

^j Includes a single individual of *Speotyto cunicularia*.

^k Although MCP is suspected, violent storms could have given rise to this incident. Other incidents in area were storm-related.

containing a double bond between the phosphorous and an oxygen atom. Most agricultural OPs are formulated with a similar bond to a sulfur atom, a less reactive (and generally less toxic) form of OPs, requiring metabolic activation to the active oxon and having greater stability in the environment. Monocrotophos levels in GI tract contents were lower than might be expected due to their reactivity with the degrading grasshopper and hawk tissues in the birds. As no other pesticides were detected in any of the samples tested, and the only OP degradates detected were monocrotophos-associated, monocrotophos was implicated in all incidents for which tissues were analyzed.²³

Brain ChE activities in dead hawks averaged over 90% inhibition (compared to reference values), while the survivors demonstrated over 60% depressions (Table 25.4). Carcasses in Argentina had remained in the field for several days in temperatures reaching daily maxima approaching 40°C. Cholinesterases are, however, particularly resilient to temperature effects, retaining 79% and 60% of their original activities after carcass storage at 36°C for 4 and 8 days postmortem, respectively.²⁴ Field degradation, therefore, would not have led to such depressed levels. Further, laboratory attempts to reactivate the inhibited enzyme using 2-PAM reactivation techniques were generally unsuccessful and led only to minor increases of activity, indicating that the inhibited ChE had aged to the point where the OP could not be chemically removed. This finding, and the overall lack of spontaneous postmortem ChE reactivation, implicate a dimethylphosphoryl-type OP, such as monocrotophos, that characteristically forms the most stable, quickly aging ChE bond of all the agricultural OPs.²⁵ Plasma ChE activities were similarly refractory to reactivation attempts. The levels of brain and plasma ChE inhibition documented in Swainson's hawks were consistent with death and incapacitation, respectively, due to anticholinesterase exposure.

Based on the combined findings of the farmer/applicator interviews, chemical analyses, and cholinesterase evaluations, it was concluded that the mortality incidents were due to organophosphate poisoning, and in most cases, the evidence pointed specifically to monocrotophos.

25.4.2 Quick Response Leads to Hawk Protection

With the discovery of hawk mortalities in Argentina and the determination that monocrotophos was responsible, the American Bird Conservancy (ABC), representing a number of bird-associated nongovernmental organizations (NGOs) in the United States, requested that the manufacturer, Novartis (formerly Ciba-Geigy, Ltd., then Novartis, currently Syngenta), remove monocrotophos from the global market. The dialog that developed from this interaction between industry and an NGO was joined by Canadian, United States, and Argentine government representatives, academicians, and several other NGOs and monocrotophos producers.

Measures were implemented to protect Swainson's hawks from further impacts. Argentine government agencies established a monocrotophos withdrawal zone that encompassed Swainson's hawk use areas, documented by ground and satellite transmitter studies in the previous year, overlain with the locations of mortality incidents. Pesticide producers and distributors in Argentina withdrew and bought back or exchanged unopened monocrotophos stocks from within this zone. SENASA (Servicio Nacional de Sanidad y Calidad Agroalimentaria), the Argentine pesticide regulatory authority, declared a specific prohibition on any use of monocrotophos on alfalfa or against tucuras on any crop, a necessary action to make these uses of monocrotophos illegal.²² Labels were modified on monocrotophos containers warning farmers of the new rules.

Intensive farmer information campaigns, focusing on chemical control of grasshoppers and IPM alternatives, were developed by the Argentine government (both INTA and provincial governments), the pesticide industry, and the Argentine NGO Asociación Ornitológica del Plata. Farmers were warned not to use monocrotophos illegally and to refrain from using it altogether when hawks or other birds were present on fields.^{26,27} These campaigns were particularly important, as demonstrated by survey findings that up to 33% of pesticide applications were made contrary to label recommendations for crop, pest species, or application rate.²⁸

Argentine regulators and scientists worked with scientists from other countries to harmonize the methods used to assess pesticide impacts on wildlife. Four cooperative training workshops led by academic, government, and corporate scientists from the United States, Canada, Switzerland, and Argentina were held in Argentina. Two of the workshops focused on field techniques to monitor and document mortality incidents associated with pesticide use, resulting in the development of a monitoring manual with government-approved methods and procedures.²⁹ The other two focused on chemical and biochemical analytical techniques to ensure that the methods used in diagnosing exposure and effects were consistent between the primary collaborators. Specialists from each area held extensive training and demonstration sessions. Within 1 year of the occurrence of the large-scale documented kills, a coordinated Argentine program, including a nucleus of trained individuals, was in place to carry out forensic investigations in the core area of the Swainson's hawk wintering range.³⁰

The Argentine summer of 1996–1997 was a particularly wet one, and tucura numbers were lower than normal. Intensive monitoring activities were performed, observing Swainson's hawk population movements using satellite and conventional radio-transmitter-fitted hawks.⁶ An intensive live-capture and release program that evaluated nonlethal exposures to pesticides demonstrated little evidence of anti-ChE exposures (Table 25.4).³¹ The network of field and laboratory personnel was ready to respond quickly to any incident. In the end, there was a single documented mortality incident outside of the intensive control zone, where 24 Swainson's hawks died from an unknown pesticide exposure (Table 25.3). Through a combination of extensive public education and outreach, intensive chemical management, and mild weather, recurrence of the mass Swainson's hawk mortalities of 1996 did not occur in 1997.

Though this good news gave reason for cautious optimism, an intentional misuse of monocrotophos on seed baits in July of 1997 led to the deaths of an estimated 100,000 birds, primarily the eared dove (*Zenaida auriculata*), in Entre Rios Province in eastern Argentina.^{27,32} This event intensified the concern for the threat that monocrotophos posed, particularly to flocking bird species.

25.4.3 Regulatory Actions since the Incidents

In the time since the activities immediately following the Argentine incidents, a number of producers have initiated phase-outs of monocrotophos, while the number of countries discontinuing registrations has grown. Though they had decided to withdraw Nuvacron® from the entire Argentine market prior to the July 1997 incident, Novartis (now Syngenta) announced in 1998 a phased withdrawal of their monocrotophos products from all world markets as part of a product portfolio review. Monocrotophos would be removed from most countries (except India) by the year 2000, with a complete phase-out by 2003. DowAgrosciences, who recently inherited monocrotophos when it merged with a smaller independent pesticide manufacturer, announced a similar decision in 2000, with a phase-out by 2004, based on concerns for safety to wildlife, particularly migratory birds. The removal of Nuvacron® and the DowAgrosciences product represented approximately 20% of the 30,000 tons of monocrotophos active ingredient marketed annually around the world. No other monocrotophos producers, neither the large multinationals such as BASF (producers of Azodrin®) and Cheminova nor the many national or regional producers in India, China, and Taiwan, have announced similar actions.

A number of national pesticide registration agencies in monocrotophos-using nations have reconsidered their position on the chemical in light of the incidents in Argentina. In 1999, Argentina cancelled all monocrotophos registrations due to the chemical's "... inherent toxicity and the continued occurrence of wildlife mortalities wherever it was used ... even after implementing special restrictions and withdrawals, and establishing an unprecedented public information campaign designed to inform farmers of use restrictions and warn them about treating areas with heavy wildlife use."^{33,34}

Australia's National Registration Authority cancelled the Australian registration of monocrotophos after extensive industry and public consultation failed to satisfy the NRA that the OP's continued use under current label guidelines would not harm people or the environment.¹⁴ Of particular note in the NRA review was the fact that, similar to the U.S. EPA reassessment in the mid-1980s, there was no effort made by any producers, distributors, or users to come forward to alleviate the NRA's concerns by performing needed field safety studies. The conclusion of their review was that "The weight of evidence indicates use of monocrotophos poses a high hazard to birds, and it is difficult to defend its continued use."

Concurrent with the implementation of protective measures in Argentina, two additional projects were established to address critical issues associated with the incidents. The first was based on the need for an international ecological risk assessment that covers the variety of uses of monocrotophos. A data review leading to an international ecological risk assessment of monocrotophos is being developed. It examines the available avian data, in the form of laboratory investigations, field studies, and incident reports, that have been produced since the compound's inception over 30 years ago. The goal is to produce an internationally applicable document that provides the background and risks involved with the use of monocrotophos. To eliminate any doubt about the risk posed by monocrotophos, this assessment will be provided to all countries carrying monocrotophos registrations and to producers of the pesticide, so that the repercussions of using the compound are fully understood. Thereafter, decisions to continue selling and using monocrotophos will be made with full understanding of the ecological risk the compound poses. The second initiative, the Avian Incident Monitoring System, is being coordinated by the ABC, with U.S. EPA support, to address the lack of a unified international reporting program for pesticide-related mortality incidents.

Participants are working to create a common format and dissemination plan for incident reporting and information access to improve regulatory decision-making.

25.5 CONSERVATION CONSIDERATIONS AND PERSPECTIVE

In their review of the relevance of mortality incidents to raptor populations, Henny and coworkers³⁵ suggest that the loss of 20,000 birds, estimated to be from 2 to 5% of the total population, cannot be detected within the normally fluctuating numbers of a raptor population. This is particularly true of the Swainson's hawk, as intensive flock observations on the Pampas⁶ and the variety of band recoveries in the documented mortality incidents²⁰ indicate that its movements on its austral range are characterized by substantial mixing of birds from regions throughout its northern range. Had the 20,000 birds been from an isolated regional population, the impacts would have been much greater and easily detectable. The authors conclude that the more pertinent consideration was that the extensive mortality occurred with a compound that was registered and approved for use within the regulatory guidelines of the country.

Though the level of mortality documented on the Argentine pampas does not appear to pose an immediate threat to the overall population of Swainson's hawks, further perspective on the nature of pesticide threats to migratory birds is provided by experiences with wintering dickcissels (*Spiza americana*). Numbers of this neotropical migrant declined steadily during the 1960s and 1970s and have since stabilized at levels 40% below those in 1966.³⁶

A North American grassland passerine during the northern summer, the dickcissel migrates every year to the central Venezuelan llanos, where it winters among the rice, sorghum, and sugarcane farms that surround the Orinoco River in the states of Portuguesa, Cojedes, and Guárico (Figure 25.3).³⁷ Though generally dispersed throughout its northern breeding grounds, the dickcissel is gregarious in the llanos, feeding and roosting in large flocks, much like Swainson's hawks in Argentina. Historically, dickcissels ranged widely across the llanos, feeding on wild grass seed. Conversion of large areas to cereal agricultural has focused their foraging activities on the concentrated food resources of rice and sorghum. Wild grass seed now accounts for less than 20% of their diet. Flocks of greater than 10,000 birds regularly forage on fields of rice and sorghum, affecting approximately 1.5 and 8% of the crops, respectively; damage has been valued at approximately U.S. \$1.9 million.³⁸ The local name for dickcissels in Venezuela is "el pájaro arrocero," the rice bird.

Measures used by farmers to repel the flocks are largely nonlethal (firecrackers, sirens, horns, burning tires), though 14% of farmers indicate that they have used lethal control measures in the past. Large nocturnal roosting flocks, averaging over 500,000 and up to 3 million birds, generally are found in sugarcane fields. OPs such as parathion and monocrotophos were sprayed by ground equipment or from the air to kill the large aggregations.³⁸ One farmer told of being "knee-deep" in dickcissel carcasses after one roost application.³⁷ Local water sources and feeding areas are also sprayed in hopes of poisoning dickcissels when they drink and feed.

Based on farmer interviews, documented mass poisonings, and demographic and behavioral characteristics of dickcissel populations on their wintering grounds, the observed population decline from 1966 to 1978 was likely due to intentional poisonings with highly toxic OP pesticides. Dickcissel impacts, when focused on the limited, newly developing farm enterprises of the 1950s and 1960s, were more severe. Established farmers described intensive persecution of dickcissels when their impacts were proportionately the greatest (the 1950s to 1970s). Though dickcissel foraging activities are now dispersed across a greater agricultural landscape, focused crop depredation still impacts farmers at local levels, and based on historical practices in the areas, farmers continue to use lethal control methods. Ongoing use of OP control methods has likely kept dickcissel populations depressed since the late 1970s.³⁸

The dickcissel population remains in eminent jeopardy. As the majority of the entire population (6–7 million birds) can be found in 5 or 6 nocturnal roosts, with up to one third of the population

Figure 25.3 North and South American ranges, migratory pathway and core austral range of dickcissels. (Based on Basili, G. D. and Temple, S. A., *Stud. Avian Biol.*, 19, 289, 1999.)

in one roost, a single poisoning event could have significant impact on the overall population. To avoid such a catastrophe, cooperating government agencies, NGOs, and academicians from the U.S. and Venezuela are attempting, as was done with the Swainson's hawks in Argentina, to find solutions to dickcissel depredation of cereal crops in the llanos. In addition to testing dickcissel response to crop-treatment materials aversive to birds, efforts are focused on modifications of crop timing and mechanisms for compensating farmers for accepting crop losses.^{38,39}

25.6 WILDLIFE AND PESTICIDES — INTERNATIONAL PROTECTION NEEDS

The experience with Swainson's hawks in Argentina demonstrates a need for improving pesticide risk assessments for migratory wildlife. Pesticide regulation and enforcement, and hence the extent to which wildlife are protected from pesticides, vary greatly from country to country. Unilateral regulation of pesticides within a single country does not provide adequate protection for wildlife that cross international borders. In many countries, regulations are often barely sufficient for the protection of human health, let alone wildlife.⁴⁰ As has been seen in the withdrawal and cancellation actions that occurred in the United States and Australia following requests for data on avian safety, pesticide use often follows the path of least regulatory resistance. The resulting lack of regulation can easily lead to chemical applications at rates and under conditions that stray from safe or optimal use. With that said, however, it should be noted that impacts on wildlife are not restricted to countries lacking comprehensive pesticide regulation. Bird kills from labeled pesticide use in the United States and Canada still occur, are often the focus of intense debate, and can result in the reevaluation and regulation of particular pesticide uses.^{35,41} Another consideration is that

migratory species may be more vulnerable during migration or on their wintering grounds than on the breeding grounds. Because of the Swainson's hawk's high density on the pampas, a handful of Argentine farmers, through no fault of their own, could have significantly more impact on the species than thousands of North American farmers using insecticides of equivalent toxicity.

The development of international assessments of pesticide risk is a new approach to wildlife protection. Current efforts to internationally harmonize pesticide evaluations focus on pesticide toxicity testing methods, primarily as they apply to European and North American regulatory processes.⁴² Toxicity and exposure data pertinent to areas outside of these regions are not generally available or incorporated into standard risk assessments. Development of pertinent and regionally applicable toxicity and exposure inputs is needed to begin examining pesticide risks in these countries. The dissemination of these assessments, and not simply a statement on a pesticide's regulatory status, would further provide countries, lacking effective regulatory support, information from which they can make better informed decisions. Monocrotophos was withdrawn from use in the United States in the late 1980s, and because it was never officially banned, its continued use elsewhere did not raise alarms, though its potential toxicity to wildlife was well known to manufacturers and U.S. regulators. A major gap exists in our ability to influence pesticide regulation and protect migratory wildlife when they are outside the bounds of our political borders. Improved communication between similar agencies — across borders — might shorten that gap.

No matter how comprehensive or sophisticated a country's regulatory system may be, it will not benefit wildlife unless chemical-impact assessments are incorporated into conservation efforts. Organized efforts, similar to those used for habitat protection by groups like Partners in Flight, are needed to protect migratory species from pesticides throughout their range. Much of the information necessary for this protection is already being generated; it just needs to be applied more broadly. Habitat use data and detailed natural history accounts of migrants,^{43,44} compiled to prioritize habitat protection programs, can be combined with satellite imagery and regional databases that locate significant agricultural areas, intensive cropping practices, and regional pesticide sales. The layering of these data through a geographic information system can identify areas of concern where wildlife assemblages and pesticide use may present particular risk scenarios. The prioritization of resources for further ground-based evaluations can then focus on these areas of concern. An initial effort of this kind is under way for Canadian migrants through the Canadian Wildlife Service.

The Swainson's hawk and dickcissel experiences are a small piece of a complex international puzzle. If it weren't for the curiosity that led to following the species to their austral range, the mortality incidents might never have been documented. In all likelihood, the current efforts to reevaluate the use of monocrotophos and improve international incident reporting would not have proceeded as they have. There are likely similar situations awaiting discovery, not only in the Americas, but throughout the world wherever wildlife habitat and intensive agricultural practices overlap. It is simply a matter of looking. There is a high probability that monocrotophos is continuing to significantly affect bird numbers wherever it is in use. The removal of monocrotophos from the market by two producers will affect less than 20% of the world's supply, and other producers will likely replace the lost supply. Progress forward will depend on continued efforts on the part of biologists to identify pesticide threats when and where they occur, the efforts of international cooperators from all sides of the problem working together to solve them, and the willingness of regulators and pesticide manufacturers to look beyond national boundaries and their own interests to protect migratory wildlife.

25.7 SUMMARY

Recent events in Argentina and Venezuela have shown that pesticide issues transcend national borders and that our migratory birds continue to be exposed to potentially damaging pesticides throughout their range. We need to be especially wary of situations, such as that of the Swainson's

hawk or the dickcissel, where a large part of a species' population occupies a small geographical area, either in the course of its migration or on wintering grounds. A localized impact, whether or not pesticide-related, could have serious consequences for the population. Mechanisms are needed to put pressure on the pesticide industry to improve its product stewardship and take action on products shown to be environmentally unsound. Currently, the battle against bad pesticides is being fought manufacturer-by-manufacturer and country-by-country, which is wasteful of the meager resources available. On the positive side, the Argentina experience has shown how readily problems can be solved when all stakeholders are willing.

26.1 INTRODUCTION

Mining began in northern Idaho in the 1880s after the discovery of deposits of lead, silver, gold, and other metals.¹ Approximately 75 million tons of metal-enriched sediments associated with mining activities in upstream locations of the Coeur d'Alene (CDA) River Basin have been deposited in the lakebed of Lake Coeur d'Alene.² The flood plain, associated wetlands, and lateral lakes of the CDA River contain large volumes of trace-element-rich material. The process of metal enrichment in the flood plain and lake occurs via the CDA River, which transports contaminated material released by mining activity in the upper basin downstream to these areas. Mining activities were sharply curtailed during the 1980s. Average monthly emissions of lead from the main smelter stack were estimated at 8.3 to 11.7 metric tons from 1955 to 1973.³ Even as recently as 1973, daily discharges of metals into the South Fork included 4400 kg of zinc, 245 kg of lead, and 57 kg of arsenic.¹ From the early 1970s to 1986, levels of lead in sediment were essentially unchanged.⁴ Lead concentrations in sediment were generally in the 3000–5000 µg/g dry weight (dw) range in

most lateral lakes during the mid-1990s.⁵ Note that all metal concentrations in this report are wet weight (ww) unless stated otherwise.

Waterfowl mortality from lead that originated from mining and smelting activities has occurred in the CDA River Basin since at least the early 1900s.⁶ Waterfowl found dead or collected in the area in 1955 had high levels of lead, zinc, and copper in their tissues; soils, plants, and water also were heavily contaminated.⁶ Lead toxicosis in North American birds is usually caused by ingestion of spent lead shotgun pellets.⁷ However, in the CDA River Basin, environmental lead in sediment, soils, and biota were believed responsible for most lead poisoning of tundra swans (*Cygnus columbianus*).⁸ Exposure to lead has resulted in reported die-offs of tundra swans (and other waterfowl) in 1974,⁹ 1982,¹⁰ 1984 and 1985,¹¹ 1987 to 1990,⁸ and annual die-offs continue.^{12,13} Livers of hunter-killed ducks in the area also contained high lead concentrations.^{11,14} From 1987 to 1995, the Idaho Department of Fish and Game collected data on the incidence of ingested lead shot (another source of lead) in hunter-killed mallards (*Anas platyrhynchos*) from the CDA River Basin. The annual incidence of lead shot varied with the following percentages by 3-year periods: 1987–89, 24.1% (n = 224); 1990–92, 18.8% (n = 192); and 1993–95, 19.3% (n = 181).¹⁵ This area was designated a steel shot hunting area in 1986, and 21 of 70 mallards (30.0%) shot in 1987 contained ingested lead shot.¹⁴ The incidence of lead-shot ingestion may be decreasing, but the percentages were not significantly different.¹⁵

26.2 APPROACHES TO EVALUATE EFFECTS OF LEAD ON BIRDS

26.2.1 Diagnosis of “Found Dead” Birds

When dead birds were found, a necropsy was performed to determine cause of death. The necropsy protocol at the National Wildlife Health Center in Madison, WI, was designed to confirm the presence or absence of lesions associated with lead poisoning. Other studies^{16–18} have shown that emaciation, green-stained perianal plumage, esophageal and proventricular impaction, bile-stained and fractured gizzard lining, enlarged gallbladder, hepatic hemosiderosis, renal degeneration with nuclear inclusion bodies, myocardial necrosis, fibrinoid necrosis of arteries, erythroid hyperplasia, and peripheral neuropathy are associated with lead poisoning of waterfowl. Some of these lesions are more specific (renal inclusion bodies, fibrinoid necrosis) than others (emaciation). A diagnosis of “lead poisoning” in waterfowl found dead or moribund was based on the absence of other apparent causes of morbidity or death and an unequivocally diagnostic combination of one or more of the following criteria: (1) a history compatible with lead poisoning, (2) gross or histopathologic lesions compatible with lead poisoning, and (3) concentrations of lead in samples of liver tissue that ranged from 3.9 to 90 $\mu\text{g/g}$. A liver lead concentration greater than 2 $\mu\text{g/g}$ indicates a significant environmental exposure; concentrations greater than 6–8 $\mu\text{g/g}$ indicate toxic exposure and are expected in waterfowl that succumb to lead poisoning.^{18,19} In the absence of pathology information, 10 $\mu\text{g/g}$ has been suggested as a reliable threshold concentration for diagnosing lead poisoning.²⁰

26.2.2 Source of Lead (Lead Shot vs. Mining Activity Lead)

From the introduction, it becomes clear that two sources of lead were present in the CDA River Basin: (1) lead from hunters’ spent shot (from shotguns) and (2) lead from the mining and smelting industry in the basin. Spent shot ingested by waterfowl, presumably as grit or food particles, has resulted in widespread waterfowl mortality in the United States, Europe, and elsewhere for over a century.¹⁹ Migratory waterfowl in the CDA River Basin with ingested spent shot may have obtained it within the basin or elsewhere, and although the use of lead shot was banned in the basin in 1986, birds containing lead shot were still present during the basin studies summarized here. Although

lead shot does not always persist in the gizzard of mallards that die from lead-shot poisoning, nearly 90% retain lead shot at the time of death,²¹ compared to only 1 of 8 (12.5%) lead-poisoned mallards found dead in the CDA River Basin.¹⁵ Similarly, for lead-poisoned Canada geese (*Branta canadensis*) found dead, 75–94% contained ingested lead shot when mortality was due to ingested lead shot, while in the CDA River Basin only 6 of 38 (15.8%) contained ingested lead shot.¹⁵ And for tundra swans dying of lead poisoning outside northern Idaho, 95% contained lead shot, while only 5 of 64 (7.8%) contained lead shot from the CDA River Basin.^{8,22} The percentage of lead-poisoned birds with lead shot in their gizzards from the CDA River Basin was much lower than found outside the influence of the mining and smelting area, which implies that lead from sources other than lead shot killed most of the ducks, geese, and swans. Thus, a careful evaluation of gizzards for the presence or absence of lead shot (from both collected and found dead birds) was very important for separating lead sources.

26.2.3 Evaluation of Living Birds

Live-captured and euthanized birds were initially evaluated based on suggested liver lead criteria ($\mu\text{g/g}$) of Pain¹⁹ i.e., < 2, background; 2–5.9, subclinical poisoning; 6–15, clinical poisoning; and > 15, severe clinical poisoning. Then, other diagnostic criteria mentioned above for “found dead” birds were evaluated for a final necropsy diagnosis. The necropsy diagnosis “sublethal lead poisoning” for live birds collected was similar to “lead poisoning” for dead or moribund birds, with the difference being that birds were alive when collected. Free-ranging waterfowl that succumb to lead poisoning generally have some combination of the preceding lesions in association with concentrations of lead in the liver $\geq 6 \mu\text{g/g}$.

The live-bird studies, when few birds were collected, basically compared blood lead residues and hematological findings from the CDA River Basin populations (lead from spent shot and sediment) with data from reference areas nearby (lead from spent shot, but no lead or low lead from sediment). All of the bird species studied migrate, but adults (except tundra swans) were in the area for several months nesting before being captured or collected. The potential effects of lead were evaluated by lead concentrations in blood and several blood measurements including δ -aminolevulinic acid dehydratase (ALAD), protoporphyrin, hematocrit, and hemoglobin. Young of different sizes (ages) were captured to evaluate lead accumulation and its effects on blood constituents. ALAD activity in blood is inhibited in the presence of lead, and baseline values were determined from reference areas for comparison with the CDA River Basin. Inhibition of ALAD, an essential enzyme for heme synthesis, has been accepted as a standard bioassay to detect lead exposure in birds.^{23–27} In laboratory studies, ALAD inhibition of 80% was associated with other physiological effects, including decreased hemoglobin concentrations and hematocrits in adult birds and precocial young.^{25–28} Some live birds were collected to evaluate lead relationships in the liver, kidney, and blood as well as associated histopathology, but data are not summarized here. Lead concentrations in the contents of gizzards and lower gastrointestinal tracts of the euthanized birds were also determined.

26.2.4 The Sediment Ingestion Link

With the lead shot source clarified (most birds dying from lead poisoning were not exposed to lead shot), the issue of lead from mining and smelting sources required attention. Inorganic lead in soils and sediment is not readily available to plants. Elias et al.²⁹ demonstrated that concentrations of lead tend to be lower in small mammals than in their diets, and they suggested that lead concentrations decrease at each successive trophic level in a food chain. Although millions of waterfowl have been killed by lead, the source has generally been lead shot and fishing sinkers³⁰ rather than contaminated biota or sediments, as reported in the CDA River Basin. Beyer et al.³¹ first investigated whether the lead ingested by wood ducks (*Aix sponsa*) from the CDA River Basin

was correlated with elements such as aluminum, which are associated with sediments. A good correlation would indicate that lead could be traced directly to sediments ingested incidentally to feeding, rather than plants or invertebrates in the diet. Wood ducks were collected, and digesta from the intestines was analyzed. The acid-insoluble ash content of the digesta was measured, and the values were used to estimate the sediment content of the diet.³² Wood ducks feeding on aquatic plants in the CDA River Basin and in the reference area ingested relatively little sediment, estimated at less than 2% of the diet (dw).³¹ Digesta with little or no sediment also contained low lead concentrations. Beyer et al.³¹ concluded that the lead ingested by the wood ducks was derived mainly from sediment. The unexpected result of their study was that even though wood ducks ingested less than 2% sediment in their diets, the sediment was the main source of lead to the wood ducks. Beyer et al.³¹ noted that exposure to lead would be expected to be greatest in species like tundra swans that eat tubers and other items associated with sediments. Thus, the parameter insoluble ash content of digesta can be used to estimate lead exposure and related lead concentrations in blood or liver to sediment ingestion.

26.2.5 Laboratory Studies

Laboratory studies were also conducted with sediment from the CDA River Basin fed to mallards, Canada geese, and mute swans (*Cygnus olor*) to determine, under laboratory conditions, whether lead from lead-contaminated sediments was bioavailable and toxic to the same or similar species when consumed as part of their diet. The same blood parameters evaluated in the field were evaluated during the laboratory studies.

26.3 LEAD EFFECTS ON BIRDS

26.3.1 Wild Populations Studied

Perhaps the most useful approach to evaluate lead exposure and effects is to compare residue concentrations and associated blood measurements for a series of living birds sampled in the CDA River Basin between 1986 and 1995 (Table 26.1.) — a period when little or no change occurred in the sediment lead concentrations. The tabular data contrasts information from reference areas with information collected in the CDA River Basin and refers to nesting species, with the exception of tundra swans. The swans stage in the area for 3–5 weeks in the spring before flying north to nest.⁶

The birds of prey (osprey [*Pandion haliaetus*], northern harrier [*Circus cyaneus*], and American kestrel [*Falco sparverius*]) consistently contained the lowest blood lead concentrations in the CDA River Basin, and a limited number of great horned owl (*Bubo virginianus*), western screech-owl (*Otus kennicotti*), and red-tailed hawk (*Buteo jamaicensis*) nestlings and adults also showed low concentrations.^{33,34} The studies in the CDA River Basin support the hypothesis that concentrations of heavy metals, such as lead, decline with increasing trophic level, as reported in marine food chains and in detritus-based and grazing food chains in dredge-spoil pond ecosystems.^{35,36} Unlike organochlorine pesticides and mercury, lead does not biomagnify. Although lead concentrations in aquatic and terrestrial vertebrates tend to increase with age (Table 26.1), distribution is localized in hard tissues (i.e., bones and teeth).³⁷

Honda et al.³⁸ reported that most lead in poisoned swans was stored in bones (71.4%), followed by muscle (7.86%), liver (6.19%), and kidney (2.38%). By recognizing that most raptors cast pellets (indigestible feathers, fur, and especially bones in owls),³⁹ and that most lead concentrates in bones, it was anticipated that lead would be less available to raptors. Ospreys feed almost exclusively on fish. For fish, the percentage of lead located in bones was not available, but lower lead concentrations were reported in fish fillets (no bones) than in whole carcasses of the same species.³³ The other raptors have diversified diets, but small mammals like voles and mice were prominently listed for

northern harriers, American kestrels, and red-tailed hawks.⁴⁰ Cast pellets found at a great horned-owl nest along the CDA River included 38 voles.³⁴ Therefore, mice and voles were collected in the CDA River Basin for lead analysis.

Two pools of *Peromyscus maniculatus* collected at the same site were analyzed.³⁴ One pool was analyzed intact, and mice in the other pool were dissected and separated into two categories: (1) bones and (2) remainder of carcass, including internal organs. The intact mice contained 45.3 µg/g lead. Bones from the second pool contained 195 µg/g lead, and the remainder of the carcass < 0.10 µg/g. Overall, the second pool (based on weight of bones and remainder of carcass) contained an estimated 59.2 µg/g. Nearly all of the lead was in the bones and, therefore, less available for absorption by species casting bones in their pellets. Jenkins⁴¹ also noted high concentrations of lead in hair, which is also cast in pellets. Osprey, in addition to not eating large bones, also cast pellets like other raptors.

The blood parameters for the Osprey, the largest raptor dataset, showed significantly increased lead concentrations in blood from the CDA River Basin as well as significantly reduced ALAD. However, the blood concentrations were still comparatively low, and mean protoporphyrin, hematocrit and hemoglobin were not significantly changed from the reference areas. The American kestrel and northern harrier also showed significantly reduced ALAD in the CDA River basin. The nestling kestrels, which were sampled in good numbers, also showed significantly reduced hemoglobin (-8.2%) and hematocrits (-5.8%) in the CDA River Basin, which were associated with about twice the blood lead concentrations of the osprey (geo. mean 0.24 vs. 0.09 µg/g). No lead-related raptor deaths were recorded. Ospreys produced young at nearly identical rates in the reference area and the CDA River Basin; these rates were among the highest ever reported in the western United States.³³ Although the number of young per nesting attempt for American kestrels was slightly lower along the CDA River Basin (1.95 young; N = 20 vs. 2.40 young, N = 10), no significant relationship was found between lead and productivity to fledgling.

Of the ducks, geese and swans studied in the CDA River Basin, Canada geese were the least contaminated with lead (Table 26.1). However, all four waterfowl species showed significant and substantial ALAD inhibition: Canada goose, -63.6 to -86.1%, mallard -90.7 to -95.5%, wood duck -86.2 to -93.8%, and the tundra swan -79.0% (but sick birds -93.5% to -97.8%). In spite of the lower lead concentrations in blood, Canada geese goslings showed significantly elevated protoporphyrin in the two smaller age classes, significantly reduced hemoglobin in the two larger age classes, and significantly reduced hematocrits in the two middle age classes.¹⁵ None of these blood parameters in the adult age class differed significantly from reference geese. The mallards, with much higher blood lead concentrations than Canada geese, had elevated protoporphyrin in the CDA River Basin but no significant changes in hemoglobin or hematocrit. Recognizing that interspecific differences exist in response and sensitivity to lead, it appears (at least for hemoglobin and hematocrit) that Canada geese were more sensitive to lead than mallards, i.e., adverse hematologic effects occur at lower blood lead concentrations.

Adult wood duck blood lead concentrations (only age class sampled) were similar to adult mallards, and like the mallards, protoporphyrin was significantly elevated and hematocrit was not significantly different from the reference areas. However, hemoglobin, unlike in mallards, was significantly reduced in female wood ducks sampled later in the season in both 1986 and 1987. It is of interest that these two groups of female wood ducks had higher geometric mean lead concentrations (1.5 and 1.6 µg/g) than those sampled earlier in the season (0.9 and 1.1 µg/g) when no change in hemoglobin was detected. Thus, the amount of time spent in the area and exposed to lead by the migratory wood duck, and probably other species, seems to be a factor.

Lead concentrations in blood of a small series of Canada goose goslings and mallards euthanized during the study were compared with lead concentrations in blood of others bled but not euthanized and showed good agreement.¹⁵ This suggests that inferences could be made for the local populations based on the additional information available from organ residues and histopathology. The series of 22 live mallards collected (10 hatch years [HYs] and 12 adults) between 2-10 August 1994 provided an assessment of the living mallard population nesting in the area. Significantly reduced

hematocrits was found in 4 of the 12 (33%) adults and 1 of 10 (10%) HYs, which was similar to 18% and 6%, respectively, for the complete series bled in the CDA River Basin. Likewise, 2 of 12 adults (17%), and 0 of 10 HYs (0%) had reduced hemoglobin concentrations, which compared favorably with the 15% and 0% for the whole series. The series of live mallards captured and necropsied revealed that 5 of 12 adults (42%) and 1 of 10 HYs (10%) were clinically lead poisoned (based upon published classifications¹⁹). By eliminating the three mallards from the series with lead shot in their gizzards (a different source of lead), none of the HYs, but 36% of the adults, were clinically lead poisoned. Subclinical lead poisoning was found in 50% of the HY mallards and 55% of the adult mallards (again excluding those with ingested lead shot). This prevalence of mallard lead poisoning causes concern for the local breeding population. Again, the presence of lead shot in mallard gizzards in the CDA River Basin is not unexpected but does tend to complicate (but not thwart) the evaluation of lead from the CDA River Basin sediment.

This study provided evidence that breeding mallards in the CDA River Basin accumulated lead, and adults as well as young (only a few months old) accumulated enough lead to adversely affect a series of blood biomarkers responsive to lead. Furthermore, there was no evidence for a decrease in blood lead concentrations in adult mallards between 1987 and 1995.¹⁵ Dead Canada geese and mallards were difficult to locate in the CDA River Basin marshes, but of the lead-poisoned mallards and Canada geese found, few contained ingested lead shot. The incidence rate of ingested lead shot in either euthanized or found dead mallards and Canada geese in the CDA River Basin does not implicate spent lead shot as the principal source of the lead poisoning. Evidence for sediment ingestion in both mallards and Canada geese was provided from fecal data.²⁰ Therefore, lead-contaminated sediment associated with upstream mining in the CDA River Basin was the lead source responsible for most of the mallard and Canada goose lead poisoning during this study.

The tundra swan only stays in the CDA River Basin for 3–5 weeks in the spring, before continuing the spring migration north to nest in Canada and Alaska. However, swans were routinely found sick or dead during this short time period. This highly visible large white bird is much more easily located than smaller ducks or more neutral colored Canada geese. The “apparently healthy” swans sampled in the CDA River Basin showed significantly higher blood lead concentrations and significantly reduced ALAD when compared to the reference swans, but no significant difference in hemoglobin or hematocrit. Some of the swans sampled may have been in the basin for only a few days. Blus et al.⁸ reported that blood lead increased from 0.60 to 0.71 $\mu\text{g/g}$ over 2 days in one swan and from 0.68 to 2.28 $\mu\text{g/g}$ over 5 days in a second swan, and overall blood lead concentrations increased significantly with time. The 19 sick swans bled showed much higher lead concentrations with significant reduction in ALAD, hemoglobin, and hematocrit. These swans were all near death at the time they were bled. The sampling of live swans showed that exposure to and accumulation of lead was rapid and that moribund swans had blood parameters that deteriorated to a critical stage.

Several other species of birds were studied to a lesser extent in 1987 including American robins (*Turdus migratorius*) and tree swallows (*Tachycineta bicolor*). Seven American robin nestlings collected from nests (one young each) in the CDA River Basin contained elevated concentrations of lead in their blood (geo. mean 0.49, range 0.27–0.87 $\mu\text{g/g}$) and liver (geo. mean 1.19, range 0.19–5.6 $\mu\text{g/g}$), while young at 11 tree-swallow nests (pooled blood from two young at each nest) contained lower concentrations of lead in their blood (geo. mean 0.19, range no detection to 0.75 $\mu\text{g/g}$) and liver (geo. mean 0.15, range no detection to 0.40 $\mu\text{g/g}$).⁴³ American robins leave the nest at 14–16 days and tree swallows at 16–24 days,⁴⁴ and since lead does not transfer appreciably into eggs, it was accumulated to potentially dangerous concentrations in some individuals of both species in about 2–3 weeks. The lead concentrations in the blood of robin nestlings were higher than in any of the raptor species studied. In the spring and early summer, robins eat primarily animal matter including many types associated with sediment (earthworms, beetles, weevils).⁴⁵ Adult American robins and song sparrows (*Melospiza melodia*) were also studied in the CDA River Basin in 1995.⁴⁶ Adult American robins and song sparrows in the CDA River Basin had significantly reduced ALAD compared to those from reference areas, but no significant differences in hematocrit were found.

26.3.2 Field and Laboratory Test Comparisons

The Canada goose and mallard field¹⁵ and laboratory⁴⁷⁻⁵⁰ studies are summarized in Table 26.2. The CDA River Basin Canada goose goslings (2100–3000 g, i.e., same size as in laboratory study) contained lower lead concentrations than Canada geese in the laboratory exposed to 12% CDA River Basin sediment and generally showed less adverse ALAD and protoporphyrin responses than reported in the laboratory, although protoporphyrin was extremely elevated in younger goslings (≤ 2000 g) in the field. The reduction of hemoglobin and hematocrit in the field was statistically significant and more severe than in the lowest laboratory treatment. With the Canada geese in the laboratory, the responses of most blood parameters were more adverse as the percentage of CDA River Basin sediment increased in the diet, although ALAD inhibition was already in excess of 95% at the lowest laboratory treatment level. It is noteworthy that two of nine goslings died at the highest dietary treatment rate (48% CDA River Basin sediment). Additional types of information were available from the laboratory study. With the 48% CDA River Basin sediment diet, plasma enzymatic activity for lactate dehydrogenase (LDH-L) increased by about 1.7X, plasma total protein was significantly lower (30–38%), and one gosling exhibited renal tubular nephrosis.⁴⁸

HY mallards in the CDA River Basin field study contained higher concentrations of lead in their blood and liver than HY Canada geese from the same area (Table 26.2) and exhibited a greater increase in protoporphyrin and a greater inhibition of ALAD. However, Canada geese in the field with the lower lead concentrations showed significant reductions in hemoglobin and hematocrit, whereas mallards in the field with higher concentrations of blood lead showed no significant reductions in hemoglobin or hematocrit.

The protoporphyrin increase in HY mallards with a 12% CDA River Basin sediment diet was only 3.7X compared to 5.9X in the field with lower blood lead concentrations in the field, and a similar pattern was shown for adult mallards (Table 26.2). Otherwise, lead values and protoporphyrin responded in a dose-response pattern. Again, ALAD reached in excess of 90% inhibition in the field study, and higher lead concentrations in the laboratory study showed little additional influence. Hemoglobin and hematocrit in mallard ducklings, in contrast with Canada geese, did not show a significant adverse effect, and none of the ducklings died during the laboratory study. Corn in the laboratory diet resulted in higher blood and kidney lead concentrations, as well as a more severe elevation of protoporphyrin, compared to the same percentage sediment in the standard diet. These findings suggest that the more severe protoporphyrin effects in the field with lower lead concentrations may have resulted from a less-than-optimum diet in the field when compared to the standard laboratory diet. The laboratory findings also indicated that duckling brain weight was 7% lower with the 24% CDA River Basin sediment diet, and LDH-L in the 12% CDA River Basin sediment was 24.6% lower than in the clean sediment diet.⁴⁹

The 12% and 24% CDA River Basin sediment fed to the Canada goose goslings and mallards in the laboratory studies seem realistic in view of the blood parameters reported and the fact that Beyer et al.²⁰ estimated arithmetic means of 11% sediment ingestion for adult Canada geese and 5.9% for adult mallards in the CDA River Basin. The 90th percentile for Canada geese was 23% and for mallards was 16%. These sediment-ingestion estimates were based on acid-soluble ash content in feces, and the latter estimate for mallards assumed a digestibility of 30% for mallard diets.³² Sediment ingestion is sometimes the principal route of exposure for environmental contaminants like lead that are not readily taken up by plants and invertebrates.³¹ The 11% sediment-ingestion rate for Canada geese vs. 5.9% rate for mallards initially seemed to pose a conundrum because HY mallards in the CDA River Basin have much higher blood lead concentrations than HY Canada geese (0.98 vs. 0.28 $\mu\text{g/g}$). The apparent enigma was solved when Hoffman et al.⁴⁸ found that under controlled laboratory conditions Canada goose goslings fed a diet with 12% CDA sediment contained a geometric mean blood lead concentration of 0.68 $\mu\text{g/g}$, while mallards fed the same percentage sediment in the diet contained 1.41 $\mu\text{g/g}$ (about twice as much), and a similar ratio of lead between species was reported for a diet containing 24% CDA sediment (Canada goose

Table 26.2 A Comparison of Blood Parameters for CDA River Basin Canada Geese and Mallards and Those Exposed to CDA River Basin Lead in the Laboratory

Species	Field/Lab	Age	Geo Mean Lead ($\mu\text{g/g}$)		Change from Reference Area or Untreated Control				References ^a

1.61 and mallards 2.56 $\mu\text{g/g}$). Reasons for accumulation rate differences for lead between the two species remain unknown, but body size and metabolic rate differences may be involved. Thus, sediment-ingestion rates (as determined from feces in the field, or as fed in controlled laboratory studies) may not directly reflect body burdens or blood lead concentrations,⁵¹ although sediment ingestion was believed the most important exposure route.

26.4 CONCLUSIONS AND PERSPECTIVES

The CDA River Basin has been the site of considerable research activity on lead during the last 15 years. Diagnostic procedures and techniques developed over 50 years to assess lead poisoning from spent shotgun pellets was used to assess another source of lead (mining activities). The body of waterfowl literature including incidence of lead shot in gizzards of birds "found dead" from lead-shot poisoning was used effectively to separate the two sources of lead (lead shot vs. mining activities) from each other, with the latter being the dominant factor in the CDA River Basin. Canada geese, tundra swans, and mallards continue to die in the CDA River Basin from lead associated with sediment. In addition to the "found dead" birds, live populations were blood-sampled to evaluate lead residues and blood parameters. Waterfowl showed the highest blood residue concentrations and the most adverse effects on blood parameters. It is important to recognize that all species of birds living in the basin were not equally exposed to lead. Beyer et al.⁵¹ concluded that exposure of waterfowl to lead in the CDA River Basin was related to the amount of sediment ingested in the diet and that the relative amount of lead from vegetation and prey was minor. Following the logic of this conclusion (and the fact that raptors do not ingest sediment, and most raptors do not digest bones of prey species [a major storage area for lead]), it becomes clear why the ospreys, hawks, and owls in the CDA River Basin were less contaminated with lead from mining sources. Of the songbirds studied, young American robins, which feed on many invertebrates associated with the soil, were more contaminated than the birds of prey, while the aerial foraging tree swallow was less contaminated than the robin. However, lead concentrations in blood apparently do not represent the complete story because of variability in species sensitivity (e.g., see different hemoglobin and hematocrit responses to lead in blood of Canada geese and mallards [Table 26.2]).

Many of the field and laboratory findings were also used to investigate relationships between sediment lead and dietary lead and then to relate dietary lead to blood lead in waterfowl. This investigation, which was beyond the scope of this review, resulted in a risk assessment related to lead sediment concentrations. However, the lowest effect concentration of sediment lead was estimated as 530 $\mu\text{g/g dw}$, with some mortality estimated at 1800 $\mu\text{g/g dw}$.⁵¹ Lead concentrations in sediment are generally in the 3000–5000 $\mu\text{g/g}$ range in most lateral lakes in the CDA River Basin.⁵

27.1 INTRODUCTION

Eagle River Flats (ERF), Alaska is an 865-ha tidal flat located on the Cook Inlet near Anchorage (Figure 27.1). It is used by waterfowl and shorebirds throughout the spring and summer and is particularly important as a spring and fall staging or stopover area for more than 75 species of migratory ducks, geese, swans, raptors, gulls, shorebirds, and passerines.¹ Massive waterfowl mortalities involving more than 2000 ducks and swans each year were first observed at ERF in 1980,² continued unabated through the mid 1990s, and are still occurring, although at substantially lower rates. The most seriously affected species in these die-offs included mallards (*Anas platyrhynchos*), green-winged teal (*A. carolinensis*), pintails (*A. acuta*), greater scaup (*Aythya marila*), and trumpeter (*Cygnus buccinator*) and tundra (*C. columbianus*) swans. Other species, such as widgeon (*Anas americana*), shovelers (*A. clypeata*), snow geese (*Chen caerulescens*), Canada geese

Figure 27.1 Location of Eagle River Flats on the Knik Arm of the Cook Inlet, Alaska.

(*Branta canadensis*), and several species of shorebirds, utilize the area but experience substantially lower mortality. Avian predators, such as bald eagles (*Haliaeetus leucocephalus*) and gulls (*Larus* sp.), feed on dead and dying waterfowl and sometimes become sick or die (Roebuck et al.³). Ten years after the first observation of dead waterfowl, the U.S. Army Corps of Engineers determined that particles of white phosphorus (P₄) originating from the firing of munitions into the area were the cause of this mortality.^{2,4} Subsequently, teams of scientists and engineers from several agencies have studied the situation using both field and laboratory methods. At present, remediation efforts include dredging and drying areas of high P₄ concentration to allow attenuation through vaporization. The site is of particular interest because, unlike most Superfund sites under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), this one has a recognized effect and a known cause. ERF also is a model for the effects and remediation of P₄ on at least 71 other sites where the contaminant been found.^{5,6} This chapter presents a case history of white-phosphorous-caused waterfowl mortality at ERF. It includes a discussion of the toxicity of white phosphorus, a hazard assessment model, and a description of efforts to remediate the problem.

27.2 DESCRIPTION OF EAGLE RIVER FLATS

Eagle River Flats is an estuarine salt marsh located on the southeast side of the Knik Arm of the Cook Inlet (61°19'N, 149°44'W). It is separated by a narrow coastal plain from the Chugach

Figure 27.2 Map of Eagle River Flats, Alaska showing major pools and vegetated areas. (From Racine, C. H. and Brouillette, M., Ecological inventory of Eagle River Flats, U.S. Army, Fort Richardson, AK, 1995.)

Mountains and surrounded on three sides by steep slopes. The Eagle River, a cold, glacial-fed river, flows through the Flats and empties into the Knik Arm (Figure 27.2). The landscape consists of the main river channels, tidal gullies ranging from a few centimeters deep to more than 4 m at low tide, standing pools of a few centimeters to over 1 m deep, open mud flats, and areas of emergent vegetation. The vegetation of ERF is generally characteristic of the Cook Inlet region; 57 species of vascular plants, dominated by sedges and grasses, have been identified.⁷ Many of these plants provide habitat or produce seeds that are food for waterfowl and shorebirds, and the area is very attractive to waterbirds, especially in spring because this tidal basin thaws earlier than most of the surrounding habitat. Water in the pools is brackish, ranging in salinity from 4–38 ppt.⁷ The central portion of ERF faces the Knik Arm and is most exposed to tidal inundation. Tides are extreme in this area and may exceed 10 m; during even moderately high tides, the entire marsh may be inundated. Soils are generally very fine glacial sediments deposited by back flow from the Eagle River and tidal gullies and by high tides from the sediment-laden Knik Arm.⁸ Sedimentation rates range from several millimeters per year on levees, 10–15 mm on mudflats, and up to 20–40 mm per year in ponds. Annually, the daily mean temperature is 1.9°C, and precipitation ranges from 330–508 mm. As will be shown, water conditions and temperatures are very important in any natural attenuation of white phosphorous that might occur on ERF.

27.2.1 Biota of Concern

Birds begin to use ERF for feeding and staging as soon as water opens in mid-April to early May. For a few weeks through mid-May to early June, large numbers of migrants come through the area, with individuals staying for a few days to a week or two.⁹ During the summer months, usage by ducks declines, but by early August southward-bound migrants begin gathering, and total bird usage is high until freeze-over in October. Over 16 species of waterfowl use ERF during the spring and summer, with mallards, green-winged teal, northern pintail, greater scaup, Canada geese, and swans predominating. Daily totals of waterfowl seen on aerial census routes of ERF vary from 2500 in spring to 100 in midsummer to 1500 in late summer/early autumn.⁹ Other species include ravens (*Corvus corax*), shorebirds, gulls, occasional sandhill cranes (*Grus canadensis*), and raptors. Bald eagles are most common during early spring and perch on trees surrounding the marsh, waiting for available prey. Except for voles (*Clethrionomys rutilus*), few mammals occupy the area, although moose (*Alces alces*), wolves (*Canis lupus*), muskrats (*Ondatra zibethicus*), and beaver (*Castor canadensis*) have been seen in the marsh, and brown bears (*Ursa arctos*) frequent the surrounding uplands.

27.2.2 Source of Contamination

The root cause of the waterfowl problem stems from the area being used for artillery practice since 1949.⁴ The most common artillery has been howitzers and mortars of various sizes. Munitions and compounds used in the area include high explosives (RDX, TNT, HMX), obscurant smoke (white phosphorus, hexachloroethane-zinc), and illumination flares (magnesium). Over a 40-year period, more than 100,000 rounds have been fired into ERF. Accurate records are not available, but of nearly 7000 rounds fired into ERF during most of 1989, about 4% were P4 munitions, and in the 4-year period from 1987–1990, 1217 white-phosphorus rounds with an approximate total P4 mass of 1200 kg impacted the area.⁴ After a thorough sediment analysis of the Flats, only P4 was found to be widespread in the shallow marsh ponds used by waterbirds for feeding. P4 also was found in tissues of dead birds.⁴ Subsequent toxicity tests showed that P4 was the primary agent of mortality in exposed waterfowl.²

27.3 CHARACTERISTICS OF WHITE PHOSPHORUS

White phosphorus is elemental phosphorus composed of four phosphorus molecules arranged in a tetrahedron configuration. It is not found in nature and only occurs through manufacturing. P4 is a waxy solid at room temperature but spontaneously combusts between 30 and 40°C. It is highly lipophilic with a high octanol/water-partitioning coefficient (Table 27.1). When in air it reacts with oxygen to form various phosphorous oxides, such as P₄O₁₀, that are hygroscopic and form a dense white cloud,⁴ a characteristic used by the military for defensive maneuvering. It is relatively inert in water (water solubility is 3 mg/L), where it forms an outer layer or crust that further reduces its solubility. The persistence of P4 in water or sediments is affected by sediment moisture and temperature. When incubated at 20°C in moist but well below saturated sediments, 99.9% of the mass of P4 pellets disappeared after 24 h.¹⁰ However, it took 56 days for 99% of the P4 mass to disappear at 15°C, and at 4°C, 50% of the P4 was still present after 56 days. When soils are saturated, no measurable loss of P4 mass occurred after 60 days, regardless of temperature. Because much of the sediments at ERF either were constantly or periodically saturated and since sediment temperatures tended to remain cool, especially when shaded by vegetation, natural attenuation of P4 is extremely slow.

The distribution of P4 at ERF is very patchy, and sediment concentrations a meter or so apart can vary by two or three orders of magnitude. Highest concentrations are found around craters formed by exploded ordinance. However, P4 can be distributed through suspension of near-colloidal

particles in the water column and subsequently transported by tides and currents to other sites. P4 particles have been detected in sediments as deep as 30 cm⁴ and have the potential of resurfacing through seismic and hydrological activity. Particles of P4 at ERF range in length from 0.15 mm to 3.5 mm and fall within the size range of naturally occurring seeds. Thus, waterbirds may confuse them as food.

27.4 TOXICITY OF WHITE PHOSPHORUS

The toxic signs of white phosphorus in birds can be clearly separated into acute, subacute, and chronic toxicity. Acute toxicity is characterized by stereotypic head bobbing, lethargy, convulsions, and death within a few hours after ingestion.^{11,12} At ERF, convulsing waterfowl are attractive to predators, which may ingest P4-contaminated tissues and suffer secondary poisoning.^{13,14} Chronic P4 toxicity results in liver and kidney damage, inappetance, multifocal petecchia in several tissues, altered blood chemistry, and cessation of reproduction in females.^{15,16} White phosphorus can be transported to eggs from exposed hens and may result in teratogenic effects.¹⁶ Egg laying may cease with a single sublethal dose of P4.

27.4.1 Acute Toxicity of P4 in Birds

Field observations on free-ranging waterfowl at ERF² reported that the first signs of toxicity appeared from 4 to 6 h after ducks (green-winged teal and pintail) arrived on a pond. These signs included rapid head shaking and frequent drinking. They were followed by periods of lethargy and attempts to hide in vegetation. Subsequently, intoxicated birds arched their heads and beaks over their backs, went into convulsions, and died. Many dead waterfowl collected at ERF appeared to have drowned, probably because they lost control of their ability to keep their heads above water.

These signs were consistent with laboratory studies that have been conducted with waterfowl. Coburn et al.¹¹ dosed wild mallards and black ducks (*Anas rubripes*) with P4 dissolved in almond oil. Time to mortality for birds dosed with ≥ 3 mg/kg body weight ranged from 3.5 to 16 h. They also observed lethargy, increased thirst, leg weakness, rhythmic head bobbing, convulsions, and death. Sparling et al.¹² described three phases of acute toxicity. Within 2 h of dosing, birds demonstrated lethargy, inappetance, increased drinking, unsteady gait, and vomiting. Only 26% of the

Figure 27.3 Dose/response curves for male and female mallards given single doses of P4 dissolved in oil and for male mallards given single doses of pelletized P4. (From Sparling, D.W. et al., *J. Wildl. Dis.*, 33, 187, 1997. With permission.)

birds that showed these signs survived. This phase was followed within several hours to 1 day by a short phase of severe tremors and stereotyped head bobbing. All birds seen with these signs died, sometimes without passing into the final phase. The last phase of acute toxicity was characterized by severe convulsions that could last for more than 2 h. The nature of these convulsions was reminiscent of mallards euthanized in an O_2/CO_2 chamber but more severe and prolonged, and the authors suggested that the convulsions may have been due to anoxia. The mean time to convulsions was 5 h post dose.

Sparling et al.¹² determined that the LD_{50} for male mallards with P4 dissolved in corn oil was 6.46 mg P4/kg body weight (95% CI = 5.19 to 7.69 mg/kg) (Figure 27.3). Females had an LD_{50} of 6.96 mg/kg (95% CI = 2.66 to 8.96 mg/kg). Although the LD_{50} values were not statistically different between males and females, females had a shallower dose/response curve than males ($p < 0.045$), which might be attributed to the greater fat stores of females. Sparling et al. assessed that the lowest observed adverse effects level (LOAEL) was between 2.6 and 3.7 mg/kg for P4 in oil. They also found that pellets of P4, made by cooling molten P4 in water, had a higher toxicity than dissolved P4 in that the LD_{50} of this more environmentally realistic form of P4 was 3.90 mg/kg (95% CI = 3.24 to 4.69 mg/kg) in male mallards. They did not conduct a separate study with pellets to determine the LOAEL; but, extrapolating from dose/response curves, it lies between 0.3 (LD_{01}) and 0.4 (LD_{10}) mg/kg.

With P4 pellets, mute swans (*Cygnus olor*) had an LD_{50} of 3.65 mg/kg (95% CI = 1.40 to 4.68 mg/kg), which is very similar to that of mallards.¹⁷ However, the average time to onset of signs was substantially longer than that seen in mallards, often exceeding 1 to 4 days rather than a few hours. The authors attributed the delayed expression of effects to the predominance of small particles of grit in swans that were about the size of P4 pellets and may have delayed passage of P4 past the gizzard; grit size in mallards averages approximately 0.25–0.5 cm in diameter. For comparison, acutely lethal doses in mammals are within the range observed for waterfowl. The LD_{50} with P4 in oil for rats was 3.03 mg/kg in females and 3.76 mg/kg in males.¹⁸ The same study showed an LD_{50} of 4.82–4.85 mg/kg for mice. The lethal dose for humans is around 1–4 g.⁵

Figure 27.4 Increased mortality in mallards given repeated doses of pelletized P4 at 2.4 and 3.4 mg P4/kg body weight. (From Sparling, D.W. et al., *Toxicological studies of white phosphorus in waterfowl*, U. S. Army, Hanover, N.H., 1993.)

Subacute mortality of waterfowl can be exacerbated by repeated exposures over a few days, a situation which is likely to occur given the very patchy distribution of P4 at ERF. Birds can encounter a patch of P4 on one day, ingest a sublethal amount, and then encounter a second patch the next day. Because P4 has some persistence, it can accumulate in tissues through repeated exposure and ultimately result in toxic effects including death. For example, when mallards were experimentally fed pelletized P4 at a rate of 2.4 mg/kg/day for 10 days, no mortality occurred until the seventh day of dosing, and by the tenth day 30% of the birds had died (Figure 27.4). At 3.4 mg/kg, birds began to die by the first day of dosing, and mortality continued until 60% of birds had died by the tenth day.

27.4.2 Chronic and Subchronic Effects

A very common chronic effect of white phosphorus is an enlarged, friable, and pale liver (Figure 27.5a,b). This has been frequently reported for birds^{11,12,14,19} and mammals.^{5,20,21} One of the functions of the liver is to package lipids for excretion by combining them with proteins to make lipoproteins. White phosphorus interferes with this metabolic step, and as a result, lipids accumulate in the organ, enlarging it and altering its texture and density.^{22,23} Other liver damage includes necroses or damaged areas, ecchymoses, which appear as blisters on the surface of the liver, and increased vacuolation of hepatocytes, signifying depletion of glycogen reserves.²⁴ Hepatocellular vacuolations were first observed at acute exposures of P4 in oil at 2 mg/kg. The frequency of hepatic foci did not become appreciable until 6.1 mg/kg, near the LD₅₀. Birds that were dosed with dissolved P4 tended to show a greater frequency of these signs than those dosed with P4 pellets.¹²

Kidneys are also frequently damaged by P4. The most consistent renal damage observed in mallards was hyaline droplet nephrosis in the renal convoluted tubules.¹² This became apparent at dosages at and above 4 mg/kg P4 in oil. As with liver, kidney histopathological changes increased in frequency with repeated chronic dosing using pelletized P4. Ancillary necrosis to heart, pancreas, duodenum, and other tissues has been reported, starting at doses around 4 mg/kg of dissolved P4.^{11,12} Congested duodena, characterized by swelling and inflamed tissue, was common in birds dosed with pelletized P4. In the lab, 9 to 64% of the dosed birds had congested duodena, depending on dose. In mammals, P4 has reportedly caused damage to cardiovascular,²⁴ respiratory, renal, muscular, and nervous systems.⁵

Figure 27.5 Photomicrographs of a healthy mallard liver (A) and a liver taken from a mallard dosed with P4 dissolved in oil (B). Note areas of fatty degeneration (FD) in photomicrograph B.

In a collection of 30 mallard, pintail, and green-winged teal carcasses taken from ERF in 1993, 40% had congested duodena, 23% had frank liver damage including foci and ecchymoses, 23% had pancreatic petechia, and 43% had coronary petechia.²⁵ Among ten game-farm mallards released into pens over P4-contaminated pools for 4 h, three died, five had congested duodena, 60% had coronary petechia, and 40% had frank liver damage.

Numerous subacute and chronic changes occur in blood with exposure to P4. Several aspects of blood chemistry respond in a dose-dependent fashion to P4 and may be useful as bioindicators.^{14,15} Notably, plasma lactate dehydrogenase (LDH), aspartate aminotransferase (AST), potassium, and uric acid increased with P4, whereas hematocrit, hemoglobin, and total protein decreased.¹⁵ The responses varied between sexes, number of doses, and whether the P4 was in pellet form or dissolved in oil. For example, in nonreproductive females, responses in AST, LDH, potassium, glucose, and hematocrit could be seen after a single dose of 5.4 mg P4/kg body weight in oil, but two doses were needed to see changes in hemoglobin. With pelletized P4 in breeding females (which would be more similar to the conditions seen at ERF), changes were observed in AST, hematocrit, and LDH with repeated doses for 7 days at 0.5 mg/kg/day. At 1.0 mg/kg and 2.0 mg/kg, plasma alanine aminotransferase (ALT), hemoglobin, inorganic P, triglycerides, and uric acid demonstrated changes, and the changes in AST, LDH, and hematocrit became more pronounced. The authors suggested that the ratio of hemoglobin/LDH could provide a good bioindicator of exposure for at least 1 week post exposure (Figure 27.6). The changes in the blood chemistry can be associated with damage in the liver and kidney²⁶ and with hemolysis. In addition, significant changes in the white blood cell count were noted with a decrease in lymphocytes and an increase in thrombocytes

Figure 27.6 Relationship between plasma LDH and hemoglobin for birds given 0, 0.5 and 1.0 mg/kg pelletized P4 for 7 days. Dot = control birds; circle = 0.5 mg/kg 1 week post dosing; square=1.0 mg/kg 1 week post dosing; triangle=1.0 mg/kg 2 weeks post dosing. (From Sparling, D.W. et al., *Environ. Toxicol. Chem.*, 17, 2521, 1998. With permission.)

with dose.¹⁵ These changes were consistent with differential cell counts in mammals²⁷ and may have an effect on the immunology of affected animals.

27.4.3 White Phosphorus in Tissues

The liver is the primary organ for detoxification of P4 and could be expected to be a center of deposition. However, due to the lipophilic nature of P4, fat and skin are preferred tissues for P4 analysis. Using autoradiography in rabbits, mice, and rats, Cameron and Patrick²⁸ determined that at 48 h post dose, tissues with intense uptake of ³²P included liver, renal cortex, epidermis, hair, pancreas, and adrenal cortex. Ovary, renal medulla, spleen, uterus, thymus, lung, and adrenal medulla showed moderate radioactivity. Tissues with low radioactivity included striated muscle, brain, fat, and bone. Goshal et al.²⁹ demonstrated similar results with autoradiography in rats and determined that within 2 to 3 h the percentage of total dose in the liver reached its maximum of 65–70%. At this time, liver had significantly higher radioactivity than blood, kidney, spleen, pancreas, and brain. Lee et al.¹⁸ also found that liver had the highest radioactivity in rats, whether they were dosed once or multiple times. However, autoradiography does not distinguish between the parent P4 and its metabolites. Because it is a site of metabolism and detoxification, one might expect that the liver would contain a mixture of P4 and associated degradates. However, not much is known about the metabolism of P4 in mammals or other animals.⁵

Fletcher et al.³⁰ used gas chromatography³¹ to examine the uptake and half-life of P4 in Atlantic cod (*Gadus morhua*) and Atlantic salmon (*Salmo salar*). This study is pertinent to the ERF situation because of the discharge and interchange of P4 and sediments into the Cook Inlet by the Eagle River and because of the fishery provided by the Inlet. Fish were exposed to suspended yellow phosphorus (white phosphorus with some impurities) for up to 24 h. Liver, muscle, esophagus, intestine, pyloric caeca, and gill were examined for P4 concentration. For all tissues there was a high degree of relatedness between water and tissue concentrations, but the liver contained the highest concentrations of P4. In cod kept in water ranging from 1.9 to 5780 ppb, liver concentrations ranged from 19 to 519 ppm and muscle concentrations from 0.25 to 30.9 ppm. Between 19 and 55% of the total P4 burden was in liver. Cod, however, are well known for high amounts of oil in

their livers, and the P4 may have been suspended in the lipid fraction. In salmon, pyloric caeca had the highest concentrations of P4 (0.08 to 55.5 ppm in water with 0.84 to 1900 ppb concentrations), but this was followed in importance by liver. The biological half-lives for P4 in cod were 5.27 h in liver (with large livers having a half-life of 13.4 h) and 4.71 h in blood. Half-lives were much shorter in salmon and were around 0.5 h for most tissues examined. Little is known about the dynamics of P4 transport into and out of ERF or its dynamics in seawater. Based on the short half-lives found in these fishes and the dilution factors undoubtedly associated with the inflow of Eagle River into the much larger Cook Inlet, it is unlikely that the P4 at ERF poses a threat to fish in the Cook Inlet or to their human consumers.

Nam et al.³² used gas chromatography to directly quantify P4 concentrations in American kestrels (*Falco sparverius*) fed P4 mixed with food at 5 ppm P4 for an average intake of 6.6 to 131 µg P4/day. Maximum concentrations of P4 were approximately 0.07 ppm in fat and 0.06 ppm in skin. The researchers found that P4 was found primarily in fat and skin, although one bird had trace amounts in thigh muscle. White phosphorus could be detected after the first day of exposure and tended to increase in concentration through time, especially in skin, where the correlation with time was statistically significant. White phosphorus concentrations quickly decreased after P4 was removed from the diet and could not be detected in fat or skin after 3 days. These dosing regimens did not produce signs of toxicity in kestrels.

All of 19 waterfowl carcasses found at ERF in 1990 had P4 in their gizzards.² The mass of P4 varied widely, however, from 0.01 µg in a green-winged teal to 3 mg in a mallard to 11 mg in a swan. Mean fat concentrations of P4 were 0.67 ppm (range 0.1 to 2.9) in swans and 0.21 ppm (< 0.01 to 0.43) in ducks. Concentrations in skin were between a tenth and a third of that found in fat.

In a study of waterbirds on ERF,²⁵ one of five greater yellowlegs (*Tringa tringa*) had measurable levels (0.4 ppm) of P4 in its skin. P4 in fat of 30 ducks (pintails, green-winged teal and mallards) varied from below detection limits of 2 ppb to 19.1 ppm. Skin concentrations ranged from below detectable to 20.5 ppm and gizzard concentrations from below detectable to 628 ppm. Four of the ducks had gizzards that emitted smoke from oxidizing P4 when dissected.

In mallards experimentally dosed with P4 dissolved in corn oil, 18 of 36 given 5.25 to 9.1 mg/kg P4 died. Of those that died, P4 residues ranged from 0.12 to 1.78 ppm in fat and 0.05 to 0.96 ppm in skin.¹² Liver concentrations were much lower, from below detection limits of 1 ppb to 0.02 ppm. Concentrations of P4 in fat differed significantly ($p = 0.003$) across doses but not always in a linear fashion because birds given higher doses died more quickly, probably before all of the P4 could be assimilated. Mallards dosed with P4 pellets at 4 or 6.5 mg/kg had from 0.12 to 3.3 ppm P4 in their fat. Mute swans gavaged with P4 pellets at dosages from 2.98 to 5.28 mg/kg had fat concentrations ranging from below detection limits to 0.38 ppm and skin concentrations from below detection limits to 0.16 ppm.¹⁷ The lower tissue concentrations in swans compared to mallards may have been due to retention of P4 pellets in the gizzards of swans and consequently slower release into the digestive system. In both mallards and swans, survivors that were euthanized after 1 week post dose — even those at the higher doses — had only trace amounts of P4 in fat or skin.

In a study to determine depuration rates of P4 in mallards, game-farm birds were gavaged with a single pellet of P4 at either 1 or 2 mg/kg body weight.¹⁹ Subsamples of birds were then euthanized at 3, 6, 8, 24, 96, and 240 h post dose. Fat, liver, kidney, and breast muscle were analyzed for P4 residues. Concentrations of P4 in fat peaked by 8 h post dose, then declined precipitously by 24 h and more slowly through the next 48 h (Figure 27.7a) The higher concentration at 240 h appears to be due to one bird that may have retained the P4 pellet, because this bird also had elevated P4 concentrations in liver and kidney. During our studies, we came upon a few birds that had smoking gizzards a week or more after dosing. Initial concentrations in fat were 10 to 100 times greater than in other tissues. In the liver and muscle, P4 showed a peak at the first sampling time of 3 h and a rapid loss by 24 h (Figure 27.7b,d). At 2 mg/kg, but not at 1 mg/kg, kidney P4 concentrations were initially high, then decreased rapidly from 3 to 24 h and were below detection at 96 h (Figure

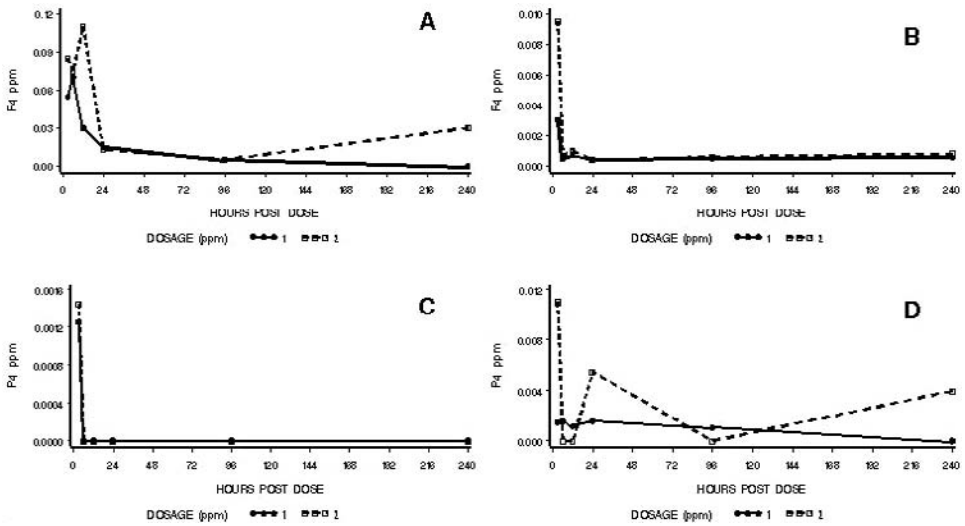

Figure 27.7 White phosphorus concentrations in different tissues of mallards given 1 or 2 mg/kg pelletized white phosphorus and then sampled at different times to determine uptake and loss; a = fat, b = liver, c = kidney, d = breast muscle. (From Sparling, D.W. et al., *Toxicological studies of white phosphorus in waterfowl*, U. S. Army, Hanover, NH, 1993.)

27.7c). Nam et al.,³³ using domestic chickens, also reported very rapid loss of P4 from liver, brain, and blood, with a slower decay in fat and skin.

27.4.4 Reproductive Effects and Teratogenesis

A proportion of the P4 a female duck ingests may be transferred to her eggs and have a potential for producing teratogenesis in her offspring. White phosphorus has been found in the egg of a gull (*Larus argentatus*), in yolk sacs of some shorebirds at ERF, and in yolk sacs of game-farm mallards treated with P4.^{1,3} In one study, domestic chickens were gavaged with P4 dissolved in tricaprillin oil either singly at 1 to 5 mg/kg body weight or daily doses of 1 mg/kg body weight for 5 days.³³ Hens given single doses at 3 or 5 mg/kg and those given repeated doses experienced a reduced rate of egg laying compared to controls or to those given a single 1-mg/kg dose; some hens stopped laying completely. At all dose levels, some P4 was transferred to the yolk of eggs, sometimes as early as the first day of dosing. However, there was considerable variation in the deposition of P4. For the single doses, P4 could be detected at 6, 8, and 9 days post dose, but only 0.003 to 0.007% of the total P4 administered was recovered in eggs. Maximal quantities of P4 in eggs ranged from 0.05 to 0.15 μg and was dose-dependent. For hens given five daily doses, P4 was measurable for 53 days past the end of dosing in stored eggs, reached a maximal mass of 0.12 μg , and accounted for 0.004% of the total administered. None of the hens dosed in that study showed obvious signs of toxicity except for the decreased rate of laying.

Vann et al.¹⁶ gavaged mallard hens with pelletized P4 at 0.5 to 2.0 mg/kg P4 for 7 days to confirm if P4 could be translocated to waterfowl eggs and to determine the effects on mallard reproduction. Although the doses were thought to be sublethal, repeated dosing at 2.0 mg/kg resulted in six of ten hens dying, and this treatment was terminated after four doses. Clinical signs of toxicity, including hepatic necrosis and enlarged spleens, were apparent at all dose levels upon necropsy. White phosphorus measurements were scheduled to be taken on the fourth (presumed to be the first egg to be formed after the onset of dosing) and eleventh (presumed to be after the effects of P4) eggs laid by each bird, but because of the reduced laying rate (see below), measurements frequently could not be taken. For those fourth eggs that could be measured, no P4 was

found in control eggs. Four of 17 (23%) of the eggs at 0.5 mg/kg, and 6 of 11 (54%) at 1.0 mg/kg had measurable (> 7 ppb) concentrations of P4. None of the birds at 2.0 mg/kg laid a fourth egg. The highest concentration of P4 detected in eggs was 0.024 mg/kg from a hen given 1.0 mg/kg P4. None of the eleventh eggs had measurable concentrations of P4, but all of these eggs from dosed birds were laid many days after the cessation of dosing.

Vann et al.¹⁶ also examined fertility and hatchability of eggs by using artificial incubation. Fertility of control eggs was 92.3% but dropped significantly ($p < 0.003$) to 86.8% for hens given 0.5 mg/kg P4 and 85.6% for those given 1.0 mg/kg. Of the fertile eggs, 90.1% of the control eggs hatched compared to 78.2% at 0.5 mg/kg and 87.9% at 1.0 mg/kg ($p < 0.01$). Some hens on 0.5 mg/kg continued laying during dosing so their embryos may have had greater exposure to P4 than most of the hens on 1.0 mg/kg who stopped laying shortly after dosing began.

There is some evidence that P4 causes malformations in embryos. Vann et al.¹⁶ dosed mallard hens with five daily doses of pelletized P4 at either 1.3 or 2.6 mg/kg. At the lower dose, 3 of 30 eggs produced deformed embryos that failed to hatch. At 2.6 mg/kg, four unhatched embryos from two hens had malformations. At both dose levels the malformations consisted of spinal defects, microphthalmia, hydrocephaly, and twisted legs and feet. The following year the researchers found that hatching weights of ducklings whose mothers were given 0.5 or 1.0 mg/kg P4 were less than those of control birds ($p < 0.003$). A large proportion, but not all, of the weight difference was due to smaller yolk sacs in treated ducklings. Rates of malformations for controls, 0.5, 1.0, and 2.0 mg/kg groups were, respectively, 1, 7.3, 6.0, and 8.1% ($p < 0.038$). The few control embryos with defects had slight scoliosis and edema, but treated embryos demonstrated more severe scoliosis and edema as well as lordosis, hydrocephaly, and bill curvature.

The greatest effect of white phosphorus on mallard reproduction was a dramatic decrease in frequency of laying. Most of the hens that were given 0.5 mg/kg P4 daily stopped laying by the fifth day of treatment and continued having low to no egg output for at least 20 days (Figure 27.8). Considering that actively laying females have ova at various stages of development, a 5-day lag in response suggests that some of these hens required a brief accumulation of P4 before effects were observed. Hens that were given 1.0 mg/kg and above stopped laying almost immediately, indicating that even partially developed eggs were inhibited from further development. Laying in this group was inhibited for at least 30 days. In the 2.0-mg/kg group, surviving birds stopped

Figure 27.8 Laying frequency of mallard hens given repeated doses of pelletized P4 daily for 7 days. Each bar marks a 5-day period with mean and standard deviation of number of eggs laid by hens laying eggs during that period. (From Vann, S.L. et al., *Environ. Toxicol. Chem.*, 19, 2525, 2000. With permission.)

laying almost immediately, and only one reinitiated laying weeks later. Control hens took an average of 13 ± 0.4 days to lay a clutch of 12 eggs, those on 0.5 mg/kg that resumed laying took 18 ± 0.7 days, those on 1.0 mg/kg took 28 ± 1.3 days, and the few left from 2.0 mg/kg needed 36.4 ± 0.24 days. Of course, under natural conditions, such abnormal laying patterns would probably lead to abandoned nests. Under the attenuated breeding season of Alaska compared to the contiguous United States, even if hens did not abandon their nests, they would not have had time to successfully produce a brood. The authors suggested that the most likely cause for the curtailment of laying was liver sequestration of lipids necessary for yolk formation. Because of the short breeding season of Alaska, ingestion of even a single dose of P4 at ERF could prevent hens from successfully breeding that year.

Vann et al.¹⁶ also studied the effects of P4 on male mallards. Males that were gavaged repeatedly with 1.0 mg/kg P4 demonstrated reduced testosterone titers in plasma, reduced body weight, and reduced hematocrit, but all these effects were transitory, and no significant differences were detected between controls and treated males at 2 weeks post treatment. There was no difference in the fertility of eggs produced by untreated hens mated with untreated or treated males.

27.4.5 Secondary Toxicity

At ERF, the convulsions and thrashings of intoxicated waterfowl attract predators such as bald eagles, ravens, and gulls. These predators feed on various parts of the ducks including gizzards with unassimilated P4 pellets and soft tissues, which may contain P4 residues. Dead eagles collected at ERF had measurable levels of P4 in their fat,²⁵ and gull eggs in nests at ERF had traces of P4.³

The potential for secondary toxicity in predators has been examined in three studies. Roebuck et al.³ observed 24 predation events on dead or dying waterfowl during a 10-day period at ERF in 1991. Of these events, 15 were by bald eagles, 7 by herring gulls (*Larus argentatus*), and 2 by ravens. During this period, the authors also found 40 fresh feather piles of waterfowl beneath a 0.5-ha tract of trees used as roosts by eagles, demonstrating a high consumption of waterfowl. Fifteen waterfowl carcasses were examined for P4 residues; from 0.02 to > 8000 μg of P4 were found in gizzards of these carcasses, fat concentrations of P4 ranged from 0.04 to 5.92 ppm, and P4 was found in several partially consumed carcasses. Thus, predators could be exposed to chronic or acute toxicity from ingesting contaminated prey.

Roebuck et al.¹³ further pointed out that the dynamics of particulate P4 in prey are important to understanding the potential for secondary poisoning. They examined the effects of pellet size on toxicity, and although they did not find any significant difference due to pellet size, they found that substantial amounts of dissolved P4 can be recovered from intestines of dead prey. They raised the question whether predators could become intoxicated only by ingesting gizzards containing intact pellets or if dissolved or assimilated P4 could also be effective. They concluded that P4 dissolved in oil and pelletized P4 were nearly equal in toxic effects and suggested that predators could become ill by ingesting other tissues containing P4.

Sparling et al.¹⁴ examined the problem of pelletized vs. dissolved or incorporated P4 by creating an experimental model of predator and prey. They repeatedly fed poultry chicks sublethal amounts of P4 over a 36-hour period to allow the P4 to pass into the intestines and become incorporated into soft tissues. They then euthanized the chicks, and to one group they added a 1.1-mg pellet of P4 into the gizzard, in another group they dissected out the gizzard to make sure that no pelletized P4 remained, and a third group of chicks were euthanized without being fed P4. The mean mass of P4 in the tissues of treated chicks was 83.9 μg , which, if the soft tissues of the carcass were eaten completely, was equivalent to 0.62 mg/kg for a 136-g kestrel. For those with added pellets, the mean mass was 1184 μg (= 8.7 mg/kg). Captive-bred American kestrels were randomly assigned to the three treatments of pellet, no pellet, and control. Each kestrel was fed a new chick daily, and the amount of food consumed and survival of kestrels were monitored daily. Eight of 15 kestrels fed chicks with P4 pellets died by the end of 7 days, with the first deaths occurring on the second

Figure 27.9 Mortality in American kestrels fed poultry chicks given P4. Control = poultry chicks with no P4; no pellet = chicks with gizzards removed to eliminate any pelletized P4 residue; pellet = chicks with gizzards intact and 1.1 mg P4 pellet added.

day of the study (Figure 27.9). Moreover, 3 of 15 kestrels that were fed treated chicks without an extra pellet died, and the first deaths occurred on the fourth day. None of the kestrels that were fed control chicks died. Food consumption and plasma LDH, ALT, glucose, hematocrit, and hemoglobin differed among treatments. Kestrels fed chicks with the pellet had lower body weight, hemoglobin, and hematocrit and higher LDH, glucose, and ALT than those on the other treatments. This study showed that predators could die from eating contaminated prey, and whereas mortality was greater when pelletized P4 was present, death could also ensue by ingesting dissolved or assimilated P4.

27.5 HAZARD ASSESSMENT OF WHITE PHOSPHORUS TOXICITY AT EAGLE RIVER FLATS

Figure 27.10 depicts the daily hazards of P4 to waterfowl at ERF. For each day, the probability of consuming P4 is dependent on the species and location of ERF that the bird uses. Of the five species of ducks that commonly use ERF, pintail mallards and green-winged teal appear to have a higher probability of ingesting P4 than widgeon or shovelers because the first three species consume more benthic invertebrates and seeds than widgeon and lack specialized bill structures of shovelers that facilitate straining and sorting of food.³⁴

Figure 27.10 Box diagram representing a daily P4 hazard assessment for waterfowl at Eagle River Flats, Alaska. (From Sparling, D.W. and Federoff, N.E., *Ecotoxicology*, 6, 239, 1997. With permission.)

Although P4 is patchily distributed throughout ERF, some areas have higher concentrations of craters and P4 loci than others; also, where a bird forages makes a substantial difference on its encountering a P4 locus.^{4,35} If a duck has encountered a P4 locus and ingests some P4 particles, the subsequent toxicity depends on a number of factors. If the total mass ingested is equivalent or more than 6 mg/kg body weight, the bird will almost assuredly experience acute toxicity and die. If the quantity is around 0.3 mg/kg or less, the bird is likely to survive without ill effects, regardless of whether or not it had a prior dose while at ERF. Males ingesting 0.5 to 1.0 mg/kg may experience no or mild effects, even if P4 had been ingested during the previous day. Females coming into reproductive condition and having consumed these levels of P4, however, may be prevented from breeding successfully that year due to the inhibition of laying. If they continue to lay, they risk decreased fertility and hatchability and increased probability of malformed embryos. The probability of inhibited laying increases with dosage up to 100% at around 2 mg/kg. For either sex, a single exposure of P4 from 1 to 5 ppm will elevate the probability of acute mortality, and the probability will be sharply elevated as the number of exposures increases. However, it is not known to what extent chronic effects of impaired liver and renal function, altered blood chemistry, reduced hematocrit and hemoglobin, and altered white blood cell counts have on the long-term survival of free-ranging waterfowl. To say that a duck is “safe” when it consumes any P4 is only in relative terms.

The total risk encountered by ducks for each day is the sum of the individual daily risks over the period of time that it spends at ERF. Radiotelemetered mallards and green-winged teal spent an average of 6.8 days on ERF during the spring staging period³⁶ and much longer periods during autumn. Of 32 birds equipped with radiotelemeters during the spring, four — or approximately 12% — died at ERF after visits ranging from 10 to 51 days.³⁶

27.6 REMEDIATION EFFORTS AT EAGLE RIVER FLATS

Based on the hazard model, the key to reducing the P4 hazard to waterfowl at ERF is to prevent waterfowl from ingesting P4. This can be done in two broadly different ways. The first way is to modify habitat usage and behavior of waterfowl to reduce their use of areas with high concentrations of P4 or restrict their feeding in such areas. At ERF, two methods were used to alter waterfowl behavior. One method employed conventional hazing devices similar to those used at airports.³⁷ Up to 15 propane cannons were located around open water ponds that were heavily used by waterfowl for foraging. These cannons were accompanied by scarecrows, mylar tape, eagle effigies, strobes, and sirens. In addition, two field technicians fired shell crackers and skyrockets over flocks of birds when they landed near P4 loci. These methods were effective during the brief staging periods in spring and fall and probably reduced avian mortality. However, they required a high commitment of resources and were only effective for the time they were actually in use; as soon as the devices were removed birds resumed their use of the areas. Birds also appeared to habituate to the presence of the noisemakers. Therefore, hazing was never considered a long-term solution to prevent exposure to P4.

Another method used to alter waterfowl behavior and use of an area was broadcasting time-release gelatin beads containing methyl anthranilate (MA) over ponds that had high concentrations of P4.^{38,39} MA is a food flavoring that gives grape soda its taste and has been found to be offensive to birds. Various formulations of MA were tested and found to vary in their effectiveness in reducing waterfowl foraging in ponds. However, one formulation (JR930413) appeared to be promising in outdoor laboratory trials and could be effective in reducing waterfowl foraging for up to 10 days post treatment.³⁹

The other broad category of methods to reduce P4 hazards is to remove P4 from the environment. The conundrums involved with this category include possible damage or destruction to the ecology of the marsh itself, the risk posed by unexploded ordinance with any excavating technique, the

extent of high tides inundating the marsh and preventing soils from drying, and the effects of short seasons and cold temperatures on any natural attenuation of P4.

For relatively small areas, some forms of geotextiles and blocks were considered. Geotextiles are mats composed of various materials that have the intended objective of isolating contaminated sediments from the sediment/water interface and from waterfowl. Blocks are aggregate materials that, when mixed with water, seal the sediment surface. Several geotextiles and blocks were considered and tested⁴⁰ including the product AquaBlok™.⁶ This block is composed of a blend of calcium, bentonite/organo clays, gravel, and polymers that bind together to form a sealant. The material was mixed on site using cement mixers and applied via helicopter to a 4000-m² pond where extensive waterfowl mortality had been observed. The barrier successfully reduced the P4 concentration at the sediment-water interface from a mean of 1.59 ± 1.06 (SEM) $\mu\text{g/g}$ sediment to 0.01 ± 0.01 $\mu\text{g/g}$. Prior to the application of the barrier, 15 of 24 experimentally confined mallards died within 9 days. After the application, only 3 of 24 mallards died. This compared to a neighboring untreated pond where 21 of 24 mallards died prior to treatment and 24 of 24 died after a simulated but not effected treatment. Foraging behavior declined in the enclosure after treatment with AquaBlok™ compared both to the control enclosure before and after a simulated treatment and to the treated one prior to the block. The long-term durability and effectiveness of the AquaBlok™ needs to be determined.⁶

Walsh et al.⁴¹ reviewed the results of three techniques found to be most effective in removing P4 at ERF. Natural attenuation due to sedimentation was considered as being too slow and too uneven compared to the need to quickly reduce waterbird mortality. *In situ* remediation of P4 is the most basic and least intrusive decontamination method examined. This method is appropriate only when sediments have a chance of naturally desaturating; thus, it can only be used in elevated sites or away from the repeated inundation from tides. Its effectiveness can be enhanced by warming the soil through heat-absorbing plastics or other means. A second method augmented natural attenuation by isolating P4 loci in low-lying sites and pumping or draining water to facilitate drying. This method can cause some disturbance in the marsh if ditches are created and can be retarded by groundwater recharge. Dredging was a third method analyzed. This causes more extensive disruption of the marsh and creates deeper pits that may actually be more difficult to dry or drain. After thoroughly evaluating the three methods, the authors concluded that each may be necessary in remediation because of the variability of the environment. Complete remediation of the marsh will take several years, regardless of techniques employed.

27.7 SUMMARY

White phosphorus has a limited distribution in the environment because it only occurs where it has been directly used by humans. It is not transported aurally for any distance and, due to its density, has a limited ability to disperse through water. Therefore, it is not a contaminant of broad-scale concern. However, where it does occur, it can cause substantial mortality or critically injure populations of waterfowl. This chronic harm includes impaired liver and kidney functioning, decreased respiratory efficiency, increased susceptibility to predation, loss of body mass, general weakening and malaise, and curtailment of reproductive functioning. Lethal effects occur around 3–4 mg/kg or approximately 3–6 ingested particles; sublethal effects can occur with ingestion of as little as a single particle. The impact of P4 on waterfowl populations nesting around ERF has never been estimated. Even if direct mortality on ERF could be estimated accurately in ducks, the delayed toxicity of P4 in swans (and presumably other species that use small grit size) and the potential for swans to fly away after ingesting a lethal dose of P4 could greatly underestimate the overall mortality. Inhibition of laying, reduced fertility and hatchability, and teratogenesis in hens ingesting even a small amount of P4 could potentially have an effect on populations greater than that exhibited by direct mortality. Predators such as bald eagles and gulls are also at risk due to

the toxicity of pelletized, dissolved, and assimilated P4 in prey organisms. Although the U.S. Army stopped using P4 in wetlands in 1993 and remediation efforts have been underway since 1995, waterfowl mortality is expected to continue for several more years. Because Eagle River Flats is only one of several sites where P4 has been found in wetland conditions, further biological investigation is warranted at these other sites.

28.1 INTRODUCTION

Hard-rock mining and associated ore processing since the mid-1800s near Leadville, Colorado have contaminated the Arkansas River with lead and other trace elements. Miners worked the watershed extensively for gold, silver, copper, zinc, manganese, and lead causing extensive contamination. Deposits from placer mines and underground mines have disposed large volumes of mining wastes into the Arkansas River. For instance, the 3.4-mile-long Yak tunnel, built between 1895 and 1909, drained numerous underground mines and discharged approximately 210 tons of metals per year into the Arkansas River basin (Environmental Protection Agency [EPA] California Gulch Superfund Web site). Additionally, mercury was used to extract gold from the ore by amalgamation.¹ There are still active, as well as abandoned, mines in the basin. As a result of these many mining activities, a number of contaminated areas designated as EPA Superfund sites exist in the Leadville area.

Water from California Gulch, one such EPA Superfund site, enters the Arkansas River at the south end of Leadville after receiving runoff from numerous tailing piles in the area. This drainage is the primary source of mining wastes in the basin. Lead in sediments of the Arkansas River, sampled in October 1988, increased by 13 times immediately below the confluence with California Gulch;² cadmium levels doubled. These sediment levels stayed high for the next 7 km downstream. Lead and cadmium levels then dropped to levels similar to upstream concentrations by approximately 50 km downstream. Concentrations in sediment continued to drop until the final sampling site was reached 190 km downstream.² A similar pattern of sediment contamination was present in May 1989 samples as well. Levels of metals at upstream sites are above normal background concentrations, however, because of other mining activities further up the drainage.³ This highly contaminated segment of the Arkansas River, from the confluence with California Gulch and extending 11 miles downstream, will be referred to in this chapter as the 11-Mile Stretch.

Sediment contamination is transferred into benthic aquatic insects in the Arkansas River. Elevated cadmium levels have been detected in benthic invertebrates immediately downstream of the California Gulch/Arkansas River confluence and for 5 km downstream compared to upstream levels;⁴ lead was not measured in that study, however. In the Clark Fork River system in Montana, elevated lead in sediments resulted in elevated lead in benthic invertebrates.⁵ Concentrations of trace elements in benthic invertebrates varied by feeding guild; detritivores were the most contaminated, and predators were the least.^{4,5}

Animals feeding on benthic aquatic insects may be more or less exposed to sediment-borne contaminants, depending on their food habits. Cadmium concentrations in brown trout (*Salmo trutta*), which feed on benthic aquatic insects from the upper Arkansas River, did not vary between an upstream site and a site 5 km downstream of the confluence with California Gulch,⁶ either during the summer or fall of 1991. This may have resulted because cadmium levels in sediment were only slightly elevated below the entry point of California Gulch² or because the fish were feeding on less contaminated guilds of benthic invertebrates. No other published data are available on whether elevated trace element concentrations in upper Arkansas River sediments are bioavailable to higher trophic levels or whether they pose a threat to other components of the aquatic food web.

Swallows, especially tree swallows, are now being more-widely used as indicators of local contamination.⁷⁻¹⁶ Tree swallows readily use nest boxes, so study sites can be established at specific locations of interest. They feed near their nest box (< 400 m¹⁷) on emergent aquatic insects,¹⁸ so residues in their tissues reflect sediment contamination for chemicals that transfer into the biota.¹⁹ Data are available on contaminant levels in tree swallows at a number of locations across the U. S. for PCBs,^{7,8,14,16} other organochlorines,^{9,10,20} metals, including lead,^{11,13,21,22} and polycyclic aromatic hydrocarbons.²²

Contaminant concentrations in tree swallow eggs and nestlings may be a more useful indicator of overall stream contamination than are concentrations in benthic invertebrates or fish. This is especially true over larger geographic areas because fish and invertebrate species composition changes as stream order changes, with the resultant inability to collect the same species at multiple

stations even over a fairly small geographic area.⁵ Additionally, there may be seasonal variation in availability of benthic aquatic insects and variation in their tolerance to pollutants, which further reduces their utility as bioindicator species.²³ Large variations in metal contamination can occur as a result of differing food habits among aquatic insect taxa,^{4,5} which further complicates data interpretation and analysis. Tree swallows integrate contaminant exposure over time and space, are generally found over a large geographic expanse, and can therefore present a much clearer picture of contaminant exposure patterns than invertebrates or fish taxa.

The objectives of this study were to determine whether lead and other trace elements were being transferred from sediments to tree swallows nesting along the Arkansas River, to document contaminant levels of trace metals if they were present, and to determine whether those levels of trace metals were injurious to tree swallows. Our working hypothesis was that there would be a gradient of trace metal contamination, with levels being highest upstream nearer Leadville, CO and lowest farthest downstream.

28.2 METHODS

28.2.1 Field Collections

In 1997 and 1998, we put up 15 to 35 tree swallow boxes at each of eight sites along the Arkansas River beginning above Leadville on the East Fork of the Arkansas River and extending downstream to Pueblo Reservoir, near Pueblo, CO (Figure 28.1). Locations of study sites (beginning upstream and moving downstream) included Colorado Belle farthest upstream along the East Fork of the Arkansas River; East Fork (near the Bureau of Reclamation's Mine Drainage treatment facility); Docs (at the upper end of the 11-Mile Stretch); Hwy 55 (at the lower end of the 11-Mile Stretch); Buena Vista, Salida, and Pueblo Reservoir. In 1998, tree swallow boxes were not put up at Pueblo Reservoir because of lack of use by tree swallows in 1997. In 1998, we added two new areas: the Shavano Fish Hatchery just downstream from Smelertown and the Lokey property just downstream from Salida (Figure 28.1); we considered these as one site, called Lokey/Shavano, due to small sample size.

Also in 1998, the Colorado Belle site was expanded to include an area just below the summit of Fremont Pass. We sampled barn swallow (*Hirundo rustica*) nestlings and cliff swallow (*Hirundo*

Figure 28.1 Upper Arkansas River Basin, Colorado tree swallow study sites, 1997–1998.

pyrrhonota) eggs at Pueblo Reservoir in lieu of tree swallows in both years because tree swallows did not nest in sufficient numbers at Pueblo Reservoir for an adequate sample. All three species eat aerial insects;²⁴ however, the similarity or dissimilarity of food habits among the three species at Pueblo Reservoir is unknown. We used two out-of-basin reference sites for comparison of δ -aminolevulinic acid dehydratase (ALAD) activities, Edness Kimball Wilkins State Park, Casper, Wyoming (1997), and Agassiz National Wildlife Refuge, Middle River, Minnesota (1998). These two reference locations were concurrently being studied for trace element exposure and accumulation.²²

Nest boxes were monitored approximately once per week, and the number of eggs and young present in each box was recorded. We collected two to three eggs from three to five nest boxes at each site approximately mid-way through incubation and collected two 12-day-old nestlings from these same nest boxes for determination of trace metal concentrations in eggs, carcass remainders (entire carcass minus the liver and upper gastrointestinal tract contents), and livers. Unhatched eggs were examined to determine when or why they failed, i.e., if they were infertile, contained dead embryos, were abandoned, etc. These unhatched eggs were not saved for contaminant analysis. Multiple eggs and livers were needed from each nest box to have adequate sample mass for contaminant analyses. Eggs were opened, the contents emptied into a chemically clean jar, and the sample then frozen in a standard freezer. Twelve-day-old nestlings were weighed and then euthanized by decapitation and blood samples collected. The livers were removed, weighed, and placed in a chemically clean jar. Brains were dissected and weighed and then returned to the carcass remainder.

The contents of the stomachs of 12-day-old nestlings were removed and composited by site. Composite diet samples as well as the liver and carcass remainder were submitted to Research Triangle Institute (RTI), Research Triangle Park, North Carolina, for chemical analysis. RTI analyzed for the standard suite of 19 trace elements using standard methodology. Samples were freeze-dried, weighed, and then homogenized in a blender. Subsamples of freeze-dried livers were digested in stages with heat and nitric-perchloric acid and then analyzed for selenium and arsenic by graphite furnace atomic absorption spectrophotometry. Aluminum, barium, beryllium, boron, cadmium, chromium, copper, iron, lead, magnesium, manganese, molybdenum, nickel, strontium, vanadium, and zinc were analyzed by inductively coupled plasma-atomic emission spectrophotometry.

Separate subsamples were digested by nitric acid reflux and analyzed for total mercury by cold vapor atomic absorption spectrophotometry. The nominal lower levels of detection, expressed as $\mu\text{g/g}$ dry weight (dw), were as follows: aluminum (5.0), arsenic (0.5), boron (2.0), barium (0.5), beryllium (0.1), cadmium (0.1), chromium (0.5), copper (0.5), iron (10.0), lead (0.05 in 1997; 0.1 in 1998), mercury (0.1), magnesium (10.0), manganese (0.4), molybdenum (0.5), nickel (0.5), selenium (0.5), strontium (0.2), vanadium (0.5), and zinc (1.0). The number of spikes, duplicates, and blanks was 6 to 8% of the total number of samples analyzed. Recovery rate averaged 106.9% (SE = 0.84, n = 60) for all metals combined; concentrations were not adjusted for recovery. Concentrations of trace elements are reported on a dry-weight basis; approximate wet-weight values can be calculated by using percent moisture values of 81.7% for eggs, 70.3% for livers, and 69.5% for carcass remainders.

Blood samples were taken during decapitation from each 12-day-old nestling for ALAD activity and hematocrit in 1997 and 1998 and for flow cytometry in 1998 only. Blood samples for ALAD were collected in heparinized cryovials and immediately frozen in liquid nitrogen. Samples were analyzed with standard techniques^{25,26} by USGS National Wildlife Health Center, Madison, Wisconsin. Each 0.1-mL blood sample was diluted with reagent-grade water and mixed with δ -aminolevulinic acid hydrochloride (ALA) in a sodium phosphate buffer, pH 6.65. The reaction was stopped after 1 h and the supernatant mixed with Ehrlich's reagent. The absorbance of this mixture was read at 555 nm in a UV-visible spectrophotometer and expressed as nmoles of ALA per minute per mL of red blood cells (RBCs). Hematocrits were determined within 4 h of collection using a microhematocrit capillary tube reader following centrifugation for 5 min at 2000 rpm. Blood for flow cytometry was collected in heparinized capillary tubes, aspirated into freezing media (Hams F10 media with 18% fetal bovine serum and 10% glycerin), inverted several times, and then frozen

in liquid nitrogen. Nuclear preparation and staining followed the method of Vindelov.²⁷ Nuclear suspensions were prepared following lysis with detergent and trypsin digestion. Nuclear suspensions were treated with RNase and stained with propidium iodide. Nuclear DNA content was analyzed in approximately 10,000 cells per individual on a Coulter Elite flow cytometer by quantification of nuclear fluorescence. The mean half-peak coefficient of variation (HPCV) in the G1 peak was quantified. This value expresses the amount of variation in the DNA content of the 10,000 cells measured. Somatic chromosome damage is suggested when the HPCV in a population is significantly greater than the HPCV in a reference population.

Additionally, food boli were collected from the throats of 8- to 12-day-old nestlings for diet composition in 15 nest boxes in July 1998 using electrical zip ties.²⁸ Two boxes were sampled twice. The second food sample was collected 4 to 7 days after the first ligature sample was taken. Young from 3 to 4 nest boxes per site were sampled from East Fork, Docs, Buena Vista, and Salida. Lotic, Inc., Unity, Maine, identified insects in one randomly selected bolus per nest box, usually to genus.

28.2.2 Statistical Analyses

For most data analyses, trace element concentration data were log-transformed to meet the homogeneity of variance assumption of analysis of variance (ANOVA) and then tested with one- and two-way ANOVA to test for differences between years and among sites within the Arkansas River basin. The antilog and 95% confidence intervals are presented in tables, figures, and text. Only trace elements detected in greater than 50% of samples were statistically analyzed. An exception was lead in eggs, which were statistically analyzed, even though only 41% of eggs had detectable concentrations. Half the detection limit was used in statistical analyses when < 100% of the samples contained detectable concentrations of a particular chemical. Means were considered significantly different if $P \leq 0.05$ for all statistical tests.

The detection limit for lead differed between years. The percent of livers above the detection limit was calculated based on the detection limit for the year in which the samples were collected. Additionally, the percent above the detection limit was recalculated for 1997 using the detection limit for 1998, the year with the higher detection limit for lead.

HPCV and ALAD were compared among sites and years using ANOVA on the mean values for a nest box, because nest box was our sampling unit. As recommended by Misra and Easton,²⁹ weighted least squares were used in the ANOVA for HPCV. Analysis of ALAD activity also included comparisons with two out-of-basin reference sites, Edness Kimball Wilkins State Park, Casper, WY (1997) and Agassiz National Wildlife Refuge, Middle River, MN (1998). Simple correlations were run between liver and carcass-remainder concentrations and between liver and diet concentrations for each trace element detected in > 50% of samples, including only those samples for which an element was detected in both the liver and carcass remainder or in both the liver and diet. Multiple correlations were run between liver and carcass concentrations of trace elements, ALAD, and HPCV for Arkansas River data only. Reproductive data were compiled using Mayfield's^{30,31} estimate of daily survival and compared among sites using methods outlined in Hensler and Nichols.³² Logistic regressions were used to determine the relationship between average lead concentrations in livers and daily survival probabilities.

28.3 RESULTS

Occupancy by tree swallows in 1997 ranged from 3% at Pueblo Reservoir to 47% at Buena Vista and East Fork; overall occupancy averaged 24% (Table 28.1). In 1998, the average occupancy averaged 37%, and occupancy ranged from 7 to 66%.

Table 28.1 Occupancy Rate of Tree Swallow Boxes in the Upper Arkansas River Basin, Colorado, 1997–1998

Sites	1997		1998	
	Number Occupied (# Boxes Available)	Percent Occupied	Number Occupied (# Boxes Available)	Percent Occupied

^a Includes 3 violet green swallow (*Tachycineta thalassina*) nests.

^b Includes 1 violet green swallow nest.

^c N/A = no boxes present.

28.3.1 Liver Tissue

Lead was detected in all ten tree swallow livers from Docs (Figure 28.2). The percentages decreased as the distance both downstream and upstream of Docs increased. At Pueblo Reservoir, no lead was detected in the single tree swallow liver (1997) nor was lead detected in the six barn swallow livers in 1997 and 1998. These percentages changed only slightly if the percent above the detection limit for both years were recalculated on the detection limit for 1998 (0.1 $\mu\text{g/g}$ dw) instead. The percent above the detection limit dropped from 83 to 67% at Hwy 55, 50 to 30% at Buena Vista, and 40 to 30% at Salida. This does not change the trend of decreasing percentage containing lead both downstream and upstream of Docs.

Although there was no difference in the concentration of lead in liver between years ($P = 0.970$), both the location ($P < 0.001$) and interaction terms ($P < 0.001$) were significant in the two-way ANOVA. Concentrations of lead were significantly higher at Docs compared to sites farther downstream at Buena Vista, Salida, and Pueblo Reservoir (Table 28.2) and generally declined as the

Figure 28.2 Proportion of liver samples from swallows nesting in the upper Arkansas River basin, Colorado, with detectable concentrations of lead, 1997–1998. Detection limits were 0.05 $\mu\text{g/g}$ dry weight in 1997 and 0.10 in 1998.

Note: Arsenic, barium, beryllium, nickel, and vanadium were not detected in any liver sample. Aluminum and chromium were detected in one liver each.

^a Years are presented separately if significantly different.

^b At Pueblo, livers were from barn and tree swallows.

^c Number of nest boxes sampled, both years combined.

^d No significant difference among sites in 1997.

^e Means sharing same letter are not significantly different.

^f Percentage with concentrations above the detection limit. Means not compared because fewer than 50% above the detection limit.

Figure 28.3 Geometric mean concentrations (horizontal lines and diamonds) and 95% CI (vertical lines) of lead ($\mu\text{g/g}$ dry weight), by year, in swallow livers in the upper Arkansas River basin, Colorado, 1997–1998.

distance from the contamination source increased. An exception was at Lokey/Shavano. The level there did not differ from Docs, although it was about half the concentration (0.38 vs. 0.54 $\mu\text{g/g}$ dw.). The interaction term in the two-way ANOVA was significant mainly because East Fork had marked differences in mean lead concentrations between years (Figure 28.3). Four of four livers in 1997 had detectable concentrations of lead, but only one of six did in 1998.

Arsenic, barium, beryllium, nickel, and vanadium were not detected in any liver samples; aluminum and chromium were detected in only one liver each. For the other 12 trace elements, concentrations in liver tissue ($n = 59$) did not vary between years except for boron, which was slightly, but significantly, higher in 1998 than in 1997 (Table 28.2). Boron in 1997 (Table 28.2), iron, magnesium, manganese, molybdenum, strontium, and zinc also did not vary among sites within the Arkansas River basin (Table 28.3). Boron in 1998, cadmium, copper, and selenium did vary among locations along the Arkansas River (Table 28.2). The upstream–downstream pattern, i.e., highest in the drainage and decreasing downstream, did not follow for the four metals that varied among sites. For example, cadmium was highest at Buena Vista, copper was highest at Lokey/Shavano, and selenium was highest at Pueblo (Table 28.2). Mercury was detected in too few liver samples to statistically analyze (19 of 59 with detectable concentrations); however, the frequency of occurrence varied among sites (χ^2 , $P = 0.002$). None of the pair-wise site differences were significant (at $P < 0.002$, $n = 28$ pair-wise comparisons); however, the frequency of mercury was higher at the three sites near Leadville, (Colorado Belle — 67% with detectable concentrations, East Fork — 50%, and Docs — 80%), than at sites farther downstream (0–20% with detectable concentrations) (χ^2 , $P < 0.001$).

28.3.2 Eggs

Concentrations of trace elements in eggs varied among sites in the Arkansas River drainage, and these differences varied slightly between years (i.e., the interaction term in the two-way ANOVA was significant); therefore, data are presented for each year separately for most trace elements (Table 28.4). Lead was detected in only 19 of 46 eggs and did not vary among sites. This was expected because lead generally does not accumulate in eggs and is not considered a tissue suitable for diagnostic purposes.³³ Lead averaged 0.09 $\mu\text{g/g}$ dw (95% CI = 0.08 – 0.11). Beryllium, cadmium, chromium, nickel, molybdenum, and vanadium were detected in fewer than 50% of the egg samples so were not statistically analyzed. For the three chemicals that varied between years, boron and

Table 28.3 Trace Element Concentrations (Geometric Mean and 95% Confidence Interval, $\mu\text{g/g}$ dry wt.) in Tree Swallow Livers That Did Not Vary among Sites or between Years, and in Carcass Reminders and Diet along the Upper Arkansas River Basin, Colorado, 1997 and 1998

^a Number with nondetectable concentrations.

^b 1998 data only due to inconsistencies with chemical analysis in 1997. Sample size for 1998 data are *n* = 32 for carcasses and 13 for diet.

^c Contains one sample with 892 $\mu\text{g/g}$ lead.

iron were higher in 1998 than in 1997, strontium was lower in 1998 than in 1997, and no other between-year differences were found. For trace elements, which varied by location, concentrations did not follow a predictable upstream/downstream pattern. Of the trace elements known to be embryotoxic, selenium was significantly higher at Pueblo Reservoir than at the other sites. Mercury was significantly lower at Pueblo Reservoir (1998 only) than at the other sites (Table 28.4). Barium was detected in all eggs and did not vary among sites; the geometric mean concentration and 95% CI were 3.67 $\mu\text{g/g}$ dw, 3.67–4.35.

28.3.3 Whole Carcass Reminders

Some trace elements were detected in carcass reminders but not in liver tissue and vice versa. Trace elements that were detected in all 59 carcass reminders, but in one or fewer livers were aluminum, barium, and chromium (Table 28.3). Detectable concentrations of nickel (35 of 59

Table 28.4 Trace Element Concentrations (Geometric Mean and 95% Confidence Interval, $\mu\text{g/g}$ dry wgt.) in Tree Swallow^a Eggs in the Upper Arkansas River Basin, Colorado, 1997 and 1998

Note: Beryllium was not detected in any sample. Cadmium was detected in 4 of 46 eggs, chromium in 3 of 46, nickel in 2 of 46, and molybdenum and vanadium were each detected in 1 of 46 eggs.

^a Pueblo site includes cliff, barn, and tree swallows.

^b *N* is number of nest boxes from which eggs were collected in 1997 and 1998 combined.

^c Years were analyzed separately because the interaction term was significant in the two-way ANOVA.

^d Means sharing same letter are not significantly different. Means only separated with Bonferonni tests if *P* for Bonferonni was set at 0.10 for both copper and iron in 1997. All other means separated at *P* < 0.05.

^e Indicates when years were significantly different.

carcasses) and vanadium (21 of 59 carcasses) were present in carcass remainders, but neither was detected in liver tissue. Boron, on the other hand, was detected in 58 of 59 livers (Table 28.2) but was detected in only two carcass remainders. For the trace elements detected in > 50% of livers and carcass remainders, there was no correlation between concentrations in the two tissue types for copper ($P = 0.684$), iron ($P = 0.728$), manganese ($P = 0.173$), strontium ($P = 0.705$), or zinc ($P = 0.640$) ($n = 59$, except for strontium with $n = 37$). There were, however, significant positive correlations between liver and carcass-remainder concentrations for cadmium ($P < 0.001$, $R = 0.519$, $n = 55$), lead ($P = 0.002$, $R = 0.444$, $n = 46$), magnesium ($P < 0.001$, $R = 0.466$, $n = 59$), and selenium ($P < 0.001$, $R = 0.857$, $n = 59$). For the 55 livers and carcasses with detectable concentrations of cadmium, concentrations averaged 25% less in liver ($0.29 \mu\text{g/g dw}$) compared with carcass remainder ($0.38 \mu\text{g/g dw}$), lead was 60% less (0.32 and $0.90 \mu\text{g/g dw}$ in liver and carcasses, $n = 46$), and magnesium was 16% less (Table 28.3). Selenium concentrations, however, were twice as high in liver compared to the carcass remainder.

28.3.4 Diet

Concentrations of trace elements in diet samples generally did not vary among locations within the Arkansas River drainage for most trace elements. This may have been due in part to the small sample sizes for diet, only one or two pooled samples per site per year (Table 28.3 and Appendix 28.1). Although not statistically different, lead concentrations in diet followed the hypothesized upstream/downstream gradient of suspected lead availability. The order of lead concentrations in the diet from highest to lowest was: Docs, Lokey/Shavano, East Fork, Hwy 55, Salida, Buena Vista, Pueblo, and Colorado Belle. Lead concentrations in the diet at East Fork were $19.2 \mu\text{g/g dw}$ in 1997 and only $2.2 \mu\text{g/g dw}$ in 1998. One diet sample from Lokey/Shavano contained $892 \mu\text{g/g dw}$ lead. If this sample is removed from the analysis, then lead concentration in diet averaged $2.30 \mu\text{g/g dw}$ (95% CI = 1.63–3.24), and the order of descending lead concentrations drops Lokey/Shavano from near the top to the bottom. Concentrations in diet significantly correlated with concentrations in liver tissues for lead ($P = 0.007$, $R^2 = 0.47$), selenium ($P = 0.028$, $R^2 = 0.34$), and boron ($P = 0.031$, $R^2 = 0.333$). There was no relationship between diet and liver concentrations for copper, magnesium, manganese, molybdenum, strontium, or zinc (all P s > 0.20). The correlation approached significance for cadmium ($P = 0.091$). Trace elements found in fewer than 50% of diet samples ($n = 20$) were beryllium (0 samples), mercury (0 samples), nickel (7 samples), and vanadium (9 samples).

Tree swallows were eating primarily insects of aquatic origin. Ninety-four percent of the boli collected from the throats of nestlings contained aquatic insects (Table 28.5). On average, there were 20 aquatic insects in each food bolus and one terrestrial insect. The two most common insect taxa were mayflies (Ephemeroptera) and true flies (Diptera, Table 28.6). Nearly all of the true flies were aquatic in origin. The most common mayfly genera in swallow boli were *Epeorus* (in seven boli), *Ephemerella* (six boli), *Rithrogena* (four boli) and *Callibaetis* (three boli). The five mayfly genera found in two or fewer boli were *Ameletus*, *Baetis*, *Paraleptophlebia*, *Siphonurus*, and *Timpanoga*.

Table 28.5 Food in Boli of Tree Swallow Nestlings along the Upper Arkansas River Basin, Colorado, 1998

Origin of Insects	Freq. of Occurrence ^a ($n = 17$ Boli)	Average Number of Insects (per Bolus)	Percent of Diet (by Number of Insects)
Aquatic	16 (94%)	20.3	86%
Terrestrial	8 (47%)	1.0	14%

^a Number and percent of boli that contained each type of insect.

^a Percent of boli that contained each taxon of insect.

^b 98% of the flies were of aquatic origin.

28.3.5 Biomarkers

28.3.5.1 ALAD

ALAD activity at the reference site averaged 74.2 nmol/min/mL of red blood cells. Mean activity of ALAD was significantly reduced along the Arkansas River at East Fork, Docs, Hwy 55, and Buena Vista when compared to the reference sites ($P < 0.001$) (Figure 28.4). Activity of ALAD at Salida, Lokey/Shavano, and Colorado Belle did not differ from the reference values. ALAD values were between 61 and 95% of the reference value. Overall, ALAD at the six Arkansas River basin sites was 74% of the reference value. ALAD values were lower in 1998 than in 1997 ($P < 0.001$), but the interaction term was not significant ($P = 0.171$). ALAD activities at the reference sites were similar between years ($P = 0.661$). The plot of mean ALAD values demonstrates a similar

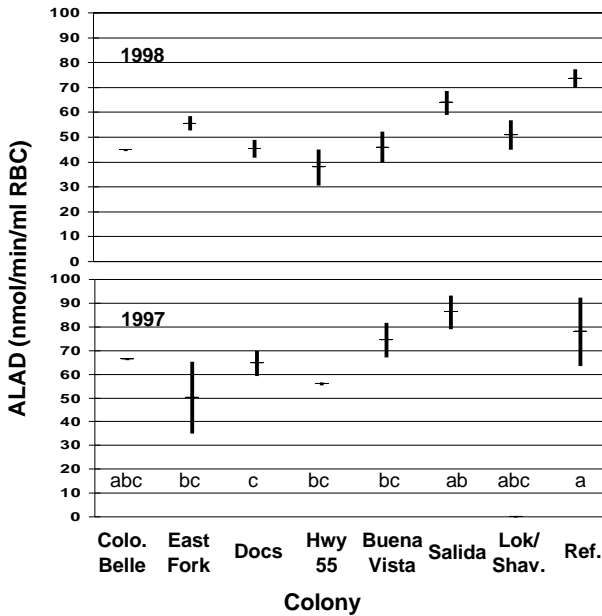

Figure 28.4 Average ALAD activity (horizontal lines), by year, in tree swallows nesting in the upper Arkansas River basin, CO, 1997–1998 and at the reference sites in Casper, WY (1997) or Agassiz National Wildlife Refuge, Middle River, MN (1998). Vertical lines are ± 1 standard error. Means sharing same letter are not significantly different, and are for both years combined.

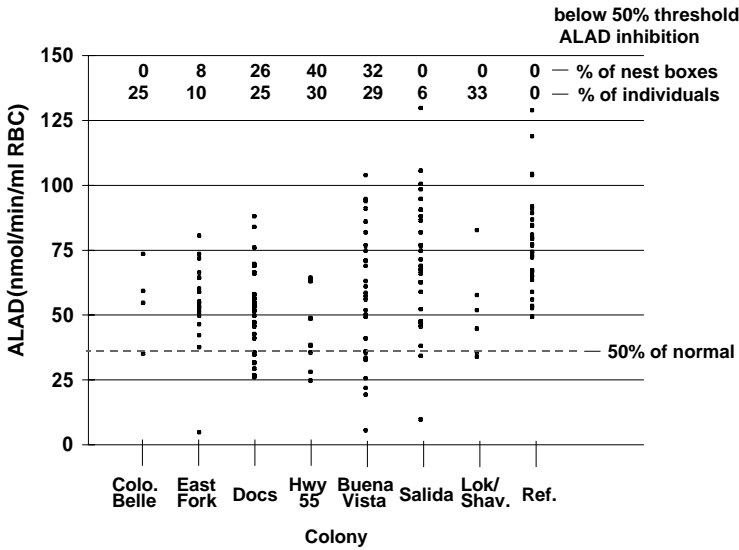

Figure 28.5 Plot of ALAD values for individual nestlings from the upper Arkansas River Basin, 1997–1998 and from reference locations in WY and MN. The dashed line indicates fifty percent of reference ALAD value.

pattern between years, except for East Fork (Figure 28.4). ALAD values at East Fork were qualitatively, but not significantly, less than Docs in 1997, but not in 1998.

The percent of the samples that had a $\geq 50\%$ reduction in ALAD, when compared to the reference mean, varied between 7 and 40% of nest boxes (Figure 28.5). The plot of individual ALAD values (Figure 28.5) also demonstrated that numerous values were less than the 50% threshold. Overall, 18% of nest boxes (16 of 89) and 20% of individual nestlings (27 of 135) had ALAD reductions $\geq 50\%$ of normal values. There was a significant negative correlation between ALAD and log lead liver concentrations ($P < 0.001$, $n = 48$); however, the amount of variation in ALAD levels explained by this relationship was small ($R^2 = 24\%$).

Hematocrit varied with altitude (Figure 28.6). Hematocrits were significantly higher at higher elevation sites — East Fork, Docs, and Hwy 55 — when compared to lower elevation sites such as Salida, Casper, WY and Agassiz NWR, MN. The slope of altitude did not appear to be linear,

Figure 28.6 Average hematocrit values (horizontal lines) ± 1 standard error (vertical lines) for tree swallows nesting along the upper Arkansas River, CO, 1997–1998, and at the reference sites at Casper, WY (1997) or Agassiz National Wildlife Refuge, Middle River, MN (1998). Elevations of nesting sites are indicated by the solid connecting line. Hematocrit values sharing the same letter are not significantly different.

Table 28.7 Correlation Matrix between Half-Peak Coefficient of Variation (HPCV) and Trace Elements That had Significant Correlations for Tree Swallows Nesting along the Upper Arkansas River, Colorado, 1998, $n = 28$

	Cadmium (Carcass)	Cadmium (Liver)	Chromium (Carcass)	Magnesium (Liver)
HPCV	0.023 (0.429)	0.019 (0.440)	0.049 (-0.376)	0.017 (-0.449)
Cadmium (carcass)		0.001 (0.573)	0.783 (0.054)	0.005 (-0.511)
Cadmium (liver)			0.907 (-0.022)	0.262 (-0.215)
Chromium (carcass)				0.747 (0.063)

Note: Significant P -values are in bold; R -values are in parentheses.

i.e., there was a maximum mean hematocrit of approximately 55% and a minimum mean hematocrit of 41%.

28.3.5.2 Flow Cytometry

Half-peak coefficient of variation (HPCV), which expresses the amount of variation in the quantity of DNA in each red blood cell, between the “a” and “b” nestlings in a box was highly correlated ($P = 0.016$, $R = 0.459$). HPCV was positively correlated with carcass and liver cadmium levels (Table 28.7), which were also correlated with one another, as might be expected ($P = 0.001$). HPCV was negatively correlated with both carcass chromium and liver magnesium (Table 28.7). No other trace elements correlated with HPCV, and no differences were found among sites ($P = 0.272$, df 6,56) within the Arkansas River basin. Mean \pm 1 SE and (n) for each site are as follows: Colorado Belle 3.46 (1); East Fork 3.86 \pm 0.08 (10); Docs 3.74 \pm 0.10 (16); Hwy55 3.62 \pm 0.18 (3); Buena Vista 4.01 \pm 0.12 (14); Salida 3.95 \pm 0.08 (16); and Lokey/Shavano 4.01 \pm 0.21 (3). Overall mean HPCV was 3.87 \pm 0.047 (SE), range = 3.07–4.91, $n = 63$.

28.3.6 Reproduction Measures

The modal clutch size was five eggs per clutch and was similar between years. The probability of daily egg survival generally did not differ between the two years of the study, except at Buena Vista (Table 28.8). Buena Vista had a higher probability of egg survival in 1998 than in 1997. In

Table 28.8 Daily Egg Survival Probabilities (Mayfield Analyses) for Tree Swallows Nesting in the Upper Arkansas River Basin, Colorado, 1997–1998

Sites	1997		1998		Signif. between Years
	Probability of Egg Survival	Standard Error	Probability of Egg Survival	Standard Error	
Colo. Belle	1.0000 a ^a	0.0000	1.0000 a ^a	0.0000	1.000
East Fork	0.9858 a	0.0054	0.9835 b,c	0.0050	0.755
Docs	0.9794 a	0.0057	0.9724 c	0.0047	0.343
Hwy. 55	0.9861 a	0.0081	0.9903 a,b	0.0069	0.693
Buena Vista	0.9802 a ^b	0.0048	0.9982 a ^b	0.0013	<0.001
Salida	0.9863 a ^b	0.0062	0.9921 b	0.0025	0.386
Lokey/Shavano			1.0000 a	0.0000	

^a Means sharing same letter do not vary among locations. Each year analyzed separately.

^b Mayfield analyses do not include the one nest lost to predation each year at these sites.

1998, the probability of egg survival was significantly less at Docs compared to the other sites, except for East Fork. There was no correlation, however, between average lead concentrations in livers and probability of daily egg survival on a colony basis ($P = 0.214$, $n = 12$). On an individual nest basis, the logistic regression between liver lead and nest success also was not significant ($P = 0.18$, $n = 52$).

The reasons for egg failure varied among sites (Table 28.9). Docs in 1997 had nearly 23% of eggs disappear at hatching. These eggs either failed to hatch or hatched and the nestlings died shortly thereafter. In 1998, lowered hatching success at Docs was due to nest abandonment or death of the adult at the box. Reduced hatching at Buena Vista in 1997 was due to depredation by bears (*Ursus* sp.) and a higher rate of infertility; hatching success at Buena Vista was excellent in 1998.

28.3.7 Morphology

Whole-body and liver weights of 12-day-old nestlings did not vary among sites along the Arkansas River, but whole-body weights of Arkansas River tree swallows (21.5 g, $n = 133$) were significantly less than those of the reference birds from WY and MN (22.9 g, $n = 55$) ($P < 0.001$). Nestling whole-body weights in 1997 (22.2 g) were significantly greater than in 1998 (21.8 g) ($P = 0.009$, Arkansas River and reference sites combined). Liver weights followed a similar pattern; livers from the Arkansas River locations (1.13 g, $n = 130$) did not differ from one another. The reference location livers (1.05 g, $n = 55$) weighed significantly less than livers from East Fork (1.21 g) and Salida (1.17 g) in 1997 and 1998 but did not differ from the other Arkansas River sites. In 1997, livers weighed significantly more (1.20 g) than they did in 1998 (1.07 g, $P = 0.003$). The ratio of liver to body weight varied among locations ($P = 0.010$); the reference location had a lower ratio (0.046, $n = 54$) than did Buena Vista (0.056, $n = 32$) or East Fork (0.056, $n = 24$). No other sites differed from one another (0.051, $n = 85$). Brain weights were similar along the Arkansas River (0.399 g, $n = 122$); only brain weights at Colorado Belle (0.341 g) differed from the reference birds (0.428 g, $n = 39$) ($P = 0.004$). When body weight was taken into consideration (brain weight divided by body weight), there were no significant differences among locations or between years ($P = 0.074$).

28.4 DISCUSSION

28.4.1 Liver Concentrations — Lead

The frequency and concentrations of lead in nestling livers conclusively demonstrated that lead from sediments was bioavailable to tree swallows nesting along the Arkansas River. All livers at Docs, the site closest to the discharges from California Gulch and the area with the highest sediment lead concentrations,² contained detectable concentrations of lead, and these concentrations were significantly higher compared to sites farther downstream at Buena Vista, Salida, and Pueblo Reservoir (Table 28.2). Over 80% of livers at Hwy 55, at the lower end of the 11-Mile Stretch, also contained detectable concentrations of lead, but at lower concentrations. Concentrations of lead in tree swallows generally declined as distance from the contamination source increased, just as sediment concentrations did.² An exception was at Lokey/Shavano (0.38 $\mu\text{g/g}$ dw in livers), which did not differ from Docs (0.54 $\mu\text{g/g}$ dw). The reason for the relatively high lead concentrations at Lokey/Shavano may be a lead source from an abandoned slag pile just upstream of Lokey/Shavano (ASA, unpublished data). The two sites above Leadville — East Fork and Colorado Belle — had similar concentrations of lead as sites downstream of the 11-Mile Stretch. These upstream sites probably reflect inputs of mining activities farther up the drainage, such as St. Kevins Gulch.³ The high correlation ($P = 0.007$, $R^2 = 0.47$) between concentrations of lead in the diet and in the liver

Table 28.9 Fate of Eggs of Tree Swallows Nesting in the Arkansas River Basin, Colorado, 1997–1998

Year & Site	No. of Nest Attempts ^a	Number of Eggs ^b	Percent Number of Eggs						
			Hatched	Failed to Hatch			Disappeared at Hatching ^d	Depredated	Abandoned

^a Tree swallow nests only. There may be more than one attempt in a single box.

^b Does not include eggs collected for contaminant analyses.

^c Eggs remained in the nest past hatching, but the reason they failed to hatch, either dead embryo or infertile, etc. is unknown.

^d Eggs remained in the nest until hatching, but whether they died at or before hatching or hatched and then died is unknown.

demonstrated the pathway of lead exposure; tree swallow body burdens were most likely a result of eating insects that had become contaminated with lead from the sediments.

Along the Arkansas River, concentrations of lead in tree swallows were less than in the sympatrically occurring American dipper (*Cinclus mexicanus*), which averaged 0.87 $\mu\text{g/g dw}$ (converted from wet weight [ww]).³⁴ Concentrations in dippers were about 1.5 times higher than in tree swallows at Docs (0.54 $\mu\text{g/g dw}$) and 7 times higher than the overall average of tree swallows on the entire Arkansas River (0.12 $\mu\text{g/g dw}$). This difference is probably due to slightly different food habits of dippers and swallows;³⁵ dippers eat aquatic insect larvae as well as some fish. Dippers probably do not accumulate much lead via ingestion of sediment because they inhabit high-gradient streams with sand and cobble bottoms.³⁵

Trace-element concentrations of lead in livers were generally consistent between years except at East Fork, where concentrations were 0.42 in 1997 but only 0.08 in 1998. This yearly difference in lead exposure is probably real, based on supporting, but independently derived, ALAD activity and diet data. ALAD values at East Fork were less than at Docs in 1997, but not in 1998. Also, lead concentrations in diet from East Fork in 1997 were eight times higher in 1997 than in 1998. All three data sets are consistent and support one another's results.

Concentrations of lead in livers of nestling tree swallows at Docs were similar to concentrations in nestling tree swallow livers from the Coeur d'Alene River basin, Idaho (mean 0.5 $\mu\text{g/g dw}$, max value 1.3),²¹ but lower than adult song sparrow (*Melospiza melodia*) livers (6.7 $\mu\text{g/g dw}$) from the same drainage.³⁶ A higher level of lead in adults compared to juveniles was present in barn swallows and starlings,^{37,38} but the reverse was true in pied flycatchers (*Ficedula hypoleuca*) in Sweden.³⁹ The Coeur d'Alene River is one of the most lead-contaminated sites in the United States.³⁶ The Arkansas River drainage had a higher frequency of livers containing lead than tree swallow study sites in Minnesota (0 of 30, CMC unpubl. data) or Wyoming (0 of 11).²² Even at the most contaminated Arkansas River site, however, liver concentrations were less than the 10 to 20 $\mu\text{g/g dry-weight}$ value where clinical signs of lead poisoning, such as anemia, tissue lesions, green diarrhea, and muscular incoordination, become evident⁴⁰ in falconiformes, columbiformes, and galliformes.

Concentrations of lead in tree swallows were also less than levels in a variety of songbird species contaminated by lead additives in gasoline or other sources of air pollution. Schilderman et al.⁴¹ found between 0.43 and 4.0 $\mu\text{g/g dw}$ (converted from ww using 70% moisture) in urban pigeon livers, and Getz et al.⁴² reported 0.6–16.1 $\mu\text{g/g dw}$ in livers of urban house sparrows (*Passer domesticus*), starlings (*Sturnus vulgaris*), grackles (*Quiscalus quiscula*), and American robins (*Turdus migratorius*) in Illinois. Pied flycatcher nestlings next to a sulfide ore smelter in Sweden contained 10 to 24 $\mu\text{g/g dw}$ lead in livers.^{39,43}

Studies of the impacts of lead on wildlife populations are limited and have mostly been on acute poisoning associated with lead shot on waterfowl. Few studies have examined reproductive effects on songbirds. Grue et al.^{37,38} found no effect of lead from automobile emissions on barn swallow or starling productivity (percent of eggs that produced fledglings) in Maryland. Concentrations of lead in whole carcasses (without feathers, feet, or bills) averaged between 0.7 and 1.5 $\mu\text{g/g dw}$ for barn swallows and 0.78–4.0 $\mu\text{g/g dw}$ for starlings, levels that are both more than those present in tree swallow carcasses in Colorado. Concentrations of lead in barn swallow diet (2.3–3.2 $\mu\text{g/g dw}$) in Maryland, however, were less than along the Arkansas River. Concentrations in starling diets (7.2–94 $\mu\text{g/g dw}$) were similar to those in our study. Nyholm^{39,43} studied pied flycatchers nesting near and far from a sulfide ore smelter in Sweden. Flycatchers nesting at the two sites closest to the smelter had a reduced clutch size, a higher percentage of unhatched eggs, and lower brain weights than those that nested farthest from the smelter. Lead concentrations in nestling liver tissue was 24.4 and 10 $\mu\text{g/g dw}$ (converted from ww) at the 2 sites nearest the smelter, 20 to 50 times higher than along the Arkansas River in Colorado.

The probability of daily egg survival (0.972) in our study was significantly reduced at the site on the Arkansas River, with the highest lead concentrations compared to other sites in 1998. This trend was also present in 1997 but was not significant. This suggests that lead could be affecting

reproduction on the Arkansas River. There was no effect of lead on tree swallow brain weights as was found in Sweden^{39,43} or in starlings in Maryland.³⁸

28.4.2 Biomarkers

28.4.2.1 ALAD

ALAD analysis is an excellent indicator of lead exposure along the Arkansas River and can aid substantially in the interpretation of tissue lead concentrations. Although mean ALAD activity at Salida did not differ statistically from the reference site, some individual ALAD values at Salida were < 50 nmol/min/mL RBC, the lowest value at the reference sites, or < 37.1 nmol/min/mL RBC, the 50% of threshold indicative of injury according to federal statute (NRDA regulation 43 CFR11.42). This agreed with the actual liver lead concentration data (35% of livers with detectable concentrations of lead) and indicated that biologically significant exposure to lead was occurring, even though mean ALAD values did not differ from reference values at Salida. The slightly reduced ALAD at Lokey/Shavano also supports the finding of lead in two of three livers at that site. There was a significant correlation between ALAD and log lead liver concentrations ($P < 0.001$). The amount of variation in ALAD levels explained by this relationship was small ($R^2 = 24\%$) but similar to the explained variation reported by others.⁴⁴

Inhibition of ALAD was at levels indicative of injury to wildlife (> 50% of normal, NRDA regulation 43 CFR11.42), both for individual values or when averaged by nest box. Between 20 and 40% of nest boxes, in and immediately below the 11-Mile Stretch, had ALAD inhibition indicative of injury to wildlife. This indicates that lead exposure may be having toxic effects on tree swallows.

Levels of ALAD inhibition at our most lead-contaminated site (Docs) was 61% of normal and was similar to the amount of ALAD inhibition in starlings (58% of normal) but more than barn swallows (86% of normal) at the most lead-contaminated freeway site in Maryland.^{37,38} On the Coeur d'Alene River, Idaho adult song sparrow and robin ALAD activities were 49% and 25% of normal, a higher inhibition level than we found on the Arkansas River. However, inhibition of ALAD in adult birds is generally greater than in nestlings.^{37,38} Urban pigeons in London, England had ALAD values between 4.4% and 21.0% of normal values.⁴⁵ Concentrations of lead in livers of these pigeons ranged up to 21.6 $\mu\text{g/g}$ dw, whereas control livers averaged 2 $\mu\text{g/g}$ lead. All were much higher than concentrations in tree swallows along the Arkansas River.

We were not able to test for effects of lead on hematocrit because our data were confounded by the different elevations of the study sites. Field and laboratory studies have shown a decrease in hematocrit with increased exposure to lead.^{37,46} Additionally, hematocrit has been shown to increase with altitude,⁴⁷ although the variation by altitude is probably not linear, as implied in that paper. Our highest elevation sites were also the sites highest in lead concentrations; there may have been some decrease in hematocrit that we were not able to detect. The maximum hematocrit for tree swallows in this study was reached at approximately 2800 m above sea level; it did not increase above that altitude. The minimum altitude where hematocrit did not decrease further was at approximately 1500 m. It is likely that there is an optimum range within which hematocrits vary according to altitude.

28.4.2.2 Flow Cytometry

Flow cytometry has identified somatic cell chromosome damage in birds due to petrochemicals, such as the polycyclic aromatic hydrocarbons,⁴⁸ and from radiation.⁴⁹ Few studies have examined the relationship between trace elements and somatic cell damage in birds. One such study⁴⁸ found no correlation between trace elements and HPCV. In that study, petrochemical concentrations, but not trace elements, including cadmium (T. Custer, unpublished data), correlated with HPCV in

lesser scaup (*Aythya affinis*). Because the petrochemical contamination in that study was quite high, it may have masked a relationship between trace elements and somatic cell damage. HPCV in tree swallow nestling blood along the Arkansas River was positively correlated with both carcass and liver concentrations of cadmium. This correlation, which was present in both tissue matrices, is intriguing and deserves further study. The negative correlation of HPCV with liver concentrations of magnesium may have resulted from the negative correlation of magnesium with both carcass and liver cadmium levels. The negative correlation of HPCV and carcass chromium levels is problematic. There is no supporting evidence in the literature, although few studies have been done in birds. Further work is needed to understand this result.

28.4.3 Diet

Pathway of lead exposure from sediment² through insects⁴ (Appendix 28.1) to tree swallows (Table 28.2) is clear. Tree swallows fed almost exclusively on aquatic insects, primarily mayflies and aquatic dipterans. Mayflies had higher trace-element contaminant levels than other benthic invertebrate taxa in the upper Arkansas River,⁴ which probably contributed to the transfer of contaminants in sediment to the avian community. Lead concentrations in diet and nestling tree swallow livers were highly correlated ($R^2 = 0.47$) and followed the upstream-to-downstream gradient in sediment contamination.² There was also a correlation between diet and liver concentrations for selenium and boron; the correlation approached significance for cadmium ($P = 0.09$) as well. Trace elements that did not correlate between diet and liver were generally those that are essential nutrients. Homeostatic processes probably ensured that the optimal amount was present for metabolic processes for these essential elements. Similar results were measured in American dipper along the same stretch of the Arkansas River.³⁴

28.4.4 Other Trace Elements

Mercury was detected in a larger proportion of tree swallow livers in and around Leadville than at sites farther downstream. Mercury was used in the metallurgy process to extract gold and silver, so the occurrence of mercury higher in the drainage seems reasonable. Average concentrations of mercury along the Arkansas River (0.067 $\mu\text{g/g dw}$ in liver and 0.16–0.18 in eggs) were far lower than concentrations reported in juvenile insectivorous passerines nesting near a mercury production plant (approx. 1.5 $\mu\text{g/g dw}$ in both livers and eggs) in Slovakia and Norway or in nearby reference areas (0.1 $\mu\text{g/g dw}$ or less for both tissue types⁵⁰). Mercury concentrations in eggs and nestling tree swallow livers on the Arkansas River were also less than those in nestling tree swallows near Casper, WY (0.3 and 0.2 $\mu\text{g/g dw}$, liver and eggs²²).

Concentrations of cadmium in tree swallow livers (0.22 $\mu\text{g/g}$) along the Arkansas River were higher than at sites in Wyoming, where all samples were below the detection limit.²² Nestling dipper livers from locations similar to ours along the Arkansas River averaged 0.497 $\mu\text{g/g dw}$ ³⁴ (converted from ww). This higher concentration may reflect the dipper's slightly higher position in the food web³⁵ compared to tree swallows. Juvenile finches and tits in Norway, however, had slightly higher cadmium concentrations (0.44–0.66 $\mu\text{g/g dw}$ ^{51,52}) in liver tissue but similar concentrations of copper and zinc compared with Arkansas River swallows. These areas of Norway are considered to be relatively well protected from long-range transport of heavy metals and have no local pollution sources. Cadmium concentrations in tree swallow livers on the Arkansas River were an order of magnitude below the 40- $\mu\text{g/g}$ dry-weight threshold for cadmium poisoning.⁵³

Concentrations of boron, iron, manganese, molybdenum, and zinc were similar to values reported in the literature for tree swallows in Wyoming.²² Boron levels in red-winged blackbirds (*Agelaius phoeniceus*) and great-tailed grackles (*Quiscalus mexicanus*) in the Mexicali Valley, Mexico (7–13 $\mu\text{g/g dw}$ ⁵⁴) were also similar to the levels we found on the Arkansas River as a whole. Average concentrations of boron for the Arkansas River (11–12 $\mu\text{g/g dw}$) are below the

33–51 $\mu\text{g/g dw}$ found in laboratory mallards (*Anas platyrhynchos*) exhibiting adverse effects.⁵⁵ Higher concentrations in boron in swallow livers at Pueblo Reservoir (25.3 $\mu\text{g/g dw}$) probably reflect inputs from agricultural drainwater.

Selenium concentrations were significantly higher at Pueblo Reservoir than sites farther upstream along the Arkansas River, perhaps due to agricultural drainage inputs farther downstream (ASA, pers. communication). Selenium concentrations in Colorado were less than those present in Wyoming tree swallows, which nested near a major agricultural drainage system²² and considerably less than the > 10 $\mu\text{g/g dw}$ (eggs) and 33 $\mu\text{g/g dw}$ (liver) thresholds considered harmful to laying females or individuals.⁵⁶

28.4.5 Reproduction Measures

Docs had the highest frequency of lead in liver tissue (100%) and also had the highest concentration in the liver (0.54 $\mu\text{g/g dw}$, average for 1997 and 1998). Although the sites with the highest lead concentrations in liver tissue — Docs in both years and East Fork in 1997 — tended to have a lower probability of egg survival, the correlation between these measurements on a colony basis was not significant ($P = 0.214$). On an individual-nest basis, the logistic regression between liver lead and nest success also was not significant ($P = 0.18$). This is understandable because some nests that were either partially or totally not successful had no nestlings that reached 12 days of age and, hence, were not available to be sampled.

The nationwide average for hatching success in tree swallows is 86.9%.⁵⁷ This number was derived only from nests that hatched at least one egg, so it is biased to the high side because it does not include those nests where all eggs failed to hatch. Nevertheless, nests at sites along the Arkansas River with lower lead concentrations either equaled or exceeded this nationwide average; nests with higher lead concentrations tended to be below this nationwide average.

28.5 SUMMARY

Lead concentrations in nestling livers conclusively demonstrated that lead from sediments is bioavailable to tree swallows nesting along the Arkansas River. Lead was detected in all tree swallow livers at Docs and in 83% of livers from Hwy 55. Both sites are in the 11-Mile Stretch, the most sediment-contaminated section of the Arkansas River. The proportion of livers with detectable lead was less both downstream and upstream of the 11-Mile Stretch. At Pueblo Reservoir, no lead was detected in the single tree swallow liver or the six barn swallow livers. Actual lead concentrations in tree swallow livers differed significantly among sites and followed the upstream/downstream gradient of sediment contamination. Concentrations of lead were similar between years, except at East Fork where a lower percentage of liver samples contained lead, and at lower concentrations, in 1998 than in 1997. This coincided with lower lead concentrations in the diet in 1998 as well as higher ALAD activity in 1998. The reason for this is unknown, but further sampling at East Fork might be warranted. Food taken from the stomachs of tree swallow nestlings exhibited the same upstream/downstream gradient in lead concentrations. This, along with the correlation between concentrations of lead in the diet and concentrations in liver tissue, demonstrated the pathway from sediment to insects to birds.

ALAD activity indicated that lead exposure was having physiological effects on tree swallow nestlings. Up to 40% of nest boxes at the nesting site nearest the California Gulch input had nestlings with ALAD inhibition > 50% of the mean activity at the reference site. This 50% inhibition threshold for injury determination is that set by federal statute. Sites with > 50% ALAD inhibition were East Fork (8% of boxes), Docs (26%), Hwy 55 (40%), and Buena Vista (32%). Over all, 18% of nest boxes had ALAD inhibition > 50% of normal.

No evidence of chromosomal damage was observed based on flow cytometric analyses. However, HPCV was positively correlated with both liver and carcass cadmium concentrations, indicating that this trace element may cause chromosomal damage in tree swallows.

Concentrations of other trace elements (cadmium, mercury, and selenium) in eggs, livers, and food were generally below known effect levels based on published information of other avian species and were similar to other sites where tree swallows have been studied in the United States.

ACKNOWLEDGMENTS

We would like to thank Kurt Broderdorp, Craig Miller, Clay Ronish, and Sean Strom of U.S. Fish and Wildlife Service for help in deploying and checking nest boxes; Joe Coogans, Bernard Smith, Department of the Interior, and the Colorado Division of Wildlife for access to their properties; Dwayne Monk and other Leadville Fish Hatchery personnel for logistical support; Milton Smith and Daniel Finley, USGS, National Wildlife Health Center for ALAD analyses; John Tipping for insect identification; and Paul M. Dummer for help with data analysis. We would also like to thank Fred Meyer, Erik I. Nyholm, Cole W. Matson, and two anonymous individuals for review of the manuscript. C.D.S. and J.W.B. were funded in part by NIEHS grants ES 04917.

29.1 INTRODUCTION

29.1.1 The Hudson River — PCB Case History

The Hudson River dominates the history and landscape of eastern New York and surrounding states (Figure 29.1). In environmental terms, the Hudson River has come to symbolize the difficulties associated with finding solutions to the problems of widespread contamination by persistent organic compounds as well as other sources of anthropogenic stress. The case history I describe here does not include many of the complicating factors that make addressing contaminant problems so difficult in the early 21st century such as complex mixtures and diffuse nonpoint sources with no easily recognizable responsible party. Instead, the story of the Hudson River is dominated by a single class of chemicals (PCBs), released from two long recognized point sources, by a still thriving corporation — in short, the very scenario that many environmental laws were written to address. It is informative that solutions to the contamination of the Hudson River have not been reached. In this case study, I review the history of PCB contamination in the context of the Hudson River ecosystem. I describe the patterns of PCB contamination in the biota of the Hudson, the risk contaminants pose to fish and wildlife, and attempts to mitigate those risks.

Figure 29.1 The Hudson River and major landmarks. Locations along the Hudson are traditionally referred to by their distance in miles from the mouth of the river at the Battery in New York City (River Mile [RM]).

Polychlorinated biphenyls, or PCBs, are a group of 209 related molecules (congeners) that were widely used in industry and have become widely distributed in the environment.^{1,2} While the broad spread of PCBs throughout the biosphere is significant cause for concern on a global scale, there continue to be significant local and regional problems associated with high concentrations of contaminants remaining in the environment from historical activity.² The widely recognized risks to human health and ecosystems posed by PCBs and related persistent organic pollutants (POPs) has led to widespread restrictions on their manufacture and use at the national and international levels.^{1,3} Documentation of potential adverse impacts on human health associated with exposure to PCBs dates back many decades and includes skin problems, liver and kidney damage, possible estrogenic activity, and possible increased cancer risk.⁴⁻⁶ In that past decade, studies of both humans and nonhuman animals provide increasing evidence that children exposed to PCBs *in utero* suffer neurodevelopmental deficits.⁷⁻¹³ These neurodevelopmental effects of PCBs are expressed as lower IQ scores, deficits in reading ability, delays in development of motor skills, and spatial learning deficits. In addition, adults exposed to PCBs through consumption of contaminated fish score lower on tests of memory and learning.¹⁴

As the threats to fish, wildlife, and the environment due to bioaccumulation and bioconcentration of organochlorines became widely recognized in the 1960s, high concentrations of PCBs were identified in a variety of organisms. Substantial field and laboratory research has documented a

wide array of adverse effects on fish and wildlife associated with PCB exposure.^{1,2} Mortality, reproductive failure, porphyria, induction of mixed function oxydase (MFOs), behavioral and developmental abnormalities, and pathologies of the liver, thyroid, spleen, and other organs have been reported in a variety of laboratory and field studies of wildlife.^{15–17} As analytical techniques have become more sophisticated, studies of the relative toxicity of individual PCB congeners have added to our understanding of PCB biology. Non-*ortho* planar congeners, such as PCBs 77, 126, and 169, appear to be especially toxic to wildlife.^{16,17}

It is far beyond the scope of this chapter to provide a comprehensive review of the thousands of pages of scientific literature on the Hudson River. Instead, it is intended to provide an overview of how the Hudson River case history has progressed, describe some of the scientific generalizations that have emerged, and to point to some of the sources of conflict. The historical background of environmental issues surrounding the Hudson River are first discussed, followed by a brief overview of some of the ecotoxicological studies that are specific to the Hudson River. Finally, I present a brief overview of the progress from identifying the scope of the PCB issue toward deciding on a course of action to mitigate the impacts of the contamination of the river and surrounding ecosystems.

29.1.2 Hudson River Ecosystems

The Hudson River watershed encompasses 35,000 km² of New York and four surrounding states (Figure 29.1). From its origin at Lake Tear of the Clouds near Mount Marcy in the Adirondack Mountains, the Hudson extends for 507 river km to its terminus at the Battery on Manhattan Island, where it empties into New York Bays and ultimately the Atlantic Ocean. The Hudson River is an important historical, cultural, economic, and natural resource for the New York region. The River continues to play a role in transportation, through shipping upriver as far as the Port of Albany and through commercial and recreational traffic on the Champlain Barge Canal, which is contiguous with the Hudson River from Albany to Ft. Edward. The Hudson is also an important source of drinking water for municipalities such as Waterford, Poughkeepsie, and Rhinebeck, NY and is used in times of shortage as a water source for New York City. In addition, the river continues to play a key role in power generation for the region, primarily through use as a source of cooling water for power plants.

The upper third of the Hudson runs through the relatively undisturbed and protected forests of the Adirondack Park, flowing down a relatively steep gradient of 3.1 m/km.¹⁸ The first major settlements on the river — Glens Falls, Hudson Falls, and Fort Edward, New York — lie less than 10 km south of the Adirondack Park boundary, at river mile 200 (320 km — it is traditional to reference locations on the Hudson as river miles (RMs), measured upstream from the terminus of the river in New York City; see Figure 29.1). South of the Adirondacks, the Hudson River valley is a mosaic of farmland and second-growth eastern deciduous forest. The gradient of the river also lessens to 0.62 m/km.¹⁸ From Fort Edward, the Hudson passes through a series of locks and dams of the Champlain Canal system before reaching the Federal Dam at Troy, 80 river km to the south. These locks form a series of pools and form important sediment deposition zones.

The Federal Dam at RM 153 (240 km) marks the transition between the upper Hudson River and the lower Hudson River. The lower Hudson is an estuary, influenced by tidal action and open to shipping. The Hudson estuary is a drowned river valley, with much of the river bottom well below sea level. Over the entire 153 mi of the lower Hudson from Troy to the Battery, the river falls only 1.5 m — an average of 0.006 m/km.¹⁸ Wetlands form an important component of the lower Hudson ecosystem. Both marshes with emergent vegetation and tidal mud flats are important habitat types, especially between RMs 25 and 140.¹⁸

The tidal estuary of the Hudson has a gradient from fresh water (salinity < 0.5%) to polyhaline (salinity 18–30%). The divide between fresh and saline waters varies both daily with tidal action and seasonally depending on freshwater runoff. Under historically typical levels of runoff, brackish water reaches to 50 to 60 mi above New York City. However, the divide can fluctuate from RM

15 to 100 in times of especially high or low river flows.¹⁸ In recent years, saline water has extended as far as 95 km upstream from the mouth of the river.¹⁹

Biological productivity of the Hudson River estuary is high. Productivity of the oligohaline and mesohaline reaches of the river between May and October in the early 1990s was estimated at 310–680 g C m⁻².²⁰ In the freshwater portions of the estuary, respiration tends to be greater than annual production. Annual phytoplankton productivity averages 300 g C m⁻², while approximately 40% of the freshwater system's organic carbon is exported directly to the lower river.²¹

29.1.3 PCBs and the Hudson Falls/Fort Edward Plants

Recognition of heavy contamination by PCBs in the early 1970s led to the eventual declaration of 320 km of the Hudson River as an EPA Superfund Site (Table 29.1). PCBs were widely used in industry, starting in the 1930s. In the United States, the principal manufacturer of PCBs was the Monsanto Corporation, which sold mixtures of PCB congeners under the trade name Aroclor from 1929 until PCBs were banned in 1977.²² PCBs are highly stable and were favored as electrical insulators. Between 1946 and 1952, General Electric (GE) began using PCBs in the manufacture of capacitors at plants in Fort Edward and Hudson Falls, New York. It is estimated that these facilities alone purchased 15% of all the PCBs used in the United States.²³ Reported uses of PCBs at these facilities consisted primarily of Aroclors 1016, 1242, and 1254.^{22,24} These plants were the largest source of the PCBs in the Hudson River.^{22,23} Estimates of total PCB discharges by these plants range from 95,000 to 603,000 kg. However, these estimates were all made prior to the discovery of ongoing inputs of PCBs from the GE plants and surrounding areas, so the true amount of PCBs entering the river is undoubtedly much higher than the commonly cited estimates.¹⁹

Until 1973, some of the PCBs released by these plants were trapped in sediments held behind a dam at Fort Edward, NY. Removal of the Fort Edward dam because of its deteriorating condition resulted in the release of an estimated 1 million m³ of contaminated sediments.²² These contaminated sediments tended to accumulate in depositional areas of the Hudson, forming pockets of highly contaminated sediment eventually labeled “hot spots.” Although limited data were available, high concentrations of PCBs in fish were in evidence before the removal of the Fort Edward dam (R. Sloan, pers. comm.).²⁵ Shortly after the dam removal and the redistribution of contaminated sediments via flooding, an increased number of analyses and the subsequent finding of high levels of PCBs in fish in the Hudson helped initiate a long series of studies and assessments of the environmental, ecological, and social impacts of the PCB contamination. These studies continue in the ongoing quest for possible solutions to the PCB problem. By 1976, commercial fishing for striped bass and other species had been banned on the Hudson, and recreational fishing was restricted.²⁵

Redistribution of the PCB-contaminated sediments by the removal of the Ft. Edward dam coupled with ongoing inputs of PCBs from the GE site continue to form an important route of entry for PCBs into the food web. Residual deposits of sediments remaining after the removal of the Ft. Edward dam (“remnant deposits”) between RMs 195 and 196 were capped in 1991 as part of the 1984 U.S. Environmental Protection Agency (EPA) Record of Decision. The importance of ongoing inputs of PCBs from the GE plants and surrounding areas into the Hudson have been recognized in recent years. One source of these continued inputs was the abandoned Allen Mill site located adjacent to the Hudson Falls plant. Between 1993 and 1995 alone, approximately 45 tons of PCBs were discovered in water conduits within this plant and removed.¹⁹ In addition, PCBs saturate the bedrock under the GE plants. These PCBs continue to seep into the Hudson from the fractured bedrock adjacent to and underlying the river at the Hudson Falls and Ft. Edward plants.¹⁹ In 1994, it was estimated that between 11 and 19 liters (3–5 gallons) per day of PCB product were being collected from seeps at the Hudson Falls GE plant.²⁵ By 1999, ongoing discharges from the GE plants were estimated at 90 mL per day (3 ounces).²⁵

Table 29.1 Timeline of Major Hudson River–PCB Events

1947–1952	General Electric begins use of large quantities of PCBs in capacitors manufactured at Ft. Edward and Hudson Falls plants adjacent to the Hudson River in New York. For the period 1966–1974, it is estimated that 15% of all PCBs sold in the United States are used by these two plants. ²³ An unknown quantity of PCBs eventually reaches the waters of the Hudson River, with early estimates ranging from 95,000 to 603,000 kg.
1969	Elevated levels of PCBs in Hudson River biota first observed. ²³ By 1971 New York State finds PCB levels of 4 to 11 ppm in striped bass.
1971	Monsanto, the primary manufacturer of PCBs in the United States, voluntarily restricts sales of PCBs to uses in “closed cycle” systems. ²³
1972	GE applies for an EPA permit to discharge 30 lb/day of chlorinated hydrocarbons. The permit goes into effect 31 January 1975. ²³
1973	Dam at Ft. Edward removed allowing sediments trapped behind the dam to move downstream. Flow of PCBs downstream is exacerbated by periods of high flow such as observed in 1976. In subsequent years, an estimated 1.3 million cubic yards of PCB-laden sediments are released downstream, redistributing contamination over 322 km (200 mi) of the Hudson River.
1974	U.S. EPA study finds high levels of PCBs in Hudson River fish.
1976	Toxic Substance Control Act restricts manufacture and use of PCBs. Monsanto halts production in 1977. U.S. EPA bans all use of PCBs in 1979.
1976	NYSDEC closes all fishing on the upper Hudson River and restricts commercial fishing along the entire Hudson River.
1976	GE is ordered to stop discharging PCBs into the Hudson River by July 1977. GE reaches an agreement with the State of New York agreeing to pay \$3 million for monitoring of the Hudson River (to be matched by \$3 million from NYSDEC), in return for not being held liable by the state.
1977	Clean Water Act prohibits discharge of PCBs into navigable waters. GE terminates active discharge from plant sites in to the river. NYSDEC implements long-term monitoring of Hudson River fish.
1983	U.S. EPA includes the Hudson River on the Superfund National Priority List.
1984	U.S. EPA issues Record of Decision including an interim “No Action” decision regarding contaminated sediments.
1989	NYSDEC requests that U.S. EPA reconsider their 1984 interim “No Action” decision. U.S. EPA begins the process of reassessment of Hudson River sediments in 1990. Phase One is completed in 1991. Phase Two reports, including the Human Health and Ecological Risk Assessment, are released between 1995 and 2000. ^{6,19,24} The Phase Three report on the feasibility of remediation is released in December 2000. ²⁸ The U.S. EPA estimates that the cost for the Reassessment will total \$21 million.
1991	New sources of PCB oil flowing from the GE site at Hudson Falls are discovered.
1993	Cleanup around the GE Hudson Falls plant begins.
1995	NYSDEC reopens the upper Hudson River to recreational fishing on a catch-and-release basis.
2000	Human Health and Ecological Risk Assessments are released by the U.S. EPA. ^{6,19} The U.S. EPA releases the Reassessment Phase 3 Feasibility Study Report and the Agency’s (nonbinding) Proposed Plan. ²⁸ The U.S. EPA preferred remedy includes dredging targeted areas in the Upper Hudson River between Fort Edward and Troy, totaling 2.65 million cubic yards. The dredged material will be shipped to existing licensed landfills outside of the Hudson River Valley for disposal. The estimated cost is \$460 million. It is planned that the remediation will take five years. The Proposed Plan is open to public comment; by the close of the public comment period in early 2001, 70,000 comments are received.
2001	Bush administration EPA Administrator Christie Whitman endorses the Clinton-Administration preferred remedy and issues the formal Record of Decision (ROD) from the Reassessment. ⁵⁵
Ongoing	Implementation of the U.S. EPA proposed plan. Debate will continue on how to best implement and evaluate the limited dredging of the Hudson River “hot spots” called for under the EPA Record of Decision. ²⁶ Natural Resources Damage Assessment: the U.S. Department of the Interior, National Oceanic and Atmospheric Administration, and New York State Department of Environmental Conservation are responsible for an ongoing evaluation of the degree of damage to the natural resources of the Hudson River. ^{25,57} This process will evaluate the degree of damage to resources, determine how the resources might be restored, and consider how the public might be compensated for past and future losses of valued resources.

While other sources of historical PCB inputs exist, it is estimated that the GE-related contamination accounts for close to 100% of the in-place and water-borne contamination of the upper Hudson, declining to 50% in the saline reaches of the lower Hudson.¹⁹

Extensive sampling of water, sediments, and aquatic biota of the Hudson has been conducted over the last 25 years. Although PCBs move through the system during low-flow periods, high-flow events are a major factor in the transport of PCBs. Contaminated sediments have also entered the surrounding terrestrial ecosystem when flood events deposit contaminated sediments on the flood plain. Earlier navigational dredging projects have also factored into redistribution of sediments within the river and into riparian and upland systems.¹⁹ A general trend toward declining PCB levels had been observed until 1991, when levels in water and the biota again climbed in response to additional, recently documented releases of PCBs from the GE site.¹⁹

29.2 PCBs IN THE HUDSON RIVER VALLEY ECOSYSTEM

29.2.1 Water and Sediments

PCBs continue to be transported downstream in the water column both from the continued inputs of PCB oil from the GE plant sites and from the contaminants contained in the sediments of the upstream pools.^{19,24} The amount of PCB transported varies greatly with location and among locations depending on seasonal and interannual changes in river flow. For example, at the Thompson Island Dam, total PCB load averaged 1.16 kg/day during periods of low flow and 18.1 kg/day during high-flow periods.²⁴ The U.S. Geological Survey (USGS) has monitored river flow at several sites along the Hudson since 1977. These data exhibit a general decline in the total PCB load from the initial measurements (2308 kg/year at RM 194.3, 3956 kg/year at RM 168.2 in 1977) through the 1980s, when they fell below 400 kg/year in many years. However, there was significant interannual variation, and a notable increase in total PCB load was evident in 1992, when loads climbed to 951 kg/year and 537 kg/year at the two sites.²⁴ This increase was probably related to high water flows washing fresh PCBs into the Hudson from the Allen Mill at the GE Hudson Falls site.²⁵

The sediments of the Hudson River form a reservoir where high levels of PCBs are stored as they cycle through the food web. Sediment surveys conducted by the New York State Department of Environmental Conservation (NYSDEC) starting in 1976–1978 noted the concentration of PCBs in areas of sediment deposition, especially in the pools that form behind the locks of the upper Hudson. Areas of especially high concentrations (mean concentration = 48.4 mg/kg)²⁴ have become known as “hot spots.” This general pattern has persisted since first described in the 1970s and is still recognized in surveys conducted by NYSDEC, GE, and U.S. EPA in the 1980s and 1990s. Sediment concentrations vary on a small spatial scale. The 1984 sediment survey of the Thompson Island Pool sampled 1100 sites and found mean PCB concentrations of 10.9 g/m² and a median of 3.5 g/m² (SD = 41.7). However, concentrations ranged from a low of 0.04 g/m² to a high of 1218 g/m².²⁴

Sediment concentrations also vary on a wider spatial scale. The highest concentrations of PCBs are found in the Thompson Island Pool sediments. Mean concentration in the upper 25 cm of sediment measured in 1991 was 42 mg/kg.²⁶ Concentrations were lower in pools immediately downstream of Thompson Island Dam, with a mean 26 mg/kg PCB (but a maximum of 4000 mg/kg in one core). Concentrations are lower still in the sediments upstream from the Federal Dam at Troy, where surface sediment concentrations were 9 mg/kg.²⁶

29.2.2 Fish and Aquatic Invertebrates

The diverse habitats of the Hudson River support several distinct assemblages of fish. Commercially valuable species, such as striped bass (*Morone saxatilis*), American shad (*Alosa sapidissima*), Atlantic Sturgeon (*Acipenser oxyrinchus*), and American eel (*Anguilla rostrata*), depend

on the estuarine portions of the lower river.¹⁹ Recreational fishers pursue a diversity of these estuarine species as well as largemouth and smallmouth bass (*Micropterus salmoides* and *M. dolomieu*), yellow perch (*Perca flavescens*), pumpkinseed (*Lepomis gibbosus*), and other freshwater species. In all, over 200 fish species are found in the Hudson River.¹⁹

Until the mid-1970s the lower Hudson supported a commercial fishery, based on striped bass, American shad, American eel, Atlantic sturgeon, and other species, valued at an estimated \$2.6 million annually.¹⁸ After high levels of PCBs in commercially exploited species from the Hudson became publicly known, the NYSDEC closed the lower Hudson River to commercial fishing for striped bass in 1976.^{25,27} The upper Hudson River was closed to both commercial and recreational fishing in 1976, although a catch-and-release recreational fishery was reopened in 1995.^{22,28} Losses to the striped bass fishery alone were estimated at \$0.75 to \$3.7 million in 1994.²⁹ In addition, the lower Hudson supports several endangered and threatened species as well as species of special concern such as the federally and state listed shortnose sturgeon (*Acipenser brevirostrum*).

Several groups have collected field data on the exposure of Hudson River fish to PCBs including the National Oceanic and Atmospheric Administration (NOAA), GE, and U.S. EPA. The most comprehensive data have been gathered by NYSDEC. Data collected by NYSDEC in 1998 show high levels of PCBs persist (reported by U.S. EPA¹⁹ and pers. comm. from R. Sloan, NYSDEC). For example, in Thompson Island Pool (Griffin Island at RM 189), average tissue concentrations in 1998 were 32.7 µg/g for carp (*Cyprinus carpio*), 16.2 µg/g for brown bullhead (*Ameiurus nebulosus*), and 18.2 µg/g for largemouth bass (Table 29.2; R. Sloan, NYSDEC, pers. comm.).

Given the social and economic importance of the fishery, much attention has been paid to the suitability of Hudson River fish for human consumption. The closure of the Hudson River fisheries in the 1970's was preceded by health advisories warning residents not to eat fish from the river. Since that time, the U.S. Food and Drug Administration (FDA) has set acceptable limits for human consumption, first at 5 ppm wet mass in 1974, then at the current lower level of 2 ppm in 1984²⁵ (Table 29.1).

Generalizations about patterns of PCB concentrations in Hudson River fish are difficult to make given the variety of factors that influence contaminant levels. Concentrations of PCBs in fish vary within a species based on the age, fat content, and size of the fish. Among species, those species that are nonmigratory, feed at higher trophic levels, and live further upstream tend to have the highest concentrations. Other factors such as sex, reproductive status and body condition, and habitat use may also contribute significant variation to PCB levels.^{30,31}

PCB levels are low in fish from sites upstream of the GE plants (Figure 29.2). Peak levels are observed near the plants and then generally decrease with distance down river. The Mohawk River enters the Hudson at RM 156. Downstream of this point approximately 50% of the river flow (though less than 50% of the sediment load) originated in the Mohawk Valley. This dilution of water from the upper Hudson is in part responsible for the drop in PCB loads in fish from Albany downstream (R. Sloan, NYSDEC, pers. comm.).

Over time, PCB levels in fish have fluctuated. When use of PCBs at the GE facilities stopped in 1977, the levels of PCBs in water and in fish tissues declined rapidly until the early 1980's (Figure 29.3). Since then, levels have changed slowly or stabilized, although they remain subject to significant interyear variation (R. Sloan, NYSDEC, pers. comm.).^{19,25,32} As late as 1999, mean concentrations of PCBs in muscle tissue of brown bullheads and largemouth bass remained as high as 13 µg/g and 21 µg/g in the upper river, well above the FDA limit for the edible portion of fish of 2 µg/g.^{26,33} Some individual largemouth bass in Thompson Island Pool still had 114 µg/g in 1999 (NYSDEC data).²⁶

The social and commercial value placed on striped bass has contributed to this species' becoming an important representative of the Hudson River PCB problem. Striped bass are anadromous, migrating as adults from the Atlantic Ocean to spawning grounds in the Hudson River in the spring, and returning to the Atlantic Ocean in the late spring and summer, although some individuals (particularly males) remain in the Hudson longer (R. Sloan, NYSDEC, pers. comm.). Because

Table 29.2 Concentration of PCBs in a Representative Range of Hudson River Organisms. Total PCBs ($\mu\text{g/g}$ Based on Wet Mass) Shown for Samples Collected in a Variety of Years and Locations

Figure 29.2 PCB levels in Hudson River fish. River Mile is the distance above the mouth of the river, with the primary source of PCBs being the Hudson Falls and Ft. Edward GE plants at RMs 195–197. Concentrations are given on a lipid-weight basis, with both total PCBs and the higher chlorinated fractions quantified as Aroclor 1254 and higher shown. Figure courtesy of R. Sloan, NYSDEC.

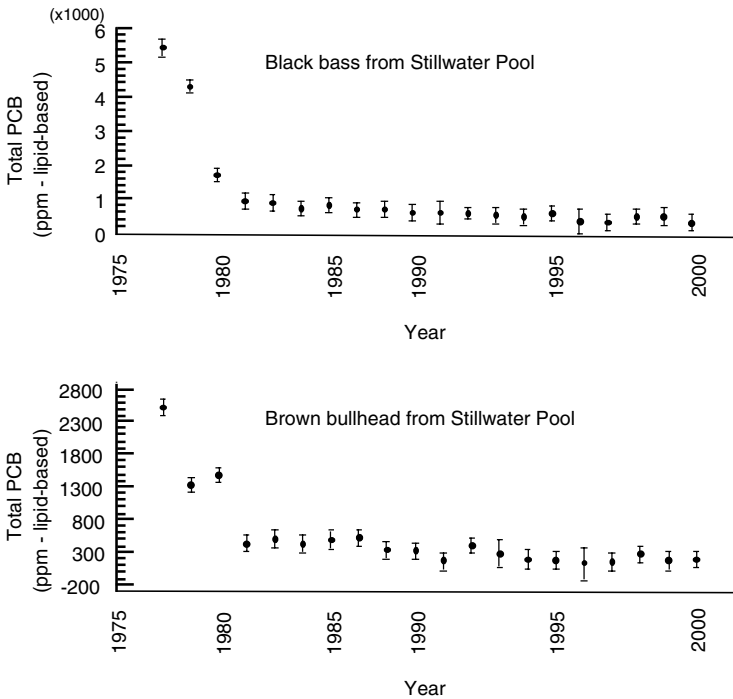

Figure 29.3 Changes in PCB levels in Hudson River fish over time. Total PCBs (lipid-weight basis) are shown for both black bass (*Micropterus*) and brown bullhead (*Ameiurus nebulosus*) from the Stillwater Pool (RMs 168–183). Figure courtesy of R. Sloan, NYSDEC.

striped bass spend only a portion of their life history in the Hudson River, overall levels of contamination in them tend to be lower than in resident species. Initial observations of PCBs in striped bass date back to at least 1970, when concentrations in excess of 4 $\mu\text{g/g}$ were observed.^{22,23} As the PCB contamination came to the public’s attention and health warnings were issued, regular sampling of striped bass was initiated.³² Mean levels of PCBs in the edible portions of striped bass were 18.1 $\mu\text{g/g}$ in 1978.²⁷ Total PCB levels fell below 10 $\mu\text{g/g}$ by 1980 but showed only a slow decline in subsequent years.³⁰ In the Hudson River below RM 80, tissue concentrations changed

slowly and were around 2 $\mu\text{g/g}$ by the 1992–1994 period.³⁰ However, in the Albany/Troy area (RM 153) interyear variation was greater than any trend toward decreasing concentrations. Levels were especially high in 1985, 1986, and 1992, when total PCB levels were greater than 15 $\mu\text{g/g}$ (wet mass).³⁰ Overall, PCB concentrations increase in fish caught further upstream. As in other species, male striped bass have higher levels of contamination than females. For example, males caught in 1997 in the lower estuary averaged 1.25 $\mu\text{g/g}$ PCBs, while females averaged 0.58 $\mu\text{g/g}$ PCB (R. Sloan, NYSDEC, pers. comm.).

While much attention has been paid to the impact of PCBs on the economics of the fishery, the impacts of this contamination on fish health and ecology have been less well studied. Effects on fish attributed to PCBs include declines in physical condition, liver, spleen and kidney cell abnormalities, abnormal bone development, and skewed sex ratios.^{34–36}

The U.S. EPA Ecological Risk Assessment evaluated the probable effects of PCB exposure on a variety of representative fish species.¹⁹ The general approach was to compare exposure of Hudson River populations to levels of PCB contamination shown to cause detectable impacts on reproduction, survival, or growth in field and laboratory studies reported in the scientific literature. Based on this approach, the EPA concluded that PCB levels in water and in sediment in the upper Hudson exceeded levels that could be reasonably considered acceptable and that these levels were predicted to remain high through the entire analysis period (e.g., through at least 2018).¹⁹ In the lower Hudson, the U.S. EPA concluded that the risk to fish is primarily limited to piscivorous fish.

29.2.3 Wildlife and the Terrestrial Ecosystem

PCBs are known to have been deposited in terrestrial habitats near the Hudson River through dumping of contaminated dredge spoils, deposition along floodplains due to flooding, and exposure of contaminated sediments in the remnant-deposit areas. PCBs enter the terrestrial food chain when primarily terrestrial species eat contaminated aquatic organisms, such as insects and fish, or are exposed to invertebrates associated with contaminated flood-plain soils.

The highly productive waters of the Hudson River attract large numbers of birds and other wildlife. Waterfowl concentrate along the Hudson in large numbers during migration and both peregrine falcons (*Falco peregrinus*) and bald eagles (*Haliaeetus leucocephalus*) have bred along the Hudson since the 1990s. Other species found in the Hudson River watershed and listed as threatened and endangered by New York State or the federal government include several amphibian and reptile species (Blanding's turtle *Emydoidea blandingii*, timber rattlesnake *Crotalus horridus*, bog turtle *Clemmys muhlenbergii*, and northern cricket frog *Acris crepitans*) and two mammals, the Indiana bat *Myotis sodalis* and eastern woodrat *Neotoma magister*.¹⁹

PCBs are suspected of causing a wide range of negative effects in birds and other wildlife, though few species have been studied under controlled conditions. PCBs are ubiquitous in wild birds, but concentrations above background levels are still found in many areas and are associated with adverse effects.^{1,15,17} Among the effects of PCBs observed in birds are developmental abnormalities (especially deformed feet and bills), liver damage, physiological and metabolic changes, reduced reproductive success, and embryonic and adult mortality.^{1,2,15,17} Concentrations in brain tissue greater than 300 $\mu\text{g/g}$ have been found in dead or dying adults and are indicative of acute toxicity.¹⁵

Compared to aquatic habitats, relatively few studies of the implications of PCB contamination for terrestrial species have been conducted along the Hudson. Available data do suggest that wildlife are exposed to high levels of Hudson River PCBs (Table 29.2).¹⁹ However, for most species, sampling has not been systematic or intensive enough to document effects of contamination or the spatial and temporal patterns of PCB concentrations. As a result, most analyses, including the U.S. EPA Ecological Risk Assessment depend on estimates of exposure and use a modeling approach to evaluate risk.¹⁹

Based on this approach, the U.S. EPA evaluated risk to a variety of wildlife. This risk analysis concluded that PCBs pose significant risk to mammals along the Hudson, including insectivores,

such as little brown bats (*Myotis*), and piscivores, such as mink (*Mustela vison*) and river otter (*Lutra canadensis*).¹⁹ Mink and otter along the upper Hudson are especially likely to be exposed to harmful levels of PCBs; the calculated toxicity quotients for these species were up to three orders of magnitude above the acceptable risk quotient of one.¹⁹

Similar conclusions were reached from the analysis of risk to birds. Based on the U.S. EPA's analysis, exposure of bald eagles along the Hudson to PCBs is likely to result in impaired reproduction.¹⁹ Other piscivores along both the upper and lower Hudson River, such as belted kingfishers (*Ceryle alcyon*) and great blue heron (*Ardea herodias*), are also at risk.¹⁹ Recent empirical data from U.S. Fish and Wildlife Service collecting supports the conclusion that species such as bald eagles and great blue herons are exposed to Hudson River PCBs. Levels of PCBs in eggs and adults of migratory game birds, such as wood ducks (*Aix sponsa*) and mallards (*Anas platyrhynchos*), are above the FDA limit for human consumption of poultry and eggs³³ (Table 29.2).

Perhaps the most detailed study of wildlife species along the Hudson River is the tree swallow (*Tachycineta bicolor*) study initiated in 1994 by the U.S. Fish and Wildlife Service (USFWS).³⁷ The overall goal of the study was to evaluate uptake of PCBs by migratory birds in the Hudson River valley. In addition to evaluating exposure, data on reproductive success and other ecologically relevant endpoints were targeted to begin to establish a basis for evaluating the risk posed by the contamination of the Hudson to migratory birds and other resources.³⁷ Tree swallows were chosen because they were known to breed along the Hudson River, feed on adults of aquatic insect larvae, and had been the subject of other studies of environmental contaminants.³⁸

Breeding colonies of tree swallows were established in nest boxes along the upper Hudson River.^{39,40} Exposure was evaluated through analysis of eggs, nestlings, and adults. In 1994–1995, average total PCB levels in tree swallow eggs ranged from 9.3 µg/g at the Saratoga site 45 km downstream of the Hudson Falls GE plant to 29.5 µg/g at Special Area 13 located just 6 km downstream.⁴⁰ Nestling contamination levels were higher than those in eggs, ranging from an average of 3.7 µg/g at Saratoga to 62.2 µg/g at Remnant Site 4 (Table 29.2).⁴⁰ A single adult from Special Area 13 had 114 µg/g. Levels of PCBs in 1998 tended to be lower, with means of 6.8 µg/g at Saratoga and 10.0 µg/g at Special Area 13 (Table 29.2). Nestlings collected from the lower Hudson in 1998 contained less than 1 µg/g PCB (Table 29.2). The levels of PCBs found in tree swallows from the upper Hudson River are greater than those found from studies at other PCB-contaminated sites and are indicative of the magnitude of the contamination of the Hudson River ecosystem.³⁸

The majority of PCBs in Hudson River tree swallows were congeners from the tri-, tetra-, and pentachlorinated homolog groups.⁴⁰ In general, PCB congeners 118, 105, and 77 were most prevalent. In most previous studies of PCB congeners in birds, PCBs 138 and 153 have predominated.¹⁶ The presence of high levels of congener 77 is noteworthy because this PCB and related non-*ortho* planar congeners, is considered especially toxic to wildlife^{16,17} and because congener 77 has not been thought to biomagnify to the same extent as other congeners.¹

Population dynamics of mobile species such as tree swallows can be dominated by dispersal among different breeding sites. This makes evaluation of the population-level consequences of a stressor such as PCBs difficult or impossible in the absence of quantitative data on dispersal. The simple fact that tree swallows were chosen in part because they are abundant in the Hudson River invalidates any attempt to draw inferences from simple estimates of local population size. While population effects cannot be evaluated directly, data on demographic parameters do indicate some effects of PCB contamination on the reproductive biology of Hudson River tree swallows. Evidence from 1994 and 1995 indicated that Hudson River tree swallows did have an excess number of large clutches (> seven eggs), and in one year the percent of eggs hatching was low.³⁹ Survival of nestlings that hatched was within normal ranges at all Hudson River sites, but females tended to bury eggs in the nest and abandon nests at a greater rate than has been observed in uncontaminated sites.³⁹

Other aspects of tree swallow ecology also appear to be impacted by PCB contamination. Parental behavior, as measured by success at building nests, is impaired along the upper Hudson and is significantly correlated with contaminant levels.⁴¹ Likewise, development of female plumage

is abnormal in the upper Hudson River population. Compared to individuals from elsewhere in the species range, the Hudson River population contains a significantly larger proportion of females whose plumage is intermediate in color between subadult and full adult categories.⁴² The possible mutagenic effects of high concentrations of PCBs were evaluated by comparing Hudson River tree swallows to individuals from uncontaminated sites using minisatellite DNA fingerprinting.⁴³ Tree swallows from the Hudson River averaged 0.010 mutations per fragment scored, while swallows from reference sites in Wisconsin, Alberta, and Ontario averaged 0.011 mutations per fragment scored, indicating that PCBs do not result in elevated rates of mutation in this population.⁴³

Based in part on these results, the U.S. EPA Ecological Risk Assessment concludes that tree swallows and related insectivorous birds did exceed acceptable exposure limits in the early 1990s along portions of the upper Hudson River. The modeling study indicated that exposure levels were likely to decline in the future (through 2018) and that levels of risk in the future would likely be low.¹⁹ However, the effect levels chosen by the U.S. EPA were not able to take into account negative effects observed on behavioral or developmental endpoints, so the broader implications of the tree swallow field study for the status of migratory birds as a public resource remains to be evaluated.

29.2.4 Other Contaminants and Stressors

The Hudson River watershed is heavily populated, and a variety of human-caused stressors are likely to impact fish, wildlife, and ecological communities in the area. Direct impacts of development, shoreline modification, and dredging are all important in portions of the river. The dramatic land use changes seen in the northeast — a period of rapid deforestation and intensive agriculture in the late 18th and 19th centuries, followed by concurrent trends towards reforestation and urbanization in the 20th century — have led to an ecosystem that is heavily influenced by human activities. In particular, inputs of organic carbon, especially from agricultural runoff, are an important influence on the functioning of the Hudson River ecosystem.²¹ Presettlement organic carbon inputs into the Hudson are estimated at only 36% of present inputs.²¹ The carbon and nutrient cycles of the ecosystem form an important basis for water quality, especially in the lower Hudson. Removal or regulation of point sources of pollution, especially sewage treatment plants, have resulted in significant increases in water quality in recent years.^{21,44}

Control of inputs from many point sources has also improved water quality through reductions in heavy metals.⁴⁵ Other chemicals of concern, such as mercury, DDT, dioxins, and dibenzofurans, are present in fish and wildlife of the Hudson River, but levels of these contaminants are generally low and judged by NYSDEC to be of secondary importance compared to PCBs.¹⁹ Since 1994, fish-consumption advisories issued by the New York State Department of Health have specifically listed PCBs as the sole chemical of concern in Hudson River fish.²⁵ Mercury levels in fish from the lower Hudson River were generally less than 1.0 µg/g (R. Sloan, NYSDEC, pers. comm.), though largemouth bass in the upper Hudson had higher levels of mercury than those in the lower river. Concentrations ranged from 0.09 to 0.29 µg/g near Poughkeepsie (RM 74), 0.13 to 0.79 µg/g near Stillwater (RM 168), and 0.15 to 0.92 µg/g near Griffin Island (RM 189; R. Sloan, NYSDEC, pers. comm.).

PCDDs and PCDFs were detected in tree swallow nestlings. Among sites, total concentrations of PCDDs ranged from 0.022 µg/g at Saratoga Battlefield to 0.054 µg/g at Special Area 13.³⁷ The highest levels (0.077 µg/g) were found at Lock 9 on the Champlain Canal, upstream from the Hudson River. Total concentrations of PCDFs ranged from 0.022 µg/g at the Remnant Site to 0.039 µg/g at Saratoga.³⁷ Analysis of tree swallow tissues found that PCDDs and PCDFs were both of minor importance when compared to PCB levels using toxic equivalency factors (TEFs), accounting for less than 3% of total TEQs.³⁷ Other organic compounds (e.g., mirex, dieldrin, DDD, DDE, and DDT) were below levels of detection in tree swallows, as were most metals.³⁷

Exotic species abound in the Hudson River ecosystem, and many have exerted significant pressures on the native ecosystems. At least 113 of these species have become established in the

freshwaters of the river.⁴⁶ Eurasian milfoil (*Myriophyllum spicatum*) and water chestnut (*Trapa natans*) are common in near-shore habitats, as are purple loosestrife (*Lythrum salicaria*) and common reed (*Phragmites australis*) in riparian areas and marshes. Exotic fishes, such as the ubiquitous carp (*Cyprinus carpio*), are also abundant. A diverse assemblage of exotic fishes is supported, including brown trout (*Salmo trutta*), as well as domestic goldfish (*Carassius auratus*).⁴⁶ Introduced predators, such as brown trout, can adversely affect native fish communities, while large populations of bottom-dwelling carp can alter both the structure and functioning of aquatic ecosystems.^{47–49}

Zebra mussels (*Dreissena polymorpha*) invaded the Hudson River in about 1990 and are abundant where suitable habitat is found. Especially high average densities (17,000/m²) are found on rocks in waters deeper than 5 m.^{50,51} Zebra mussels have had a profound effect on the ecosystem. Recent estimates suggest that the zebra mussel population of the lower Hudson River may filter a volume of water equal to the entire volume of the tidal freshwater river every 2 days,⁵² altering the planktonic community.⁵¹ In addition, a recent decline in summertime dissolved oxygen levels can be attributed to the arrival and spread of zebra mussels.⁵³ Much research remains on how or if the zebra mussel influences the dynamics of PCB bioaccumulation and transfer through the Hudson River ecosystem.

29.3 MITIGATION ACTIVITIES: PAST AND FUTURE

Any attempt to understand the Hudson River case history that focuses solely on the scientific studies will be incomplete. Much of the focus of the science, such as the emphasis on the biology of striped bass, has been driven by concerns of the public or policymakers. Unfortunately, the link between the products of these scientific efforts and the decisions of the public and policymakers has not always been as direct.

Public awareness and concern about the fate of the Hudson River came early relative to the rise of environmental awareness in many areas of the United States.⁵⁴ Regulations and pressure from environmental groups have been successful in bringing controls of many sources of pollution that are most offensive to public senses and have resulted in significant improvements in water quality, especially in the lower Hudson where the majority of the population is concentrated.^{44,45}

The PCB issue arose after public support for cleaning up the Hudson had already developed. Indicators of problems emerged by 1970, by which time PCBs had been found in Hudson River fish and Monsanto (manufacturer of PCBs) had warned its customers (including GE) that release of PCBs posed a threat to the environment (Table 29.1). By 1972, GE applied for permission to release 30 lbs of PCBs per day into the Hudson River (13.6 kg/day).

When the public became aware of the magnitude of the PCB problem in the Hudson River, GE and the State of New York were forced into negotiations. The outcome of their negotiations in 1975 resulted in blame being assigned both to GE for release of PCBs and to the state for “regulatory failure” in allowing the releases to continue. The settlement included an agreement by GE to contribute \$3 million for monitoring of the Hudson River, matched by \$3 million from NYSDEC. In addition, GE agreed to devote \$1 million to research on development of an alternative dielectric fluid and to phase out use of PCBs (Table 29.1).²² The U.S. EPA became involved in 1975. Federal involvement increased when New York State requested federal funds to clean up PCBs under the Clean Water Act (CWA).²² In 1980, Congress authorized the U.S. EPA to spend \$20 million on the Hudson River cleanup under the CWA. The U.S. EPA was first required to conduct an environmental impact statement, which was completed in 1982.²² While the environmental impact statement supported remediation and was backed by most stakeholders, U.S. EPA Administrator Ann Gorsuch issued a surprise ruling that the project was not suited for funding under CWA but should be funded under Superfund (Comprehensive Environmental Response, Compensation, and Liability Act [CERCLA]).²² This began the process of listing the Hudson River site under the National Priorities List of Superfund.

In 1984, the U.S. EPA released its initial Record of Decision (ROD) for the Hudson River Superfund Site. The ROD recognized the problem of PCBs in the Hudson River sediments but selected an interim "No Action" decision because it considered technologies at the time insufficient to safely remediate the site.²⁶ The ROD did require GE to contain and cap the contaminated sediments and debris in the exposed Remnant Deposits (RMs 195–196).

In 1989, the U.S. EPA announced the reassessment of its 1984 interim "No Action" decision for the upper Hudson River at the request of NYSDEC.²⁶ In 1991, GE reported an increase in PCBs in the water of the upper Hudson River. This was eventually attributed to releases of contaminated sediment and oil from the Allen Mill located at the GE Hudson Falls site. Between 1993 and 1995, an estimated 45 tons of PCB-saturated sediments were removed from Allen Mill.²⁶ Additional fresh inputs of PCB oil from the bedrock adjacent to the Hudson Falls site were also discovered in the early 1990s as the Allen Mill site was investigated and stabilized and as the adjacent Bakers Falls was dewatered as part of reconstruction of a hydroelectric plant on the opposite bank of the river.²⁵

In the fall of 2000, the U.S. EPA completed its reassessment and released its proposed plan for the upper Hudson River sediments.²⁶ The reassessment concluded that the PCBs in the sediments of the Hudson River posed significant risk to human health and ecosystem integrity.^{6,19} The assessment noted that natural river dynamics prevent the contaminated sediments from being buried by clean sediments in a timely manner, that rates of dechlorination are insufficient to "naturally remediate" the PCBs, and that PCBs from the upper river are transported to the ecosystems of the estuarine Hudson at rate of approximately 214 kg/year.²⁶ The proposed plan called for the limited dredging of Hudson River sediments, focusing on the "hot spots" of highest concentration.²⁸ The efficacy of currently available dredging technologies creates a need to weigh risks from allowing PCBs to remain in the river against risks associated with dredging. The U.S. EPA decision is in part based on recent advances in technology and experience with remediation of other PCB sites.²⁸ While the U.S. Congress ordered the EPA to fund a study by the National Academy of Sciences on alternative remediation strategies (in part because of the controversy over the Hudson River), the final National Research Council Report failed to provide a strong statement for or against dredging on the Hudson River.¹

Starting in the fall of 2000, the U.S. EPA solicited comments on the plan from the public and other interested parties. After considering the more than 70,000 comments received, the EPA Administrator for the Bush administration, Christie Whitman, supported the preferred remedy of dredging, drafted by the previous Clinton Administration.⁵⁵

Estimates of the cost of implementing the U.S. EPA plan vary from \$460 to \$500 million. The "targeted dredging" of the hot spots is intended to removed 2.65 million cubic yards (2.03×10^6 m³) of sediment.²⁶ Sediments will then be transported to preexisting disposal facilities outside of the Hudson River valley.²⁶ This dredging is expected to remove approximately 45,000 kg (100,600 pounds) of PCBs from the river, out of the estimated 603,000 kg of PCBs released by the GE plants prior to 1977.

Currently, there are several routes by which this plan could be implemented. GE could undertake the work described, or the U.S. EPA could seek a court order, forcing GE to undertake the cleanup. If GE were to challenge the court order, the EPA could proceed with the work itself. In that case, Superfund allows the Federal Government to pursue up to triple the cost of the work from GE. Today, it is unclear when this issue will be resolved, and it is likely that the final outcome will involve extensive interactions between GE, the EPA, and the federal courts.

Additional issues remain to be resolved on the Hudson River. There is growing public awareness of the magnitude of PCB contamination in terrestrial habitats along the upper Hudson River. By some estimates, six times more PCBs from the GE plants at Ft. Edward and Hudson Falls were dumped on land than were released directly into the river.⁵⁶ The implications of these releases for human and ecological health have received little attention.

Further government action is also likely. CERCLA (and other federal and state laws) grants federal and state agencies the authority to investigate damage to natural resources caused by releases

of harmful substances. With respect to the Hudson River, the Department of the Interior (DOI), the National Oceanic and Atmospheric Administration (NOAA), along with the New York State Department of Environmental Conservation, acting on behalf of the public in their roles as trustees of the natural resources, have begun to evaluate damage to natural resources.⁵⁷ This process, a Natural Resources Damage Assessment, allows trustees to pursue claims against parties responsible for release of harmful substances. To date, the emphasis of this process has been on the fish resources of the Hudson. The trustees have determined that restrictions and closures of recreational and commercial fisheries and advisories against eating Hudson River fish resulting from PCB contamination have curtailed the public's use of the Hudson's fish resources and constitute an injury to the resource.²⁵ Future activities will likely focus on other sources of injury, means of restoring the resources, and compensation to the public for past and future losses of resources.²⁵

Emphasis on a broader range of scientific research along the Hudson River is called for to support improved risk assessments. There is surprisingly little empirical data on exposure of humans along the Hudson to PCBs or health effects for the residents of the Hudson Valley. While the U.S. EPA's Human Health Risk Assessment did find significant health risks in the absence of remediation, future work on risks under different remediation scenarios is now called for.⁶ These assessments would benefit from empirical data on exposure and PCB body burdens of subpopulations living along the Hudson River. Data on human health patterns is also needed, especially noncancer endpoints in children.⁸⁻¹⁰

Exposure data for fish and a few wildlife species do exist. For assessments of ecological risk, the greatest need is for studies of the impact of exposure on individuals and populations of fish and wildlife species. Given the uncertainties about how individual PCB congeners affect different species and how congeners interact within the body, site-specific studies of fish and wildlife are called for. Until recently, terrestrial wildlife have been largely ignored. However, the exposure data from the tree swallow studies clearly indicate that terrestrial species can have very high exposure levels.⁴⁰

There is an especially urgent need for studies of other species of terrestrial animals to assess risk from PCB exposure. Tree swallows appear to be exceptionally resistant to the effects of PCBs.³⁸ Other, more susceptible species may be at much greater risk but have not been adequately studied.^{19,37} A simple set of population surveys is unlikely to be sufficient to answer this question, since even heavily impacted populations can be supplemented by immigration from other populations.³⁸ PCB levels along the Hudson are high enough to potentially exclude susceptible species,^{37,38} so a combination of site-specific lab studies and work with both free-ranging and confined individuals is likely to be needed.

In 1985, one of the first attempts to synthesize the ecological and environmental issues surrounding the Hudson River lamented the fact that over 2 years had passed since the Hudson had become a federal Superfund site, yet efforts at finding a solution to the problem had come to a standstill.^{22,58} Earlier reports on the Hudson River noted the difficulties in trying to reach a scientifically sound solution to the Hudson River PCB issue, describing the environmental assessments of the Hudson River as the "illegitimate offspring of an unhappy union between law and science"⁵⁹ and noting the delays caused by some scientists "interpreting their analyses with their employers' implicit biases" as their primary consideration.⁵⁸ As this chapter is written, 25 years after the Hudson River PCB problem became widely recognized, many of the same issues as described by Limburg are still being debated, and only limited progress has been made toward remediation.¹

29.4 SUMMARY

The amount of PCBs released by GE into the Hudson River will never be known. The total amount is almost certainly greater than the widely cited estimated range of 95,000 to 603,000 kg calculated prior to the discovery of the ongoing inputs of fresh PCB oils from the GE sites at Hudson Falls and Ft. Edward in the early 1990s (estimated at > 11–19 liters, or 3–5 gallons, per

day). The pattern that has emerged over the past 25 years of extensive scientific study is that while the levels of PCBs in the ecosystem have declined from the high levels observed in the 1970's, the combination of continued discharges of PCB oil from the GE sites and the continued availability of PCBs in sediments act to ensure that high levels of contamination remain available to the biota.

Much of the attention has focused on the damage to the freshwater and estuarine fisheries, and concentrations of PCBs in most Hudson River species remain above the FDA threshold of 2 ppm. Other wildlife in the Hudson River valley are also exposed to significant levels of PCBs. The USFWS study of tree swallows along the upper Hudson River found PCB concentrations similar to those found in fish living in adjacent areas of the river. These high levels of contamination far exceed those found in other studies using tree swallows and are likely responsible for abnormal reproductive behavior and development observed in the Hudson River population of tree swallows.

While the weight of scientific evidence points to a significant risk of Hudson River PCBs to both human health and the environment, questions remain about the best course of action to remediate that risk and how long the contaminants will remain available if no remediation is attempted.

ACKNOWLEDGMENTS

I am grateful to the American Association for the Advancement of Science for support through the Science Policy Fellowship program. I extend my gratitude to Dr. Ron Sloan of the NYSDEC for providing access to data on PCBs in fish. Anne Secord and an anonymous reviewer provided helpful comments on an earlier draft.

30.1 INTRODUCTION

Watersheds in mining districts in the western United States are frequently impacted by metals and other inorganic constituents released during extraction and processing activities. Metal-enriched materials, such as soil eroded from exposed and disturbed landscapes and tailings generated during processing, may be released to the environment and associated with increased metal concentrations in surface water and groundwater. Similarly, dispersed sediments may have been deposited as alluvial materials in riparian areas, yielding soils having metal concentrations much greater than predepositional conditions. The present chapter summarizes ecological risk assessment studies focused on metal-contaminated soil, sediment, and surface water for a series of Superfund sites located in the Clark Fork River (CFR) watershed of western Montana (Figure 30.1).

30.2 CASE STUDY BACKGROUND

In the early 1980s, various locations throughout the CFR watershed were recognized as “Superfund” sites, which fell under the regulatory statutes developed as a result of the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (CERCLA, or Superfund). For

Figure 30.1 Clark Fork River watershed in western Montana.

Figure 30.2 Milltown Reservoir Wetlands at the western terminus of the series of Superfund sites where work was originally completed to support baseline ecological risk assessments for terrestrial, wetland, and aquatic habitats.

example, the reservoir near Milltown, Montana, which is located at the western end of a series of Superfund sites on CFR, was initially listed on the National Priority List, or NPL, in 1982 as a result of a hydrologic investigation that identified reservoir sediments as the likely source of arsenic contamination in drinking water taken from groundwater wells. Subsequently, during the late 1980s and early 1990s, numerous studies contributed to the baseline ecological risk assessment completed for CFR and associated terrestrial and wetland habitats.¹⁻¹⁴ These studies evaluated the aquatic and terrestrial habitats that had been impacted by historical copper mining activities in the Butte and Anaconda areas.¹ Extraction and processing activities in the mining district had released disturbed soils and tailing materials enriched in arsenic, cadmium, copper, lead, and zinc that subsequently contributed to sediment loading of CFR.¹⁵⁻¹⁹ As the primary focus of these baseline studies, the upper CFR consists of approximately 200 km (125 mi) along CFR from Warm Springs, Montana to Milltown Dam, a hydroelectric facility located near Missoula, Montana (see Figures 30.1 and 30.2). The dam lies immediately downstream from the confluence of CFR and Blackfoot River, with Milltown Reservoir occurring behind the dam to a maximum pool elevation of 995 m (3264 ft). The reservoir, associated wetlands, and the reach of CFR from the up-river boundary of Milltown Reservoir (maximum pool elevation) to just down river of Warm Springs Ponds delineates the area of concern discussed in this review.¹

30.2.1 Historic Releases to CFR

Mining had occurred in the Clark Fork Basin since the discovery of gold at Butte in the mid-1860s, and mining-related activities continued until the early 1980s. During that period, an estimated 100 million tons of tailings were lost to CFR and transported down river. With construction of Milltown Dam in 1906-1907, sediments transported down CFR subsequently accumulated behind the dam and contributed to the development of wetlands associated with the reservoir. In 1982, Woessner et al.²⁰ estimated that 29 ft of sediment were present at the upstream face of the dam. Sediment volume contained within the reservoir was estimated at 3.5 to 4.6 million cubic m (4.5 to 6 million cubic yards, or over 2750 acre-ft).²⁰⁻²²

Early mining wastes were primarily coarse-grained materials resulting from placer mining and stamping milling, while later developments in mining technology yielded finer-grained mining wastes, which likely increased mining impacts to the river basin.^{23,24} Disposal of tailings, milling and smelting wastes, and mine waste water directly into tributaries of the CFR was common practice throughout the mining districts along CFR until regulatory guidance was established. Waste materials associated with these activities were characterized by concentrations of arsenic, cadmium, copper, lead, and zinc that exceeded expected background concentrations by 10 to 100 times.^{17,20,21}

In the present summary of the ecological risk assessment process for the CFR, we briefly summarize the findings and ecological risks to habitats of the upper CFR and Milltown Reservoir Wetlands (MRW). As indicated by the numerous citations in the summary that follows, many studies have been published as a result of these efforts to characterize the baseline ecological risks for the upper CFR-MRW complex, and we encourage the reader to consult these publications for detail beyond our present scope.

30.3 ENVIRONMENTAL SETTING

30.3.1 The Clark Fork River Basin and Upper Clark Fork River Subbasin

The CFR system drains over 57,000 square km (22,000 square mi) of western Montana as it flows 550 km (340 mi) to Lake Pend Oreille in northern Idaho. The upper Clark Fork subbasin includes the headwaters of the CFR downstream to Milltown Dam, about 200 km to the north and west of the river's origin (125 river miles) (see Figure 30.1). Historically, the CFR was a major corridor and spawning ground for trout migrating out of Lake Pend Oreille in northern Idaho. Migrations ceased, however, with the construction of control structures such as Milltown Dam. The upper river currently supports high-quality game fish in certain river segments, and the basin is valued for its big game, upland bird, and waterfowl hunting. These resources of the basin have created a large recreational and tourism industry in the area.¹

30.3.2 Milltown Reservoir Wetlands

Milltown Reservoir is the first major impoundment on the CFR. It is about 2 km (1.25 mi) in length and is generally shallow except for the two channels of the Clark Fork and Blackfoot Rivers. Sediment accumulation in the impoundment behind Milltown Dam has created a 541-acre wetland, with total jurisdictional wetland acreage at 86% (Figure 30.2).

MRW contains a variety of habitats from riverine to upland. Palustrine wetlands comprise about 56% of the area and have been classified as aquatic bed, emergent persistent, scrub/shrub, and scrub/shrub farmed.^{25,26} The major depositional areas of the wetland are lacustrine littoral and palustrine emergent persistent wetlands. In general, the vegetation and wildlife at MRW are typical of riverine wetlands of western Montana, with the wetland habitat characteristically consisting of submerged and emergent herbaceous plants.^{2,26,27} The wetland supports a wide variety of terrestrial vertebrate wildlife, including current or former range occupied by threatened or endangered species, e.g., Peregrine falcon (*Falco peregrinus*).²⁷

30.4 AQUATIC RESOURCES AT RISK

Numerous studies have assessed the potential impact of metals contamination on wildlife and aquatic resources of the CFR, and the results of these investigations suggest that metals contamination in the CFR has degraded the aquatic resource.^{14,28}

30.4.1 Metals Contamination of Sediments and Effects on Benthic Invertebrates

Sediments of the upper CFR, from Butte and Anaconda to Missoula, are contaminated with arsenic, cadmium, copper, lead, and zinc,^{14,28} but sediment from Milltown Reservoir and the CFR was not generally lethal to test organisms in the laboratory.⁴ However, Ingersoll et al.⁵ found that sediment is a significant source of metals to invertebrates in the CFR. For example, concentrations of metals in amphipods exposed to CFR sediments in relative short-term laboratory exposures resulted in metal bioaccumulation to 50% of that measured in field-collected invertebrates from the CFR. Besser et al.²⁹ found that sediments from most sites in the Clark Fork and Milltown Reservoir caused (1) significant bioaccumulation of copper and (2) significantly reduced survival and growth in larvae of the midge. Additional studies found that the bioavailability of copper to midges exposed to sediments from the CFR and MRW — as indicated by copper bioaccumulation and growth — were largely controlled by concentrations of acid-volatile sulfides (AVS).³⁰ These studies also suggested that bioavailability of copper in Clark Fork sediments could vary seasonally, as AVS concentrations change in response to factors such as water temperature, flow regime, and loading of nutrients and organic matter.

Aufwuchs — the biofilm consisting of fine detrital sediment, attached algae, and bacteria — is an important link between particle-bound metals of colloidal size and aquatic invertebrates that feed by grazing and scraping at this trophic level.³¹ The accumulation of metals in invertebrates was dependent on functional feeding group, and shredders-scrapers that feed on biofilm accumulated the largest concentration of metals. In a system like the CFR that has received chronic contamination resulting in metals loading in sediment and food-chain organisms, the total load to the biological system is dependent on water, sediment, and food chain. Consequently, any consideration of exposure and toxicity should consider all routes of exposure in a system like the CFR, or the risks associated with exposures in the field would be underestimated.

The adverse effect of metals on aquatic invertebrates may affect benthic community structure and bioaccumulation potential in biota from CFR and MRW.^{5,6} Where concentration of metals are highest, community structure will likely be affected, but when biological effects are subtle, community structure may be less affected. Even in the absence of altered community structure, bioaccumulation still occurs, and metals are transferred through the food chain. Poulton et al.¹³ identified significant differences in benthic invertebrate community composition (i.e., number of invertebrate taxa and predominance of pollution-intolerant taxa) of metal-contaminated sites in the Clark Fork and recommended that both benthic community structure and metals concentration in invertebrates be used to determine relative impacts in metal-contaminated river systems. This recommendation was based on the close relationships among metal availability, metals accumulation in benthic invertebrates, and transfer to higher trophic levels. The authors stated that, of importance, moderate to high densities of benthic organisms are present in the CFR, even at sites containing high levels of metals in invertebrates, which indicates that, to some degree, the benthic community may be able to tolerate and adjust to metals contamination. Ecologically, this phenomenon may be more important than altered community structure (e.g., changes in taxa richness) and biomass because metal-contaminated invertebrates represent a major source of metal uptake and accumulation in salmonids.

30.4.2 Toxicity of Metal-Contaminated Food Organisms to Fish

Benthic macroinvertebrates are an important source of food for the larval trout that inhabit the CFR. Studies conducted between 1992 and 1995 using invertebrates collected from the CFR and fed to fish in the laboratory suggested that such spiked-feeding studies may underestimate dietary exposures in the field.^{7,8} In these studies, early-life-stage brown trout and rainbow trout were exposed for 88 to 91 days to simulated CFR water and a diet of benthic invertebrates collected from the river. These exposures resulted in reduced growth and elevated levels of metals in the whole bodies

of both species and, in some cases, elevated concentrations in liver. Additionally, these experiments and those of Farag et al.¹⁰ observed that fish fed diets collected from near Warm Springs and from Gold Creek had elevated concentrations of products of lipid peroxidation and histological abnormalities (such as effects on hepatocytes, pancreatic tissue, and the mucosal epithelium of the intestine). These alterations in tissue structure and impaired physiology were also associated with an increase in tissue metals.

In contrast, another feeding study focused on dietary exposures used rainbow trout fed brine shrimp (*Artemia* sp.), which had been exposed to an aqueous metals mixture for 24 h after hatching.¹² Here, metal concentrations in brine shrimp were comparable to metal concentrations in CFR field-collected diets, but rainbow trout fed on the exposed brine shrimp did not show reduced survival or growth. Although additional study would be necessary to focus on mechanisms that contribute to these differences, the duration of exposure in the brine shrimp study was very short relative to exposures in the field, and the metals likely occurred primarily in the free form, adhering to external surfaces of the brine shrimp and not fully incorporated into the biological matrix. Ionic metals are not absorbed as efficiently and may not be as toxic as metals bound to proteins. Exposure differences between laboratory-generated and field-collected diets likely explain differences in experimental outcomes. Similar studies on the Coeur d'Alene River in Idaho, which has metals contamination similar to the CFR, support this explanation for differences noted between studies using field-collected and laboratory-exposed diets. For example, Farag et al.³² used procedures similar to those of Woodward et al.^{7,8} and Farag et al.¹⁰ for their studies on the Coeur d'Alene, and toxicological endpoints similar to those noted from studies on the CFR were observed in feeding studies using field-collected materials from the Coeur d'Alene River (i.e., reduced survival, decreased growth, reduced feeding activity, and histopathological abnormalities). These toxicological endpoints were also associated with accumulations of metals in tissues of dietary-exposed fish.

Observations and measurements on wild fish collected from the CFR are also consistent with dietary exposure pathways and the associated physiological impairment observed in the laboratory.¹¹ Arsenic, cadmium, copper, and lead accumulated in specific tissues (gill, liver, kidney, pyloric caeca, stomach, large intestine, stomach contents, and whole fish) in a pattern that suggested the dietary source was a major pathway of exposure. An association between tissue metal residues and physiological responses strongly suggested a cause-and-effect relationship between metals in the CFR and physiological impairment of resident fish in the river. Metallothionein, lipid peroxidation, and histological lesions were used as indicators of tissue injury, with damage being present in those tissues associated with digestion (intestine and pyloric caeca) or systemic exposure (liver). Food-chain transfer of metals appears to be a dominant route of exposure for fishes in the upper CFR.

30.4.3 Avoidance of Metals by Fish in the Laboratory

Water-quality criteria were formulated to protect survival, growth, and reproduction of sensitive species;³³ however, behavioral avoidance of unfavorable concentrations of metals such as copper and zinc may be an additional cause of reduced fish populations in natural systems. Behavioral avoidance is particularly important because it can occur at concentrations lower than those causing effects on survival and growth. The limiting factor on fish populations may not be acute toxicity or physiological impairment but the displacement of fish from preferred habitats by avoidance of unfavorable conditions.

Copper in the CFR is at or above the concentrations that have previously been avoided by fishes. Woodward et al.⁹ and Hansen et al.³⁴ conducted several experiments to determine if CFR water resulted in an unfavorable behavioral response by brown trout and rainbow trout. These tests were conducted in a cylindrical chamber that received reference water at one end and metal-contaminated water at the other; a distinct boundary formed at the center where the chamber drained. Reference water simulated the CFR without metals and was used for acclimation and as the alternative choice for the fish to the test water. Test water was identical to reference water but was

altered by the addition of metals to simulate concentrations existing in the river. Brown trout and rainbow trout avoided conditions simulating the presence of copper and other metals in the CFR, with rainbow trout appearing to be more sensitive to the metals than brown trout. Following 45 days of acclimation to an ambient metals mixture that simulated the CFR, rainbow trout preferred clean water and avoided higher metal concentrations. These controlled laboratory experiments show that both trout species will avoid typical metal concentrations observed in the CFR and may explain, in part, the reduced wild trout population in the CFR.

Snake River cutthroat trout have also been shown to avoid a mixture of metals simulating the Coeur d'Alene Basin, Idaho under similar test conditions as those used for the CFR.³⁵ Cutthroat trout avoided the mixture of metals, and it was determined that avoidance was due to copper and zinc and not to cadmium and lead. The avoidance response to either copper or zinc alone was similar to the avoidance response to the mixture. Furthermore, fish were raised in water containing metals at water-quality criteria for 90 days. At the end of 90 days, cutthroat detected and preferred a lower zinc concentration and avoided a higher zinc concentration. This study provides further evidence that fish can survive and grow in water containing metals but can detect a gradient in metals concentration, and they prefer the cleaner water.

30.4.4 Avoidance of Metals by Wild Fish Populations

Detection and avoidance of undesirable substances in the water has been documented in the laboratory, but wild populations of fish are influenced by numerous other factors. Goldstein et al.³⁶ used radio telemetry and a migrating population of Chinook salmon to determine the response of this wild population to the presence of metals. In this study, salmon were transferred from their natal stream to a point 2 mi below the confluence of the North Fork and the South Fork of the Coeur d'Alene River. As with CFR, the South Fork of the Coeur d'Alene River has metals contamination from mining (mainly cadmium, lead, and zinc, with some copper), while the North Fork is relatively clean. Fish were tagged with radio transmitters and allowed to move upstream. While other variables were present — flow, temperature, general water quality, and cover — the higher metals concentration in the South Fork tributary was the factor of greatest difference. The majority (70%) of the fish tagged selected the North Fork. The results of this experiment, coupled with the companion laboratory study, indicates that the abundance of free-ranging populations of fish are likely reduced by their unfavorable avoidance reaction to certain metals. Also, the demonstration of an avoidance response in a natural fish population validated results of laboratory avoidance experiments and explained the distribution and movement of fishes in relation to metals contamination.

30.5 TERRESTRIAL AND WETLAND RESOURCES AT RISK: BIOLOGICAL ASSESSMENT OF SOILS

In parallel with studies completed on CFR, studies at MRW were also undertaken. Here, designed field and laboratory studies focused on evaluations of soil physicochemical characteristics and biological tests of soils using invertebrates (e.g., earthworm toxicity and bioaccumulation tests and plant tests as currently standardized by ASTM^{37,38}). Biological sampling of diet items, such as invertebrates, plants, and wildlife (i.e., small mammals), was also completed, with a primary focus on analyzing dietary exposures to terrestrial and wetland wildlife.^{39–42}

30.5.1 Soil Physicochemical Characterizations and Metals Analysis

As part of an ecological assessment for MRW, biological effects measured in toxicity tests considered interactions, or potential interactions, between the soil matrix and metals in the soil, particularly with respect to bioavailability of metals.⁴³ Among other physicochemical characteristics,

soil pH, cation-exchange capacity (CEC), and percent organic material (OM) were measured on soil samples collected at MRW. Soil-texture analysis was also completed, and DTPA (diethylenetriaminepentaacetic acid, 0.025M)-extractable metals were analyzed as an indirect estimate of metal bioavailability.^{44,45} With these characteristics of the soil matrix available, potential confounding effects associated with soil physicochemical properties could be identified, and interpretations of metal toxicity were subsequently developed with more confidence.^{14,46}

Soils throughout MRW were xerofluvents and ranged from loams to silty loams to occasional silty-clay loams that were heterogeneous with respect to soil texture, OM, and CEC.^{2,46} For example, OM was variable across MRW but was relatively invariant within defined sampling strata, as were total nitrogen, soil pH, and CEC. Similarly, the distribution of metals — both total and extractable — in soil varied spatially, but variation within sample units identified across the wetland was much less than the variation among all sample units within MRW.² The spatial distribution of metals of greatest concern — cadmium, copper, zinc — clearly indicated that sample units could be ranked with respect to concentrations of these metals in soil.^{14,46} And when these target analyte rankings were evaluated relative to the biological tests completed on colocated soil samples, an integrated assessment of risk to biological receptors was developed (see Sections 30.5.2 and 30.5.3).^{14,46,47}

30.5.2 Plant Studies to Evaluate Wetland and Upland Soils

MRW was characterized by a range of terrestrial and wetland habitats and soil types; hence, numerous biological assessment tools were used to evaluate potential adverse effects associated with metal exposures.^{2,40}

30.5.2.1 Plant Tests Completed Using Bulk Soils Collected from MRW

During preliminary studies, seed-germination tests were completed using site soils, with both field and laboratory methods being employed.⁴⁸ No statistically significant acute phytotoxicity was observed in these bulk soil tests, which suggested that definitive studies should be focused on the soil-soil interstitial water interface.^{2,14,46}

30.5.2.2 Root Elongation and Groundwater Phytotoxicity Assessments

Groundwater levels at MRW during the definitive investigation generally varied between 24 and 48 in. below ground level, although the upland sampling locations presented groundwater generally characterized by depths to groundwater from 48 to 84 in. below ground level. A limited number of upland locations presented depths to groundwater between 84 and 120 in. below ground level.² Phytotoxicity assessments available from root elongation tests with groundwater indicated that samples collected with hand-driven well points were quite heterogeneous with respect to metal concentrations, as would be expected, considering other measurements taken in the rhizosphere (e.g., soil physical structure and metal concentrations in soil). Biological activity associated with groundwater collected from sample units across MRW was relatively low and not statistically significant relative to laboratory controls, but a trend toward reduced root growth was noted across all samples from depositional areas. No samples, however, expressed acute toxicity, as indicated by germination failure in the root-elongation test. From the work with root-elongation testing, reduced growth in plant roots may be linked to elevated metal concentrations in groundwater collected from depositional areas at MRW.^{2,14,46}

30.5.2.3 Root Elongation Tests on Soil Eluates

In conjunction with tests completed with groundwater, standard phytotoxicity toxicity tests using lettuce seeds were also completed using soil eluates.⁴⁸ As were groundwater test results, no

statistically significant reductions in root length were recorded. Nonetheless, the trend in the data presented biologically significant responses such as consistent reduction in root growth, again in samples collected from depositional locations in MRW. While these biological effects were not statistically significant, these trends were also observed in other tests (e.g., root-elongation tests with groundwater) used for the biological assessment at MRW.^{2,46}

30.5.2.4 Metals Accumulation in Terrestrial Plants

Vegetation samples collected coincident with soil and groundwater samples indicated that target metals did bioaccumulate in vegetation growing at MRW. The extent of accumulation varied spatially among species and anatomically within plants (i.e., metal residues in roots differed from stems differed from leaves). Emergent wetland vegetation, e.g., cattail and sedge, appeared to accumulate the most metals, while upland vegetation appeared to accumulate metals, especially those having little nutrient value, to relatively low concentrations.^{2,41,49,50} Metals with known nutritional value to plants, e.g., zinc, were bioaccumulated many-fold relative to the concentration of metal in soil.

30.5.2.5 Summary of Plant Tests

In addition to vegetation tests completed with groundwater, field and laboratory tests with submerged aquatic vascular plants (*Potamogeton pectinatus*^{51,52} and *Hydrilla verticillata*^{51,53}) were used to evaluate emergent-zone habitats at MRW. In general, emergent-vegetation testing in the laboratory and in the field suggested that biological effects, when evident, were sublethal. Field tests with sago pondweed indicated no adverse effects for growth endpoints (root and shoot length), and physiological markers (peroxidase activity [POD]) indicative of plant stress were unremarkable. Indigenous plant samples (*Elodea* spp.) were also collected concurrent with field tests on sago pondweed and were analyzed for POD activity. For indigenous *Elodea* spp., statistically significant differences among sites were noted across MRW sampling locations, which may be indicative of general plant stress. In parallel laboratory exposures, however, no consistent pattern was noted with respect to growth endpoints (e.g., root and shoot lengths and chlorophyll a) for either test species when tested with bulk sediments collected from MRW sites. While morphologic endpoints related to growth suggested no acute toxicity in laboratory or field exposures with MRW sediments, differences in POD activity across MRW may reflect the spatial variability in metals that are differentially bioavailable.

On the basis of these studies with emergent plants, terrestrial plants exposed to bulk soils, and biological evaluations of groundwater and sediment, rhizosphere exposures to sediment pore water, soil interstitial water, and groundwater coincident were generally not acutely phytotoxic. Yet all groundwater samples collected from deposition zones in the wetlands and upstream braided stretches of CFR appeared to have an inhibitory effect on root elongation as measured using the standard laboratory test species.^{14,46} Field surveys completed in conjunction with the sampling and laboratory testing, however, did not suggest that this biological effect was currently being exhibited at these sampling locations during the period of study.^{2,26,27}

Soil eluates were also prepared from soils collected at MRW and were tested using root elongation as the toxicity endpoint. While qualitative differences were observed with respect to the inhibition of root growth, no soil-derived eluate showed statistically significant results. As with tests with groundwater, reduced root growth was noted in eluates derived from soils collected in depositional areas; for example, biological effects reflected in reduced root growth appeared to be associated with soils collected from old “oxbow” reaches along the river.²

In parallel with these controlled plant tests, field surveys noted no widespread effects on vegetation in the sampled area. For example, from a jurisdictional wetlands delineation²⁶ and wildlife survey,²⁷ and from the supporting field surveys completed during the study,² the wetlands

and adjoining upland habitats at MRW presented a relatively complex plant community, with numerous obligate as well as facultative wetland plant species.⁵⁴ In part, the physicochemical characteristics of the soils across MRW may explain, or contribute to, the variation in growth reduction observed in laboratory tests, particularly in those areas occasionally associated with reduced plant vigor in laboratory tests. The physicochemical heterogeneity of soils across MRW was readily apparent, even in sampling units that were similar with respect to texture. The reduced root elongation noted in groundwater evaluations, however, may be an effect directly associated with metal-contaminated groundwater. Again, field surveys indicated that no adverse effects were currently being expressed, though some emergent plants were clearly displaying relatively increased uptake of metal from sediments. CECs varied across soil at MRW and may have influenced the apparent differences in bioavailability of metals in the rhizosphere of these soils, as could the interrelationships among soil texture, organic content, and the geochemical composition of the soils.

These interacting soil-matrix characteristics undoubtedly contribute to the heterogeneity of metal uptake in exposed wetland or upland plants.^{2,14,46} Metals did accumulate in plant tissues, with the trend suggesting that roots would accumulate metals to a greater extent than leaves. The pattern of metal accumulation in roots differed, in part, as a function of soil type.^{2,46}

30.5.3 Animal Studies Completed for Terrestrial and Wetland Evaluations

30.5.3.1 Earthworm Tests in Field and Laboratory

Earthworms expressed no acute toxicity in either laboratory or field tests;^{2,46,55} however, correlation analysis suggested that subtle biological response data (e.g., behavioral, morphologic, and dermatopathologic effects) from field tests were most significantly associated with soils having elevated total and DTPA-extractable copper. The spatial distribution noted in these sublethal-effect biological markers was consistent with other biological assessments completed at MRW (e.g., root-elongation tests).^{2,14,46} These observations supported interpretations that subtle biological effects were associated with soils collected from depositional areas having relatively high metal concentrations. For example, exposures to soil associated with sublethal effects in *E. foetida* also presented subtle effects on plant growth (e.g., root elongation reduction) in groundwater and soil eluate tests.

Estimates of the bioaccumulation potential of metal in MRW soils were considered by analyzing earthworm tissues for metals following laboratory exposures.³⁷ To make these data more relevant for evaluating wildlife risk (that is, earthworms are consumed intact by predators in the field), earthworms were not purged prior to analysis. Bioaccumulation tests clearly suggested that metals in soils from MRW are potentially available to wildlife that prey upon earthworms,^{2,46} and the extent to which metals are available for trophic transfer (either as metal incorporated into earthworm tissue through bioaccumulation or transferred via coincidental ingestion of gut contents) varies as a function of metal concentrations in soil and its physicochemical properties, e.g., high vs. low organic material, different levels of extractable metals at relatively similar total metal concentrations. Differential bioavailability of metals may be considered a possible source of these spatially variable expressions of chronic effects associated with metal bioaccumulation.^{14,46}

30.5.3.2 Wildlife Surveys and Bioaccumulation Sampling

Aquatic invertebrates, fish, amphibians, birds, and small mammals inhabiting MRW were surveyed in 1990 following Warren-Hicks et al.⁴⁸ and other routine guidance for conducting wildlife surveys.⁵⁶⁻⁵⁸ Different wetland habitat types were highly interspersed at Milltown Reservoir, resulting in diverse vegetative structure.²⁶ By design, surveys were not intended to completely assess the presence or absence of species expected to occur in riverine, lake, or wetland habitats; however, 14 taxa of aquatic macroinvertebrates and 20 vertebrate taxa other than birds were observed at the site.

Terrestrial and wetland wildlife were the primary focus of these field surveys. Species of small mammals and other terrestrial vertebrates found on the site were typical of riparian sites in western Montana, and birds observed at MRW from April through October 1990 were reported as either probable or confirmed breeders for this area.^{27,59} Water bird and passerine bird species diversity was similar to avian communities occupying similar habitats at nearby Lee Metcalf National Wildlife Refuge, Stevensville, MT, and most of the birds at MRW were characterized as either wetland or edge species.^{2,27} For amphibians, preliminary tests following Linder et al.⁶⁰ suggested that surface-water exposures would not present acute toxicity. No statistically significant acute toxicity was found in tadpoles exposed to any site samples in the laboratory for 96 h, and, relative to laboratory exposures using defined metal mixtures and single-metal exposures, analysis of these site samples suggested that metal concentrations in surface waters were not sufficient to mediate acute effects at the time the samples were collected and the study was completed. Chronic effects observed following laboratory exposures to some MRW surface-water samples were generally associated with reduced growth, and only a limited number of embryos presented terata. Gross malformations were occasionally noted and included mild abdominal edema and hyperpigmentation. No contaminant-specific malformations were noted in these preliminary tests.⁶⁰

Evaluation of dietary exposure to metals by primary consumers and higher trophic organisms in the wetland habitat was performed by a food-chain evaluation. Exposures, expressed as daily oral intake, were compared to dose-response information (i.e., no observed adverse effects levels, NOAELs, in mg/kg/day) from the scientific literature.⁴² The lack of toxicity information on most metals for many of the exposed species necessitated the use of dose-response data from rodents as surrogate toxicity criteria. Exposures were modeled on the results of field measurements in vegetation and lower trophic biota as well as sediments, soils, and water.^{41,42} Complete reports of the food-chain analysis are reported in Pascoe et al.,⁴² but the site-specific data on body burden measurements of arsenic, cadmium, copper, lead, and zinc in the meadow vole (*Microtus pennsylvanicus*) and deer mouse (*Peromyscus maniculatus*) suggested that soil-metal bioavailability was limited to < 0.1% at the MRW. For example, for small mammals, the highest estimated daily doses for arsenic, cadmium, copper, and zinc were below the toxicity criteria pertinent to the analysis.^{14,42} In contrast, for muskrat (*Ondatra zibethicus*), the consumption of aquatic vegetation from the depositional areas of the wetland where metal concentrations were two- to tenfold greater than site-wide concentrations, the calculated lead intake rate (0.23 mg/kg/day) exceeded the toxicity criterion. This was largely influenced by the preference of muskrat for cattails as the primary food source, which had elevated tissue concentrations of lead in these areas.⁴²

30.6 ECOLOGICAL SIGNIFICANCE OF RISK ASSESSMENT FINDINGS

Evaluating the ecological significance of the results of these analyses was critical to the assessment of risks associated with metal exposures in the CFR-MRW system. Biologically important impacts were defined as those affecting populations, communities, and ecosystems, which acknowledged that measurement of impacts to individuals does not necessarily indicate impacts to the ecosystem.^{61,62} The biologically important results would then be the focus in setting remedial goals for the CFR-MWR system.⁶³

30.6.1 Defining Ecological Significance

For evaluating the studies completed throughout CFR-MRW, the definition of ecological significance focused on a relative ranking of impacts as outlined by Duinker and Beanlands:⁶²

- *Major Impact:* affects an entire population or species in sufficient magnitude to cause a decline in abundance or change in distribution beyond which natural recruitment (reproduction, immigra-

tion from unaffected areas) would not return that population or species, or any population or species dependent upon it, to its natural level.

- *Moderate Impact*: affects a portion of a population and may bring about a change in abundance and distribution over one or more generations but does not threaten the integrity of that population or any population dependent upon it.
- *Minor Impact*: affects a specific group of localized individuals within a population over a short period of time but does not affect other trophic levels or the population itself.
- *Negligible Impact*: any impacts below the minor category are considered negligible.

For the CRF-MRW ecological risk assessment, the inclusion of quantitative studies on chemical exposures, biological effects assessment, and ecological studies helped characterize the ecological significance of the results.¹⁴

30.6.2 Terrestrial Habitat Findings

Results of the integrated field and laboratory studies for the ecological risk assessment for MRW have been summarized in detail elsewhere.^{2,14,46} For the terrestrial wildlife relying on upland and wetland habitats at MRW, the studies found that the bioavailability of metals and arsenic to small mammals was more limited than expected.^{41,42} The apparent bioavailability of soil elements to small mammals was less than 0.1%.

The effect of the limited bioavailability of mining waste metals on toxicity tests is illustrated by results of earthworm (*Eisenia foetida*) biological tests.^{2,55} Based on the concentrations of total copper in soils collected at MRW, substantial toxicity was predicted for earthworms,⁶⁴ yet only subtle effects were observed at the highest concentrations of metals in soil.^{2,55} The subtle findings of toxicity tests performed with both terrestrial and aquatic exposure media at MRW generally were consistent with the lack of overt ecological impacts observed in terrestrial and aquatic habitats at the site.^{2,14,46} Altered benthic community structure in sediments (e.g., increased number of genera of Chironomidae) was observed in sediments at locations in MRW having the highest extractable metals under oxidizing conditions (i.e., low flow and low acid-volatile-sulfide content).^{3,6} However, the ecological significance of the altered benthic community structure was considered of lesser importance to the ecological risk assessment than the potential transfer of metals from benthic invertebrates through the food chain to consumer fish.¹⁴

The ecological assessment at MRW indicated that no acute toxicity or adverse biological effects were being expressed at the time these studies were completed. Similarly, biological tests and field observations suggested only limited chronic effects were being expressed during the study period.¹⁴ Consistently, and regardless of the field- or laboratory-test methods used, biological assessments at MRW were unable to demonstrate acute toxicity; however, evidence of subtle biological effects was noted in samples collected from depositional areas.^{2,14,46}

Sublethal effects observed in biological tests could suggest subtle ecological impacts that could be potentially significant within ecological contexts. For example, the rooting zone tests demonstrated inhibition of root growth in plants exposed to interstitial water collected from the rhizosphere in depositional areas in MRW that presented high metal concentrations. An inhibition in root elongation suggests that lateral root growth might be inhibited in certain plants, which could result in decreased absorption of nutrients including copper, zinc, and iron. Altered root growth, in turn, could affect aboveground biomass, as demonstrated during greenhouse studies with soils from depositional areas, and result in iron-deficiency-induced chlorosis. Thus, the risks to wetland vegetation in depositional areas of MRW may be considered minor to moderate, especially if other stressors became prominent in the multiple-stressor picture characteristic of any riparian wetland field setting (e.g., altered flow regimes, drought).

For the terrestrial habitat, the findings of the exposure and biological effects assessments need to be placed in context with those of the ecological assessment to identify the significance of

ecological risk. For example, results of the wildlife survey and wetland delineation study suggested a healthy wetland ecosystem. Thus, integration of the results of the ecological studies with the subtle effects observed in the biological tests suggests that the wetlands did not express significant ecological effects despite possible local impacts related to vegetation stress associated with potential nutrient deficiencies.

In contrast to potential effects expressed by vegetation, very little is available in the scientific literature to form a basis for translating the subtle toxicity test results, such as earthworm morphological changes, to impacts on ecological endpoints related to populations and wetland communities. However, the food-web analysis demonstrated that primary consumers and higher trophic organisms, such as predatory birds, waterfowl, and wild mammals, are not at high risk from exposures to metals in soils at MRW.^{41,42} This conclusion was supported by the finding of low bioavailability of metals in soil.⁴⁶ The only potential concern was the effect of the modeled intake of metals on muskrat.^{14,42} Given the uncertainties in the modeled intake and assumptions related to bioavailability, it is unlikely that the exposures in muskrat would be expressed by adverse effects in their population or ecosystem impacts. In addition, the waterfowl survey at the wetland suggested that the waterfowl populations were healthy and reproducing.²⁷ No evidence was observed of contaminated sediment invertebrates affecting the health of waterfowl in the wetland. Similarly, the food-chain-transfer study did not suggest that metals in the invertebrates or aquatic plants would impact muskrats, beaver, or mink in the wetland. In summary, the biological investigations completed at MRW assessment studies and food-chain analysis suggested little, if any, acute toxicity from exposures to upland or wetland soils and that the sublethal effects observed would not likely increase ecosystem risks. From this, risks to the terrestrial habitat can best be characterized as minor.^{14,62}

In order to develop an integrated snapshot of MRW at the time of these studies and a technical framework for evaluating and managing ecological risks, a relative ranking scheme was used to summarize and integrate exposures and biological effects for the terrestrial habitat^{14,46} (Table 30.1). In this procedure, where consistent statistical differences in biological effects were observed in each of the sample units at MRW, a rank score of plus (+) was assigned to units having a consistent "signature" of adverse effects, a mixed signature of adverse effects and no effects was assigned a plus/minus (+/-), and consistently no effects was ranked as a minus (-). Each sample unit was then considered by the sum of ranks for the biological responses and by the concentrations of total copper; for this ranking, a rating of "++" depicts the high-ranked units, "+" the moderate-ranked units, and "-" the low-ranked units. This comparison demonstrates the apparent association between total copper concentrations and a variety of biological effects across the site, with highest rankings for both chemistry and biological responses generally being characteristic of depositional areas at MRW.^{2,14,46} The results of this integration of chemical and biological data are depicted geographically on a map of the wetland sampling units in Figure 30.3, where concentrations of total copper and the sum of biological responses are shaded for moderate (+) to high (++) ranks (i.e., "+" is shaded with single lines and "++" with double lines, with the chemistry ranking depicted by vertical lines and the biological ranking by horizontal lines; the triangular representations are described below for sediment ranking). The graphical depiction in Figure 30.3 allows a better illustration of the spatial correlation of biological responses with metal concentrations in the reservoir wetland soils. This type of presentation also more clearly demonstrates the higher concentrations of copper and greater biological effects in sediments that have accumulated directly behind the dam in the old river channel and behind the old railway berm.

Like the soil evaluations in terrestrial and wetland habitats, the sediment evaluations were critical to the evaluation of emergent zone habitats in the wetland. The weight of evidence from the sediment quality triad of chemistry, ecology, and toxicity studies⁴⁷ suggests that benthic invertebrate communities in the reservoir are at risk in sediments where metal concentrations are elevated and AVS concentrations are low. Elevated metals in oxidizing environments are found in sediments of the old river channel and upstream of the railroad berm in the MRW (Figure 30.3). Oxidizing environments at risk in the reservoir and upper CFR have been observed in shallow or fast-moving

Table 30.1 Integration of Biological and Chemical Data for Evaluation of Ecological Risks at MRW*

Biological Test ^b	Sample Units ^a									
	7 ^c	6 ^d	8 ^c	2 ^c	10 ^e	9 ^e	11	3 ^e	12	4 ^f
Earthworm (field)	+	-	+	+	-	-	-	+/-	-	+/-
Earthworm (lab)	+/-	+	+	+	+/-	-	-	+	-	++
Root elongation	+		+	+	+/-	-	-	+	-	-
Seed germination				+						-
Biomass	+			+						
Sum biological ^g	++	+	++	++	+	+	-	+	-	++
Cu concentration (µg/g) ^h	975	870	761	734	654	595	585	529	470	244
Sum chemistry ⁱ	++	++	++	++	+	+	+	+	-	-

* See Figure 30.3 for locations of sample units (after Linder, Pascoe, and DalSoglio, 1999).

^a Sample Units rank-ordered by concentration of total Cu; sample Units 1 and 5 were not tested (see Linder et al. 1994).

^b Consistent statistically significant differences in biological effects observed in various tests completed on soil samples collected in each sample unit were graded as (+), inconsistent but positive responses in some tests as (+/-), and negative responses as (-). Sample Unit 4 was scored (++) for the laboratory earthworm test because of the much greater level of adverse effects observed in these soils relative to laboratory earthworm tests completed with soil samples collected from other sample units.

^c Biological effects likely associated with metal contamination; sample units included major depositional areas of the wetland.

^d Inconsistent results in biological tests likely due to low bioavailability of metals; poor association between biological effects and metals concentrations likely occurred due to ameliorating effects of soil physicochemical properties (e.g., cation-exchange capacity, organic material, pH).

^e Moderate biological responses may be related to low metals contamination.

^f Biological effects likely due to other factors and not metals.

^g Relative ranking of biological tests completed as part of the ecological assessment. A value of (++) was assigned to the high-ranked sample units, (+) the moderate-ranked sample units, and (-) the low-ranked sample units.

^h Mean concentration of total Cu in soil samples.

ⁱ Relative ranking of concentrations of Cu, Zn, and Cd in soils; soils with Cu concentrations less than 500mg/kg were scored (-), greater than or equal to 500 mg/kg, but less than 700 mg/kg were scored (+), and greater than or equal to 700 mg/kg were scored (++).

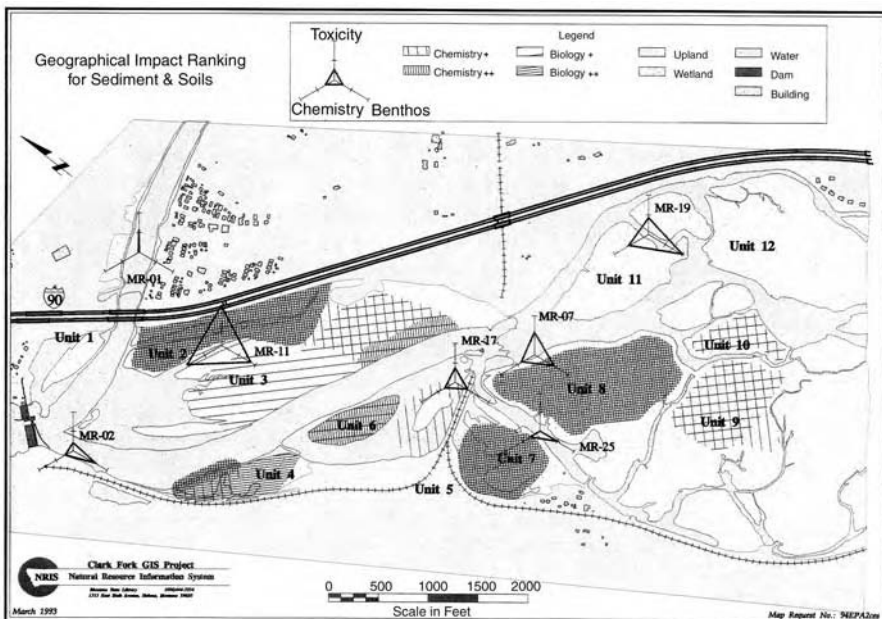

Figure 30.3 Integration of laboratory and field work completed at MRW yielded a spatial distribution of risks that corresponded to depositional areas on CFR.

waters in depositional areas where metal concentrations are elevated. Sediment toxicity was generally observed where molar SEM Cu/AVS ratios exceeded unity.⁵ In contrast, a comparison of sediment-toxicity criteria with no-effect concentrations (NECs) calculated from sediment toxicity tests completed at MRW illustrates the limitations in relying solely on benchmark comparisons for characterizing ecological risks associated with contaminated sediments.⁶⁵ For example, at MRW both copper and zinc NECs exceeded commonly applied guidance values,⁶⁶ which reflects on the conservativeness inherent in guidance values as pointed out by O'Conner et al.⁶⁷

For evaluation of risks associated with sediments at MRW, the scaled ranking for the chemistry, toxicity, and benthos variables are plotted on maps of the reservoir operable unit as tri-axial graphs in Figure 30.3, as suggested by Chapman et al.⁶⁸ The tri-axial graphs help to visualize geographic trends and the magnitude in the differences among station responses. A symmetrical triangle indicates similar chemistry, toxicity, and benthos responses; a larger triangle indicates a more severely degraded station. Here, a large and relatively symmetrical triangle would be representative of a location having elevated chemistry, toxicity, and impacted benthos, suggesting metal-induced degradation of the sediment habitats in this area. In contrast, a smaller symmetrical triangle would represent an area having relatively little, if any, chemical, biological, or ecological data suggestive of adverse effects being characteristic of that location.

30.6.3 Aquatic Habitat Findings

Like the sediments collected in MRW, surface waters and sediments collected from CFR presented elevated exposures to sediment metals, which correlated with toxicity to benthic invertebrates and impacted benthic community structure. The finding of increased number of genera of Chironomidae in sediments that exhibited toxicity to benthic invertebrates suggested that benthic-community impacts were likely due to the metal contamination. However, overt effects, such as decreased abundance or loss of taxa in major groups of biota, were not apparent in MRW or CFR sediments. Nonetheless, Canfield et al.⁶ note that altered benthic-community structure such as that at CFR and at MRW have been observed in other studies of sediments with high metal concentrations^{69,70} and can be explained by a disturbance in population competition dynamics.

A number of lines of evidence indicate severe impacts of contaminant metals on the fishery of the upper CFR. For example, concentrations of various metals in surface water of the upper CFR have exceeded water-quality criteria; metal concentrations are elevated in invertebrates from riffle and depositional areas; toxicity tests have demonstrated that fish health is adversely affected following exposure to water and sediment at metal concentrations typical of the upper CFR; and trout behavior in toxicity tests suggests avoidance of elevated metal concentrations. Fish with reduced growth rate and health could be eliminated from natural populations where metal stresses are present, and their potential avoidance of CFR surface waters may prevent adequate access to suitable habitat and food sources. The weight of evidence from fishery studies indicates that the health of trout populations and the fishery ecology of the upper CFR are at major risk from the metal contamination.¹⁴

30.7 SUMMARY

One of the driving concerns for evaluating the CFR-MRW system was the potential for chronic impacts from metals released during episodic events such as spring snowmelt and summer thunderstorms. Since the ecological surveys and biological assessments (both field and laboratory tests) were performed during summer and fall, the results of the studies could be representative of conditions after the spring snowmelt. Since spring flows of the upper CFR prior to the risk-assessment sampling program were high enough to increase metal concentrations in surface waters, the study results may be reflective of conditions during recovery from acute impacts.^{14,46}

Within a risk-assessment context, the adverse effects associated with exposures to sediments can be described as moderate, especially for benthic communities in oxidizing environments. Although sediment biota are impacted at contaminated stations under oxidizing conditions, it is unknown if other ecological parameters such as predator-prey relationships are subsequently affected. The impacted benthic invertebrates in the upper CFR and MRW are likely of greater significance to trout populations through the transfer of metals during feeding where mining wastes have contaminated water, sediment, food-chain organisms, and fish. Because of the potential for metals to affect fish through dietary sources, total load of metals to the system should be evaluated, including concentrations of metals in water, sediment, and biota. Biofilm and benthic invertebrates are important in concentrating and cycling metals up the food chain, and the dependence of early-life-stage fry on invertebrate food sources and their sensitivity to metals in the diet makes these receptors a weak link in the dietary food web. While avoidance of copper by juvenile fishes is the most sensitive endpoint for evaluating degraded water quality in CFR, contributions from all of the studies summarized here clearly indicate that the CFR is a degraded biological resource, particularly in areas impacted by historic deposition of metal-contaminated sediments.

31.1 INTRODUCTION

In most instances, pollutant sources are relatively easy to identify. Point sources especially present few problems of quantification, while diffuse sources (e.g., runoff from agricultural land) are more difficult to determine with certainty. The source is, however, only the first part of the picture, and the period that exists between emission/discharge of a pollutant and contact with the receptor may contain many varied and interesting processes. It is the aim of this chapter to describe

some of the more important processes involved in pollutant transport and removal from the environment and to demonstrate how such processes influence the distribution of pollutants within the environment. Of particular interest are processes leading to the transfer of chemical substances between environmental compartments, i.e., water to air, air to soil, etc.

Environmental cycles of chemical elements and compounds are generally termed "biogeochemical cycles." Ideally, such cycles include quantitative estimates (however uncertain) of the fluxes between compartments and the total inventory of substance within a given compartment. Such quantification is difficult even for chemical elements, especially in relation to the flux component. For chemical compounds subject in some cases to rather rapid chemical change, estimation of fluxes is even more problematic.

In this chapter, the transport mechanisms responsible for pollutant transfer within and between environmental compartments are first considered. Mathematical treatments allowing calculation of transfer fluxes and lifetimes are then described. Some examples of pollutant distributions are given, indicating where possible the processes responsible. Finally, some examples are provided of the use of present-day environmental measurements to infer historical concentrations of pollutants.

31.2 ENVIRONMENTAL TRANSPORT MECHANISMS

31.2.1 Atmospheric Transport

Atmospheric motions occur on a number of spatial scales, most notably:

1. Global
2. Synoptic, or large-scale (thousands of kilometers)
3. Mesoscale, or intermediate (tens and hundreds of kilometers)
4. Microscale (ten kilometers and less)

In addition to horizontal transfer processes, movements in the vertical are important, especially for substances with long atmospheric lifetimes. The atmosphere, viewed in the vertical (Figure 31.1), divides readily into discrete regions. The lowermost part, known as the troposphere, is characterized by decreasing temperature with increasing altitude. This region is the most accessible to us and consequently is the part most thoroughly observed in scientific terms. Above the troposphere lies the stratosphere, a region within which temperature increases with altitude. This is the region in which ozone mixing ratios peak, as discussed later. The atmospheric regions above the stratosphere are of little concern in relation to pollution phenomena.

The troposphere is typically also thermally stratified (see Figure 31.1). The main regions are the boundary layer, typically about 1 km in depth during the daytime but often reducing to only around 100 m at night, and the free troposphere, which lies between the boundary layer and the tropopause. These regions are separated by a temperature inversion, which severely limits exchange between them.

The extent to which a pollutant is subject to either vertical or horizontal movement in the atmosphere is a function of its atmospheric lifetime, defined in section 31.4. For *substantial* movement of a substance between compartments, the approximate minimum lifetimes τ are indicated below:

Boundary layer to free troposphere	$\tau > 5$ days
Entire tropospheric hemisphere	$\tau > 1$ month
Global troposphere	$\tau > 2$ years
Troposphere to stratosphere	$\tau > 10$ years

Figure 31.1 Vertical structure of the atmosphere indicating approximate temperatures and the main regions.

To cite some examples, nitrogen dioxide has a chemical lifetime of about a day, and little of that emitted in the tropospheric boundary layer transfers to the free troposphere. Aerosol emitted from Chernobyl, which had a lifetime of around 1 month, led to contamination of much of the northern hemisphere. Methane, with an atmospheric lifetime of about 9 years, is rather well mixed between northern and southern hemispheres and penetrates in modest amounts into the lower stratosphere. Chlorofluorocarbons and nitrous oxide, with lifetimes in excess of 100 years, have no significant tropospheric sinks and mix appreciably into the stratosphere.

Horizontal atmospheric motions are driven by gradients in temperature and pressure that lead to general circulation, as described in Figure 31.2. Wind speeds in the boundary layer vary greatly

Figure 31.2 The general circulation of the atmosphere.

from place to place but are typically of the order of 5 m/sec, implying transport distances of around 400 km/day. It is thus possible for a pollutant to travel around the globe at a given latitude in a matter of days, but more substantial north–south mixing takes months. Atmospheric circulation at low latitude is dominated by the Hadley circulation, which involves updrafts of air in equatorial regions, with subsequent movement both north and south at high tropospheric altitudes and subsidence to form the subtropical high–pressure regions. The existence of two such circulatory cells on either side of the equator ensures inefficient mixing between northern and southern hemispheres, and only substances with lifetimes measured in years mix appreciably between the hemispheres. This is particularly important in limiting movement of contaminants from the heavily populated northern hemisphere into the far cleaner southern hemisphere.

Mesoscale circulations involve such processes as land–sea breeze circulations that can profoundly influence pollutant movements in coastal regions. Mountain upslope and downslope winds driven by thermal convective motions may also act as an important transfer route. Processes occurring on the micro- and mesoscale are important in influencing concentrations of locally generated pollutants but play only a minor role in transferring pollutants on a larger scale.

31.2.2 Freshwaters

Pollutants entering freshwater may be in the dissolved ($< 1\text{ nm}$), colloidal ($1\text{ nm} - 1\text{ }\mu\text{m}$), or particulate ($> 1\text{ }\mu\text{m}$) form. The exact nature of the pollutant species has important implications for both bioavailability and environmental transport. For instance, biological impact of trace metals is often related directly to the dissolved (free) metal concentration.¹ In addition, dissolved and colloidal forms of the pollutant will tend to remain in the water column due to mixing processes, while particulate forms will tend to settle out of the water column and be incorporated in the sediments.² Once in a river or lake, they may remain in their original form or repartition between these different forms in response to a changed matrix. Important parameters affecting the distribution of pollutants include microbiological activity, concentration, and nature of organic matter, pH, ionic strength, redox potential, and so on. These changes can be illustrated by the following examples:

- *Rain water (pH ~ 5) falling on lake water (pH ~ 7–8).* As the pH increases, metals in the dissolved form will tend to bind to solid phases. Over this pH range many metals change from 0 to 100% bound to solid phases.
- *Freshwater mixing with seawater in estuaries.* Increased ionic strength will cause colloids, and subsequently sediment, to aggregate out of the water column. The fate of associated pollutants will also be affected.
- *Oxic–anoxic boundary in lakes.* The oxidized form of iron (Fe [III]) exists as the solid phase in oxygenated surface waters. The particles sediment from the water column (with any associated pollutants) and come into contact with the deoxygenated bottom waters. At this point the iron is reduced, forming Fe (II), which exists in the dissolved phase. Particulate-phase pollutants may therefore pass into the dissolved phase.

In reality, the processes occurring are much more complex than indicated, with many competing reactions occurring on different spatial and temporal scales. For instance, in estuaries, both pH and chloride concentration as well as ionic strength increase dramatically, with many consequences for pollutant behavior. In the case of lake waters, as the iron is reductively solubilized across the oxic–anoxic interface, released trace pollutants may bind to other solid phases and not be released into the dissolved phase.

Processes such as sorption, precipitation, microbiological activity, and others may affect both organic and inorganic pollutants. Therefore, the assumption that a substance entering a river in an effluent will maintain its original physicochemical form will often prove to be incorrect.

Metals are important contaminants that may undergo a wide range of physical changes such as those outlined above and, in some instances, may also undergo changes in oxidation state leading

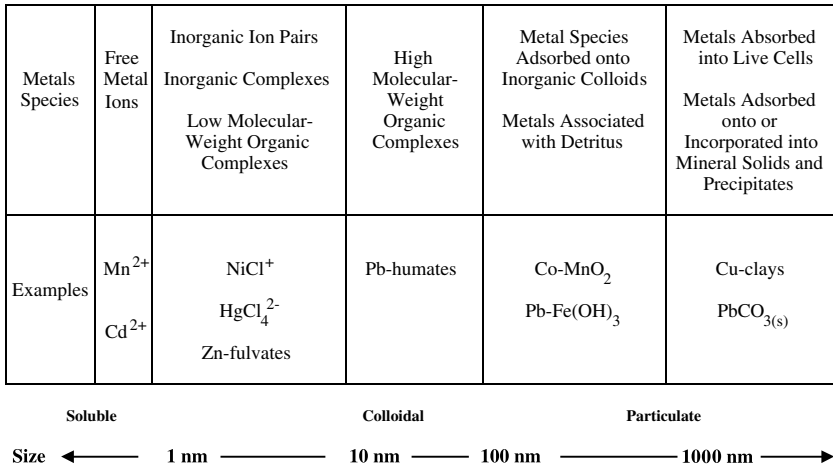

Figure 31.3 Typical physicochemical forms of trace metals in aquatic systems, as related to size association. (From de Mora, S. J. and Harrison, R. M., *Water Res.*, 17, 723, 1983. With permission.)

to a complete change in physical form. The relevance of such changes to environmental transport is that they affect the size association and hence the mode of movement in the freshwater system. Figure 31.3 exemplifies the possible forms of trace metals and their size association.³

Dissolved contaminants will move freely with flowing water and, although subject to diffusive movements caused by turbulence, are predominantly influenced by advective transport (i.e., they are mainly carried along by the water, rather than diffused within it). The behavior of particulate material is more complex, as it may deposit, entering the bottom sediment. This process is controlled by two processes. First, the tendency to deposit is a function of the size and settling velocity of the particles with which the contaminant is associated. However, this tendency is counteracted by turbulence forces that keep particles in suspension and make them available for movement with the water. Thus, in relatively static waters (lakes and ponds), there is a strong tendency for particles to be incorporated into bottom sediments. In fast-moving rivers and estuaries, the turbulent energy of the water keeps the particles in motion and may even lead to resuspension of bottom sediment. In such circumstances, contaminant transport may occur by three main mechanisms:

- As truly suspended particles
- By saltation, or “bouncing” of particles along the sediment surface
- As bed load, or bulk motion, of surface sediment

Changing flow conditions within a river may lead to rapidly altering transport properties. An example is given in Figure 31.4, which shows measurements of total (suspended plus dissolved) concentrations of chromium in the River Thames (U.K.) as a function of discharge (flow). As flow increases from very low values, concentrations of contaminant fall due to dilution of dissolved material in a greater volume of water. They reach a minimum and then begin to increase for flows of greater than about 70 m³ s⁻¹. This flow is known (from other measurements) to correspond to that at which riverbed sediments begin to become resuspended. Concentrations of chromium continue to increase with increasing flow as more bed sediment enters the water.

In slow-moving waters, where much of the suspended sediment enters the bottom sediment, a historical record of inputs to the lake may be preserved in the bottom sediment. For instance, the concentration of lead, zinc, and copper in recently deposited sediments in Lake Erie have increased by several-fold in comparison to sediments deposited ca. 1900.⁴ Such records often reflect changes in atmospheric deposition to the lake surface, and for substances such as heavy metals⁵ and polynuclear aromatic hydrocarbons, they have been used to reconstruct a record of air quality in the past.

Figure 31.4 Concentration of chromium (suspended plus dissolved) in the waters of the River Thames as a function of flow rate.

The behavior shown in Figure 31.4 for chromium in the River Thames is not common to all contaminants. In the same study, measurements were made of nitrate and soluble reactive phosphate (SRP). For nitrate, concentrations were almost independent of flow, suggesting the dominance of inputs in waters making up the major part of the river flow (surface runoff and groundwater). In the case of SRP, concentrations of this dissolved species showed a monotonic decrease with flow rate reflective of dilution of effluent inputs (from sewage treatment works) and no input from resuspended sedimentary materials.

31.2.3 Marine Transport

While rivers generally take only hours or days to flow to the sea, water has a very long residence time in the ocean. Consequently, transport and transformation processes control the distribution of contaminants. The oceanic surface layers to a depth of around 100 m are driven largely by the wind, the water motion being modified by the Coriolis force that arises from the rotation of the earth. Oceanic circulations in large part consist of gyres constrained by continental boundaries. Faster currents occur along western margins, leading to pronounced circulatory features such as the Gulf Stream, Brazil Current, and Kuroshio Current.

At greater depths within the ocean, circulations are determined by the chemistry and temperature of the water. Dense waters (either cold or more saline) form in cold polar regions, where the sea ice formation leads to an increase in salinity. Antarctic bottom water flows north from the Weddell Sea into the south Atlantic, while North Atlantic deep water moves on a timescale of around 1000 years from the Norwegian Sea through the Indian Ocean into the Pacific.⁶

Surface ocean waters are relatively well mixed and show little variation of temperature with depth. In the layer beneath, termed the “thermocline,” temperatures decline rapidly with depth, with the most dramatic temperature changes occurring down to about 1 km in equatorial and temperate latitudes. The deep layers beneath the thermocline show little change in temperature with depth. The thermocline presents a rather sharp boundary and a considerable barrier against mixing of the surface and deep layers.

Owing to the relatively slow time scales of oceanic water movement, even in the surface layers, highest concentrations of contaminants occur in the coastal regions, where inputs are greatest — from rivers, direct coastal discharges, and atmospheric deposition. Much of this contaminant load may deposit to the sediments before mixing processes carry it far from coastal waters.

31.2.4 Soils

Soils are by their nature rather immobile. If undisturbed, they may retain a record of contaminant inputs over a very long period. Many pollutants bind strongly to soils and, if there is input from the atmosphere, show a very strong surface enrichment. Mechanical mixing by plowing or other agricultural practices, or bioturbation by burrowing organisms, can cause some vertical and lateral mixing of pollutants in soils.

Following deposition from the atmosphere, some organic pollutants, particularly polychlorinated biphenyls (PCBs), readily undergo volatilization from soil to the extent that for many such compounds, volatilization represents the principal loss mechanism from soil.⁷ This has important implications for understanding the origins of the continuing atmospheric presence of PCBs (the manufacture of which was ceased in most western countries in the late 1970s). Specifically, although accidental releases from PCBs remaining in use continue, such volatilization of previously deposited material is widely considered to represent the main contemporary source of PCBs in the atmosphere.

31.3 TRANSFER MECHANISMS AND FLUXES BETWEEN ENVIRONMENTAL COMPARTMENTS

Every time it rains, small amounts of highly persistent compounds, such as chlorinated pesticides, are deposited to land and sea. Dry deposition of particles and gases also contributes to inputs. This occurs even for some compounds no longer in large-scale production or use. Residues in soils and waters in parts of the world where heavy usage has occurred are still evaporating into the atmosphere and are carried to locations remote from their sources, where deposition takes place. Exchange between environmental compartments is a major route of transfer for some substances and can lead to unexpected instances of pollution. One such phenomenon occurred in West Cumbria, U.K., where abnormally high levels of plutonium were found in coastal soils. Detailed investigation showed that plutonium discharged from the Sellafield reprocessing plant to the Irish Sea was incorporated into sea spray with an efficiency greater than that expected from its abundance in seawater and carried back to land in marine aerosol.^{5,8}

Some of the major processes involved in intercompartmental transfer will now be considered.

31.3.1 Atmosphere–Land Surface Exchange

Transfer from air to land can occur by two major routes:

1. Rainfall (termed “wet deposition”)
2. As dry particles or gas, without the intervention of rain (termed “dry deposition”)

A third pathway, involving “occult” deposition of fog and/or cloudwater droplets, may also be of localized importance.

Concepts of dry deposition were originally developed to describe the transfer of radioactive gases and particles from the atmosphere into terrestrial systems. The process of deposition is first order; that is, the flux to the surface depends linearly upon the atmospheric concentration. The constant of proportionality is termed the “deposition velocity,” v_g , defined as:

$$v_g = \frac{\text{flux to surface}}{\text{atmospheric concentration at 1 m}}$$

For gases, deposition velocities to soils and vegetation vary greatly according to the affinity of the gas for the individual surface. Thus, for chlorofluorocarbons, deposition velocities are essentially zero, while for highly reactive and water-soluble nitric acid vapor, v_g has a typical value of 2 to 3 cm s^{-1} . The deposition velocity is not constant for a given gas or a given surface. While one can make approximate statements about the magnitude of v_g (such as that above for nitric acid), in reality v_g varies with the surface characteristics and atmospheric properties at the time of deposition. This may be expressed as follows for the total resistance to deposition, R .

$$R = \frac{1}{v_g} = r_a + r_b + r_c \quad (31.1)$$

where r_a is the aerodynamic resistance, or the resistance to transfer downward through the atmosphere to within 1 to 2 mm of the surface; r_b is the boundary layer resistance, which is the resistance to transfer through a laminar layer of air of about 1 mm thick over the individual roughness elements of a surface; and r_c is the canopy, or surface resistance, which describes the resistance of the surface itself to take-up of the gas. For a sticky, reactive molecule like nitric acid, r_c is essentially zero, while for chlorofluorocarbons, it is almost infinite and accounts for the differing depositional behavior of these gases. For ozone, r_c over vegetation typically varies with time of day according to the opening of stomatal apertures of the vegetation, necessary for rapid ozone deposition.

Deposition velocities are not as strong a function of chemical properties in airborne particles as in gases. The main determinant of deposition velocity is the particle size (see Figure 31.5), with high values of v_g applicable to large particles due to their inertial properties and very small particles due to their high diffusivities, which cause them to behave more like gases.⁹ Between the two lies a region of low dry depositional efficiency. For particles in this size range, around 0.1 to 1 μm in diameter, wet scavenging is also inefficient, and atmospheric lifetimes are long — of the order of 7 to 40 days. Chemical composition may affect dry deposition, as hygroscopic particles are liable to grow adjacent to a humid surface, leading to enhanced deposition.

Some gases are released by soils or vegetation. If their concentration immediately adjacent to the surface exceeds that in the atmosphere above, the concentration gradient will cause them to diffuse upward, and the net flux will be from surface to atmosphere. In this instance, the concept of deposition velocity is of little value. A gas that normally exhibits upward fluxes from soil is

Figure 31.5 Typical variation of aerosol particle deposition velocity with particle size over land.

nitrous oxide, N_2O . Ammonia, NH_3 , shows ambivalent behavior; net fluxes from fertilized soils are commonly upward into the atmosphere, while over unfertilized soils, within which concentrations of ammonium (and by inference ammonia) are very low, deposition normally occurs.

31.3.2 Air–Plant Exchange

Air-to-plant transfer of persistent organic pollutants (POPs), such as dioxins, PCBs, and polycyclic aromatic hydrocarbons (PAH), occurs readily, primarily as a result of vapor-phase deposition onto the leaf surface, either as an equilibrium partitioning process or as a kinetically-controlled process, although particle-bound deposition can be influential for some compounds.¹⁰ Given the facile nature of air–plant transfer of POPs, it is important to evaluate the quantitative role that vegetation plays within the overall biogeochemical cycling of such pollutants. Several authors have speculated that because of the vast surface area covered by vegetation, this role could be significant. Indeed, there is ample evidence that vegetation, particularly forests, remove a substantial quantity of airborne POPs, with consequent reductions in their atmospheric residence times. A steady-state mass-balance model determined that vegetation removed 4% of PAHs from the atmosphere in the northeastern region of the United States. It is evident that vegetation plays a significant role in the biogeochemical cycling of PAHs and other POPs possessing similar propensity for atmosphere-to-foilage transfer. The implications of this phenomenon in terms of human and ecotoxicological impacts are at present unclear, and this research topic is likely to receive much attention in the future.

31.3.3 Air–Sea Exchange

For many large bodies of water, the atmosphere is a major route of contaminant input. For example, for the North Sea, which is heavily influenced by adjacent industrialized countries, atmospheric deposition is the major source of some trace metal inputs.

Particles deposit to water surfaces in much the same manner as to land. There are clearly differences arising from the resistance terms in Equation 31.1 that are not identical for the two surfaces or the air above them. In general, similar patterns of behavior are observed, although there is stronger wind-speed dependence in the case of the sea, since surface characteristics change appreciably as high winds break up the sea surface into waves and spray.

Aerosol produced from the sea surface itself can be enriched in trace elements that are transported over land. The extent of enrichment is controversial, with some research indicating a major impact on aerosol and rainwater composition and other papers suggesting little effect in the case of trace metals. One clear example of enrichment is plutonium, cited above. Plutonium is enriched in aerosol and deposition some 30- to 500-fold relative to its abundance in bulk seawater. Fortunately, marine aerosol is of relatively large particle size and deposits within a rather narrow coastal band of land; the majority of deposition occurs within 5 km of the coast.

Incorporation of contaminants in rainwater leads to wet deposition to both land and sea surfaces. Scavenging of contaminants may occur either within the cloud (termed “rainout”) or by falling raindrops (termed “washout”). The overall efficiency of the process is often described by the scavenging ratio, W , also known historically as the Washout Factor:

$$W = \frac{\text{concentration in rain (mg kg}^{-1}\text{)}}{\text{concentration in air (mg kg}^{-1}\text{)}}$$

Values of W for particulate species are typically around 200 to 1000, implying crudely that substances present in air at microgram-per-cubic-meter concentrations will occur in rain at milligram-per-liter-levels, as a cubic meter of air weighs 1.2 kg at 25°C and 1 atm pressure. An alternative

descriptor of wet removal used by numerical modelers is the washout coefficient, λ . This is a first-order rate constant in the equation

$$\frac{dc}{dt} = -\lambda t$$

where dc/dt is the rate of change of airborne concentration with time, t . For aerosol species, λ typically takes values of around 10^{-4} s^{-1} .

The sea may act as a source of atmospheric trace gases. A notable example is that of dimethyl sulfide released by marine phytoplankton. It may also act as a sink for reactive gases such as nitric acid and other soluble species.

The direction of flux between air and sea¹¹ is determined by Henry's Law, which describes the equilibrium between dissolved and gaseous forms of a substance. At equilibrium:

$$C_w(\text{eq}) = C_a H^{-1}$$

where C_w and C_a are the concentrations in water and air, respectively, $C_w(\text{eq})$ is the concentration in water at equilibrium with the atmosphere, and H is Henry's Law constant.

If, however, $C_w \neq C_w(\text{eq})$, then a net flux of material to air, or from water to air, will occur. If $C_a H^{-1} > C_w$, net transfer into the water occurs; and if $C_a H^{-1} < C_w$, then the net flux is to the atmosphere.

Suppose that:

$$\Delta C = C_a H^{-1} - C_w$$

The rate of gas transfer is:

$$F = K_{(T)w} \Delta C$$

where $K_{(T)w}$ is termed the "transfer velocity." By analogy with Equation 31.1, one can write:

$$\frac{1}{K_{(T)w}} = \frac{1}{\alpha k_w} + \frac{1}{H k_a} = r_w + r_a \quad (31.2)$$

where k_a and k_w are individual transfer velocities for chemically nonreactive gases in air and water phases, respectively, and $\alpha (= k_{\text{reactive}}/k_{\text{inert}})$ is a factor that quantifies any enhancement of gas transfer in the water due to chemical reaction. The resistance r_a and r_w are directly analogous to those in Equation 31.1; and for chemically reactive gases, usually $r_a \gg r_w$, and atmospheric transfer limits the overall flux. For less reactive gases, r_w is more difficult to predict. It is highly wind-speed dependent, as exemplified by Figure 31.6, which shows the overall transfer velocity for carbon dioxide (for which k_w is dominant) as a function of wind speed at 10 m.¹³

31.3.4 Sediment–Water Exchange

The distribution of trace elements in aquatic systems is affected by a number of processes, which are exemplified in Figure 31.7. One important process in the water column is the distribution between the solid-solution interface (see next section). Incorporation of contaminants into suspended solids that subsequently aggregate and deposit to form bottom sediments is a major removal mechanism of the pollutants. Sedimentation rates, as expressed by the rate of increase at the bottom sediment surface, vary greatly from millimeters per 100 years in the deep ocean to centimeters per

Figure 31.6 Air-sea transfer velocities for carbon dioxide at 20°C as a function of wind speed at 10 m (ms^{-1} or Beaufort Scale). The graph combines experimental data (points) with a theoretical line. (From Watson, A.J., Upstill-Goddard, R.C., and Liss, P.S., *Nature [London]*, 349, 145, 1991. With permission.)

year in some lakes and coastal environments. Other important controls on the transport of contaminants are the resuspension of particles, the entrapment of water in pore spaces, the upward flow of pore water due to hydrostatic pressure gradients, and diffusional fluxes of dissolved species.² Recent work with microelectrodes and other microscale techniques¹⁴ has shown that sediments are extremely heterogeneous over ranges of hundreds of microns and that dissolved concentrations of major and minor species will fluctuate not only vertically and temporally but also laterally, i.e., in three dimensions. These heterogeneities often relate to the effects of biogenic processes.¹⁵

Figure 31.7 Processes affecting the distribution of trace elements in aquatic systems. (From Tessier, A. et al., in *Chemical and Biological Regulation of Aquatic Systems*, CRC Press, Boca Raton, FL, 1994.)

The net flux of a substance across the water-sediment interface, $F_{z=0}$, is expressed by

$$F_{z=0} = \phi \left(-D \frac{dC}{dz} + UC + U_s C_s \right) \quad (31.3)$$

where

- ϕ = porosity (volume fraction occupied by water)
- D = diffusion coefficient
- C = concentration in solution
- C_s = concentration in solids
- U = rate pore water advection
- U_s = sedimentation rate
- z = vertical distance

Thus, of the three terms in the right-hand side, the first term represents diffusive transfer, the second term advection in pore water, and the third term transfer in solids.

In a uniform, noncompacting sediment, $U = U_s$, and from above, $C_s = K_d C$. Substitution yields:

$$F_{z=0} = \phi \left[-D \frac{dC}{dz} + U(K_d + 1)C \right]_{z=0} \quad (31.4)$$

The relative importance of the two terms, representing diffusion and sedimentation, depends upon the sedimentation rate and the magnitude of K_d . If either of these is large, it is likely that sedimentation processes will dominate the flux. If both are small, diffusive transfer may be dominant, as often occurs in the deep ocean.

A fuller consideration of solute transport would also consider biological processes (bioturbation and bioirrigation by macroinvertebrates) and physical processes (waves, currents, and tides).¹² Although bioturbation appears to be negligible, the other processes can significantly enhance movement. The role of the biofilms may also be important in pollutant dispersion.

Interesting processes can arise in redox-active sediment components. Examples are with iron and manganese. Both elements are present in oxidizing waters in highly insoluble oxidized forms such as Fe_2O_3 and MnO_2 , which become incorporated in surface sediments. Progressively, the sediment becomes buried with freshly sedimenting solids and becomes anoxic as microorganisms consume oxygen more rapidly than it can be supplied from the overlying water. In the anoxic region, chemical reduction takes place, and Fe(III) and Mn(IV) are converted to, respectively, Fe(II) and Mn(II). These are both liable to be more soluble than the more oxidized forms (especially Mn), and Mn(II) diffuses upward through the interstitial water, from where it may either enter the overlying water or reprecipitate in the oxic layer.¹⁶ Figure 31.8 shows typical schematic profiles of solid-associated and dissolved manganese. The subsurface maximum in dissolved manganese occurs where the outward flux and reprecipitation balance the upward supply from greater depth. Solid manganese below this depth is mostly present as $MnCO_3$. Analysis of a core of sediment for manganese is liable to reveal a near-surface maximum for the above reasons. This should not be confused with near-surface enrichment of other sediment components not subject to the same redox chemistry, which in more recent years has often been seen as a result of enhanced rates of contaminant deposition (see Section 31.6). Post-depositional changes in sediments are common and varied and are grouped under the term *diagenesis*.

Diagenetic processes in sediments can lead to the release of contaminants to the overlying water. Thus, for example, microbial decay of organic matter and reduction of iron and manganese in sedimentary solids can lead to rerelease of adsorbed or complexed material that, if not reabsorbed,

Figure 31.8 Schematic profiles of manganese in bottom sediment dissolved in the interstitial waters (broken lines) and associated with the solid sedimentary components (solid line).

may be released into the overlying water. This is most likely to occur to an appreciable degree if the bottom water of a lake becomes anoxic for an appreciable period, causing even the surface sediment to be anaerobic.

31.3.5 Solid–Solution Exchange

Although these exchanges occur within — rather than between — environmental compartments, e.g., in surface waters, groundwaters, or sediment pore waters, the processes occurring at the solid–solution interface within the water body are essential to understanding the transport of pollutants. Controlling processes, such as biological activity and sedimentation, are highly dependent on reactions occurring at the solid–solution interface. The chemical weathering of minerals that, in large part, determines the composition of natural waters and plays a part in controlling atmospheric carbon dioxide levels through the action of carbonic acid (see below, dissolution of silicates and calcium carbonate) is also dependent on these solid–solution reactions.

The solid–solution interface is often dominant in regulating the concentrations of dissolved trace elements and can be modelled through the use of a distribution coefficient given by the equation,

$$K_d = \frac{\text{concentration in solid phase material (mg kg}^{-1}\text{)}}{\text{concentration in dissolved phase (mg kg}^{-1}\text{)}}$$

Although the distribution coefficient is useful in modelling processes such as the sorption of organic pollutants on organically coated particles, it is also limited in that it provides a conditional constant, which will change with changing solution conditions. More recently, understanding the partitioning of metals to oxide or natural organic surfaces has been performed in terms of surface complexation theory.^{17,18} However, full understanding of these processes will come only in the

distant future. The fate of organic pollutants such as PCBs is modified as the “hydrophobic effect.” This results in a tendency of organic chemicals to avoid contact with water and results in sorption, particularly on natural organic matter (primarily humic substances). The humic substances themselves tend to sorb to the surface of mineral and microbiological particles, with significant consequences for the fate of the pollutants.

31.4 CHEMICAL AND MICROBIOLOGICAL BREAKDOWN

The atmospheric lifetime of many chemical species is dictated by chemical reactions rather than depositional processes. This is also true for some more reactive species in aquatic systems. A simplistic description of relevant processes is given here.

31.4.1 Rate Expressions

If contaminant X is removed by reaction with reagent Y in a one-step chemical process,

the rate of loss of X is given by:

$$\frac{-d[X]}{dt} = k[X][Y]$$

where k is the rate constant for the reaction. If Y is a species whose concentration is not greatly variable with time, either because it is present in great excess or it is continually replaced after consumption, such that $[Y] \cong \text{constant}$, then

$$\frac{-d[X]}{dt} = k'[X]$$

where $k' = k[Y]$.

This rate expression has a first-order form and is termed “pseudo first-order.” The implication of this form of equation, which prevails frequently in the environment, is that a contaminant that ceases to be emitted diminishes in concentration according to a negative exponential form, as with the decay of a radioactive source.

The second-order equation, if applicable, may be used to estimate the rate of removal of a substance by a specific chemical reaction. For example, the main sink for nitrogen dioxide is conversion to nitric acid by reaction with the hydroxyl radical, $\cdot\text{OH}$. For this reaction,

$$k = 1.1 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

and

$$-\frac{d}{dt}[\text{NO}_2] = (1.1 \times 10^{-11})(1 \times 10^6)[\text{NO}_2]$$

and

$$\frac{-\frac{d}{dt}[\text{NO}_2]}{[\text{NO}_2]} = 1.1 \times 10^{-5} \text{ s}^{-1} = 0.04 \text{ h}^{-1}$$

Thus, loss of NO_2 occurs at a rate of approximately 4% per hour at the above concentration of OH radical. At twice that OH radical concentration, the loss is 8% per hour.

In aquatic chemistry, many of the reaction processes are not simple one-step reactions, and complex rate expressions result in noninteger reaction orders.

In soils and sediments, many decay and transformations affecting chemicals are microbiologically mediated. For example, in oxidizing sediments, organic materials are oxidized, with consumption of molecular oxygen, O_2 . When the O_2 is depleted, the system becomes anoxic, and anaerobic organisms take over. Initially, nitrate-reducing bacteria are favored. Nitrate is used as an oxygen source and ammonium is produced as product. Subsequently, sulfate is used as an oxygen source and converted to sulfide in the process. Finally, carbohydrate material itself is used as a source of oxygen by methanogenic bacteria, and methane and carbon dioxide are the products.

31.4.2 Environmental Lifetimes

In discussing environmental lifetimes, it is useful to think of the analogy of a bath, with a source of input water and removal via an overflow. At equilibrium, the level of water is constant, and the inflow is exactly equaled by the outflow through the overflow. Then, the faster the input, the more rapid the outflow and the shorter the residence time (or lifetime) of water in the bath. This concept is easily related to a mixed reservoir, such as the atmosphere or ocean, but becomes more nebulous when considering solid-earth processes.

To a crude approximation, many environmental contaminants are in some form of equilibrium, and sources (S) equal removal rates (termed “sinks”[®]):

$$S = R$$

If R and S refer to a given environmental compartment, and A is the total quantity of the contaminant in that compartment, the lifetime (or residence time), τ , is defined as:

$$\tau = \frac{A(\text{kg})}{S(\text{kg s}^{-1})} = \frac{A}{R}$$

In practice, the lifetime defined in this way is the time taken for the concentration of the species to diminish to $1/e$ of its initial concentration if all source processes ceased.

Alternatively, dividing top and bottom by the volume of the environmental compartment gives:

$$\tau = \frac{[A](\text{kg m}^{-3})}{S'(\text{kg m}^{-3} \text{ s}^{-1})}$$

or ratio of concentration to flux, S' .

If removal is via a first-order or pseudo first-order process, as described above, then:

$$S' = \frac{d[A]}{dt} = k[A]$$

and

$$\tau = \frac{[A]}{k[A]} = \frac{1}{k}$$

where k is the first-order constant for the loss of component A. This is a very useful result and can be used in the context of removal by chemical or depositional pathways. Taking the example of nitrogen dioxide above,

$$\begin{aligned}k' &= k[\cdot\text{OH}] \\ &= 0.04 \text{ h}^{-1}\end{aligned}$$

and

$$\tau = 25 \text{ h}$$

For many atmospheric trace gases, removal is by reaction with the hydroxyl radical, and

$$\tau = \frac{1}{k[\cdot\text{OH}]}$$

For methane,

$$k = 5.6 \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

and

$$\tau = 5.7 \text{ years for } [\cdot\text{OH}] = 1 \times 10^6 \text{ molecule cm}^{-3}$$

Concentrations of hydroxyl radical do in fact vary diurnally and with latitude and season. The use of long-term average values (as above) for lifetime estimation is therefore justified for the longer-lived substances (e.g., methane); but for short-lived species like nitrogen dioxide, more precise values for the location and time are appropriate.

As mentioned in Section 31.3, washout coefficients are first-order rate constants for wet deposition. Thus, for $\lambda = 10^{-4} \text{ sec}^{-1}$, the lifetime with respect to removal by this pathway is 10^4 sec , or 2.8 h. Such a value could obviously apply only during periods of rain and would not be relevant to dry spells.

Lifetimes can also be calculated in relation to dry deposition processes. In this case, the rate constant is given by

$$k = v_g/H$$

where v_g is the deposition velocity and H the mixing depth, or depth of the lowest mixed layer of the atmosphere, normally the boundary layer. Thus, for sulphur dioxide, for which $v_g \cong 1 \text{ cm s}^{-1}$ and a typical mixing depth of 1000 m,

$$\begin{aligned}\tau &= H/v_g \\ &= 28 \text{ h}\end{aligned}$$

Within the ocean, dissolved materials may be scavenged by adsorption onto particles, thereby accelerating their deposition. Using the same form of mathematical analysis, deep-water scavenging residence times vary from 0.4 years for particles, to 10 to 50 years for metals such as tin, iron, cobalt, and lead, to over 10^4 years for cadmium.

31.5 SPATIAL DISTRIBUTION OF CONTAMINANTS

As discussed above, spatial distributions of contaminants result from a number of factors, including source locations, dispersal processes, and sink processes. The spatial extent of the distribution from a single source will depend critically on the lifetime of the contaminant, as those of shorter lifetimes will not survive over any great distance.

31.5.1 Microscale

Good examples of microscale distributions of contaminants arise from dispersion from point sources. Effective numerical models exist for describing the three-dimensional concentration distribution of pollutants emitted from elevated point sources into the atmosphere. The instantaneous distribution of concentrations is described adequately for most purposes by the Gaussian plume model.^{19,20}

Emissions to atmosphere of pollutants such as heavy metals from point sources can lead to distributions of pollutants in local surface soils directly analogous to those for atmospheric concentrations. Many surveys have been carried out of metal concentrations in soils and vegetation around smelters, exhibiting just this kind of distribution, except where low-level, fugitive sources of coarse dusts, such as stockpiles, lead to highly enhanced deposition close to the works. Frequently, this has led to severe contamination, which persists unless subject to cleanup.

A well-known phenomenon of past decades has been the contamination of roadside soils with lead from vehicle exhausts. A typical distribution involves highly elevated concentrations at curbside, falling exponentially to background levels within about 100 m. Such soils typically show a strong surface enrichment of lead, with concentrations declining rapidly in lower layers, reaching local background concentrations by about 15 cm deep. Highly elevated concentrations of lead in soils may also be found in areas of lead mineralization and historical lead mining, where lead-rich soils have contaminated local soils.

Both comparable methods based on Fickian diffusion and systems procedures are available to estimate by numerical means the dispersion of contaminants in rivers.²¹

31.5.2 National and Regional Scales

Pollutants with major localized sources may give substantial and significant variations in concentration on the micro- or mesoscale but contribute in only a minor way to national or regional patterns of concentration. Secondary atmospheric pollutants often yield more meaningful patterns on the latter scale, as they are produced more slowly and are less influenced by individual sources; an example is hydrogen ion in rainwater. Strong acidity is generated only rather slowly from oxidation of sulphur dioxide (ca. 1 to 2% per hour) and nitrogen dioxide (ca. 5% per hour). Figure 31.9 shows the distribution of rainwater pH over North America at the height of the acidification problem, which is now less severe. Distinct spatial gradients relate to sources, meteorology, and local geology, since airborne carbonate particles can neutralize acids. Another example of a secondary pollutant showing meaningful spatial patterns in concentration is ozone. Analysis of measurement data in Europe indicates clear north-south gradients in episodic peak hourly ozone, both nationally and across western Europe as a whole.

31.5.3 Hemispheric and Global Scales

As mentioned above, the atmospheric circulation provides a strong barrier to tropospheric mixing between northern and southern hemispheres; crossing of the equatorial regions occurs appreciably only for pollutants with lifetimes of a year or more. Ship-borne measurements of air

Figure 31.9 Calculated ground-level concentration distributions ($\mu\text{g m}^{-3}$) of NO_x around an elevated point source within a fertilizer works. + denotes center of works; • denotes sampling sites used to measure ground-level concentrations. (From Boutron, C.F. et al., *Nature*, 353, 153, 1991. With permission.)

composition have revealed north–south gradients of many atmospheric constituents. In some instances, these show sharp discontinuities at the equator, which is consistent with a predominantly northern hemisphere source and little transfer into the southern hemisphere.

As previously mentioned, persistent organic pollutants (POPs) like PCBs are capable of volatilizing from soils and water. Once airborne, they readily undergo long-range atmospheric transport either in the vapor phase or bound to aerosol. It is via such atmospheric transport, which occurs in a repeated cycle sometimes referred to as “the grasshopper effect,” that these chemicals distribute in a ubiquitous fashion. This universal distribution is illustrated by the presence of POPs in polar regions, which is a matter of concern, for although inputs to such locations are small, the low temperatures minimize volatilization losses, leading to a steady accumulation of the overall pollutant burden. This accumulation is compounded by the reduced biomass-to-surface-area ratio of polar regions, with the result that the pollutant burden is distributed among a much smaller biomass than in industrial areas. These factors account for the observations of PCB concentrations in the breast milk of Canadian Inuit mothers, which exceed those found in women from urban Canada.

31.6 TEMPORAL TRENDS IN CONTAMINANT CONCENTRATIONS

High-quality environmental measurements of trace contaminants have been made only in relatively recent years. There are, therefore, relatively few examples of clear temporal trends discernible from contemporaneous environmental measurements. One very clear example is that of tropospheric carbon dioxide measured at Mauna Loa, Hawaii by Keeling and coworkers²² since the late 1950s. High-quality data show a very clear upward trend modulated by a seasonal cycle due to varying exchange fluxes with terrestrial biota. Since CO_2 has a relatively long tropospheric lifetime, similar general trends are seen at other sites within both northern and southern hemispheres.

It is more difficult to determine trends that predate contemporaneous measurements. However, two methods have been particularly successful. The first involves analysis of ice cores. Gases

Figure 31.10 Changes in lead concentrations in Greenland ice and snow from 5500 BP to present. (From Boutron, C.F. et al., *Nature*, 353, 153, 1991. With permission.)

become trapped in ice during snowfall, and careful retrospective analysis of dated ice core samples has revealed valuable information. Examples are carbon dioxide and methane, determined in Antarctic ice²³ up to 1.6×10^5 years old. Metallic pollutants are also incorporated into snow and ice, and Figure 31.10 shows data for lead in Greenland ice, determined from several studies, showing a massive increase in atmospheric lead deposition, commencing with the Industrial Revolution and accelerating rapidly after 1950 as use of leaded gasoline increased. More recently, deposited ice shows a strong decline from around 1970, when leaded gasoline use was curtailed, first in North America and subsequently in many other developed countries.

Lake sediment cores can also reveal interesting patterns of historical inputs, as the sediments are built up of layers laid down sequentially, the most recent at the water interface. Concentrations of trace contaminants in such sediment cores reflect input processes and subsequent diagenetic changes. In some instances, however, profiles of pollutants have been shown to reflect clearly historical inputs of pollutants such as trace metals from the atmosphere to the water body and hence provide a relative measure of trends in airborne concentrations.

The environmental persistence of POPs means that correctly stored archived samples as well as sediment and snow-pack cores provide an invaluable resource for elucidating past changes in contaminant concentrations.²⁵ Knowledge of such past trends can be correlated with contemporaneous trends in source activities and used to build further understanding of the likely impact of emission-control strategies on future concentrations. Figure 31.11 shows the temporal variation

Figure 31.11 Temporal trends in concentrations of dioxins (PCDD/Fs) in soil measured in the southern United Kingdom.

of dioxin concentrations in archived soil taken in south England between 1850 and 1990.²⁶ This study shows that a low, essentially constant “background” of dioxins existed in the soil throughout the latter part of the 19th century; since then, dioxin concentrations have risen dramatically. The inference from this is that, while some natural sources do exist, notably forest fires (which may arguably be of significance in some countries), the environmental burden of these compounds has its source in human activity, in particular, the manufacture and use of organochlorine chemicals (such as chlorophenols) and combustion processes (such as waste incineration and coal combustion).

31.7 SUMMARY

Distributions of many pollutants are measured on spatial scales varying from the local micro-scale to the global scale. These may generally be understood in terms of:

1. Distribution of sources
2. Transport mechanisms and intercompartmental transfer
3. Environmental lifetimes
4. Distribution of sinks

While short-lived contaminants are most readily identified close to their source, the more persistent substances, such as heavy metals and PCBs, may achieve a truly global distribution due to atmospheric transport and deposition to soils and surface waters.

Good mathematical treatments are available from many transfer processes and sink mechanisms, although considerable uncertainties still exist in relation to the use of appropriate values of parameters such as diffusion coefficients and transfer velocities. The analysis of pollutant deposits accumulated historically in media such as sediments and polar ice may be used to construct a picture of past pollutant concentrations.

32.1 INTRODUCTION

Concern for the bioaccumulation of contaminants arose in the 1960s because of incidents such as toxicity from methylmercury residues in shellfish and avian reproductive failure due to chlorinated pesticide residues in aquatic species. Bioaccumulation models were developed in the 1970s to account for processes such as the partitioning of hydrophobic chemicals from water to aquatic organisms.¹ The study of contaminant accumulation and predictive model development expanded in the 1980s to include bioaccumulation from sediments, food chain biomagnification, and carcinogenesis in feral species. Today, determining contaminant bioaccumulation in aquatic organisms is an essential component of assessing risks to piscivorous wildlife. Additionally, current research is evaluating the association between contaminant tissue residues and adverse effects in aquatic organisms.²

This chapter presents an overview of the principles and determinants governing bioaccumulation from sediments and water and biomagnification in aquatic-based food webs. Organic and metal contaminants are discussed, with an emphasis on hydrophobic organics. The objective of this chapter is to elucidate concepts relating to bioaccumulation rather than present an exhaustive review of the literature.

32.2 BIOACCUMULATION FROM SEDIMENTS

32.2.1 Determinants of Bioaccumulation

Aquatic sediments are formed from the deposition of particles and colloids and can act as both a sink and a source of pollutants. Long-term contaminant input leads to sediment concentrations that can exceed the water concentration by several orders of magnitude because of partitioning of chemicals onto sediment-binding sites. Determinants of the bioavailability of sediment-associated contaminants to aquatic organisms include physical/chemical interactions between the chemical and sediment constituents and biological processes determining exposure and uptake. Binding of hydrophobic organics and metals to sediment appears to be controlled by different mechanisms. The majority of information relating to bioaccumulation from sediments relates to hydrophobic organics, with more limited information on metal or organic anion and cation bioaccumulation.

Bioaccumulation of sediment-associated contaminants is highly species-dependent because of the diversity of feeding ecology and living habits of benthic organisms.³⁻⁵ Exposure pathways from sediment-associated contaminants include exposure to sediment pore water (interstitial water), ingestion of sediment particles and dissolved organic matter, direct contact of sediment with body surfaces, and exposure to the boundary layer of water overlying the sediment.⁶ Utilization of sediments as a food source by benthic organisms is common.⁵ Particle ingestion via filtration of the water column or direct consumption may be a significant route of exposure because benthic organisms may preferentially ingest this fraction of the sediments.⁷

Mode of feeding can significantly influence contaminant bioaccumulation from sediment.⁶ For example, deposit-feeding invertebrates may accumulate contaminants to a greater extent than filter feeders. Digestion of sediment by an organism may be required for contaminant absorption because of slow desorption of chemicals bound to sediment.⁸ Sediment reprocessing by benthic invertebrates may introduce nonequilibrium conditions in the sediment by removal of rapidly desorbable contaminants.⁹ Benthic organisms may also preferentially select higher organic carbon sediments, influencing their exposure sediment-associated contaminants.⁹ Types of organic carbon food sources included in sediment can include encrusted mineral grains, organic–mineral aggregates, fecal pellets, plant fragments, microalgae, and fungi.⁵ A fraction of organic carbon is digestible, but some organic carbon is present as refractory humic polymers that are not readily digestible.⁵ Lee⁹ described additional factors that may influence contaminant bioaccumulation. (1) Burrowing organ-

isms (e.g., amphipods) may ventilate pore waters, whereas surface deposit feeders may not, and (2) the formation of tubes and burrows may affect the spatial distribution of contaminants. Ultimately, contaminant bioaccumulation in benthic organisms will be influenced by the heterogeneous nature of sediment, which can vary in composition in scales of millimeters.⁵

32.2.2 Bioaccumulation Factors

A term used to quantify bioaccumulation from sediments at equilibrium is the bioaccumulation factor (BAF), defined as the chemical concentration in the organism (ng chemical/g tissue) divided by the concentration in sediment (ng/g sediment). Either the wet or dry weight may be used; use of dry weight may eliminate variability due to tissue or sediment hydration. The BAF is a unitless number between 0 and infinity. A biota to sediment accumulation factor (BSAF) can also be calculated from the lipid-normalized chemical concentration (ng chemical/g animal lipid) divided by the organic-carbon-normalized sediment concentration (ng/g sediment organic carbon). The BSAF provides a unitless number between 0 and infinity, with typical values reported for benthic invertebrates ranging from 1 to 10.⁴ BAFs and BSAFs are frequently used in ecological risk assessments to estimate contaminant concentrations in benthic organisms.¹⁰ BSAFs for polychlorinated biphenyl (PCB) congeners determined in four species of benthic invertebrates collected from Lake Erie, ranged from 0.1 to 10 and generally increased with increasing $\log K_{ow}$ of the congener.³ BSAFs for polycyclic aromatic hydrocarbons (PAHs) ranged from 0.04 to 8 and generally decreased with $\log K_{ow}$, suggesting biotransformation of the larger PAHs.³ Mean BAFs for eight metals in benthic invertebrates ranged from 0.1 to 3.5 and from 9 to 37 for PCBs.¹⁰

32.2.3 Bioaccumulation of Metals

Concentrations of heavy metals in sediments can exceed those of the overlying water by three to five orders of magnitude.¹¹ The bioavailability of sediment-associated heavy metals is related to the presence of metal binding sites on the sediment. Increasing the concentration of iron oxides or organic materials in the sediment appeared to reduce metal bioavailability by increasing the number of metal binding sites.¹¹ Metals can also form insoluble sulfides, and the sulfide fraction of sediments may represent a pool of adsorption sites for metal binding.¹² The toxicity of cadmium has been shown to be related to the acid-volatile sulfide (AVS) content of sediments,^{12,13} whereas the binding of cadmium added to oxic sediments was explained by the humic acid content of the sediment.¹⁴ Fu et al.¹⁴ concluded that in oxic sediments, humic substances were the major absorbent for cadmium and possibly other metals. Other factors that may influence metal bioaccumulation from sediments include metal speciation, transformation (e.g., methylation to form hydrophobic alkyl metals), inhibitory interactions of different metals, sediment chemistry (salinity, redox or pH), and binding to dissolved organic matter (DOM).¹¹ DOM is an important energy source for microbially based aquatic food webs, and the presence of DOM can affect both the distribution of a metal between water and sediments and the bioavailability of pore-water contaminants.^{9,15} Benthic organisms may directly affect DOM concentrations through their feeding behaviors and excretory processes.⁹

32.2.4 Bioaccumulation of Organic Contaminants

32.2.4.1 Bioavailability

Binding of organic contaminants to sediments has been attributed to the organic carbon content, clay type and content, cation-exchange capacity, pH, and particle surface area of the sediment.⁶ The organic carbon content of sediment can be predictive of contaminant bioavailability because hydrophobic organics can reversibly bind to the pool of organic carbon (typically comprises 0.5 to

Figure 32.1 Schematic representation of contaminant bioaccumulation from sediment based on Equilibrium Partitioning theory.

3% of a sediment mass).^{16,17} Variability in the bioaccumulation factors for hydrophobic contaminants can be reduced by normalizing for organism lipid content and sediment organic carbon.^{16,17} The source of the organic carbon (e.g., mud, plant material) may also influence the bioavailability and bioaccumulation, although De Witt et al.,¹⁸ in a study with fluoranthene, found that only plant material had a significant influence. Contaminant bioavailability has been primarily assessed by the observed increase in toxicity with decreasing organic carbon content of sediments rather than a direct measurement of bioaccumulation.^{16,17} Landrum,¹⁹ Lee,⁹ and others have assessed bioavailability from the magnitude of the uptake rate or clearance constant. Bioavailability appeared to decrease with increasing contact time between the sediment and contaminant, a phenomenon known as sediment aging.¹⁹

32.2.4.2 Equilibrium Partitioning Theory

The Equilibrium Partitioning (EqP) theory of bioaccumulation from sediments (Figure 32.1) is based on thermodynamically driven partitioning between the hydrophobic contaminant and sediment, pore water, and an organism. The EqP theory assumes that a chemical bound to sediment organic carbon is in equilibrium with the chemical dissolved in the aqueous phase of the sediment (pore water) and in the lipid components of the exposed organism. Additional assumptions of EqP theory include absence of steric hindrance, concentration-independent uptake, and absence of metabolism or degradation of the contaminant.⁴ An implicit assumption of EqP theory is that the bioavailable concentration in water is the freely dissolved portion, and the presence of DOM does not affect equilibrium partitioning. The equilibrium level accumulated by benthic organisms is assumed to be independent of the number and types of exposure routes (e.g., sediment ingestion and exposure via pore water).¹⁷ The EqP theory predicts that the concentration in the organism can be accurately estimated from the contaminant concentration freely dissolved in pore water or the organic-carbon-normalized sediment concentration. An extensive review of the data supporting EqP theory (based primarily on halogenated organics resistant to degradation) was presented by Di Toro et al.,¹⁶ who concluded that sediment-to-sediment variation in bioavailability (assessed by toxicity) can be reduced to a factor of two to three by application of the EqP theory, and the influence of particle size appears minimal.

Di Toro and McGrath²⁰ showed that EqP theory may be applicable to chemicals causing short-term toxicity through a narcosis mode of action, but EqP theory may prove to be less useful at accounting for changes in bioavailability across broad chemical classes.⁷ Bierman¹⁷ concluded that EqP theory could predict bioaccumulation within an order of magnitude for specific classes of chemicals, but bioaccumulation varied considerably with the species of organism. Limitations of EqP theory include the assumptions that equilibrium conditions exist and that lipid content is the principal biotic determinant of bioaccumulation. True equilibrium conditions are unlikely to exist

because of bioturbation, biodegradation, slow contaminant uptake by organisms, spatial and temporal heterogeneity in pore-water concentrations, variation in organism lipid content and composition over time, and heterogeneity in organic carbon, particle number, and contaminant concentration. Desorption kinetics from the sediment may also become important when pore-water concentrations are depleted.¹⁷ Lee⁹ has stated that benthic organisms are not “static players driven solely by thermodynamic partitioning with the external environment.” Alternative methods to the EqP approach include estimating contaminant bioaccumulation and bioavailability from (1) direct measurements of chemical concentrations in field-collected sediment and organisms, (2) equilibrium laboratory exposures, and (3) kinetic models that determine the ratio of uptake and elimination-rate coefficients in shorter-term laboratory exposures.

32.3 BIOCONCENTRATION FROM WATER

32.3.1 Bioconcentration Processes

32.3.1.1 Uptake

Bioconcentration is the accumulation of waterborne chemicals by aquatic animals through nondietary routes.²¹ Bioconcentration can be viewed simply as the result of the competing rates of chemical uptake and elimination. A more complex view of bioconcentration was presented as a conceptual model by Barron (Figure 32.2).²² Steps in the uptake process include delivery of the waterborne contaminant to the absorbing epithelium (e.g., the gill), contaminant movement across diffusion barriers (e.g., mucus, membranes) into the blood, and internal distribution of the contaminant by the circulatory fluids. In general, hydrophobic organic chemicals will diffuse through cells (permeation), while metals move intercellularly or through intracellular channels (filtration).²³ The permeability of the absorbing membrane (e.g., gill, skin) and other tissues constitutes a series of barriers to absorption and transfer of chemicals.^{1,24} The absorption of a chemical from water by an aquatic animal can be viewed as a series of steps, each of which can govern the rate of uptake as well as the extent of accumulation.²²

Figure 32.2 Conceptual model of bioconcentration from water. (From Barron, M.G., *Environ. Sci. Technol.*, 24, 1612, 1990. With permission.)

Figure 32.3 The fish gill. (Adapted from Hickman, C. P., Hickman, C. P., and Hickman, F. M., *Integrated Principles of Zoology*, 5th ed., C.V. Mosby Company, St. Louis, 1974, 473.)

The skin, gill, and digestive tract are potential sites of absorption of waterborne chemicals. In fish, the gill is considered the dominant site of contaminant uptake because of anatomical/physiological properties that maximize absorption efficiency. For example, the gill has high countercurrent flows of blood and water, large absorbing surface, and a small diffusion distance between blood and water (Figure 32.3).²⁴ Skin may be an important absorption route in very small fish because of the large surface-to-volume ratio.²⁵ Hayton and Barron²⁴ concluded that the determining factors of uptake in fish were ventilation volume, blood flow, and membrane permeability. Erickson and McKim²⁶ incorporated these factors into a simplified model and were able to accurately predict organic-chemical uptake by fish.

32.3.1.2 Distribution and Lipid Partitioning

The tissue distribution of a chemical is dependent on three processes: (1) binding/partitioning with circulatory fluid and tissue components, (2) crossing permeability barriers, and (3) distributing via the species- and tissue-specific blood flows.²⁷ In aquatic toxicology, it is generally accepted that lipid partitioning of organic chemicals is an important determinant of bioconcentration.²² Lipids are an important storage site because of large mass, distribution throughout the body, and high affinity and capacity to bind hydrophobic organics. Various authors have shown that normalizing bioconcentration for the lipid content of an organism can reduce interspecific variation in bioconcentration factors. Lipid content and composition of the gill may be more important in controlling uptake than lipid content of the whole animal because hydrophobic chemicals must initially pass through the gill.²⁸ Bickel²⁷ concluded that while chemical lipophilicity will determine binding to lipids, structural features of the chemical are important in determining the binding of contaminants to other macromolecules.

The presence of tissue-specific blood perfusion rates causes tissue groups to act as kinetically distinct compartments and prevents many chemicals from rapidly reaching equilibrium.²⁹ Following absorption, hydrophobic contaminants are redistributed from blood to high-perfusion tissues (e.g., liver), to low-perfusion tissues (skin, muscle), and finally to lipoidal tissues.²⁷ The prevalence of distributional effects on contaminant accumulation can be seen in the biphasic elimination of a variety of chemicals in both fish and invertebrates.³⁰ Thus, blood flow as well as binding/partitioning determines the rate of transfer during uptake and elimination of a chemical.³¹

32.3.1.3 Elimination

Elimination consists of biotransformation and excretion processes. Biotransformation is considered an elimination process because the parent chemical is transformed and thus removed from the organism. Aquatic animals are capable of rapidly and extensively metabolizing a variety of chemical substrates. Biotransformation of organic chemicals acts to decrease bioconcentration by increasing the rate of elimination.²² Although biotransformation generally acts to increase the excretion rate of chemical residues, some metabolites may be more persistent in tissues than the parent compound.³²

Excretion processes include passive diffusion across biological membranes and active or facilitated transport in organs of elimination. The hepatobiliary system, gill, and kidney are key excretory systems in fish. Generally, large nonpolar molecules and metabolites formed from hepatic biotransformation will be excreted via the liver. Factors determining renal excretion include: filtration (filtration rate is species specific and only small molecules are filtered) and active secretion (vertebrate kidneys have active organic anion/cation transport systems).³³ Factors determining gill excretion include proper lipid solubility (e.g., rapid excretion of chemicals with $\log K_{ow}$ between 1 and 3) and maximum gill clearance is equal to cardiac output.^{24,26,34} Excretion of metals may occur by active transport across membranes or by processes such as diapedesis in invertebrates.³⁵ Slow elimination of hydrophobic organics may ultimately be due to slow distributional processes, such as slow transfer from storage tissues, rather than from limited biotransformation.²⁴ Some metals may exhibit extremely slow elimination from deep storage compartments such as bone, with half-lives greater than a year.³⁶

32.3.2 Estimation of Bioconcentration

The term used to quantify the magnitude of bioconcentration is the bioconcentration factor (BCF). The BCF is defined as the proportionality constant relating the concentration of a chemical in the aquatic animal to the concentration in water, under equilibrium conditions (e.g., [fish]/[water]).²¹ The BCF is an estimate of a chemical's propensity to accumulate in an aquatic animal at equilibrium, with values between 0 and infinity. BCFs have units of water volume per unit tissue weight (e.g., mL/g) and can be viewed conceptually as the water volume containing the amount of chemical concentrated in 1 g of animal tissue.³⁰ A BCF can be converted to a unitless number by assuming 1 g of tissue is equal to 1 mL of exposure water.

Procedures used to estimate BCFs are the equilibrium method, kinetic modeling methods, physiologically based methods, and quantitative structure activity relationship (QSAR) methods. The equilibrium method exposes an organism to a constant concentration of waterborne chemical until equilibrium is reached.³⁷ Kinetic methods apply a compartmental representation of the organism and estimate BCF from uptake- and elimination-rate constants (e.g., $BCF = k_{in}/k_{out}$) or fugacity-based constants.^{30,38,39} Physiologically based methods estimate chemical uptake from physiological and morphological parameters such as body weight, gill surface area, and oxygen uptake.^{40,41} QSAR methods estimate BCF from physical properties of the chemical. The majority of QSAR models have been linear regression models of the log transformations of BCF and the chemical's hydrophobicity (indexed by the octanol:water partition coefficient).²² QSAR models for organic chemicals have generally been developed from data for halogenated organics resistant to biotransformation.^{22,42}

QSAR models have not been available for estimating the bioconcentration of metals. Implicit in QSAR models based on chemical hydrophobicity are assumptions that (1) the octanol-water system is an appropriate surrogate for a fish lipid system, (2) biotransformation is negligible, and (3) bioconcentration is simply the thermodynamically driven partitioning between water and the lipid phase of the animal.⁴³ Several research groups have noted that octanol may not be a suitable surrogate for fish lipids,⁴² and bioconcentration is dependent upon organism physiology and biochemistry (e.g., biotransformation) as well as lipid content and chemical hydrophobicity.^{22,24,39,40}

Figure 32.4 Representation of concentrations over time for chemicals with low and high bioavailability.

32.3.3 Bioavailability of Waterborne Contaminants

Bioavailability of waterborne contaminants refers to the rate and extent of contaminant absorption (Figure 32.4). In aquatic toxicology, contaminant bioavailability of waterborne contaminants has usually been assessed using the rate of uptake rather than the extent of contaminant absorption. A decrease in bioavailability indicates that less chemical reaches the systemic circulation of an organism. Factors influencing the bioavailability of waterborne chemicals include the exposure concentration, the presence of particulates or DOM, and steric hindrance. Generally, chemicals must be in solution (each molecule with a hydration shell) to be transferred across the absorbing epithelium. Thus, some chemicals may not be accumulated because of their insolubility in water. Binding of chemicals to particulates and DOM (e.g., humic acids) results in a decrease in the freely dissolved fraction, which causes a reduction in uptake and bioconcentration.^{6,22} Additionally, DOM may interact directly at the cell surface to affect chemical uptake.⁴⁴

A reduction in bioavailability due to decreased absorption of chemicals with large molecular size or shape is termed steric hindrance. Opperhuizen et al.⁴⁵ suggested that the structure of the phospholipid membrane of the gill epithelium can restrict uptake of hydrophobic molecules of long chain length or large cross-sectional area by imposing a physical barrier to diffusion. Slow solvation (cavity formation) in membrane lipids or in blood may also slow or limit accumulation.⁴⁵ The bioavailability of metals may be reduced because of high affinity binding to ionized sites on the gill surface, which reduces internal diffusion.⁴⁶ Finally, presystemic biotransformation of a chemical during uptake may also reduce bioavailability by lowering the amount of parent chemical reaching the systemic circulation.⁴⁷ Ultimately, the temporal and spatial heterogeneity of the environment as well as physiological/biochemical variability in organisms will make an accurate prediction of contaminant bioavailability difficult, particularly for metals.

32.3.4 Bioconcentration of Metals

Relative to hydrophobic organics, knowledge of the determinants of metal bioconcentration is limited. Water-quality parameters (e.g., pH, water hardness) may influence metal accumulation by affecting metal speciation and form insoluble organic and inorganic complexes that precipitate and become unavailable for bioconcentration.^{48,49} Metals can exist in solution as free ions and inorganic complexes, which will affect bioavailability.⁴⁸ Water hardness may influence metal uptake independent of effects on metal speciation. For example, hardness ions may reduce zinc uptake through a chemical mechanism (e.g., inhibition of metal absorption) or biological mechanism (e.g., reduction in membrane permeability).⁵⁰ Acclimation of an organism through prior exposure to a metal can also lower metal uptake in subsequent exposures.⁵¹ Formation of organic metals (e.g., alkylation)

increases hydrophobicity and causes the metal to bioconcentrate as a hydrophobic organic.^{52,53} For example, Besser et al.⁵² found that an organic form of selenium had BCFs of 16,000 in algae, 200,000 in daphnids, and 5000 in fish.

The bioconcentration of metals varies greatly with the species of organism and the specific metal.^{49,54} Some species can accumulate metals to high levels (e.g., zooplankton), while other species such as fish closely regulate internal concentrations or sequester the metal with cellular binding proteins (e.g., metallothioneins).⁴⁹ Uptake of metals has been frequently reported as a zero-order process in both invertebrates and fish.^{36,55} Spry and Wood⁵⁵ found uptake of zinc to be a saturable process exhibiting Michaelis–Menten kinetics. Thus, saturation of transport processes involved in metal uptake appears responsible for the zero-order uptake of some metals. Size of the organism can also influence metal bioconcentration; there appears to be a negative correlation between body size and metal bioaccumulation.⁵⁶ Metals initially accumulate in the gills of both invertebrates and fish.^{46,50,51,57} The gill surface is negatively charged and thus provides sites for ionic binding with the metal.⁴⁶ Reid and McDonald⁴⁶ speculated that lower-binding-affinity metals such as copper have a greater likelihood of entering the fish rather than binding at the gill surface.

32.3.5 Bioconcentration of Organic Contaminants

Bioconcentration factors of organic contaminants can vary 100-fold with species and environmental conditions. Some of the species variation in bioconcentration may result from differences in size rather than the species or lipid content of an organism.⁵⁸ Lipid content generally varies less than tenfold between species of organisms. Body-size-dependent uptake may be explained by the size dependence of the components of the uptake process.⁵⁸ For example, gill surface area and ventilation volume per unit body weight generally decrease with an increase in body size.^{22,24}

The effects of environmental conditions on bioconcentration have generally been unpredictable. Temperature can have dramatic effects on bioconcentration because of the effect on biochemistry and physiology of aquatic animals.²² For example, Karara and Hayton⁵⁹ found that the bioconcentration factor for a phthalate ester increased from 45 at 10°C to 6500 at 35°C. The effect of the ionic composition of the water on bioconcentration has received limited investigation.²² The pH of exposure water will significantly influence the uptake of weak electrolytes by influencing the concentration of the more rapidly absorbed nonionized fraction.⁶⁰ Other environmental parameters that can affect bioconcentration include salinity and dissolved oxygen.⁶¹

The importance of animal physiology and biochemistry in determining organic chemical accumulation was recognized by earlier workers based on drug kinetics in mammalian species.⁶² Barron²² concluded that absorption of hydrophobic organics across the gill was analogous to inhalation of volatile organics in mammals, where ventilation volume may limit the uptake of highly lipid soluble chemicals. Although membrane permeability as a diffusion barrier had been recognized as a significant determinant of bioconcentration, the importance of blood flow in bioconcentration was only recently recognized.²⁴ Prediction of bioconcentration under various environmental conditions will require an understanding of the influence of physiological and biochemical processes.^{22,61}

32.4 BIOMAGNIFICATION AND TROPHIC TRANSFER

32.4.1 Overview

Biomagnification is the increase in contaminant concentration in an organism in excess of bioconcentration and is caused by the transfer of contaminant residues from lower to higher trophic levels (trophic transfer). Bioconcentration of waterborne chemicals can usually account for contaminant accumulation in aquatic organisms, but many persistent hydrophobic contaminants exhibit increasing concentrations with trophic level in aquatic-based food webs and in piscivorous

birds.⁶³ Further, observations of contaminant concentrations greater than those predicted from BCFs argue for a significant role of biomagnification for chlorinated pesticides, PCBs, dioxins, and many other contaminants.⁶⁴

As in sediment bioaccumulation studies, a BAF can be used to assess the magnitude of accumulation from multiple exposure pathways (e.g., trophic transfer, bioconcentration). The BAF relates concentration in an organism resulting from dietary and aqueous exposures to the concentration in water. To reduce variability, a lipid-normalized BAF can be calculated as: $\mu\text{g contaminant/Kg lipid}$ divided by $\mu\text{g contaminant/liter water}$. The BAF is generally used to assess the magnitude of site- or study-specific bioaccumulation. A biomagnification factor (BMF; e.g., [fish]/[diet]) can also be computed to evaluate an elevation in fish tissue concentrations above contaminant concentrations in prey species.

32.4.2 Dietary Absorption

The fundamental process in trophic transfer of a contaminant is dietary absorption. In fish and mammals, absorption of food occurs primarily in the intestine.⁶⁵ Passive diffusion is the most important process in contaminant adsorption for unionized chemicals or ion pairs, whereas some metals may be absorbed through carrier-mediated or facilitated diffusion.⁶⁶ In general, chemicals that are water soluble and have moderate lipid solubility are normally absorbed best.⁶⁶ Intestinal absorption of hydrophobic contaminants is dependent upon the lipid content of the food source and may exhibit substantial variability in adsorption between individuals and between species.^{66,67} Dietary triglycerides and micelles generally increase bioavailability, and contaminant absorption appears to occur concomitantly with lipid absorption.⁶⁸ Dissolution from the food source may be the rate limiting determinant of contaminant absorption. For example, desorption half-lives from ingested sediments may be greater than a week, which likely exceeds the intestinal transit time of most organisms.⁸ The lipid-associated contaminants are processed into fat vacuoles and chylomicrons (mammals) or very-low-density lipoproteins (fish), which are subsequently released into lymph and the systemic circulation.⁶⁸ The process of hydrophobic chemical absorption into blood is presented in Figure 32.5, adapted from Sire et al.⁶⁹ The food matrix and physiological parameters will substantially affect the dietary absorption of contaminants including the (1) digestibility and composition of food, (2) drinking water rates, (3) environmental temperature, (4) gastric evacuation rates and pH, and (5) activity of gastrointestinal digestive and metabolic enzymes.⁶⁶

Figure 32.5 Schematic representation of the intestinal absorption process (adapted from Reference 68). Arrows indicate the movement of food through the intestinal lumen (L), absorption into the epithelium (E), and transport in the circulatory system (V_b) by passive diffusion and cosecretion with lipids.

32.4.3 Dietary Bioavailability

Dietary or oral bioavailability, defined as the relative amount of chemical that reaches the systemic circulation, is a unitless number between zero and one. Oral bioavailability may be expressed relative to 100% (complete bioavailability). Pharmacological studies calculate drug bioavailability from the area under the blood-concentration-time curve (AUC), referenced to an intravascular dose.³⁰ The AUC approach has been applied to aquatic organisms including lobsters, rainbow trout, and channel catfish.^{69,70} Oral bioavailability is species- and chemical-specific and in aquatic animals ranges from near zero (e.g., tetracycline) to near 100% (e.g., quinoline).^{69,71,72}

In aquatic toxicology, oral bioavailability is frequently termed “absorption efficiency” and is estimated from chemical concentrations in the whole organism.⁷³ In a study of 17 halogenated organic chemicals fed to rainbow trout, Niimi and Oliver⁷³ found that most absorption efficiencies were between 0.5 and 0.8 and decreased rapidly at a molecular volume of greater than 0.3 nm.³ Gobas et al.⁷⁴ found a similar relationship for halogenated organics compiled from data for several fish species: absorption efficiencies were approximately 0.5, then declined toward 0 at log K_{ow} greater than 7. In contrast, Fisk et al.⁷⁵ reported that adsorption efficiencies of hydrophobic organochlorine compounds exhibited a curvilinear relationship with K_{ow} , with maximum values at log K_{ow} 6.9. Causes of reduced bioavailability include incomplete absorption (e.g., poor membrane permeability due to steric hindrance or incomplete dissolution), and biotransformation during the absorption process (e.g., intestinal lumen, enterocytes, liver).

32.4.4 Aquatic-Based Food Webs

32.4.4.1 Biomagnification

Evidence for biomagnification in aquatic-based food webs has generally been restricted to contaminants that are persistent, halogenated, and very hydrophobic. For example, Thomann and Connolly⁷⁶ concluded that 99% of the PCB residues in a Lake Michigan aquatic food web were due to trophic transfer. Based on theoretical modeling, Thomann and coworkers⁶⁴ concluded that food-chain biomagnification will not be significant for chemicals with a log K_{ow} less than 5. Of 23 hydrophobic organochlorine compounds fed to rainbow trout, 20 had BMFs ($[fish]/[diet]$) greater than 1, indicating a potential to biomagnify.⁷⁵ Maximum biomagnification occurred at a log K_{ow} of 7.⁷⁵ Rasmussen et al.⁷⁷ demonstrated that PCBs in lake trout increased with the length of the benthic-based food web and with the lipid content of the tissue. PCB bioaccumulation in algae was consistent with partitioning from water to algal lipids, but uptake was slow relative to growth in biomass.⁷⁷ Axelman et al.⁷⁸ concluded that equilibrium concentrations of PCBs in plankton do not occur in the environment and should not be used in food-web modeling. Multiple studies have reported biomagnification of chlorinated pesticides in marine mammals and birds.^{64,79} Varanasi and Stein³³ concluded that trophic transfer of low-molecular-weight PAHs to higher vertebrates was probable because of low metabolism in fish. Trophic transfer of higher-molecular-weight carcinogenic PAHs — for example, benzo(a)pyrene — was unlikely because of rapid and extensive metabolism by fish.³³ For metals, significant biomagnification in higher vertebrates appears to occur only for hydrophobic alkyl metals because metals are internally regulated by higher organisms.¹¹ Biomagnification of organic contaminants appears most significant for benthic-based food webs and for very hydrophobic chemicals resistant to biotransformation and biodegradation.⁶⁴

32.4.4.2 Food-Web Models

Aquatic food-web models describe the transfer of contaminants from surface water and sediment to higher trophic levels and can be used to predict contaminant bioaccumulation in organisms

exposed by multiple pathways.⁶⁴ The models are composed of a series of equations that calculate contaminant concentrations in predator organisms (e.g., fish) from intake of contaminated food and uptake from water and processes that reduce contaminant concentrations such as growth and excretion.⁸⁰ Contaminant concentrations in sediment and water are typically assumed to be in steady-state equilibrium with the aquatic organisms composing the food web.⁸¹

32.4.4.3 Maternal Transfer

The transfer of contaminants from the maternal parent to eggs and embryos of aquatic organisms represents an additional bioaccumulation pathway. Maternal transfer occurs as contaminants stored in lipids are mobilized and transferred to the gonads, resulting in egg concentrations that can vary substantially with the contaminant. For example, eggs of five species of fish contained 5 to 30% of the total contaminant burden.⁸² In contrast, spawning of brook trout fed TCDD did not represent an important route of elimination, and methylmercury concentrations in walleye eggs represented only 0.2 to 2.1% of the total body burden.^{83,84}

32.5 SUMMARY

Bioaccumulation and bioconcentration are terms describing the transfer of contaminants from the external environment to an organism. In aquatic organisms, bioaccumulation can occur from exposure to sediment (including pore water) or via the food chain (termed trophic transfer). Bioconcentration is the accumulation of waterborne contaminants by aquatic animals through nondietary exposure routes. Biomagnification is defined as the increase in contaminant concentration in an organism in excess of bioconcentration. Biomagnification appears most significant for benthic-based food webs and for very hydrophobic contaminants resistant to biotransformation and biodegradation.

A multitude of factors influence contaminant bioaccumulation and bioconcentration including biological processes (e.g., feeding ecology, living habits, physiology/biochemistry) and the chemistry and composition of the aquatic environment. For organic chemicals, equilibrium partitioning between the organism and the aquatic environment is an important process driving contaminant accumulation. Following absorption of the contaminant, internal distribution and elimination processes as well as partitioning control the rate and extent of contaminant accumulation. Bioaccumulation and bioconcentration of metals is additionally complex because of saturable uptake (even at low exposure concentrations) and regulation of internal concentrations. Estimation and measurement of bioaccumulation has become increasingly important in ecological risk assessment but will remain difficult because of the spatial and temporal heterogeneity of the environment and the biological diversity of aquatic organisms.

33.1 INTRODUCTION

Structure activity relationships (SARs) are comparisons or relationships between a chemical structure, chemical substructure or some physical or chemical property associated with that structure or substructure, and a biological (e.g., acute toxicity) or chemical (e.g., hydrolysis) activity.¹

When the result is expressed quantitatively, the relationship is a quantitative structure activity relationship (QSAR).

Most SARs have been developed for predicting ecological effects of organic chemicals. However, there are some publications that discuss SARs for predicting ecological effects of polymers,² mixtures,^{3–6} ionic organic chemicals,⁷ metals,⁸ and organometals.^{9–12} The majority of SARs for predicting ecological effects have been developed for fish (fathead minnow, (*Pimephales promelas*) and guppy (*Poecilia reticulata*), aquatic invertebrates (e.g., *Tetrahymena pyriformis* and *Daphnia* spp.), and bacteria (e.g., *Vibrio fischeri*, *Escherichia coli* and *Pseudomonas* spp.). However, a few publications describe SARs for predicting ecological effects of chemicals to terrestrial invertebrates and insects.^{13–15}

For SARs that predict ecological effects, this chapter provides some examples, developmental approaches, universal principles, applications, and recommendations for new QSARs. For additional information on QSARs for predicting ecological effects and their applications, readers are referred to other chapters, reviews,^{16–20} and several books.^{21–33} For readers interested in information on QSARs related to human health or human–health–environment interactions, several books are also available.^{33–48}

33.2 EXAMPLES OF STRUCTURE ACTIVITY RELATIONSHIPS

A few examples of SARs are provided here to illustrate how they can be used to predict ecological effects. The first example illustrates how SARs can be used to distinguish clusters of benzaldehydes based on type, number, and position of substituents on a benzaldehyde substructure (Figure 33.1).^{48,49} The second example illustrates how QSARs account for the effects of hydrophobicity on growth inhibition manifested by alcohols, amines, and aminoalkanols.^{50–52} The third example demonstrates how molecular structure within a congeneric series of carboxylic acids affects teratogenicity.^{53–54}

33.2.1 Distinguishing Clusters of Benzaldehydes

Fish LC₅₀ values for benzaldehydes were used to separate clusters of benzaldehydes into two-dimensional space (Figure 33.1). All of the ortho-hydroxy benzaldehydes were more toxic than benzaldehyde (in rectangle), para-hydroxy benzaldehydes, or alkoxy benzaldehydes, because of hydrogen bonding. The ortho-hydroxy benzaldehydes were equally toxic to hexoxybenzaldehyde, which was highly toxic to fish because of its high log octanol/water partition coefficient (log P or log K_{ow}).^{48,49}

33.2.2 Effects of Hydrophobicity on Growth Inhibition Manifested by Aliphatic Saturated Alcohols, Primary Amines, and Aminoalkanols

The classic approach to developing SARs has been to use a congeneric series of chemicals. A congeneric series consists of chemicals with a common functional group or toxicophore but different sizes or shapes of alkyl groups. Thus, the reactivity imparted by the toxicophore is constant, and potency varies with hydrophobicity imparted by the alkyl group. The toxicophores in the examples illustrated here are alcohol, amine, and aminoalkanol functional groups. Examples of QSARs for the congeneric series that consists of alcohols, amines, and aminoalkanols developed with toxicity data for the freshwater ciliate *Tetrahymena pyriformis*⁵⁰ can be seen in Equations 33.1–33.3.⁵¹

Using population growth inhibition of *T. pyriformis* (log IGC50⁻¹) and hydrophobicity (log K_{ow}) data, the following QSAR was developed for aliphatic alcohols:

Figure 33.1 Fish LC₅₀ values of hydroxy, alkoxy, and hydroxy-halogen benzaldehydes, compared to benzaldehyde (in rectangle); arrows are used to indicate fish LC₅₀ values of alkoxy benzaldehydes that exceed 90 mmol/L.

$$\log (\text{IGC}_{50}^{-1}) = 0.80 (\log K_{ow}) - 2.04 \quad (33.1)$$

where IGC_{50}^{-1} is the inverse of concentration (mM) resulting in 50% population growth inhibition as compared to controls, and K_{ow} is the 1-octanol/water partition coefficient.⁵¹

Since the neural narcotic toxicity of saturated alcohols depends only on the uptake of the chemical, the modeling of this mechanism yields a simple hydrophobicity-dependent QSAR. Theoretically, the slope of these models is unity. Deviations from one reflect alterations in bioavailability. In the case of the *T. pyriformis* growth assay, this is the result of two phenomena: volatilization of low-molecular-weight compounds and the binding of high-molecular-weight compounds to hydrophobic components in the medium. To illustrate further, Sinks et al.⁵² developed a QSAR for aliphatic primary amines:

$$\log (\text{IGC}_{50}^{-1}) = 0.72 (\log K_{\text{ow}}) - 1.32 \quad (33.2)$$

A comparison of Equations 33.1 and 33.2 showed that the difference in slopes is minimal, and the difference in intercept is greater than 0.7 of a log unit, with each primary amine being more toxic than its corresponding alcohol. Because of their higher basicity ($\text{pK}_a > 10$), the aliphatic amines are almost completely ionized at physiological pH. Thus, it is implied that the protonated form of the chemical is the active toxicant. The above implication may account for the difference in intercept. Regression analysis of hydrophobicity vs. toxicity for the aminoalcohols yielded the QSAR

$$\log (\text{IGC}_{50}^{-1}) = 0.17 (\log K_{\text{ow}}) - 0.70 \quad (33.3)$$

A comparison of Equation 33.3 with both Equations 33.1 and 33.2 showed both a difference in slopes and a difference in intercepts because each aminoalcohol is more toxic than either corresponding alcohol or primary amine.⁵²

33.2.3 Effects of Hydrophobicity and Molecular Structure on the Developmental Toxicities Manifested by Carboxylic Acids

Developmental toxicity effects of chemicals, especially teratogenic ones, are among the most difficult to determine experimentally. However, test systems such as the Frog Embryo Teratogenesis Assay–*Xenopus* (FETAX)^{55,56} have provided a means of collecting quantitative data for SAR analyses. Since valproic acid (2-propylpentanoic acid) was implicated as a human teratogen,⁵⁷ the developmental toxicity and teratogenic effects of carboxylic acids have received noteworthy consideration. Dawson et al.⁵⁴ developed a QSAR for acute embryo toxicity for a set of carboxylic acids. The resulting QSAR was:

$$\log (\text{LC}_{50}^{-1}) = 0.70 (\log K_{\text{ow}}) - 0.39 (\text{pK}_a) - 0.51 \quad (33.4)$$

where mortality was related to orthogonal descriptors of both hydrophobicity and ionization.

The principal malformation induced in developing frog embryos exposed to valproic acid was microcephaly, with other craniofacial defects also being observed.⁵⁴ Dawson and co-workers also applied QSAR techniques to analyze a data set of 45 carboxylic acids with the dependent variable being the 50% teratogenic effect concentration (EC_{50}^{-1}). The result was the QSAR:

$$\log (\text{EC}_{50}^{-1}) = 0.66 (\log K_{\text{ow}}) - 1.47 \quad (33.5)$$

The addition of the ionization constant as a second variable did not improve the fit of the QSAR for malformation.

Hazard index data for selected acyclic carboxylic acids evaluated in FETAX are presented in Table 33.1. Examination of these data reveal a number of molecular structural features associated with a high hazard index. Specifically, these include the presence of (1) a free carboxyl group, (2) an H-saturated C-chain with the optimal length of five C-atoms, and (3) branching of the C-chain, especially in the 2-position.

33.3 DEVELOPING QSARS

The development of a QSAR starts with a description of the domain. This comprises the identification of a group of chemicals that behave in the same way with respect to the endpoint to be estimated (e.g., a common mode of action [MOA] for an effect QSAR). This group of chemicals

Table 33.1 The Hazard Index of Selected Carboxylic Acids Evaluated with *Xenopus* Embryos

Compound	Hydrocarbon Moiety	Hazard Index
Pentane	CH ₃ -(CH ₂) ₃ -CH ₃	not teratogenic
Acetic acid	CH ₃ -C	1.4
Butyric acid	CH ₃ (CH ₂) ₂ -C	8.4
Pentanoic acid	CH ₃ (CH ₂) ₃ -C	13.2
Hexanoic acid	CH ₃ (CH ₂) ₄ -C	12.4
Octanoic acid	CH ₃ (CH ₂) ₆ -C	4.5
Decanoic acid	CH ₃ (CH ₂) ₈ -C	3.2
Lauric acid	CH ₃ (CH ₂) ₁₀ -C	1.5
2-Pentenoic acid	CH ₃ -CH ₂ -CH=CH-C	6.8
4-Pentenoic acid	CH ₂ -CH-CH ₂ -CH ₂ -C	5.8
4-Pentynoic acid	CH ₂ -C-CH ₂ -CH ₂ -C	7.2
2-Methyl pentanoic acid	CH ₃ -CH ₂ -CH ₂ -CH(CH ₃)-C	13.8
3-Methyl pentanoic acid	CH ₃ -CH ₂ -CH(CH ₃)-CH ₂ -C	8.9
2-Propyl pentanoic acid	CH ₃ -CH ₂ -CH ₂ -CH(CH ₂ -CH ₂ -CH ₃)-C	27.9
2-Ethyl hexanoic acid	CH ₃ -CH ₂ -CH ₂ -CH ₂ -CH(CH ₂ -CH ₃)-C	13.6

Note: Hazard Index = LC₅₀/EC₅₀.

is called the *training set*. The training set is described by identifying a common sub-structure, the class of chemicals to which the training set belongs, structural rules, or MOA information.⁵⁸

The selection of a *training set* is dependent on the skills of the QSAR expert and requires a full range of multidisciplinary scientific knowledge. The domain limits the QSAR's use to the endpoint to be described and the group of chemicals for which it is valid. Furthermore, it limits the valid range of the descriptor within the boundaries of the lowest and highest values of those in the training set. It is also essential that for all the chemicals selected, data on the descriptor (e.g., log P or log K_{ow}, water solubility, etc.) are available.

When a QSAR is developed, it must be tested or verified. For this, a further set of substances, with known measured endpoints, that fulfill the requirements of the QSAR domain should have been identified. This group of substances is called the *test set*.

There are three approaches that have been used in the past to develop QSARs. The approach that is used depends on the nature of the scientific data on which the QSAR will be based.

33.3.1 Statistical Approach

In many cases, the available test results are correlated with a known descriptor or descriptors by statistical evaluations. This statistical approach is used when the understanding of how the descriptor describes the endpoint is either unknown or poorly understood. In aquatic toxicology, this approach appears to have some application, especially when the independent variables are limited to universal descriptors of hydrophobicity and stereoelectronic interactions.^{59,60}

33.3.2 Chemical-Class-Based Approach

The chemical-class-based approach is based predominantly on the assumption that compounds from the same two-dimensional chemical class should behave in a toxicologically similar manner. Consequently, homologous series of chemicals have been used to develop structure-toxicity relationships. For each homologous series of chemicals, it was assumed that toxic effects were imparted by common structural components used in two-dimensional chemical-class assignments. This approach has been most commonly applied to neutral nonionic discrete organic chemicals that have no reactive functional groups. The approach has been used by the Toxics Substances Control Act (TSCA) Interagency Testing Committee (ITC) to organize chemicals into structural classes that may be associated with the potential to cause ecological effects to algae, plants, invertebrates, and vertebrates or the potential to cause specific health effects such as acute, carcinogenic, mutagenic,

Table 33.2 Chemical Classes for Which There are Published QSARs to Predict Ecological Effects

Chemical Class	References
Acrylates	68
Alcohols	69
Aldehydes	49, 70, 71
Amines	72–75
Anilines	76, 77
Benzenes	60, 78
Chlorophenols	79
Epoxides	80, 81

Phenols	77, 91–93
Polyhalogenated aromatics	94

neurotoxic, or reproductive effects.^{61–65} The ITC uses this approach to facilitate review of structurally related chemicals and to examine SARs, but not to develop QSARs. A similar approach has been used by the National Toxicology Program to identify “structural alerts” or structural fragments that are associated with a chemical’s potential to cause cancer in rodents.^{66,67} Chemical classes for which there are published QSARs to predict ecological effects are listed in Table 33.2.

The problem with the chemical-class-based approach is defining a chemical class. This problem is illustrated in Section 33.2.2, where the aquatic toxicity of aminoalkanol (see Equation 33.3) is not predicted well by either the QSAR for amines (see Equation 33.2) or alcohols (see Equation 33.1). Thus, the class-based approach becomes very conservative with models being constructed for a series of toxicants that have the same single functional group or toxicophore and alkyl moieties of varied size. In such series, reactivity is the constant attributable to the functional group, while the methylene groups do not alter reactivity but increase hydrophobicity (i.e., log K_{ow} by approximately 1/2 log unit per group). The net result is a variety of QSARs that predict the toxicity of basic toxicants of varying alkyl chain length but have little application to more complex molecules.

33.3.3 Mode-of-Action-Based Approach

The MOA-based approach is the most reliable approach to developing QSARs. It is used when there is clear evidence for understanding the MOA for a group of chemicals and molecular descriptors that impact a specific biological endpoint. Recently, the ITC has combined the chemical-class-based approach with the MOA-based approach.⁹⁵

Research conducted over the past several years addressing the joint toxic action of chemicals and toxicological responses observed in fish have challenged the notion that QSARs can be reliable based on typical chemical classification schemes.^{3,96–101} Furthermore, an evaluation of the fathead minnow database by Russom et al.¹⁰² illustrates that toxicological classifications based on typically-used chemical classes can be problematic. Many chemical classes are associated with a baseline narcosis QSAR^{103–105} (e.g., ethers, alcohols, ketones, esters, and benzenes) including chemicals acting by a baseline narcosis MOA as well as chemicals acting through an electrophilic-based mode of action (Figure 33.2). Conversely, chemical classes not usually identified as acting by a baseline narcosis mode of action (e.g., the phenols) include chemicals determined to act either through baseline narcosis, polar narcosis, oxidative phosphorylation uncoupling, or electrophilic-based modes of action. Subsequently, QSAR developments and applications have evolved from a chemical-class perspective to one that is more consistent with assumptions regarding MOA.^{106,107} The use of MOA-based QSARs, therefore, requires an appreciation of toxic mechanisms, critical structural characteristics, and chemical properties.¹⁹

Figure 33.2 Observed modes of toxic action associated with fathead minnow 96-hour LC_{50} values as a function of chemical classes. (From Russon, C.L. et al., *Environ. Toxicol. Chem.*, 16, 948, 1997. With permission.)

There are at least three advantages of MOA-based QSARs. One advantage is that it is easier to assess a new substance and identify whether it behaves in the same way as those chemicals in the original domain of the QSAR. A second advantage is that the application of MOA-based QSARs is not restricted to congeneric series of chemicals with similar two-dimensional structures; MOA-based QSARs can be applied to chemicals with different two-dimensional structures but identical MOAs. A third advantage is that with MOA-based QSARs, it may be possible to extrapolate QSARs from one species to another.¹⁰⁸

The problem with the MOA-based approach is determining the specific MOA for a given toxicant. As noted by Bradbury,¹⁰⁹ the assignment of a mode or mechanism of toxic action to a specific toxicant can be a daunting task. This problem is illustrated in Section 33.2.1 and shows how the aquatic toxicity of benzaldehydes varies markedly based on molecular structure. This variability in potency would not have been predicted *a priori*. The reason for such difficulties, as noted by Nendza and Russon,¹¹⁰ may rest on the fact that the MOA of a given toxicant in a given organism depends upon a plethora of molecular interactions, the vast majority of which are not well understood.

33.4 UNIVERSAL PRINCIPLES FOR QSARS TO PREDICT AQUATIC TOXICITY

The establishment of universal principles for predicting aquatic toxicity is far more complicated than for other endpoints. This is in large part due to the availability of four large data sets that

were created specifically for predicting adverse effects to aquatic organisms. These databases contain toxicity results for aquatic effects in the fathead minnow,¹⁰² guppy,¹⁰⁶ *pyriformis*,^{50,60,111,112} and *V. fischeri* (formerly known as *Photobacterium phosphoreum*).^{113,114} In each case, except for *V. fischeri*, the data originated with a single research group using standardized protocols. Moreover, the data derived for a single endpoint (e.g., EC₅₀ or LC₅₀) includes a wide range of molecular structures representing a variety of MOAs.

While modeling approaches used in SARs can be correlative or pattern recognition, the most commonly used approach in aquatic toxicity is the correlative approach, which employs regression analysis. Regression analyses are quantitative in nature and fit the continuous character of the EC₅₀ or LC₅₀ data of the four data sets most often used in SAR development in aquatic toxicology. Regression-type analyses relating the similarity or dissimilarity of one or a few molecular properties with a corresponding similarity or dissimilarity in toxicity has its roots in the work of Hansch and Fujita.¹¹⁵ This methodology is typified by the generic regression model:

$$\log(C^{-1}) = a(\text{hydrophobicity}) + b(\text{electronic}) + c(\text{steric}) \quad (33.6)$$

where C, the toxicant concentration at which an endpoint (e.g., LC₅₀ or EC₅₀) is manifested, is related to a parameter quantifying hydrophobic, electronic, and steric properties.

Nowhere in the SAR arena is the Hansch approach more often the approach of choice than in aquatic toxicity. Moreover, an examination of the literature of the past quarter century reveals that the most useful structure–toxicity relationships for aquatic toxicity are those derived using regression analysis, continuous data for both toxic potency and molecular properties, and three-dimensional, whole-molecule-based descriptors.

Absorption, transport, and distribution of the toxicant are thought of as the toxicokinetic phase. These processes are governed largely by a toxicant's ability to partition between lipid and aqueous phases and dissolution in body fluids. Partitioning and dissolution vary with hydrophobicity and water solubility, respectively. Both of these processes are also influenced by the pH of the system and its components. Passive diffusion is the primary means of transport of most xenobiotics within aquatic systems. While the rate of transport depends on a number of properties, such as hydrophobicity, polarity, degree of ionization, and molecular shape and size, it is often assumed in aquatic toxicity modeling that partitioning of a chemical between aquatic organisms and water can be related to hydrophobicity, with K_{ow} being the most commonly used measure of this hydrophobicity.

The typical endpoints used in predictive modeling in aquatic toxicity are not strictly dependent on highly structured interactions; thus, accurate QSARs based on one or a few descriptors are easily constructed. This lack of structured interaction allows for a relaxation of the constraints on molecular structure imposed by modeling a strictly congeneric series without the trepidation of stumbling upon unexpected disruptions in toxic potency. This is indeed the case with narcosis where, in the case of many chemicals, the most important consideration is the absorption characteristics of the toxicant.^{73,75}

In aquatic toxicology, the physiological and biochemical characteristics of an organism on structure-toxicity relationships are often limited, especially for nonvertebrate species. However, biotic factors control the rate at which toxicants undergo metabolism and thus control the rate at which a given toxicant reaches the site of action. Metabolism itself is controlled by the energetics of covalent bond cleavage as well as the electronic and steric factors governing interaction with the corresponding enzymes. Steric factors (e.g., size and shape) can shield a bond from metabolic attack. Steric factors also relate to ability of a toxicant to pass into or through biomembranes. These factors are important in the global modeling of aquatic toxicity. An example of this is the proelectrophile mechanism of toxic action.¹¹⁶

In aquatic toxicity, interaction with the site of action (i.e., the toxicodynamic phase) is considered to be under electronic or steric control and is typically an electrophilic covalent event.¹¹⁷ More specifically, the majority of the electrophilic interactions associated with aquatic toxicity are controlled by molecular orbital events.¹¹⁸ Therefore, quantum chemical descriptors, especially

frontier orbital energies, are important global parameters for modeling the toxicodynamic phase of aquatic toxicity.

Utilizing quantitative descriptors for passive transport (i.e., uptake by the biophase) and reactivity (i.e., interaction) with the molecular site of action, especially when coupled with multiple linear regression, is a straightforward approach. This tandem of descriptor limitations and methodology typically leads to a model for aquatic toxicity that is easy to understand and often provides a mechanistic basis. In other words, the overall hydrophobic properties of a toxicant (responsible for its toxicokinetics) as well as its electronic, hydrophobic, and steric properties (determine its toxicodynamics) can be captured, for a wide variety of aquatic toxicants, in a very small number of global descriptors.

The seminal work of Veith and Mekenyan¹¹⁹ demonstrated the applicability of the toxicokinetic–toxicodynamic approach to predictive modeling of aquatic toxicity. They modeled fish lethality as a plane in a three-dimensional surface by using the $\log K_{ow}$ to model the biouptake and the quantum chemical property; also, they used the energy of the lowest unoccupied molecular orbital (E_{LUMO}) to model electro(nucleo)philic interaction. The resulting “toxic space” was a continuum, with toxicants showing no evidence of reactive toxicity being distributed along the toxicity- $\log K_{ow}$ facet of the surface. At the same time, toxicants of moderate electrophilicity were distributed in the central area of the plane. Toxicants acting as strong electrophiles or those being respiratory uncouplers were distributed nearer the potency- E_{LUMO} facet of the space.

More recently, the investigations of Karabunarliev et al.⁵⁹ and Schultz⁶⁰ modeled aquatic toxicity data for *P. promelas* and *T. pyriformis*, respectively. Data, while confined to substituted benzenes, represented the neutral narcosis, polar narcosis, respiratory uncoupling, and weak and strong electrophilic MOAs. The fish toxicity model:

$$\log (LC_{50}^{-1}) = 0.62 (\log K_{ow}) + 9.17 (S_{max}) - 3.21 \quad (33.7)$$

where hydrophobicity was quantified by $\log K_{ow}$ and electrophilic reactivity was quantified by the molecular orbital parameter. Maximum superdelocalizability (S_{max}) was similar in terms of slopes, intercept, and statistical fit to the ciliate toxicity model:

$$\log (IGC_{50}^{-1}) = 0.50 (\log K_{ow}) + 9.85 (S_{max}) - 3.47 \quad (33.8)$$

While on the surface Equation 33.8 may appear to be global in nature, in fact, it too is limited in applicability. Equation 33.8 covers a substantial chemical domain of the aquatic toxicity arena.¹²⁰ However, it is not applicable to all quinones,¹²¹ photoactivated toxicants,¹²² carboxylic acids^{123,124} or many aliphatic chemicals.¹¹² Thus, in modeling aquatic toxicity, it is necessary to cover the chemical universe with smaller chemical domains. This requires a separate QSAR for each chemical domain and a means of defining the limits of each domain.

One approach to defining the chemical domains of aquatic toxicity is the development of rules-based expert systems. Rules-based systems build associations and generalizations from relatively small groups of chemicals. Typically, the rules-based expert systems are more limited in their application than regression-based approaches. However, they offer greater interpretability. Thus, combining both approaches may provide a means of improving predictability. Such rules-based systems dealing with aquatic toxicology have recently been described.¹²⁵

33.5 USES OF QSARS FOR PREDICTING AQUATIC TOXICITY

As noted above, most QSARs for predicting ecological effects have been developed for aquatic organisms. Hence, it is more feasible at this time to describe uses of QSARs for predicting aquatic

toxicity than for predicting ecological effects. QSARs for predicting aquatic toxicity have been used by industry and government organizations.

QSARs for predicting aquatic toxicity have been used by industry to promote pollution prevention.³⁰ QSARs for pollution prevention are driven by simple economics. It is simple and inexpensive to use QSARs at any stage of a chemical's presence in the environment. However, it is more cost-effective to use QSARs in the early stages of a chemical's life cycle to predict chemical toxicity, bioconcentration, or persistence potential than after the chemical is incorporated into a marketplace product. QSARs for pollution prevention are used by chemical manufacturers and the government organizations that regulate those manufacturers.

The use of SARs and QSARs by other U.S. government organizations and by global government organizations has been described recently.^{126,127} QSARs for predicting aquatic toxicity have been used by government organizations to screen chemicals for potential toxicity.³⁰ Government organizations that have used QSARs for predicting aquatic toxicity include the ITC, the U.S. Environmental Protection Agency (U.S. EPA), the European Union (EU), and Environment Canada. The use of QSARs for predicting aquatic toxicity by these government organizations is briefly described below.

33.5.1 Toxic Substances Control Act Interagency Testing Committee

The ITC was created to (1) screen and review "existing" chemicals and identify chemicals or classes of chemicals with suspicions of toxicity, but few if any data, (2) add those chemicals or classes of chemicals to the TSCA section 4(e) *Priority Testing List*, and (3) recommend them for testing to the U.S. EPA Administrator. To ensure that the ITC discharged its mandate effectively, the U.S. Congress itemized eight factors in section 4(e) of TSCA that the ITC must consider when recommending a chemical for testing to the Administrator of the U.S. EPA.⁶³ In fulfilling the ITC's mandate, the members of the 15 U.S. Government organizations represented on the ITC have been careful to meet their obligations under TSCA and consider all relevant factors when making a recommendation. With the fifth factor in this mandatory list — "the extent to which the substance or mixture is closely related to a chemical substance or mixture which is known to present an unreasonable risk of injury to health or the environment" — the U.S. Congress clearly demonstrated its desire that SARs and QSARs be considered during Committee deliberations. With the seventh factor in this mandatory list — "the extent to which testing of the substance or mixture may result in the development of data upon which the effects of the substance or mixture on health or the environment can reasonably be determined or predicted" — the U.S. Congress clearly demonstrated its desire that data be developed to predict effects on human health or the environment (i.e., environment-human-health interactions through development of SARs and QSARs).⁹⁵

The ITC used the substructure-based computerized chemical selection expert system (SuCCSES) and SARs to identify numerous chemicals and structural classes of chemicals that are likely to cause aquatic toxicity.⁶¹⁻⁶⁵ A few examples of individual chemicals that the ITC has identified as likely to cause aquatic toxicity include acrylamide, biphenyl, bisphenol A, hexachloro-cyclopentadiene, and tetrabromobisphenol A. A few examples of these structural classes that the ITC has identified as likely to cause aquatic toxicity include aldehydes, alkylphenols, alkylphenol ethoxylates, alkyl phthalate esters, alkyl tins, anilines, antimony compounds, aryl phosphates, benzidine dyes, bromo diphenyl ethers, chlorinated benzenes, chlorinated paraffins, cresols, fluoroalkenes, phenols, siloxanes, toluidine dyes, and xylenes. Data developed as a result of the U.S. EPA's implementation of the ITC's testing recommendations have verified the ITC's predictions.¹²⁸⁻¹³⁰

33.5.2 U.S. Environmental Protection Agency

The U.S. EPA Office of Pollution Prevention and Toxics uses SARs and QSARs in combination with expert opinions for predicting the aquatic toxicity of new chemicals (chemicals submitted to the U.S. EPA under section 5 of TSCA as Pre-Manufacturing Notices or PMNs). The U.S. EPA has

90 days to predict the aquatic toxicity of PMNs, the annual number of which has ranged from a low of 8 in 1979 to a high of 2991 in 1988. The U.S. EPA developed the ecological effects structure activity relationships (ECOSAR) tool for predicting the aquatic toxicity. (<http://www.epa.gov/oppt/exposure/docs>).

33.5.3 European Union

The EU, through the European Economic Commission (EEC), enacted legislative changes that provided an opportunity to use QSARs for screening and priority setting.¹³⁹ These changes in EEC legislation accelerated the need for practical applications of QSARs including the use of QSARs for predicting aquatic toxicity.^{140,141} EEC Directive 93/67/EEC provided an opportunity to evaluate existing data and to develop estimates or predictions to fill gaps of missing data during the evaluation of existing chemicals.⁵⁸ The EEC Technical Guidance Document provided supporting documentation for Commission Directive 93/67/EEC and guidance on using QSARs to estimate fish 96-hour LC₅₀ and daphnid 48-hour EC₅₀ values to predict the aquatic toxicity of nonpolar discrete organic chemicals.^{142,143}

33.5.4 Environment Canada

The recently revised Canadian Environmental Protection Act (CEPA) requires Environment Canada to “categorize” and then “screen” substances listed on Canada’s Domestic Substances List (DSL) to determine whether they are “toxic” as defined under CEPA. Since experimental aquatic toxicity data needed to “categorize” and then “screen” substances are only available for a small number of the substances on the DSL, QSARs and other predictive methods are being considered to provide aquatic toxicity estimates needed to “categorize” and then “screen” DSL substances.¹⁴⁴

33.6 RECOMMENDATIONS FOR NEW QSARS TO PREDICT ECOLOGICAL EFFECTS

The major limitation in the further development and validation of QSARs to predict ecological effects is the lack of data of sufficient depth and breadth on biological endpoints of significance. Germane to this problem is limiting the number of compounds known to exhibit the neutral narcosis mechanism of toxic action. This mechanism of toxic action can be modeled well for a wide variety of endpoints and test systems.

33.6.1 Organic Chemicals

Since most QSARs for predicting ecological effects have been developed for aquatic organisms, it is recommended that additional QSARs be developed for predicting effects of chemicals on terrestrial and sediment-dwelling organisms. QSARs are needed for such organisms because they account for the bioavailability and effects of chemicals in the soil and sediment environments. As such, predicting the hazard or risk of chemicals to terrestrial and sediment-dwelling organisms and their environments may continue to be resource-intensive until such QSARs are available.

Most QSARs for predicting ecological effects to aquatic organisms have been developed for freshwater aquatic organisms (except for those developed for *V. fischeri*).¹¹⁴ While some interspecies modeling of toxicity has occurred for aquatic organisms,¹⁴⁵ clearly there is a need for QSARs to predict the effects of chemicals on estuarine and marine organisms to account for the speciation of ionizable chemicals in brackish and salt waters.

There are no QSARs for predicting effects of chemicals on terrestrial wildlife, i.e., birds and wild mammals. There is a critical need for these QSARs, especially given the high exposure potential of terrestrial wildlife to pesticide active and other formulation ingredients that are

intentionally dispersed to the environment and the potential exposure to industrial chemicals with potential for long-range transport, persistence, bioconcentration, and toxicity.

33.6.2 Organo-Metallic Chemicals

Very few QSAR models have been designed to predict the toxicity of organo-metallic chemicals.⁹⁻¹² All of these models were developed to predict the toxicity of organo-tin chemicals and demonstrated that tri-alkyl tin was more toxic than mono-, di- or tetra-alkyl tin. More QSAR models are needed to predict the toxicity of organo-metallic chemicals.

34.1 GENESIS OF PREDICTIVE ECOTOXICOLOGY

When population centers were small and scattered, human activities often did not impair the surrounding environment. However, as human populations grew, increasing sewage loads and harvesting pressure led to local collapses in the ecosystem services upon which human society depended. Waste processing, provision of potable water, and food production are examples of ecosystem services that were pushed beyond sustainability. The inconvenience and hardship resulting from failures in ecosystem services motivated early attempts at proactive management of the environment, including prediction and mitigation of damage before the fact. The ability to predict environmental outcome has improved. However, the development of robust predictive techniques for subtle damage and larger spatial scales remains challenging.

34.2 APPRAISAL VS. PREDICTION

Ecotoxicology requires an appreciation for different time frames. Successful management requires not only techniques to appraise existing damage in natural systems but also techniques to predict the environmental outcome of proposed actions. Appraisal defines the problem. Prediction allows for prevention of damage before it occurs. Without prediction, environmental management is doomed to react to each crisis after the fact.

Predictive ecotoxicology is distinct from environmental appraisal because often there is no “real world” to survey. “Reality checks” (i.e., characterizations of the accuracy of predictions) are more difficult and indirect for predictive ecotoxicology than in the case of environmental appraisal. Instead, predictive ecotoxicology must rely on models.

The process of predicting risk involves many steps.¹⁻⁴ First, the problem must be defined. What is it that is worthy of protection? While setting goals is the responsibility of society at large, scientists may be called upon both to interpret the significance of changes to the natural world and to operationalize societal goals. Second, a scientific risk assessment compares a prediction of the level of stress that will occur in the environment after some human activity to a prediction of likely biological effects at that level of stress. Third, after the scientific risk assessment has estimated the probability of various adverse effects and the uncertainties of these estimates, these risks are considered along with options, costs, benefits, and political will to arrive at a risk-management plan. Fourth, after a course of action is implemented, the resulting effects in the real world must be compared with the predictions of risk made before the fact. These comparisons serve a quality-control function for environmental management and provide insight into the adequacy of the predictive models and management techniques.

In many regulatory agencies, a commonly accepted framework is used for determining the nature and likelihood of the effects of human actions on the environment. This framework is ecological risk assessment (ERA),^{3,4} which is used to organize ecological information and assess its quality so that management decisions can proceed based on the best information available. Solomon and colleagues⁵ and Giesy and colleagues⁶ provide two excellent examples of the process. Purposes can include predictive applications such as screening new chemicals prior to commercial production, evaluating risks associated with land use changes or exotic species introduction, and ranking the relative environmental consequences of different proposed actions. But ERA is not always predictive.⁷ Other applications of ERA are essentially for appraisal: are present uses of chemicals of concern? The question is not what will happen, but what has already happened. The best instances of ERA for this purpose provide the opportunity to assess the accuracy of predictions by comparing predictions of harm to observations in natural systems. Even though predictive ecotoxicology and ERA are not synonymous, the structure and definitions used in ERA provide a useful framework in which to discuss predictive ecotoxicology.

34.3 OPERATIONALIZING SOCIETAL GOALS

34.3.1 Endpoint Selection

Although society at large sets goals for environmental protection, scientists are called upon to develop efficient ways of measuring change and to interpret the importance of changes in the environment. The relationship between societal goals for environmental protection and scientific methods for assessing the environment have been described by Suter.⁸ Concerns about maintaining quality of life have led to the development of amorphous societal goals. For example, current goals in the United States include: “to promote efforts that will prevent or eliminate damage to the environment and biosphere,” “to maintain and enhance long-term productivity,” to avoid “any irreversible or irretrievable commitments of resources,” and “to restore and maintain the chemical,

Table 34.1 Characteristics Desirable in Endpoints for Appraising, Monitoring, and Predicting Environmental Impact

1. *Biologically relevant*, i.e., important in maintaining biotic integrity
2. *Socially relevant*, i.e., of obvious value to and observable by shareholders or predictive of an endpoint that is
3. *Sensitive* to hazards with a high signal-to-noise ratio
4. Broadly *applicable* to many hazards and sites
5. *Diagnostic* of the particular hazard causing the problem
6. *Measurable*, i.e., capable of being operationally defined and measured using a standard procedure with documented performance and low measurement error
7. *Interpretable*, i.e., capable of distinguishing acceptable from unacceptable conditions in a scientifically and legally defensible way
8. *Cost-effective*, i.e., inexpensive to measure, providing the maximum amount of information per unit effort
9. *Integrative*, i.e., summarizing information from many unmeasured endpoints
10. One for which *historical data are available* to define normal operating range, trends, and possibly acceptable and unacceptable conditions
11. *Anticipatory*, i.e., capable of providing an indication of degradation before serious harm has occurred, early warning
12. *Nondestructive* of the ecosystem
13. One with potential for *continuity* in measurement over time
14. Of an *appropriate scale* to the management goal
15. *Not redundant* with other measured endpoints, i.e., providing unique information
16. *Timely*, i.e., providing information quickly enough to initiate effective management action before unacceptable damage has occurred

physical, and biological integrity of the nation's water."⁸ Scientists are charged with taking these amorphous goals and, based on them, defining assessment endpoints, i.e., formal expressions of actual environmental values worthy of protection. Assessment endpoints may include properties such as sustainable production of various species, retention of soil and nutrients in the ecosystem, maintenance of water supplies, or maintenance of aesthetics or biodiversity. A measurement endpoint — an expression of an observed or measured response to a hazard — is the next step in operationalizing societal goals. While no instrument can measure ecosystem health on a scale from 1 to 100, scientists can determine catch of fish per unit effort or yield per acre, standing crop of preferred species, number of different taxa in an ecosystem, rates of nutrient removal, or rate of flooding. Many examples of measurement endpoints are provided in Section I of this book. These measurable qualities underlie all predictive methods. Obviously, the wider the net is cast in looking for environmental consequences of human actions, the more likely that change can be detected. However, there are inescapable practical limits on how many endpoints can be practically monitored. As such, endpoints must be selected carefully, and criteria for selection of the most efficient and useful endpoints for environmental analyses have been described (Table 34.1).⁸⁻¹¹

34.3.2 Relevance

Among the many desirable characteristics cited is relevance. Relevant endpoints are those closely related to management goals or ecological integrity. While some endpoints are widely valued by society at large (i.e., catchable fish), other endpoints are equally relevant ecologically but less obvious in their value (i.e., status of organisms at the base of the food web). Still other endpoints are clearly irrelevant to many systems because they monitor the response of organisms that do not live in the system or the response to conditions that do not occur in the system. These endpoints are useful only if general properties of living material allow extrapolation from one situation to another.

These extrapolations are the basic tool in predictive ecotoxicology and must be critically evaluated. When endpoints that are far removed from attributes of interest in a particular ecosystem are used because they can be efficiently and crisply measured, a model must then translate the easily measured endpoint into terms of effects on an important attribute. For example, it may not be important to protect the ability of exotic bioluminescent bacteria to produce light in a particular

system. However, luminescence may be a useful endpoint because impairment may be an easily measured indication of potential for adverse effects on more important endpoints. In order to be useful as a management tool, the endpoint in the simple test must be related to environmental outcome in a complex natural system. For example, we must predict impairments in biodiversity from impairments in light production.

The nature of this relationship between endpoints and the degree of uncertainty involved must be characterized. Is it a strong relationship? Is it consistent over stresses? What kinds of predictive errors are likely?

Models have been developed to predict the response of one species to a toxicant from the measured response of another, to predict chronic response from measurements of acute response, and to predict the response to a novel toxicant from measured response to structurally similar chemicals.¹² Each extrapolation from one endpoint or hazard to another more closely related to the problem at hand increases the complexity of the predictive model and adds another layer of uncertainty to the predictions. For example, Barnthouse and colleagues¹² estimated that the uncertainty associated with the prediction of a concentration of concern for a population was within an order of magnitude when life-cycle-toxicity test data were available for the species of interest. However, when prediction involved extrapolations across species, length of exposure, or chemicals, uncertainty approached three orders of magnitude. In addition, these estimates of uncertainty are based on variability of data used for model construction. Additional uncertainty will stem from relevant environmental factors (e.g., pH, hardness, or flow changes) or interactions (e.g., competition, harvesting pressure, or disease prevalence) not incorporated into the model. Predictions of adverse impact on clearly relevant endpoints will more likely be accepted as a sufficient basis for decision-making than those based on other endpoints because there is less extrapolation and less uncertainty.

34.3.3 Signal-to-Noise Ratios

Another scientific problem with operationalizing management goals is that a point exists at which the discriminatory power demanded by increasingly ambitious management goals outstrips the power of the measurement endpoints. Both laymen and scientists can identify and define characteristics of a grossly damaged environment. However, it is more difficult to identify and measure subtle damage in natural systems (Table 34.2) or the characteristics of healthy ecosystems worthy of protection (Table 34.3).

In order to be useful in appraising or predicting environmental impact, the response to an impact must be large enough to be distinct from normal variations. Either the signal (i.e., the change in response to hazard) must be large or the noise (i.e., normal variation) must be small (Figure 34.1). Appraising, monitoring, and predicting extreme damage are easier than doing so for subtle damage because the signal-to-noise ratio is higher. In the case of extreme damage, the magnitude of the

Table 34.2 Characteristics of Damaged Ecosystems

-
1. Loss of sensitive species, decreased species diversity
 2. Increased instability in component populations, greater amplitude of fluctuations
 3. Changes in the size spectrum to smaller organisms
 4. Retrogression to opportunistic species
 5. Decreased life spans, increased turnover of organisms
 6. Increased disease and parasite prevalence, decreased condition
 7. Shift in trophic dynamics, shortening of food chains, and decline in functional redundancy and diversity
 8. Changes in primary production
 9. Decreased efficiency of nutrient recycling and increased loss of nutrients
 10. Decreased efficiency of energy use, increased respiration
 11. Increased circulation of contaminants

Figure 34.1 Differences in signal-to-noise ratios of endpoints in biomonitoring. Part (a) illustrates a high signal-to-noise ratio. The change in response after stress is large, and the response does not vary widely. In this case, it is easy to see the impact of the stress. Part (b) illustrates a low signal-to-noise ratio. The signal (i.e., the change in response after stress) is small, but the response varies widely, so there is a large amount of noise.

impairment overwhelms any natural changes in the ecosystems over time and space. In order to interpret the significance of smaller changes, better information must be available on the normal operating range of minimally impacted systems. The significance of a predicted change can be judged only in reference to the normal operating range in similar, minimally impacted systems. Because natural systems are diverse, patchy, and constantly changing diurnally, seasonally, and successionaly, some change cannot be attributed to hazard.

Better measurement methods will improve the ability to detect small or early impairments in ecosystem health. Endpoints are being screened in terms of their signal-to-noise ratios. Sampling methods are incorporating blocking, compositing, and other techniques to accommodate natural variability.¹³ Multiple relevant variables are being incorporated into dose-response models.¹⁴ In addition, the normal operating ranges for natural systems are being better characterized so that meaningful evaluations of change can be made.¹⁵

34.3.4 Integrating Multiple Effects

Unfortunately, no single endpoint will adequately operationalize all goals for environmental protection. Instead, the multiple effects of a single hazard must be integrated. However, they can be integrated at different stages of a prediction. Some assessments choose one endpoint that depends on the integrity of many responses at lower trophic levels or quicker time scales (e.g., catch per unit effort of predacious, long-lived fish).¹⁶ Other assessments integrate multiple endpoints before

the prediction (e.g., the index of biotic integrity [IBI] or other multimetric indices).¹⁵ Alternatively, independent predictive models can be developed for a variety of endpoints and the information integrated at the point of decision making.

34.4 DEVELOPMENT OF PREDICTIVE MODELS

34.4.1 Dose-Response Models

A scientific risk assessment compares a prediction of the level of stress that will occur in the environment after some human activity to a prediction of likely biological effects at that level of stress. At least two predictive models are involved in this process. In this discussion, predictive models of biological effects are the focus rather than models of environmental fate, but many of the same considerations apply in both cases. Models of environmental fate are well described by Burns and Baughman¹⁷ and Wolfe and Crossland¹⁸ as well as in this book (Chapter 29) and in examples of ERA.^{5,6} The most commonly used models for prediction of biological effects are dose-response curves. The pattern of response over increasing levels of hazard is used to predict the probability and magnitude of response to the same hazard under similar circumstances.

Several types of curves are repeatedly found in studies of responses to stress (Figure 34.2). Figure 34.2A shows a distinct change in the rate of response that constitutes a threshold, that is, a point at which an effect begins to be produced. An example of this pattern of response was observed in bacterial numbers in microbial communities exposed to increasing levels of ammonia.¹⁹ Figure 34.2B shows how a stimulation of response at low doses may serve as a practical threshold when impairment is defined as change in one direction, that is, subsidy vs. stress.²⁰ An example of stimulation of response at low doses has been observed for periphyton production in response to atrazine.²¹ Figure 34.2C shows an asymptotic rate of change in response²² with no absolute threshold; however, at some point, decreases in impairment with decreasing dose may be so small as to be biologically unimportant. In this case, there may be a practical threshold in absence of an absolute threshold. Finally, Figure 34.2D shows a response that changes linearly from background to severe stress levels. There is no discontinuity in the dose-response curve; there is no threshold. This is the pattern described by Woodwell²³ for radiation effects on mutants in *Tradescantia*.

Figure 34.2 Types of dose-response curves. Curve (a) shows an abrupt change in response with dose, i.e., a threshold. Curve (b) shows a subsidy at low doses that may serve as a practical threshold. Curve (c) is asymptotic with a practical threshold. Curve (d) shows no threshold.

34.4.2 Thresholds and Concentrations of Concern

As the power of measurement techniques has improved and the ability to detect small changes has increased, fewer clear thresholds for adverse biological effects are found. Woodwell²³ asked, “Is it reasonable to assume that thresholds for effects of disturbance exist in natural ecosystems or are all disturbances effective, cumulative, and detrimental to the normal functioning of natural ecosystems?” Reports of dose-response curves that are linear down to background levels, like that in Figure 34.2D, undermine sole reliance on estimates of threshold concentrations for environmental prediction and management. If thresholds are an artifact of the statistical power of the measurement methods, then scientists must instead rely on active judgments about the biological importance of the changes involved. This is the basis of the ongoing debate about statistical vs. biological significance of changes and the increasing dependence on regression analyses rather than hypothesis testing to determine concentrations of concern for management.^{3,24} While no-observed effect concentrations (NOECs) appear decisive and do provide an indication of signal-to-noise ratio, they are not necessarily objective and accurate estimates of real thresholds. Reliance on professional judgment of the biological importance of changes is required in both methods for deriving concentrations of concern.

34.4.3 Data Used to Develop Predictive Models

Most predictive models of biological effects of toxic substances are based on toxicity test data or synoptic surveys of natural systems. A toxicity test is an attempt to simulate, under controlled conditions, some of the chemical or physical conditions to which organisms in natural systems might, at least theoretically, be exposed. Synoptic surveys provide a broad overview of conditions in natural systems. The data used to construct predictive models can be characterized along covarying gradients of complexity, spatial scale, time scale, and similarity to appraisals of natural systems (Table 34.4). In natural systems, complexity, size, and time scale increase together. However, in designed systems, complexity and size can be individually manipulated so that small, complex systems and large, simple systems are possible.

There is a countervailing gradient of complexity in the methods by which toxicity test data are applied to the prediction of environmental outcome. The uncertainty involved in prediction increases with the discrepancy in scale between the measurement endpoint and the assessment endpoint or management goal.

An example of a small extrapolation with relatively little uncertainty is the prediction that repeating a simple toxicity test will yield similar results. Larger extrapolations with greater uncertainty include those from species to species and from chemical to chemical. Still larger extrapolations with larger uncertainty are those from one level of biological organization to another, from one ecosystem type to another, or from one extreme of the temporal or spatial scale to another.

While the simplest toxicity tests require more accessory information and the most complex methods for translation into prediction of environmental outcome, the most complex test methods measure endpoints that are most closely related to management goals and are more simply translated into site-specific effects. At the same time, however, toxicity tests with few components provide simpler and less expensive tools for the comparisons used to rank hazards, to discern trends over time, and to link a causative agent with an observed biological impairment. More data from simple toxicity tests are available to decision makers.

Different objectives require different levels of design complexity; thus, data requirements change from one application to the next. For example, screening in order to prioritize management of various toxins may require little complexity and great generality, but prediction of environmental outcome in site-specific situations with low tolerance for error may dictate greater complexity and little generality.

Table 34.4 Covarying Gradients in the Design and Application of Toxicity Tests

Design Complexity	Low <-> High
Few components	<-> Many components
Few endpoints	<-> Many endpoints
Standardizable	<-> Site specific
Replicable	<-> Realistic background variation
Capable of high precision	<-> Capable of high accuracy
Low cost per experiment unit	<-> High cost per experimental unit
Design Scale	Low <-> High
Small experimental units	<-> Large experimental units
Small receptors (e.g., bacteria)	<-> Large receptors (e.g., fish)
Receptor low in biological hierarchy (e.g., cells, populations)	<-> Receptor high, integrating effects at lower levels (e.g., ecosystem dynamics)
Receptor low in phylogenetic hierarchy (e.g., procaryotes)	<-> Receptor high (e.g., vertebrates)
Receptor low in food web (e.g., primary producers)	<-> Receptor high, integrating effects at lower levels (e.g., piscivores)
Endpoint early in progression of impairment (e.g., biomarker)	<-> Endpoint of obvious social and biological importance (e.g., fisheries harvest)
Short observation time in human terms	<-> Long observation time
Short observation time in relation to receptor's life history	<-> Long observation time
Difference in Complexity and Scale between Test and Application	High <-> Low
Endpoints and hazards are qualitatively different from those in assessments of quality in natural systems	<-> Qualitatively similar to those in assessments of natural systems
Bottom-up appraisal of risk	<-> Top-down appraisal of risk
Cause and mechanics known	<-> Environmental effects known
An array of individual tests are combined to provide information to model environmental effects (many experimental units)	<-> A single test is used to predict environmental effects (few experimental units)
Model necessary to translate test results to prediction of environmental effects (with error)	<-> Information directly applied to site-specific prediction (with error)

34.4.4 Examples of Predictive Models in Ecotoxicology

Although the results of a single toxicity test on a “sensitive species” were previously used to predict general environmental outcome, this approach is no longer commonly used. No one species is reliably most sensitive over toxicant and water-quality conditions.²⁵ The uncertainty involved in predictions of environmental outcome based on the response of one species has been judged too high. Models predicting environmental outcome from laboratory toxicity tests on individual species now rely on arrays of data. Rather than trying to find one species that is representative of sensitive organisms in the natural systems, several species are tested, and the tolerance of organisms in general is described from this sample. A tolerance distribution for aquatic organisms in general is modeled from an array of data on the LC₅₀ values or NOECs of the individual species tested. From this model of the tolerance distribution, the number of taxa affected by some concentration of toxicant can be predicted. An example of this approach can be found in the derivation of numerical water-quality criteria for protection of aquatic life.²⁶ The same approach, but using different models for distributions of tolerance, has been used by van Straalen and Denneman²⁷ and van Leeuwen.²⁸

Using arrays of data from single-species toxicity tests to model the tolerance distributions of species in general is a good way to address the variation in sensitivity among the many species

likely to be affected by any discharge; but problems remain. First, the species that can conveniently be tested may not be a random sample.²⁹ Second, there may be considerable difference between the endpoints measured and qualities that are worthy of management protection, resulting in large uncertainties.¹² Third, this approach usually does not incorporate the interaction between species in determining environmental outcome. The potential importance of interactive factors can be seen in validation studies in which predictions from an array of single-species toxicity tests failed to identify significant features of environmental outcome. LaPoint and Perry³⁰ list three interactive factors that significantly affect environmental outcome: (1) differences in actual exposure conditions in the laboratory and field (e.g., mobilization of metals under acidification or microbial methylation of mercury), (2) ability of organisms to avoid the hazard, and (3) secondary effects such as loss of a trophic guild or keystone species.

Interactive factors have been incorporated into predictions in two ways. Mathematical models can incorporate interactions into predictions of outcome, or interactions can be included in toxicity tests. An example of a simulation model of toxicant fate and effects that includes interactions is that described by Bartell and colleagues.³¹ Simulated patterns of production at different naphthalene exposures support the importance of secondary trophic effects in predicting environmental outcome. This approach to prediction is attractive because it is applicable to many different ecosystems and relies on the type of data that is most readily available. However, each of the many extrapolations in such a model adds to uncertainty. Without validation studies comparing predictions to observed effects, the degree of confidence warranted is unknown and suspect.

More complex toxicity tests empirically include interactions between species and maximize the correspondence between endpoints measured in toxicity tests and characteristics worthy of protection. For example, Tolle and colleagues³² compared the predictive accuracy of test systems with varying physical complexity. Flower pot and intact soil microcosms were used to predict the yield and uptake of elements by plants in field plots amended with fly ash. They concluded that microcosms were superior to pots for predicting the dose-response curve for alfalfa, but neither type of test accurately predicted dose-response curves for oats. Niederlehner and colleagues³³ used multi-species toxicity tests to simultaneously evaluate the response of many interacting taxa to cadmium, copper, industrial effluents, and changes in pH. They compared predictions from the multispecies test to arrays of conventional toxicity tests, whole-ecosystem studies, and synoptic surveys and concluded that the multispecies test yielded reasonable predictions of chronic tolerance distributions for aquatic organisms in general, with considerable cost savings.

Even more complex test systems have been used in tests for predicting the environmental effects of pesticide usage.^{5,6,34,35} When simple tests suggest that adverse effects are possible at estimated environmental concentrations, artificial pond mesocosm tests were used to comprehensively evaluate this presumption of risk. By maximizing physical realism and the correspondence between management goals and measurement endpoints, pond mesocosms can convincingly predict environmental outcome.

Synoptic surveys of natural systems can also be used to develop predictive models. Relationships between chemical, physical, and biological data across many systems are examined. As with all correlative approaches, the ability to identify cause and effect is limited. However, consistent patterns across diverse ecosystems are convincing, especially when supported by toxicity test results. Examples of predictive models based on synoptic surveys include the model relating nutrient loading to eutrophication.³⁶ Many predictive models have been developed from synoptic surveys of lake acidity.³⁷ Some of these models predict population-level responses such as the probability of the presence of a valued fish species in waters of various pH. Other models predict community-level effects such as the loss of biotic richness in waters of various pH. In one such study, a model of biotic damage due to lake acidification from a synoptic survey was used to predict total impact on biodiversity of a regional resource resulting from different levels of sulfur emissions.³⁸ That study provides an excellent example of the progression through problem definition, identification of goal, measurement, modeling, and predictive application.

34.5 HOW ACCURATE ARE OUR PREDICTIONS?

A risk assessment depends on at least two predictive models — one for chemical fate and one for biological effects. Obviously, the uncertainty involved in a concatenation of predictions is much greater than in an appraisal of existing damage that relies on direct observation. The degree of uncertainty involved is an important component in decision making based on predictions of environmental outcome.³⁹ The decision maker must evaluate the probability and magnitude of an impact as well as the margins of error implicit in that estimate and the consequences of being wrong.

Validation is the comparison of predictions to observed effects in the real world or perhaps in a surrogate of the real world such as a mesocosm. Without validation studies, any one predictive model is as useful or useless as any other. There is no criterion for selection. Validation studies characterize the error involved in prediction in order to control and improve the quality of the predictive techniques. If environmental outcome cannot be predicted with sufficient accuracy to prevent excessive costs from underprotection or overprotection of the environment, resources must be devoted to improving predictive models. There are different approaches to the comparisons that constitute validation.^{40,41} There are also different judgments about what constitutes sufficient agreement between prediction and appraisal.

A common approach to validation of predictions is a comparison of point estimates or classifications.^{42,43} Typically, if an impairment is predicted from toxicity test results (i.e., the concentration exceeds an NOEC value or other threshold estimate) and a statistically significant impairment is observed at a field site similar in exposure, this is taken as evidence of validity. However, point-estimate comparisons rarely examine the magnitude and, thus, significance of impairments. This approach relies on the existence of thresholds that may or may not be an artifact of statistical power.

Another approach is to correlate the magnitude of the toxicity test response with the response in the natural system.⁴⁴ Because this approach abandons reliance on point estimates of a threshold and encompasses a gradient of effects, it is a more rigorous test of validity. However, a significant correlation means only that the pattern in response is similar in the toxicity test and the natural system. This is surely to be expected, but it is insufficient for validation. It does not indicate that toxicity tests can predict field effects with accuracy sufficient for management.⁴⁵

Regression analysis makes explicit the intention to predict field effects from toxicity test results. The dose-response curves in the predictive method and natural system can be compared directly. The margins of error can be characterized, and differences in accuracy at different magnitudes of response can be described.

Also important to validation is an analysis of errors in prediction. The frequency and seriousness of the consequences of errors in predictions of biological impairment must be identified. There are three steps in the demonstration of predictive validity.⁴⁰ First, predictions of response in the natural system must be made from toxicity tests. Second, these predictions must be compared to actual response. And third, the adequacy of predictions must be evaluated according to a predetermined criterion based on management needs. An example of predictive validation of multispecies toxicity test data using this approach is discussed by Niederlehner and colleagues.⁴⁶

If the system of interest is very large or the biological response occurs over a very long time span, it may not be possible to measure model error in the system of interest. In the absence of empirical determinations of the size of predictive errors, some indication of the relative credibility of alternate models can be obtained from comparisons of the predictive errors of their testable components⁴⁷ or from peer review.⁸ However, it is important to note that even models with large predictive errors can be useful if they are the best tools available. For example, even though weather forecasts are often wrong, they remain useful.

34.6 FUTURE TRENDS

Future developments in predictive ecotoxicology may be focused in several areas. The first area is the development of more robust predictive models for larger spatial scales. For example, the oceans constitute 97% of the planet's water supply. The liquid surface of the planet is substantially larger than the land surface. The spatial scales are enormous, and controls transcend political boundaries to an extent unparalleled for freshwater and terrestrial ecotoxicology problems. Because of the aggregate size of the oceans, the temporal scales are also likely to be equally daunting. Point sources of pollution for the oceans are the world's great rivers, and nonpoint sources include land runoff that goes directly into the oceans and direct inputs from atmospheric deposition. A very readable overview of the challenges involved is provided by Thorne-Miller.⁴⁸

Another major area affecting the development of predictive models in ecotoxicology is the linkage of the precautionary principle with environmental policy. Increasingly, individuals in the United States and elsewhere in the world regard prevention and precaution as "best practices." The precautionary principle calls for preventative and anticipatory measures to be taken when an activity raises threats of harm to the environment or human health, even if significant uncertainty remains in the scientific evidence. The Rio Declaration on environment and development thrust the precautionary principle to the global level in 1992, when the United Nations conference (the Earth Summit) provided a declaration that listed precaution as the fifteenth of 27 principles to guide environmental and development policies. Other countries, such as Germany, introduced what is called "Vorsorgeprinzip,"⁴⁹ which roughly translates as the "foresight principle."

In matters of personal health, a precautionary approach might indicate adoption of additional exercise, diets higher in fiber, meditation, and avoiding excessive use or even any use of tobacco and, to a lesser extent, alcohol (since some wine, for example, may have health benefits). In matters of environmental health, a precautionary approach leads to an increased attention to pollution prevention.

The exact role that ecotoxicology will play in the implementation of the precautionary principle in international law is just beginning to emerge.⁵⁰ Lyons and colleagues⁵¹ suggest one means of operationalizing the precautionary principle in the management of chemicals. They believe that it is possible to balance the dual societal expectations of a clean and healthy environment and access to technological developments. Such important issues are addressed as the misuse of the precautionary principle to create unjustified barriers to trade and also the unacceptability of a situation in which all countries had to be bound by the lowest standards of human health and environmental protection.

34.7 CONCLUSIONS

Prediction of environmental outcome is different from appraisal of existing damage. In prediction, the dependence on a model is absolute. There is often no way to check the accuracy of prediction through field survey. However, accuracy checks are essential in order to make sure that predictive techniques are adequate to meet management needs. Validation studies compare predictions to appraisals of damage in natural systems. Through these comparisons, the magnitude and significance of predictive errors can be evaluated. If the potential costs of acting on imperfect predictions are too high, then predictive methods must be improved.

There are several areas in which methods for predictive models can be improved. In the absence of validated models for extrapolating between endpoints, the correspondence between measurement and assessment endpoints should be maximized. A suite of the most relevant endpoints with good signal-to-noise ratios must be identified. Sole reliance on estimates of thresholds must be replaced with evaluations of biological significance of changes relative to normal operating ranges. Where many societal goals must be addressed, multiple endpoints must be monitored. Techniques for

integrating multiple endpoints must be developed. Validation studies must characterize predictive accuracy of various techniques and evaluate the potential costs of errors. The efficiency of test methods must be judged not just on testing costs but also on the costs of acting on that information. If the test method is inexpensive, but predictive inaccuracies lead to environmental damage or unnecessary treatment, the total cost is too high. Areas of extrapolation and errors involved should be clearly communicated to decision makers.

While uncertainty can never be eliminated, society and its representatives must make decisions now on various risks with whatever methodologies are available. Predictions must be made even as the methodologies improve. This is similar to what George Bernard Shaw is reported to have responded when asked what he thought of life: "It is preferable to the alternative." The application of existing methods for predicting environmental outcome has improved environmental quality. Improved methods will reduce costs and answer the needs of increasingly ambitious management goals.

35.1 WHAT IS A POPULATION MODEL?

A model is a simplification of a real system that is used to provide some insights into the system. Population models are often (although not always) formulated as a set of rules or assumptions, expressed as mathematical equations, that describe change in population size over time as a consequence of survival and reproduction, and they include external factors that affect these characteristics. A model simplifies a system, retaining essential components while eliminating parts that are not of interest. Ecology has a rich history of using models to gain insights into populations, often borrowing both model structures and analysis methods from demographers and engineers. Much of the development of the models has been a consequence of mathematicians and physicists seeing simple analogies between their models and patterns in natural systems. Consequently, one major application of ecological modeling has been to emphasize the analysis of dynamics of often complex models to provide insights into theoretical aspects of ecology.¹

Population models are also an intrinsic part of experimental studies and population management. Prediction of future population dynamics in the context of a model is an essential component of understanding the consequences of changes in demographic parameters such as survival or productivity. The model provides the context for assessing population consequences of environmental influences on the demographic parameters. Obviously, any population manager needs the integrative and predictive ability of models to assess the consequences of management, and the extensive use of models in population viability analysis² (PVA) and in management of exploited populations³ reflects this need. Adaptive management⁴ is explicitly model-based in that models provide a basis for evaluating alternative management actions and are revised and updated based on the monitored response to management.

These practical uses of models have created a great deal of interest in both the process of modeling and the estimation of parameters and model structure. Modeling efforts can now draw upon a variety of books and other published works on modeling^{5,6,7} and computer software packages for modeling (e.g., Ramas Software⁸). Practical aspects of estimation of survival and reproduction parameters for animals in the field have also been the subject of extensive development,⁹ and general estimation programs for survival rates, such as MARK, are now available on the Internet.¹⁰ Finally, papers such as Nichols et al.¹¹ provide a good example of modeling efforts that integrate existing data into a population model, show how changes in elements of the model affect the theoretical population, and discuss the practical consequences of the model structure in the management of a species. The relevance of population modeling to toxicological studies is demonstrated by increasing numbers of modeling papers appearing in journals specializing in toxicology.^{12,13}

In this chapter, we discuss some of the uses of population modeling for toxicological studies and review the basic ideas of population modeling. After reviewing some of the terminology and types of population models, we discuss (1) the use of modeling procedures that assume that populations can be grouped into discernible age classes, and that survival and fecundity rates can be measured over intervals for these groups; (2) methods for analyzing the stable population attributes of these models; (3) methods for assessing the effects of changes in the parameters of

the models; and (4) applications of the models to evaluation of the effects of changes in the demographic parameters. These discrete-time, discrete-age class models are commonly used for vertebrates. We also briefly review the analysis of other kinds of models, such as individual-based simulation models and time series models, and discuss the uses of intervention analysis to assess the effects of a given toxin on a population. And, because models are useless without reasonable estimates of parameters, we review methods of obtaining reliable estimates of parameters and relationships used in the model. Our discussion and analysis are somewhat idiosyncratic, and further information and more general expositions on the topic can be found in several textbooks.^{5,7}

35.2 HOW ARE MODELS OF USE IN ECOTOXICOLOGICAL STUDIES?

For ecotoxicological studies, models have several roles:

1. Field and laboratory studies can provide information on how pesticides or other contaminants affect survival and reproduction.¹⁴ It is often unclear how a specific change in a demographic parameter affects the overall dynamics of the population, as some changes may have little effect on the overall population growth rate while others may have relatively large effects. After survival and reproduction parameters are estimated, models provide a context for examination of population effects of changes in the population parameters. Once the model is developed, it can be tested to see if it does provide a reasonable analogue to the dynamics observed in nature, and the stable population attributes of population growth rates, age distributions, and reproductive values can be estimated.
2. If the model is a realistic mimic of nature, it can be used to predict the possible effects on the population of changes in survival and reproduction rates. Changes in survival and reproductive rates, such as those caused by contaminants, can be hypothesized, and the effects of the changes on growth of the population can be assessed, both analytically from mathematical analysis of the model and through simulation of the model with computers. Direct analysis of models using mathematical procedures can be extremely complex. Analysis of the sensitivity of rates of population growth to changes in the components of the model has traditionally been an important, and sometimes controversial, part of population modeling. PVA seeks to predict extinction probabilities for declining species from models.²
3. Modeling provides a logical way of summarizing relevant information regarding the population of interest¹⁵ and is therefore a reasonable way of sorting and summarizing existing information, identifying gaps in knowledge, and directing future research. It often becomes apparent early in the process where additional research is needed to supply information to the model.¹⁶ Developing a quantitative model also requires explicit statement of model assumptions, which can then be tested through appropriate data gathering and experimentation.^{15,17}
4. In toxicological studies, it is generally difficult to take information from laboratory and limited field studies and extrapolate to population effects in natural situations. Modeling provides one way of integrating the information and predicting population response. However, uncertainty still exists in translating simulation and analytical results from models to field situations. The adaptive management paradigm is an important philosophical advance that integrates management, modeling, and population monitoring information to increase our understanding of causal factors that influence population change. In adaptive management, it is assumed that uncertainty exists in population response to management and that models can be developed to predict the outcome of management activities (e.g., a demographic model that predicts the population response to a pesticide application).

Often, the model structure is not well defined, and alternative models can be formulated that provide different predictions of the population response. We use our best information on which model is appropriate to predict the population response and then conduct the management. After management, we monitor the population to determine the response and establish which model best predicted the response. The system is adaptive in that future predictions are then based on the best model, and the management helps us determine which model is most likely. This model-based

approach to extracting causal relationships is appealing in that it avoids both the weak inference characteristic of association analyses based simply on monitoring data and the reductionist approaches associated with laboratory or limited field studies. Adaptive management has been implemented in fisheries⁴ and in waterfowl management³ and is advocated as an alternative to PVA, especially when uncertainty occurs in model structure and parameter estimates.² It is likely that adequate understanding of the role of toxins in population dynamics of widespread species will require use of a model-based adaptive-management approach in which toxins are modeled in conjunction with other exogenous factors that influence the populations.

5. Many alternative forms of population modeling can be used in toxicological studies, and new modeling methods, such as neural networks,¹² are being applied to toxicology studies. Many monitoring programs are of potential use for correlation studies of toxicology, and in these programs population change is frequently modeled from a series of population estimates. The effects of introducing a pesticide to the population can be directly assessed using time-series analysis methods. This modeling of population changes directly from population size estimates uses estimation procedures from the statistical field of time-series analysis¹⁸ and has only infrequently been used in ecological research.¹⁹

35.3 CONSIDERATIONS IN MODEL BUILDING

35.3.1 The Iterative Nature of Modeling

We assume that readers of this chapter will be interested in the general question of how the presence of toxins in the environment modify the population dynamics of a species. Why do we need a model to address this question, when we can evaluate the presence of toxins on individual survival and productivity rates and possibly even detect direct effects of toxins on population sizes of animals? It is easy to detect consequences of toxins for survival and reproduction, but evaluation of these effects at the population level is difficult. A model provides a framework for specifying the effects of the toxins on demographic parameters in the context of other factors that influence population dynamics, allowing investigators to evaluate the possible consequences of toxins for the populations. This integration and extrapolation of information is a critical component of modeling and opens the door to both simulation and analytical studies of the population effects of toxins; in addition, it provides the basis for prediction and information updating needed for adaptive management. However, models are abstractions, and care is needed in developing and updating models to ensure that they are reasonable descriptions of the systems of interest.

To address any question using a model, we must (1) develop a preliminary model of the population dynamics of the species, (2) estimate the parameters of interest, and (3) validate the model using additional information from the population. Obviously, no model is complete, and often the steps will be repeated many times as new information about the population becomes available. Remaining uncertainties in the model can be retained by considering a model set in which alternative models that embody the different assumptions are developed. Adaptive management methods explicitly allow for use of future population information to identify the most likely model from the set.³ After the model has been shown to be appropriate for the population, we can use the model to evaluate the dynamics of the population. The effects of toxins on the population can be simulated by changing the values of parameters in the model that are likely to be affected by the toxins and observing the consequences to the dynamics of the model or by modeling the effect of the toxin explicitly within the model.

35.3.2 What Type of Model Is Appropriate?

A large number of model structures exist. Models can be very simple and designed to give general insights into population processes, or they can be exceedingly complex, if they are needed

to evaluate a specific situation. They can be individual-based, in which individual animals are characterized by a vector of state variables and their probability of surviving and reproducing depend on the values of these variables, or aggregated, in which groups of animals are assumed to have similar characteristics and common survival and fecundity rates. Some models have analytical solutions in which an equation can be written for equilibrium population sizes, while other models can be analyzed only through computer simulation. Finally, models can be indexed by discrete increments of time, in which the population is only defined at specific points in time, or continuous, when the population is defined at all times. The appropriate model structure is a consequence of the characteristics of the modeled population, the type of information available for the population, and the desired product.

Selection of the model structure should be guided by both the goals of the modeling exercise and the practical constraints of the existing data. Individual-based models allow each individual to have a series of attributes that could influence its survival, and therefore many opportunities exist for evaluating the influence of the environment (as shown by the values of the attributes) on survival. One difficulty in developing these models, however, is that we often do not know how the attributes influence individuals, so the model becomes a series of guesses with little predictive value. Instead, we usually estimate survival and fecundity for groups of animals, and models that are based upon age classes are more relevant to those data.

Several works provide extensive background into appropriate formulations of model structure.^{5,7} The model-building process involves clearly defining (1) the system of interest in space and time; (2) state variables, such as population size, that the model parameters act to change over time; (3) endogenous variables that influence the population and are intrinsic to the system and can be managed; (4) exogenous variables that are outside the system and cannot be managed but also influence the population; (5) a transition equation that is used to predict the change in state variables over time; and (6) a time scale of the modeling effort.

35.3.3 Model Output

Once a model is constructed, outputs from the model are used first to verify and validate the model, to judge the success of the modeling effort based on existing information about the population. Once the model is documented to be technically correct and an accurate reflection of the actions of the population under known conditions, it can then be used as a predictive tool to evaluate possible population-level effects of toxins. Several characteristics of the model population that might be affected by toxin-induced changes in survival or reproduction rates might be of interest, depending on the nature of the model and the objectives in building the model. Some of these are applicable to virtually all population models, others to only a few.

In discrete-time demographic models, a characteristic of interest is the asymptotic finite rate of population increase, λ . Estimates of λ indicate whether the population is decreasing, stable, or increasing. Other characteristics that might be of interest, particularly in stochastic models, include probability of extinction or pseudoextinction, average population size over time and the associated variation in population size, and average recovery time following perturbation.²⁰ Pseudoextinction differs from extinction by being the probability that population size will decline to a specified positive value rather than to 0.²⁰ Many types of contaminants affect wildlife populations as a short-term source of mortality (e.g., Blus et al.²¹). The time required for a population to return to pre-effect size following a short-term phenomenon could be of interest in toxicological investigations.

35.3.4 Range of Applicability

In obtaining reliable estimates of model inputs and their variances, it is important to clearly define the system defined by the model, which includes species, habitat, region, etc. Following this, the sample unit for the various model variables must also be identified. For example, the desired

range of applicability for a small mammal population model might be *Microtus* sp. populations in all areas of a specific habitat type (e.g., grasslands) within a physiographic region (e.g., coastal plain). The sampling unit within these grassland areas might be trapping grids where a capture-recapture procedure is used to estimate survival rates.

35.3.5 Sources of Variability

Several sources of variation might be considered when estimating precision of model outputs.

Total variability associated with estimates of parameters used in models results from process variation (i.e., inherent geographic or temporal variability) within the range of applicability (even if all possible samples within the region were measured), sampling variability (because not all samples are measured), and measurement variability (within a single sample point the parameter might not be known exactly) (Skalski and Robson,²² Burnham et al.,²³ Wisdom et al.²⁴). It is important to identify and, if possible, to estimate the magnitude of all sources of variability affecting model output variables. In the small mammal example, survival rates estimated at each trapping grid have an associated, model-based variance estimate.²⁵ This is an estimate of the measurement error associated with a single data point. However, this estimate does not contain all of the variability associated with survival-rate estimates for the region. Process and sampling (intergrid) variation in survival rates is likely to be a large component of the variability. For this reason, a single sample grid, although it provides an estimate of one source of variability, would not be sufficient for many purposes. Replicated grids in space and time are necessary for estimating the sample variance component²⁶ (Burnham et al.,²³ Skalski and Robson²²). Not all types of variability will be applicable or relevant to all models. For example, if a model were to apply only to a small population covered by a single trapping grid, the model-based variance would be the estimate of sampling variation as well as measurement variation.

An additional source of variability is that associated with estimating relationships between variables. Uncertainty associated with these estimates also affects the variability of model outputs.

35.3.6 Sensitivity Analysis

Sensitivity analysis is used to determine which of the model parameters have the greatest effect on the outputs of interest. Sensitivities are important to know, for two reasons. First, if the model is a good approximation of the real population of interest, components in the model that are highly influential in shaping model outputs might also be the factors that influence the actual population, and knowledge of the importance of components will suggest effective management strategies. Second, sensitivity analyses can give insights into how to construct and improve the model. Elements of survival and reproduction that most influence population dynamics should be estimated with the most precision, and relative sensitivities can guide efforts to generate more precise estimates of variables or relationships, to generate parameter estimates from other locations to expand the region of applicability, or to develop improved measurement procedures.

Two general categories of sensitivity analysis are useful in investigating the characteristics of population models, which we call *structural sensitivity* and *statistical sensitivity*.

Structural sensitivity estimates reflects inherent model relationships without regard to variability associated with estimates of model parameters. Often, mathematicians will conduct local sensitivity analyses on models. In these analyses, the effects of adding a very small value to parameters on model output are assessed analytically.^{27,28}

Statistical sensitivity determines which model variables have the greatest effect on the model output because of the precision with which they are estimated.^{24,29} Even if a component of a model (such as survival rate) does not have great structural sensitivity, variability resulting from sampling and measurement processes could greatly affect the model. Model variables estimated with high variability could produce large changes in model output by chance alone. In some sense, statistical sensitivity measures reliability of model outputs as a function of the data quality of the input variables.

As discussed in the preceding section, variability in estimates of model variables can result from several sources, including measurement variation, sampling variation, and process variation. Examining sensitivity of model output with respect to each source of variation that applies to that particular model could be informative.²⁴ For example, variables highly sensitive to measurement variation would be good candidates for increased effort to achieve more precise estimates or to develop better measurement procedures, and variables sensitive to sampling variation might suggest larger samples. In addition, sensitivity to process variability could indicate where caution is needed in applying the model to different areas or populations.

All of the sensitivity analyses discussed above are contingent on a fixed model structure and emphasize variation in the magnitude of the variables. However, one could also think of model sensitivity in terms of changes in model structure. Simple models incorporating only survival and fecundity rates are often not accurate, but little is known about the structure of density dependence and other associations among model components. Sensitivity analysis can also investigate variability induced in the model as a consequence of changes in model structure. For example, the consequences for population growth rates of two different models for density dependence could be explored by sensitivity analysis of the two alternative models under different conditions. This model uncertainty is an explicit component of adaptive management. Often, model sets are developed that embody differing assumptions about the model structure. The predictive abilities of each model in the set are “tested” by management, and our understanding of which model best fits the system is updated over time by evaluating the outcome of the management.^{3,4,7}

35.3.7 Estimating Parameters and Testing Assumptions

When a preliminary model has been developed, reliable estimates of model parameters and relationships must be obtained whenever possible. Using models with only poorly estimated parameters or guesses at relationships is largely an academic exercise. Detailed and complex analyses of such models reveal only information regarding the dynamics of the model, and little or nothing about the dynamics of the population of interest. As was previously discussed, models are a set of assumptions expressed as equations; using data, experimentation, and adaptive management to evaluate the validity of these assumptions is another important component of the modeling process. Testing of assumptions allows for informed refinement of the model structure.

35.4 DISCRETE-TIME POPULATION MODELS

We begin our discussion of specific models with the simplest of models, a difference equation model for a population without age structure. In this model, we specify the state of the population at some time (generally denoted as t) and a set of rules that govern the transition of the population from its state at time t to that at a future time $t + 1$. This leads to the equation

$$N_{t+1} = \lambda N_t \quad (35.1)$$

where N_t is the number of animals at time t , and λ is the finite rate of increase. In this simple model, the only information one has on the dynamics of the population is the size of λ : if $\lambda = 1$, the population is stationary; if $\lambda > 1$, the population is increasing exponentially; and if $\lambda < 1$, the population is declining.

As written in Equation 35.1, this model provides little insight into factors that influence change in population size, and the only way to estimate λ is from direct observation of population counts at different times. Although modeling can be done from population counts (we discuss the potential for this in later sections), demographic analyses usually attempt to divide λ into parts that represent the four basic causes of population change: births, deaths, immigration, and emigration. We can

rewrite λ in terms of births and deaths to provide a set of rules for the projection of population size from t to $t + 1$.

For example, we could specify that an individual in the population at t has to survive with probability P to still be in the population at time $t + 1$ and that individuals reproduce right before time $t + 1$ to produce F young/adult in the next period. If this occurs,

$$N_{t+1} = PN_t + PFN_t = P(1 + F)N_t = \lambda N_t \quad (35.2)$$

Alternatively, we could specify that an individual could survive with probability P but reproduce right after count to produce F young, which then survive with probability P' until the next period. In this case,

$$N_{t+1} = PN_t + FP'N_t = (P + FP')N_t = \lambda N_t \quad (35.3)$$

Consideration of these models suggests that we must make several assumptions for these structures to accurately model the population:

1. The interval of time t to $t + 1$ must be defined in terms of the life cycle of the organism of study. Often, this interval refers to the time between annual reproductive events (i.e., generations). This implies that births within the interval must occur at the same time, which is referred to as a birth pulse. For white-tailed deer (*Odocoileus virginianus*) in Maryland, for example, young are born during a relatively restricted time in spring, and the natural interval is 1 year.
2. The model requires that we set a time of census, which specifies the time at which we reference the population relative to when the birth pulse occurs. The two formulations of λ presented above differ in time of census relative to when the animals breed. The first case is called a *post-breeding census*, and the second case is the *prebreeding census*. To actually apply these models to a real population, choice of census time is critical in determining the structure of the model and what has to be estimated.
3. To make general statements about population parameters, the model requires that survival and fecundity rates are constant over time. Assumptions of a stable population are critical for the validity of this type of model because analyses of the dynamics of the model are valid only if the model is appropriate for the data. The assumption of a stable population can be tested via estimation of parameters. If λ changes over time, it must be indexed by time (λ_t), which introduces a great deal of complexity for analysis of the model. This can be accommodated by either assuming a model for changes in λ over time, treating the survival and fecundity rates as random variables that have variances, or modeling changes in survival and fecundity with covariates.
4. We must also assume that all individuals survive and reproduce at the same rates. In practice, N is often not homogeneous, and the simple model (Equation 35.1) must be extended to allow for age groups or other stages in the population that differ with regard to survival or fecundity. One major source of heterogeneity is sex, and population models are generally constructed for females only.

The ramifications of these assumptions, and the consequences of their violation, have been well described (e.g., Caughley,³⁰ Caswell⁵). Some of them are relaxed somewhat by developing more complex models that incorporate age-structure or density dependence, and some can be tested by estimation of model parameters. However, adding complexity (and realism) to the model complicates both estimation of the parameters in the model and analysis of the dynamics of the model. The goal of most analyses is to fit the simplest model that accurately describes the population. Ideally, the result is a model complex enough to mimic the population of interest, while being simple enough so that its workings are understandable.

35.4.1 Adding Realism

35.4.1.1 Density Dependence

Observation of real populations indicates that population size changes over time, but populations never experience exponential growth or decay for very long. Therefore, it would be reasonable to

make λ dependent either on time (λ_t) or on population size λ_{N_t} . One reasonable elaboration of Equation 35.1 would be to incorporate a density-dependent effect, so that the population would be limited at some level k , or

$$N_{t+1} = N_t e^{r(1-N_t/k)} \quad (35.4)$$

This simple nonlinear difference equation can have extremely complex dynamics for certain values of r and k , and the possibility that natural systems with these complex (chaotic) dynamics could be modeled by these simple equations has been the topic of much discussion in recent years.³¹ Proponents of chaos theory suggest that other modeling efforts could miss this crucial dynamical feature (e.g., Schaffer³²). Generally, it is claimed that the presence of these chaotic systems can be detected from long time-series of population counts, and much controversy exists regarding the ability of these methods to detect chaos in the presence of sampling error in the counts. Consequently, this philosophical approach to modeling may be of limited value to applied studies of the effects of toxicants on wildlife populations.

There are ways of incorporating density dependence into models that do not produce chaotic results, and even models that produce chaos under certain parameter values are stable under other conditions. In the models we discuss later in the paper, there are values of parameters for which the model is stable. We also (briefly) discuss density dependence in more complex models and review some of the nuances involved in the estimation of density dependence in nature.

35.4.1.2 Age Specificity

It is unlikely that all individuals in a population have the same λ . Different individuals have different probabilities of surviving and reproducing, hence N_t is often divided into groups, such as age classes, members of which have similar survival and fecundity rates. To model this case we use several simultaneous difference equations, which are usually presented as matrices, or

$$N_{t+1} = \mathbf{A}N_t \quad (35.5)$$

N_t is a vector of numbers of animals in each age class, or $N'_t = [n_{1,t}, n_{2,t}, \dots, n_{m,t}]$, (the prime indicates transpose), and the matrix \mathbf{A} is composed of fecundity and survival elements that project the number of animals in each of the M age class from time t to time $t + 1$. This model is often called the Leslie matrix and was proposed by Lewis³³ and Leslie.³⁴ Note that \mathbf{A} is not subscripted, suggesting that it is valid for any time. This is a critical assumption that will be discussed later.

Some care is necessary in developing the elements of the matrix \mathbf{A} , and a good deal of confusion exists in the literature regarding the definition of age classes and transitions between age classes. The elements determine the contributions of each age class to all other age classes from a specific time (the time of census) to some time in the future. As with λ in the simple difference equation, the structure of \mathbf{A} , and consequently what features must be estimated to construct \mathbf{A} , depend on when the time of census occurs relative to the birth pulse.

Noon and Sauer²⁸ discuss the structure of matrix \mathbf{A} and the numbering of the age classes at time of census for pre- and post-birth-pulse censuses. They suggest that age classes be labeled as the number of intercensus intervals that animals in the model have lived. For prebreeding censuses, animals in the first visible age class have lived one interval, while for post-breeding census the first age class is newborns of age 0. Survival is indexed by the age class at the start of the interval, and fecundity is indexed by the age class at the time births occur. We outline the structure of the matrix \mathbf{A} for pre- and post-breeding censuses (Figure 35.1).

a. Pre-Breeding Census

$$N_t = \begin{pmatrix} n_1 \\ n_2 \\ n_3 \end{pmatrix}, \quad A = \begin{pmatrix} s_0 p_1 & s_0 p_2 & s_0 p_3 \\ s_1 & 0 & 0 \\ 0 & s_2 & 0 \end{pmatrix}$$

b. Post-Breeding Census

$$N_t = \begin{pmatrix} n_0 \\ n_1 \\ n_2 \\ n_3 \end{pmatrix}, \quad A = \begin{pmatrix} s_0 p_1 & s_1 p_2 & s_2 p_3 & 0 \\ s_0 & 0 & 0 & 0 \\ 0 & s_1 & 0 & 0 \\ 0 & 0 & s_2 & 0 \end{pmatrix}$$

c. Post-Breeding Census, Stage-Based

$$N_t = \begin{pmatrix} n_0 \\ n_1 \\ n_2 \\ n_3 \end{pmatrix}, \quad A = \begin{pmatrix} s_0 p_1 & s_1 p_2 & s_2 p_3 & s p_3 \\ s_0 & 0 & 0 & 0 \\ 0 & s_1 & 0 & 0 \\ 0 & 0 & s_2 & s \end{pmatrix}$$

Figure 35.1 Leslie matrices for (a) pre-breeding and (b) post-breeding censuses. The matrices project the age classes from time t to time $t + 1$, and survival rates (s) and probabilities of individuals reproducing (p) apply to the age class i for the interval, with survival always indexed to age class at start of interval, but reproductive rates are indexed by the age class at the time of adjacent census. A simple stage-based variation, in which survival and reproductive rates become constant after age 3, is presented in (c). We also indicate the vectors of age classes, showing the number of visible classes at the time of census.

35.4.2 Stable Population Analysis

The population change defined by matrix A is dependent on the number of animals in different age classes, and λ will differ as the age structure of the population changes. However, under certain circumstances, matrix A can be “solved” to provide information on the long-term dynamics of the population. If the matrix A is correct in that the structure is appropriately defined and the component survival and fecundity rates correctly estimated, over time the original age structure is lost, and the matrix defines both the long-term growth rate of the population and the asymptotic structure of the population. This property is called *ergodicity*, and if it occurs, we can use matrix theory to analyze the structure of A , which provides information on asymptotic rate of increase, stable age

distributions, age-specific reproductive values, and the effects of changing elements of \mathbf{A} on population growth rate.⁵

In a stable population, the rate of change from year to year will become constant. This growth rate is analogous to the λ of Equation 35.1 and is a structural component of matrix \mathbf{A} called the dominant eigenvalue. Corresponding to the dominant eigenvalue is an eigenvector (the right eigenvector), which contains the proportion of the population in each age class. In a stable population growing according to \mathbf{A} , λ , the eigenvector (\mathbf{x}), and \mathbf{A} are related by:

$$\mathbf{A}\mathbf{x} = \lambda\mathbf{x} \quad (35.6)$$

Now, we can also analyze the structure of the transpose matrix \mathbf{A}' , which leads to the same eigenvalue but a different (left) eigenvector \mathbf{y}

$$\mathbf{A}'\mathbf{y} = \lambda\mathbf{y} \quad (35.7)$$

The rows of the vector \mathbf{y} represent the reproductive values of each age class in the stable population. These numbers indicate the relative contribution of individuals in each age class to future generations expressed relative to the contribution of a new individual. When these vectors are presented, they are often normalized to set the first value of \mathbf{y} to 1 ($y_1 = 1$).

The stable-population model can be reparameterized to be the actuarial life table, which is used in human demographic studies.²⁸ It has provided the basis for a good deal of evolutionary theory, dating back to Fisher,³⁵ who recognized that it provided a framework for analysis of the effects of natural selection on life histories and suggested that natural selection should act to maximize population growth rate.³⁵

35.4.2.1 When Are Population Models Unstable?

There exist circumstances under which the difference equations will not be stable.³⁶ If this occurs, matrix \mathbf{A} cannot be solved to provide stable population attributes, and the actual dynamics of the population will be much different than that predicted by the stable-population analysis. Sometimes, the model simply does not meet the structural conditions for stability. A theorem of matrix algebra called the Perron-Frobenius theorem defines structural conditions under which a matrix will have a dominant eigenvalue. Basically, if the matrix is primitive (meaning all elements of the matrix become positive in the matrix \mathbf{A}^k for some $k > 0$) it can achieve stability under appropriate conditions. In some biologically relevant cases, this is not true, for example, if only a single age class is reproductive such as occurs in semelparous organisms.⁵

Often, matrix models are not appropriate because the population is undergoing perturbations in survival and fecundity; hence, the conditions expressed in the model do not apply. For example, attributes of a stable population are generally valid only if the matrix \mathbf{A} is constant and the population has been growing according to \mathbf{A} for some time. If the population has only been growing according to \mathbf{A} for a short time, it may not be stable, and the transient dynamics or rate of approach to the stable age distribution is of interest. And, if elements of the matrix \mathbf{A} are not fixed but change over time, the population will be stable only under very restrictive conditions. See Caswell⁵ for an excellent discussion of stability in population matrices.

35.4.3 Sensitivity Analysis

35.4.3.1 Analytical Approaches to Sensitivity Analysis

Caswell⁵ observed that the eigenvectors of stable age distributions and reproductive values can be used to define (structural) sensitivities of the dominant eigenvalue of the matrix \mathbf{A} to small changes in the elements of \mathbf{A} . A matrix of sensitivities can be defined using

$$\frac{d\lambda}{da_{ij}} = \frac{x_i y_j}{\langle x, y \rangle} \quad (35.8)$$

where lowercase letters represent specific elements of \mathbf{A} (i, j represent row i and column j), x , and y , and the expression on the left of the equal sign represents the derivative of λ with respect to a_{ij} . Because these sensitivities may be difficult to understand due to differences in the magnitudes of fecundity and survival elements, de Kroon et al.³⁷ suggested estimating a proportional sensitivity (or elasticity) using

$$\frac{d \ln \lambda}{d \ln a_{i,j}} = \frac{a_{i,j} x_i y_j}{\lambda \langle x, y \rangle} \quad (35.9)$$

The sum of the elasticities is 1, allowing direct comparisons of the contributions of matrix elements. See Caswell⁵ for examples of this approach.

Goodman³⁸ and others have discussed analogous sensitivity analyses in the classic life table framework. Meyer and Boyce³⁹ have also presented methods for sensitivity analysis in the context of toxicology studies.

35.4.3.2 Simulation Approaches to Sensitivity Analysis

Once the matrix is estimated, we can change any of the elements and recalculate the stable-population attributes. For example, if we have evidence that a contaminant decreases survival in an age class, we can change the element in question and find the predicted λ .

35.4.4 Deficiencies with Stable Analyses of Simple Matrix Models

Sykes⁴⁰ noted that most applications of the matrix model for human and wildlife populations do not provide a reasonable simulation of population dynamics, which he attributed to changes in survival and reproductive rates over time. In general, the assumption of constant survival rates over time is false for most animals. For example, Anderson and Burnham⁴¹ documented that survival rates varied over time in Mallards (*Anas platyrhynchos*), invalidating the use of composite dynamic life-table methods of survival estimation.

Caswell⁵ makes a distinction between *projections*, which are defined as population dynamic consequences of demographic parameter values that characterize the system at present, and *forecasts*, which are predictions of the future state of the population. Eigenvalue and simulation analyses are projections in which the present state of the population is defined by \mathbf{A} , and we evaluate growth and effects of changes conditional on \mathbf{A} . Clearly, forecasting requires many more assumptions about the structure of the population and knowledge of how the matrix elements interrelate over time.

Generally, matrix models work best when the sources of parameter change are relatively small and chronic, rather than large and abrupt. Asymptotic theory of population growth and stability does not apply to a population with erratic changes in survival and fecundity. Therefore, modeling of abrupt population changes may be best done with simulation models.

35.4.4.1 Incorporating Density Dependence in the Age-Class Model

The assumption that \mathbf{A} is constant over time is unlikely to be valid in practice. Interactions between population size and survival and fecundity is classically thought to be important in regulating populations, although few quantitative demonstrations of it exist in nature.²⁸ Density dependence can be incorporated into \mathbf{A} in several ways, some of which lead to stable populations.

Leslie³⁴ formulated a time-specific version of \mathbf{A} , \mathbf{A}_t , in which a time-invariant matrix \mathbf{A} is multiplied by an additional matrix \mathbf{Q}^{-1} , in which matrix \mathbf{Q} is a diagonal matrix with elements

$$q_{i,t} = 1 + aN_{t-i-1} + bN_t \quad (35.10)$$

where the N_t represent the total population size at time t and a and b are constants. This density-dependent formulation will result in a stationary population, i.e., the population size will become constant. Other density-dependent formulations also exist, some of which are considerably less stable.⁵

35.4.4.2 Stochastic Matrices

Another way that \mathbf{A} can change over time stems from the possibility that the elements of survival and fecundity are not constant but differ as random variables over time. Because the elements are never exactly the same from time to time, the population is never exactly stable. Under certain conditions, the stochastic matrix \mathbf{A} can provide a stable population (weak ergodicity⁵). See Caswell⁵ for a review of the properties of long-term probabilities of extinction based on stochastic matrices.

Two kinds of variability are often discussed when modeling population dynamics. Demographic stochasticity is a consequence of random variation in survival and fecundity, which May⁴² discusses as a consequence of animals existing only in integer units. Environmental stochasticity is caused by the action of the environment on population size and in practice can be thought of as treating population size, survival rates, and birth rates as random variables. In simulation models, both sources of stochasticity should be used.

35.4.4.3 Stage-Based Analyses

The age-class model discussed above tends to be restrictive — we often consider survival to be age-dependent only in that young animals' survival is less than that of adults. Therefore, a simplification of the age-specific model that allows only a single adult class is appropriate. More generally, the classes we divide N_t into can be any grouping (or stage) for which survival and fecundity rates tend to differ in the population. For example, we could place animals into body-mass classes⁴³ and estimate probabilities of surviving and changing mass classes.⁴⁴ These stage-based transition matrices are often called Lefkovich matrices and are widely used in botanical applications.^{45,46} The stable population and sensitivity analysis can also generally be applied to these models.

35.4.5 Life Table Response Experiments

Caswell⁵ suggested using life table response experiments to assess the effects of contaminants. In these studies, populations are used as replicates and exposed to experimental applications of factors that modify vital rates. Models are constructed for the replicates, and population growth rates are used as summary statistics of the effects of the factors. To evaluate how the factors influence growth, the treatment effects are decomposed to see how the perturbation affects elements of the matrices and hence survival and productivity. These experiments can include analysis of variance, random, and regression designs, and the analysis procedure can also be applied to nonexperimental situations to assess observational results. Caswell provides an informative summary of a two-factor (DDT exposure and food amount) experiment conducted by Rao and Sarma⁴⁷ on a rotifer population, extracting effects of food levels and DDT exposure on growth rate and age-specific fertility and survival.

35.4.6 Examples of Population Matrix Models

Because the Leslie matrix model has been in the literature since 1942, there have been many examples presented of its use. Unfortunately, most of the early applications do not have realistic estimates of survival and reproductive rates, and a great deal of confusion exists regarding the structure of the matrix. There are many examples of stage-based matrix models. Crouse et al.⁴⁸ provide an excellent example of population modeling and sensitivity analyses of a Loggerhead Sea Turtle (*Caretta caretta*) population. Martin et al.⁴⁹ analyzed Mallard populations in North America using a stage-based model incorporating age and sex classes.

Van Straalen and Kammenga⁵⁰ review 29 studies that apply demographic approaches to ecotoxicology, and Kuhn et al.¹³ apply age-structured population models to mysid shrimp to project concentrations of p-nonylphenol at which population-level effects would occur.

35.5 INDIVIDUAL-BASED POPULATION MODELS

Another class of models is based on individual animals rather than on homogeneous groups of animals.⁵¹ These models gain additional flexibility, and perhaps realism, through variation in parameter values at the individual level at a cost of greatly increased complexity in the model. Many more variables and relationships often must be estimated to implement individual-based models compared with aggregated models.¹⁷ Individual-based models are usually based on computer simulation and track each individual in the model population among several states.⁵² The cycle time at which individuals can change states, die, reproduce, etc. is often short (e.g., 1 day⁵³) in relation to between-census (generation) times, unlike many discrete-time models that have cycle and between-census times equal. Survival rate, reproductive rates, and other factors vary among states. Output characteristics of individual-based models are usually determined through computer simulation, while those from aggregated models can often be derived analytically from the model equations.⁵² Individual-based models have not been frequently used to investigate the effects of toxic substances, but Samuel^{53,54} used an individual-based model of midcontinent North America Mallard populations to examine the effects of lead poisoning and disease.

In aggregated models, external influences, such as contaminant exposure, are included for each age/sex class as the mean level of exposure acting on the mean level of a parameter (survival, fecundity). In individual-based models, a range of values of the external factors can act on the individuals' survival and reproduction probabilities in the model. Individual-based models facilitate incorporation of heterogeneity in parameter values and responses to external factors,⁵² nonlinear responses to external factors (e.g., individuals exposed to contaminant levels above the mean have disproportionately higher responses⁵⁵), and rare events, such as contaminant spills.¹⁶ Individual-based models also can be useful for species that have a protracted breeding season and multiple litters or clutches, which violates the assumptions of some aggregated models.

Aggregated models can be thought of as special cases of individual-based models.⁵² Because realism is often easier to incorporate into individual-based models, they can serve as a starting point to encourage formation of testable hypotheses.¹⁷ Following testing of hypotheses about model assumptions and structure, extraneous complexity might be rejected, leading to simpler aggregated models and their associated powerful analytical evaluation methods.⁵²

35.5.1 Sensitivity Analysis

In individual-based population models, virtually all sensitivity analyses are performed through simulation. Input variables are varied singly by a small amount, and the model is then run for a specified number of iterations. Results are summarized as the proportional change in model outputs caused by the change in the model input. These simulations can be based on either sensitivity

(change in output for a constant level [i.e., additive] change in input) or elasticity (change in output for a proportional [i.e., multiplicative] change in input), although elasticity is often more easily interpreted when variables have very different measurement scales (e.g., survival rates and clutch sizes in birds). Structural sensitivity and statistical sensitivity (possibly based on several sources of variation) vary only in how the input variables are changed. For structural sensitivity, inputs are varied by a constant amount across variables. For statistical sensitivity, estimates are varied by a constant fraction of the variance estimate for the variable (e.g., 0.5 standard errors). Investigation of sensitivity to different sources of variation would require repeating the analysis with each variance source (such as measurement variance or sampling variance).²⁹ Most sensitivity analyses are conducted by examining variables one at a time. However, if input variables are correlated, estimates of sensitivity or elasticity could be misleading if the correlation structure among variables is not accounted for. Incorporating covariation among inputs or nonlinear patterns of sensitivity into sensitivity analyses would add greatly to the complexity of the analyses; data are frequently lacking on broad-scale relationships among variables of interest. But if the types of data were available, it would be valuable to incorporate them when estimating sensitivity.

35.6 ESTIMATION OF MODEL PARAMETERS AND RELATIONSHIPS

Population change is a consequence of survival, reproduction, immigration, and emigration. Important relationships in the model structure include how these factors influence each other and how they interact with population size (e.g., density dependence, compensatory mortality). Survival and reproductive rates can be estimated, but identifying and quantifying features such as density dependence, compensatory mortality, and the influences of exogenous variables can be extremely difficult.^{56,57}

To make models more useful for investigating population dynamics, the effects of external factors on survival and reproductive rates are often included. The effects of the external factors might also interact. For example, the effect of contaminant exposure on survival rate might be affected by exposure to other contaminants or by weather. Obtaining reliable estimates of model parameters and relationships and accompanying variance estimates is an important component of the modeling process. Acquiring these estimates requires experimental work that applies appropriate designs and statistical methods. A variety of books and internet products exist that discuss these methods,^{7,10} and their application is prerequisite for successful model development.

One consideration in obtaining reliable parameter estimates is heterogeneity in vital rates, which can cause biased estimates if not recognized.⁵⁸⁻⁶⁰ A common source of heterogeneity occurs among identifiable groups such as age, sex, or size classes. This possibility should be investigated, and, if necessary, estimates should be produced separately for each group. Unfortunately, other sources of heterogeneity can be more difficult to detect,⁵⁸ which is one of many reasons for caution in interpreting model results.

35.6.1 Survival

Several approaches are available to estimate survival rates from wildlife populations, depending on the sources of data available. Data from field studies are usually of a different form than data from captive animal studies, and different estimation methods are sometimes used (Table 35.1). Survival rates from all of these methods can be expressed as a period-specific survival rate (i.e., the probability of surviving an interval of a specific length), differing in how the pattern of mortality is modeled within the period. If the period length for the survival estimate differs from that of the model, conversion of the survival to the model interval will be necessary, which is relatively easy with constant survival methods but more difficult for methods that have nonlinear changes in survival rates over time.

Table 35.1 Methods for Estimating Survival Rates for Several Types of Data, with Selected References and Computer Programs for Implementing the Methods

Data Type	Analysis Method	References	Software
Continuous monitoring (includes captive animals and most radio telemetry data)	Direct estimation (i.e., dead/exposed)		
	Parametric models	Kalbfleish and Prentice, ⁶¹ Cox and Oakes ⁶² SAS Inst. ⁹¹	Proc Lifereg
	Kaplan-Meier product limit	Pollock et al. ⁶⁴ White and Garrott ⁶³ Cox and Oakes ⁶² SAS Inst. ⁹¹	Proc Lifetest

Release-recovery	Band recovery models	Brownie et al. ⁶⁸ White ⁹² Conroy and Williams ⁸⁰ White and Burnham ¹⁰	BROWNIE ESTIMATE SURVIV MULT MARK
Capture-recapture	Jolly-Seber open population models and extensions	Pollock et al. ²⁵ Lebreton et al. ⁹ Burnham et al. ²³ White ⁹² White and Burnham ¹⁰	JOLLY JOLLYAGE SURGE RELEASE SURVIV MARK

If animals in the population can be monitored continually and all enter the study at the same time (e.g., captive animals and some radio telemetry studies), the survival rate for a specific time period can be estimated through direct estimation of the proportion of the study animals that survive the interval. This is a common measure in captive animal toxicology studies. With direct estimation, no assumptions about intraperiod mortality patterns are required unless conversion to a different interval is necessary. Estimation methods for intraperiod survival with this type of data include those that specify a parametric form for the survival rates,^{61,62} the parametric methods can have either constant or nonconstant survival rates. Nonparametric methods, such as the Kaplan-Meier product limit,^{61,62,63} are also applicable. The Kaplan-Meier estimator has been extended for use when study animals enter the study at different times, which is common with field radio telemetry projects.^{63,64} If constant survival is assumed, the Mayfield method is of use,⁶⁵⁻⁶⁷ particularly when animals are monitored periodically rather than continuously.

If animals are captured, marked, and released and recovered dead at some later time, band-recovery models are useful for estimating survival rates.⁶⁸ To use these models there must be a series of equally spaced capture, mark, and release events (e.g., annually) with sufficient animals for a series of recoveries from each of these release times. Period survival rates are produced for the interval between release events. Survival rates can vary among periods, and no assumptions are made about the pattern of intraperiod survival. High recovery rates (or extremely large samples) of the previously marked animals are required to get precise survival estimates. Also, estimates of annual survival rates from band-recovery models are not possible if only young-of-the-year animals are marked.^{68,69}

Another set of methods for estimating survival rates is open population capture-mark-recapture models.^{9,25} These differ from the band-recovery models in that animals are captured and released on more than one occasion, rather than a single capture and later recovery. "Open population" refers to the fact that deaths, births, and some types of movements can be accommodated by model estimation procedures. Period survival estimates are produced (along with estimates of population size and recruitment) for the intervals between capture occasions, and these rates need not be equal among periods.

An important assumption of these methods is that, on any capture occasion, all animals have the same probability of capture. This assumption can be relaxed by altering sample designs and incorporating closed-population capture-recapture methods in the estimation scheme.^{70,71} A further assumption of capture-recapture models is that all emigration is permanent (animals cannot leave the study population and subsequently return). However, this presents a limitation of the survival-rate estimates from these models, as permanent emigration cannot be separated from mortality without additional information^{25,72} (but see Nichols et al.⁷³). If emigration rates are substantial, survival rates estimated with these methods will be too low. To our knowledge, increased emigration has not been attributed to contaminant exposure, although estimation of emigration rates and causes have not been extensively investigated.⁷²

A very general computer package for estimation of survival and other attributes from marked animals is a program called MARK, developed by White and Burnham.¹⁰ This package provides a general structure for estimation from capture data, encompassing band-recovery models, Cormack-Jolly-Seber models, joint live-and-dead-encounter models, modeling of known fates, robust design analyses (incorporating both open- and closed-population models), and multi-strata designs that permit migration among strata. Comprehensive documentation of the package is available through the Internet at (http://www.cnr.colostate.edu/class_info/fw663/Mark.html).

35.6.2 Reproduction

Approaches for estimating reproductive rates are somewhat more limited than for survival rates (Table 35.2). As with estimates of survival rate, it is essential that a specific definition of reproductive rate be decided upon when building the model and obtaining estimates.⁷² Net natality (the number of female young produced per adult female) is a commonly used measure, but other measures might be more appropriate in some situations. What constitutes reproduction is relatively clear-cut for mammals but less so for birds. For birds, reproduction can be defined on the basis of eggs, hatchlings, or fledglings, with the difference that survival rates at these various stages are either combined into the reproductive rate or into the juvenile survival rate.⁷² Individual-based models might have a separate survival rate for each of these life stages, and contaminant exposure could be modeled to affect each separately.

It is often assumed with wildlife populations that when animals reach a certain age, all will attempt to reproduce. However, population dynamics can be affected if the proportion of breeders in a population is less than 1,⁷⁴ which might result from contaminant exposure. Changes in the age of first reproduction can be thought of as a special case of changes in the yearly proportion of breeders. Estimates of the proportion of the population breeding could be important for some models.⁷⁵

For captive animals or those that can be monitored at will (e.g., some radio telemetry studies with animals marked before the reproductive season), reproductive rate can be estimated directly (e.g., mean brood size, etc.). The proportion of the population breeding can also be estimated directly. With captive animals, assumptions about the applicability of survival-, reproduction-, and breeding-rate estimates to the wild are necessary. It is also necessary to assume that the animals observed to provide data for the estimate are representative of the population of interest, which is best achieved

Table 35.2 Methods for Estimating Reproductive Rates for Several Types of Data Along with References and Computer Programs

Data Type	Analysis Method	References	Software
Continuous monitoring (includes captive animals and most radio telemetry data)	Direction observation (i.e., average number fledging, etc.)		
Capture-recapture	Jolly-Seber open population models and extensions	Pollock et al. ²⁵ Lebreton et al. ⁹ Clobert et al. ⁷²	JOLLY JOLLYAGE SURGE

if they are randomly selected. To ensure unbiased estimates in modeling, random selection of samples should be made in all phases of data gathering whenever possible (see Hurlbert²⁶).

For field data, care must also be taken to account for complete reproductive failure, such as complete nest or brood loss. If not detected, complete nest or brood loss will result in biased estimates (too high) of reproductive rates.^{66,76}

Another source of recruitment estimates is open-population capture-recapture models. Unlike using direct observation, capture-recapture estimates of recruitment estimate the number of new individuals added to the population between sampling occasions without providing a direct estimate of average production per female or per adult. An estimate of average reproductive rate could be derived using the capture-recapture population estimate along with the recruitment estimate. For species where distinguishing sexes is difficult, a reproductive measure other than net natality will be required. However, one complication associated with capture-recapture estimates of recruitment is that *in situ* reproduction is often indistinguishable from immigration without additional information. Important assumptions for open-population capture-recapture were discussed in the preceding section on estimating survival rates.

Using capture-recapture models to estimate the proportion of the population breeding is a relatively new application. See Lebreton et al.⁷⁵ and Clobert et al.⁷⁴ for a discussion of these methods.

35.6.3 Relationships to External Factors

Period survival rates or reproductive rates estimated from any of the described methods can be related to external variables through the use of regression methods. A critical factor in estimating these relationships is having a sufficient number of survival- or reproductive-rate estimates and explanatory variables to produce an adequate estimate. Multiple explanatory variables and nonlinear relationships require more data (i.e., estimates of survival rates) than linear relationships. Interactions among explanatory variables can also complicate the estimation process, particularly for data from field samples where confounding of variables is a common problem.

For example, levels of contaminants often vary together (e.g., DDE and PCBs), making it difficult to determine which contaminant causes which effect. Or, levels of one contaminant will be high at one location, and levels of another contaminant will be high at another location. Extreme caution should be used before attributing differences in population variables between the two sites to the contaminants; the differences could be due to site-specific habitat differences, an unmeasured contaminant, or many other factors. It should also be remembered that relationships estimated from observational field data rather than from manipulative experimentation (i.e., deliberately applied levels of the explanatory variable) indicate only correlation between the explanatory and response variables rather than cause and effect. The necessity of using such estimated relationships in population models also necessitates caution in use of model outputs. In contrast, manipulative field experiments⁷⁷ can be used to estimate cause and effect relationships providing greater confidence in models using these estimates.²² The adaptive-management approach allows for stronger inference from observed population changes, as the observational data are used to test the predictions from alternative models.³

Relating nonconstant survival rates, such as from Kaplan-Meier or some parametric models, to external variables for use in population modeling is difficult and requires carefully designed experiments.⁷⁸ Incorporating these types of survival-rate functions would probably be possible only for individual-based models.

Survival probabilities of individuals (or other binomial variables⁶⁴) can be related to explanatory variables using logistic regression⁷⁹ or proportional-hazards models.^{52,62} More complex capture-recapture and band-recovery models allow direct incorporation of external effects in estimating survival rates.^{9,57,78,80}

Modeling of density dependence should be viewed as an analysis of an external factor (population size) on survival or fecundity. If independent estimates of survival and population size exist,

analysis of density dependence can proceed as outlined above. However, most of the experimental evidence of density dependence has been derived from nonindependent data sources such as time-series or through key-factor analysis. Kuno⁸¹ and others have shown that these results should be viewed with caution due to the possibility of spurious relationships derived from the sampling procedures. Barker and Sauer⁵⁶ review some of the problems associated with analyzing density dependence from a series of annual counts. See Lebreton⁸² for a useful discussion of estimating density dependence from population data.

35.7 MODELS BASED ON ESTIMATES OF POPULATION SIZE

Occasionally, we only have a time series of population size estimates and want to model the effects of covariates, such as pesticide levels, on population size. Often, these data are collected from a population in the field, and we want to model the effects of the addition of a toxin on subsequent population sizes. However, the methods are also relevant to simulations in which we change the level of survival at a known time and want to see how it affects the output of the model. Although these analyses could also reasonably be discussed in a chapter on statistical models, we have chosen to briefly discuss them here because they are relevant to the analysis of the models described above. The input data for these models are a time series of population sizes generally collected (or calculated from a model simulation) at evenly spaced intervals. Values of the level of toxins or other environmental covariable are also available at each time period, although these data could simply be a dummy variable with value 0 at times when the toxin was not present and 1 at times when it was. The goal of the analysis is to determine if the levels of the covariable were associated with the levels of the population.

A naive analysis of these data would simply use linear regression or correlation to determine if an association existed between the variables. Sauer et al.⁸³ reviewed how correlation analyses can be used in this context. Unfortunately, this analysis is usually not appropriate because time-series data tend to be autocorrelated, with population sizes dependent upon population sizes in earlier years. This autocorrelation leads to an inflated alpha value in correlations, rejecting the null hypothesis more frequently than is correct.^{83,84} To correctly analyze the data, the autocorrelation in the data must be appropriately modeled and incorporated into the analysis.

35.7.1 Time-Series Analysis

Time-series analysis provides a means of accurately analyzing these data. Box and Jenkins¹⁸ have provided a framework for modeling autocorrelation in time-series data. These models require that a time series be stationary (i.e., without trend or other features that change the autocorrelation over time), and often the count data are transformed by taking logarithms or differencing the data to remove trend. Then, autocorrelation is modeled by correlation of the data at different lags. The structure of the resulting autocorrelation function (i.e., the correlations between population sizes at a year t and sizes at other years $t + i$, $i = 1, \dots$) is used to fit an ARMA (autoregressive moving average model). ARMA models have the form:

$$\sum_{j=0}^p \alpha_j X_{t-j} = \sum_{k=0}^q \beta_k \varepsilon_{t-k} \quad (35.11)$$

where X is the time series of counts, α are the coefficients of the autoregressive part of the model (there are p of them, so it is said to be of order p), β are the coefficients of the moving average part of the model (there are q of them), and ε is the error term, which is assumed to be normally distributed with mean 0 and variance σ^2 . The α and β terms model the autocorrelation (or

correlations between counts at different time differences, or lags). Because this model will only be valid for a stationary time series, often the X will be transformed by subtracting X_t from X_{t+k} (where k is an integer ≥ 1), which is called k th differencing. If the data are differenced, the ARMA model becomes an ARIMA model (for autoregressive *integrated* moving average model).

To actually fit these models to data, one uses a statistical package such as SAS.⁸⁵ Inspection of the temporal patterns of autocorrelation vs. the number of lags in the data is performed to evaluate the need for differencing and p and q (the number of α and β terms). Based on this inspection, a model is fit and the estimated parameters are tested for statistical significance using t tests, as in a linear regression. Residuals from the model are subjected to autocorrelation analysis to see if additional patterns exist, and new models are fitted. Often, several possible models are fit to the data, and the model that best fits the data (as determined by a minimal value of Akaike's Information Criterion, a measure of goodness of fit discounted by the number of estimated parameters⁷) and provides residuals that do not contain any autocorrelation is selected as the appropriate model.

35.7.1.1 *Trend in Time Series*

This modeling structure can accommodate many complex sorts of long-term autocorrelation such as seasonality and other patterns. Note, however, that while population growth rate, or trend, is treated as a nuisance parameter in these models, it is the parameter of interest for the stage-structured population models discussed previously. If we are interested in modeling trend, the other time-series components can influence both our view of the trend in the time series and the variance of the trend estimate.⁵⁶ For example, if the population has a long-term cycle, estimates of trend from a time period shorter than the cycle will result in a "trend" that is really just a portion of the cycle and is not representative of the long-term dynamics of the system.

Sauer et al.⁸³ provide a discussion of modeling population trend from time series using linear models. They discuss methods for determining if population trend changed at a specific time or if populations changed over an interval of interest. The crucial result from their work is that it is difficult to model changes in trends from short time series because the time-series components can produce apparent changes in trend. However, if independent replicates of the population time series exist, they can be used to determine if the changes are consistent among the time series.

Although trend is only a nuisance variable in most time-series models, there are cases in which changes in the level of the time series can be modeled in the context of autocorrelation. A covariate can be modeled with the time series to explain some of the variation in population size. We will briefly consider intervention analyses and other transfer-function models as examples of covariate modeling.

35.7.1.2 *Intervention Analysis*

Single time-series models can be modified to allow assessment of the effects of covariates on the system. Often, we are interested in determining whether the level of a population time series changes at a specified time t_0 . One could consider the change at time t_0 as a permanent change, a step in the level of the series corresponding to the time of initiation of a new pesticide or some other contaminant, or a pulse corresponding to a single episode of exposure. Box and Tiao⁸⁶ discuss modeling these changes with indicator variables, where the step variable has value 0 at time $< t_0$ but value 1 at times $\geq t_0$. The indicator for the pulse has value 1 at time t_0 but value 0 at all other times.

The effects of these indicator values on the population are determined by a transfer function. The value of this function models the population response to the indicator variable and describes both the change in population associated with the indicator and the return of the population to equilibrium. For example, the transfer function may treat the population response to the change as an instantaneous shift to a different level similar to an indicator variable in regression. If so, the transfer function has a single parameter representing the shift in level. Alternatively, the change to

the new level could be gradual, resulting in a function with two parameters. See Box and Tiao⁸⁶ for descriptions of some of the possible shapes of the transfer function.

To fit the intervention model, Box and Tiao⁸⁶ suggest that an investigator (1) develop a transfer model that best summarizes the effects of the intervention, (2) conduct the data analysis to fit the model, and (3) see if the model adequately fits the data. If not, go back to Step (1) and try alternative models. This procedure has been used to model wildlife populations. Bautista et al.⁸⁷ used intervention models to model the effects of hunting and land use changes on Common Crane (*Grus grus*) population changes.

35.7.1.3 Transfer-Function Analyses

If the covariable is itself a time series, a transfer-function model can be developed using time-series methods. Both time series are assumed to be stationary, and if not stationary they must be transformed to stationarity through differencing. Then, time-series components are fit to the covariable using the procedures outlined above. This model transforms the series to a white-noise series. The model is then applied to the population time series. Then, cross-covariances (correlation between the two time series at different lags) are estimated between the two transformed time series and are used to estimate the transfer function.

35.7.1.4 Additional Methods

One of the limitations of standard time-series methods is the requirement of observations equally spaced in time, which might not be available. However, recently developed methods allow appropriate analysis of time-series data with unequal spacing. If relatively few data points are missing (including below detection limit estimates for chemical concentrations), these can be imputed using the correlation structure from the available data and, possibly, auxiliary variables. With the missing data imputed, standard time-series methods are then applied. However, this overestimates the precision of the resulting estimates because some of the points used are the imputed points. To overcome this, the missing data are imputed several times (e.g., 5–10) with the analysis performed for each of the "complete" data sets. These multiple results are then combined to get estimates and variances that include the variation due to the multiple imputations.^{88,89} An advantage of this approach is that standard methods can be used while accounting for the uncertainty caused by the missing data. The second recent innovation is the ability to perform regression analyses with a variety of autocorrelated error structures.⁹⁰ These include spatial error structures that can be used to model autocorrelation with unequally spaced observations. These regression models also allow incorporation of random (i.e., nested) effects and, unlike standard time-series models, nonnormal error distributions.⁹⁰ The flexibility of autocorrelated regression models allows for appropriate analyses, producing valid estimates and variances from many types of commonly encountered field data.

35.8 SUMMARY

Population models provide a means for evaluating the effects of a toxin in the context of the life cycle of an organism. By developing a model and estimating demographic parameters, effects of toxins on demographic parameters, population growth rates, and model stability can be assessed. Also, modeling allows us to identify what portions of the life cycle are most sensitive to toxins and can guide future data collection and field experiments. Several types of population models are potentially of use in modeling the effects of toxins on wildlife populations. Choice of model should be based on the available demographic data and characteristics of the population of interest. We describe three classes of models: discrete-time difference equation (Leslie matrix) models, indi-

vidual-based models, and time-series models. For each class, we discuss some of the nuances of developing, refining, and analyzing the models.

Estimation of model parameters is a crucial component of modeling, and we discuss methods for estimating survival and reproduction of animal populations. Most models have been based on poor estimates of the parameters, and only recently have appropriate methods been developed for estimation. Although interactions among demographic parameters may play a crucial role in the dynamics of the models, remarkably little is known about the actual form of the interactions. We emphasize the importance of the interaction between experiments to estimate demographic parameters and realistic modeling based on these estimates, and of the direct use of models in life table response experiments. The emerging science of adaptive management provides an important new role for modeling as a tool for increasing our understanding of toxicant effects on populations.

36.1 INTRODUCTION

Environmental problems facing scientists and decision makers are numerous and varied; they include potential global climate change, spread of pathogens and invasive species, habitat loss, acid deposition, and the release and detection of multiple human-made chemicals in the environment. The types of questions that scientists are asked to inform managers about range from defining the nature and extent of anticipated or observed effects of environmental changes, to prioritizing research and collecting, to comparing management alternatives. Doing this requires a process that flexibly accommodates the diversity of issues yet provides the consistency and rigor needed to have confidence in conclusions.

Ecological risk assessment (ERA) is a process that evaluates the likelihood that adverse ecological effects may occur as a result of exposure to one or more stressors.¹ It is a process for evaluating information, assumptions, and uncertainties to understand the relationships between stressors and ecological effects; its ultimate goal is to inform environmental decisions. It has been used to evaluate a wide variety of environmental issues of interest such as water-regime management in South Florida,^{2,3} the chemical and biological stressors used to control gypsy moths,⁴ and chemicals that are used in industrial processes for pest control or are present at hazardous waste sites (e.g., References 5–7).

This chapter discusses the ERA process as developed by the U.S. Environmental Protection Agency (EPA); government entities in other countries have also developed guidance and methods (e.g., References 8–13). The field also has benefitted from National Research Council reports,¹⁴ textbooks like this one, and the startup in 1995 of a new journal entitled *Human and Ecological Risk Assessment*. While the term has become more common recently, ERA draws from the experiences of adaptive environmental management,¹⁵ environmental impact statements,¹⁶ hazard evaluation,¹⁷ and biological monitoring of environmental condition.¹⁸ It also builds on procedures used to analyze risks to human health.¹⁹

ERA has several features that contribute to effective environmental decision-making:

- It can iteratively incorporate new information to improve environmental decision-making. This feature is consistent with adaptive-management principles¹⁵ used in managing natural resources.
- It can be used to express changes in ecological effects as a function of changes in exposure to stressors. This capability may be particularly useful to the decision maker who must evaluate tradeoffs, examine different alternatives, or determine how much stressors must be reduced to achieve a given outcome.
- It explicitly evaluates uncertainty. Uncertainty analysis describes the degree of confidence in the assessment and can help the risk manager focus additional monitoring, modeling, or experiments on those areas that will lead to the greatest reductions in uncertainty.
- It provides a consistent basis for comparing, ranking, and prioritizing risks.
- It considers management goals and objectives as well as scientific issues during planning and problem formulation to ensure that results will be useful to risk managers and other stakeholders.

This chapter describes some recent and ongoing activities in ERA. Section 36.2 summarizes the EPA's Guidelines for Ecological Risk Assessment.¹ Section 36.3 discusses several new technical developments and applications. Section 36.4 discusses ERA's role in broader risk-management activities, including objectives development and economic and human-welfare assessments. These activities can offer additional interpretation of the effects of alternative management options.

36.2 THE EPA'S GUIDELINES FOR ECOLOGICAL RISK ASSESSMENT

In 1998, the U.S. EPA published the Guidelines for Ecological Risk Assessment.¹ The Guidelines are intended to promote consistency across EPA risk assessments, improve the quality of the science underlying risk assessments, and inform the public about the EPA's approach to risk assessment. They are the culmination of a long-term effort at the EPA, including the Framework for Ecological Assessment,²⁰ issue papers,²¹ and case studies.^{22,23}

The Guidelines describe three phases of ERA: problem formulation, analysis, and risk characterization (Figure 36.1). In problem formulation, risk assessors develop a conceptual model of how ecological effects may result from human activities. A critical component of problem formulation is linking endpoints that can be measured (e.g., survival of fish in a laboratory experiment) with management goals (e.g., preventing fish kills in streams). This link is aided by defining assessment endpoints that are intermediate between broad management goals and specific measurements. During the subsequent analysis phase, the conceptual model guides data evaluation to reach

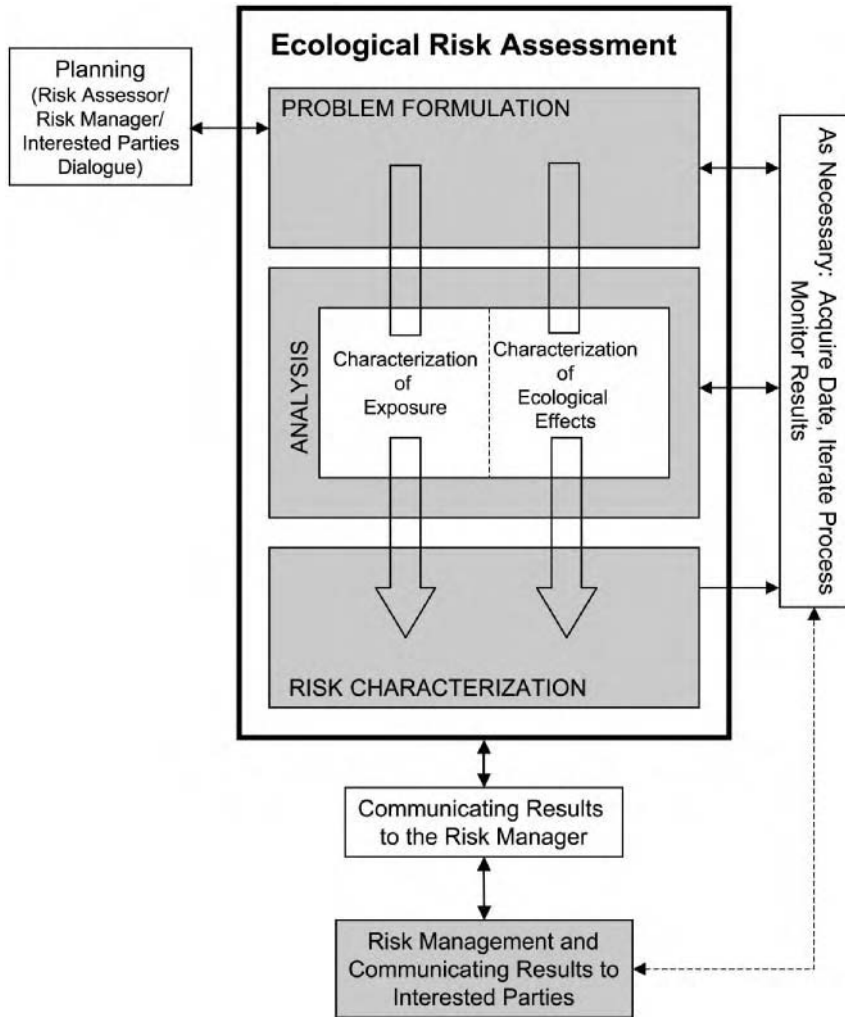

Figure 36.1 The ecological risk assessment process. (From U.S. Environmental Protection Agency, Guidelines for Ecological Risk Assessment, Washington, D.C., 1988.)

conclusions about exposure and the relationships between stressors and effects. In risk characterization, the information on exposure and stressor-response relationships is integrated to estimate risk, and all of the evidence is brought together to reach final conclusions about the likelihood and magnitude of effects. Effective risk characterizations acknowledge uncertainties and assumptions; in addition, they separate scientific conclusions from policy judgements.^{24,25}

The processes for eliciting the views of managers and other stakeholders are critical for ensuring that the results of the assessment can be used to support a management decision.²⁶ These processes are particularly important in providing input to problem formulation (the “Planning” box shown in the upper left-hand side of Figure 36.1). They include articulating management goals, management alternatives, and the resources available to conduct the assessment. The interactions between risk assessment and risk management during the early phases of the project are discussed further in Section 36.2.1.

The box on the right-hand side of Figure 36.1 represents data collection and monitoring. Risk analysis is a data-driven process. However, the data may have been collected specifically for the risk assessment or developed for another purpose (e.g., routine environmental monitoring). In the latter case, assessors need to critically evaluate the data to ensure that the information can support the assessment (Section 36.2.3). Monitoring data can also be used to evaluate the efficacy of a risk-management decision. For example, if a risk were to be mitigated by reducing exposure, monitoring could help determine whether the desired reductions in exposure and effects were achieved. Monitoring can also document ecological recovery and help determine whether the management approach needs adjustment.¹⁵ Finally, focused monitoring can be used to evaluate the risk assessment approach and improve the process.

36.2.1 Planning the Risk Assessment

ERAs are conducted to translate environmental data into information risk managers can use to make informed decisions. To make sure ERAs are useful, risk managers, risk assessors, and, where appropriate, stakeholders plan the process before beginning. Planning generates three outputs: (1) clear management goals, (2) decisions to be made, and (3) the ERA’s scope and complexity.

The first step is to decide whether an ERA is really needed. Participants explore what is known about the risk, what can be done to mitigate or prevent it, and whether ERA is the best way to evaluate environmental concerns. An ERA may add little value to the decision process if there are alternatives that circumvent the need for it. Or a discussion with stakeholders may reveal that there is so much opposition to a particular action that there is no point in considering it, much less going to the trouble of preparing an ERA.

36.2.1.1 Involve the Players

Once planning begins, the next step is to ensure that all the right people are involved. Not all participants have the same roles and responsibilities. Clarifying who the assessment is for, who will judge its worth, who will use it, and who will be affected by any ensuing management actions are critical components of planning an assessment.

Managers bring the most in-depth knowledge of the purpose for the assessment, the context for decisions, and the regulatory frameworks that help frame the question. They are the ultimate users of the assessment’s results. A manager may be a single individual (e.g., a government manager) or a group of dispersed decision makers (e.g., landowners in a watershed).

Local stakeholders contribute in-depth knowledge of area concerns, knowledge about the system, and a historical perspective to the planning process. Although stakeholders may include decision makers, scientists, and analysts, it is important to also include individuals who may be concerned with or impacted by decisions, if possible. In addition to helping to define and articulate

the decision context, stakeholders can provide unique knowledge and information for the assessment. Without their involvement, it can be much more difficult to solidify public and political support for assessment activities, particularly over the long term. In addition, environmental-protection strategies built on partnership models are increasingly used to augment the command-and-control methods historically used for managing point sources. If ecological assessment is to inform these new strategies, then the assessment must engage the stakeholders.

For assessments conducted under specific regulations or laws, substantial stakeholder involvement likely occurred during the development of the law or regulation. In these cases, the assessment team may have a starting point that articulates stakeholder concerns.²⁷

Scientists usually conduct the assessment and are responsible for integrating the decision context and stakeholder concerns with scientific issues. They also gather information on the ecosystem (structure, function, status, and history of system), known or suspected stressors, and susceptible species or communities. They bring knowledge of environmental processes and causal linkages as well as strengths and limitations of different variables and measurement techniques. They are also most likely to understand what and how many resources will be needed to complete the analysis.

36.2.1.2 Identify Management Goals

Risk assessments are conducted to provide information relevant to achieving a management goal. They reflect the decision-maker's overall goals and may address an organism, an ecosystem, or some part or feature of an ecosystem. Early discussions and clear management goals help the risk assessor identify and gather critical information. No matter how they are established, goals that explicitly define what will be protected provide the best foundation for risk-assessment objectives and actions to reduce risk.

It is well worth any time spent to explore goals and make sure they are explicit. A well-defined goal specifies an entity, some attribute, and a desired state. For example, if the management goal is a general statement such as "maintain a sustainable aquatic community," the entity is the aquatic community and one (implicit) attribute is the population size of each member species. The desired state is unclear, probably something to the effect of "enough so they'll still be with us next year," and would be much more helpful if it was expressed as something like "that can sustain a sport fishery for organisms x and y and a commercial fishery for organism z ." Similarly, "restore a wetland" could be stated more clearly as "restore the prairie pothole wetland at Puddle Prairie State Park (entity) to its areal extent (attribute) before tile drains are installed (desired state)," and "prevent toxicity" could be expressed as "reduce toxic discharges to Lake Serenity (entity; the implicit attribute is the aquatic community structure) to concentrations below Ambient Water-Quality Criteria (desired state)." Explicit goals not only guide the risk assessment and subsequent management decisions; they provide a way to tell whether the action taken was successful.

When goals are very broad, it may be useful to break them down into multiple management objectives. Keeney²⁸ provides a structured procedure for developing objectives, and Hammond et al.²⁹ provide a somewhat simplified approach. A series of management objectives can clarify the inherent assumptions within the goal and help determine which ecological entities and attributes best represent each objective.

36.2.1.3 Describe Management Options

ERAs are conducted for a number of purposes including prioritizing stressors, resources, or places for protection or further investigation; identifying causes of observed impacts; predicting the effects of a new or continuing release; and selecting among alternatives for restoration. The investigation's purpose and management goals will influence what options are considered. In turn,

a clear understanding of the range of management options under consideration helps to focus the ERA and clarify the degree of confidence that will be needed.

Risk assessors can also provide a scientific perspective on candidate management options. For example, if the management goal is to reestablish spawning habitat for free-living anadromous salmon in a river impounded by multiple dams, a risk assessor might advise the decision maker that several actions will be needed (dam removal, nutrient input reduction, erosion control, pest management) and that none of them will make any difference unless the dams are removed. If this is not among the management options, the planning group might work together to reconsider the goal, abandon it, or present it as a work in progress with interim goals such as water clarity and quality.

ERAs for a region or watershed that address multiple stressors and ecological values are often based on a general goal with multiple potential decisions and many possible options. Such assessments tend to be complex because they involve the multiple stressors, ecological values, and political and economic factors that influence decisions at larger spatial scales (see Section 36.4.2. below). Although time-consuming, ERAs at large spatial scales can be valuable in bringing together diverse stakeholders and focusing management efforts on key stressors.

36.2.1.4 Define Scope and Complexity

An ERA's purpose determines its geographic scope and complexity (e.g., national, regional, site specific). The scope and complexity are also a function of how sure a decision-maker needs to be about risks to decide what to do about them. The level of confidence needed is influenced by the cost of potential management actions, the level of interest, the degree of difficulty, and the legal context for the decision. ERAs that are completed under legal mandates and likely to be contested or appealed must pay strict attention to uncertainties to ensure that they will stand up in court. The risk manager and risk assessor should be frank with each other about sources of uncertainty, the comfort level needed for the decision, and ways uncertainty can be reduced. For example, successive iterations or tiers of increasing cost and complexity may help reduce uncertainty.

Advice on how to address the interplay of management decisions, study boundaries, data needs, and uncertainty, and specify limits on decision errors may be found in the EPA's guidance on data-quality objectives.³⁰ The planning group considers the type of decision (e.g., national policy, local impact), available resources, opportunities for increasing resources (e.g., partnering, new data collection, alternative analytical tools), expertise at hand, and what information is needed to make the decision. Detailed analysis is not always needed, and sometimes a simple screening-level assessment is enough.

Planning is complete when the group has decided on (1) management goals, (2) the range of management options the ERA is to address, (3) the ERA's focus and scope, and (4) resource availability. If needed, formal agreements may be used to document the technical approach, spatial scale, temporal scale, and, of course, product deadlines.

36.2.2 Problem Formulation

Problem formulation is a process for developing and evaluating preliminary questions about why ecological effects might occur. This step is crucial — it provides the foundation for the ERA. First, participants refine the focus and scope of the ERA, based on the results of the planning step described above. Then, they develop a plan for analyzing data and characterizing risk. Any shortcomings in problem formulation will haunt future work, so it is worth spending time here to refine objectives and plan carefully.

Problem formulation generates three products: assessment endpoints, a conceptual model or models, and an analysis plan. In all but the simplest analyses, the problem-formulation process is interactive and iterative and may require several cycles.

Problem formulation begins with a review of information about the situation that is readily available. Useful information includes stressor sources and characteristics, exposure opportunities, characteristics of the ecosystem potentially at risk, and any potential or observed ecological effects. When information is plentiful, problem formulation goes quickly. If not, the ERA begins with the information at hand, and the problem-formulation process helps identify missing data and provides a framework for further data collection.

36.2.2.1 Select Assessment Endpoints

Assessment endpoints are explicit expressions of the actual environmental value to be protected and provide the focal point for ERA. They are operationally defined by an ecological entity and some attribute. The entity identifies what is being protected. This can be a species (e.g., eelgrass, piping plover), a functional group (e.g., piscivores), a community (e.g., benthic invertebrates), an ecosystem (e.g., lake), a specific habitat (e.g., wet meadows), a unique place (e.g., a remnant of native prairie), or other entity of concern. The second is the attribute or characteristic of that entity that is important to protect and potentially at risk. For piping plovers, it may be reproductive rates; for a lake, frequency and severity of algal blooms; for a wet meadow, the number of native plants. An assessment endpoint needs both an entity and an attribute to serve as a clear link to management goals and the basis for measurement.

Assessment endpoints are similar to management goals but are distinguished by their neutrality and specificity. Assessment endpoints do not describe a desired achievement (i.e., goal), so they do not contain words like “protect,” “maintain,” or “restore,” or indicate a direction for change such as “loss” or “increase.”

It can be a challenge to choose the characteristics that will be most useful for the assessment. Ecosystems may be examined at several organizational levels (individual, population, community, ecosystem, landscape) and through multiple ecosystem processes. It is rarely clear which of these attributes are most critical to ecosystem structure or function, and professionals and the public don't always agree on which are most valuable. Three useful criteria to consider are: (1) ecological relevance (the entity should be a current or historical part of the ecosystem being studied), (2) susceptibility (it should be both exposed and sensitive to the effects of the stressor), and (3) relevance to management goals (it should be something the manager can do something about). Ecological relevance and susceptibility are essential for scientifically defensible assessment endpoints. However, endpoints that reflect societal values and management goals are more likely to be used in management decisions. Assessment endpoints that meet all three criteria provide the best foundation for an effective ERA.

The challenge is to find endpoints that meet the selection criteria and are also important to those who make and have to live with the decision — risk managers and the public. Suppose, for example, an assessment is designed to evaluate the risk of applying pesticide around a lake to control insects. It turns out that at this lake midges are susceptible to the pesticide and form the base of a complex food web that supports native fish popular with local anglers. While both midges and fish are key components of the aquatic community in this scenario, evaluating midges alone would not address both ecological and community concerns (and it would probably be difficult to convince local residents that annoying insects should be protected). Selecting the fishery would allow assessors to characterize the risk to the fishery if the midge population is adversely affected and address both sets of issues. (Notice that this may require a trip back to the planning stage to revisit management goals, which on further examination may evolve from something like “eliminate biting insects” to “minimize biting insects while maintaining sport fishing opportunities.”) This strategy addresses ecological issues while responding to management concerns. If there is no choice but to use an unpopular assessment endpoint, the risk assessor will need to link it convincingly to values that people do care about.

Practical issues, such as what is required by statute (e.g., the Endangered Species Act) or management options, may influence assessment endpoint selection. Another concern is whether important variables can be measured directly. Assessment endpoint attributes that can be measured directly are best because they avoid the uncertainty introduced by having to extrapolate or estimate values. Nevertheless, sometimes the only data that are available are those measured indirectly or generated by a model. Note also that data availability and measurement convenience are *not* selection criteria: while established measurement protocols may be familiar and easy to use, convenience is no guarantee of appropriateness. For practical reasons, it may be helpful to use assessment endpoints that have well-developed test methods, field measurement techniques, and predictive models.³¹ However, it is not necessary to use standardized protocols, and assessment endpoints should not be selected simply because protocols are readily available.

Finally, assessment endpoint selection is an important risk manager–risk assessor checkpoint: all parties should agree that selected assessment endpoints effectively represent the management goals, and the rationale for their selection should be explicit.

36.2.2.2 Conceptual Models

Conceptual models describe key causal relationships that will be evaluated in the risk assessment. They have two components: (1) a set of written hypotheses that propose relationships between ecological effects and stressors and (2) a diagram of the relationships. Conceptual models may include elements such as ecosystem processes that influence receptor responses or exposure scenarios that qualitatively link land-use activities to stressors. They may describe primary, secondary, and tertiary exposure pathways or co-occurrence between exposure pathways, ecological effects, and ecological receptors. The process also identifies what additional information is needed. A carefully prepared conceptual model will provide a helpful reference point throughout the ERA; it can be used to refine models or assumptions, keep the assessment on course, and serve as an outline when preparing outreach materials.

Risk hypotheses (sometimes called assessment questions) articulate how exposure to stressors could cause adverse effects. They are used to guide the analyses conducted in the risk assessment and are not usually designed to be tested statistically. They may predict effects of a stressor prior to its release or explain why observed ecological effects occurred and, ultimately, what caused the effect. Risk hypotheses may range from very simple (e.g., receptor *x* will be exposed to stressor *y* at a particular place and time) to very complex (thermal discharge will increase species *a*'s recruitment, decrease species *b*'s recruitment, increase species *c*'s biomass, increase species *d*'s food supply, and increase nutrient levels over time...with possible effects to a predator that happens to be endangered locally, but not regionally).

Diagrams are extremely useful in communicating and exploring conceptual models. They can show important pathways clearly and concisely and be used to refine or generate new questions about relationships. Sometimes they are flow diagrams with boxes and arrows to illustrate relationships (see, for example, Figure 36.2); cartoons are also very helpful. Early conceptual models are usually quite general in that they identify as many potential relationships as possible. As more information is incorporated, risk assessors sort through stressor–effect relationships and the ecosystem processes that influence them to identify the questions most appropriate for the analysis phase. Several documents offer examples and advice on conceptual-model development.^{1,32–34}

Conceptual-model development may be one of the most important sources of uncertainty in ERA. If important relationships are missed or incorrectly described, the risk characterization may misrepresent actual risks. Uncertainty may arise from ignorance about how the ecosystem functions, failing to identify and interrelate temporal and spatial parameters, omitting stressors, or overlooking cascading effects. Although it's impossible to avoid simplification and ignorance, conceptual models can help document what is known.^{33,35}

Figure 36.2 Conceptual model for tracking stress associated with lead shot through upland ecosystems. (From Kendall, R.J. et al., *Environ. Toxicol. Chem.*, 15, 4, 1996. With permission.)

36.2.2.3 Analysis Plan

The analysis plan completes problem formulation. Here, participants evaluate the conceptual model to determine how it can be assessed. The plan delineates the assessment design, data needs, analytical methods, and anticipated uncertainties. For assessment approaches that are conducted repeatedly with different stressors (e.g., EPA's new chemical assessments), an analysis plan in a standard format may be available. The more unique and complex the assessment, the more important it is to have a good analysis plan.

The analysis plan identifies the pathways and relationships that will be pursued and emphasizes those most likely to contribute to risk. It also may compare the confidence desired for the management decision with that expected from alternative analyses to help decide what data are still needed and which analytical approach is best. If data are scanty, the analysis plan may recommend data collection or propose a phased or tiered approach. If new data collection is impossible, this should be acknowledged as a source of uncertainty.

When assessment endpoint responses cannot be measured directly, surrogates must be used. The selection of what, where, and how to measure surrogate responses determines whether the ERA is still relevant to the risk-management decisions. For example, an assessment may evaluate the risk of a pesticide used on seeds to an endangered seed-eating bird to help decide whether to register it for use. The assessment endpoint entity is the endangered species. Example attributes include feeding behavior, survival, growth, and reproduction. While it may be possible to directly collect measures of exposure and life-history characteristics, it would not be appropriate to dose the bird with the pesticide to measure sensitivity. So to evaluate susceptibility one would measure (or review the literature for data on) response to the pesticide in an appropriate surrogate. Depending

on the chemical, this could be another species with similar life-history characteristics, physiology, or phylogeny.

The analysis plan identifies the pathways and relationships that will be pursued in the assessment and emphasizes those most likely to contribute to risk. It can serve as a checkpoint with managers to compare the results expected from the assessment with the information needs and confidence desired for the management decision (e.g., do they meet Data Quality Objectives³⁰)? If suitable data are available, the assessment proceeds. If data are scanty, the analysis plan may recommend additional data collection or propose a phased or tiered approach that begins with available information.

36.2.3 The Analysis Phase

Analysis is a process that examines the two primary components of risk — exposure and effects and their relationships with the ecosystem. The objective is to provide the ingredients necessary to determine or predict ecological responses to stressors under specific exposure conditions.

The analysis phase is flexible, with substantial interaction between the effects and exposure characterizations as illustrated by the dotted line in Figure 36.1. In particular, when secondary stressors and effects are of concern, analyses of exposure and effects can become intertwined and difficult to differentiate. An assessment of bottomland hardwoods, for example, examined potential changes in the plant and animal communities under different flooding scenarios.³⁶ Analysts combined the stressor-response and exposure analyses within the FORFLO model for primary effects on the plant community and within the Habitat Suitability Index for secondary effects on the animal community. The model results were used directly in risk characterization and thus also blurred the distinction between analysis and risk estimation.

The nature of the stressor influences the types of analyses conducted. For chemical stressors, exposure estimates emphasize contact and uptake into the organism, and effect estimations often entail extrapolating toxicological data from one test organism to another. For physical stressors, the initial disturbance may cause primary effects on the assessment endpoint (e.g., loss of wetland acreage). But in many cases, secondary effects (e.g., decline of wildlife populations that depend on wetlands) are the main concern; the point of view depends on the assessment endpoints. Because adverse effects can occur even if receptors do not physically contact disturbed habitat, exposure analyses may emphasize co-occurrence with physical stressors rather than contact. For biological stressors, exposure analysis evaluates entry, dispersal, survival, and reproduction³⁷ (discussed further in Section 36.3.2).

The assessor's first task of the analysis phase is to determine whether available studies are right for the ERA objectives. Data are rarely as complete as one would like, but eventually one must decide whether to make do with what is available, fill gaps with models, or collect new data. Reviewing the data and information that will be used in the risk assessment also provides the opportunity to evaluate how uncertainties in the assessment will be described and, where possible, quantified. Uncertainty analysis can improve credibility because it explicitly describes the size and direction of errors, and it can show where additional data or analytical refinements would do the most good. The development of quantitative methods to evaluate uncertainty is a currently active area, discussed further in Section 36.3.1.

36.2.3.1 Characterize Exposure

Exposure characterization describes potential or actual contact or co-occurrence of stressors with receptors. The evaluation encompasses stressor sources, receptor behavior, stressor and receptor distribution and movement in the environment, and the extent and pattern of contact or co-occurrence. The objective is to describe how receptors and stressors interact with the environment and each other and the likelihood of any contact or co-occurrence. Exposure analysis describes exposure in terms of intensity, space, and time in units that can be combined with the effects assessment.

36.2.3.1.1 *Describe the Source(s)*

A source can be defined in two general ways: as the place from which the stressor either originates or is released (e.g., a smokestack, historically contaminated sediments) or the management practice or action (e.g., dredging) that produces stressors. In some assessments, the original source no longer exists and so is defined as the current location of the stressors. For example, contaminated sediments might be considered a source because the industrial plant that produced the chemicals that ended up there no longer operates. A source influences where and when stressors eventually will be found.

Many stressors have natural counterparts or multiple sources, so it may be necessary to characterize these as well. Many chemicals occur naturally (e.g., most metals), are widespread due to other sources (e.g., polycyclic aromatic hydrocarbons in urban ecosystems), or have significant sources outside the boundaries of the current assessment (e.g., atmospheric nitrogen deposited in Chesapeake Bay). Many physical stressors also have natural counterparts. For instance, construction activities may release sediments into a stream in addition to those already coming from a naturally undercut bank. Human activities may also change the magnitude or frequency of natural disturbance cycles. For example, fire suppression may decrease the frequency but increase the severity of fires because fuel accumulates without small fires to consume it.

36.2.3.1.2 *Describe the Distribution of the Stressors or Disturbed Environment*

The second objective of exposure analysis is to describe where and when stressors occur in the environment. For physical stressors that directly alter or eliminate portions of the environment, the assessor describes the disturbed environment. Stressor distribution is examined by evaluating transport pathways from the source as well as the formation and subsequent distribution of secondary stressors.

Secondary stressors may be even more of a concern than the primary stressor. For chemicals, the evaluation usually focuses on metabolites, biodegradation products, or chemicals formed through abiotic processes. As an example, microbial action increases mercury bioaccumulation by transforming inorganic forms to organic species. Ecosystem processes may also form secondary stressors. For example, nutrient inputs into an estuary can increase primary production and subsequent decomposition and deplete dissolved oxygen. Physical disturbances also can generate secondary stressors, and identifying the one that most affects the assessment endpoint can be a difficult task. The removal of riparian vegetation, for example, may increase nutrient levels, stream temperature, sedimentation, and stream flow extremes. However, temperature change may have the greatest effect on adult salmon survival in a particular stream.

If stressors have already been released, direct measurement of environmental media or a combination of mechanistic and empirical modeling and measurement is ideal. If not, models make it possible to either make predictions or interpolate between available measurements. Models also are useful for quantifying relationships between sources and stressors. Models of fate and transport of chemicals are particularly well developed (e.g., Lahlou³⁸), and the concept can be extended to other types of sources and stressors. For example, Johnson et al.³⁹ used wetland extent to predict downstream flood peaks.

36.2.3.1.3 *Describe Contact or Co-Occurrence*

The third objective is to describe the intensity and spatial and temporal extent of co-occurrence or contact between stressors and receptors. This is critical — if there is no exposure, there can be no risk. The analysis may consider exposure that may occur in the future, exposure that has already occurred but is not currently evident (e.g., in some retrospective assessments), and exposure of food or habitat resources that might cause a cascade of effects.

People usually think of exposure as actual contact with a stressor, but sometimes a stressor's presence can affect an organism even if there is no contact. Whooping cranes provide a case in point: they use river sandbars as resting areas, and they prefer sandbars with unobstructed views. Without ever actually contacting the birds, dams can modify the flood regime that maintains the sandbars by scouring and redepositing sand, and obstructions such as bridges can interfere with resting behavior. Most stressors must contact receptors to produce an effect. For example, aluminum floc in low pH lakes alters fish gills that it contacts. Finally, some stressors must not only be contacted but also reach the target organ. A toxicant that causes liver tumors in fish, for example, must be absorbed and reach the liver to cause the effect.

Intensity is the most familiar dimension for describing exposure to chemical and biological stressors. Exposure intensity may be expressed as the amount of chemical or number of pathogenic organisms contacted. The temporal dimension comprises duration (the time over which exposure occurs) and frequency (how often it occurs). Finally, exposure timing, including the order or sequence of events, can be an important consideration. Adirondack Mountain lakes receive high concentrations of hydrogen ions and aluminum during snow melt; this period corresponds to the sensitive life stages of some aquatic organisms.

Spatial extent is another exposure dimension. It usually is expressed as area (e.g., hectares of paved habitat, square meters that exceed a particular chemical threshold). At larger spatial scales, the shape or arrangement of exposure may be an important issue, and area alone may not be enough to describe spatial extent for risk assessment. Geographic Information Systems (GISs) provide many options for analyzing and presenting the spatial dimension of exposure (e.g., Pastorok et al.⁴⁰).

36.2.3.2 Characterization of Ecological Effects

Effect characterization describes the stressor's effects, links them to the assessment endpoints, and examines the relationship between the amount of exposure and the magnitude of response. The objective is to describe the relationship between stressor levels and ecological effects and, further, to relate the measurable ecological effects to assessment endpoints when the latter cannot be directly measured.

36.2.3.2.1 Stressor-Response Analysis

To evaluate ecological risks one must examine the relationships between stressors and responses postulated in the analysis plan. For example, an assessor may need point estimates of an effect (such as an LC_{50}) to compare the effects of several stressors. The shape of the stressor–response curve may be needed to determine the presence or absence of an effects threshold or for evaluating incremental risks, or stressor–response curves may be used as input for effects models. Assessors usually examine one response (e.g., mortality, mutations), and most quantitative techniques have been developed for univariate analysis. If the response of interest reflects many individual variables (e.g., species abundances in an aquatic community), multivariate techniques may be needed.⁴¹ If it is not possible to quantify stressor–response relationships, they may be described qualitatively.

Stressor–response relationships are described using intensity, time, or space for consistency with exposure estimates. Intensity is most often used for chemicals (e.g., dose, concentration) and pathogens (e.g., spores per milliliter; propagules per unit of substrate). Point estimates and stressor–response curves can be generated for chemicals and some biological stressors. Exposure duration also is commonly used for chemical stressor–response relationships; for example, median acute effect levels are always associated with a time parameter (e.g., 24 h). Space or area is usually used for physical stressors: Thomas et al.⁴² related the chance of sighting a spotted owl to the extent and pattern of suitable habitat, and Phipps⁴³ related tree growth to water-table depth.

If enough data are available, multiple-point estimates can be displayed as cumulative distribution functions. Figure 36.3 shows how this was done for species sensitivity derived from multiple-point

Figure 36.3 Risk estimation techniques: comparison of exposure distribution of an herbicide in surface waters with freshwater single-species toxicity data. (Redrawn with permission from Baker et al., *Pesticide Risk Assessment and Mitigation*, SETAC, Pensacola, FL, 1994.) (Centile ranks for species EC₅₀ data were obtained using the formula $(100 - n/[N + 1])$, where n is the rank number of the EC₅₀, and N is the total number of data points in the set. (Adapted from Parkhurst, B.R. et al., *Methodology for Aquatic Ecological Risk Assessment*, Water Research Foundation, Alexandria, VA, 1995.)

estimates (EC₅₀s) for algae (and one vascular plant) exposed to an herbicide. These distributions can help identify stressor levels that affect a chosen proportion of species.

36.2.3.2.2 Establishing Cause-and-Effect Relationships (Causality)

Causality is the relationship between cause (a stressor) and effect (response). Without a clear connection between cause and effect, one cannot place much confidence in the ERA's conclusions. Causal relationships are especially important in risk assessments driven by observed effects such as bird or fish kills or a shift in species composition. When multiple stressors occur, a causal evaluation helps identify the stressors most responsible for effects and eliminate those that are unimportant (Section 36.3.3). Evidence that can be used to support causal inferences may come from observed (e.g., bird kills associated with field application of a pesticide, with death caused by an effect the pesticide is known to elicit) or experimental data (e.g., laboratory tests with the pesticides in question show mortality at tissue concentrations similar to those found in the field). Confidence increases when the effects of different causes can be isolated (e.g., as in controlled experiments) and when multiple lines of evidence support a particular cause. Since we cannot always arrange an experiment, scientists have looked for other ways to support an argument for cause and effect. Human health and ecoepidemiologists have developed a series of considerations that are useful for evaluating causality.⁴⁴⁻⁴⁷ These include whether the cause preceded the effect in time, whether the cause is consistently associated with an effect, whether effects increase with increasing levels of stress, and whether there is a plausible mechanism.

For chemicals, a modification of Koch's postulates⁴⁸⁻⁵⁰ has been proposed, and was applied in an evaluation of air pollution impacts on trees:⁵¹

- The injury, dysfunction, or other putative effect of the toxicant must be regularly associated with exposure to the toxicant and any contributory causal factors.
- Indicators of exposure to the toxicant must be found in the affected organisms.

- The toxic effects must be seen when organisms or communities are exposed to the toxicant under controlled conditions, and any contributory factors should be manifested in the same way during controlled exposures.
- The same indicators of exposure and effects must be identified in the controlled exposures as in the field.

36.2.3.2.3 *Linking Effects to Assessment Endpoints*

Stressor–response and causal relationships are most easily evaluated using very specific measures of effects that can be readily measured. These measures may be closely linked with the assessment endpoint. When they are not, extrapolations are used to make this link explicit and preferably quantified. Common extrapolations include those between taxa (e.g., bluegill sunfish mortality to rainbow trout mortality), between responses (from mortality to growth or reproduction) from laboratory to field (from bluegill mortality in laboratory tests to that under field conditions), between geographic areas (an empirical model in one region to another) between spatial scales (local effects to regional effects), and between temporal scales (short-term exposure to longer-term exposure).

Uncertainty factors are commonly used to account for uncertainty associated with different extrapolations. The objective is usually to estimate a stressor level that should not cause adverse effects to the assessment endpoint. Uncertainty factors have been most extensively developed for chemicals because extensive ecotoxicological data are available, especially for aquatic organisms. They are useful when decisions must be made about stressors in a short time and with little information.⁵² Despite their usefulness, uncertainty factors can be misused, especially when applied too conservatively such as when several factors are multiplied together without sufficient justification.

Process models for extrapolation are abstractions of a system or process⁵³ that incorporate causal relationships and can generate predictions even when data are not available.⁵⁴ They make it possible to translate data on individual effects (e.g., mortality, growth, and reproduction) to potential alterations in specific populations, communities, or ecosystems. They can be used to evaluate risk questions about a stressor's effect on an assessment endpoint that cannot easily be tested in the laboratory. Population models describe how demographic attributes of a group of individuals of the same species change through time; they have been used in both wildlife and fisheries management and to assess the impacts of power plants and toxicants on specific fish populations.^{55–57} Community and ecosystem models (e.g., Jorgensen³² and Bartell et al.⁵⁸) are useful when the assessment endpoint involves structural (e.g., community composition) or functional (primary production) elements. They can also be useful for examining how effects may cascade through an ecosystem and for estimating changes in ecosystem components such as populations, functional types, feeding guilds, or environmental processes.

The final product of ecological response analysis is a summary of what effects a stressor may elicit in the various receptors of concern, under what conditions these effects occur, and how such effects relate to the assessment endpoints.

36.2.4 Risk Characterization

Risk characterization is the final phase of ERA, in which the risk assessor reaches conclusions about the existing or anticipated effects. The assessor uses the results of analysis to estimate risk to the entities included in the assessment endpoints identified in problem formulation (Section 36.2.5.1). Next, the assessor provides context — the significance of any adverse effects and lines of evidence supporting conclusions (Section 36.2.5.2). Finally, the assessor identifies and summarizes the uncertainties, assumptions, and qualifiers in the risk assessment and reports the conclusions (Section 36.2.5.3).

36.2.4.1 Risk Estimation

Risk estimation is the process of integrating exposure and effects data and evaluating any associated uncertainties. The process uses exposure and stressor–response estimates developed in the analysis phase. The output may be qualitative or quantitative and is used to place the risks in the risk-management context.

A variety of methods are used to combine exposure and effects information into an estimate of risk. Even with limited data, risks may be categorized or ranked using professional judgment. If there are enough data to quantify exposure and effects estimates, the simplest comparative approach is a ratio or quotient; this usually is expressed as an exposure concentration divided by an effects concentration. Quotients are most commonly used for chemical stressors, for which reference or benchmark toxicity values are widely available. The quotient method can be enhanced by using the entire stressor–response curve or by incorporating variability in exposure or effects estimates. Process models can be used to combine empirical estimates with mechanistic data. Even field observations can be used, when a particular exposure scenario and effects co-occur. Because each method has its strengths and limitations, a risk assessment may use more than one approach.

36.2.4.2 Risk Description

After preparing risk estimates, risk assessors explain the supporting information by evaluating the lines of evidence and the significance of the adverse effects. Ideally, the relationship between the assessment endpoints, measures of effect, and associated lines of evidence will have been established during the analysis phase. If not, the risk assessor can qualitatively link lines of evidence to the assessment endpoints. Regardless of the technique, the technical narrative supporting a risk estimate is as important as the estimate itself.

Confidence in an ERA's conclusions may be increased by using several lines of evidence to interpret and compare risk estimates. These may be derived from different sources or by different techniques, such as quotient estimates, modeling results, or field observational studies. Three factors are used to evaluate lines of evidence: (1) data quality and adequacy, (2) degree and type of uncertainty associated with the evidence, and (3) relationship of the evidence to the risk assessment questions.

This evaluation is more than just a list of the evidence that supports or refutes the risk estimate. The risk assessor should examine each line of evidence and evaluate its contribution in the risk assessment's context. Data or study results often are not reported or carried forward in the risk assessment because they are of insufficient quality. Note that such data may still be valuable if they provide information about topics such as how methodologies could be improved and provide recommendations for further studies.

At this point, the assessment has described potential changes in the assessment endpoints and evaluated lines of evidence. The next step is to explain whether these changes are in fact adverse. For our purposes, adverse effects are changes that are undesirable because they alter valued structural or functional attributes of the entities of interest, that is, the assessment endpoints identified back in problem formulation. The risk assessor evaluates the degree of adversity, a challenging task frequently based on professional judgment. The assessor should also recognize that ecological effects will be considered along with economic, legal, or social factors when a risk-management decision is made and be prepared to discuss adverse effects in that context, if necessary. The risk manager will use all this information to decide whether a particular adverse effect can be tolerated, and may also find it useful when communicating the risk to stakeholders.

The criteria for evaluating the degree of adversity are (1) nature and intensity of effects, (2) spatial and temporal scale, and (3) recovery potential. The nature and intensity of effects help distinguish adverse changes from normal ecosystem variability or those resulting in little or no significant change. For example, for an assessment endpoint involving survival, growth, and repro-

duction of a species, do predicted effects involve survival and reproduction or only growth? If offspring survival will be affected, by what percentage will it diminish?

Although statistical significance does not necessarily mean ecological significance, risk assessors should consider both ecological and statistical effects when evaluating intensity. For example, a 10% decline in reproduction may be worse for a population of slowly reproducing trees than for rapidly reproducing planktonic algae, even if both can be statistically differentiated from a reference or control condition. Natural ecosystem variation can make it hard to statistically detect stressor-related perturbations. For example, normal intra- and interannual variability in the size of marine fish populations is several orders of magnitude. Furthermore, cyclic events (e.g., migration, tides) are very important in natural systems and may mask or delay stressor-related effects. A field study's inability to detect statistically significant effects does not automatically mean that there are none. Risk assessors should consider the test's power to detect changes, the degree or magnitude of change, and other lines of evidence in reaching their conclusions.

The spatial dimension of risk encompasses both the extent and pattern of effect as well as the context of the effect within the landscape. Factors to consider include the absolute area affected, the extent of critical habitats affected compared with a larger area of interest, and the affected area's role within the landscape. A larger affected area may be (1) subject to a greater number of other stressors and complications from stressor interactions, (2) more likely to contain sensitive species or habitats, or (3) more susceptible to landscape-level changes because many ecosystems may be altered by the stressors. Nevertheless, a smaller area of effect is not always associated with lower risk. An area's function within the landscape may be more important than its absolute area. Destruction of small but unique areas such as critical wetlands may have important effects on local and regional wildlife populations.

The temporal scale for ecosystem change can range from seconds (photosynthesis, prokaryotic reproduction) to centuries (global climate change). Changes within a forest ecosystem can occur gradually over decades or centuries and may be affected by slowly changing external factors such as climate. When interpreting adversity, risk assessors should recognize that any stressor-induced changes occur within the context of multiple natural time scales. In addition, ecosystem changes may involve intrinsic time lags, so observable responses to a stressor may be delayed. Analysts should make an effort to distinguish a stressor's long-term impacts from its immediately visible effects. For example, fish population changes resulting from eutrophication may not become evident for many years after initial increases in nutrient levels and observations of algal blooms.

Considering the temporal scale of adverse effects leads logically to a consideration of recovery. Recovery is the rate and extent of return of a population or community to some aspect of its condition prior to a stressor's introduction.⁵⁹ Because ecosystems are dynamic and, even under natural conditions, constantly changing in response to changes in the physical environment (e.g., weather, natural disturbances) or other factors, it is unrealistic to expect that a system will remain static at some level or return to exactly the same state that it was before it was disturbed.⁶⁰ Therefore, the assessment should be clear about what attributes define "recovered" in a particular system. Examples might include productivity declines in a eutrophic system, species reestablishment at a particular density, species recolonization of a damaged habitat, or diseased organisms' recovery.

Recovery can be evaluated in spite of the difficulty in predicting events in ecosystems.⁶¹ We can distinguish changes that are usually reversible (e.g., stream recovery from sewage effluent discharge), frequently irreversible (e.g., establishment of introduced species), and always irreversible (e.g., extinction). For example, physical alterations, such as deforestation in the coastal hills of Venezuela in recent history and in Britain during the Neolithic period, changed soil structure and seed sources such that forests cannot easily grow again.⁵⁹

36.2.4.3 Reporting Risks

When risk characterization is complete, risk assessors should be able to estimate the likelihood and magnitude of ecological effects, indicate the overall degree of confidence in the risk estimates,

cite lines of evidence supporting the risk estimates, and interpret the adversity of ecological effects. Usually this information is included in a risk assessment report (sometimes called a risk characterization report).

To ensure that readers can understand the ERA and eventually use its conclusions, its results should be clear (written in ordinary language accessible to others outside the risk-assessment field) and transparent (a reader can tell how analyses and conclusions were developed). It also helps if they are reasonable (do not contain any unusual or unprecedented conclusions) and consistent with other similar assessments.⁶²

It is in the assessor's interest to present the results in terms that will be meaningful to the decision maker and other readers. It is a good idea to find out what format the decision maker prefers. If this person only wants the big picture, prepare a summary that tells where supporting information can be found if needed. Or if your reader typically searches for details, by all means provide them — do what it takes to get the assessment read. Although the risk characterization should include enough details somewhere so readers can see clearly how its conclusions were derived, eventually the results need to be distilled into a smaller package such as an executive summary or briefing packet.

Risk managers need to know the major risks and get an idea of whether the conclusions are strongly or weakly supported. Insufficient resources, lack of consensus, or other factors may make it impossible to prepare a detailed and well-documented risk characterization. If this is the case, the risk assessor should carefully explain any issues, obstacles, and correctable shortcomings for the risk manager's consideration.

Risk managers typically decide whether additional follow-up activities are needed. Depending on the importance and visibility of the assessment, confidence in its results, and available resources, it may be advisable to conduct another iteration of the risk assessment to inform a final management decision. Another option is to proceed with the decision, implement management action, and develop a monitoring plan to evaluate the results (see Section 36.1). If the decision is to mitigate risks through exposure reduction, for example, monitoring could help determine whether the action taken really did reduce exposure (and effects).

Finally, risk characterization provides the basis for communicating ecological risks to stakeholders and the general public. This task is usually the risk manager's responsibility, but it may be shared with risk assessors. An even better approach is to use communication specialists familiar with common concerns about risk and effective strategies for addressing them. Although the final version of a risk assessment prepared for the government is usually made available to the public, the communication process is best served by tailoring information to a particular audience. This is the time to refer both to the questions posed by managers and other stakeholders that were involved in planning the assessment and to the conceptual model.

36.3 RECENT DEVELOPMENTS AND APPLICATIONS OF ECOLOGICAL RISK ASSESSMENT

As ERA is applied to specific problems, methods and concepts are being refined to meet particular needs. This section explores three evolving applications: probabilistic methods (Section 36.3.1) for pesticides and other chemicals, exposure concepts for biological stressors (Section 36.3.2), and place-based analyses for multiple stressors (Section 36.3.3).

36.3.1 Assessing Ecological Risks from Chemicals Using Probabilistic Methods

Deterministic methods are widely accepted by regulatory groups and decision-makers and can produce scientifically sound ERAs.⁶³ However, distilling toxicity and exposure information into a single value can lead to inconsistency and confusion about the assessment's conclusions. Probabi-

Figure 36.4 Probabilistic risk assessments combine distributions of effects and exposure to produce estimates of the probability that effects will occur. (From ECOFRAM, Terrestrial Draft Report, U.S. EPA, Washington, D.C., 1999.)

listic ERA methods have been proposed as a way to quantitatively describe natural variability and lack of knowledge and their effect on conclusions.

Probabilistic risk assessments (PRAs) use exposure equations and effects estimates similar to those in deterministic ERAs, but PRAs use distributions rather than single point values for parameters. Distributions for each value used to calculate toxicity or exposure are specified based on available data and the professional judgment of the assessor. Then the distributions can be combined mathematically to yield a range or distribution of risks faced by the endpoint of concern (Figure 36.4). More usually, the distributions are combined using simulations: values for each variable are selected randomly from the distribution and combined, and then the process is repeated thousands of times with programs such as Crystal Ball™. Risk is shown as a curve that combines the exposure and toxicity distributions such as the probability of different levels of effect (e.g., EC_{10}).⁶⁴ Detailed descriptions of probabilistic risk estimation can be found in several publications.^{58,63–67}

Rumbold⁶⁸ conducted a PRA on the risk of methylmercury exposure to wading birds in the Everglades. He used an extensive database of fish collected from the Everglades to generate a distribution of the dose of methylmercury from fish consumption to several species of wading birds. From this distribution, he generated curves that showed the fraction of the population that would exceed different toxicological doses.

Probabilistic methods make better use of the information available in dose-response curves, monitoring data, and exposure data. By using ranges or distributions of parameters, probabilistic methods can address both known variability and the lack of knowledge of a parameter's true value. Sensitivity analysis can be conducted to identify the uncertainties that have the greatest impact on the results of the assessment. This can help to focus the ERA on the critical parameters or identify needs for further data collection or research.

Challenges with PRA include gaps in our understanding of how the variables are distributed.⁶⁴ Careless treatment of these gaps can create serious flaws in the output. Mathematical assumptions, such as independence of variables, can lead to inaccurate assessments if ignored by assessors. It can also be difficult to describe probabilistic ecological risk assessment results to managers or the public. Deterministic risk assessments typically produce a “bright line” number (concentration or dose) that is considered protective of a given endpoint. In contrast, PRAs typically generate curves that reflect different degrees of protection, for example, 10% of the species has a 1% risk of

Figure 36.5 Example curves illustrating possible interpretations of probabilistic risk-assessment results. (From ECOFRAM Terrestrial Draft Report, U.S. EPA, Washington, D.C., 1999.)

exceeding a criterion; 1% has a 10% risk of exceeding it (Figure 36.5). Expressing risks in curves may require additional effort from the risk assessor to effectively communicate results and additional effort from the risk manager to consider the degree of protectiveness required.

Despite the difficulties in calculating and communicating PRA results, these methods provide many benefits. PRA addresses uncertainty and variability by analyzing information available in dose-response curves, exposure distributions, and environmental variability. Probabilistic approaches can increase the realism and credibility of assessments. They can provide insights into low-probability, high-consequence scenarios as well as scenarios that will frequently occur. By providing more information to risk managers, decisions can be better informed, flexible, and appropriately protective.

36.3.2 Ecological Risk Assessment of Biological Stressors: Expanding Concepts of Exposure

The most familiar applications of the EPA's Guidelines¹ are for chemical stressors such as pesticides and industrial chemicals, but they also address physical and biological stressors. This section discusses how the general ecological risk paradigm can be adapted to biological stressors, specifically, nonindigenous species. Further discussion and example case studies may be found in Orr.⁶⁹

A significant difference between chemical and biological stressors is that living organisms reproduce. Equally important is that they can adjust to or modify the environment to fit their needs. In addition, a newly established population can, over successive generations, adapt themselves to the new environment. These basic characteristics of life pose a challenge for conducting risk assessments for living organisms. In spite of these difficulties, the principles described in the EPA's Guidelines¹ can be used to evaluate the risks posed by invasive species. This requires a reevaluation of exposure as traditionally applied to chemical stressors.

Exposure is contact or co-occurrence of a stressor with a receptor — a familiar concept for chemical stressors. For biological stressors, exposure analysis evaluates the probability of several factors:³⁷ (1) organism presence in a pathway leading to their introduction into an area (e.g., insect pests on imported logs); (2) successful entry via the pathway (e.g., the insects survive risk-mitigation measures such as log debarking or fumigation during transport and processing); (3) organism colonization at the entry point (e.g., escape of insect into trees near a pulp mill); and (4) organism potential for spread beyond the initial colonization point.

Evaluating entry pathways is analogous to conducting a source characterization for chemical stressors. It is particularly important for invasive species, since many risk-reduction strategies focus

on preventing initial entry. Once the source is identified, the likelihood of entry may be characterized qualitatively or quantitatively or by using a hybrid of both. In their risk analysis of Chilean log importation, for example, the assessment team concluded that the beetle *Hylurgus ligniperda* had a high potential for entry into the United States. Their conclusion was based on the beetle's attraction to freshly cut logs and tendency to burrow under the bark, which would provide protection during transport.⁷⁰

Once the analyst has determined whether a species can enter an area, the next step is to examine whether it can colonize the new habitat and spread beyond the point of introduction. Environmental conditions such as climate, habitat, and suitable hosts determine whether a species becomes established. For example, climate would prevent establishment of the Mediterranean fruit fly in the northeastern United States. Thus, a thorough evaluation of environmental conditions in the area vs. the natural habitat of the stressor is important. Even so, many species can adapt to varying environmental conditions, and the absence of natural predators or diseases may play an even more important role than abiotic factors.

Because of the uncertainty in predicting the effects of potentially invasive species, professional-judgment approaches are commonly used. For example, there may be measures of effect data on a pathogen that attacks a certain tree species not found in the United States, but the assessment endpoint concerns the survival of a commercially important tree found only in the United States. In this case, the analyst would compare the life history and environmental requirements of both the pathogen and the two tree species. Expert panels are typically used for this kind of evaluation.⁷¹ For example, the U.S. Department of Agriculture Forest Service used an expert panel to evaluate the risks of introduced pests to U.S. forests from imported logs.⁷⁰ The purpose was to determine whether actions to restrict or regulate the importation of Chilean logs were needed to protect U.S. forests. Stressors included insects, forest pathogens (e.g., fungi), and other pests. The assessment endpoint was the survival and growth of tree species (particularly conifers) in the western United States. Damage that would affect the commercial value of the trees as lumber was also clearly of interest.

The analysis phase was carried out by eliciting professional opinions from a team of six experts. Measures of exposure included distribution information for the imported logs and insect and pathogen attributes such as dispersal mechanisms and life-history characteristics. Measures of ecosystem and receptor characteristics included U.S. climate data, location of geographic barriers, host suitability, and potential host species' ranges. Measures of effect included infectivity of these pests in other countries and the infectivity of similar pests in U.S. hosts (Figure 36.6).

This information was used by the risk-assessment team to evaluate the potential for exposure. They began by evaluating the likelihood of infested logs entering the United States. The distribution of the organism's entry was evaluated by considering the potential for colonization and spread beyond the point of entry as well as its survival and reproduction. Exposure potential was summarized by assigning each of the above elements a judgment-based value of high, medium, or low. Ecological effects were also evaluated by collective professional judgment. Specifically, environmental damage potential was defined as the likelihood of ecosystem destabilization, reduction in biodiversity, loss of keystone species, or reduction or elimination of endangered or threatened species. The team also considered negative impacts beyond environmental damage (e.g., negative economic and social impacts). Again, each factor was assigned a value of high, medium, or low to summarize the potential for ecological effects. The values assigned to the exposure and effect elements were combined into a total risk characterization value using a series of risk tables.⁷⁰

Risk assessment provides a framework for placing information about nonindigenous species into a format that can be used and understood by policy makers for making risk-management decisions. The major difficulty is the high uncertainty associated with predicting the likelihood that a species will establish itself in a new environment and estimating the degree of subsequent impact. This difficulty likely will continue given the lack of information on specific organisms and our current understanding of how ecosystems function. Nevertheless, the degree of uncertainty sur-

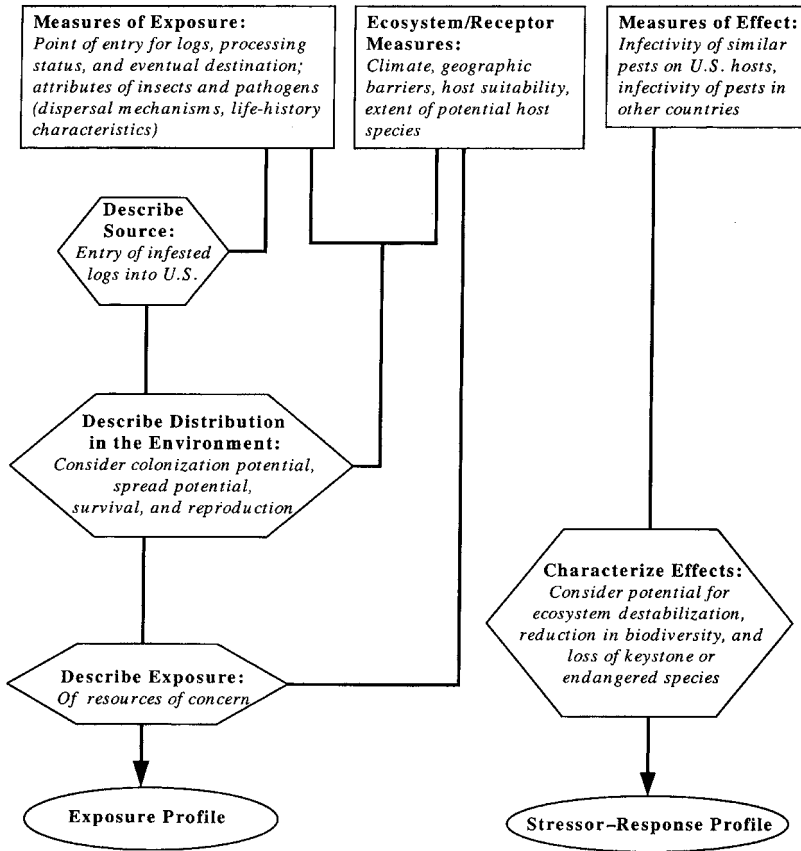

Figure 36.6 The analysis phase of an ecological risk assessment for invasive species: pest risk assessment of the importation of logs from Chile.⁷⁰ Rectangles indicate inputs, hexagons indicate actions, and ovals indicate outputs.

rounding the introduction of nonindigenous organisms only increases the need for careful, unbiased risk assessments before deciding whether to allow an introduction or take other management actions.

36.3.3 Evaluating Risks from Multiple Stressors

Risk assessment has a long history of evaluating risks from single (usually chemical) stressors. However, in reality, organisms are exposed to many stressors. Risk assessments that focus on a valued resource (e.g., salmon) or place (e.g., a watershed) must integrate risks across stressors in order to present a complete picture of threats and to identify which stressors may be most urgent or important for management action.

Integrating risks across multiple stressors poses some significant challenges. Stressors usually occur at different temporal and spatial scales. They may operate via different modes of action on different ecosystem components and interact through different physical, chemical, or biological processes. For example, a prototype watershed ERA was performed on a part of the Snake River in Idaho. Demands on water resources have transformed this once free-flowing segment to one with multiple impoundments, flow diversions, and increased chemical and microbiological pollutant loadings. The diversity, reproduction, growth, and survival of representative species from three major trophic levels (fish, invertebrates, and plants) were chosen as assessment endpoints to capture the broad range of potential risks.

Careful selection of assessment endpoints can identify characteristics of the ecosystem that respond to the various stressors under investigation and thus provide a mechanism to integrate across them. Conceptual models provide a useful way to explore and communicate the pathways by which multiple stressors interact. Even these qualitative hypotheses may be helpful for decision-making. As with single-stressor ERAs, they also help identify and select the most important pathways, relationships, and assessment endpoints and help identify uncertainty. For example, Figure 36.7 shows how interactions between siltation and temperature can affect salmon. Cormier et al.³⁴ used conceptual models to evaluate multiple stressors in the Big Darby Creek of Ohio. This assessment focused on the common endpoint of aquatic community structure to evaluate multiple stressors.

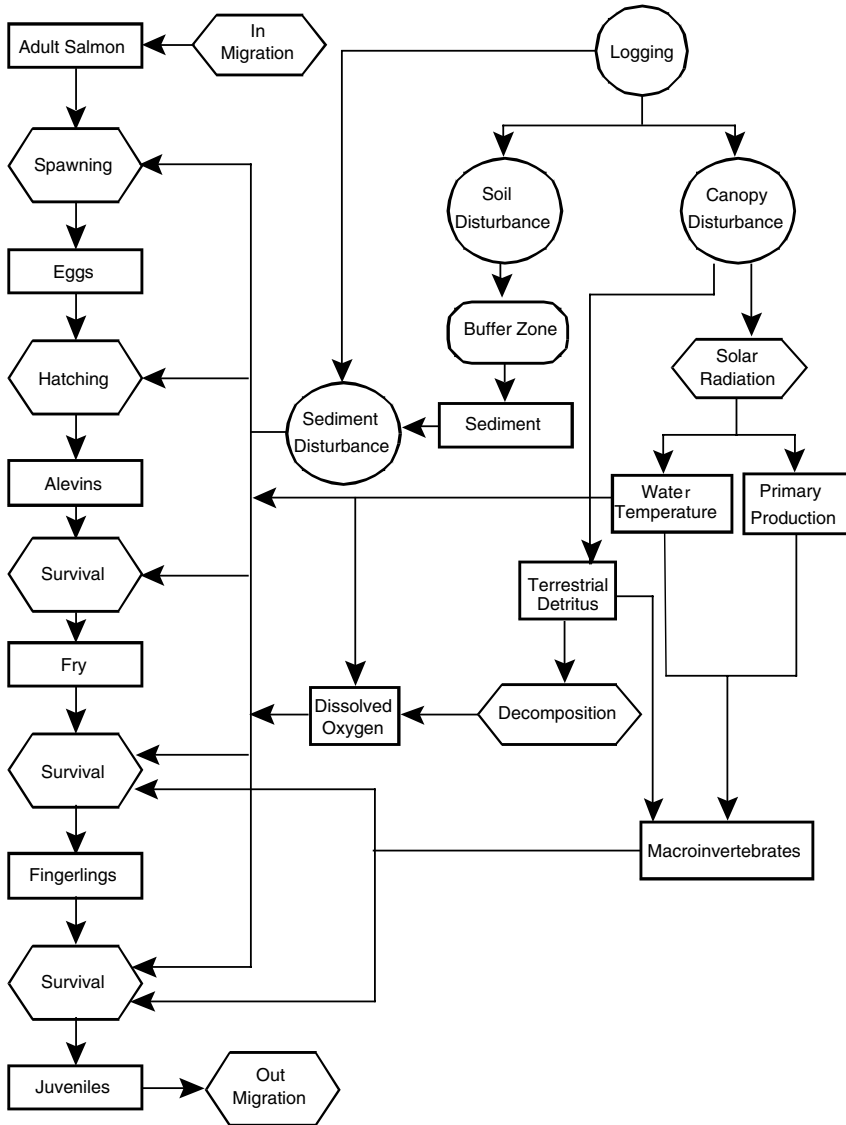

Figure 36.7 A conceptual model for ecological risk assessment illustrating the effect of multiple stressors on salmon production in a forest stream. (The assessment includes a series of exposures and responses. In the diagram, the circles are stressors, the rectangles are states of receptors, and the hexagons are processes of receptors. The rectangle with rounded corners is an intervention — establishment of buffer zones — that is being considered. (From Suter, G.W. et al., Issue Paper on Characterization of Exposure, U.S. EPA, Washington, D.C., 1994.)

The decision about which pathways and stressors to analyze is best made by an interdisciplinary team's best professional judgment. Foran and Ferenc⁷² summarize a variety of techniques, the majority of which involve having team members score the impact of stressors on assessment endpoints (see Reference 73 for an example).

While developing exposure and effects estimates is desirable, it is often difficult for multiple stressors. Different stressors may co-occur in different places, and some may occur only episodically, making them difficult to measure and interpret. Due to the relatively large spatial scale and the multiple stressors that could be present, detailed quantitative exposure information is often unavailable. When sufficient data are available, multivariate statistical models can be used to quantify the associations between sources (e.g., an agricultural field), stressors (e.g., excess nutrients, sediments, and toxic substances), and effects.⁴¹ Process models such as CASM and Aquatox can be useful if they can be parameterized for the system of interest.⁷⁴ When models are not available, the system may be simplified by using surrogates such as land-use categories.⁷⁵ Or the analyses may need to be limited to the most disruptive stressor.

The Clinch and Powell watershed risk assessment focused on the impacts of multiple stressors on one of the richest assemblages of native fish and freshwater mussels in the world. Nearly half of the species once present in the watershed are now extinct, threatened, or endangered. The ecological assessment used GISs and ERA to structure a multivariate analysis to quantify relationships between instream stressors and land-use patterns and their effects on the fish and mussel communities.⁷⁶ One of the most useful analyses in this effort showed how mussel and fish communities declined with proximity to mining, agriculture, and urban land use.

Assessments initiated by an observed effect may need to tease out which of many stressors is the predominant cause. Recently, the EPA has explored how to evaluate causality in situations where an aquatic effect has been observed.⁷⁷⁻⁸⁰ Methods include eliminating candidate causes, using diagnostic symptoms or protocols, and comparing the strength of evidence for different causes. A formal method may be helpful when the situation is complex or contentious.

36.4 ECOLOGICAL RISK ASSESSMENT AND ENVIRONMENTAL MANAGEMENT

The planning phase of the EPA's Guidelines¹ describes interaction between risk assessors and risk managers, albeit in rather general terms and as something that should take place outside the risk assessment process *per se*. This section discusses several ways that the interactions between ERA and management are being explored further. Section 36.4.1 discusses the development of management objectives for ERA, Section 36.4.2 discusses the interface between ERA and management in the context of watershed assessments, and Section 36.4.3 discusses the interactions of ERA with economic benefits analysis and other societal concerns.

36.4.1 Developing Management Objectives for Ecological Risk Assessment

ERAs may examine many different species and multiple levels of biological organization, from individual to population, community, and ecosystem. Not everyone values organisms or ecosystems equally, and there is no general agreement on the level of protection they should be afforded. Moreover, a stressor or ecological change may harm some species but benefit others, making it more difficult to decide whether the effects should be avoided. ERAs may also consider species interactions, indirect effects, and nonchemical stressors. Because of these complexities, the process for planning an ERA and deciding on priorities for protection is particularly important.

The bridge between general regulatory goals and specific subjects for protection has been explored from two perspectives. First, the EPA recently collected and organized information about what the EPA had protected in the past.²⁷ They identified three categories of what they called *Priorities for Ecological Protection*: (1) plants, animals, and their habitats; (2) whole ecosystems,

their functions, and services; and (3) special places, and they suggest that these priorities could provide a specific focal point for assessment activities. Second, the processes used to focus broad goals has been further explored, both for assessments prompted by a regulation and those conducted within more flexible partnership processes.

Building on the *Priorities* document, the EPA has described three steps in the planning process: identifying the decision context, developing management objectives, and identifying what is needed to make the decision.⁸¹ These three steps interact substantially with the problem-formulation tasks of integrating available information, describing conceptual models, and identifying endpoints for the assessment. The National Academy of Sciences describes this interaction as an analytic–deliberative process, where the political processes of risk management and the scientific processes of risk assessment are closely intertwined.²⁶

The planning process is illustrated in an environmental impact assessment prepared for the Salton Sea restoration effort.⁸² The Salton Sea was created by flooding after irrigation water was brought into the southern California desert to support agriculture. Over the years, it became an important recreation area and wetland habitat, although agriculture remains the primary land use in the area. The water level is maintained mainly by agricultural drainwater, which contributes nutrients, pesticides, and other contaminants (e.g., salts) that are concentrated by evaporation, since there is no outlet. Today, the water level is rising and has flooded buildings, roads, and agricultural land. Disease outbreaks among birds have increased in frequency and severity, and recreational use has declined.

Identifying the decision context includes delineating the decision to be made, the context in which it will be made (e.g., public values, legal and policy issues, risk-management options, and geographic and temporal scale), and who needs to be involved (risk managers, risk assessors, and local stakeholders). For the Salton Sea example, two laws were particularly relevant: Public Law 102–575 of 1992 and the Salton Sea Reclamation Act (Public Law 105–372) of 1998. The laws direct the project to, among other things, “provide endangered species habitat, enhance fisheries, and protect human recreational values.” The project also needed to comply with the National Environmental Policy Act (NEPA) and the California Environmental Quality Act (CEQA). Two agencies, the Bureau of Reclamation (federal government) and the Salton Sea Authority (state government) led the Environmental Impact Statement (EIS) process and the restoration effort.

The step of developing objectives comprises deciding what is meant by “protect,” what is really important and how to achieve it, and choosing objectives. The five major objectives identified in the Salton Sea EIS were to (1) maintain the Sea as a repository for agricultural drainage from the Imperial and Coachella Valleys; (2) provide a safe, productive environment for resident and migratory birds and endangered species; (3) restore recreational uses; (4) maintain a viable sport fishery; and (5) provide opportunities for economic development along the shoreline. Notice that some of these goals contradict each other. While there are no easy remedies to resolving contradictory goals, a facilitated dialog process may be useful. Briefly, the dialog process features (1) equality and the absence of coercive influences (everyone has an equal standing and feels free to speak), (2) listening with empathy (everyone is heard and taken seriously), and (3) bringing assumptions into the open (people explore and explain what’s behind their positions).⁸³ Goals developed by consensus are usually general, so the planning group should be prepared to spend some time making them specific and measurable enough to use in the ERA.

Identifying information needs includes determining what is needed to make the decision (be it from the risk assessment or other analyses), considering what resources are available, deciding what questions the risk assessment should address, and recognizing what the risk manager can expect from the risk assessment. The first and major job of the scientific analysis component of the Salton Sea assessment was to evaluate the potential environmental impacts of five possible restoration alternatives listed in the EIS. The objectives listed above were used to guide this analysis.

A formal planning process to identify management goals and objectives can improve risk assessment by helping decision-makers set specific, measurable objectives that can be used to track

progress and document success. It also provides opportunities to incorporate public values into decision-making and to identify potentially conflicting objectives early enough in the process so that the assessment can address them. In addition, it can help focus assessment efforts on resources that are truly valued, ensuring that the assessment provides information relevant to the risk manager's decisions. Finally, a formal process promotes consistency, increases transparency, and aids in communication and improvement of the overall ERA process.

36.4.2 Ecological Risk Assessment for Watershed Management

Watershed and other place-based environmental-management approaches use defined geographic areas, partnerships, and science in decision-making.⁸⁴ For example, the *Watershed Approach Framework*⁸⁵ suggests coordinating environmental management by focusing public- and private-sector efforts on addressing the highest-priority problems within hydrologically defined areas, taking into consideration both surface and ground water. Partnerships with stakeholders are used to achieve the greatest environmental improvements with the resources available. The Watershed Approach has become a key tool for managing over 2000 watersheds in the country.⁸⁶

Assessments conducted in a partnership context are often initiated out of concern for a valued resource or place. A place-based focus facilitates the formation and activities of partnerships that can work together to resolve problems and consider making changes that will improve environmental quality. However, it may be necessary to reconcile multiple values to develop management objectives. In the Big Darby Creek watershed assessment, the partners established three environmental management objectives: (1) establish water-quality criteria for designated uses throughout the watershed, (2) maintain exceptional warm-water criteria for stream segments having that designation between 1990 and 1995, and (3) ensure the continued existence of native species.³⁴ These were then used to identify information needs that might be fulfilled by the assessment; in the Big Darby, many revolved around better understanding the relationships between human activities throughout the watershed and the diverse aquatic stream community.

A sound plan can form the basis of effective communication. While this is true for all types of risk assessments, place-based assessments generally involve many impacted and interested organizations and individuals, and so the need for more effective communication increases. Many authors have emphasized that stakeholder and manager communication needs to begin during planning, and that recurring discussions are necessary to make the findings most useful.^{26,72,87,88} The iterative aspect of the ERA process includes a regularly occurring dialog between the scientists and managers. This feedback loop is intended to incorporate new scientific information and changing risk-management needs into the developing risk assessment. This is especially important in watershed ERA because there are many potential risk managers, with diverse interests, and there is often no legislative mandate for them to take action based on the assessment findings. Instead, their involvement is based on their individual desires to address their respective environmental management objectives. Thus, scientists and managers need to interact regularly to share information, refine the scope of the analysis, and improve the clarity and value of the scientific information to the end users. In the Clinch and Powell Valley assessment, interim results and discussions refined the analyses by focusing work on assessing the impacts of mining, identifying the optimal spatial scale for evaluating riparian land use, and incorporating additional data on toxic-material spills.⁷⁶ In the Big Darby Creek assessment, similar discussions stimulated managers and stakeholders to take management actions including removing low-head dams, retargeting erosion-control efforts. The watershed assessment activities also contributed to a proposal to designate a Darby Prairie National Wildlife Refuge, which would protect areas with some of the best aquatic conditions.⁸⁹

ERAs can inform and support watershed management decisions by (1) helping scientists focus on decision makers' needs so managers better understand the ecological implications of their actions and (2) providing watershed-management groups a systematic method for incorporating environmental monitoring and assessment data into decision-making.^{90,91}

36.4.3 Integrating Ecological Risk Assessment with Economic, Human Health, and Cultural Assessments

Humans and their activities have always been part of the environment, and ecologists and land and resource managers are increasingly asked to provide information to help integrate economic, social, and human-health consequences with ecological issues. Difficult and contentious issues include managing western rivers and natural areas to balance human demands for energy with endangered species' needs for food and habitat. To make good choices, decision-makers must consider ecosystem functions and attributes, human health, and economic and cultural issues. Where economic development compromises ecosystems, this in turn can affect human health and cultural integrity as well as economic opportunities.

ERA information can be used to estimate the value of the services that ecosystems provide (e.g., flood control, nutrient recycling). An economic analysis of ecological benefits is based on the premise that actions affecting the state of an ecological resource will change the goods and services provided by that resource (i.e., the economic benefit endpoints).⁹² Typically, these results are presented in terms of dollars, or monetized. Because economic benefits are fundamentally based on ecological resources, economists need to work with ecologists and other scientists to understand what resources are likely to be affected and estimate the magnitude and economic consequences of those changes. In addition, by working with economists to identify and describe resources, ecologists can help ensure that the economic analysis does not overlook significant but less obvious or less direct effects.

Risk assessors and economists begin collaborating during planning, where risk managers, risk assessors, economic analysts, and stakeholders discuss the nature of the problem at hand and alternatives for addressing it. During problem formulation, risk assessors and economists work together to identify and define the linkages between ecological resources and economic benefits (i.e., the goods and services provided or supported by the ecological resource that have economic value to society such as recreation and flood control) (Figure 36.8). During conceptual model development, the economist can explain to the risk assessor how the ERA information will be used in subsequent economic analyses. The ecological risk assessor can identify direct and indirect effects of a risk-management action and explain how the ecological cascade of effects might result in changes that are not immediately apparent. Both viewpoints are needed to extend the conceptual model to include the economic endpoints.

Linking economic benefit endpoints to ecological endpoints can result in several types of findings including good matches between some ecological changes and some economic benefit endpoints as well as ecological changes that economists had not considered and potential economic valuation endpoints for which there are no clear connections to ecological changes identified in the conceptual model. Ecologists and economists can then consider these findings to see if linkages can be further refined or extended. Identification of linkages is an iterative process, and both disciplines should also consider whether there are feedback loops between ecological and economic endpoints. At this point in the process, the goal of collaboration is to be all inclusive and to extend the conceptual diagram to include as many linkages between ecological changes and economic benefit endpoints as is reasonable.

Interactions between the risk assessors and economists may also be useful for prioritizing which endpoints to evaluate and the extent to which relationships will be quantified. ERAs and economic benefit assessments are typically carried out independently. If necessary, analysis plans for the risk assessment and economic assessment can be coordinated to ensure analytical compatibility and to identify any feedback loops whereby economic information may affect the results of the ERA.

The characterization and presentation of ecological risks and the results of the economic benefit analysis are usually also performed independently. Because it may not be possible to monetize or quantify many of the economic benefits of an ecological change, both analysts should make sure the conceptual model allows benefits to be described qualitatively.

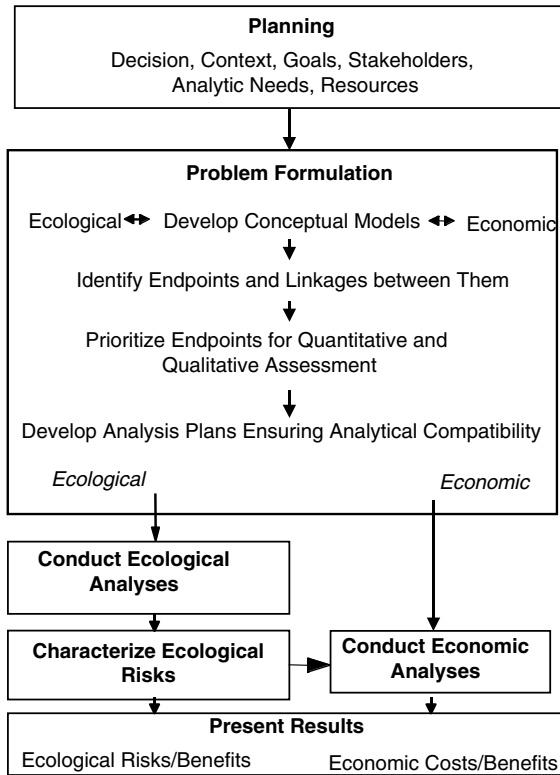

Figure 36.8 Framework for integrating ecological and economic analyses.

This same general process can be applied to integrate ERA with other analyses: important attributes for human health and cultural values can be defined during planning just as they are for ecosystems. This approach is now being used to evaluate the inter-relationships of human health, economic viability, and ecological and cultural integrity in Arctic ecosystems.⁹³ Subsistence lifestyles serve as a focal point because subsistence is directly linked to all four topics: (1) subsistence is a principal economic base for most communities in Alaska, (2) success in obtaining subsistence foods is a function of ecological condition, (3) community culture centers around the subsistence harvest, and (4) native people’s health directly benefits from eating subsistence foods and is adversely affected by more urban diets. The planning process will be expanded to identify values for all four areas of interest, and the risk assessment process will be used within this broader context. The effort is being approached both on a large regional scale — the Bering Sea — and in small communities.⁹³

For example, in the small island village of St. Paul, a village of 750 Aleuts is struggling for economic survival. To broaden its tax base, the community built a deep-sea-fishing port to capitalize on the Bering Sea fishery. Because the current winter fishery is being depleted, the community is considering enlarging the harbor and developing a summer finfish-processing industry. Although this may increase income, finfish processing is not without its own impacts. Preliminary planning activities identified the following scenarios:

The enlarged harbor will allow more ships to use the island, which will increase noise during the breeding season and the risk of fuel spills. Vulnerable wildlife include northern fur seal, kittiwakes and other seabirds, and the endangered Steller sea lion; these organisms, the resources they provide, and an unspoiled environment are integral components of Aleut culture.

Finfish processing uses freshwater. The community’s water source is an aquifer, accessed through a well. Although they are currently outside the well’s zone of influence, pollutants such

as nitrates and petroleum have been introduced into the aquifer. Increased water use may draw the pollutants into the water supply and may also cause salt-water intrusion.

An integrated risk assessment that incorporates ecological, health, economic, and cultural risk can provide managers with a series of potential outcomes for a variety of possible decisions helping them forestall unintended consequences and make reasoned and balanced decisions. As we learn more about how societal goals such as human health, economic benefits, and cultural concerns are influenced by ecological factors, new opportunities for responsible management may become apparent. ERA can provide the cornerstone for these evaluations.

36.5 CONCLUSIONS

ERA is a science-based process that allows for a consistent and formal approach for applying ecological information to a broad array of environmental decisions. By providing a common language and process, it increases the reproducibility and clarity of assessments, the credibility of practitioners, and the reasonableness of decisions that it informs. ERA can also provide the framework for examining the interactions between human health, welfare, economics, and ecological condition.

The hallmark of good science is its ability to predict what we will or will not see.⁹⁴ ERA has a critical role in predicting when human activities may degrade or improve environmental quality. By reviewing and validating those predictions and using information to improve ERA, we can advance the practical application of ecological and toxicological knowledge. In addition, we can provide managers with means for considering the full range of ecological consequences of their decisions and a sound basis for protecting and improving environmental quality. Finally, as managers increasingly consider the balance between ecological and human systems, ERA can provide a useful foundation for examining the interactions among human health, welfare, the economy, and ecological condition.

37.1 INTRODUCTION

37.1.1 Site Background

Kesterson Reservoir is located in the Grasslands area of northern Merced County, within the San Joaquin Valley of California. The reservoir was constructed between 1968 and 1975 as a series of 12 shallow ponds totaling about 500 ha (1200 acres) that served as a disposal site for subsurface agricultural drainage. Shallow saline groundwater was collected by drainage collection systems from fields in Fresno County and conveyed to the reservoir by the concrete-lined San Luis Drain. Following the discovery of selenium contamination in Kesterson Reservoir, the U.S. Bureau of Reclamation (USBR) halted discharge of agricultural drainage to Kesterson in 1986. The reservoir was subsequently dewatered, and lower elevation portions were filled with soil in 1988 to prevent groundwater from rising to the ground surface. Further description of the site and its early history are provided by USBR et al.,¹ USDI,² and Ohlendorf.³ A map showing the location and configuration of the subdivided, dry “ponds” of the reservoir as well as the three main habitat types is shown in Figure 37.1.

37.1.2 Previous Investigations

Beginning in 1983, a series of investigations documented the nature and occurrence of selenium contamination in soils, surface water, and groundwater at Kesterson Reservoir. Early investigations focused on surface water and the physicochemical processes associated with selenium bioaccumulation in the aquatic food chain.¹⁻⁵ These studies demonstrated that while selenate was the predominant form of selenium in surface waters, the pond-bottom sediments accumulated very high concentrations (tens to hundreds of mg/kg) of selenium in the elemental and organically associated forms. This accumulation resulted from a combination of microbial transformation of selenate to elemental selenium in the pond-bottom sediments and decomposition of aquatic vegetation such as the macroalgae chara and cattails.⁶⁻⁸

In 1988, with the drying out of Kesterson and filling of low-lying areas with soil, studies shifted to focus on the upland environment and the ephemeral pools that form during the rainy winter months. Specific investigations related to the physical and chemical behavior of selenium in the Kesterson environment include the following:

1. Ephemeral-pool occurrence and waterborne-selenium concentrations

- Field measurements of selenium concentrations in ephemeral pools from 1992 through 1999 (see summary by Zawislanski,⁹ CH2M HILL¹⁰)
- Field observations of the inception and duration of ephemeral pools from 1990 through 1999⁹
- Development of a model relating inception and duration of ponding to the difference between precipitation and cumulative evapotranspiration⁹

Figure 37.1 Kesterson Reservoir location and habitats.

- Aerial photographs taken early to mid-spring showing the location and extent of ephemeral pools
- Laboratory studies elucidating the physical and chemical processes contributing to intra-annual trends in selenium concentrations in ephemeral pools^{11,12}

2. Spatial distribution and time trends in soil-selenium concentrations

- Selenium speciation and fractionation investigations showing the depth distribution of elemental selenium, selenate, selenite and organically associated selenium at numerous sites throughout Kesterson^{6,13}
- Long-term monitoring of the depth distribution of extractable and total selenium concentrations at several sites from 1988 through 1998^{13,14}
- Synoptic measurements of total and water-extractable-selenium concentrations at 54 locations across Kesterson from 1990 to 1998 in conjunction with the biological monitoring program¹⁵ (for summary see Zawislanski et al.⁹)
- Field-measured volatilization rates from several experimental plots^{16,17}

- Laboratory measurements of selenium reoxidation rates under controlled conditions¹⁸⁻²⁰
- Modeling studies of the above-mentioned data to determine re-oxidation and leaching rates of selenium^{21,22}

Together these studies have been sufficient to develop an understanding of the current status of selenium in soils and ephemeral pools at Kesterson. Most of the selenium is confined to the top 15 cm of soil. Only a small fraction of the selenium in surface soils, typically less than 5%, is currently in extractable or mobile forms (e.g., dissolved selenate and selenite).⁹

Ephemeral pools at Kesterson are formed primarily by the accumulation of rainwater on the soil surface. Selenium concentrations in these pools range from 1 to as much as 1000 µg/L. The highest selenium concentrations occur immediately after the pools have formed and then decrease to relatively stable concentrations in the range of 1 to 200 µg/L after a few weeks (Figure 37.2). The selenium in these pools results from dissolution of salt crusts and diffusion of dissolved selenium from pore waters into the overlying surface waters. Once the pool is formed, anoxic conditions may develop in the underlying soils. Over time, diffusion of selenium from the pools back into the underlying soils depletes the concentration of selenium in surface water. Simultaneously, selenium diffused back into the soils is reduced to immobile forms. As demonstrated by nearly a decade of monitoring, the net effect of these processes is for selenium concentrations in ephemeral pools to remain in the current range for several decades.

3. Biological monitoring and ecological risk assessment (ERA)

A series of field and laboratory studies, beginning in 1983, documented the bioaccumulation of selenium in food-chain organisms and its adverse effects on aquatic birds feeding at Kesterson (summarized by Ohlendorf³). These birds exhibited high rates of embryo deformities and mortality as well as mortality of adult birds. In contrast, studies of mammals and terrestrial birds using Kesterson showed significant levels of selenium bioaccumulation, but no clear evidence of adverse effects. These findings, among others, contributed to the decision to dewater the reservoir and fill low-lying areas as a means of site remediation.

Selenium monitoring and several focused studies have been conducted at Kesterson since 1988 to determine temporal and spatial trends in selenium levels and to determine whether existing conditions cause adverse effects in wildlife (see, for example, CH2M HILL¹⁰). Although selenium concentrations are elevated in all environmental media (soils, plants, and animals), the monitoring has not found evidence of embryo deformities, reduced egg viability, or wildlife mortality.

Figure 37.2 Typical ephemeral-pool-selenium concentration pattern following initial ponding, site 3NW.

An ERA was conducted in 1993 to (1) review pertinent information available at that time, (2) estimate future levels of selenium in various biota (plants and animals) at Kesterson, (3) estimate the risks to animals caused by the site's selenium inventory, (4) assess the significance of the site's selenium toxicosis risks, (5) identify contingency plans and evaluate their effectiveness in eliminating or reducing any potentially significant risks of selenium toxicosis, and (6) recommend research and monitoring that would provide information needed to improve management efficiency for Kesterson or other projects.^{23,24}

That risk assessment analyzed data available from the Kesterson Reservoir Biological Monitoring Program (KR BMP) through November 1992 as well as other published and unpublished reports. Total and water-soluble selenium concentrations in the top 15 cm of soil, along with selenium concentrations in a wide range of plants and animals, were used to model potential exposures and predict effects to terrestrial wildlife over a period of 20 years into the future. In addition, waterborne-selenium concentrations and selenium in aquatic invertebrates from ephemeral pools were used to evaluate potential risks to aquatic birds.

The overall conclusions of the risk assessment were that (1) selenium concentrations in the plants and animals at Kesterson were not expected to change markedly during the next 20 years, (2) the selenium concentrations in small mammals were expected to remain below those measured during a study in 1984 when the reservoir was partially flooded with drainwater (and there were no clear effects on small mammal reproduction), (3) selenium concentrations in insectivorous birds were not expected to increase to biologically significant levels, (4) the greatest risk of selenium exposure to terrestrial wildlife appeared to be the possible consumption of mushrooms that contain the highest levels of selenium found at Kesterson (but there was little evidence that birds or mammals ate the mushrooms), (5) much of the reservoir could be covered with standing water during very wet years as a result of pooling of rainwater, and (6) although selenium concentrations in these pools (water and biota) are lower than pre-1989 levels, aquatic birds may feed in pools that persist into spring and be exposed to selenium at levels that could cause adverse reproductive effects. Monitoring of these pools has been included each year during which they occur during late winter and early spring.¹⁰ Waterborne-selenium concentrations in the pools constitute some of the highest potential levels of selenium exposure available to wildlife at Kesterson. The importance of this route of exposure to overall risk could not be understood without conducting a risk assessment with recent data to define exposure and risk from ephemeral pools. This chapter provides a summary of the risk assessment for aquatic exposures completed in 2000 for the USBR by CH2M HILL and Lawrence Berkeley National Laboratory (LBNL).²⁵ Although that ERA also evaluated terrestrial exposures, they are not included in this chapter.

37.1.3 Objectives

The objectives of the current ERA were to:

1. Assess the risks to wildlife from the site's selenium inventory, based on observed and estimated levels of biologically available selenium, particularly as resulting from the site's ephemeral pools.
2. Develop contingency plans for controlling the routes of exposure and risk identified in the assessment.
3. Recommend appropriate monitoring for Kesterson and additional research (if any) that would provide information needed to improve management efficiency for Kesterson and/or other projects.

The basic approach of this study was to assess risk to wildlife using a standard ERA framework, similar to that outlined in U.S. Environmental Protection Agency (EPA) guidance.²⁶ The primary method of risk determination was to estimate the variability in risk as provided by the natural variation in annual climatic regime. In all cases, Kesterson physical, chemical, and biological monitoring results formed the basis for modeling and risk estimates.

37.2 PROBLEM FORMULATION

Problem formulation presents information that was used to develop and focus the Analysis phase of the ERA by describing the ecological characteristics of the ephemeral-pool environment at Kesterson Reservoir, summarizing previously existing data and specifying the goals of the assessment.

37.2.1 Physical Setting

Ephemeral pools formed by rainfall ponding reflect conditions where seepage rates into soils lag behind “net” rainfall (rainfall minus evapotranspiration). Thus, primary factors controlling ephemeral-pool formation at Kesterson Reservoir are rainfall, evapotranspiration, soil permeability, and the soil profile hydraulic potential gradient.

The Kesterson area has a semi-arid, Mediterranean climate typical of its location in the San Joaquin Valley. The wet-season months — November through May — receive over 95% of the mean annual rainfall (226 mm) and have relatively low pan evaporation rates. The hot, dry months of June through September have average temperatures ranging from 19 to 26°C.

Field saturated hydraulic conductivity measurements of surface soils at Kesterson Reservoir have shown that permeabilities are typically moderately low to low. The wet season at Kesterson Reservoir coincides with months during which the shallow groundwater rises to nearly reach the soil surface. Under post-closure, prefill conditions, much of the area was topographically low enough to permit surfacing of the groundwater during winter months. This type of groundwater-supported ephemeral-pool formation can be practically independent of rainfall. The recognition that Kesterson ephemeral pools formed by groundwater rise were extremely seleniferous²⁷ led to the filling of topographically low areas with imported soil.² As a result, only a very small portion (< 1%) of Kesterson Reservoir exhibits this mode of pooling. The vast majority of current ephemeral pools form by ponding of rainwater in low-permeability depressions.

37.2.2 Ecological Setting: Ephemeral-Pool Habitat

Although the goal of remediation at Kesterson Reservoir in the late 1980s was to dry the reservoir and remove aquatic habitats, pools form at widespread locations in the former reservoir in response to the winter rainy season. In many years the pools are very ephemeral and never achieve significant aquatic invertebrate populations. However, in some years, with higher rainfall or a more extended rainy period, pools persist for several months. Those longest-lasting pools with developed invertebrate populations offer the possibility of exposure from redissolved and bioaccumulated selenium to the Kesterson wildlife community. Waterfowl and shorebirds are of particular concern for exposure from the pools as they begin nesting at the time of pool occurrence in the late winter and early spring.

The ephemeral pools typically form in December or January and may last until March or April in wet years. They vary from a few cm to 1 m in depth and several square meters to several hectares in area. Size, depth, and longevity of the pools are determined by rainfall distribution and regional hydrology. Pools tend to form in the same locations each year when they occur.

37.2.3 Chemicals of Potential Ecological Concern

Studies at Kesterson Reservoir have included analyses of water and biota for a number of organic and inorganic constituents that could potentially be found in agricultural drainage.^{3,28–31} Although some other chemicals (such as boron) occur at elevated levels at Kesterson, studies at Kesterson, other field sites, and in the laboratory indicate that selenium is responsible for the adverse effects observed in the past in aquatic birds at the site. Therefore, selenium has been the focus of

the ongoing monitoring program (as described above) and is the only chemical of potential ecological concern (COPEC) to be considered in this ERA.

Selenium bioavailability and mobility are controlled by selenium speciation. When first introduced to Kesterson Reservoir, selenium was in its most oxidized state of selenate — Se(VI) — which is most mobile due to its high solubility and low sorption. Subsequently, selenium was largely reduced under ponded conditions and very little (< 5%) selenium is currently found as Se(VI). More chemically reduced and less soluble species (elemental selenium, organically-associated selenium, and selenite, Se [IV]), have since dominated. These species can all be oxidized to Se(VI), and both elemental selenium and organoselenium can be oxidized to Se(IV). Long-term monitoring has shown that although selenium may be seasonally reoxidized, it also tends to be reduced during wet months.³² Because selenium reduction is far more rapid than oxidation,^{18,20} the average selenium oxidation state does not change significantly from year to year. The net result is a stable set of species, with roughly equal fractions of elemental selenium, organoselenium, and Se(IV), with minor Se(VI).

The uptake of selenium by biota is limited by soluble selenium concentrations. Despite its high solubility, Se(IV) sorbs strongly onto iron oxides,³³ clay minerals,³⁴ and soil organic matter.³⁵ Generally, around 2–10% of total selenium remains in the soil solution of near-surface soils.^{18,36} At Kesterson, that translates to an average soluble selenium concentration around 0.1 to 1 mg/kg.⁹

37.2.4 Assessment and Measurement Endpoints

The identification of assessment and measurement endpoints is critical to problem formulation because these endpoints structure the assessment to address management concerns and are central to conceptual model development.²⁶ Assessment endpoints provide a transition between the ecological management goals for the site and measures used to evaluate the endpoints. Ecological management goals for Kesterson include soil, surface-water quality, and food-source conditions capable of supporting small mammal populations that would be typical of similar habitats in the region; and soil, surface-water quality, and food-source conditions capable of supporting migratory birds without significant adverse effects on reproduction.

Although the recent ERA for the site²⁵ also evaluated risks to mammals (the first goal), the ERA presented in this chapter focuses only on the second goal.

37.2.4.1 Assessment Endpoints

Assessment endpoints are explicit expressions of the environmental value that is to be protected and are operationally defined by an ecological entity and its attributes.²⁶ Their relevance is determined by how well they focus on susceptible ecological entities and whether they adequately represent management goals. The following three criteria were used in selection of assessment endpoints:

1. Ecological relevance — migratory birds are integral components of the terrestrial ecosystem of the site, and aquatic species are known to use the ephemeral rainwater pools when pools are present.
2. Susceptibility to the stressor — research has shown that aquatic birds may be adversely affected by exposure to selenium.
3. Relevance to management goals — migratory birds are valued ecological resources for the site, and their protection represents management goals identified above.

The assessment endpoint selected for this ERA is stated as follows: Survival and reproduction of aquatic birds without ecologically significant adverse effects.

37.2.4.2 Measurement Endpoints

Measurement endpoints (also known as “measures”) are the characteristics that are evaluated to provide an indication of whether adverse effects on assessment endpoints have occurred or are

Table 37.1 Measures of Exposure and Effects and Associated Risk Estimation Used in the Kesterson ERA Model

Model	Exposure	Effects	Risk Estimation
Aquatic model for risk from ephemeral pool environments.	Selenium concentrations in water, aquatic invertebrates, and avian eggs.	Literature toxicity values for concentrations of concern for selenium in the avian diet and eggs. Monitoring for teratogenic effects to semiaquatic birds.	Model estimates of the frequency of occurrence of dietary concentrations and potentially exposed eggs of receptor bird species.

likely to occur. Two categories of measures that are predictive of the assessment endpoints were used for this assessment: (1) measures of exposure were used to evaluate how selenium exposures could be occurring and (2) measures of ecological effects were used to evaluate the response of the aquatic birds when exposed to selenium.

Measures of exposure include measured or modeled (estimated) concentrations of selenium in soil, surface water, and food-chain organisms as well as receptor species. Measures of effects include food-chain bioaccumulation and the responses of aquatic invertebrates and birds to environmental and dietary exposure of selenium. Measures of exposure and effects as well as risk estimation modeling used in the Kesterson Reservoir ERA are shown in Table 37.1.

37.2.5 Ecological Conceptual Site Model

The conceptual site model combines information on selenium, potential ecological receptors, potential exposure pathways, assessment endpoints, and measures of exposure and ecological effects. The model provides an overall picture of site-related exposures that can be used to focus the evaluation of selenium in the ERA.

37.2.5.1 Physical/Chemical Parameters

The physical/chemical parameters used in the ERA models were:

- Soil-selenium concentrations
- Soil pore-water-selenium concentrations
- Pool-water-selenium concentrations
- Estimates of the extent of surface-water ponding for various months

Data sources and synthesis of these parameters are discussed in Section 37.3.1.1. They are critical components of the model, so they are explained in some detail.

37.2.5.2 Identification of Representative Species

Representative ecological receptors were identified as the aquatic and semiaquatic wildlife that are most likely to be affected by selenium. They include primary and secondary consumers that are aquatic (e.g., macroinvertebrates) and semiaquatic (e.g., shorebirds and waterfowl that feed on aquatic biota). Representative species selected are from communities that are commonly found at Kesterson Reservoir ephemeral pools. The communities potentially exposed directly or indirectly (i.e., through the food chain) to selenium at Kesterson Reservoir are composed of free-swimming or benthic aquatic invertebrates and semiaquatic birds. Representative ecological receptors were selected from these communities to fulfill as many of the following criteria as possible:

- Species that are known to occur or are likely to occur at the site
- Species that relate to the assessment endpoints selected

- Species that are likely to be maximally exposed to selenium
- Sedentary species or species with a small home range
- Species with high reproductive rates
- Species that are known to play an integral role in the ecological community structure at the site
- Species that are known or likely to be especially sensitive to selenium, and thus are an indication of ecological change
- Species that are susceptible to bioaccumulation of selenium from a limited number of food items
- Species that are representative of the foraging guild or serve as food items for higher trophic levels

The aquatic and semiaquatic representative species selected for the Kesterson Reservoir ERA are: (1) free-swimming and benthic insects and microcrustaceans; and (2) semiaquatic birds — killdeer, black-necked stilt, and mallard.

Benthic and free-swimming macroinvertebrates and microcrustaceans are primary consumers that fulfill many of the selection criteria. They would be in direct contact with potentially contaminated sediments and surface water and therefore would be exposed to selenium. They have a small range, have high reproductive rates, and serve an integral role in the aquatic and semiaquatic ecosystem. They serve as important prey items for the semiaquatic bird species chosen for the ERA (i.e., stilt, killdeer, mallard). Various species of aquatic insects (e.g., midge larvae, water boatmen, beetles) and microcrustaceans (ostracods, cladocerans) were collected from ephemeral pools at Kesterson Reservoir during most years from 1990 through 1999.

Semiaquatic birds feed primarily on species associated with aquatic habitats. Black-necked stilts, killdeer, and mallards were chosen as the receptors to assess the effects of selenium exposure through ephemeral aquatic habitats at Kesterson. Their habit of feeding in shallow waters for crustaceans and insects gives them a high potential for exposure to selenium through the ephemeral-pool food-chain pathway. In addition, killdeer consume some terrestrial insects and mallards some terrestrial plants. Representative bioaccumulation levels are available for those terrestrial diet items through ongoing Kesterson Biological Monitoring Program results. Eggs of all three species have been sampled at Kesterson Reservoir.

37.2.5.3 Exposure Pathway Inclusion/Exclusion

The exposure pathway inclusion/exclusion evaluation is based on information gathered from the problem formulation and the selection of representative species, the probable completeness of each exposure pathway, and the potential for that pathway to be a major or minor route of exposure and risk.

A complete exposure pathway must exist for an exposure to occur, and it must have the following elements, in addition to the presence of suitable habitat for ecological receptors:

- Contaminant source (e.g., selenium in soils and water)
- Mechanism for contaminant release and transport (e.g., solubility in poolwater)
- Exposure point (e.g., ephemeral pool)
- Feasible route of exposure (e.g., ingestion)
- Receptor (e.g., bird)

Contaminant sources and release mechanisms at Kesterson Reservoir consist primarily of on-site source areas (soil-selenium inventory) and availability for movement of solubilized selenium through the soil profile into ephemeral pools. Ecological receptors at the pools can be exposed to chemicals in sediment or surface water via direct or secondary exposure pathways. Direct exposure pathways include ingestion and dermal contact. Secondary exposure pathways are limited to food-chain transfer of bioaccumulated selenium. Potential exposure pathways for representative species are summarized below along with the rationale for inclusion/exclusion in the quantitative and qualitative evaluations to be conducted in the ERA.

Aquatic invertebrates can absorb selenium through their epidermis and can accidentally or purposefully ingest sediment during feeding or burrowing. Benthic organisms are especially prone to exposure to selenium present in sediments as some consume the organic materials from within the sediment (e.g., midge larvae). Aquatic invertebrates serve as a major route of food-chain transfer because they are prey for semiaquatic birds (e.g., waterfowl, shorebirds).

Semiaquatic birds can be exposed to selenium in sediment and surface water from several different behaviors. Birds can inadvertently or purposefully ingest sediment while grooming or while consuming contaminated prey species. Surface water can be ingested as a drinking-water source or during bathing or grooming activities. Dermal contact with sediment or surface water is considered to be a secondary route of exposure for birds and mammals, and it is not considered an important exposure route for selenium (as compared to some organic contaminants).

Food-chain exposure is the primary exposure route of concern for these birds. Food-chain exposure may occur because selenium can be accumulated directly by aquatic invertebrates or in aquatic plants or algae that are consumed by herbivorous invertebrates (and secondarily by predatory insects) that are then eaten by semiaquatic birds. A diagram of the conceptual site model is presented in Figure 37.3.

37.2.6 Data Sources and Synthesis

37.2.6.1 Pool Formation Parameters

This section describes the database and procedures used to estimate probabilities of ephemeral-pool formation and areal pool coverage at Kesterson Reservoir. The estimates to be obtained through analysis of weather data are (1) the probabilities for ephemeral-pool occurrence during individual months and (2) estimates of the fraction of the reservoir that will be ponded. These estimates are based on the following four basic assumptions:

1. Monthly rainfall data from the nearby city of Los Banos can supplement the smaller rainfall record at Kesterson Reservoir.
2. A simple algorithm for predicting pool initiation and duration within a given wet season yields adequate results. This algorithm was found to be successful at calculating the initial date of major ponding to within 10 days of actual dates based on field observations in 10 out of the 11 available calibration years. It also predicted duration of typical ephemeral pools to within 32 days and, in most cases, to within 22 days.
3. The algorithm for predicting ponding can also be extended to estimate areal coverage by ephemeral pools.
4. The 127-year historical rainfall record (Los Banos and Kesterson data) will be representative of future rainfall distributions.

Based on these assumptions, estimated probabilities of pooling and of ponded area are given below.

37.2.6.1.1 Weather Database

Rainfall records at Kesterson Reservoir begin in 1982, with detailed records available only since 1985. Although this time interval includes drought years as well as the extreme 1997–1998 El Niño year, a larger rainfall record was needed for purposes of estimating rainfall probabilities. Monthly rainfall data are available for the Los Banos weather station from the California Department of Water Resources with records since 1874. Los Banos is located only 20 km (12 mi) away from Kesterson Reservoir, with very little topographic variation between the two locations. Nevertheless, we examined the correlation between their rainfall records before relying on the Los Banos data. Because of the short Kesterson record, this comparison can only be done for the years 1985 through

Figure 37.3 Conceptual site model for Kesterson Reservoir.

Figure 37.4 Cumulative probability of exceeding seasonal cumulative rainfall = x mm by Feb. 1, March 1, Apr. 1, and June 1. Cumulative rainfall from the 1989 (drought), 1997 (above average), and 1998 (El Niño) years are indicated on monthly curves. Also shown are segments along the cumulative rainfall probability curves that do not (lighter trace), and that do (darker trace) exceed 0.89 times the cumulative average ET_0 .

2000. Los Banos monthly rainfall data do provide a fair estimate of monthly rainfall at Kesterson Reservoir. The near-zero (2.4 mm) intercept, near-unit (0.998) slope, and high correlation ($r = 0.946$) indicate that the Los Banos monthly rainfall data can be used directly for predicting Kesterson rainfall. Thus, for purposes of this analysis, the Los Banos monthly rainfall data from 1874 through 1984 were combined with the Kesterson Reservoir rainfall data from 1985 through 2000. The compiled rainfall record shows a mean annual precipitation of 22.6 cm, with a range in annual totals of 5 to 53 cm. The fact that the available data set includes the 1997–1998 El Niño year substantially improves our chances of fairly estimating ponding probabilities because that year yielded the highest rainfall in the available 127-year record. Furthermore, the bulk of the El Niño rainfall occurred within late winter and spring months when ephemeral-pool environments have greatest potential for wildlife impacts (Figure 37.4).

37.2.6.1.2 Predicting the Timing and Duration of Ephemeral Pools at Kesterson Reservoir

One of the two main inputs into our previously derived ponding model¹⁷ is the CIMIS ET_0 parameter. ET_0 is the estimated evaporation rate from a reference “crop” (irrigated grass surface) and depends on the local temperature, wind speed, and humidity. Inspection of 9 years of Kesterson Reservoir CIMIS data has shown that while daily ET_0 records are quite variable from year to year, the cumulative ET_0 record is not. Average ET_0 values for Kesterson Reservoir can be used instead of actual daily ET_0 values, without much loss of accuracy throughout most of the wet season. For Kesterson Reservoir, cumulative ET_0 amounts to 71% of cumulative pan evaporation.

We now consider the simplification that soil water storage has a minor influence on rainfall ponding at Kesterson Reservoir. This simplification is based on two factors previously mentioned. The first is the recognition that the water table is close to the soil surface during the wet season, even during drought years. This factor, combined with the partially saturated soil profile, leaves limited air-filled porosity for storage. In addition, the moderately low permeability of soils at sites most susceptible to rainfall ponding lessens the extent to which infiltration and drainage influences ponding. Thus, for purposes of estimating the inception and duration of wet-season ponding, it appears reasonable as an approximation to overlook hydraulic interactions with the soil profile.

Figure 37.5 Predicted vs. observed days for initial ponding and cessation of ponding for the years when ponding is predicted.

With these two simplifications (use of the average ET_o , and neglecting soil-water exchanges), only information on the temporal variation of rainfall within a given season is needed to estimate timing of ephemeral-pool formation and duration. In the approximation that only rainfall and evaporation control ponding, pools will form at any time when the cumulative rainfall exceeds cumulative evaporation. As an initial approximation, the raw, average cumulative ET_o values were used. However, model calculations were found to underpredict ponding periods. Scaling down the average cumulative ET_o by a constant factor of 0.89 yielded optimized agreement between field-observed and predicted ponding. The optimization criterion selected was that of maximizing the number of correctly predicted minus incorrectly predicted days. This optimization approach yielded a ratio of modeled vs. observed ponding days of 0.965, with 86% of the observed ponding days correctly predicted.

Good agreement is usually obtained between field observations of ponding and model predictions. Predictions vs. observations of ponding for the subset of water years in which ponding is expected by the simple model (9 years out of the 11) are compared graphically in Figure 37.5. The fact that a wide range of rainfall distributions and rainfall totals is included in these results gives support to the model’s predictive ability, especially for nondrought years, in which such information is most relevant. The success that this simplified model has had in predicting ephemeral-pool formation and duration indicates that it could be useful in estimating future ponding at Kesterson Reservoir under a range of possible rainfall patterns.

The calculations up to this point have been based on daily rainfall and daily average ET_o data. However, the larger historical weather data only provide monthly rainfall data, so we tested the reliability of calculations based on monthly values. Using the previously described algorithm, but with only the monthly discretized Kesterson Reservoir rainfall data, the ponding model was applied to the 1990–2000 wet seasons. As before, the start of each wet season was defined to begin on November 1. For example, the 1990 wet season begins on November 1, 1989. The cumulative monthly rainfall (CMR) was calculated within a given season relative to November 1. The CMR was compared on a month-by-month basis to 0.89 times the cumulative monthly average ET_o (i.e., $0.89 \times CMET_o$), to determine which months have CMR in excess of $0.89 \times CMET_o$. The whole data set was then evaluated to determine the number of years in which CMR begins to exceed $0.89 \times CMET_o$ in a given month. The number of months within each year (beginning November 1) in which CMR exceeds $0.89 \times CMET_o$ was also calculated. These results provided the basis for estimating probabilities of pond initiation by a given month and probabilities of pond duration, respectively.

37.2.6.1.3 Estimating the Areal Extent of Ponding

Information limited to whether ephemeral pools occur at Kesterson Reservoir within a given month is not very useful without information on the areal extent of the pools. The potential for

Figure 37.6 Aerial photograph-based estimates of percent areal ponding at Kesterson Reservoir, correlated to $\text{CMR} - 0.89 \times \text{CMET}_0$. This fit is optimized to minimum root mean square deviation, excluding the single point (shown) that would yield low predicted areal ponding.

wildlife exposure and effects of 1% vs. 50% areal ponding within Kesterson Reservoir is clearly very different. Estimating the areal extent of ephemeral pools at Kesterson Reservoir with a simple model is difficult. There is a very limited database on ephemeral-pool areal coverage. Such information, obtained from USBR aerial photographs, was available only for 8 days from 1995 through 1999 (for example, see USDI³⁷). However, estimates of ephemeral-pool areal extent are needed as part of the risk-assessment model to provide a link to bird use and exposure.

Because [cumulative rainfall $-0.89 \times$ cumulative ET_0] (hereinafter referred to as “net rainfall”) appears to provide a good estimate of whether pools occur, we tested this parameter for predicting the areal extent of ponding at Kesterson Reservoir. Qualitatively, negative to slightly positive values of net rainfall should be associated with insignificant ponding, while larger positive values should correlate with greater areal ponding. The available ephemeral-pool area data plotted against net rainfall show this rough correlation (Figure 37.6). A second-order polynomial fit, $y = 1.4 + 0.135x + 0.00127x^2$, is shown with these data ($r^2 = 0.90$). The fitting was done with exclusion of the one data point indicative of low ponded area at high net rainfall in order to obtain more conservative predictions. By “conservative” we mean predictions weighted to greater ponded areas. The fit shown in Figure 37.6 was obtained by minimizing the root mean square deviation with respect to all data except the single value mentioned above.

37.2.6.2 Estimating Ephemeral-Pool Selenium Concentrations

Reservoir-wide data collected between 1989 and 1998 were used to define the statistical distribution of selenium concentrations by habitat and trisection. This data set had been collected as part of the ongoing biological and soil monitoring program.^{9,10} For a determination of the water-soluble-selenium distribution in surface soils, a subsample of the homogenized soil from each sampling station (20 to 25 g) was used to prepare a 1:5 soil:water extract. Water-soluble-selenium was then analyzed using hydride generation atomic absorption spectroscopy (HGAAS). Selenium concentrations were summarized as standard statistical characterizations (arithmetic, geometric, and harmonic mean, median, standard deviation and error, skewness, and kurtosis) for each combination of habitat and trisection, for both total and soluble selenium.

A transfer factor between soil selenium and ephemeral-pool water was calculated via regression between existing ephemeral-pool-selenium concentration data and 1999 soil-selenium data. Ephemeral-pool water has been collected annually during the wet season. Although some ephemeral-pool sampling began in 1987, regular sampling at selected monitoring sites started during the 1992 wet season. During years when ephemeral-pool formation is significant, pool waters are sampled several

(2 to 4) times per month by the USBR and LBNL for analyses of selenium and other constituents. Within a given site, pool-selenium concentrations typically follow a general seasonal trend. During the initial days of ponding, selenium concentrations are relatively high (Figure 37.2). Over the first 20 to 40 days of ponding, pool-selenium concentrations decrease because of dilution with additional rainwater and because of diffusive transport and reduction in surface sediments. During this interval, pool-selenium concentrations often exhibit more than tenfold decreases. At still longer times, gradual increases in pool-selenium concentrations occur, primarily due to evaporative concentration. This cycle is observed during years when ephemeral pools are persistent, without any evident systematic year-to-year trends. Given the very dynamic nature of pool-selenium concentrations, it is desirable to identify concentrations that are characteristic of each site. For this purpose, a selenium concentration typical of pool waters at 30 to 80 days within each site was selected for estimating soil–pool-water-selenium transfer factors. In addition, as presented below, this age of pool offers the best choice for characterizing ecological exposure.

37.2.6.3 Aquatic Habitats

Conducting an ERA for Kesterson that incorporates aquatic habitats required the summary of long-term monitoring data on ephemeral-pool and aquatic invertebrate tissue-selenium concentrations. Data from 1990 through 1999 were summarized by individual pool and averaged by trisection. All data were used to develop a regression relationship between waterborne-selenium and aquatic invertebrate tissue-selenium. Terrestrial components of bird diets were taken from the distribution of tissue-selenium results (geometric mean, standard deviation) for those necessary terrestrial components of receptor diets (i.e., plants and terrestrial invertebrates). The relationship between ephemeral-pool waterborne-selenium and aquatic dietary-item-selenium concentrations used as ERA model inputs is shown in Figure 37.7.

In addition to the data on pool water and bird dietary item chemistry, waterfowl and shorebird daily use data from the ongoing Kesterson Reservoir Monitoring Program were summarized by trisection to use in the ERA model. Bird-use data during the late winter and early spring were required to develop a regression relationship to predict bird use based on the extent of ponding by trisection. Bird-use records were chosen for their proximity in timing to the aerial photography estimates of the extent of ephemeral pools. A summary of the regression relationships of bird-use data vs. extent of ponding by trisection is presented below.

Figure 37.7 Aquatic invertebrate:water relationship, Kesterson Reservoir ephemeral pools (1990–1998).

37.2.7 Modeling

37.2.7.1 Physical/Chemical Model

The physical/chemical databases and models used to predict water-extractable selenium-transfer factors to pool-selenium concentrations and the extent of ponding by month were discussed previously and are developed into model predictions below.

37.2.7.2 Aquatic Habitat Model

The aquatic habitats Kesterson ERA model was used to predict exposure of semiaquatic birds to selenium through the ephemeral-pool environment. Terrestrial plants and invertebrates were added to the model for mallards and killdeer (respectively) because these birds do not feed exclusively in the aquatic environment. In contrast, black-necked stilt were assumed to feed exclusively in the ephemeral pools.

The high year-to-year, climate-driven variability of ponding determines all aspects of the exposure of wildlife at Kesterson to selenium available through the ephemeral pools. The Monte Carlo simulation model was structured to represent natural climatic variability as measured at Kesterson for a hypothetical 1000 years of data.

The aquatic habitat model depends on estimates of the areal extent of ephemeral pools. Total month-end ponding was predicted based on the ponding model (Figure 37.5). Ponding by trisection was related to total ponding, as shown in the digital aerial photography record. Regression relationships were then developed that predicted ponding by trisection based on cumulative precipitation. The first step in the aquatic habitat model was to estimate the extent of ponding by trisection at the ends of January, February, and March for any given year (the months where ponding overlaps with bird exposure at Kesterson). A summary of the steps in the aquatic habitat model is as follows:

1. Establish a random distribution of 1000 data points for total ponding at Kesterson Reservoir based on the statistical distribution of ponding as determined by precipitation and ET. All bird use and extent of ponding predictions were calculated based on those hypothetical 1000 years of climatic record.
2. Predict ponding by trisection for the period at the end of January, February, and March (using total to trisection-specific ponding relationships).
3. Predict bird use by trisection based on trisection-specific ponding (using bird use to ponding relationships).
4. Predict ephemeral-pool-selenium concentrations by habitat type based on the transfer factors from soil-water extractable to pool-water-selenium as described above. Create a database of 1000 random selenium-transfer factors based on the measured statistical distribution of transfer factors. Then use the area of habitat types by trisection (as shown in Figure 37.1) to create weighted-average pool-selenium concentrations by trisection (1000 each). Measured habitat type distributions are:

Trisection 1 = 61.1% Filled, 8.8% Grassland, and 30.1% Open.

Trisection 2 = 49.9% Filled, 35.1% Grassland, and 15% Open.

Trisection 3 = 55% Filled, 44.8% Grassland, and 0.2% Open.

5. Predict aquatic invertebrate concentrations by trisection (1000 each) based on the modeled pool-water-selenium concentrations (from Step 4) and the Kesterson-specific regression relationship between those variables. Black-necked stilt were assumed to feed exclusively on these aquatic invertebrates.
6. Estimate the trisection-specific selenium concentrations of the killdeer and mallard diets by adding selected terrestrial dietary items to the aquatic invertebrate diet. Create a random distribution of 1000 data points for terrestrial plants (mallard diet) and insects (killdeer diet) based on the statistical distribution for these items by trisection from the KRBMP. Create average combined diets based

on the assumptions that killdeer diets were 25% pool and 75% terrestrial invertebrates and mallard diets were 75% pool invertebrates and 25% terrestrial plants.

7. Predict average Kesterson-wide dietary concentrations of selenium based on diet weighted by bird use by trisection (1000 average dietary concentrations per species).
8. Predict potential nests and eggs per species by trisection based on predicted bird use and estimates of the average number of eggs per nest (four each for killdeer and black-necked stilt, eight for mallard).
9. Predict the potential egg-selenium concentrations based on Kesterson-specific data on transfer factors for dietary selenium to egg selenium for the three species.
10. For killdeer and stilt only, predict the potential number of hens having at least one egg per nest affected as a result of dietary-selenium exposure (relationship based on egg-selenium concentrations; limited to an extensive database for shorebirds only).

The basic approach of the aquatic habitat model was to predict daily average bird use and dietary exposure from estimates of the extent of ponding. The diet and egg concentrations of selenium can be directly related to literature values on the potential effects of selenium on birds. As described in the literature on black-necked stilts and extended in our model to include killdeer (see Step 10 above), it was possible to predict the number of shorebird hens potentially affected by egg loss over the modeled 1000 years of climate record.

37.3 ANALYSIS

37.3.1 Exposure Characterization

37.3.1.1 *Physicochemical*

37.3.1.1.1 *Statistical Distribution of Soil Selenium Concentration*

Total and soluble soil-selenium concentrations have been measured from reservoir-wide synoptic sampling. There are very few year-to-year changes in the Filled and Grassland habitats. In the Open habitat, which comprises only 13% of the reservoir area, there are many year-to-year differences, but an overall trend is absent. Moreover, due to the large degree of spatial variability, discerning statistically meaningful interannual and long-term trends is difficult. As discussed earlier, the most likely change in selenium distribution is one of selenium oxidation to species of higher solubility. It is selenium solubility that largely determines its bioavailability and ecological exposure.

Year-to-year and long-term changes in soluble-selenium concentrations may be neglected with respect to the ERA model. The entire 9-year data set of selenium concentrations, split by habitat and trisection, was used. Differences in selenium concentrations are most pronounced among habitats, with highest levels in the Open habitat and lowest in the Filled habitat. Soil in Trisection 1 generally contains the highest selenium concentrations, except in the Filled habitat, where total selenium does not significantly differ amongst trisections (Table 37.2).

Statistical parameters can be used to determine the type of distribution present. Most data sets are skewed and dominated by low values. In those cases, the distribution is log-normal. In a few cases, skewness is close to 1 and the median and mean values are similar, suggesting an approximately normal distribution (Table 37.2).

37.3.1.1.2 *Rainfall Distribution and Pool Formation*

It is necessary to apply the pool-prediction model to the 1874–2000 monthly rainfall data set to obtain estimated probabilities of ponding. Given the fair success of the CMR-($0.89 \times \text{CMET}_0$) model for matching the available field observations of ephemeral-pool formation and duration, we

estimated probabilities of pond initiation within a given month and probabilities of pool duration. This was done by analysis of the larger (1874–2000) data set using the aforementioned procedure and assuming that the 127-year record is representative of future rainfall distributions. The estimated probability of ponding and estimated probability of pool duration are shown in Figure 37.8. Based on the historical monthly data, no significant ponding is expected for 43% of the wet seasons. Ponding for durations of 1, 2, 3, 4, 5, and 6 months is expected in about 9%, 11%, 14%, 15%, 6%, and 1% of the wet seasons, respectively. Of the years in which ephemeral pools form, they are expected to initially form by the end of November, December, January, February, and March with probabilities of about 27%, 32%, 33%, 7% and 1%, respectively.

Because wildlife use and nesting associated with ephemeral pools occurs during the later months of the wet season, we estimated probabilities of ephemeral-pool occurrence relative to January 1. For this purpose, the CMR-($0.89 \times \text{CMET}_0$) model was applied to the 1874–2000 monthly database and examined for expected ponding in the months of February through May. These results show that if February ponding occurs (based on calculations for January 31), there also was ponding in the immediately preceding months. There is a low probability (about 7% of the years in which ponding occurs and about 4% of all years) that ephemeral pools will form in March without ponding in previous months. These results also show that the expected frequency of ponding through the

**Figure 37.8** Estimated probability of ponding and estimated probability of pool duration.

Figure 37.9 Estimated probability for ephemeral-pool areal coverage exceeding X% at the end of February, March, April, and May.

months of April and May is very low. Based on the historical rainfall record and the CMR-(0.89 × CMET₀) model, only 7 out of the past 127 years would have resulted in ephemeral pools persisting through the end of April. One of these 7 years was 1998, which is consistent with field observations. The model also correctly predicts that no ponding persists through the end of June.

Estimates of ephemeral-pool areal coverage were obtained for periods during the wet season critical to wildlife impacts. Predictions were made for the end of the months of February, March, and April. The 127-year record of monthly CMR-(0.89 × CMET₀) was combined with the second-order polynomial correlation described previously to obtain estimated percent ponding by month. This result indicates that both areally and temporally extensive ephemeral-pool coverage of Kesterson Reservoir is rare. For example, the estimated probabilities of > 10% areal coverage at the end of February, March, and April are about 25%, 16%, and 2%, respectively, based on the historical rainfall data (Figure 37.9).

Pool area by trisection was estimated based on aerial photographic records of pool coverage by trisection as compared to total pool area using the following relationships:

$$T1Pools (m^2) = (Total Kesterson pool area (m^2) \times 0.304) + 18026 \quad (37.1)$$

$$T2Pools (m^2) = (Total Kesterson pool area (m^2) \times 0.463) - 1580 \quad (37.2)$$

$$T3Pools (m^2) = (Total Kesterson pool area (m^2) \times 0.233) - 16446 \quad (37.3)$$

37.3.1.1.3 Pool-selenium Concentration and Transfer Factors

As discussed earlier, ephemeral-pool concentrations typically start at relatively high values, decrease during the main ponding period, and increase to varying degrees towards the later stages of ponding (Figure 37.2). Selenium in ephemeral pools occurs primarily as Se(VI), with up to 30% as Se(IV). The decreases in pool-selenium concentrations during the initial stages of ponding result from transport into shallow sediments, in some cases also by dilution by additional rainfall, and a relatively smaller loss due to volatilization. Year-to-year comparisons in selenium concentrations within individual pools reveal no obvious trends, and over the years the concentrations in individual pools have remained in a consistent range.¹⁷ This also applies to the “stable” concentration range shown in Figure 37.2. This concentration is ecologically more important than the initial high selenium spike, because (a) it is much longer in duration and (b) it is closer in timing to the springtime period coincident with bird nesting. In addition, there is typically a lag of 30 or more days between pool formation and development of invertebrate communities that would provide food for semiaquatic birds. The average “stable” concentrations for each pool were used in calculating a soil-to-pool-water transfer factor.

A ratio of pool selenium to soluble soil selenium was calculated for each of ten sites and subsequently averaged at 0.024. This means that if the concentration of soluble selenium in the

Figure 37.10 Measured and predicted ephemeral-pool Se based on soluble Se in surface soil.

surface soils is 100 $\mu\text{g}/\text{kg}$, the corresponding concentration in the overlying ephemeral pool will be approximately 2.4 $\mu\text{g}/\text{L}$. In some cases, this approximation slightly underestimates pool concentrations, and in a few cases it substantially overestimates those values (Figure 37.10). This is due to the fact that the partitioning between soil and pool water depends on several variables, some of which are site-specific and include selenium fractionation in surface soils, ground cover, and the amount of decomposing litter, soil permeability, and depth to the water table. Therefore, it is impossible to derive a single transfer factor capable of precisely defining pool selenium levels. A polynomial relationship may better reproduce the actual pool-selenium concentrations, but the linear approximation is accurate within a factor of 2 to 3 and is adequate given the spatial and temporal variability in soil-selenium concentrations.

37.3.1.2 Ecological

37.3.1.2.1 Bird Use

Bird use is measured at Kesterson Reservoir as part of the long-term monitoring program. Daily use was estimated by trisection for days close to the time of aerial photographs. Those use estimates by trisection and by species were compared to measured flooded area to create regression relationships to be used in the ERA aquatic exposure model. The selected receptor species showed positive, linear relationships between daily use and the extent of ponding. Regression equations are presented in Table 37.3. The relationships were all derived from ponding and bird use in the January-through-March period and were used to predict bird use for those months in the model.

Table 37.3 Bird Use as a Function of Ponded Area by Trisection*

Species	Trisection 1 Daily Use	Trisection 2 Daily Use	Trisection 3 Daily Use
Black-necked stilt	$[0.048 + 0.00000229 \times \text{pool area (m}^2\text{)}]$ $r^2 = 0.441$	$[-0.007 + 0.00000313 \times \text{pool area (m}^2\text{)}]$ $r^2 = 0.527$	$[-0.041 + 0.00000598 \times \text{pool area (m}^2\text{)}]$ $r^2 = 0.413$
Killdeer	$[0.126 + 0.000000917 \times \text{pool area (m}^2\text{)}]$ $r^2 = 0.587$	$[0.125 + 0.00000065 \times \text{pool area (m}^2\text{)}]$ $r^2 = 0.520$	$[0.074 + 0.000000801 \times \text{pool area (m}^2\text{)}]$ $r^2 = 0.637$
Mallard	$[-0.085 + 0.00000196 \times \text{pool area (m}^2\text{)}]$ $r^2 = 0.503$	$[0.05 + 0.000000661 \times \text{pool area (m}^2\text{)}]$ $r^2 = 0.723$	$[0.053 + 0.00000112 \times \text{pool area (m}^2\text{)}]$ $r^2 = 0.490$

* Regressions based on monitoring data.

Table 37.4 Geometric Mean Water and Dietary Selenium Concentrations, Kesterson Reservoir (Number of Samples in Parentheses)

Parameter	Trisection 1	Trisection 2	Trisection 3
Water, 1992–1999 (total selenium, µg/L)	8.4 (62)	6.6 (49)	7.4 (39)
Aquatic Invertebrates, 1992–1999 (whole body concentrations, mg/kg as dry weight)	27.4 (74)	17.4 (56)	14.9 (53)
Terrestrial Invertebrates, 1989–1998 (whole body concentrations, mg/kg as dry weight)	11.6 (400)	9.9 (409)	7.4 (365)
Terrestrial Plants, 1989–1998 (whole-plant concentrations, mg/kg as dry weight)	4.4 (690)	3.4 (691)	3.3 (749)

37.3.1.2.2 Pool Water and Aquatic Invertebrate Selenium Concentrations

Some exposure of wildlife to selenium from ephemeral pools occurs through direct exposure to waterborne selenium, but the primary exposure is through ingestion of aquatic invertebrates along with ingestion of terrestrial invertebrates and plants (for some species). Average concentrations of selenium in water and bird receptor dietary items from the 1990–1999 Kesterson Reservoir Monitoring Program are given in Table 37.4.

Waterborne- and aquatic-invertebrate-selenium concentrations are positively correlated for the Kesterson Reservoir ephemeral pools. Therefore, the following relationship (as shown in Figure 37.7) was used to predict invertebrate tissue concentrations based on predicted poolwater concentrations, where:

$$\text{Pool aquatic invertebrate selenium (mg/kg as DW)} = 10^{(\log(\text{Pool Water Se}) \times 0.393 + 0.986)} \tag{37.4}$$

In addition to their aquatic invertebrate diet when pools are present, killdeer were assumed to consume terrestrial invertebrates 75% of the time, while mallards were assumed to feed 25% of the time on terrestrial plants. Black-necked stilts were assumed to feed solely on aquatic invertebrates in the ephemeral-pool environment and to leave Kesterson when the pools were not present. Terrestrial components of mallard and killdeer diets were estimated based on the mean selenium concentrations for plants and invertebrates, as taken from the terrestrial model. Mean terrestrial component concentrations by trisection are shown in Table 37.4.

Waterborne-selenium concentrations were predicted in the ERA model based on changing climatic regime and estimates of the month-end extent of ponding. The model uses the statistical distribution of transfer factors from water-extractable soil selenium to poolwater selenium to predict an array of possible poolwater-selenium concentrations by trisection. The predictive relationships, expanded in the model to an array of 1000 random average conditions, are shown in Table 37.5. The basic construction of the model was described above.

37.3.2 Ecological Effects Characterization

Impacts to waterfowl and shorebirds using Kesterson Reservoir can be estimated by comparing the selenium concentrations in dietary items or eggs to known toxic-effect levels. Recently established guidelines for trace element exposure indicate dietary concentrations of concern from 3 to 7 mg/kg selenium (dry-weight basis) and potential toxic effects when dietary concentrations exceed 7 mg/kg.^{38,39} Table 37.6 provides a summary of dietary and egg effect levels that can be used to evaluate potential toxic effects of environmental-selenium concentrations to birds. There are differences in potential dietary exposures and sensitivity among aquatic bird species that may use Kesterson Reservoir in wet years. Mallards are among the most sensitive species, black-necked stilts and killdeer are moderately sensitive, and American avocets are less sensitive.

Table 37.5 Means and Standard Deviations of Data Expanded in the Monte Carlo Simulations of the Aquatic ERA Model

Parameter	Mean	Standard Deviation
Water-extractable-selenium concentration ($\mu\text{g}/\text{kg}$) to poolwater-selenium concentration ($\mu\text{g}/\text{L}$) transfer factor	0.0239	0.0188
Total percent ponded area, Kesterson Reservoir	End of Jan. = 6.3 End of Feb. = 6.6 End of Mar. = 3.4	End of Jan. = 13 End of Feb. = 14 End of Mar. = 8
Terrestrial plants, selenium concentration	T1 = 5.0 T2 = 4.0 T3 = 3.5	T1 = 10.024 T2 = 4.845 T3 = 8.087
Terrestrial invertebrates, selenium concentration	T1 = 12.5 T2 = 9.4 T3 = 8.1	T1 = 8.916 T2 = 7.738 T3 = 6.768

Measured and modeled egg concentrations may be compared to probably toxic-effect levels, as well. Toxicity guidelines suggest that egg-selenium concentrations exceeding 6 mg/kg are of concern because of potential reproductive impairment (Table 37.6).

37.4 RISK CHARACTERIZATION

The risk characterization evaluates the evidence linking exposures to COPECs with their potential ecological effects among the representative species identified for the site. Based on the potential risks of adverse effects to those ecological receptors (and similarly exposed species), it leads to conclusions (presented below) and recommendations (which were presented in the original report²⁵ but are not presented here). The risk characterization consists of three portions: (1) risk estimation, (2) risk description, and (3) uncertainty analysis.

37.4.1 Risk Estimation

37.4.1.1 Quantitative Evaluation

The model output produced predictions of the frequency of given bird use and average dietary concentrations. Figures 37.11 through 37.13 show the potential bird use for each species for the months of interest (as predicted, based on the extent of ponding). The model also produced estimates of the expected frequency for various dietary-selenium concentrations for the three species, which are shown in Figures 37.14 through 37.16. Figures 37.15 and 37.16 also reflect inclusion of terrestrial components in the average diet concentrations for killdeer and mallards, respectively. April was not included in the model due to the low probability of ponding (6%) of a small percentage of the reservoir (< 10%). Bird use and dietary exposure were predicted from ponding and indicated nonexistent risk for April conditions.

Table 37.6 Toxicity Guidelines for Selenium Exposure in Water, Diet, and Eggs

Criteria	Level of Effect ^a		
	None/Background	Level of Concern	Toxicity Threshold
Water ($\mu\text{g}/\text{L}$, total recoverable Se)	<2	2 to 5	>5
Diet (mg/kg dw)	<3	3 to 7	>7
Waterbird eggs (mg/kg dw)	<6	6 to 10	>10

^a Except for avian eggs, these guidelines are intended to be population-based. Thus, trends in means over time should be evaluated. Guidelines for avian eggs are based on individual level response thresholds.³⁸⁻⁴¹

Source: From Beckon, W.N. and Dunne, M., *Grasslands Bypass Project Annual Report, 1998-99*, San Francisco Estuary Institute, Richmond, CA, 2000; Skorupa, J.P., U.S. Fish and Wildlife Service, pers. comm.

Figure 37.11 Black-necked stilt daily use estimates.

Estimation of risk based on selenium exposure required the prediction of selenium concentrations in eggs. Monitoring results for selenium concentrations in invertebrate and plant dietary items for birds were compared to egg-selenium concentrations from the 1998 KRBMP data set to yield Kesterson-specific environmental transfer factors. (These site-specific transfer factors are relatively low because they do not represent true diet-to-egg transfers, which can be documented only if 100% of the birds’ diets come from within the site and diet composition is well known. Thus, the transfer factors are referred to as “environmental transfer factors.”) Extensive ponding and higher-than-normal bird use characterized the year 1998. In addition, we were able to collect a relatively large number of samples of aquatic invertebrates, terrestrial invertebrates, and terrestrial plants that could be used to estimate bird dietary-selenium concentrations for the bird species in the model. The 1998 sampling year was of most value, however, because an unusually high number of semiaquatic birds nested at Kesterson. The average egg-selenium concentrations of black-necked stilts, killdeer, and mallards from 1998 were compared to estimated dietary-selenium concentrations (from measured concentrations of selenium in aquatic invertebrates, terrestrial invertebrates, and terrestrial plants) to yield average environmental transfer factors for selenium. Based on 1998 data, the transfer factors for stilts, killdeer, and mallards were 0.57, 0.51, and 0.48, respectively.

Figure 37.12 Killdeer daily use estimates.

Figure 37.13 Mallard daily use estimates.

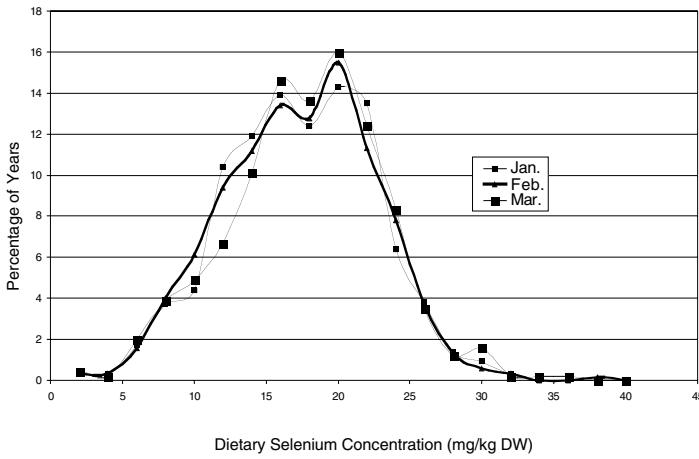

Figure 37.14 Black-necked stilt dietary selenium.

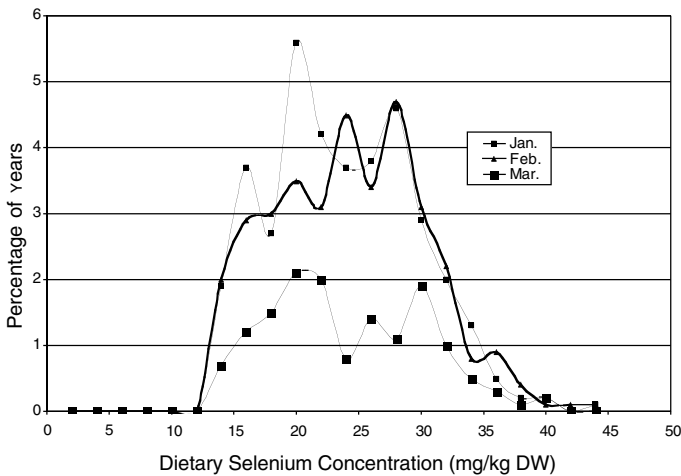

Figure 37.15 Killdeer dietary selenium.

Figure 37.16 Mallard dietary selenium.

Skorupa³⁹ developed a relationship between black-necked stilt egg failures and egg-selenium concentrations from a large database of egg chemistry and nesting success. We were able to use Skorupa’s equation with our egg-selenium concentration estimates (based on the above environmental transfer factors) to calculate the number of stilt hens with at least one probable egg failure, as follows:

$$\text{Raw percentage of hens affected} = \frac{\exp(-2.327 + 0.0503 \times \text{Egg-selenium conc.})}{(1 + \exp(-2.327 + 0.0503 \times \text{Egg-selenium conc.}))} \quad (37.5)$$

$$\text{Actual percentage of hens affected} = \frac{[(1 - \text{background}\%) - (1 - \text{raw}\%)]}{(1 - \text{background}\%)} \quad (37.6)$$

$$\text{Number of affected hens} = (\text{No. of birds counted}/2) \times \text{Percentage of hens affected where background}\% = 8.9\% \quad (37.7)$$

The calculation was run as a function of the set of 1000 estimated egg-selenium concentrations for both black-necked stilts and killdeer because of the similarities between the species. No such estimating technique was available for mallards. Although shorebirds may nest in April, April model results were not shown because they demonstrate no exposure. Kesterson is dry 94% of the time in April and shows minimal ponding in years of April flooding.

The probable number of hens affected by egg failure was estimated to exceed the background failure rate of about 8.9% (the calculated background failure rate for black-necked stilts) in a very limited number of cases. The model results indicated less than one killdeer hen would be affected by a loss of eggs due to selenium toxicity (0.1–0.3 hens affected). The results for black-necked stilts showed possible affected hens for the month of January only, with less than three hens affected. However, stilts typically begin nesting later in the season and therefore would rarely be affected. Similarly, the weighted mean selenium concentrations in killdeer eggs predicted by the terrestrial food chain model indicate that the percentage of hens affected (based on purely terrestrial exposure routes) would be less than the background failure rate of 8.9%.

37.4.1.2 Qualitative Evaluation

Kesterson Reservoir has been managed since 1988 as a terrestrial habitat. Terrestrial exposure to the selenium inventory of the reservoir has not resulted in demonstrable effects on local wildlife and is not expected to cause such effects in the future.

The overall summary of selenium exposure from the ephemeral-pool habitats at Kesterson Reservoir suggests insignificant risk to waterfowl and shorebirds. In most cases, ponding is too limited to represent significant exposure. In the rare cases when ponding persists, a very small number of birds (one or two) may be adversely affected during a small percentage of the years (less than 5%).

37.4.2 Risk Description

The evaluation of ecological risk from selenium exposure in the terrestrial and aquatic environments at Kesterson Reservoir is based on several lines of evidence. We have evaluated risks based on a long-term record of water-extractable soil selenium and extensive records of waterborne- and bird dietary-selenium concentrations, combined with an overall low frequency of ponding and the infrequent persistence of ephemeral pools for 1 month or more during the bird nesting season. Risks associated with the ephemeral pools were strongly determined by the balance between exposure (the degree of ponding at critical seasons during the year) and the spatial variation of both waterborne-selenium concentrations and bird use. In particular, bird use was the single most important direct determinant of risk. Although the water and invertebrate fauna of ephemeral pools contain relatively elevated selenium concentrations, risk is most often minimized through the limited ponding and lack of pool use by birds.

There is uncertainty in the modeled predictions of bird use and pool concentrations, but the modeled concentrations and predictions of impairment frequency closely match observed data. As predicted by the model, only a small number of birds are expected to be adversely affected from selenium concentrations in their diet. Monitoring data over 12 years did not show evidence of reproductive impairment to birds nesting at Kesterson attributable to selenium toxicity.

37.4.3 Uncertainties/Data Limitations

There are uncertainties and limitations at all levels of this analysis, as is typical of all ERAs. In this section, we describe the sources of uncertainty and specific limitations of the data and analysis.

37.4.3.1 Available Data

The Kesterson Reservoir database of selenium concentrations in various media, climatic variation, extent of ponding, and bird use is unusually comprehensive for an ERA. Rather than the typical 1 or 2 years of data, most of the summary statistics for selenium are based on 10 to 12 years of data gathered over a full range of seasons and interannual climatic variation. The climate record is based on 127 years of precipitation and estimated evapotranspiration data, incorporating periods of extended drought as well as extreme flooding (such as the 1997–1998 El Niño year). However, in some cases, such as data associated with the aerial photographic record, data sets are more limited. Ranges and measures of variability are presented with individual data summaries and regression relationships in the appropriate sections of this chapter.

It is unclear why the detected rates of egg inviability in killdeer (the most frequently sampled species; 4.3% of nests containing at least one fail-to-hatch [FTH] egg) are somewhat lower than background (8.9% of black-necked stilt nests containing at least one FTH egg), as reported by Skorupa.³⁹ Since Kesterson Reservoir was filled in 1988, the KRBMP has found seven inviable eggs in the 209 nests that were located during the monitoring. In general, nests were monitored on a weekly basis after they were found and marked. However, eggs in many of those nests were lost to predation, desertion, or destruction of nests (e.g., road grading) before they hatched, and from 1996 to 1999, when 64% of the eggs were collected, over 50% of the nests were lost. Therefore, it was not possible to determine accurately the rate of egg inviability in killdeer. In 1998, when 21 killdeer and 16 black-necked stilt eggs were collected at Kesterson and incubated in the laboratory

at UC Davis, there were no killdeer eggs in which embryos died before hatching, and there were two stilt eggs in which embryos did not develop (12.5%). In addition, 41 eggs were collected for examination and selenium analysis; no dead embryos were found in any of those eggs. Thus, it has not been possible to establish relationships between egg-selenium concentrations and reproductive impairment in killdeer, or to document the incidence of egg inviability (due to the high rates of eggs being lost to predation or perhaps other confounding factors).

37.4.3.2 Analytical Techniques and Modeling Assumptions

Analytical techniques used in the terrestrial and aquatic habitat models are based on a series of linear and log-linear relationships among environmental variables. In each case, assumptions were made about the underlying distribution of the data and the appropriateness of the regression relationship in explaining covariance of the variables. Individual regression equations and bivariate plots are presented in the appropriate sections in this report. As is to be expected from environmental-monitoring data, there is much unexplained variation in predictions, even in cases of statistically significant relationships. However, the basic assumption of the ERA models is that the predictive relationships are all descriptive of underlying causal relationships.

The ERA models are based on Monte Carlo simulations of the distribution of selected input variables. In this case, the underlying assumption is that the true distribution of the environmental variable can be accurately duplicated using random-number sets generated from the mean, standard deviation, and assumed type of distribution of the monitoring data. Most simulated variables (annual extent of ponding, dietary concentrations, bird use) were based on log-normal relationships.

37.5 CONCLUSIONS

As a result of this study, several summary conclusions can be made in relation to soil chemistry, the transfer of soluble selenium to surface-water pools, and the extent of ponding on the reservoir:

1. Anticipated future soluble (i.e., bioavailable) soil-selenium levels will fall within the range of concentrations observed over the last decade of soil-selenium monitoring and research.
2. The overall values for soil-to-ephemeral-pool transfer of selenium are not expected to change in the future and can be predicted within a factor of 2 based on historical data.
3. A ponding model based on the historic (127-year) Kesterson-area rainfall record predicts that in 43% of wet seasons, ephemeral pools will not form, or if they do form, they will have a duration of less than 1 month. Ponding for 2 or more months (needed to cause the development of invertebrate pond fauna) is expected to occur in approximately 11% of wet seasons. Ponding for 3 or more months is estimated to occur in about 37% of wet seasons.
4. During the period of spring waterfowl and shorebird nesting, the ponding model predicts that there is a high probability (57% to 94%, depending on the month) that less than 1% of Kesterson Reservoir will be ponded.
5. Ponding during the winter and spring of 1997–1998 represented the maximum ponded condition, based on the historical record and the near worst-case condition, in terms of modeling results for the extent of ephemeral pools.

The Ecological Risk Assessment model yielded the following conclusions:

1. Predicted selenium concentrations in bird dietary items (composed of aquatic invertebrates, terrestrial invertebrates, or terrestrial plants) exceeded dietary levels of concern for reproductive impairment in black-necked stilt and killdeer and exceeded levels of concern 16 to 43% of the time for mallards. However, no evidence of toxicological impact has been observed for these species during the 12 years of the Kesterson Reservoir Biological Monitoring Program, including results for 1997–1998, the year of highest observed ponding at Kesterson.

2. Daily bird use (i.e., potentially exposed individuals) during the months of concern, based on the extent of ponding, was predicted to be less than 20 birds more than 90% of the time for black-necked stilt, killdeer, and mallard.
3. The average number of black-necked stilt and killdeer hens expected to have one or more eggs fail to hatch due to elevated selenium exposure through the Kesterson Reservoir ephemeral pools was expected to be fewer than two hens for 99% of modeled years.

Sustainable development is the development that meets the needs of the present without compromising the ability of future generations to meet their own needs.

**World Commission on the Environment and Development
as quoted in the U.S. Man and the Biosphere Bulletin,
December 1991, 15(4):2**

38.1 INTRODUCTION

Since the first edition of the *Handbook of Ecotoxicology* was published, the primary impetus for the developing relationship of restoration ecology and ecotoxicology has been the rapidly developing interest in natural capitalism and industrial ecology (these issues are addressed in detail in Chapter 42 of this volume, “The Role of Ecotoxicology in Industrial Ecology and Natural

Capitalism"). An important related development is the recognition of the environmentally perverse effects of governmental subsidies.¹ While ecological restoration is poorly subsidized, environmental damage and destruction are often heavily subsidized by governmental agencies in all parts of the planet. In addition, the means for more accurate determinations of individual and societal impacts upon natural systems have advanced markedly.²

Arguably, the most important rapidly developing trend is the increasing acceptance of the need for implementing the precautionary principle.³ The precautionary principle essentially states that, when an activity raises threats of harm to human health or the environment, precautionary measures should be taken, even if some cause-and-effect relationships are not fully established scientifically. The importance of this principle to ecotoxicologists is the need to develop methods for predicting toxicological harm before it occurs and to estimate which toxicological thresholds, when crossed, will pose substantial ecological restoration problems. Another development is the establishment by the American Association for the Advancement of Science of the Program in Scientific Freedom, Responsibility and Law: Court Appointed Scientific Experts. This group of advisors may well have profound effects upon the field of ecotoxicology (for details, see <http://www.aaas.org/spp/case/case.htm>). If successful, this program will ensure a greater role for ecotoxicologists in courts of law in the United States and, concomitantly, a greater responsibility.

The Program in Scientific Freedom, Responsibility and Law: Court Appointed Scientific Experts has launched a demonstration project that will assist federal district judges in obtaining independent scientific and technical experts. Judges wishing to appoint experts under any source of authority will be able to call for assistance in identifying highly qualified scientists and engineers who will serve as experts to the courts, rather than to parties in litigation. An important aspect of the project is a rigorous and independent evaluation that will be conducted by the Federal Judicial Center, the research and education arm of the judiciary. Ecotoxicologists and restoration ecologists will be well advised to keep track of this initiative because it affects not only each profession independently but also the relationship between the two professions. An important volume in this regard is the National Research Council's report *Ecological Indicators for the Nation*.⁴ This volume has some useful discussions of thresholds and breakpoints for the types of situations in which both restoration ecologists and ecotoxicologists are likely to be involved. Another useful National Research Council book is *Global Change: Ecosystems Research*.⁵ It provides similar but different guidance on assessing ecological change at large temporal and spatial scales.

Humans have three options regarding their relationship to the earth's ecosystems: (1) continue ecological destruction at the present rate, (2) stop ecological damage and achieve a no-net-ecological-loss situation, and (3) maintain ecosystem services per capita, even with a growing population. Most citizens of developed countries would agree that option (1) is unacceptable, although these same people may not yet be prepared to accept the policies that will be essential to embrace either option (2) or option (3). Adopting a no-net-ecological-loss policy will require ecological restoration to restore systems damaged by ecoterrorism (e.g., the Arabian Gulf), by accidental spills (e.g., the Exxon Valdez in Prince William Sound, Alaska), or by cumulative impact of anthropogenic stresses over a long period of time. Ecotoxicology will be essential to ensure that the management practices associated with potentially toxic materials are well understood. Nevertheless, even if the option is fully successful and the population continues to grow, there will be fewer ecosystem services per capita simply because the population is growing in a finite space.

Option (3) will require more vigorous restoration efforts, as well as reduced risk in terms of ecotoxicological effects. Option (3) will be essential to maintain just the present ecosystem services per capita with a growing global population. These ecosystem services are well described by Ehrlich and Ehrlich,⁶ but a few illustrative examples include maintaining the atmospheric gas balance, transforming societal wastes into less objectionable compounds, maintaining a genetic inventory that will be helpful during climatic and other large-scale changes, regulating the rainfall pattern and other microclimatic events, and, of course, maintaining water quality.

38.2 THE RELATIONSHIP BETWEEN ECOTOXICOLOGY AND RESTORATION ECOLOGY

Environmental damage occurs from ecoaccidents, ecoterrorism, or because an ecological prediction of a safe concentration or course of action was incorrect. In each case, the damaged system should be repaired; when the spill involves hazardous and toxic materials, the fields of ecotoxicology and restoration ecology must be integrated. Additionally, restoration makes use of ecological resiliency — that is, the ability of natural systems to snap back to some semblance of their former condition, either with or without human assistance. Ecological resilience should be included in the safety or application factor used in conjunction with ecotoxicological tests.⁷ That is, protection should be greater for ecosystems less likely to “snap back” after disturbance than those that do. Other relationships should be explored by both groups of professionals.

38.2.1 Multiple Use and Cumulative Impacts

The news media have numerous examples each day of human impact on the environment. Both the frequency and severity, as well as the complexity, of impacts have been increasing. Multiple use is becoming increasingly favored with a growing population and a finite planet, but multiple use increases the probability of multiple or cumulative impacts. At the same time, the planet's ecological capital is shrinking, thus requiring increasingly effective management of natural resources. The nature of adverse environmental impacts has changed radically since the beginning of the industrial revolution from small, localized effects to the now increasing importance of regional effects (e.g., acid precipitation) and global effects (e.g., climate change). Other factors that have markedly changed include nonpoint sources of stress relative to point-source discharges, the increasing number of potential stressors, and the importance of aggregate or cumulative impacts. In most developed nations, the focus of environmental protection has broadened from the development of stress-specific environmental quality standards to the achievement of broad objectives for restoring self-maintaining ecosystems inextricably coupled with the maintenance of the quality of human life.⁸ Coping effectively with the transition in the way society presently affects ecosystem health to restoring and protecting the environment will require substantive improvements in the effectiveness of environmental management strategies.

38.2.2 Can Ecosystem Health be Measured?

Ecotoxicologists measure injury to representatives of individual species in laboratory jars or the effects at higher levels of biological organization in laboratory microcosms, but ultimately the desire is to predict concentrations with minimal effects in natural systems (generally referred to as ecosystems). Because humans are health conscious and wish to preserve their health, many wish to do the same thing for ecosystems. However, Glenn W. Suter, II (personal communication) disagrees with treating the metaphor of ecosystem health as a reality because it is not an observable property. Suter feels that the metaphor misrepresents both ecology and health science. Ecosystems are not organisms, he feels, so they do not behave like organisms and do not have properties of organisms, such as health. Additionally, Suter feels that health is not an operational concept for physicians or health-risk assessors because they must predict, diagnose, and treat specific states called diseases or injuries; they do not calculate indices of health. Finally, Suter believes that attempts to operationally define ecosystem health result in the creation of indices of heterogeneous variables. These indices, he says, have no meaning; they cannot be predicted, so they are not applicable to most regulatory problems; they have no diagnostic power; effects on one component are eclipsed by responses of other components; and the reason for high or low index value is unknown. Suter feels

Figure 38.1 Results of a survey of journal literature in ecology, indicating the dominance in ecology of research that ignores the influence of climate, soil, water, and air on species interactions.

that a better alternative is to assess the real array of ecosystem responses so that causes can be diagnosed, future states can be predicted, and benefits of treatments can be compared.

Unfortunately, perhaps, ecosystem health is a powerful metaphor that focuses desires and aspirations of large numbers of people. It has been frequently advocated as a goal for environmental regulation and management.^{9–12} Ecosystem health was the subject of a recent workshop¹³ and is used in the title of a new journal (*Journal of Aquatic Ecosystem Health*). Putting aside for the moment the undeniably poetic power of this metaphor, one wonders why it has been so persistent and durable in the field of environmental science. Harte and his colleagues¹⁴ examined 285 articles in four consecutive issues during 1987–1990 of the journals *Ecology*, *American Naturalist*, *Oecologia*, and *Conservation Biology*. They found that:

If we turn to the current journal literature in ecology and conservation biology, we will not get as much help as we would like. Figure 7 (Figure 38.1 in this discussion), based on our survey of all the articles appearing in some recent volumes of leading journals, illustrates the “Pluto Syndrome” that afflicts ecology today. It shows that most research in ecology might just as well have been carried out on the planet Pluto — climate and the chemical and physical properties of the soil, the water, and the atmosphere of Earth were irrelevant to the research. Even in the 22% of the articles that mentioned at least one of these factors, the reference was generally made as part of a site description and played no role in the interpretation of results. In none of the papers surveyed were the interactions among these factors even mentioned.

In short, most ecologists study populations and not ecosystems; thus, a dearth of terminology and methodology is used to describe and inventory ecosystem condition. Although Whittaker¹⁵ had no doubt that “ecosystems are not organisms,” more recently Lovelock,¹⁶ in espousing the Gaia hypothesis, has resurrected the view of the planet as a superorganism.

This discussion explores the relationship between restoration ecology and ecotoxicology. Scientists wish to prevent damage to natural systems, detect damage when it occurs, and restore the damaged system to a close resemblance of its predisturbance condition. Presumably, the same attributes or endpoints could be used for all three purposes. Regrettably, the field of ecotoxicology has yet to achieve a recognizable identity,^{17,18} and the field of ecology is presently more concerned with populations than with interactions among the chemical, physical, and biological components of the entities called ecosystems.¹⁴ Both ecotoxicology and restoration ecology purportedly are concerned with the condition (structural and functional) of complex multivariate natural systems. While it is true that

ecotoxicology focuses on causes of deterioration from the nominative state and restoration ecology focuses on how to return a disturbed system to its predisturbance nominative state, the number of system attributes shared by these two fields in their diagnoses should be remarkably similar. In fact, a charitable but dispassionate observer would, in examining both fields as they presently exist, have difficulty making any robust connections between the two. However, both groups almost certainly should be using nearly identical ultimate attributes to judge success or failure.

38.2.3 Top-Down vs. Bottom-Up Strategies

The top-down and bottom-up approaches appear quite different in the evaluation of environmental degradation at the community and ecosystem levels.^{19,20} The top-down method involves directly assessing changes in natural communities and ecosystems and then subsequently diagnosing problems and causative agents. This might also be regarded as a reactive measure, which would include the saprobian approach.²¹ The contrasting bottom-up methods use laboratory data that demonstrate effects on simple systems, generally low in environmental realism, and then use the data to model or predict changes in more complex natural ecosystems. The hazard-assessment protocols illustrate this approach.²² Routine bottom-up procedures for estimating hazard (e.g., laboratory testing with human or ecosystem surrogates, models of fate transport and partitioning) are limited in their ability to predict impacts on natural ecosystems for a number of reasons.²³⁻²⁷ A list of the most important of these limitations follows.

1. Difficulties involved in the use of effects observed in the laboratory to predict responses in the natural environment.
2. Difficulties involved in the use of different degrees of environmental realism (simple laboratory test systems vs. complex natural systems) and different levels of biological organization (single species laboratory tests vs. complex natural communities and ecosystems).
3. Difficulties in measuring aggregate effects in the laboratory. Most hazard protocols consider the effect of each type of stress individually, even though impacts are inevitably cumulative or aggregative in natural systems. In short, reductionist science is pushed beyond the limits of its capabilities, and integrative science is not given the attention it deserves. Not to be misunderstood, all scientists must be reductionists at times because the scientific method requires this.
4. Difficulties in determining all the chemicals to which organisms are exposed in natural systems. The American Chemical Society Computer Registry of Chemicals has had over 8 million chemicals on the register. Fortunately, only an estimated 76,000 of these are in daily use, including shelf-life extenders for foods, etc. Nevertheless, 76,000 chemicals, when released into the environment following use, can have a bewildering array of interactions. Current testing capabilities cannot test all possible combinations of these chemicals under all possible environmental conditions with all species that are probably exposed. As a consequence, all estimates of hazard or environmental risk will necessarily have a substantial uncertainty involved. Nevertheless, the uncertainty need not be as large as it presently is since methods currently available could be utilized more extensively to reduce the uncertainty substantively.
5. Difficulties of scale and complexity of detail. It seems highly improbable that successful management of sizable ecological landscapes or major ecosystems to achieve broad environmental and socioeconomic objectives is possible without a substantial broadening of the environmental assessment framework to encompass top-down ecosystem objectives. Figure 38.2 provides a simplified flow pattern for an ecosystem quality control system.

38.3 RESTORATION OF NATURAL ECOSYSTEMS ALREADY IMPACTED BY HAZARDOUS CHEMICALS AND OTHER ANTHROPOGENIC STRESSES

It is difficult to find any ecosystem in the world, especially aquatic ecosystems, totally unaffected by human activities. Even relatively remote areas have now accumulated trash and other debris

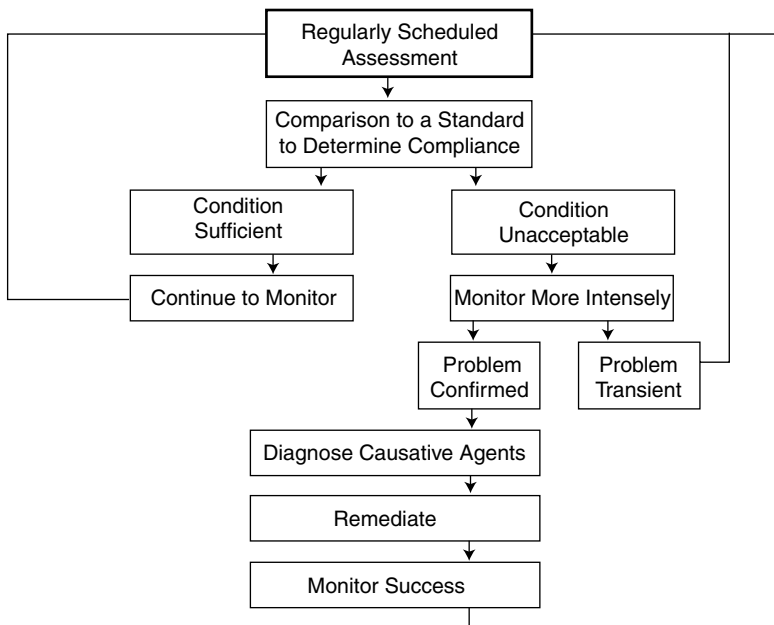

Figure 38.2 Monitoring the health of an ecosystem over time. (Reproduced with the permission of the International Joint Commission (United States and Canada) from *A Proposed Framework for Developing Indicators of Ecosystem Health for the Great Lakes Region*, a report prepared by Cairns, J.R., Jr., McCormick, P.V., and Niederlehner, B.R., July, 1991.)

from expeditions and may be affected by global climate change or changes in the ozone layer and the like. Furthermore, the human population globally is still increasing dramatically,²⁸ and considerable restoration is necessary just to retain the per-capita ecosystem services now available.²⁹ Ecotoxicologists need to determine for restoration ecologists the degree of restoration possible at different levels or concentrations of hazardous materials for ecosystems affected by anthropogenic toxics and hazardous materials.

One of the daunting problems for any professional is attempting to communicate outside the discipline. Can one make the assumption that the specialized jargon, presumably understood by a limited number of initiates, will be equally well understood or even intelligible to those with other backgrounds, however intelligent they might be? Should professionals have a semantic debate about words used in a limited context within the profession (or even avoided entirely) or should they attempt to convey the essence of their beliefs using the common language of the general public? Persuasive evidence indicates that legislators and the general public are disenchanted with scientists. This may well be because scientists avoid simple, direct terms such as *health* in favor of those more scientifically accurate but more easily misunderstood by the general public. I am most sympathetic to Suter's misgivings, but these are outweighed (just barely) by my apprehensions that unfamiliar terminology may cause laypersons to either misunderstand or ignore the message.

An important aspect of restoring ecosystems displaced by anthropogenic or other stresses is relating the development of indicators of ecosystem health to management goals for that particular ecoregion. Figure 38.3 is a crude schematic of the alternative trajectories for an ecosystem for which some management option is contemplated.

All restoration efforts should be accompanied by an effective monitoring program, which is the only way of determining whether the expected events are occurring. Since everything cannot be measured, selected attributes related to objectives for the ecosystem should be developed. "Indicators" should be selected that are useful in determining the extent to which specific objectives have been achieved (e.g., that selected quality control parameters are within the predicted range or

Figure 38.3 Crude conceptual model of alternative trajectories of an ecosystem. (Reproduced with the permission of the International Joint Commission (United States and Canada) from *A Proposed Framework for Developing Indicators of Ecosystem Health for the Great Lakes Region*, a report prepared by Cairns, J., Jr., McCormick, P.V., and Niederlehner, B.R., July, 1991.)

are approaching the predicted range). However, indicators or attributes cannot be identified until the goals and objectives are explicitly stated. Regrettably, many regulatory agencies frequently select indicators or attributes without explicitly stating ecosystem objectives and goals. Of course, just stating “a healthy ecosystem,” while laudable, is not of itself a desirable management objective unless it is specified, both structurally and functionally, what “a healthy ecosystem” means.

Structural attributes are relatively straightforward, although uncertainty about any measurement is always present. Some of the structural attributes involve “critter counting” (such as relationships between different trophic levels), comparison of species array or community structure with others characteristic of that particular habitat, and topographical (slopes, etc.) and hydrologic characteristics. These are the attributes most commonly measured and most easily quantified.

Functional attributes are no less important, but they generally receive less attention. Functional attributes most commonly involve rate processes of one sort or another. Some illustrative examples for a wetlands restoration include: (1) rate of carbon fixation, (2) rate of nutrient spiraling, (3) rate of detritus processing and storage, (4) rate of suspended-solid trapping, and (5) nutrient trapping and storage.

Each wetland, of course, may require a somewhat different mixture of attributes — although a list of attributes may be commonly shared, some will be more important in one system than in another. Success means being on trajectory toward development of the predicted state, and failure means getting a result strikingly different from that predicted.

Whenever a restoration project is underway, it becomes considerably more difficult to admit failure. If an industry is charged with restoration and is bonded to achieve this result (e.g., in association with surface mining), failure to achieve the desired goals or attributes may result in forfeiture of the bond, extension of the period during which bonding is required, or an unexpected expenditure of funds to realign the recovery process with the predicted pathway. In the same sense, a regulatory agency may have to admit that some goals it has set for a restoration project are unachievable and that the organization responsible for the restoration is not accountable for these goals. In this era of reduced public funding, such an admission could be a real threat to the continuance of the regulatory agency at its present level of funding. Finally, for the scientists involved, admission of failure means that their hypothesis was invalid and that all or some of their assumptions were false. While this is painful to admit, even among fellow scientists, it is far, far worse to make this admission to the general public or legislators who have little understanding that failure is a constant part of the scientific process. However, some failures could easily have been prevented by a systematic and orderly approach in project planning. Some worst-case reasons for failure, not involving uncertainty in predictive models, are:

1. No specific goals were set. Instead, vague generalities, such as “fishable, swimmable waters,” are utilized instead of more explicit statements of testable objectives. Sometimes, if the objectives are listed, they may describe only the proposed structure and not the proposed functioning of the restored ecosystem. In this case, success in terms of functional attributes may be missed, despite the fact that some of the biological structural attributes do not match the predicted model.
2. In some cases of extreme fragmentation, a fragment may appear to be restored, but in the process of doing so, serious damage may occur in another part of the ecological landscape. For example, increased discharge from a reservoir may enhance wetlands recovery downstream but damage the ecological integrity of wetlands behind the dam.
3. There is no monitoring or follow-up to determine if the project was actually carried to completion, whether it has in fact achieved the stated restoration goals, or whether the mitigation proposed has actually been achieved.
4. Unexpected problems are encountered during the restoration process that make it impossible to follow the original plans. Course corrections may be made on the spur of the moment on site and without consultation with the mixture of organizations that had reached a consensus on the original project. Construction crews may make errors that are difficult to correct because ecologists or hydrologists were not present during critical stages of the restoration process. For example, in Colorado, one mitigation project required that an access road be built through relatively undisturbed wetlands to reach the mitigation site where both restored and constructed wetlands were being developed as a part of the mitigation process.
5. No substantive documentation of the restoration efforts is available that can be given rigorous peer review by appropriate specialists. As a consequence, instead of being required to correct minor flaws in design early in the restoration process, a disaster discloses the inadequacies of the project.
6. Access is often denied to those charged with evaluating a restoration project on private land.
7. Regulatory agencies have insufficient personnel to track the restoration effort or have sufficient personnel but with inadequate professional experience.
8. Cosmetic restoration (greening or revegetation) produces enchanting photographs that can persuade the unknowledgeable that true restoration has occurred. However, when a careful examination is made by trained personnel, the deficiencies are discovered. Nevertheless, course corrections should be made early in the project, and glossing over inadequacies with colorful photographs is all too often substituted for scientifically justifiable evidence.

38.4 ESTABLISHING A PROTOCOL FOR INTERACTIONS BETWEEN RESTORATION ECOLOGISTS AND TOXICOLOGISTS

Ecologists and toxicologists have exceedingly limited interactions at present, and establishing a common ground between what appear to be quite distinct professions is difficult. Human society appears to be developing four goals with regard to its relationship with natural systems:

1. Develop predictive models that will accurately estimate effects upon natural systems of various anthropogenic stresses before these potential stressors are utilized, or at least before they are utilized on a wide scale. Lemons³⁰ identifies a number of important organizational characteristics of ecosystems: ecosystem processes; productivity; decomposition and nutrient cycling; interactions among the biosphere, atmosphere, hydrosphere, and lithosphere; communities; community structure; dynamic networks of interacting individuals and species; symbiotic and mutualistic species; populations; individual organisms; and overall homeostasis. These are illustrative only because any attribute of a natural system might well be used in the assessment process. Naturally, key attributes will vary from one ecosystem to another, and professional judgment will be required to make an appropriate selection.
2. Detect damage in natural systems as soon as possible after its occurrence while the extent of the damage is still minimal. Damage could result from inaccurate predictive models improperly validated or from spurious validation. Additionally, damage frequently occurs from accidental spills and other ecoaccidents, including ecoterrorism. Finally, since natural systems respond to the aggre-

gate of stresses to which they are exposed under conditions not always utilized in the development of the predictive model, aggregate or cumulative impacts may not have been properly evaluated.

3. Restore damaged systems to as close an approximation of predisturbance conditions as possible. Attributes useful in all three of these activities may be quite similar. In short, ecotoxicologists will need system-level attributes to predict and validate anthropogenic effects at higher levels of biological organization such as communities and ecosystems. Second, these same system attributes should be equally useful in providing early warning of damage. The attributes used in resolving the uncertainties posed in both (1) and (2) are now similar at present; this seems to be an accident of the development of the two fields rather than a sound, scientifically justifiable strategy.
4. Have objective quantitative means of determining success or failure in restoration efforts. The system-level attributes used in implementing (1) and (2) should be equally useful in restoration. In fact, if they cannot be used, then an overall management plan integrating these three activities could not be developed. Almost certainly, all three activities would benefit from a dialog discussing suitable attributes among the practitioners of ecotoxicology, biological and ecological monitoring, and ecological restoration.

The crude, illustrative protocol presented in Figure 38.4 is intended to stimulate discussion on the relationship between restoration ecologists and ecotoxicologists. Successful rehabilitation requires information flow between these two specialties. In Phase I, description of the community that is the desired endpoint of restoration efforts serves as the basis for determinations of the necessity for reductions in hazard. In Phase II, tolerance information will guide the choice of species, maximizing success. In Phase III, after species are introduced, observations of their success can be compared to expectations. It would be astonishing if predictions were completely accurate; therefore, Phase III focuses on detecting errors and identifying needs for more robust information where substantial error occurred. This process provides feedback loops that improve the quality of the information used to make decisions. In Phases IV–VI, the new information is incorporated into the rehabilitation plan. Ultimately, an entire book could be allotted to this subject, as was the case for the relationship between those who determined environmental concentrations of chemicals and those who determined the biological effects of these chemicals.²²

It now seems unthinkable that the two groups whose relationship was explored in detail in the book just cited were not working together from the outset, but the need to develop an effective relationship was not apparent in the 1940s, 1950s, and 1960s. In addition, the relationship between restoration ecologists and ecotoxicologists will not be viewed at the end of this century as it is today. One event that makes this change seem probable was the April 13, 1992 issue of *U.S. News and World Report*, which had extensive documentation of the poisoning of Russia. Problems had already surfaced in various Eastern European bloc countries. Reducing all this damage and its threats to human health and the environment, together with restoration to a closer approximation of predisturbance condition, will definitely require collaboration between ecotoxicologists and restoration ecologists. Since the attributes at the system level for both ecological restoration and ecotoxicology could easily be more robust, energy should be spent on this aspect rather than an extended conflict over which methods of which group should take precedence.

38.5 FINANCING ECOSYSTEM RESTORATION

Ecological restoration represents a major shift from increasingly more environmental services that society expects to responsible stewardship. Hazardous-waste sites by definition pose a threat to either human health or the environment or both. The latter is the most likely case since, while living material is not identical in its response to hazardous materials, they are of sufficient similarity to make the assumption that anything adversely affecting environmental health will have some negative impact on human health. In his budget message for 1991, President Bush stated “Today, a consensus is emerging in our society: investments in maintaining and restoring the health of the

Figure 38.4 Interactions between restoration ecologists and ecotoxicologists charged with rehabilitating a hazardous waste site.

environment can now be seen as responsible investments for the future.” Unfortunately, the present governmental structure of programs and policies related to the environment is fragmented and will probably not adequately approach restoration as a challenge requiring management of rather large systems (i.e., drainage basins, etc.). President Bush’s aspiration requires a national, but not solely federal, ecosystem-restoration strategy to meet the changing societal demands on natural resources.

An article in *U.S. News and World Report* (page 40, April 13, 1992 issue) notes that, in the former Soviet Union, economic growth was worth any price. The price has been enormous, even though the order of magnitude is not known. In terms of financing, every country of the world, developed or developing, has sacrificed ecological capital to spur economic development. American citizens decry the loss of the Amazon rain forests but are not equally vocal about the loss of their own forests in the Pacific Northwest and elsewhere. As is the case with medicine, preventing disease

is far less costly than curing disease. Ironically, widespread development and implementation of the field of ecotoxicology may only occur when the cost of restoring ecosystems damaged by inattention to this field are fully and robustly documented. The problem, of course, is that, for such things as old-growth forests and a number of other ecosystems, restoration is unlikely to occur in the lifetime of humans now living and may not be possible in the lifetimes of any future generations. Nevertheless, by starting now to restore ecosystems damaged by hazardous materials, especially in those instances such as Russia where extreme contamination has occurred, the economics of restoration will be better understood than it is now. The basic question is where to acquire funds to begin the restoration effort.

After funding is available, a number of elements deserve attention (Chapter 8 of the National Research Council report⁸ discusses these for aquatic ecosystems in broad general terms).

1. A national restoration strategy should be directed to broad-based and measurable goals.
2. A national aquatic ecosystem assessment process should monitor the achievements of the nation's goals for wetlands, rivers, and lakes.
3. Policies and programs for aquatic ecosystem restoration should emphasize a landscape perspective.
4. Restoration policies and individual restoration projects should be designed and executed according to the principles of adaptive planning and management.
5. Evaluation and ranking of restoration alternatives should be based on an assessment of opportunity costs rather than a traditional cost-benefit analysis.
6. A single definition of restoration should be incorporated into all appropriate national legislation.
7. A national restoration strategy should allocate leadership to the central government for landscape restoration of national significance and should rely on nongovernmental and governmental units to coordinate restoration programs in local areas.
8. The central government should initiate an interagency and intergovernmental process to develop a unified national strategy for aquatic ecosystem restoration.
9. The development of a unified national program for aquatic ecosystem restoration should be facilitated, and then maintained, under the leadership of a single responsible organizational unit.
10. Current and proposed federal programs should exploit available opportunities for ecosystem restoration.
11. Government should establish a national aquatic ecosystem restoration fund.
12. Reliance should be increased on local and environmental restoration boards for program planning, synthesis, and leadership.
13. Central governments should allow states and local governments to trade governmental funds designated for development, construction, maintenance, and major repair of water projects and to obtain funds instead for aquatic restoration programs.
14. The U.S. government should authorize expansion of the Agricultural Wetlands Reserve Program with funds from Farm Program Cost Savings.
15. The U.S. government should encourage water-pollution credit-trading programs to finance aquatic-ecosystem-restoration programs.
16. The central government and state government should encourage the trading of water rights to promote aquatic ecosystem restoration.
17. Governmental and state agencies should cooperatively design landowner-finance regional restoration projects.

Although these elements relate to aquatic ecosystems, relatively slight modification could include terrestrial ecosystems. Financing, in short, will come from a variety of sources, not the least important of which would be the savings resulting from integrated environmental management as the replacement for the fragmented and relatively uncoordinated present environmental management. Unfortunately, Russia and some other countries are examples of what happens when the life-support system is damaged for short-term gains in the economic life-support system. The vast and expensive military organization maintained by the former Soviet Union contributed to, rather than protected it from, many dangers.

38.6 DEVELOPMENT OF AN INTEGRATED ENVIRONMENTAL MANAGEMENT SYSTEM

Ultimately, society will determine that preventing damage is less expensive than restoring damaged ecosystems. Thus, preventative measures will likely become much more important than they now are. Additionally, if the economic evaluation uses opportunity analysis instead of the traditional cost-benefit analysis, many more situations will occur in which ecotoxicologists and restoration ecologists should interact to provide the evidence on which the opportunity-analysis decisions are made.

Integrated environmental management may be defined as proactive or preventative measures that maintain the environment in good condition for a variety of long-range, sustainable uses.³¹ Alternatively, integrated environmental management may be regarded as coordinated control, direction, or influence of all human activities in a defined environmental system to achieve and balance the broadest possible range of short- and long-term objectives. Sometimes, a course of action becomes clearer by stating what it is not. Environmental management is NOT fragmented decision making so that only one use is considered at a time. Short-range goals that benefit a single group are not preferred.

The more obvious benefits of integrated environmental management are:

1. Long-term protection of the resource
2. Enhanced potential for nondeleterious multiple use
3. Reduced expenditure of energy and money on conflicts over competing uses and the possibility of redirecting these energies and funds to environmental management
4. More rapid and effective rehabilitation of damaged ecosystems to a more usable condition (more ecosystem services provided)
5. Cost effectiveness

Resource managers have long recognized that the institutional problems associated with managing natural resources are invariably more aggravating and intractable than the scientific and technical problems. Typically, it is not lack of methodology that impedes more effective use of natural systems (although methodology could certainly be improved), but rather the fact that many institutions (each charged with a fragment of resource use or management) fail to integrate system-management responsibilities. This situation was an inevitable consequence of a policy that made specialization a dominant theme in science and engineering. The field of human medicine has recently been redirected toward a more holistic approach, even though specialists still play a critical role. Environmental management might well adopt a similar strategy.

The barriers to integrated environmental management are indeed formidable! The 24 illustrative barriers used by Cairns³⁰ are listed here in an abbreviated form.

1. Institutions of higher learning are primarily reductionist, not integrative. Students graduating from these educational institutions have had their attention directed primarily toward specialization and reductionist science, with very little, if any, time spent on integrative science.
2. Integrated environmental management takes time, and budgeting this time is often neglected.
3. Turf battles run rampant in many organizations, including universities and colleges.
4. Integrated environmental management is often viewed as a threat to job security.
5. Many individuals and organizations are unwilling to compromise.
6. Short-term profits are too enticing.
7. There is a "what has posterity done for me" attitude.
8. Issues are not simple "good guys/bad guys" for decision makers.
9. The uncertainty of the outcome is often unacceptably high, for example, predicting the precise environmental benefits of reducing stack emissions from fossil fuel power plants.
10. At the global level, developing countries aspire to material benefits per capita now enjoyed by developed countries.

11. Changes in lifestyle (recycling, lower per capita use of energy, etc.) are strongly resisted by some individuals.
12. Specialists feel more comfortable working with “their own kind” rather than alien (from other disciplines) specialists.
13. Environmental despoilers fear the general public will not have the same value system.
14. The present use is considered a “right” or entitlement not open to discussion or compromise (e.g., prior appropriation water rights of western states in the United States).
15. Society is oriented toward growth rather than maintenance.
16. Change is only acceptable in a crisis, not always when the problem is more manageable.
17. There is a general fear that management authority will be abused.
18. Specialists fear criticism resulting from oversimplification sometimes needed for effective communication in integrated environmental management.
19. The belief that all systems are too complex to permit any prescriptive (read: standard methods and procedures) legislation or professional endorsement halts some scientists in their attempts to resolve complex issues.
20. People “turn off” when they face complex issues requiring a substantial effort to understand them properly.
21. Technical information is viewed as inadequate at the present time.
22. Nonspecialists have difficulty determining which evidence is credible, especially when there are specialists taking strong positions that are diametrically opposed.
23. The number of professionals skilled in integrated environmental management or some component of integrated environmental management is inadequate.
24. The political process is oriented toward polarized issues rather than integrated environmental management.

38.7 CONCLUSIONS

Ecological restoration in many situations could be facilitated by the interaction of restoration ecologists and ecotoxicologists. It is a *sine qua non* that human society must be motivated to restore at least some of the damaged ecosystems. The National Research Council report⁸ provides some case histories for aquatic systems that clearly demonstrate such support. For terrestrial systems, Janzen³² provides a splendid example for a developing country, and the two-volume set of which the Janzen chapter is a part provides other examples. Illustrative examples of where the relationship between restoration ecology and ecotoxicology might be most effective are rivers and other parts of the hydrologic system where there has been a long-term cumulative impact of hazardous materials or an unexpected spill of hazardous materials. For terrestrial systems, the Superfund sites in the United States, where accumulations of hazardous materials pose a threat to human health and the environment, provide another example.

Although this section of the *Handbook* emphasizes the relationship between restoration ecology and ecotoxicology, it would be most unfortunate if there were a perception that the interaction of these two specialties alone would be adequate for resolving the problems just described. A large number of other disciplines should be involved for a truly integrated problem-solving team capable of providing a long-term solution to a complex multivariate problem. Illustrative areas of competence to be included would be urban and regional planners, economists, sociologists, chemists, groundwater and other types of hydrologists, and a variety of other disciplines. Decision analysis³³ should show how each type of information would affect a given decision, and, of course, if not too difficult or impossible, what type of information is clearly inappropriate for that decision. Regrettably, substantial amounts of data are sometimes gathered for long-term, large-scale projects because certain types of data are thought to be inherently valuable, although no effort is made to determine how the information, once gathered, will be used in the decision-making process. Determining how the information will be used in the decision-making process also provides unmistakable indications of what type of working relationship should be developed between and among specialists.

There is persuasive evidence⁶ that the earth's population will continue to increase well into the next century. Additionally, individual expectations of a better life are also rising. With a finite planet that is not expandable, this means the single-purpose use for land and water areas acceptable during frontier days is no longer possible. Each individual and nation will have to remember that it is part of a larger system and will often be required to modify its behavior so that ecological capital is not destroyed and, better yet, so that ecological capital is generated. Long-term sustainable use of the planet requires nothing less. Placed in this context, developing a relationship between restoration ecologists and ecotoxicologists is clearly only a necessary first step in the development of a larger integrated environmental management strategy. Nevertheless, if these first steps in developing a relationship between what have been until now more or less independent professions fail, it is highly unlikely that the ultimate complex interdisciplinary teams will be effective. This process should begin in our educational institutions, which, regrettably, have hardly begun to acquaint students with integrative science. Some have made tentative beginnings, often in the face of considerable resistance from the faculty. If the educational system is to change as rapidly as the situation demands, the consumers (i.e., students) and society as a whole must exert some pressure on the educational system.

39.1 INTRODUCTION AND HISTORICAL BACKGROUND

It has been established that a wide variety of anthropogenic (man-made) chemicals in the environment are capable of modulating and adversely affecting or disrupting endocrine function in vertebrate organisms.^{1–13} The physiological effects of exposure to these chemicals have been termed “endocrine disruption” and the active compounds labeled as “endocrine-disrupting chemicals” (EDCs) or “endocrine-active-agents.” Endocrine disruption has been defined by the U.S. Environmental Protection Agency (EPA)¹² as the action of “an exogenous agent that interferes with the production, release, transport, metabolism, binding, action, or elimination of natural hormones in the body responsible for the maintenance of homeostasis and the regulation of developmental processes.” This definition was further expanded by the U.S. EPA Endocrine Disruption Screening and Testing Advisory Committee (EDSTAC)¹⁴ to indicate that these effects are “adverse” and may involve a wide assortment of endocrine-mediated functions and potential receptor-mediated events. Indeed, effects may involve the steroid receptor superfamily, including the sex steroids, thyroid hormones, and adrenal hormones, as well as hypothalamic-pituitary and other protein hormones.

The physiological processes regulated by the endocrine system are diverse and numerous. Likewise, the mechanisms of action and effects of potential EDCs are equally diverse (see Figure 39.1). Receptor-mediated events involve EDCs acting as hormone mimics (agonists or antagonists) and adversely impacting hormone synthesis, catabolism, secretion, transport, and signal transduction. Examples of nonreceptor-mediated modes of EDC action include altered enzyme function and selective toxicities for endocrine-active or target tissues, whereas altered gene expression and induction of oxidative stress are types of receptor mediated events. EDCs may also act by altering developmental processes, often producing multigenerational effects.

Endocrine-active anthropogenic chemicals are also numerous and diverse (see References 1–13). Evidence for endocrine-disrupting effects due to these chemicals comes from a diverse array of

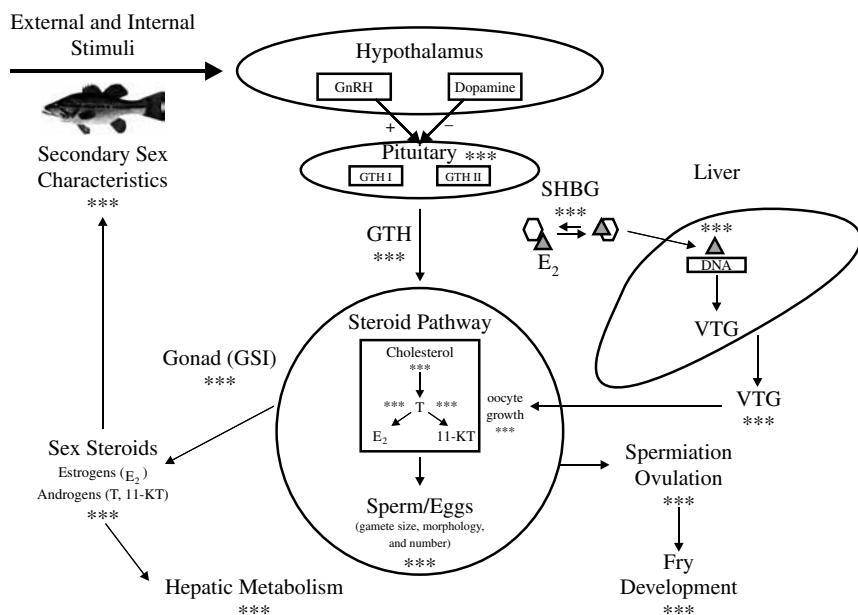

Figure 39.1 Schematic representation of the hypothalamic-pituitary-gonad-liver axis of teleost fishes. Asterisks denote areas at which EDCs can exert their effects. In general, this model is also applicable for other oviparous vertebrates. Abbreviations: GnRH (gonadotropin releasing hormone); GTH (gonadotropin hormone); GSI (gonadosomatic index); SHBG (serum binding hormone globulin); VTG (vitellogenin); T (testosterone); E₂ (17β estradiol); 11KT (11-ketotestosterone).

reports involving multiple vertebrate taxonomic groups, limited invertebrate taxa, and results from both *in vitro* and *in vivo* studies. Reported effects of EDCs have included effects at multiple levels of biological organization including molecular, biochemical, cellular, tissue, and organismal. However, few reports have documented effects at the population level and higher. In addition, most studies have focused upon reproductive effects; however, effects on growth, metabolism, and thyroid and immune function have also been noted. This chapter summarizes the current evidence for the endocrine-disrupting effects of specific chemicals and chemical classes in vertebrate wildlife with a discussion on potential mechanisms/modes of action.

39.1.1 General and Comparative Endocrinology

To fully understand the mechanisms by which anthropogenic or natural EDCs may modulate endocrine function, normal functioning of the endocrine system must be understood. Indeed, an assessment of the risk of potential EDC exposures and effects requires critical information from a variety of disciplines, including endocrinology, and an understanding of the variation among and within vertebrate classes. The following section is a brief overview of vertebrate endocrinology and the hormones that may be involved in endocrine modulation or disruption.

The endocrine system is a collection of hormone-secreting cells, tissues, and ductless glands (e.g., pituitary, thyroid, adrenal, and gonads) that play an important role in growth, development, reproduction, and homeostasis. Tissues of the endocrine system synthesize and secrete hormones that influence virtually every stage of the life cycle of an organism, from gametogenesis and fertilization, through development into a sexually mature organism and senescence. Endocrinology is the study of tissues that secrete hormones into the blood and the subsequent effects hormones have on target tissues. Hormones are released into the extracellular environments and affect neighboring cells (paracrine control), the emitting cell (autocrine control), or other target tissues (endocrine control). Some nerve cells also release hormones into the blood (neuroendocrine control) or into extracellular fluid for communication with other nerve cells or nonnerve cells (neurotransmission). Pheromones are hormones secreted into the external environment for communication with other individuals or species. In addition, there are several hormones that act through more than one of these chemical-signaling modes.

Figure 39.1 summarizes the hypothalamic-pituitary-gonadal axis for fish as an example of the endocrine system, its diverse control over reproductive and developmental processes, and sites at which EDCs may exert endocrine-disrupting effects. In general, this model is also applicable to other oviparous vertebrate species including birds, amphibians, and reptiles.

The vertebrate hypothalamus and the pituitary gland (or hypophysis) have an essential role in regulating endocrine and nonendocrine target tissues.¹⁵⁻¹⁷ The hypothalamus and pituitary are functionally and anatomically linked, forming the hypothalamic-pituitary axis. In mammals, the pituitary is composed of four anatomically and functionally distinct regions: the adenohypophysial *pars distalis* and *pars intermedia*, and the neurohypophysial median eminence and *pars nervosa*. In fish, the *pars distalis* is additionally separated into two regions that contain different cell types and produce different hormones.¹⁸ The pituitary gland of amphibians, birds, and reptiles is similar to the mammalian pituitary gland.¹⁶ Indeed, the basic arrangement of the hypothalamic-pituitary axis is essentially the same in all vertebrate groups, with the exception of teleost fishes, which lack a median eminence.¹⁶

The hypothalamus directly controls pituitary hormone secretion via the production and release of a number of peptide and nonpeptide hormones. These pituitary-tropic hormones are generally categorized as releasing hormones (RH) or release-inhibiting hormones (RIH), depending on their function. Hypothalamic hormones include corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), growth-hormone-releasing hormone (GHRH), growth-hormone release-inhibiting hormone (GHRH, somatostatin), and prolactin release-inhibiting hormone (PRIH). Other hypothalamic hormones also include critical neurotransmitters such as catecholamine and dopamine.¹⁹

The principal neurohypophysial (neuropituitary) hormones in mammals are arginine vasopressin and oxytocin. Birds, reptiles, and amphibians have structurally-related peptides: mesotocin and arginine vasotocin,²⁰ while fish in general have arginine vasotocin and isotocin or mesotocin, depending on the species.¹⁶ These hormones are critical for milk secretion, oviductal and uterine contraction, renal water absorption, and vaso-constriction and dilation. In all vertebrates, these neurohypophysial hormones are produced in the hypothalamus and are transported to the pituitary, where they are stored until release into the bloodstream.

Hormones produced by the mammalian adenohypophysis are the pituitary-derived tropic hormones including growth hormone (GH), adrenocorticotropin (ACTH), melanotropin (MSH), thyroid-stimulating hormone (TSH), prolactin (PRL), and the gonadotropins — follicle-stimulating hormone (FSH), and luteinizing hormone (LH). Secretions of ACTH, TSH, and the gonadotropins (FSH and LH) are each regulated by negative feedback. Although structurally related counterparts for the adenohypophysial hormones have been identified in fish, amphibians, birds, and reptiles,¹⁶ there are important differences in hormone actions across vertebrate groups. For instance, PRL is associated with reproduction and lactation in mammals but is an important osmoregulatory hormone in fish.²¹ Although FSH and LH function similarly in mammalian and avian reproduction, reptiles do not synthesize an LH-like gonadotropin and instead utilize FSH to regulate gonadotropin-related functions.¹⁵ In fish and amphibians, two different gonadotropins, GTH-I and GTH-II, have been identified that act similarly to mammalian FSH and LH, respectively.¹⁷ GH generally regulates body and tissue growth; however, in nonmammalian vertebrates, it is also involved in osmoregulation. In mammals and birds, ACTH is responsible for stimulating the production of corticosteroids by the adrenal gland, which in turn plays a role in metabolism, ion regulation, and stress responses. The role of ACTH in fish and amphibians is less clear, however, and MSH may have similar properties in these taxonomic groups. Indeed, similarities in hormone structure may not necessarily represent similar hormone function in nonmammalian vertebrates.

GH is important for bone growth and as an anabolic hormone during development.²² It has direct effects on a wide variety of tissues as well as indirect effects that are modulated by growth factors such as insulin-like growth factor-I (IGF-I).²² In conjunction with thyroid hormones, GH is necessary for the development of a wide number of tissues ranging from cardiac²³ and skeletal muscle,²⁴ to bone²⁵ and brain development.²⁶ In nonmammalian species, GH probably functions in a similar manner; however, less is known about growth hormone in fish, amphibians, and reptiles.

The adrenal glands, thyroid gland, and gonads are all directly regulated by the pituitary gland.¹⁶ Thyroid hormones, which are produced by thyroid glands, and steroids produced by the adrenal cortex and gonads can indirectly inhibit their own secretion by inhibiting the release of pituitary and hypothalamic hormones (negative feedback). In response to TSH, the thyroid gland produces two hormones, triiodothyronine (T_3) and tetraiodothyronine (T_4). In mammals, T_3 and T_4 have important effects on metabolism and development.¹⁶ Thyroid hormones also play an essential role in fish and amphibian metamorphosis. Indeed, thyroid hormones determine the timing of developmental processes, and metamorphosis is almost entirely controlled directly by thyroid hormones.^{16,27–29} Some metamorphic processes that are under the control of thyroid hormones include the migration of the eye and dorsal fin growth in fish,^{30,31} amphibian tail and gut resorption,^{27,32,33} restructuring of the amphibian head,^{34,35} amphibian limb development,³⁶ and amphibian gill resorption.³⁷ Thyroid hormones also have important roles during fish smoltification.^{38–40}

The mammalian adrenal gland produces two important steroid hormones — aldosterone and corticosterone. Aldosterone plays an important role in the maintenance of sodium concentrations, and corticosterone is primarily involved in regulating blood glucose.¹⁶ Adrenal steroids function similarly in birds but very differently in other nonmammalian vertebrates. In amphibians, aldosterone and corticosterone are equally effective as regulators of blood glucose, whereas in fish and reptiles, corticosterone serves to regulate blood glucose and sodium. While adrenal hormones have critical roles in all vertebrates, characterizations of their functions in nonmammalian vertebrates are limited, and interspecies differences have not been thoroughly evaluated.

In all vertebrate classes, gonadal function is dependent upon the hypothalamic-pituitary axis through the production of GnRH and gonadotropins.¹⁶ In mammals, the gonadotropins include FSH and LH, which control different gonadal events. In females, FSH promotes ovarian follicular growth, and LH induces ovulation. Both gonadotropins are also required for normal estrogen synthesis: LH stimulates the synthesis of androgens, and FSH stimulates aromatization of androgens to estrogen. In males, FSH promotes spermatogenesis, and LH promotes steroidogenesis and spermiation. The mammalian gonad also produces the peptide hormone inhibin, which feeds back to inhibit FSH production. In both males and females, the pulsatile release of GnRH is regulated by the feedback of high circulating levels of androgens and estrogens. In birds, gonadotropins function in a similar manner; however, reptiles do not synthesize an LH-like gonadotropin and utilize FSH to regulate all gonadotropin-related functions.¹⁵ In fish and amphibians, two different gonadotropins — GTH-I and GTH-II — have been identified, and they act similarly to mammalian FSH and LH, respectively. GTH-I is involved in gonadal development, gamete production, and vitellogenesis, a process that involves the hepatic synthesis of yolk protein precursors, vitellogenin (VTG), under the stimulus of estrogens.^{16,17} GTH-II stimulates the final stages of oocyte maturation as well as ovulation in females and spermiation in males.

In general, gonadotropins exert effects on vertebrate gonads by binding to specific receptors. The primary gonadal response to gonadotropins is the synthesis and secretion of assorted sex steroids. In all vertebrates, the primary reproductive sex steroids include androgens [e.g., testosterone (T), 11-ketotestosterone (11KT), androstenedione (A), dihydrotestosterone (DHT)], estrogens [estradiol (E₂), estrone (E₁), estriol (E₃)], and progestins [progesterone (P₄), dihydroxyprogesterone (DHP)]. Gonadal steroid hormones are involved in every aspect of reproduction, from sex determination to the control of courtship behaviors and the development of secondary sex characteristics.

Sex steroids also play an important role in brain development. For example, in mammals, E₂ and DHT are involved in normal sexual differentiation of the brain.^{41–43} Although reproductive function is regulated and modulated by sex steroids in all vertebrates,^{16,28,44–47} there are distinct functional differences that must be noted. Indeed, functional differences in sex steroids are most evident for fish, amphibians, and reptiles, with significant differences also existing within each of these taxonomic classes.¹⁷ For instance, the primary androgen for spermatogenesis in mammals, birds, and reptiles is T, but in many fish and some amphibians the critical androgen for spermatogenesis is 11KT. Preliminary results from our laboratory would suggest that 11KT might not be the predominant androgen in live-bearing fish (such as mosquito fish *Gambusia holbrooki*). E₂ is the sex steroid responsible for oocyte growth and maturation in all vertebrates; however, it also regulates and induces the synthesis of VTG in oviporous vertebrate species.^{16,17,48,49}

Progestins are critical to pregnancy in mammals but function in reptiles and birds in post-ovulatory events such as the regulation of eggshell deposition. In fish, progestins are responsible for final egg maturation prior to oviposition. Gonadal sex steroids can also have dramatic effects on sex differentiation in fish, amphibians, and reptiles, effects that are not observed in birds or mammals.^{17,28,50} When applied early during development, sex steroids can cause sex reversal in fish, amphibians, and reptiles. Therefore, the genetic sex of the individual can be different from the phenotypic sex. Finally, the effects of sex steroids on gonadal differentiation and sex reversal vary dramatically between species and across developmental stages, and therefore these differences need to be noted and considered in any study of potential EDC effects in vertebrate wildlife.

39.1.2 Mechanisms of Endocrine Modulation

There is significant evidence to suggest that a wide variety of anthropogenic chemical contaminants in the environment can disrupt or modulate endocrine function in a wide variety of vertebrate and some invertebrate organisms. However, information regarding the mechanisms that lead to these endocrine modifications is limited. It is, nonetheless, critical that mechanisms and modes of action for EDCs and endocrine-active agents be understood. Mechanisms of action are generally

difficult to elucidate and are complicated by multiple factors including chemical properties, routes, timing, and lengths of exposure, as well as endocrine-system and species- and tissue-specific physiological differences. Furthermore, the integration of the nervous, endocrine, reproductive, hepatic, and other target systems, as well as multiple feedback regulatory pathways, adds to the complexity of understanding EDC mechanisms (see, for example, Figure 39.1).

Potential mechanisms of action for EDCs are diverse. EDCs may interrupt multiple pathways along the hypothalamic-pituitary–target-tissue axis, potentially disturbing the normal synthesis, transport, release, binding, action, biotransformation, or elimination of natural hormones in the body. EDCs may alter the hypothalamic-pituitary axis, which can have widespread effects through the disruption of endocrine functions downstream of the hypothalamus. There is increasing evidence that EDCs may disrupt endocrine function by influencing the regulation/release of the pituitary-tropic hormones. Indeed, polychlorinated biphenyls (PCBs) have been shown to interfere with the neurotransmitters that control GnRH secretion, resulting in decreased GnRH production as well as subsequent reductions in gonad size and plasma concentrations of sex steroids.⁵¹ In mammals, neonatal exposure to diethylstilbestrol (DES) or dichlorodiphenyltrichloroethane (DDT) results in both reduced GnRH and LH production.⁵¹ These results demonstrate that interference at one site along the hypothalamic-pituitary axis can affect multiple downstream events. Furthermore, the hypothalamus and pituitary are regulated by the feedback of hormones from several other endocrine-active tissues; therefore, alterations in different hormone concentrations can also affect hypothalamic and pituitary function.

EDCs can exert effects and disrupt the function of other endocrine tissues and hormones downstream of the hypothalamus and pituitary. Hormones are synthesized by specific endocrine tissues, secreted into the bloodstream, and transported by binding proteins to target tissues to interact with receptors, elicit responses, and be metabolized or degraded. EDCs can block or enhance the function of hormones by interfering with any one or several of these critical steps. For instance, EDCs may interfere with hormone synthesis, thereby altering endocrine activity by directly affecting the availability of specific hormones or critical precursors.^{28,52} Failure to synthesize appropriate hormones can result from either an alteration in the biosynthetic enzymes and in the availability of precursor molecules. The initial, as well as rate-limiting, step in the biosynthesis of hormones may often be affected. EDCs can inhibit the uptake of critical precursors and the subsequent conversion to hormone products.^{53–55}

EDCs can alter the rate at which hormones are metabolized. The cytochrome P450 (CYP450) monooxygenases constitute a super family of enzymes that play essential roles in both the synthesis (steroidogenesis) and metabolism of steroid hormones. Many of these enzymes appear to be sensitive to EDCs.^{52,56–59} EDCs can affect the number or activity of specific monooxygenases, thereby affecting the rate of hormone metabolism and clearance. Since specific CYP450 enzymes — like CYP1A — are also responsible for metabolizing foreign compounds — like EDCs — EDC stimulation of CYP1A and other monooxygenases that hydroxylate them prior to their elimination may in turn contribute to increased clearance of sex hormones by inducing other monooxygenase activities.⁶⁰ EDCs have also been reported to increase the activity of several other microsomal enzymes including aminopyrine demethylase, glucuronyl transferase, and p-nitroreductase.^{61,62} Some EDCs may also induce hormone-like effects due to alternating rates of degradation. For example, many synthetic hormones, such as ethynyl estradiol (EE₂), a synthetic estrogen used in birth control pills, are not degraded readily by the enzymes that normally metabolize the endogenous hormones.⁶³ EDCs can also interfere with the binding of hormones to transport proteins, preventing their delivery to target tissues.^{64,65} The absence of available binding proteins may result in both faster uptake or increased degradation of free-circulating hormones.^{66–68} For example, the sex-hormone-binding globulin (SHBG) has high affinity for both T and E₂, which is necessary to prevent degradation and clearance of these hormones as well as enable their transport to target tissues.⁶⁹ EDCs, which mimic estrogens or androgens, may bind to these globulin proteins and displace the endogenous sex

steroids, thereby increasing the elimination rates for endogenous hormones. Although several studies suggest that globulins may also facilitate the transport of EDCs to target tissues,⁶⁹ the greater binding affinity of globulins for endogenous hormones probably limits this process.⁷⁰

EDCs may bind to hormone receptors and either activate (agonize)⁷¹⁻⁷³ or inhibit (antagonize)⁷⁴ receptor function. Indeed, many studies have focused on EDCs as hormone-mimics and the potential for these compounds to interact with hormone-specific receptors. Potential EDCs have been evaluated extensively for their ability to bind to the estrogen receptor (ER). Estrogens normally bind to the ER located in the nucleus of target cells. The E₂-bound ER has a high affinity for DNA sequences called estrogen response elements (ERE). After binding the ERE, the ER-DNA complex interacts with various transcription factors, chromosomal proteins, and regulatory factors in order to induce or inhibit the transcription of specific genes and enable endocrine-specific response. EDCs can block or enhance the function of a hormone or endocrine target tissue by interfering with any one or several of these critical steps. Although the potential estrogenic activities of EDCs have overshadowed studies of other receptor-mediated EDC activities, EDCs that act as androgens or antiandrogens via interaction with the androgen receptor (AR) have also been noted.⁷⁴⁻⁷⁶

Unlike the ER, which has an E₂ specific response element, the response element for the AR is shared with other steroid receptors including the glucocorticoid (GR), progesterone (P₄), and mineralocorticoid (MR) receptors. Therefore, EDCs that have androgenic activities may exert broader effects than those attributed to a simple androgen mimic. EDCs may also interact with a wider variety of receptors important for endocrine function. For example, some EDCs (e.g., 2,3,7,8-tetrachlorodibenzo-dioxin [TCDD] and other planar hydrocarbons) are reported to have antiestrogenic activities by interacting with the aryl hydrocarbon receptor (AhR) rather than by competitively binding to the ER. The AhR is an intracellular receptor that is expressed by many different cell types and that functions as a transcription factor.^{77,78} EDC interactions with the AhR may interfere with estrogen responses in a number of ways: by reducing E₂ binding to the ER,⁷⁹ by blocking the binding of the ER to the ERE,⁸⁰ by impairing nuclear translocation,⁸¹ or by suppressing gene transcription.⁸² These examples demonstrate the varied receptor-mediated activities of EDCs.

Endocrine-disrupting effects may also occur due to direct or indirect toxicities for specific endocrine-active or target tissues. For example, many lipophilic EDCs will accumulate primarily in fatty tissues, such as the liver and gonads, potentially interfering with the synthesis and mobilization of lipids and thereby inhibiting specific endocrine-related functions such as vitellogenesis. It is important to point out, however, that specific mechanisms or modes of action for most EDCs are not well elucidated or understood. This stems from the fact that mechanisms are often difficult to identify and are complicated by multiple factors including differences in EDC-specific properties, routes of exposure, and vertebrate class and species differences. Nonetheless, it is critical that mechanisms of action for EDCs and endocrine-active agents be understood in order that effects in wildlife be prevented and that appropriate screening and testing methods be developed.

39.2 SCREENING AND MONITORING FOR ENDOCRINE DISRUPTING CHEMICALS

Analytical methods have long been used to determine concentrations of chemical residues that persist in the environment (e.g., water, sediment) and accumulate in biota (e.g., tissue and body burdens). Although these approaches are useful for characterizing the presence and distribution of specific EDCs in the environment, they fail to indicate whether chemical exposures have biological consequences. The development of EDC-specific screening and monitoring procedures aid in the establishment of potential relationships between environmental EDC concentrations and biological responses. In the past decade, several *in vitro* and *in vivo* assays have been proposed that can be used to screen or monitor individual EDCs, specific EDC mixtures, or complex environmental mixtures for potential endocrine disrupting or modulating activity.

39.2.1 *In Vitro* Assays

Several *in vitro* assays have been described for evaluating potential endocrine-disrupting or modulating activities of EDCs.⁷⁵ These assays are based on several specific mechanisms of action for EDCs, including receptor binding, gene expression, cell proliferation, and cell differentiation.⁸³ Advantages of *in vitro* systems include low cost, high reproducibility, and the rapid analysis of large numbers of samples. These assays are also valuable for studying mechanisms of action of compounds, screening effects of mixtures, and detecting potential interaction effects. Results from these screening procedures can aid in the subsequent development and validation of assays. *In vitro* assays, however, generally lack ecorelevance because pharmacokinetics, biotransformation, and binding to carrier proteins may not be accurately represented. For example, some EDCs are activated or deactivated *in vivo* by enzymatic conversion during metabolism, conjugation, and excretion. These limitations must be considered when interpreting or applying results from *in vitro* screening tests.

Receptor-binding assays can be utilized to screen for and identify potential EDCs (which function via receptor-mediated pathways) since they can evaluate whether specific EDCs can bind to specific receptors. Depending on the receptor of interest, receptor-binding assays utilize either crude cell fractions such as plasma membranes, cytosol, or the nucleus. Cell fractions may be obtained from specific vertebrate organisms or from established cell lines, transformed cells,^{84,85} or transfected cells.⁸⁶ Although *in vitro* receptor-binding assays are relatively simple and inexpensive to conduct, they do not necessarily reflect binding under *in vivo* conditions and are of very little use in screening for EDCs that operate by nonreceptor-mediated pathways. Finally, these assays do not differentiate between agonist and antagonist properties.

Additional *in vitro* assays have utilized the ability of EDCs to induce target-cell-specific proliferation and differentiation. For instance, MCF-7 cells, derived from human breast cancer cells, have been widely utilized for the development of the E-screen assay, which evaluates the ability of specific EDCs or EDC mixtures to both bind and express the ER⁸⁷ and the resultant cell proliferation as a response.^{88–94} EDCs are identified as potential E₂ agonists if there is a significant increase in cell proliferation, which in turn is quantified by counting cell nuclei⁹² or measuring other responses such as metabolic reductions. Although the E-screen assay has been extensively used as a screen for estrogenicity,^{76,92,95} a positive response cannot be necessarily interpreted as an indicator for the presence of E₂ agonists. In addition, ER antagonists and antiandrogens are not detected using this assay, and thus a significant number of false negatives are common. Before a compound is identified as an EDC, positive responses with the E-screen assay should be confirmed by *in vivo* studies.

A number of additional *in vitro* cell-based expression assays have also been developed to measure receptor-dependent biological responses. Expression assays evaluate the induction or suppression of proteins by specific genes in response to potential receptor-mediated EDCs and mixtures. Measured protein endpoints for these receptor-specific expression assays include: VTG,^{71–73,94,96,97} sex-hormone-binding globulins,⁹⁸ luciferase,⁹⁹ galactosidase,¹⁰⁰ and chloramphenicol acetyltransferase (CAT).⁸⁶ However, these assays are general and are not limited to the action of EDCs. Additional cell types/lines that have also been utilized for *in vitro* expression assays include fish hepatocytes,^{71,73,94,98} MCF-7,^{95,101} HeLA,^{86,98} and yeast.¹⁰¹ The types of cells used in expression assays are critical to any interpretations. Indeed, significant differences in responses between yeast-cell-based assays and mammalian-cell assays have been reported,⁹⁸ and sensitivities vary greatly.¹⁰⁰ Nonetheless, expression assays have several advantages as compared to other *in vitro* screening assays. Unlike receptor-binding or cell-proliferation assays, expression assays can be used to detect both agonists and antagonists.^{86,99,102} Expression assays can also evaluate potential EDCs that influence many aspects of gene expression in addition to those that operate through receptor-mediated functions. Nonetheless, *in vitro* expression assays generally have high variability and lack ecorelevance.

39.2.2 *In Vivo* Assays

The effects of EDCs occur at many biological levels of organization including molecular, biochemical, organelle, cell, tissue, organism, population, community, and ecosystem. The use of a battery of biomarkers that reflect multiple biological levels of organization would enable a more thorough evaluation of both exposure and the potential mechanism of action. Although responses at the population level and higher are the most biologically ecorelevant, they are rarely utilized as biomarkers since these responses are complex, less specific, and require greater effort and time. Indeed, most of the current biomarkers are limited to the measurement of responses at the molecular, biochemical, cellular, and organism levels. *In vivo* assays for the identification of EDCs are not mechanism-dependent and provide results that are more environmentally relevant than *in vitro* assays. Indeed, *in vivo* assays rely upon either natural exposures or controlled exposures based on expected or predicted environmental exposures. *In vivo* assays for EDCs can detect effects on endocrine function, regardless of the mechanism of action, as well as identify a potential EDC that would not necessarily exhibit activity in an *in vitro* screening assay. Most importantly, *in vivo* screening assays both identify potential EDCs and enable the description and evaluation of potential effects.

In vivo assays for evaluating EDCs may involve the utilization of specific endocrine biomarkers as a way to evaluate potential effects. Widely used endocrine-endpoint-based *in vivo* assays have included the uterotrophic assay, the Hershberger assay, and the thyroid-function assay. Although these assays were not originally designed for the evaluation or identification of EDCs, they have demonstrated the utility of *in vivo* assays for the identification of potential EDCs. The uterotrophic assay utilizes prepubertal or adult ovariectomized female rats to assess uterine weight and histological responses to potential EDCs. The Hershberger assay evaluates androgenicity using androgen-dependent tissue (e.g., prostate and seminal vesicles) responses to potential EDCs. The thyroid-gland-function assay evaluates potential EDC exposures and the subsequent evaluation of plasma concentrations of T_3 , T_4 , and TSH.

Biomarkers that detect alterations at the biochemical and molecular levels are frequently utilized for *in vivo* EDC-screening assays.¹⁰³ Biochemical and molecular responses are generally the first detectable responses to an environmental change or stressor and can serve as early indicators of both exposure and effect. Aside from being highly sensitive changes at the molecular and biochemical level, they can sometimes be predictive of responses at higher levels of organization (tissue and organism levels). Examples of molecular-based *in vivo* EDC-screening assays include receptor analyses, transcriptional-based analyses, and differential display.¹⁴ These assays are, in general, based on an analysis of specific molecular parameters for tissues collected following either natural or experimental exposures to potential EDCs. Although molecular-based *in vivo* assays are highly sensitive, they are difficult to validate and often lack ecorelevance. Examples of current biochemical-based *in vivo* EDC-screening assays include: measurement of VTG production¹⁰⁴ and systemic hormone concentrations (e.g., plasma sex steroids, T_3 , and T_4). In fact, systemic concentrations of various hormones have been frequently utilized as biomarkers for EDCs in fish,^{105–110} amphibians,^{111,112} reptiles,^{113,114} birds,^{5,115–120} and mammals.¹²¹ These procedures have broad application to all vertebrate classes since hormones, especially the steroid and thyroid hormones, are evolutionarily conserved across all vertebrate classes. However, it must be noted that the same hormones may differ in function significantly between and within vertebrate classes. For example, the primary androgen for spermatogenesis in mammals, birds, and reptiles is T, but in many fish and some amphibians, the critical androgen for spermatogenesis is 11KT.

VTG has been utilized as a bioindicator of potential exposure and effects of estrogenic EDCs in fish and other oviparous vertebrates.^{96,122–124} This phospholipoprotein is produced by the liver under the control of E_2 in oviparous female fish, amphibians, reptiles, and birds.¹¹¹ Oviparous species have vitellogenic cycles that correspond to egg production. Potential EDCs, which mimic or alter endogenous E_2 , may induce the expression of VTG. This assay has, in general, focused on

responses in males, which do not exhibit clear vitellogenic cycles. However, it must be noted that low background levels of VTG are likely to be normal in males. Thus, an identification of a potential EDC by this method cannot be based solely on the presence of detectable VTG; it must additionally be based on a species-specific VTG response that is significantly increased above background levels.

Additional *in vivo* EDC-screening assays involve endpoints based on responses at the tissue and organism levels. Although these assays may have higher biological and ecological relevance, they are more variable and often specific to vertebrate classes or species. Examples of screening assays that rely on tissue-level responses include tissue somatic indices (e.g., gonadosomatic index-GSI), tissue histopathology, altered secondary sex characteristics,¹²⁵⁻¹²⁸ and egg- and sperm-quality assessments.⁹⁴ *In vivo* assays that rely on organism responses may include assessments of egg numbers/ovarian development,¹²⁸⁻¹³² sexual maturity,¹²⁸ neonatal/embryonic mortality,^{129-131,133-135} reproductive impairment,^{108,136} and evaluation of egg hatchabilities^{129,134,135,137} and nest numbers.^{133,134} Population and ecosystem endpoints of reproductive success may include evaluation of pod size, age-class analyses, and population numbers.^{135,138,139}

Valid *in vivo* screening procedures should provide information about EDC exposure and be indicative of expected or predicted physiological effects. In addition, *in vivo* biomarkers reflect the complex pharmacokinetic and metabolic factors that can affect EDC uptake and metabolism. It is important to keep in mind, however, that *in vivo* assays and endpoints are influenced by both physiological and environmental variables, which make it difficult to establish clear cause-and-effect relationships between responses and specific EDCs. Nonetheless, these assays are often the most useful for evaluating potential EDC effects and for the identification of environmentally relevant EDCs.

39.3 EDC EFFECTS: EVIDENCE FOR SPECIFIC CHEMICALS AND CHEMICAL CLASSES

The previous section reviewed many of the possible mechanisms by which environmental contaminants may alter endocrine function in fish and wildlife. The following section introduces several classes of environmentally relevant contaminants with reported or potential endocrine-disrupting activity in invertebrates and vertebrates. This review presents evidence for EDC effects for several specific chemical classes: polycyclic aromatic hydrocarbons, polychlorinated and polybrominated biphenyls, dioxins, organochlorine and other pesticides, complex environmental mixtures, and metals. For most chemicals, the specific mechanism of action is not well understood, and chemical structure does not necessarily indicate or suggest endocrine functionality, mimicry, or EDC activity (see Figure 39.2 as an example of chemical structures for several environmental estrogens). In fact, direct evidence of endocrine activity is often difficult to demonstrate and thus is generally absent. This review includes reports from a variety of laboratory and field studies that have explored the effects of EDCs in fish and wildlife and discusses the potential or suspected modes of action (MOAs) (see Table 39.1).

39.3.1 Polycyclic Aromatic Hydrocarbons (PAHs)

Polycyclic aromatic hydrocarbons (PAHs), whether of natural or anthropogenic origin, are products of incomplete combustion of organic compounds and enter aquatic environments via oil spills, waste discharge, runoff, and dry or wet deposition. Although they are biodegraded in soils and water within weeks to months, the metabolites are often longer lasting and more toxic.

Birds can be exposed to PAHs through ingestion of contaminated food and water, by preening feathers, or through the skin in cases of oil spills. Petroleum hydrocarbons can also be absorbed through the eggshell.¹⁴⁰ In a review by Hoffman,¹⁴¹ PAHs applied to the shells of eggs caused mortality and reduced hatchability. In studies reviewed by Fry,¹⁴² exposure to petroleum oil

Figure 39.2 Structures of some selected natural and environmental estrogens.

increased circulating corticosterone levels and disrupted reproduction through negative feedback to the hypothalamic-pituitary-gonadal system. However other studies^{143,144} have shown decreased levels of plasma corticosterone, suggesting that ingested petroleum may interfere with adrenocortical function. Yolk formation may also be depressed after exposure to oil, resulting in a reduction in egg numbers.¹⁴⁵ Exposure to as little as 0.1-mL weathered crude oil (equivalent to 2.5 mL/kg body wt.) interferes with egg production, laying, incubation, and pair bonding. Field exposure of adult storm petrels (*Oceanodroma* sp.) with dependent chicks reduced foraging and feeding of chicks, resulting in reduced growth or death.¹⁴⁶

Population studies with pigeon guillemots (*Cephus columba*) after the *Exxon Valdez* spill indicated a decline in numbers for three consecutive years but no effects on reproduction.¹⁴⁷ Reproductive effects in the black oystercatcher (*Haematopus bachmani*) were noted.¹⁴⁸ There was a decrease in nonbreeding pairs, a decrease in egg size, and higher chick mortality, all of which directly related to the amount of oil present in the foraging territory. Birds exposed to oil may exhibit changes in adrenal hormone synthesis and elevated hepatic mixed oxidase activity, which may increase metabolic clearance of corticosterone.^{140,149,150} In a laboratory study, female mallards (*Anas platyrhynchos*) that ingested crude oil hatched fewer live ducklings per pair.^{116,140} In this study, there was evidence of suppression of follicular development, eggshell thinning, decreased hatchability, and reduced levels of plasma E₂, E₁, P₄, and LH in females. These results suggest that the oil acts on ovarian steroidogenesis, reducing positive feedback to the pituitary and causing a decline in LH, a delay in ovarian maturation, and reduced fertility.

Several field studies have documented altered reproductive activity in fish residing in PAH-contaminated waters. For instance, gonadal development was impaired and E₂ concentrations were depressed in English sole (*Parophrys vetulus*) from highly contaminated areas of Puget Sound, Washington. Reproductive impairment was statistically correlated with elevated PAH concentrations, as measured by the presence of fluorescent aromatic compounds (FACs) in the bile of fish.^{151,152} Other examples in which PAH exposure may have been related to endocrine alterations or reproductive dysfunction include altered ovarian development in plaice (*Pleuronectes platessa*) exposed to crude oil,¹⁵³ reduced GSI, increased liver size and ethoxyresorufin O-deethylase activity (EROD) in white sucker (*Catostomus commersoni*) residing downstream of pulp and paper mills,¹⁵⁴

Table 39.1 Summary of Effects and Possible Modes of Action (MOAs) of Endocrine Disrupting Chemicals (EDCs) by Chemical Class and Taxa

Chemical	Taxa	Effects	Possible MOA	Sample Reference
PAHs	Birds	↓Hatchability	DNA damage Oxidative stress ER agonist	141
	Fish	↓GSI Impaired gonadal development	DNA damage Oxidative stress ER agonist	155 152
PCBs	Mammals	Abortions & stillbirths	Antiestrogens Act through Ah receptor	175

and decreased GSI in bream (*Abramis brama*) inhabiting contaminated areas of the Rhine River.¹⁵⁵ Although PAH concentrations were abnormally high in the field studies described above, they were only one of a group of pollutants that may have caused the observed effects. Furthermore, several histological studies report no differences in the gonads of male and female fish from control and PAH-contaminated sites.^{156,157} A combination of field and laboratory experiments is still necessary before the reproductive alterations observed in the wild can be clearly attributed to PAH exposure.

Laboratory and field studies present clear evidence for the adverse effects of PAHs in fish. Thomas et al.¹⁵⁸ have elucidated the impact of benzo(a)pyrene (BaP) on endocrine and reproductive activities in female Atlantic croaker (*Micropogonias undulatus*). Atlantic croaker fed 0.4 mg BaP/70g/day for 30 days during the period of ovarian recrudescence experienced impaired ovarian growth with a concomitant reduction in plasma E₂ and T. GSI in control females increased fivefold over the course of the study, whereas GSI of exposed females reached only 66% of controls.

In vitro production of sex steroids was not impaired by BaP, and there appeared to be a relationship between the amount of ovarian tissue (i.e., size of ovaries) and steroidogenic capacity. Similar results were reported in a separate study of female Atlantic croaker exposed to BaP via injection for 30 days.¹⁵⁹ In this study, in addition to reduced GSI and plasma sex steroids, a reduction in the number of hepatic ERs and plasma VTG was observed. BaP did not interfere with the binding of E₂ to the ER under *in vitro* competition studies, and again there was no clear evidence for a direct effect of BaP on steroidogenesis. *In vitro* competition studies using hepatic ER from spotted seatrout supported earlier results on Atlantic croaker.¹⁶⁰ This is consistent with mammalian studies, and suggests that BaP must undergo metabolic activation in order to interact with the ER. The effects of the PAH 3-methylcholanthrene on endocrine and reproductive function in ricefield eels (*Monopterus albus*) were similar to those observed for BaP-treated Atlantic croaker. Exposure to 4 ppm 3-methylcholanthrene for 7 days resulted in reduced E₂, T, VTG, GSI, and altered ovarian histology.¹⁶¹

PAHs are known CYP450 inducers. For example, the PAH naphthoflavone induced the expression of CYP4501A1 (the primary xenobiotic-metabolizing enzyme) and inhibited VTG synthesis in E₂-stimulated liver cells from rainbow trout (*Oncorhynchus mykiss*).⁷² However, naphthoflavone had no effect on vitellogenesis when incubated without E₂. The degree of CYP4501A1 induction was directly related to the extent of VTG inhibition, which suggests that naphthoflavone may be acting as an antiestrogen via the AhR, the intracellular receptor involved in CYP4501A1 expression. The effect of naphthoflavone on vitellogenesis *in vivo* appears to be more complicated. When juvenile rainbow trout were treated with 0.5 ppm E₂ and 25 or 50 ppm of naphthoflavone, an inhibitory effect on VTG synthesis was observed; however, lower concentrations of naphthoflavone (5 or 12.5 ppm) appeared to potentiate E₂-stimulated VTG production.⁷² Furthermore, reduced VTG synthesis by higher concentrations of naphthoflavone was correlated with a decrease in radiolabeled E₂ binding to the ER. These results suggest that naphthoflavone influences VTG synthesis by regulating ER function, although it is likely that the antiestrogenic activity of PAHs involves multiple mechanisms. Several investigators have proposed that CYP4501A1-inducing compounds affect sex-steroid concentrations by increasing their catabolism.¹⁶² Evidence from a recent study,¹⁶³ however, suggests that PAHs may also interfere with steroid biosynthesis. Incubating vitellogenic ovarian tissue from female European flounder (*Platichthys flesus*) with 3 PAHs (phenanthrene, BaP, and chrysene) decreased A and E₂ secretion. In addition, phenanthrene inhibited steroid conjugation, and it was concluded that these PAHs inhibited key steroidogenic enzymes, including CYP450 17, 20 lyase, which is responsible for converting C21 to C19 steroids.

39.3.2 Polychlorinated and Polybrominated Biphenyls (PCBs and PBBs)

PCBs are a group of synthetic organic chemicals, formed by the chlorination of biphenyls, which include 209 individual compounds (congeners). These substances were manufactured for a

wide range of industrial applications including use as hydraulic fluids, lubricants, plasticizers, and coolant/insulation fluids in transformers. Several chemical properties make these compounds both highly useful and potentially hazardous. For instance, their chemical stability makes them ideal for industrial activities involving high temperatures; however, this stability also renders them persistent in the environment. The majority of PCBs that enter the water adsorb to organic particles and sediments, although they are essentially nonbiodegradable in soils and sediments.¹⁶⁴ Furthermore, they are hydrophobic, which makes them excellent lubricants, yet allows them to bioaccumulate in tissues and biomagnify as they are passed along the food chain. Concentrations of PCBs in fish at contaminated sites may range from ppb to ppm. The production of PCBs is currently banned or highly restricted and the use of certain mixtures permitted only under tightly regulated conditions. Nonetheless, PCBs originating from industrial wastes, accidental leaks or spills, and careless disposal continue to be a source of pollution and environmental concern.

Many studies examining the health hazards of PCBs describe the effects of occupational exposure in humans and the physiological responses of mammals and birds that have consumed large quantities of contaminated fish. These studies provide strong evidence that PCB exposure can lead to the development of cancer; disturbances of the immune, hepatic, pulmonary, and nervous systems; and impaired reproduction and development. Many of these abnormalities are enhanced in the offspring, even if exposure occurs prior to conception. Responses are believed to be dependent on species, sex, age, and chemical structure.¹⁶⁵

Laboratory studies with mink (*Mustela vison*) have established an association between PCB residues and reproductive effects in wildlife,¹⁶⁶ but there are no field studies linking PCBs with reproductive effects.¹⁶⁷ In one study in which mink were fed meat from cows contaminated with Aroclor 1254, concentrations as low as 0.87–1.33 ppm resulted in reproductive failure.¹⁶⁸ Other feeding studies have shown impaired reproduction in mink with fat concentrations of 13.3 ppm and reproductive failure at concentrations of 24.8 ppm.¹⁶⁹

Field studies with big brown (*Eptiseucus fuscus*) and little brown bats (*Myotis lucifugus*) suggested a correlation between PCB residue levels and reproductive toxicity;^{170,171} however, captive studies have not supported this link.¹⁷² Studies with ringed seals (*Pusa hispida*) have found a relationship between fat PCB concentrations and uterine-horn occlusions.¹⁷³ Later studies with ringed and gray seals (*Halichoerus grypus*), however, failed to detect any relationship between PCB levels and pregnancy or impairment of the uterine horns.¹⁷⁴ Other studies have linked PCBs with abortions and premature pupping in California sea lions (*Zalophus californianus*),¹⁷⁵ tumors and decreased fecundity in Beluga whales (*Delphinapterus leucas*),¹⁷⁶ skeletal lesions in harbor (*Phoca vitulina*) and grey seals,^{177,178} and immunosuppression in harbor seals.¹⁷⁹ In a field experiment with harbor seals, animals fed PCB-contaminated fish had a significant reduction in reproductive success; however, in this study it was difficult to separate out the influence of other possible factors and contaminants.^{180,181}

PCBs have been associated with embryonic mortality, deformities, and low reproductive success in many species of birds. Laboratory studies with chickens (*Gallus gallus*), ringed turtledoves (*Streptopelia risoria*), and mallards have shown reproductive impairment following ingestion of PCB-laden feed. In three studies, eggs of chickens that received 10–80 ppm Aroclor 1248 in the diet exhibited reduced hatching success;^{182–184} however, in another study, a diet of 20 ppm Aroclor 1254 did not affect this parameter.¹⁸⁵ Aroclor 1242 in the drinking water at 50 ppm produced chick embryo mortality and teratogenesis.¹⁸⁶ Aroclor 1254 in the diet of ringed turtledoves has increased embryonic mortality, decreased parental attentiveness,¹⁸⁷ and depleted brain dopamine and norepinephrine.¹⁸⁸ Eggshell thickness was affected in mallard hens,¹⁸⁹ but another study produced no eggshell changes.¹⁹⁰ Studies with screech owls (*Otus asio*)¹⁹¹ and Atlantic puffins (*Fratercula arctica*)¹⁹² also produced no reproductive effects.

Field studies have indicated PCBs as the cause of mortality of ring-billed gulls (*Larus delawarensis*) in southern Ontario¹⁹³ as well as the cause for increased embryo/chick mortality and reduced hatching success.^{194,195} PCBs have also been blamed for the low reproductive success and eggshell

damage in Lake Michigan herring gulls (*Larus argentatus*).^{196,197} Reproductive success of Forsters terns (*Sterna forsteri*) from a Green Bay colony was 52% of that from inland colonies.^{198,199} In this study, hatchlings also weighed less, had shorter femurs, exhibited edema, and were malformed. The toxicity was attributed to the PCB congeners 105 and 126, and results indicated PCB congener 77 as accounting for some of the toxicity in the tern eggs.^{199–201} PCBs have also been implicated as embryotoxic in eagles,²⁰² as producing decreased embryonic weight in black-crowned night herons (*Nycticorax nycticorax*),²⁰³ as reducing hatching success of American kestrels (*Falco sparverius*),²⁰⁴ and as the cause of congenital anomalies and embryonic death in double-crested cormorants (*Phalacrocorax auritus*).^{205,206} In cormorants, however, there is discussion as to whether DDT or PCBs are more strongly associated with nest failure.^{207,208}

American alligator eggs (*Alligator mississippiensis*) from Lake Apopka, Florida have residues of PCBs as well as a combination of organochlorine pesticides.²⁰⁹ Alligators from this site have also been documented to have abnormally developed reproductive organs, altered serum hormone concentrations, and decreased egg viability.^{135,139,210} However, alligators from Lake Apopka are known to be exposed to a complex mixture of potential EDCs, and therefore it is difficult to pinpoint which compounds are responsible for the observed effects. In red-eared slider turtles (*Trachemys scripta elegans*), males exposed to Aroclor 1242 had significantly lower T concentrations than controls.²¹¹

The African clawed frog (*Xenopus laevis*) and the European common frog (*Rana temporaria*) were exposed to the PCB mixture Clophen A50 or to PCB 126 for either 10 days or until metamorphosis. Exposed frogs had increased mortality, higher malformation rates, and lower thyroid hormone concentrations.²¹² In a similar study, the same frog species were exposed to the mixtures Clophen A50 and Aroclor 1254 or to PCB 126; effects of exposure depended on route and time and length of exposure. This study also indicated a relationship between lowered concentrations of retinoid and PCB exposure.²¹² In another study, green frogs (*Rana clamitans*) and leopard frog (*Rana pipiens*) were exposed throughout metamorphosis to PCB 126 at concentrations ranging from 0.005 to 50 ppb. Survival of larvae decreased at the higher concentrations in both species.²¹³

In fish, reproductive impairment has been demonstrated under both *in vivo* laboratory studies and in field studies of fish residing in PCB-contaminated waters. Several field studies have attempted to correlate PCB tissue levels with observed reproductive alterations. For instance, PCB levels in the liver and ovarian tissue of female English sole from Puget Sound were associated with the spawning of fewer eggs.²¹⁴ Similarly, a negative correlation was found between egg hatchability and total PCB concentrations in the eggs of lake trout (*Salvelinus namaycush*) from the Great Lakes.²¹⁵ In a study of the reproductive success of lake trout residing in Lake Michigan, Mac and Edsall²¹⁶ suggested that maternally derived PCBs were the cause of reduced egg hatchability and increased fry mortality. Johnson et al.²¹⁷ reported decreased egg weight and increased oocyte atresia in female winter flounder (*Pseudopleuronectes americanus*) with high tissue concentrations of PCBs, although there was no evidence that PCBs altered GSI, plasma E₂, or fecundity in this species. Interestingly, English sole residing in the same location had reduced plasma E₂ concentrations and impaired gonadal development. It was proposed that the different migratory practices of both fish species might have resulted in different susceptibilities to the chemicals, since these behaviors resulted in differences in the timing and duration of exposure to the most highly contaminated waters.

In the laboratory, female Japanese medaka (*Oryzias latipes*) had reduced GSI and were unable to spawn following an injection of 150 ppm of PCB.²¹⁸ It was suggested that PCB exposure disrupted E₂ metabolism since only control fish, excreted E₂ into the water 8 days after the injection. In male goldfish (*Carassius auratus*), PCB exposure resulted in decreased plasma T and 11KT concentrations, while hepatic EROD activity was increased 15-fold.²¹⁹ Reduced plasma T in males and E₂ and P₄ in females, accompanied by an increase in several sex-steroid-metabolizing enzymes, was observed in carp (*Cyprinus carpio*) injected with 250 ppm of the commercial PCB Aroclor 1248.²²⁰ In another study, E₂-treated juvenile rainbow trout fed a diet contaminated with PCBs (3, 30, or 300 ppm) for 6 months showed decreased synthesis of VTG.²²¹

The decline in estrogens and androgens combined with the elevation of EROD (or other metabolizing enzymes) would suggest that the reduction in sex steroids is related to an increase in metabolism rather than a decreased synthesis. However, this is probably not the only mechanism for PCB-induced damage since several studies also report abnormalities at the organ e.g., GSI, testicular abnormalities) and organism levels (offspring survival, hatchability) in fish showing normal sex-steroid and VTG concentrations.²²²⁻²²⁴ In some of these cases, it is believed that the reproductive abnormalities (e.g., delayed spawning, reduced hatchability) may be caused by the accumulation of toxic levels of PCBs in the ovaries and maturing oocytes.²²⁵ Evidence that PCBs bind VTG suggest that lipoproteins are involved in the transport of the contaminants from extra-gonadal tissue into the ovaries.²²⁶ One explanation for the inconsistencies observed between studies might be related to timing of exposure. For instance, the lack of effects of 3,3',4,4'-tetrachlorobiphenyl (TCB) on plasma concentrations of sex steroids and VTG in female striped bass (*Morone saxatilis*) and white perch (*Morone americana*) may have been related to the fact that the fish used in these studies were already vitellogenic and not in a highly active stage of gonadal maturation.^{222,223}

The stage of gonadal maturation may also be important in males exposed to PCBs. Atlantic cod (*Gadus morhua*) fed Aroclor 1254 (1–50 ppm) for 5.5 months accumulated significant levels of the PCB in the testes and liver and exhibited considerable testicular damage including fibrosis of lobule walls, necrosis and disintegration of lobule elements, and decreased spermatogenesis.²²⁷ These authors suggest that the stage of gonadal maturation may be related to the degree of chemical sensitivity since only males experiencing rapid spermatogenic proliferation or fully mature males suffered testicular damage (i.e., sexually immature and regressed males were unaffected). In several cases, substantial concentrations of PCBs have been detected in tissues of fish that showed no signs of adverse reproductive effects.²²⁸

It is not surprising that a wide range of responses has been observed in studies that have differed with regards to species and experimental design. However, the chemical complexity of this class of compounds is an additional factor that complicates interpretation. Slight structural differences in the 209 possible PCB congeners, as well as different compositions of the mixtures, may result in vastly different physiological responses.

There is considerable evidence that PCBs act at multiple sites along the hypothalamic-pituitary-gonadal (HPG) axis,^{158,229} and *in vitro* experiments are providing insight into the mechanisms underlying these reproductive alterations. However, extrapolating the actual risks that PCBs impose on the environment and biota are difficult due to the complexity and diversity of the commercial mixtures (of congeners). In addition to understanding the interaction of the PCB mixtures with other environmental pollutants and stressors, consideration must be given to the interaction (additivity, synergism, antagonism) of the individual components that make up these mixtures.

PBBs, formed by the bromination of biphenyls, are similar in structure to PCBs. These chemicals are stable and lipophilic and, therefore, present many of the same environmental hazards as PCBs (e.g., persistence in the environment and long biological half-lives). There are 209 possible PBB congeners, although only 45 have been actually synthesized.²³⁰ FireMaster BP-6, used primarily as a flame-retardant additive in the early 1970s, was the most widely used PBB, although its production was discontinued in 1978.^{231,232} The production and distribution of PBBs was insufficient to result in widespread contamination of the environment; however, the accidental contamination of cattle feed by the Michigan Chemical Company in 1973 resulted in the pollution of many Michigan farmlands. Significant concentrations of PBBs were subsequently detected in water and sediment samples and in tissues of fish and ducks residing downstream of the Michigan Chemical Company.²³³

Although information concerning the reproductive effects of PBBs in fish is lacking, there is substantial evidence that these chemicals adversely affect reproductive processes in other species.²³⁴ For instance, feeding adult female chickens a diet contaminated with 45 ppm of the commercial PBB FireMaster FF-1 for 5 weeks resulted in impaired production and hatchability of eggs and in reduced viability of offspring.^{235,236} A variety of reproductive effects following PBB exposure have

also been reported from other avian (quail) and mammalian (rodents, monkey, cow, and mink) species.^{230,234} Although PBBs have been detected in aquatic environments and are known to accumulate in fish tissues,²³⁷ there is very little information regarding the effects of these chemicals on exposed fish. Like PCBs, PBBs are believed to be potent inducers of several monooxygenase enzymes (including EROD), although it is not known whether this induction affects the metabolism of circulating reproductive hormones.

39.3.3 Polychlorinated Dibenzo-*p*-Dioxins (PCDDs) and Polychlorinated Dibenzo-*p*-Furans (PCDFs)

PCDDs and PCDFs are structurally related compounds produced during a variety of thermal and chemical reactions including the combustion of PCBs, production of steel and other compounds, and disposal of industrial wastes (via the interaction of chlorophenols). These compounds have also been identified as components of bleached-pulp-mill effluents. PCDDs and PCDFs are halogenated aromatic hydrocarbons with high chemical stability, low water solubility, and limited solubility in many organic solvents. There are 75 possible PCDD congeners and 135 PCDF congeners, although 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, known as TCDD or dioxin, has received the most attention. Concerns regarding TCDD stem from its wide distribution in the environment and extreme toxicity to both humans and wildlife. Although a variety of PCDDs and PCDFs have been detected in fish and wildlife, the 2,3,7,8-substituted congeners are believed to be the most persistent and prevalent in tissue samples analyzed to date, with half-lives of over a year in some fish species.²³⁸ TCDD and related compounds have been implicated in a number of health-related problems including neurotoxicity, hepatotoxicity, cardiotoxicity, chloracne, birth defects, immunosuppression, wasting syndrome, and endocrine and reproductive alterations.^{240,241,269} In nonhuman primates and rodents, although developmental effects of the immune, reproductive, and nervous systems occur at body burdens in the range of 30–80 ppb, biochemical changes on cytokine expression and metabolizing enzymes are seen at doses ten times lower.²⁴⁰ Many of the toxic effects associated with exposure to dioxins appear to be dependent on target tissue, species, sex, and age.

Studies on the developmental effects of TCDD in rodents have demonstrated that only transient exposure to relatively low concentrations of TCDD during critical windows of development are capable of eliciting irreversible disruption of organ functioning in offspring. For example, gestational exposure of rats to low concentrations of TCDD (0.064–1.0 ppb) during a critical period of development (day 15 of gestation) causes impaired sexual differentiation in male fetuses including persistence of female traits; decrease in the concentration of T, in the weight of testis and epididymis, and in the production of sperm; and altered sexual behavior during adulthood.^{242–244} Similarly, Gray et al.²⁴⁵ reported a delay in testicular descent and puberty, with a subsequent reduction in sperm counts and fertility in adult male rodents after a single maternal dose of 1 µg TCDD/kg on day 15 of gestation. Other signs of developmental toxicity in mammals include decreased growth, structural malformations (e.g., cleft palate and hydronephrosis), prenatal mortality, and neurobehavioral changes (e.g., impaired learning in rhesus monkeys).²³⁹

Laboratory studies on the effects of TCDD in birds have shown significant variation in sensitivity across species, with over 40-fold differences on embryo mortality (reviewed in References 239 and 246). For example, doses of only 20–50 ppt of TCDD in chicken eggs cause mortality and malformations, as opposed to 1000–10,000 ppt in eggs of ring-necked pheasants (*Phasianus colchinus*) and eastern bluebirds (*Sialia sialis*). Chicken embryos are also much more sensitive to the teratogenic effects of TCDD, particularly cardiovascular malformations.

In birds, there is considerable evidence indicating that embryonic exposure to dioxin and dioxin-like compounds can induce developmental alterations. Indeed, several field studies with colonial fish-eating birds from the Great Lakes have implicated dioxin equivalents (the aggregate of AhR-active substances) as the causative factors for the increased incidence of developmental deformities and embryo lethality observed in certain contaminated areas (see reviews in References 247–250).

Together, these epidemiological studies have provided one of the strongest links between contaminant exposure and reproductive/developmental effects in wildlife.

The Great Lakes Embryo Mortality, Edema and Deformities Syndrome (GLEMEDS) was first described in double-crested cormorants but has also been reported in other species including the great blue heron (*Ardea herodias*) and the Caspian tern (*Sterna caspia*). The syndrome is characterized by increased embryo mortality; growth retardation; subcutaneous, pericardial, and peritoneal edema; congenital deformities of the bill and limbs; feminization of embryos; and abnormal parental behavior.²⁴⁷ This syndrome closely resembles the “chick edema disease” observed in chickens after *in ovo* exposure of hens to PCDDs and PCDFs. Embryotoxicity in piscivorous birds from the Great Lakes has been associated with TCDD concentrations above 100 pg/g (reviewed in Reference 241). Although a reduction in the release of pollutants to the Great Lakes has resulted in significant population improvements for several avian species, particularly double-crested-cormorants and ring-billed gulls (*Larus delawarensis*), reproductive and physiological alterations due to contaminants are still associated with population-level effects in birds that feed on highly contaminated fish (such as Caspian terns and bald eagles, *Haliaeetus leucocephalus*).^{249,251}

Similar reproductive and developmental effects due to PCDDs have also been reported from free-ranging populations of great blue herons,^{252,253} double-crested cormorants,²⁵⁴ and wood ducks (*Aix sponsa*)²⁵⁵ sampled elsewhere. In addition, *in ovo* exposure to dioxins has been associated with the development of asymmetric brains in wild (great blue herons, double-crested cormorants, and bald eagles) and domestic (chickens) species.²⁵⁶ The behavioral and physiological repercussions of this gross brain deformity, however, are unknown at this time. Other sublethal effects observed in birds exposed to dioxins include decrease bursa and spleen weights in developing embryos²⁵⁷ and altered thyroid-gland structure, circulating thyroid hormones, and vitamin A (retinoid) status (reviewed in Reference 258). In Belgium and The Netherlands, PCDDs/PCDFs in common tern (*Sterna hirundo*) were correlated with lower yolk sac retinoids and plasma-thyroid concentrations in hatchlings and with unfavorable breeding parameters (delayed laying and smaller eggs and chicks).²⁵⁹ Similarly, cormorant (*Phalacrocorax carbo*) hatchlings from a PCDD/PCDF-contaminated site in The Netherlands had decreased plasma-thyroid concentrations and an increased *in ovo* respiration rate.²⁶⁰ Results from laboratory studies, however, have failed to replicate what has been reported from wild avian species, and *in ovo* exposure to TCDD has caused either increases or no changes in thyroid hormones.^{120,261,262}

Information on the developmental toxicity effects of TCDD in amphibians and reptiles is scarce. Neal et al.²⁶³ reported no effects in tadpoles and adult bullfrogs (*Rana catesbeiana*) after a single injection of TCDD (500 ppb). Jung and Walker²⁶⁴ exposed anuran eggs and tadpoles to TCDD for 24 h and observed that American toads (*Bufo americanus*) treated with at least 0.03 ppb appeared to metamorphose earlier than controls and that metamorphosis tended to occur at larger body masses after exposure to higher doses of dioxin. The authors concluded that anuran eggs and tadpoles eliminate TCDD more rapidly and are 100- to 1000-fold less sensitive to its deleterious developmental effects when compared to fish. Differential sensitivity to TCDD and related compounds could be related to differences in metabolism or to different patterns in AhR binding and signal transduction across taxa. In this respect, there is recent information showing a high degree of amino-acid-sequence conservation for the AhR among bird species (97% amino acid identity) but a much lower percent identity across taxa (79 and 74% identity between the amphibian *Necturus maculosus* and bird and mouse sequences, respectively).²⁶⁵

In an epidemiological study, developmental abnormalities and hatch rates from eggs of the common snapping turtle (*Chelydra serpentina serpentina*) were assessed in relation to over 70 PAHs, including 8 PCDDs and 14 PCDFs.²⁶⁶ This study found an increase in the frequency of deformities with increasing contaminant exposure in eggs, particularly PCDDs and PCDFs concentrations. In the laboratory, American alligator eggs (embryo stages 19–22) were treated with TCDD (at doses ranging from 0.1 to 10 ppm) and incubated at male-producing temperatures

(33°C).²⁶⁷ High doses of TCDD in eggs resulted in dose-dependent alterations in sex ratios, with a higher incidence of female hatchlings.

Results from several field and laboratory studies have established that fish, in particular early life stages, are extremely sensitive to the effects caused by TCDD when compared to other taxa. Effects on fry survival are significant at egg doses ranging from 50 to 5000 pg/TCDD/g, which corresponds to concentrations of 75 to 750 pg TCDD/g in parent fish.²⁴¹ Signs of TCDD-induced developmental toxicity resemble blue sac disease, which is an edematous syndrome characterized by yolk sac and pericardial edema, subcutaneous hemorrhages, craniofacial malformations, retarded growth, and death.²⁶⁸ This syndrome has been well characterized in salmonids after exposure of eggs via water, injection, or maternally derived TCDD. Studies with salmonids have established differential sensitivity to induce sac fry mortality, with LD₅₀ values varying from less than 100 pg TCDD/g egg in lake trout (the most sensitive fish species to TCDD developmental toxicity) to 200 and over 300 pg TCDD/g egg in brook trout (*Salvelinus fontinalis*) and in some strains of rainbow trout, respectively.^{269–271} TCDD-developmental toxicity has also been reported in several nonsalmonid species including the northern pike (*Esox lucius*), the mummichog (*Fundulus heteroclitus*), the Japanese medaka,²⁷² and the zebrafish (*Brachydanio rerio*).²⁷³ Regardless of species or egg exposure route, early-life-stage mortality occurs during the sac-fry stage, probably as a consequence of the generalized edema.

Exposure of eggs to TCDD and related compounds may have been responsible for the decline of some fish populations in the Great Lakes since concentrations of dioxin and dioxin equivalent in eggs and fry of salmonids have fallen within the range of those known to induce blue sac disease in the laboratory.²⁶⁹ The reader is advised to refer to References 269 and 274 for comprehensive reviews on the effects of TCDD and related compounds on fish of the Great Lakes.

Fish reproduction can also be affected after exposure to TCDD. In the laboratory, adult female zebrafish fed 5–20 ng TCDD showed impaired oocyte development with fewer eggs produced and lethal developmental abnormalities in offspring (e.g., malformations of notocord).²⁷³ In a separate study, although TCDD treatment of newly fertilized zebrafish eggs did not affect hatchability, doses of 1.5 ng TCDD/g or more resulted in a variety of structural and physiological abnormalities in larvae.²⁷⁵

The mechanisms by which TCDD and structurally related compounds cause endocrine/developmental effects are complex and not completely understood. The relative toxicity of TCDD and other halogenated aromatics is likely dependent on their ability to bind and activate the AhR. Although this AhR mechanism is known for its involvement in the antiestrogenic action of TCDD as well as for its ability to induce structural malformations, its MOA in causing other reproductive and developmental toxicity is less clear.²³⁹ There is substantial evidence that these contaminants induce the expression of certain genes (e.g., translation products comprising Phase I and Phase II enzymes) while altering the transcription of others (ER).

Indeed, the antiestrogenic effects of TCDD in mice have been attributed to its ability to suppress ER gene expression, probably through an inhibition of ER transcription after binding of the TCDD-AhR complex to promoter regions of the ER gene (see Reference 276 for a review of mechanisms of action of dioxins). Antiestrogenic effects of these contaminants have also been documented *in vitro* using fish cell lines. Using carp hepatocytes, Smeets et al.²⁷⁷ demonstrated that although low concentrations of TCDD caused a suppression of VTG secretion and an induction of CYP1A, the two phenomena were not correlated to each other. From these results, the authors concluded that the antiestrogenic effects of TCDD were probably not caused by increased metabolism of E₂ due to induction of CYP1A. Mechanistic studies using mammalian cell lines also support this theory,⁸⁰ although increased metabolism of sex steroids may provide an additional or secondary mechanism of antiestrogenicity. In this respect, great blue heron hatchlings and adults exposed to TCDD had increased testosterone hydroxylase activity, a result that was coupled with increased CYP1A1 activity.²⁷⁸ Changes in hydroxylase activity, however, have not been associated with alterations in circulating sex-steroid concentrations in TCDD-exposed herons.^{119,120,261} An additional MOA of

TCDD could be through the pituitary, disrupting normal feedback mechanisms between hormones and LH secretion.²⁷⁹

Since vitamin A and thyroid hormones are essential for normal differentiation and development of tissues, alterations in their homeostasis might result in malformations and altered growth. In this respect, there is evidence showing that dioxin may interfere with the metabolism and storage of vitamin A (retinoids)²⁸⁰ and of thyroid hormones²⁸¹ through the co-induction of Phase I (P450) and Phase II (uridine diphosphate-glucosyltransferase (T₄-UDPGT) enzymes. In addition, hydroxy metabolites of PCDDs and PCDFs can compete for thyroxine on the transthyretin (the thyroxine binding prealbumin) binding site.²⁸² Finally, recent evidence suggests that the hemodynamic and teratogenic effects observed in fish fry affected by blue sac disease could be due to the ability of TCDD to induce oxidative stress and oxidative DNA damage. In the Japanese medaka, oxidative stress to the vascular endothelium of developing embryos induces programmed cell death, or apoptosis.²⁸³ Apoptosis of vascular cells causes alterations in hemodynamics, leading to a generalized loss of function and subsequent mortality.

39.3.4 Organochlorine Pesticides and Fungicides

Organochlorine pesticides (OCPs) comprise a large group of structurally diverse compounds used to control agricultural pests and vectors of human disease. Many of these compounds, as well as their metabolites, are environmentally persistent due to their chemical stability, low water solubility, and high lipophilicity. The exact mode of neurotoxicity is not well understood, although OCPs are believed to disrupt the balance of sodium and potassium in nerve cells. The ability of these toxic compounds to bioaccumulate in and often harm unintended species has led to the restricted use of most OCPs. Despite a general reduction in use, several field studies have suggested that OCPs adversely affect endocrine function in fish, indicating that aquatic wildlife is still being exposed to levels capable of altering endocrine and reproductive parameters. For instance, a negative correlation was found between total OCPs and E₂ in male carp (*Cyprinus carpio*) in a large-scale field effort to assess the reproductive health of fish in U.S. streams.¹⁰⁶ Similar results were reported in largemouth bass (*Micropterus salmoides*) collected from a contaminated (with OCPs) site in Florida.²⁸⁴ In the following section, OCPs are discussed according to accepted structural classifications, although effects within the same chemical class may differ drastically. Furthermore, Pickering et al.²⁸⁵ have suggested that pesticide toxicity is species specific, and a single species may be differentially susceptible to different pesticides. Indeed, the reported effects and mechanisms of action may vary significantly between the various OCPs.

39.3.4.1 Cyclodienes

The chlorinated cyclodiene pesticides are lipophilic, stable solids with low solubility in water. Although differing from the dichlorodiphenylethanes (i.e., DDT) in their mode of action, they served a similar function in controlling a variety of insect pests. Examples of pesticides in this class include endrin, dieldrin, chlordane, toxaphene, telodrin, isodrin, endosulfan, and heptachlor. Consistent with the nature of organochlorine compounds, cyclodiene pesticides are persistent in soils and sediments with a half-life of 1–14 years in soils following application.

The cyclodienes are believed to produce a wide range of toxic responses in wildlife and adverse effects in laboratory animals. For example, rats exposed to endosulfan had alterations to the nervous, immune, hepatic, renal, and reproductive systems.²⁸⁶

Dieldrin levels of 9.4 ppm in purple gallinule (*Porphyryla martinica*) and of 17.5 ppm in the common gallinule (*Gallinula chloropus*) showed no significant effects on percentage of eggs hatched or in the survival of young.²⁸⁷ Lockie et al.²⁸⁸ reported that the proportion of successful eyries of the golden eagle (*Aquila chrysaetos*) increased from 31 to 69% as the levels of dieldrin fell from a mean of 0.86 ppm to 0.34 ppm. It has been postulated that dieldrin poisoning of adult

birds is the likely mechanism for population decline of bird-of-prey populations, such as the peregrine falcon (*Falco peregrinus*) and Eurasian sparrow hawk (*Accipiter nisus*) in Great Britain and the peregrine falcon in the United States, rather than DDE effects on shell quality.^{289–291} Screech owls (*Otus asio*) with egg aldrin concentrations ranging from 0.12 to 0.46 ppm were 57% as productive as controls, with lower clutch sizes, hatch rates, and survival.²⁹² Heptachlor epoxide reduced nest success in Canada geese (*Branta canadensis*) when eggs contained > 10 ppm²⁹³ and reduced productivity in American kestrels when eggs contained > 1.5 ppm.²⁹⁴ No relationship was found between heptachlor epoxide residues and shell thickness in eggs of Swainson's hawk (*Buteo swainsoni*), and reproduction was not affected in wild prairie falcons (*Falco mexicanus*) and merlins (*Falco columbarius*).^{294,295} Chlordane fed to northern bobwhites (*Colinus virginianus*) in concentrations of 3 and 15 ppm and to mallards at 8 ppm had no effect on reproduction. Similarly, toxaphene fed at 100 ppm to chickens had no significant effect on reproduction.²⁹⁶ A 2-year study with American black ducks fed a diet containing 1, 10, or 50 ppm toxaphene produced no reproductive effects, although duckling growth, skeletal development, and collagen was decreased in offspring of parents fed 50 ppm.²⁹⁷

Chlordane, dieldrin, and toxaphene were tested for their ability to override male-producing incubation temperature in the red-eared slider turtle. Chlordane produced significant sex reversal alone and when administered with E₂.¹¹³ In another study, treated male turtles exposed to chlordane had significantly lower testosterone concentrations, and females had significantly lower P₄, T, and 5- α -DHT concentrations than controls.²¹¹

Studies involving the effects of cyclodienes on the reproductive success of fish have produced a range of results, most likely resulting from species- and chemical-specific sensitivities as well as differences in experimental design. For instance, toxaphene at concentrations ranging from 0.02–2.2 ppt did not affect the reproductive success of female zebrafish, as measured by total number of eggs spawned, percentage of fertilized eggs, embryo mortality, and egg hatchability.²⁹⁸ However, in this species, oviposition appeared to be affected by toxaphene exposure in a dose-dependent manner. Conversely, decreased fertilization has been observed in winter flounder after exposure to 0.001–0.002 ppm dieldrin,²⁹⁹ reproduction of first-generation flagfish (*Jordanella floridae*) was affected after exposure to 0.3 ppb endrin,³⁰⁰ and sublethal concentrations of dieldrin and aldrin were reported to induce abortion in mosquitofish.

Although less information is available regarding the effects of cyclodienes on reproductive function in male fish, a laboratory study with tilapia (*Oreochromis mossambicus*) showed disrupted nest-building and decreased reproductive activity.³⁰¹ In a study with male striped snakehead (*Channa striatus*), testicular damage and disrupted spermatogenesis were observed after exposure to 0.75–1 ppm of endosulfan for 2–30 days.³⁰²

Several reports indicate that oocyte development may be a target for cyclodiene-mediated reproductive toxicity. An increase in oocyte atresia was observed in rosy barb (*Barbus conchoni*) exposed to a low dose (46.6 ppb) of aldrin for 2–4 months.³⁰³ Impaired oocyte development and reduced GSI have also been observed in striped snakehead³⁰⁴ and carp minnow (*Rasbora daniconius*)³⁰⁵ exposed to endosulfan. Other toxic effects related to endosulfan exposure include reduction in the percentage of maturing and mature oocytes, rupturing of oocyte walls, damage to yolk vesicles, and multiple other histopathological changes in ovarian morphology.³⁰⁴ Consistent with the observations of oocyte damage and decreased GSI, endosulfan was shown to have an inhibitory effect on vitellogenesis in clarias catfish (*Clarias batrachus*).³⁰⁶ It is possible that endosulfan directly interferes with VTG synthesis in the liver, a theory that is supported by evidence that endosulfan alters protein synthesis in the liver of clarias catfish. Alternatively, other studies suggest that endosulfan impairs steroidogenesis by interfering with enzymes along the steroid biosynthetic pathway.³⁰⁷ Likewise, the authors of the later study concluded that endosulfan affected VTG synthesis by interfering with the production or activity of hormones responsible for regulating VTG production. Multiple effects along the hypothalamus-hypophysial-ovarian axis of the Mozambique tilapia (*Sarotherodon mossambicus*) were also observed following an exposure to 0.001 ppm

endosulfan for 20 days.³⁰⁸ In addition to reduced GSI and various histopathological abnormalities associated with ovarian growth and oocyte maturation, degeneration of basophils and acidophils (gonadotrops) in pituitary tissue of endosulfan-treated fish was apparent.

39.3.4.2 Chlordecones (Kepone and Mirex)

Chlordecone, also known as Kepone, and mirex are two structurally similar OCPs that were manufactured and used primarily in the 1960s and 1970s. No longer permitted in the U.S., mirex was used as a pesticide to control fire ants as well as a flame-retardant additive, and chlordecone was used to control insects on a variety of crops and for household purposes. The toxicological effects of chlordecone exposure in humans are well documented as a result of an incident known as the “Kepone Episode,” in which many employees and residents in the vicinity of several Kepone manufacturing companies were exposed to intoxicating concentrations of the chemical.³⁰⁹ The central nervous system, liver, and reproductive organs appeared to be most sensitive to the toxic effects of chlordecone. Comparative studies using laboratory animals have since concluded that the target organs as well as the excretion pathways for chlordecone are similar in humans and rodents, although metabolic pathways differ significantly.

Reproductive impairment in a variety of mammalian and nonmammalian species has been attributed to the estrogenic properties of chlordecone.^{309,310} Chlordecone induced constant estrus in mice,^{311,312} and neonatal injections in female rodents accelerated vaginal opening and the onset of prolonged vaginal cornification with reductions in ovarian weight.³¹³ In Japanese quail (*Coturnix coturnix japonica*), Kepone caused oviduct hypertrophy in females³¹⁴ and suppressed spermatogenesis in males.^{315,316} Mirex fed to mallards at concentrations of 100 ppm decreased duckling survival, and hatch rates were reduced in chickens fed 600 ppm mirex.³¹⁷ Hatchability and chick survival were reduced when adults were fed 150 ppm and 75 ppm chlordecone, respectively.³¹⁸

In fish, there is evidence that chlordecone competes with radiolabeled E₂ for binding to the hepatic ER in spotted seatrout (*Cynoscion nebulosus*),^{160,319} rainbow trout,³²⁰ Atlantic croaker,³²¹ and channel catfish (*Ictalurus punctatus*). Other alterations attributed to chlordecone exposure include inhibition of oviposition in Japanese medaka,³²² reduced egg production and hatchability in sheephead minnow (*Cyprinodon variegatus*), and histopathological abnormalities in freshwater catfish (*Heteropneustes fossilis*). For instance, exposure of female catfish to chlordecone (0.024 ppm) for 1–2 months resulted in a decrease in the diameter of stage 1–3 oocytes, the formation of interfollicular spaces in the ovaries, and an increase in oocyte atresia.³²³ In male catfish, subacute doses (0.024 ppm) over the same time period resulted in significant damage to the seminiferous tubules and cystolysis of spermatids and sperm.

39.3.4.3 Dichlorodiphenylethanes

The dichlorodiphenylethane pesticide reported most often as having endocrine activity is 1,1,1-trichloro-2,2-bis *p*-chlorophenylethane (DDT). Used extensively during World War II to control insect-borne diseases, DDT was released into the environment in substantial quantities and, consequently, accumulated in soil, water, and tissues of many animals including fish. The *p,p'*- and *o,p'*-substituted isoforms of DDT; the dechlorinated analogs, *p,p'*- and *o,p'*-DDD; and the metabolites *o,p'*- and *p,p'*-DDE are various forms that frequently exist in the environment. In highly polluted areas (e.g., Palos Verdes Shelf in southern California), concentrations of DDT (total measured DDT, DDE, and DDD) have exceeded 100 ppm wet weight in the livers of several species. *p,p'*-DDE is one of the most commonly detected and highly persistent OCPs in tissues of aquatic animals, and in a recent study by the U.S. EPA, this metabolite was detected in 98% of fish surveyed at 388 locations in the United States. Over the last two decades, concentrations of DDT and its derivatives have decreased in fish of the United States, Canada, western Europe, and Japan as a result of strict regulation on its use. In addition to DDT, this category of OCPs includes DMC (Dimite), dicofol (Kelthane), methlocholor, methoxychlor, and chlorbenzylate.

Laboratory tests have shown increased uterine weight and persistent vaginal estrus in rats exposed to *o,p'*-DDT.^{324,325} Mammals concentrate DDT in adipose tissue, where it can become toxic when fat is lost due to migration or hibernation and the pesticide is unbound.³²⁶ Although concentrations in wildlife have decreased since DDT was banned, little information exists linking DDT exposure in the environment to estrogenic or adverse reproductive effects in wild mammals.³¹⁰

The use of OCPs, especially DDT, was responsible for the declines in populations of many species of predatory birds during the 1950s and 1960s. Most bird declines were due to eggshell thinning, with DDE being responsible for most of this problem; however, some species are more sensitive than others. For example, 3.0 ppm DDE in egg produces eggshell thinning and reduced productivity in the brown pelican (*Pelecanus occidentalis*), with residues > 3.7 ppm leading to total reproductive failure.^{327–329} Black-crowned night herons have a gradual decline in productivity as residues increase.³³⁰ Eggshell thinning due to DDE has had a major impact on populations of bald eagles^{331,332} and is considered a current risk to double-crested cormorants in Green Bay, Michigan.²⁰⁷ The mechanism for eggshell thinning, although previously thought to be caused by the estrogenic effects of DDE, is now proposed to involve the inhibition of prostaglandin synthesis in the eggshell gland muscosa.^{332,333} Additional reports of DDT effects in birds include decreased egg hatchability in eastern bluebirds (*Sialia sialis*)³³⁴ and the persistence of high concentrations of DDT and metabolites in foodchains in orchard and former orchard areas of the northwest.^{335,336} Population declines in raptors, such as the Eurasian sparrowhawk and peregrine falcon, have been linked to dieldrin, which increased adult mortality, in association with the adverse reproductive effects of DDE.²⁸⁹

American alligator eggs from Lake Apopka in Florida are known to contain residues of several OCPs including toxaphene, dieldrin, chlordane, DDT and metabolites, as well as PCBs.²⁰⁹ Several studies have described adverse reproductive effects to the alligator population on this lake including increased embryo mortality^{337,338} and morphological and endocrine abnormalities in juvenile alligators (including altered secondary sex characteristics).^{135,139} DDE also has been shown to cause sex reversal in alligators and red-eared slider turtles following the treatment of eggs at early embryonic stages and at incubation temperatures necessary for the production of male offspring.¹¹³ DDT has also been reported to induce VTG in the red-eared slider as well as in frogs.³³⁹ Clark et al.³⁴⁰ reported that technical-grade DDT acted as an antiestrogen and *p,p'*-DDE as an estrogen in tiger salamander (*Ambystoma tigrinum*). In a study with the reed frog (*Hyperolius argus*), *o,p'*-DDT, *o,p'*-DDE and *o,p'*-DDD prematurely induced adult female color patterns in juveniles, but not with *p-p*-substituted isoforms.³⁴¹

A number of studies have demonstrated the effects of DDT and related compounds on the reproductive success of exposed fish. Increased fry mortality has been observed in brown trout (*Salmo trutta*) and brook trout exposed to DDT concentrations ranging from 0.5 to 3.4 ppm/week for 98–308 days.³⁴² Fry mortality was also reported in a field study of lake trout inhabiting a lake polluted with DDT.³⁴³ In the laboratory, white croaker (*Genyonemus lineatus*) collected from a contaminated site were unable to spawn when total ovarian DDT concentrations exceeded 4 ppm. An increase in oocyte atresia and reduced fecundity and fertility were also observed in white croaker from a DDT-contaminated site.¹³⁶ Organism- and population-level effects due to DDT and derivatives include decreased fertilization and embryo deformity in winter flounder,²⁹⁹ decreased fertility and early oocyte loss in white croaker,³⁴⁴ and egg mortality in arctic char (*Salvelinus alpinus*).³⁴⁵ Functional male-to-female sex reversal in Japanese medaka has also been reported following the injection of approximately 227 ng *o,p'*-DDT/egg during the course of fertilization. A reduction in viable hatch has also been observed in atlantic herring (*Clupea harengus*) chronically exposed to 0.018 mg DDE/kg ovary.

Substantial evidence from *in vitro* studies (particularly in mammals) suggests that DDT and related OCPs are estrogenic and, thus, mediate endocrine disruption through interaction with the ER. A study by Spies et al.³⁴⁶ found that female kelp bass (*Paralabrax clathratus*) from a polluted site had lower GTH, T, and E₂ concentrations compared to fish from a reference site. Furthermore, the rate of GTH release from the pituitary was enhanced and correlated with hepatic concentrations

of DDT. In laboratory studies, an increased rate of GTH release from the pituitary of female kelp bass exposed to DDT was consistent with field observations, yet T production in laboratory exposed fish was enhanced. Receptor binding studies found that E_2 binding to the ER was reduced in DDT-exposed fish and, conversely, that DDT was capable of displacing E_2 from the ER.³⁴⁶ While the estrogenic potential of DDT may vary among different species of fish and other vertebrates, the above studies demonstrate the complexities of the reproductive system and the difficulty when interpreting alterations induced by this group of OCPs.

39.3.4.4 Hexachlorocyclohexane

Hexachlorocyclohexane (HCH) is an organochlorine chemical for which there are eight isomers, and several are used to prepare the technical-grade product. HCH was used primarily as an agricultural pesticide and is, to some extent, still applied as an insecticidal seed dressing. The precise mode of toxicity is unclear, although the α and γ isomers are known convulsants, and the β -isomer is a central nervous system depressant. The technical-grade product, known as HCH or benzene hexachloride (BHC), contains a mixture of alpha (α), beta (β), delta (δ), gamma (γ), and epsilon (ϵ) isomers; however, most of the insecticidal properties come from the γ -isomer, lindane. This product has received extensive use as an insecticide for fruit, vegetable, and forest crops and as a component of the ointments used to treat head and body lice. Lindane shares many chemical properties with other OCPs, but it has greater polarity and water solubility than most. Although in the U.S. its production has been discontinued since 1977, lindane is still imported and used by U.S. EPA-certified applicators. Lindane can accumulate in the fatty tissues of fish; however, it is easily degraded to less toxic metabolites by algae, fungi, and bacteria inhabiting soil, sediment, and water. Less water-soluble than its gamma counterpart, beta-hexachlorocyclohexane (β -HCH; a by-product generated during the synthesis of γ -HCH) is the most persistent of the HCH isomers and has been known to bioconcentrate in the tissues of invertebrates, fish, birds, and mammals.

Wester et al.³⁴⁷⁻³⁴⁹ have examined the effects of β -HCH on the development of the reproductive organs of several fish species. Four-week-old guppies (*Poecilia reticulata*) and post-fertilization Japanese medaka eggs were exposed to a range of concentrations (0.0032–1.0 ppm) for 1–3 m.³⁴⁹ Female guppies exposed to 0.32–1.0 ppm had a high incidence of premature and abnormal yolk formation despite having no fully mature oocytes. In the absence of developed oocytes, VTG accumulated in the body fluids, including the glomerular filtrate of the kidneys, and may have contributed to several toxic lesions observed in various nonreproductive tissues. VTG was also detected in male guppies exposed to 0.32 and 1.0 ppm β -HCH, and although GTH production by the pituitary was activated, testicular development was delayed and evidence of intersexuality or hermaphroditism was reported. Japanese medaka exposed to β -HCH also exhibited intersexuality or hermaphroditism following exposure to concentrations higher than 0.1 ppm. Overall, these authors concluded that the alterations observed in both species were the direct result of the estrogenic activity of β -HCH or its metabolites.^{348,349}

Singh et al.³⁵⁰⁻³⁵² conducted a series of *in vivo* studies that examined the effects of γ -HCH (lindane) on steroidogenesis at different phases of the reproductive cycle of goldfish and two species of catfish (*Clarias batrachus* and *Heteropneustes fossilis*). Regardless of reproductive stage, 4 weeks of exposure to 8 ppm γ -HCH resulted in reduced plasma T and E_2 concentrations in female clarias catfish, although effects at this dose were more dramatic in females in the later stages of vitellogenesis.³⁵² Similar results were obtained following exposure of female freshwater catfish to 4 and 8 ppm γ -HCH for 4 weeks.³⁵⁰ A decrease in T and E_2 was observed in all stages of females examined (preparatory, pre-spawning, spawning, post-spawning, and resting), and sensitivities appeared to increase from the preparatory to the spawning phase. Although the exact mechanism underlying the effects of γ -HCH remains unknown, it has been suggested that this insecticide may inhibit gonadal recrudescence by reducing GTH secretion or the number of GTH receptors, which would likely interfere with steroidogenesis.^{350,352}

39.3.4.5 Vinclozolin

Vinclozolin (3-(3,5-dichlorophenyl)-5-ethenyl-5-methyl-2,4-oxazolidinedione) is a dicarboximide fungicide used on vegetables and fruits. Two metabolites, M1 and M2, have been reported to be antiandrogens. Pregnant rats that received vinclozolin during gestation produced male offspring with reduced anogenital distance, cleft phallus, retained nipples, and hypospadias.^{353,354} Laboratory studies have reported Leydig cell hyperplasia, testicular tubular cell atrophy, penile hypoplasia, as well as hypospadias and infertility in male offspring.³⁵⁵ Vinclozolin exerts its effects by binding to the androgen receptor.^{310,356}

39.3.5 Non-Organochlorine Pesticides

39.3.5.1 Organophosphate Pesticides (OPs)

Organophosphate chemicals have been used as nerve gas and insecticides. Their effectiveness as chemical-warfare agents and insecticides stems from their ability to inhibit acetylcholinesterase, an enzyme required for basic neuronal function.³²⁷ The majority of OPs are lipophilic liquids, although they tend to have greater polarity and water-solubility than OCPs. Due to their innate instability, most OPs are not believed to bioconcentrate in aquatic species, although select fish species are highly sensitive to the toxic effects of these chemicals. Currently, many OPs are still used in a number of countries to protect crops from insects and farm and domestic animals from endo- and ectoparasites. They may also be used to control disease vectors (e.g., mosquitoes).

There is some indication that OPs might induce endocrine-disrupting effects in wild mammals. Reproductive depression, including decreased percentage of females with embryos and a decreased percentage of births, has been observed in rodents (*Sigmodon hispidus*, *Microtus ochrogaster*, and *Reithrodontomys fulvescens*) exposed to diazinon.³⁵⁷ Reproductive activity was also depressed in hispid cotton rats (*S. hispidus*) exposed to carbaryl, a carbamate.³⁵⁸ A recent study on the population effects of terbufos, however, found no changes on reproductive activity, number of births, or litter size in deer mice (*Peromyscus maniculatus*) and white-footed mice (*P. leucopus*).³⁵⁹

In birds, there is some evidence showing altered gonadotrophin release after exposure to OPs. Japanese quail exposed to 10-ppm parathion responded with a decrease in LH levels.³⁶⁰ Since this effect was observed at near-lethal concentrations (brain cholinesterase activity was inhibited by over 50%), it is unclear whether this represents a case of endocrine disruption or acute toxicity. Bobwhite quail (*Colinus virginianus*) fed 100-ppm parathion exhibited cessation of egg production, inhibition of follicular development, and reduced plasma LH concentrations.³⁶¹ Other laboratory studies have reported changes on incubation behavior and egg laying^{362–365} and decreased gametogenic function in adult birds exposed to OPs.³⁶⁶ OPs are also known to induce developmental toxicity effects in birds¹⁴¹ such as short limbs and parrot beak (known as Type I defects) and skeletal deformities (Type II defects). Results from field studies, however, have generally failed to find effects on several reproductive success parameters (clutch size, hatchability, and number of young fledged/nest) in populations of birds exposed to OPs after agricultural spraying.^{367–370}

Exposure of amphibians to OPs may result in altered metamorphosis. Development of bullfrog (*Rana catesbeiana*) tadpoles was significantly delayed after exposures to at least 1000-ppb malathion, possibly because of decreased thyroid function.³⁷¹ These concentrations, however, are above those commonly found in wetlands or streams after pesticide application. In a separate study, exposure of premetamorphic northern leopard and green frogs to environmentally relevant concentrations of OPs (< 0.01 ppm of basudin 500EC and technical-grade diazinon) caused deformities and delayed development.³⁷² Although exposure to the OP methyl parathion (1 ppm) has been associated with bone deformities in amphibians, similar to the Type II defects observed in birds,³⁷³ its effects on metamorphosis are less clear.³⁷⁴

Chronic exposure to low environmental concentrations of OPs may lead to a variety of reproductive and developmental effects in fish. For example, Ram and Sathyanesan³⁷⁵ exposed murrel (*Channa punctatus*) to 20-ppt cythion (50% malathion, 50% organic solvents) for 6 months and observed an increase in oocyte degeneration, which resulted in retarded ovarian growth and lower GSI. These responses were correlated with fewer and less active gonadotropin-producing cells in the pituitary. In males, spermatogenesis was arrested, and some necrotic spermatocytes were apparent. The authors speculated that reduced GTH levels might have contributed to the observed reproductive abnormalities. In freshwater perch (*Anabas testudineus*), although no short-term effects were observed after an exposure to 0.106 ppb Metacid-50 (50% methyl parathion), a reduction in GSI and plasma and ovarian E_2 concentrations was evident after 20 days.³⁷⁶ Exposure to OP pesticides has been documented to elicit a series of histological alterations in ovaries of several fish species. Exposure to 0.1 ppm methyl parathion for 75 days resulted in substantial oocyte damage in carp minnow (*Rasbora daniconius*).³⁰⁵ Similar effects have been observed in guppies (*Puntius conchonius*) exposed to 53 ppb monocrotophos for 2–4 months.³⁰³ Guppies exposed to fenitrothion have also responded with decreased egg production and abortion.³⁷⁷ Gonad weights and vitellogenesis were reduced in female striped catfish (*Mystus vittatus*) after 12 weeks of exposure to four different OPs (malathion, birlane, gardona, and phosdrin).³⁷⁸ Histological abnormalities of the testis has been a common response in male fish exposed to OPs, having been reported in at least ten fish species.^{56,161,379–387} Recent evidence indicates that exposure of newly hatched larvae to malathion might also result in developmental alterations (deformed notochord).³⁸⁸

Exposure of fish to OPs has also been associated with declines in the concentrations of hormones and VTG. For instance, exposure to malathion and to cythion results in reduced plasma concentrations of E_2 , T, and VTG.¹⁶¹ In another study, female catfish (*Heteropneustes fossilis*) had decreased plasma E_2 concentrations after an exposure to 1.2-ppm malathion for 72 h.³⁸⁹ Similar results were reported in studies examining the effect of malathion on sex-steroid concentrations during different phases of the reproductive cycle of the clarias catfish.³⁵² It was concluded from this study that sensitivity to malathion appeared to increase from the pre- to the post-vitellogenic phases, the latter of which involves ovulation and spawning. Carbaryl-induced thyroid dysfunction has also been reported in this species of freshwater fish.³⁹⁰

Evidence suggests that OPs may affect steroidogenesis by acting at multiple sites along the hypothalamic-pituitary-gonadal-liver axis. In fish, exposure to certain OPs reduces GnRH-like factor levels in the hypothalamus and impairs pituitary activity and release of GTH.^{391–393} Additional studies have shown reduced 3-hydroxycorticosteroids and 17 hydroxycorticosteroids (3-HSD and 17-HSD) activities in ovaries and testis of exposed fish.^{56,57} Singh³⁸⁴ proposed that malathion reduces E_2 in the Asian rice eel by interfering with the enzyme aromatase. Malathion, however, appears not to affect cholesterol biosynthesis, although it has been shown to alter the synthesis and mobilization of other lipids as well as the hydrolysis of esterified cholesterol to free cholesterol.^{394,395}

39.3.5.2 Carbamate Pesticides

The carbamate pesticides, many of which are in current use, are derivatives of carbamic acid. Like the OPs, they act as acetylcholinesterase inhibitors, vary with regard to water solubility, and are relatively nonpersistent in the environment. Carbaryl is a carbamate pesticide that controls over 100 species of insects on a variety of crops, agricultural animals, and pets. Although carbaryl has been reported to accumulate in certain species of fish and invertebrates, the risk of biomagnification is low due to its rapid metabolism and degradation. Carbofuran is another carbamate pesticide with wide application, although granular forms were banned in the U.S. in 1994 following a number of bird kills. Carbofuran is used to protect field, fruit, vegetable, and forest crops from insects, mites, and nematodes.

Laboratory studies with amphibians have reported growth inhibition and increased incidence of developmental deformities in tadpoles exposed to carbamate pesticides.^{372,373,396} In fish, carbamate pesticides have been shown to induce histopathological alterations in the ovaries and testes. Female fish exposed to carbofuran (range of 1 to 5 ppt) have responded with reductions in GSI, inhibitions in oocyte growth, and increases in oocyte atresia.^{379,397} Some of the lesions seen in ovarian tissue of carbofuran-exposed fish have included decreased oocyte diameter, a predominance of immature oocytes, and damage to yolk vesicles and oocyte structure.^{305,398} In males, carbofuran causes declines in testes weight and delays in spermatogenesis and induces necrosis of spermatogonia and spermatocytes.^{379,380} Although generally less toxic to fish than carbofuran, carbaryl exposure results in many of the same reproductive alterations. Carbaryl-induced alterations, including reduced GSI and plasma E₂ concentrations, inhibited oocyte growth, increased oocyte atresia, and damage to yolk vesicles and oocyte structure has been observed in several species of fish after exposures ranging from 2 to 20 ppt.^{304,376,387} Increased larval mortality and decreased production and hatchability of eggs are additional responses to carbaryl exposure.³⁹⁹

Little information is known regarding the mechanisms by which carbamate pesticides induce reproductive anomalies in fish, although results from both field and laboratory experiments suggest that carbaryl may act at the level of the pituitary by altering GnRH and GTH serum concentrations.³⁹¹ Results from the *in vitro* E-screen indicate that neither carbaryl nor carbofuran are estrogenic in nature.⁴⁰⁰ Carbofuran also appears to raise cholesterol and phospholipid concentrations in the ovaries and testes of fish, while lowering overall protein, RNA, total lipids, and ascorbic acid.⁴⁰¹

39.3.5.3 Organometal Pesticides

Certain metals are highly insoluble in their inorganic form and, therefore, possess little to no toxicity. However, since metal toxicity may be greatly enhanced if binding to an organic ligand occurs, some metals have been modified intentionally to increase their toxicity for use as pesticides. Until 1993, organomercury was used as an antifungal seed dressing in the United Kingdom, organolead has been applied to fruit crops to control caterpillars, and organotin compounds have served a number of functions due to their extreme toxicity. For example, tributyltin (TBT) has served as an algicide, miticide, fungicide, and insecticide, and since the 1960s it has also functioned as a marine antifouling agent. Both agricultural and maritime applications have led to the contamination of aquatic environments. Although the half-life of TBT in water is brief (days to weeks), organotin compounds have the potential to bioaccumulate in aquatic organisms.

One of the best-documented cases of endocrine disruption comes from the work done with marine gastropods exposed to organotin compounds (mainly TBT) contained in antifouling paints. Laboratory and field studies have demonstrated that female gastropods exposed to environmentally relevant doses of TBT develop an irreversible sexual abnormality known as “imposex.” This masculinization process involves an increase in T concentrations, which is followed by the impo- sition of male sex organs (penis and vas deferens) over the oviductal tissues, causing abnormal breeding activity and, in many cases, sterility and population declines.^{402–407} Depending on the species and dose attained, oogenesis might be completely supplanted by spermatogenesis. TBT can also induce alterations in the behavior and development of bivalve larvae.⁴⁰⁷ It is estimated that about 72 species and 49 genera of prosobranchs have been affected worldwide.⁸ In the case of the highly sensitive common dogwhelk (*Nucella lapillus*), imposex is induced at exposures as low as 1–2 ppt, with complete suppression of oogenesis at TBT concentrations above 3–5 ppt.⁴⁰³ Birds that feed on mollusks have been shown to accumulate butyltins to a greater degree than birds preying on fish, birds, or mammals.⁴⁰⁸

Although the precise mechanisms by which TBT causes endocrine disruption in invertebrates are not entirely known, recent evidence suggests that this compound may act as a competitive inhibitor of CYP450-mediated aromatase.^{402,404} TBT may also interfere with sex-steroid metabolism, inhibiting

the formation of sulphur conjugates of T and its active metabolites. In addition, TBT is capable of inducing cytotoxic and genotoxic damage to embryonic and larval stages in invertebrates.^{409,410}

In fish, organotin compounds are readily bioaccumulated and stored in different tissues, including the gonads.⁴¹¹ In several fish species, exposure to organotins has been associated with delayed hatching, high embryo and larval mortality, and retarded yolk-sac resorption.^{412–417} In guppies, exposure to TBT (11.2–22.3 ppb) and BPA (274–549 ppb) results in significant declines (by 40–75%) in total sperm counts after 21 days.⁴¹⁸ Organotin compounds also induce several alterations in ovaries and testes of fish. Three-spined sticklebacks (*Gasterosteus aculeatus*) exposed to bis(tributyltin)oxide (TBTO) for up to 7.5 months experienced no seasonal increase in GSI, as was apparent in control animals. In addition, ovaries from exposed animals contained 25% resorbing oocytes, as opposed to 0% in controls.⁴¹⁹ In this study, however, several other reproductive endpoints (including spawning behavior, fecundity, hatchability, frequency of deformed fry, and secondary sex characteristics) were not affected by treatment.

39.3.5.4 Triazine Pesticides

The triazine pesticides include some of the most extensively used herbicides in North America. Indeed, atrazine is used to control weeds on more than two thirds of the U.S. acreage containing corn and sorghum as well as 90% of sugarcane acreage. Simazine, another member of this class of herbicides, is currently applied to 30 high-value crops including a variety of fruits, vegetables, nuts, turfgrass, and conifers. Despite the widespread use of these chemicals, relatively little is known regarding their potential health effects to humans and wildlife. Atrazine is only slightly toxic to fish, and the risk for bioaccumulation is extremely low due to its propensity for rapid degradation to less or nontoxic metabolites.

The effects of atrazine on amphibian metamorphosis have been examined in some detail. Tiger salamanders (*Ambystoma tigrinum*) exposed to low concentrations of atrazine (75 ppb) developed at slower rates but were similar in size when compared to controls.⁴²⁰ In contrast, exposure to high atrazine concentrations (250 ppb) resulted in similar developmental rates but decreased sizes. In addition, T_4 was elevated in both groups, whereas corticosterone was depressed in the low-dose group only. These authors hypothesized that the suppression of corticosterone could have resulted in a decreased conversion of T_4 to the active form T_3 , thereby slowing metamorphosis and allowing increased growth. In contrast, Allran and Karasov⁴²¹ found no effects on developmental rate and metamorphosis in northern leopard frogs exposed to atrazine (20 and 200 ppb). Atrazine has also been shown to induce teratogenic changes in frog embryos, but at concentrations approaching maximum solubility in water.⁴²²

Few studies have examined endocrine or reproductive function in fish exposed to atrazine or other triazine pesticides. Channel catfish and gizzard shad (*Dorosoma cepedianum*) maintained for 4.5 months in ponds containing 20-ppb atrazine failed to reproduce, and reproductive success of bluegills (*Lepomis macrochirus*) was reduced by more than 95%.⁴²³ Since the dietary habits of bluegill were largely affected by the herbicide treatment, the authors suggested that impaired reproduction might have been due to impoverishment rather than to direct effect of atrazine exposure. Results from our laboratories have shown that atrazine affects sex steroids in male and female largemouth bass (Gross et al., unpublished data). After 20 days of exposure, plasma 11KT concentrations were elevated in males exposed to 100-ppb atrazine, and E_2 concentrations were increased in females exposed to 50- and 100-ppb atrazine. Studies with largemouth bass have also shown that when ovarian follicles are incubated with 10 ppb atrazine, it results in an increased E_2 and a decreased T production. Furthermore, *in vitro* T synthesis is greatly reduced when gonads are incubated with a combination of atrazine and flordione or atrazine and chlordane.

Studies with American alligators have shown that atrazine might induce differential responses in developing embryos depending on timing of exposure. Crain et al.⁴²⁴ reported that atrazine (14 ppb) induced gonadal aromatase activity in male hatchling alligators exposed *in ovo*. In a later

study, however, incubation of alligator eggs with atrazine prior to the critical period of gonadal differentiation did not influence sex determination and had no apparent effect on gonadal structure (measured as sex-cord diameter in males, Müllerian duct epithelial cell height, and medullary regression of the ovaries in females) or hepatic aromatase activity.⁴²⁵ Since most endocrine changes associated with atrazine have been reported in normally organized reproductive systems, the authors hypothesized that the lack of noticeable effects in the latter study was the result of exposing embryos during very early developmental stages, i.e., prior to or during the development of the reproductive system.

Current evidence suggests that atrazine induces endocrine-disruptive effects by acting as a steroid hormone antagonist (antiandrogen or antiestrogen), probably through nonreceptor-mediated mechanisms. Indeed, a number of *in vivo* and *in vitro* studies have failed to detect estrogenic activity for triazines. In two independent studies, oral exposure to atrazine and simazine did not increase uterine weight in immature or ovariectomized female Sprague-Dawley rats,^{426,427} and cell-proliferation and binding studies found no evidence for either agonistic or antagonist activity for this herbicide.⁴²⁶ Furthermore, atrazine and related compounds failed to demonstrate estrogenic activity in human and yeast cells expressing the ER and an estrogen-sensitive reporter gene,^{428,429} although the triazines have displaced radiolabeled estradiol from the ER in competition studies.^{363,429} Also, a study by Danzo⁷⁴ showed that atrazine did not reduce radiolabeled E₂ binding to rabbit uterine ER, although it inhibited the binding of DHT to androgen receptor sites in rat testes and reduced the binding of DHT to the androgen-binding protein by 40%. Triazines may also disrupt reproductive function by altering LH and PRL concentrations.⁴³⁰

39.3.6 Complex Environmental Mixtures

39.3.6.1 Pulp- and Paper-Mill Effluents

Over the past 15 years, a number of investigators have studied the effects of pulp- and paper-mill effluents on feral and laboratory fish populations. In general, fish exposed to these effluents experience alterations in steroid biosynthesis, gonadal development, sexual maturation, and expression of secondary sex characteristics. Identifying the causative agents in the effluent and establishing cause-and-effect relationships, however, have been challenging tasks, since pulp- and paper-mill effluents are complex mixtures, and the components are not entirely known. Furthermore, variations in wood finish, in the pulping and bleaching process, and in the treatment of effluents between mills lead to different effluent compositions. Nevertheless, all pulping protocols involve the separation and discharge of natural wood components, such as sugars, lipids, resins, and fatty acids, which generally undergo bacteriological treatment in settling and aeration ponds. Depending on the bleaching techniques used, pulp- and paper-mill effluents may also contain different kinds and concentrations of chlorinated organic compounds such as PCDDs and PCDFs.

The most thorough field studies on the reproductive effects of paper-mill effluents have been conducted at Jackfish Bay, Lake Superior. Jackfish Bay has received bleached kraft-mill effluent (BKME) from a nearby pulp mill since 1949 and, therefore, has provided a convenient site for studying the impact of BKME on several fish species. BKME-exposed white suckers show decreased concentrations of several sex-steroid hormones (T, 11KT, and E₂).^{128,431–435} Declines in steroid concentrations have also been documented in longnose sucker (*Catostomus catostomus*) and lake whitefish (*Coregonus clupeaformis*) from Jackfish Bay,^{432,434} in white sucker at other mills,^{436–439} and in other effluent-exposed fish species sampled elsewhere.^{432,440,441} The consequences of these similar endocrine alterations to whole-animal reproductive fitness and population dynamics, however, have varied greatly among species. For example, longnose sucker exposed to BKME show no organism responses other than an altered age distribution, whereas white sucker and lake whitefish show decreased gonadal sizes, secondary sexual characteristics and egg sizes, and increased age to maturity.⁴³² In a review of whole-organism responses of fish exposed to different kinds of mill

effluents (including unbleached pulps), 80% showed increased age to sexual maturation, and reduced gonadal size was reported in 58% of the studies.⁴⁴² These observations provide evidence for species differences in susceptibility to BKME but also show the inherent difficulty when trying to compare biological responses in fish populations inhabiting highly different environments and exposed to complex mixtures likely to vary in chemical composition.

There are relatively few studies on the effects of BKME on egg and fry parameters, and the results from these studies are conflicting. Fertility (as indicated by the percentage of spawned eggs that hatched) was decreased in zebrafish after exposure to chlorinated phenolics from a bleach plant effluent⁴⁴³ and in brown trout after exposure to BKME.⁴⁴⁴ Hatchability was also reduced in pike after exposure of eggs to BKME concentrations as low as 0.5%.⁴⁴⁵ Similarly, many field and laboratory studies have reported decline in fecundity in several fish species exposed to paper-mill effluents.^{435,436,443,446,447} McMaster et al.,⁴⁴⁸ on the other hand, found equal or greater fertilization rates and no effects on hatchabilities of white sucker eggs, despite declines in sex-steroid concentrations, gonad and egg sizes, and sperm motility in BKME-exposed fish. In addition, fecundity and hatchability were not altered after exposures to BKME in several other field^{440,449,450} and laboratory studies.^{441,451} There is very little information on the developmental effects of BKME. In the laboratory, survival from larvae to adult and growth of fathead minnows (*Pimephales promelas*) were not affected after exposures to up to 20% effluent concentrations.^{446,451,452} Studies conducted in our laboratories with largemouth bass, however, have found similar fecundities and hatchabilities but decreased fry growth and survival after exposures to 10% bleached/unbleached kraft-mill effluent (B/UKME).⁴⁴¹ Similarly, Karås et al.⁴⁵⁰ reported comparable fecundity and egg mortality in perch (*Perca fluviatilis*) from a BKME-exposed area, but fry hatched from this site were smaller and had an increased frequency of abnormalities, which was translated into lower abundances of fry and young-of-the-year fish. These authors concluded that exposure of perch to BKME had resulted in high mortality rates close to the time of hatching due to either chronic failure of parental reproductive systems or acute toxicity to embryos or early larvae.

Exposure to pulp- and paper-mill effluents has also been associated with alterations in secondary sex characteristics (see Reference 453 for a review of the evidence for masculinization in poeciliids from Florida). Female mosquitofish in Florida inhabiting a stream receiving paper-mill effluents were reported to be strongly masculinized, showing both physical secondary sex characteristics (fully developed gonopodium) and reproductive behavior of males.⁴⁵⁴ More recently, masculinization of female fish has been identified from an additional two species (least killifish, *Heterandria formosa* and sailfin molly, *Poecilia latipinna*) collected from an effluent-dominated stream.⁴⁵⁵ Masculinization of female fish has been attributed to the action of androgenic hormones that result from the biotransformation of plant sterols (and also cholesterol and stigmasterol) by bacteria such as *Mycobacterium*.⁴⁵⁶

Results from studies on white sucker indicate that several sites within the pituitary-gonadal axis are affected after exposure to BKME. Fish from exposed sites had significantly lower plasma levels of gonadotropin (GTH-II) and showed depressed responsiveness of sex steroids and 17,20 β -dihydroxy-4-pregnen-3-one (a maturation-inducing steroid) after GnRH injections.⁴⁵⁷ BKME-exposed fish also had lower circulating levels of testosterone glucuronide, which would be suggestive of altered peripheral steroid metabolism. Similarly to what was observed under *in vivo* conditions, *in vitro* incubations of ovarian follicles collected from BKME-exposed females have also shown reduced steroid production.^{433,457} The similarities between both types of studies would suggest that reductions in plasma steroid levels in BKME-exposed fish are mainly due to alterations in ovarian steroid production. Recent studies on white sucker have shown increased apoptotic DNA fragmentation and increased expression of a 70-kDa heat-shock protein in oocytes from prespawning females, which coupled with lower sex steroids may explain the observed decreased gonad weights and delayed sexual maturity.⁴⁵⁸

Although there is extensive literature on the reproductive effects of BKME on fish, very little is known about the chemical compounds that could be held responsible for such changes. Com-

pounds such as dioxins and furans were the first to blame, because of their persistence, bioaccumulative properties, and their known deleterious reproductive and antiestrogenic effects.⁴³⁴ Recent evidence, however, suggests that the chemicals in pulp-mill effluents responsible for reproductive alterations are relatively short-lived and readily metabolized by fish. For example, mixed-function oxygenase induction and endocrine alterations have also been reported downstream from mills that do not use chlorine bleaching,⁴³² and these parameters have rapidly returned to normal after cessation of exposure.⁴³⁴ Indeed, several of the natural wood components in the final effluent, such as sterols, lignans, stilbenes, and resin acids, are believed to be weak estrogens.^{459,460} For example, the plant sterol β -sitosterol has demonstrated estrogenic activity by its ability to induce VTG in juvenile rainbow trout⁴⁶⁰ and male goldfish⁴⁶¹ and bind to the ER in rainbow trout hepatocytes.⁴⁶² Conversely, various phytosterols that survive the treatment process have displayed masculinizing effects under controlled experimental conditions.⁴⁶³

39.3.6.2 Sewage-Treatment Effluents

Researchers have shown that effluents coming from sewage-treatment plants might cause estrogenic effects in fish due to their ability to induce the production of VTG (a female specific egg-yolk precursor) in males.^{9,464} Recent information has also shown an increase in the incidence of intersex, or hermaphroditism, in populations of wild fish inhabiting rivers contaminated with sewage effluent.⁴⁶⁵ Presently, the population-level effects of increased VTG in male fish remain poorly understood, although they are known to be associated with decreased testicular growth.^{466,467} Chemical analysis of effluents from sewage-treatment plants has identified several compounds with estrogenic properties, including natural estrogens (E_2 and E_1), synthetic estrogens widely used in birth-control pills, alkylphenolic chemicals (resulting from the breakdown of nonionic surfactants), plasticizers (bisphenol-A), and phthalates.^{466,468,469} The following section reviews the major findings on the endocrine-disrupting effects of the above groups of chemicals in fish.

39.3.6.2.1 Natural and Synthetic Estrogens

Recent studies using chemical fractionation and biologic screening techniques suggest that natural and synthetic steroidal estrogens may be causing the greatest estrogenic effects in fish inhabiting streams contaminated with sewage effluents.⁴⁷⁰ This stems from the fact that both types of estrogens, but especially the synthetic ones, are highly potent hormones, and thus concentrations in the ppb or less are capable of inducing biological effects. For example, EE_2 induces VTG synthesis in male rainbow trout at concentrations as low as 0.1 ppb.⁴⁷¹ EE_2 concentration in English rivers has ranged from 0.2 to 7 ppb.⁴⁷² Although the reproductive consequences of EE_2 exposure in fish are mainly unknown at this time, they have been associated with decreased testicular growth and development in immature fish.⁴⁶⁶ Altered spermatogenesis has also been reported in fish exposed to natural estrogens.⁴⁷³ Women are the primary sources of natural and synthetic estrogens in sewage effluents, either because of the excretion of natural and synthetic estrogens as inactive conjugates during menstrual cycling or because of the use of contraceptive pills. During the sewage-treatment process, these conjugates are biotransformed into their parent and biological active compounds.

39.3.6.2.2 Alkyl Phenol Ethoxylates (APEs) and Alkyl Phenols (APs)

APEs are effective nonionic surfactants serving as components of industrial and domestic detergents, pesticide formulations, cosmetics, and paints. Of all APEs produced, nonylphenol-polyethoxylates and octylphenol-polyethoxylates constitute approximately 80% and 20%, respectively. These chemicals are biodegraded during sewage treatment to form APs such as nonylphenol and octylphenol. Industrial effluents might contain over 100 ppb of nonylphenol, although most streams surveyed in the United Kingdom and in the United States contained equal to or less than

10 and 0.1 ppb, respectively.^{474,475} Nonylphenol and octylphenol are hydrophobic and lipophilic and thus can accumulate in sediment and fish adipose tissue. Both APEs and APs are known to have estrogenic properties, as discussed below.

Alkylphenolic chemicals might also be playing an important role as xenoestrogens in sewage effluents. Male rainbow trout exposed to four AP chemicals responded with significant increases in plasma VTG concentrations, particularly after treatment with at least 3 ppb octylphenol.⁴⁶⁶ Nonylphenol and two carboxylic acid APE degradation products also induced VTG production in males in this study, but at higher concentrations. Testicular growth was inhibited in response to all four chemicals, with octylphenol having the greatest inhibitory effect. Christianson et al.⁴⁷⁶ reported similar effects in male eelpout (*Zoarces viviparous*) exposed to nonylphenol. Twenty-five days after a 10- to 100-ppm nonylphenol injection, a significant increase in plasma VTG with a concomitant decrease in GSI was observed. Histological examination revealed degenerated seminiferous lobules in exposed males as well as decreased guanosine triphosphate (GTP) activity (a marker for Sertoli cell function). Plasma VTG induction has also been reported following nonylphenol exposure in male and immature female rainbow trout,⁴⁷⁷ male flounder,⁴⁷⁸ male and female Atlantic salmon (*Salmo salar*),^{479,480} Japanese medaka,^{479,481} and immature channel catfish.⁴⁸² Nonylphenol (25 ppm) has also caused a dramatic increase in plasma zona radiata proteins in juvenile female Atlantic salmon.⁴⁸⁰ Gray et al.⁴⁸³ recently reported a reduction in courtship activity in adult Japanese medaka males exposed to octylphenol from 1 day post hatch to 6 months post hatch. In this study, transgenerational effects were also observed (i.e., an increase in fry developmental abnormalities). Similarly, AP-induced developmental toxicity effects have been reported in embryos and larvae of killifish after exposures to octylphenol and 4-*tert*-octylphenol.⁴⁸⁴ Disruption of sexual differentiation is yet another effect observed in fish exposed to APs, having been reported in common carp⁴⁸⁵ and mosquitofish.⁴⁸⁶

The endocrine-disrupting properties of APs and APEs are mainly related to their ability to bind to the ER. Indeed, APEs have been shown to be estrogenic using several *in vitro* bioassays.^{94,104,487} Similarly, APs substituted at position 4 (e.g., 4-nonylphenol) have demonstrated estrogenic activity in various *in vitro* and *in vivo* bioassays.^{73,89,91,94,488} P-substituted phenols, such as 4-*t*-pentylphenol (TPP), are believed to be among the most potent estrogens.^{488,489} Ren et al.⁴⁹⁰ suggested that nonylphenol may also be involved in the post-transcriptional regulation of VTG mRNA processing. Finally, recent research shows that APs can induce reproductive alterations through an increase in the rate of apoptosis of Sertoli cells, phenomena that can negatively affect the development and release of sperm.⁴⁹¹

39.3.6.2.3 Bisphenol A

Bisphenol is the generic name given to a group of diphenylalkanes commonly used in the production of plastics. Bisphenols consist of two phenolic rings joined by a carbon bridge. The bridging carbon has no substituent in bisphenol F and two methyl groups in bisphenol A (BPA). Incomplete polymerization or depolymerization of plastics from heating may result in the release of BPA into the environment and subsequent human and animal exposure. The first reports to document the estrogenic potential of the bisphenols appeared in the 1930s,⁴⁹² and a number of investigators employing a variety of techniques have since confirmed those results.^{493,494} Evidence suggests that estrogenic potency of these compounds increases with the length of the alkyl substituent at the bridging carbon as well as due to the chemical nature of the substituents.⁴⁹⁵ Bisphenols with hydroxyl groups in the para position and an angular conformation are suitable for binding the ER at the acceptor site.

The estrogenicity of BPA has been demonstrated by several *in vitro* assays.^{91,95,100,400,489,496,497} More recently, BPA has been shown to induce the synthesis of the VTG protein in rainbow trout liver slices;⁴⁹⁸ VTG mRNA in rainbow trout primary hepatocyte cultures;⁴⁹⁹ and VTG and zona radiata proteins in Atlantic salmon primary hepatocytes.⁵⁰⁰ In the latter study, BPA inhibited the

E₂-stimulated induction of VTG and zona radiata proteins, suggesting that the effects of the plasticizer are truly estrogenic in nature. Arukwe et al.⁴⁸⁰ observed a dose-dependent increase in plasma VTG and zona radiata proteins following a single intraperitoneal injection of BPA.

Interestingly, recent evidence suggests that the *in vivo* estrogenicity of BPA may be greater than predicted by *in vitro* assays.⁵⁰¹ Male Japanese medaka were exposed to BPA for two weeks and then introduced to a tank with untreated females for spawning studies.⁴⁸¹ In the experimental group, the number of hatchings was reduced, and the concentrations that affected reproduction in this study were lower than concentrations that produced effects in some *in vitro* studies. Furthermore, VTG synthesis was observed at concentrations below those affecting reproduction. BPA is also known to cause significant declines in sperm production.^{418,502}

39.3.6.2.4 Other Phenolics

Several phenolic compounds other than alkyl phenols and BPA have been evaluated for their impact on fish reproduction. For example, polychlorinated phenols are often formed during the chemical reaction of chlorine and phenolic compounds in wood pulp. The polychlorinated phenols are acidic and are chemically reactive compounds of low persistence because of their water solubility. Pentachlorophenol (PCP), a commonly used fungicide in wood preservation, often enters the environment as a component of domestic and industrial effluents, primarily from the forest-products industry.

There is evidence that reproductive effects can be elicited when fish are exposed to PCP. Female rainbow trout exposed for 18 days to sublethal concentrations of PCP (22 and 49 ppm) during the primary ovarian growth phase displayed a significant increase in oocyte atresia and a trend toward decreasing oocyte diameter.⁵⁰³ The use of purified PCP in this study rebutted the claim that toxicity of technical PCP is due to contamination by PCDDs, PCDFs, or other chlorinated phenols.⁵⁰⁴ It has been suggested that in rainbow trout, PCP affects oogenesis by interfering with the production of yolk in the liver.⁷³ These authors found that PCP may act as an estrogen antagonist since it has shown a slight inhibitory effect on E₂-stimulated induction of the ER mRNA and a substantial inhibitory effect on E₂-stimulated induction of VTG mRNA. In addition, a study with *Daphnia magna* found that PCP is capable of altering steroid hormone biotransformation and elimination pathways.⁵⁰⁵ The potential estrogenicity of several other phenolic compounds was tested by Jobling et al.⁴⁶⁸ using a trout ER competition study and several mammalian cell assays. 2,4-dichlorophenol, a component of fungicides and germicides, reduced the binding of radiolabeled E₂ to the trout ER. Conversely, 3,4-dimethylphenol and 2-methylphenol, which also serve as fungicides and disinfectants but have no chlorine group, failed to compete for ER binding. In another study, Mukherjee et al.⁵³ examined the effect of phenol on the steroidogenesis and reproductive activity in sexually maturing carp. After 48 days of exposure to 8-ppt phenol, GSI was reduced, ovarian and liver cholesterol concentrations were increased, and cholesterol conversion to sterol products was inhibited. Previous studies by Kumar and Mukherjee⁵⁰⁶ also demonstrated phenol-induced alterations in plasma, ovarian, and hepatic cholesterol concentrations in several species of fish.

39.3.7 Metals

Although metals are natural substances, human activity is largely responsible for their abnormal release and accumulation in the environment. Metal toxicity usually results from exposure to high levels of nonessential metals such as mercury (Hg) or cadmium (Cd). Since these and all other metals are nonbiodegradable, the body cannot metabolize them into less toxic forms. Instead, detoxification involves binding to specific proteins (e.g., metallothionein) that function to shield toxic properties or to produce insoluble forms (e.g., intracellular granules) for long-term storage or excretion. If not excreted, some metals can bioaccumulate in tissues, especially if the individual occupies a position at the top of the food chain. Metals probably do not act as classic EDCs, i.e.,

modulating receptor-mediated effects. Instead, their mechanism of action may involve toxicity of endocrine tissues, altered enzyme binding, and CNS interactions.

39.3.7.1 Mercury (Hg)

Mercury is a nonessential heavy metal found naturally in the environment and used in many industries including battery, paper, paint, chemical, and agriculture, as well as dentistry and medicine. The burning of coal, natural gas, and refining of petroleum products adds 5000 tons of Hg per year to the atmosphere, increasing Hg contamination of aquatic ecosystems worldwide.^{507,508} Hg enters aquatic systems either indirectly by atmospheric deposition or from direct discharge of mercuriferous wastes into watersheds.^{509,510} Conditions of low pH and high dissolved organic carbon increase the methylation of inorganic Hg to the more toxic methylmercury (MeHg).⁵¹¹ This methylated form is rapidly bioaccumulated by aquatic species, with body burdens in piscivores increasing with trophic level.⁵¹² While there have been many studies measuring Hg concentrations in wildlife,^{513–519} little information is available on its potential effects.

In laboratory tests, Hg has produced stillbirths in dogs and pigs and abortions,⁵²⁰ abnormal sperm,⁵²¹ and low conception rates in the macaque (*Macaca fascicularis*).⁵²² Hg-laden rats have reduced litter size⁵²³ and decreased survival.⁵²⁴ In mice, Hg produces decreased fetal survival,⁵²⁵ fetal malformations,⁵²⁶ embryo resorption,⁵²⁷ low sperm counts,⁵²⁸ and tubular atrophy of testes.⁵²⁹ Abortions have been reported in guinea pigs (*Cavia porcellus*),^{530,531} and Hg in the Florida panther (*Puma concolor coryi*) is thought to reduce kitten survival.⁵³² These effects in offspring are expected because Hg (both inorganic and organic) is able to cross the placenta, producing behavioral deficits, impaired fertility, and fetal death.^{533,534}

Hg impairs reproductive success in birds. Some studies have found a negative correlation between hatching success and Hg concentrations in eggs^{518,535,536} or feathers.^{537,538} Common terns with liver Hg concentrations between 9 and 21 ppm wet weight showed decreased hatchability and reduced nesting success.⁵³⁹ Concentrations between 3 and 14 ppm in common loons decreased hatchability and at 52 ppm reduced nesting success.⁵³⁵ In this same study, brain concentrations >2 ppm reduced egg laying and decreased nest and territory fidelity.⁵³⁵ Egg concentrations from 0.5 to 1.5 ppm wet weight decreased hatchability in pheasants.^{540,541} Mallard eggs with externally applied methylmercury chloride (Me-HgCl) showed decreased embryo weights, developmental abnormalities, and embryonic death.⁵⁴² Juvenile survival was also decreased in these studies because of neurological damage. Ducks fed Hg over three generations had decreased reproduction, and ducklings exhibited altered behavior.⁵⁴²

There is little information on Hg reproductive toxicity in reptiles and amphibians. Frogs (*Rana cyanophlyctis*) kept in water for less than 3 months had decreased GSI as well as reduced numbers of sperm bundles and increased secondary spermatogonia, indicating a blockage in mitosis and thus in the conversion of spermatogonia into primary spermatocytes.⁵⁴³ Hg contamination is also reported to have caused a loss in germ cells and sterility in *Rana nigromaculata*⁵⁴⁴ and reduced survival in African clawed frog.⁵⁴⁵

In fish, Hg exposure has caused decreased GSI and a variety of gonadal abnormalities.⁵⁴⁶ Other responses to exposure involve altered lipid and cholesterol ovarian content,⁵⁴⁷ reduced spermatogenesis,³⁴⁷ and impaired fertilization.^{548,549} Studies with tilapia (*Oreochromis niloticus*) have shown reduced plasma E₂ in females and plasma 11KT in males with muscle concentrations ranging from 1 to 7 ppm wet weight.⁵⁵⁰ Similar effects have been seen in largemouth bass with muscle Hg as low as 0.25 ppm wet weight.¹⁰⁷ These studies suggest a CNS involvement with potential effects on the hypothalamic-pituitary-gonadal axis in fish. Hg may depress hormone production by acting on the gonads and interfering with their development. Testicular atrophy was observed in tilapia with Hg concentrations between 0.4 and 2.7 ppm dry weight and in guppies (*Poecilia reticulata*).^{347,550}

39.3.7.2 Other Metals

Lead (Pb) is a heavy metal released into the atmosphere from industrial emissions and motor exhaust. It is a nonessential, toxic metal that affects all body systems. Reproductive effects in mammals include alterations in implantation, embryonic development, and reproductive organs.^{551,552} Hildebrand et al.⁵⁵³ found that blood levels of Pb above 390 ppm in male rats induced prostatic hyperplasia, impaired sperm motility, reduced testicular weight, and caused seminiferous tubular damage and spermatogenic cell arrest. Pb is also capable of crossing the blood-brain barrier, interfering with the central nervous system.^{554,555} Young can also be exposed through the maternal milk.⁵⁵⁶ The fetus and developing young are most sensitive to chronic levels of Pb exposure. Pb blood levels as low as 70–80 ppm can result in neurobehavioral symptoms.^{557,558} During embryo development, Pb can cross the placenta and be linked to reduced gestational age and lowered birth weight.⁵⁵⁹

Birds become contaminated with Pb through the consumption of Pb shot or bullets or fishing sinkers. After ingestion, these items gradually dissolve and the birds become progressively weaker and emaciated. Other species, especially raptors, which may prey on these species, are poisoned by ingesting contaminated prey.⁵⁶⁰

There is little research on the reproductive effects of Pb in reptiles. Red-eared slider turtles injected with Pb had reduced righting response,⁵⁶¹ and this heavy metal reduced the rate of development of the Jefferson salamander (*Apystoma jeffersonianum*).⁵⁶² Although known to accumulate in fish tissues,⁵⁶³ few studies have examined the effects of Pb exposure on fish reproduction or endocrine functions. Female Atlantic croaker fed as little as 0.05–0.2 ppm/day for 1 month had reduced GSI, E₂, and T.^{158,159} Female climbing perch (*Anabas testudineus*) exposed via water to 1.25 ppm Pb for 1 month had lower GSI,⁵⁶⁴ and retarded ovarian growth was observed in clarias catfish following long-term exposure (275 days) to 5 ppm.⁵⁶⁵ In addition, decreased spermatogenesis and ovarian atresia have been observed in rosy barb exposed to a low dose of Pb nitrate (0.12 ppm) for 60–120 days,⁵⁶⁶ and decreased spermatogenesis and testicular hemorrhage were reported in the striped gourami (*Colisa fasciatus*) following 4 days of exposure to 15 ppm Pb nitrate.⁵⁶⁷

Copper (Cu) is an essential metal that is necessary for the activity of various enzymes and for iron utilization. This metal has received widespread use in the preservation and coloring of foods, in brass and copper water pipes and domestic utensils, and in fungicides and insecticides, the latter providing the primary route of exposure to aquatic animals. Egg and larval mortality of the Jefferson salamander were decreased by exposure to Cu.⁵⁶² Several studies involving different fish species report a spectrum of reproductive abnormalities following exposure to Cu. Decreased spermatogenesis and ovarian atresia were observed in female rosy barb,⁵⁶⁶ whereas testicular abnormalities and arrested spermatogenesis were observed in the male guppy (*Lebistes reticularis*).⁵⁶⁸ Although VTG is known to serve as a carrier for many metals, including Cu, the effects of this metal on vitellogenesis are not clear. Cu suppressed vitellogenesis in female mussels (*Mytilus edulis*),⁵⁶⁹ whereas cupric acetate appeared to have no effect on vitellogenesis in female clarias catfish.⁵⁶⁵ Additional studies involving Cu exposure report decreased egg size and a propensity for deformities on larvae of white sucker,⁵⁷⁰ reduced egg viability and hatchability in brook trout,⁵⁷¹ and impaired fertilization and increased larval abnormalities in topsmelt (*Atherinops affinis*).⁵⁷²

Cadmium (Cd) is a by-product of copper, lead, and zinc mining and is also found in industrial sludges and phosphate fertilizers. Cd has been reported to accumulate primarily in the liver and kidneys,^{573,574} however, several investigators have also detected Cd in the gonads.^{575,576} In rats, Cd has been shown to cause Leydig cell tumors⁵⁷⁷ and induce prostatic and interstitial cell tumors.^{578,579} Cd suppresses egg production in mallards⁵⁸⁰ and chickens.⁵⁸¹ Slight gonadal alterations were found in mallards fed Cd and accumulating kidney concentrations up to 50 ppm, while those with kidney concentrations of 100 ppm exhibited testicular atrophy and no sperm production.⁵⁸² Again, actively reproducing seabirds have been found with similar kidney concentrations.⁵⁸³ In amphibians, studies with the African clawed frog showed that females exposed to Cd for 4 weeks produced malformed

embryos.⁵⁸⁴ Malformations were also seen in *Xenopus* embryos exposed to concentrations ranging from 0.1 to 10 mg Ca²⁺/L. This study showed that embryos were more susceptible from stages 2 to 40, although malformations occurred at all stages.⁵⁸⁵

Diverse effects of Cd exposure have been reported in a number of fish species, although results from different studies are occasionally conflicting. For instance, Cd exposure has led to reduced plasma sex steroids in Asian swamp eel (*Monopterus albus*) and brook trout; reduced VTG in *Monopterus albus*, rainbow trout, bleaker (*Lepidocephalichthys thermalis*), winter flounder, and European flounder; and decreased GSI in Asian swamp eel and winter flounder.^{161,586–590} Conversely, Cd has also stimulated steroidogenesis in several fish species.^{110,159,591,592} The latter could be explained by evidence showing increased *in vitro* production of GTH after administration of Cd, which is consistent with the enhanced ovarian activity observed in female Atlantic croaker.⁵⁹¹ A wide range of Cd concentrations (0.001–1000 ppm) and durations of exposure (several hours to 90 days) were used in the experiments described above, which could explain the different responses observed.

Cd treatment has also been associated with degenerative changes in the gonads of several fish species.^{588,593–595} Adult female guppies exposed to dietary Cd for 30–120 days produced less fry compared with controls, demonstrating the effect of Cd at the organism and possibly at the population level.⁵⁹⁶ The mechanisms underlying Cd-induced alterations are poorly understood, although several theories have emerged. There is speculation that vitellogenesis may be impaired because the synthesis of metallothioneins by the liver in response to metal exposure takes priority over the synthesis of VTG.⁵⁹⁰ On the other hand, Cd may directly interfere with VTG synthesis at the transcriptional or translational levels. Others suggest that Cd may interfere with the incorporation of VTG into the developing oocyte. In a study by Victor et al.,⁵⁸⁸ Cd appeared to impede the transport of VTG across the oolemma into the oocyte. However, Cd-VTG complexes injected into Atlantic croaker were shown to incorporate into the ovaries.⁵⁷⁵

Zinc (Zn) is a component of over 70 metalloenzymes and serves as an important essential metal. Although Zn toxicity is rare, it has been reported in several species. For instance, Zn has been shown to influence hatching success and developmental rates in the Jefferson salamander.⁵⁶² Multiple studies also document reproductive alterations in fish following Zn exposure. For example, in a study using clarias catfish, Zn was reported to decrease circulating levels of VTG.⁵⁶⁵ Other observed effects in fish include delayed spawning and decreased egg viability in zebrafish,⁵⁹⁷ impaired spermatogenesis and increased oocyte atresia in rosy barb,⁵⁶⁶ and reduced egg size and increased larval deformities in white sucker.⁵⁹⁸

Selenium (Se) is a natural element/metal required for healthy nutrition in small amounts, but it is toxic at higher concentrations. The processing of fossil fuels releases Se to the environment, where it then accumulates in coal fly ash. Se is also found in high concentrations in certain soils, remaining in wetlands as a by-product of irrigation.^{203,599} Reproductive success of birds and fish is more sensitive to Se toxicity than are growth and survival of young or adults.^{600–602} In fish, Se exposure can result in subtle but dramatic reproductive failure.⁶⁰³ In birds, Se egg concentrations of 3 ppm wet weight are considered the threshold for reproductive impairment.^{601,604,605}

39.4 SUMMARY AND CONCLUSIONS

This chapter has reviewed and selectively summarized the current evidence for potential endocrine-disrupting effects of specific chemicals and chemical classes in vertebrate wildlife and their potential modes of action. Although evidence of endocrine disruption in wild species has accumulated during recent years, most studies are based on indirect evidence rather than defined mechanisms and exposures to specific ECDs. Indeed, most studies of potential EDC effects in wildlife are based on observed adverse reproductive and developmental effects rather than direct evidence of endocrine-modified function or defined endocrine pathways. Nonetheless, a consideration of

whether the effects of specific chemicals can be attributed to hormonal properties, mechanisms, or pathways is critical to the identification of a chemical as an EDC or EAA.

This review also evaluated the evidence for endocrine disruption for wildlife and fish in field/natural and control/experimental situations. A wide variety of chemicals have been reported as potential EDCs in wildlife. The major chemical classes summarized here include PAHs, PCBs and PBBs, PCDDs and PCDFs, OCPs, nonorganochlorine pesticides, complex environmental mixtures, and selected metals. In addition, the evidence of potential EDC effects are summarized and reviewed for multiple vertebrate species, with an emphasis on reproductive and developmental effects, which are often modulated by endocrine mechanisms and pathways. Collectively, there is strong evidence of altered reproductive and developmental processes in wildlife exposed to EDCs. Although from most of these studies the mechanisms of action and direct link to endocrine-mediated pathways are often unclear, there is general evidence of an association between effects and chemical/contaminant exposures as well as evidence of effects in multiple vertebrate classes. Much of the evidence for EDC effects in wildlife is derived from observations and studies involving fish. These studies present the clearest link between environmental chemical contaminants and endocrine-disrupting effects. The potential mechanisms of action are diverse (see Figure 39.1), and several endocrine/hormonal mediated pathways are likely.

In recent years, great progress has been made in the development of *in vitro* screening and testing procedures for the identification of potential EDCs. However, these assays have been based primarily on receptor-mediated responses and hormone mimicry. It is important to mention that a wide variety of other potential mechanisms also exist for EDCs (see Figure 39.1 and Table 39.1), and thus there is a strong need for the development of additional screening and testing procedures. On the other hand, *in vivo* studies are more ecologically relevant and thus better suited for the assessment of risk in wildlife due to EDCs. However, the interpretation of effects at the organism level and above is difficult and potentially affected by multiple stressors (other than EDCs). Paired studies, involving both field- and laboratory-based exposures as well as *in vitro* assessments of mechanisms are likely needed to adequately identify and evaluate potential EDCs. Nonetheless, studies in wildlife and fish have provided the strongest evidence for accepting the endocrine-disrupting hypothesis and have been critical in the identification and evaluation of potential environmental EDCs.

40.1 INTRODUCTION

For the past decade, there has been growing concern about worldwide declines in amphibian populations,^{1,2} and a general phenomenon of declining populations was recognized in the mid-1990's. Subsequent research has validated this concern.^{3,4} These population declines have been defined either as decreases in numbers of individuals in an area or, preferably because of greater reliability, a decrease in the number of sites occupied by breeding amphibians. Widespread population declines have occurred in North America,⁵⁻⁷ Europe,^{3,8,9} Australia,¹⁰ and Central and South America.^{11,12} Population declines in eastern Europe, Asia, and Africa have been suggested but are not as well documented. Worldwide, more than 500 populations of frogs and salamanders have been listed as declining or of concern.^{4,13} In the United States, a third of known amphibian species are thought to be in trouble.¹⁴ While the most severely affected populations are in the mountains of the western United States, serious declines have also been observed among some species in the Midwest and Southeast.²

Several reasons for these population declines have been proposed including habitat destruction or degradation, disease, climate change, introduction of exotic predators or competitors, increased solar radiation, and contaminants. These factors can operate in isolation of others, or two or more factors may interact to impact a population. The purpose of this chapter is to examine how contaminants may be involved with amphibian population declines, including their possible interaction with other factors. This is an overview, not an exhaustive summary of the literature; a thorough review of the literature is in the recent book edited by Sparling, Linder, and Bishop.¹⁵

Habitat destruction or degradation is a primary factor for many population declines. Because many species of amphibians require both land and water to complete their life cycles, draining of wetlands, clear-cutting of forests, and fragmentation and isolation of suitable patches of habitat all contribute to decreased breeding and survival.^{7,16} Many other factors, such as grazing of riparian shorelines, discharge of effluents, and channelization, can degrade streams and rivers, making them unsuitable as amphibian habitat.

Little is known about amphibian diseases in general, but they are apparent problems in some areas.¹⁷⁻¹⁹ Amphibians are subject to many bacterial, fungal, and viral diseases,¹⁹ some of which have been implicated in epizootics. According to one hypothesis, disappearance of several Australian frogs has been associated with epizootics of an iridovirus that traveled in a northward wave of contagion, causing widespread extinctions.¹⁰ Lips¹¹ proposed that a combination of disease and environmental contamination led to the decline of six species of frogs and salamanders in Costa Rica and suggested that these factors were responsible for declines in most tropical upland sites. Many of the tadpoles she collected had damaged and missing labial tooth rows. This type of damage has been subsequently attributed to chytrid fungi (*Phylum Chytridiomycota*). Not much is known about these fungi except that they typically digest chitin, but one or more species may have adapted to digesting keratin, which composes tadpole mouth parts. They have been linked to amphibian population declines in Australia and Central America²⁰ and seem to be very widespread among tadpoles in the United States (D. E. Green, G. Fellers, personal communication).

In a 7-year study of the endangered Wyoming toad (*Bufo baxteri*), the most common mortality factor in captive and free-ranging adults was mycotic dermatitis with a secondary infection of the bacterium *Basidiobolus ranarum*.²¹ Of particular interest was the observation that the bacterium has been very common in the toad's environment for a long time, yet the toad apparently has become highly susceptible to infection, which begs the question of whether other factors have reduced its tolerance to the bacterium.

While diseases are potentially very important, additional epidemiological work is required to satisfy Koch's postulates of infectious diseases for most of the proposed agents and populations, and there is a strong likelihood that other factors like environmental contaminants are interacting with disease agents to increase their virility or decrease amphibian immune responses.

Another proposed cause for amphibian population declines is exotic species — especially introduced predators and competitors. Populations of the Cascades toad (*Bufo cascadae*), red-legged frogs (*Rana aurora*), mountain yellow-legged frogs (*R. muscosa*), and foothill yellow-legged frogs (*R. boylei*) are declining in the western Sierra Nevada Mountains of California.^{5,6} Many of the lakes that were inhabited by these amphibians have been stocked with nonnative salmonids that are predacious on eggs, tadpoles, and young frogs. The presence of these exotic predators showed a clear discontinuity with the occurrence of native amphibian species.^{22,23} Also, a survey using direct-sight locations of trout and long-toed salamanders (*Ambystoma macrodactylum*) in the Bitterroot Mountains of Montana demonstrated a high degree of correlation between the presence of trout and the absence of salamander larvae.²⁴ Direct-observation surveying methods are more limited than seining or electrofishing techniques, but the relationship between trout and salamanders was strengthened through historical data — 10 years earlier six lakes that had trout also had no salamander larvae, but the trout had been extirpated in the interim, and salamanders had repopulated the lakes.

Bullfrogs (*R. catesbeiana*), which feed on adult and larvae of other amphibians, have also been introduced into western lakes and have been blamed for amphibian population declines.^{25,26} A study

using experimental ponds inoculated with *R. catesbeiana* tadpoles, *R. aurora* tadpoles, and mosquitofish (*Gambusia affinis*) showed that survival of *R. aurora* tadpoles was less than 5% in ponds stocked with *R. catesbeiana*. Whereas mosquitofish had no measurable effect on *R. aurora* survival, there was significant depression of *R. aurora* tadpole growth and an increase in the frequency of injuries among frogs in ponds stocked with mosquitofish compared to controls.²⁷ A similar relationship between the occurrence of frogs and fish has been recorded in Spain.²⁸

Over the past several years, scientists have been concerned about increased ultraviolet radiation, especially UV-B due to thinning of the atmospheric ozone layer. Because this thinning is related to air pollutants, including CO₂, NO_x, and difluorocarbons, increased UV-B radiation is indirectly anthropogenic. Direct exposure to ultraviolet radiation in the laboratory reduces hatchability and increases mortality of tadpoles. Ankley et al.^{29,30} demonstrated that northern leopard frog (*R. pipiens*) tadpoles exhibited a significantly higher frequency and severity of hindlimb malformations when exposed to UV-B light than did controls. These malformations, however, were not like those found under field conditions because the experimental ones were usually bilaterally symmetrical, whereas those observed in the field are typically unilateral.³¹ An understanding of the role of ultraviolet radiation in amphibian population declines is confounded by several factors: (1) many of the older laboratory experiments that subjected amphibians to ultraviolet radiation did not emulate natural conditions or did not see an effect;³²⁻³⁴ (2) there are important species-specific and life-stage differences in the sensitivity of amphibians; for example, exposure to UV-B decreased larval and egg survival of *R. aurora* but affected only larval Pacific treefrogs (*Hyla [Pseudacris] regilla*);³⁵ (3) unless the water is exceptionally clear and colorless, UV-B penetration into the water column is rapidly attenuated, and tadpole shelter-seeking behavior may further reduce exposure;³⁶ and (4) tadpoles of several species of amphibians produce photolyase, an enzyme that repairs photodamaged tissues under low light conditions.^{37,38}

Contaminants have been frequently cited as contributing to amphibian population declines.^{7,16,39,40} Arguments used to support the role of contaminants include multiple life stages that may expose amphibians to a variety of contaminants in the water and on land, a highly permeable skin that facilitates uptake of contaminants, a moderate to high sensitivity in acute and chronic toxicity tests compared to other aquatic organisms, reproductive seasons that overlap with agrochemical applications that can affect reproduction, and varying degrees of mobility that may affect the probability of exposure, particularly to pesticides in agricultural landscapes. Prior to 1998, most of the information on contaminant exposure in amphibians was residue information with little information on the effects of these contaminants. Most of the available information on effects comes from laboratory toxicity studies, with little information from field experiments. To date, no studies have been published that show a clear cause-and-effect relationship between contaminants and long-term population declines in amphibians. This absence of evidence is most likely due to the lack of research, not because contaminants are unimportant.

40.2 CRITERIA FOR DETERMINING A POPULATION EFFECT

Any attempt to determine if a contaminant, or any stressor, has an effect on a population of amphibians is constrained by several factors. First, local groups of many species exist as metapopulations — adults that inhabit nearby ponds, sometimes separated by a kilometer or more, move from one pond to another and breed with those in other ponds, resulting in genetic mixing and opportunities to recolonize depopulated ponds.⁴¹ Thus, local events that reduce a group of amphibians inhabiting one pond may be compensated by neighboring ponds. Alternatively, an impacted pond may serve as a sink for immigrating individuals. Second, generally it is not known if mortality caused by contaminants is additive or compensatory. Many species of anurans (frogs and toads) have high fecundity, so that eggs, embryos, or tadpoles that die from exposure to contaminants could have died anyway from other factors, and the overall insult is no different. Conversely, long-

term population recruitment and mortality may be delicately balanced so that the addition of a contaminant that restricts reproduction or increases mortality may be more than a population can tolerate and decline occurs.

Therefore, to determine whether a particular factor such as a contaminant has a negative effect on a population two conditions must be met: (1) the ecologically relevant levels or concentrations (i.e., the levels that could be expected to occur under typical conditions) of the contaminant must result either in significantly reduced recruitment via immigration and impaired reproduction or increased loss above that caused by other stressors through emigration or mortality rates within a free-ranging population and (2) the effect on the population must be additive to other stressors such as predation, parasitism, or energy requirements. That is, decreases in population recruitment or increases in population losses cannot be totally compensated by other factors.

In reality, these criteria are seldom, if ever, met in ecotoxicological studies; thus, only indirect evidence is available to determine the role contaminants may have in amphibian population declines.

40.3 LEVELS OF EVIDENCE

Although there are no studies to date that show an unambiguous relationship between environmental contaminants and long-term amphibian population declines, we can use less direct evidence to investigate if such relationships can occur. Based on immediacy and ecological relevance, this evidence can be categorized into three groups:

1. Data collected under field conditions that document at least temporary declines in amphibian numbers when they are exposed to environmental contaminants.
2. Data obtained from laboratory studies that demonstrate lethal or severe sublethal responses to contaminants at or below concentrations typically expected or observed in the field; ideally populations should increase when these contaminants are remediated.
3. Laboratory or field studies that show that contaminants can interact with other hypothesized causes for amphibian declines and increase the probability of population effects.

The most direct and reliable evidence for contaminant-related population declines would come from field studies that reflect or report natural situations. However, the majority of contaminant effects studies on amphibians have occurred in the laboratory under highly artificial conditions. In nature, amphibians are exposed to a host of potentially interacting forces of abiotic factors and water chemistry, predators, parasites, competitors, and habitat that are absent from laboratory investigations. Often, laboratory studies use single, technical-grade chemicals, whereas natural populations are exposed to formulations (e.g., pesticides) or to mixtures of contaminants (e.g., metals, polychlorinated biphenyls [PCBs], polycyclic aromatic hydrocarbons [PAHs]). Under laboratory situations, stressors such as predators and competition are ameliorated or absent, but the stark habitat provided by glass aquaria and fluorescent lighting adds undetermined stresses to organisms. Many other factors that affect response to contaminants (e.g., dissolved organic carbons, temperature and oxygen fluctuations, refugia) are absent in laboratories. Thus, the effective or lethal concentrations determined under laboratory conditions, although frequently our only clue to response, may be at best rough approximations of toxic exposures in natural wetlands.

Ecological relevance can be increased by the use of outdoor laboratories, which allow natural variation in weather and lighting conditions. Relevancy increases as other organisms such as predators, competitors, or vegetation are incorporated in mesocosm and macrocosm studies, but the ability to control all relevant variables decreases as size and complexity increase. A few attempts have been made to strike a balance between experimental control and ecological relevance in amphibian tests. Experimental manipulation of natural wetlands may be difficult due to size and logistics, legal restrictions on applying contaminants to existing wetlands, lack of true controls or replicates, or uncontrollable factors related to land-use practices.

40.3.1 Evidence for Direct Involvement

Contaminants can have a direct effect on amphibian populations by impairing physiological processes or resulting in mortality. In contrast to indirect effects, discussed later, direct effects are often easier to identify and to establish causal links.

40.3.1.1 Field Studies Showing Population Effects

Most of the studies that have examined the direct effects of contaminants on amphibian populations have dealt with acid deposition. Some of these studies also examined correlates of acidification including sulfates, dissolved aluminum and other metals, alkalinity, and cations. Many have been correlative in nature, i.e., drawing relationships between wetland chemistry and presence of species or relative abundance, but several have been experimental.

One correlative study examined 35 wetlands in Pennsylvania.⁴² The number of egg masses deposited by Jefferson salamanders (*Ambystoma jeffersonianum*) was positively correlated with pH and alkalinity and negatively correlated with aluminum concentration. In the same study, egg mass deposition by spotted salamanders (*A. maculatum*) correlated positively with pH and negatively with total cations (Na, K, Mg, Ca) and specific conductance. Another correlative study in Ontario, Canada found only weak relationships among species richness of amphibians and water characteristics among 180 wetlands.⁴³ Although species richness correlated negatively with chloride, magnesium, and turbidity, multiple regression analysis only accounted for 19% of the variance in richness. However, those wetlands were well buffered and not prone to acidification.

In a field experiment in England, variation in egg fertility could be explained primarily by the concentration of monomeric aluminum with additional explanation provided by the concentration of zinc, silicon, and molybdenum.⁴⁴ Monomeric aluminum also accounted for the greatest amount of variance in the frequency of abnormal yolk plugs in eggs. Aluminum is the most common metal in the earth's crust, but acidic conditions cause it to dissolve and form toxic species of which monomeric (Al^{3+}) is among the most toxic to amphibians.

Horne and Dunson⁴⁵ used outdoor mesocosms to test the effects of low pH, dissolved organic carbons (DOC), and metals on survivorship in three species of amphibians. Exposure concentrations were set to reflect typical conditions in central Pennsylvania (pH 4.5 to 5.5, DOC 15–30 mg/L). The time required for wood frog (*R. sylvatica*) larvae to metamorphose increased with high DOC and low pH. Delayed metamorphosis can be disadvantageous to species such as *R. sylvatica* that inhabit temporary wetlands by increasing the risk of desiccation. Survival of *A. jeffersonianum* and *A. maculatum* was reduced by pH and metal concentrations in the same study.

The relative abundances of northern cricket frogs (*Acris crepitans*) and gray treefrogs (*Hyla versicolor*) were significantly lower in experimental wetlands that had been acidified to a pH of 5 to 5.5 than in wetlands with a pH range of 6 to 6.8.⁴⁶ In this study, all the experimental wetlands were naturally colonized by four species of anurans from surrounding wetlands. For *H. versicolor*, there was a soil \times pH interaction in that the greatest effects of pH were seen in wetlands with a clay base rather than a loam base. The soil effect could be explained by the fact that clay soils had approximately twice the concentration of metals as the loam soils and that acidification of sediment and water facilitates metal dissolution. No pH or soil effects were observed in green frogs (*R. clamitans*) or southern leopard frogs (*R. sphenocephala*).

Some amphibians, such as the salamander genus *Plethodon*, spend their entire life cycle on land. Yet these species may also be limited by acid deposition. The distribution and population density of the red-backed salamander (*P. cinereus*) was restricted by soil pH \leq 3.7.⁴⁷ While this was a very acidic soil, it is not uncommon in coniferous and deciduous forests in the Northeast where humic acids combine with atmospheric deposition of acid-causing anions.

The effects of acidification on amphibian health and populations are well known, and acid deposition certainly may be a contributing factor to population declines in some areas. However,

as stated by Rowe and Freda,⁴⁸ no studies have documented specifically that acid deposition has been involved with any long-lasting decline in amphibian populations. Hazards due to acid deposition would be greatest where subsoils are granitic, poorly buffered, with low acid-neutralizing capacity (ANC) and where anthropogenic sources of acid-causing anions such as sulfates and nitrates are downwind. Within North America, these areas tend to be most abundant in the northeastern United States and eastern Canada. The Rocky Mountains have poorly buffered soils but lack an abundant source of acid-causing anions. Florida has many ponds and wetlands with low pH, but the source of the acidity appears to be organic acids rather than anthropogenic sources,⁴⁹ and the amphibians have probably adapted to low pH over long evolutionary periods. Bradford et al.⁵⁰ did not find any relation between ANC and populations of anurans in the Sierra Mountains, and they did not find any regional differences in ANC or other water-chemistry parameters related to acid deposition. They concluded that acid deposition was not important in the decline of these anurans.

There are fewer experimental or correlative studies with other contaminants and amphibians under natural conditions. Another pervasive potential source of contaminants is nitrogen fertilizers. Nitrogen is used or found in nature in various forms from ammonium ion to ammonia, nitrite, and nitrate. Of these, ammonia and ammonium are the most toxic forms to amphibians, followed by nitrites and nitrates. The use of nitrogen fertilizers in North America is tremendous, with application rates sometimes exceeding 8 metric tons/km² on agricultural lands and more than 72 million tons worldwide;⁵¹ greatest use in the United States is in the East and in the Midwest. Aqueous concentrations may exceed 100 mg/L in ponds and between 2 and 40 mg/L in streams.

In one study in Britain, Oldham et al.⁵² released adult common frogs (*R. temporaria*) into plastic arenas situated in the middle of a field that had been treated with ammonium nitrate at 10.8 g/m². Adults began displaying signs of toxicity — increased rate of breathing — and one died; although these signs were considered predictive of death, frogs were removed before they succumbed. Based on laboratory data, the authors estimated that the EC₅₀ for *R. temporaria* was 6.9 g/m², well below the application rate. Fortunately, the toxicity of ammonium nitrate disappears rapidly as the solution is absorbed by moist soil. However, laboratory toxicity tests (see below) frequently conclude that lethal concentrations are below anticipated ambient levels.

A 20-year decline in amphibian numbers in Poland was ascribed to high levels of nitrogen in surface waters coming from the use of fertilizers on surrounding agricultural lands.⁵³ In an agricultural study area in Ontario, Bishop et al.⁵⁴ determined that habitat loss and nitrogen from fertilizers were more important than pesticides in restricting amphibian survival and species richness. A recent review of the subject⁵¹ concluded that the problem of nitrogen-based fertilizers is extensive and toxic enough to represent one of the most pervasive contaminant threats to amphibian survival in North America and perhaps elsewhere. Of more than 8500 water samples collected from states and provinces around the Great Lakes, 19.8% had nitrate concentrations that exceeded those found to produce sublethal effects in amphibians. Sublethal and lethal effects can be caused by nitrate concentrations ranging from 2.5 to 100 mg/L, depending on species and study.

Chlorpyrifos is a highly toxic but widely used pesticide. In June 2000, the U.S. Environmental Protection Agency ordered a phase-out of chlorpyrifos use in several applications because of human health risks.* The pesticide is also very highly toxic to aquatic organisms, having an LC₅₀ of around 9–15 µg/L. A field study by Moulton⁵⁵ found adverse effects, including mortality in adult and larval *Hyla femoralis*, after exposure to environmentally realistic concentrations of chlorpyrifos.

Mazanti⁵⁶ conducted a combined field and laboratory study on the effects of two commercial pesticide formulations: Lorsban 4E (44.9% chlorpyrifos) and Bicep II (27.4% atrazine, 35.6% metolachlor). Both formulations are used extensively in agriculture, with Bicep II sprayed as a preemergent herbicide for broadleaved plants and Lorsban 4E applied about 3 weeks later to control insects. In the laboratory, a combination of both pesticides was far more toxic than either pesticide alone, and a high dose (2.0 mg/L atrazine, 2.5 mg/L metolachlor, 1.0 mg/L chlorpyrifos) killed

* <http://www.epa.gov/pesticides/op/chlorpyrifos-methyl/summary.htm>.

Figure 40.1 Growth (\pm SD) of gray treefrog (*Hyla versicolor*) tadpoles through time when exposed to low and high concentrations of the insecticide Lorsban (active ingredient is chlorpyrifos), low and high concentrations of the herbicide Bicep II (active ingredients atrazine and metolochlor) and low concentrations of both insecticide and herbicide. See text for concentrations. The primary size difference at 28 days is due to a lack of metamorphosis in high and low insecticide rather than to growth per se. All tadpoles exposed to combined high herbicide and high insecticide died by 11 days.

100% of *H. versicolor* tadpoles within 11 days. A low combined dose and high individual doses of insecticide or herbicide alone caused lethargy and reduced growth but did not increase mortality over controls. In naturally colonized, experimental wetlands, low-herbicide/low-insecticide (0.2 mg/L atrazine, 0.25 mg/L metolochlor, 0.1 mg/L chlorpyrifos) and high-herbicide/low-insecticide treatments resulted in almost complete, short-term extirpation of *H. versicolor* and *R. clamitans* tadpoles compared to controls (Figure 40.1). By the end of the summer, however, these prolonged breeding species had repopulated the treated wetlands. If species with contracted or explosive breeding seasons had been similarly affected, their reproduction would have been severely curtailed for the year.

A recent study implicates chlorpyrifos and other insecticides in the declines of ranid populations in the Sierra Mountains of California. The Central Valley of California is an intensely agricultural region that sits between the Pacific Coast and the Sierra Mountains. The most severely impacted sites for *R. aurora*, *R. mucosa*, and *R. boylei* are in the mountains east and above the Central Valley in what appear as pristine wetlands. However, 60% of California pesticides used in agriculture, thousands of kilograms of active ingredient pesticides, are aerially sprayed on the croplands of the Central Valley every year.* A large proportion of these pesticides are organophosphorus insecticides such as chlorpyrifos, malathion and diazinon which inhibit cholinesterase.

* <http://www.cdpr.ca.gov/docs/pur/purmain.htm>.

Other highly toxic pesticides such as endosulfan and trifluralin are also sprayed in large quantities. *Pseudacris regilla* occupies many of the same habitats as the declining ranid species but its numbers are not nearly as depressed as the ranids. Using *P. regilla* as a sentinel species, the authors found that cholinesterase activity was significantly depressed in tadpoles in the Sierra Nevada downwind of the Central Valley compared to coastal populations.¹⁹⁹ The samples with the lowest cholinesterase values came from Yosemite and Sequoia National Parks where mean activity level was often less than 50% of reference means on the coast. In the mountains, more than 83% of the tadpoles and adults collected from Lake Tahoe region had measurable concentrations of endosulfan and 50% of those sampled in Yosemite and Sequoia National Parks contained diazinon or chlorpyrifos residues (Figure 40.2). Both endosulfan and the organophosphorus pesticides have half-lives measured in days so detection of these pesticides in *P. regilla* signified very recent exposure.

Figure 40.2 Mean (\pm SD) concentrations (a) and frequencies of detection (b) for chlorpyrifos, diazinon and endosulfan in Pacific treefrog (*Hyla [Pseudacris] regilla*) adults and tadpoles collected from California, 1999.

Fenitrothion, an organophosphorus insecticide, used to be sprayed widely to control spruce budworm (*Choristoneura fumiferana*). The relative abundance of mink frogs (*R. septentrionalis*) among New Brunswick ponds was inversely related to the intensity of spraying in forest ponds.⁵⁷ Ponds that had been sprayed in 3 of the preceding 4 years had significantly lower relative abundances of frogs than ponds that had been sprayed less often. In addition, the percent cover of submerged vegetation related positively to frog abundance, perhaps because it provided shelter from direct exposure to the insecticide.

Although DDT and most other chlorinated hydrocarbon pesticides are no longer used in developed countries, these compounds have been associated with die-offs of amphibians and could still be having some effect in Third World countries, where they are being used. For example, DDT was applied to forests to control tussock moths (*Orgyia pseudotsugata*). A die-off of western spotted frogs (*R. pretiosia*) occurred following a spraying of DDT with fuel oil as solvent at a rate of 0.72 kg DDT/ha. An unknown percentage of the adult frogs were dead, and those that were found dead had 5–10 times the concentration of DDT derivatives on a lipid basis than those that were still alive.⁵⁸ There was 100% egg mortality in *R. pipiens* inhabiting a wetland adjacent to cropland that had been sprayed with aldrin.⁵⁹ A mixture of endrin, aldrin, dieldrin, and toxaphene at 2.7 kg/ha used in mosquito control killed all the *R. catesbeiana* inhabiting a wetland.⁶⁰

Whereas the number of documented cases of die-offs in amphibians due to contaminants is sparse, certainly the vast majority of cases either are unreported, or causal factors are not identified. Both acid deposition, with the elevated concentrations of metals produced by increased acidity, and pesticides can cause local reductions or extirpations of amphibian communities, and in some cases, they may be related to regional declines.

40.3.1.2 Toxicity in the Laboratory at Ecologically Relevant Concentrations

As with field studies, more research on amphibian ecotoxicology has been conducted in conjunction with acid deposition than with any other contaminant. Studies have examined direct effects of elevated hydrogen ion concentration plus associated effects due to the dynamics of dissolved aluminum; mitigating effects of water hardness, dissolved organic content, and organic acids; effects of temperature; and other factors. Endpoints in these studies have included survivorship at various life stages (egg, embryo, tadpoles), ion regulation, metal uptake, respiration and energy conversion, and behavioral responses. More complete reviews of the effects on aquatic biota in general have been published.^{61,62} Here we focus on the direct effects of acid deposition and pesticides on factors that affect amphibian population dynamics — survivorship and reproduction.

Readers are referred to several reviews of the effects and tolerance limits of amphibians to acidity.^{48,61,63–65} Sensitivity to pH varies among species. Among the most sensitive species are the natterjack toad (*Bufo calamita*), with a lower pH limit (at which substantial or total mortality occurs) of 4.5 and an upper effects level (where sublethal effects or mild mortality can be seen) of pH 4.7. In comparison, the more tolerant pine barrens treefrog (*Hyla andersoni*) can tolerate pH as low as 3.1.^{61,65} Most amphibian species are sensitive to pH = 4.5 or 4.6. In general, the toxicity of pH decreases as water hardness increases. Dissolved organic carbon can ameliorate the toxic effect of pH and Al but can itself be toxic to amphibians^{66,67} and can complex with Al to alter its availability. The speciation and toxicity of aluminum is complex as pH drops below 5.5, and three response categories to Al have been identified.⁶⁸ These range from sensitivity only to pH below 4.5 to sensitivity to pH and aluminum between 4.5 and 5.5, to Al sensitivity only at pH > 4.5 and even an amelioration of pH toxicity by Al at pH < 4.5. Because of these dynamics, toxicity due to pH, Al, and DOC often cannot be totally distinguished under natural conditions.⁶¹

As a very brief synopsis of the relatively extensive literature on acid deposition and amphibians, embryos tend to be the most sensitive life stage, especially with elevated concentrations of Al⁶⁹ that induce a characteristic curling of the tail due to alterations in the vitelline membrane of the

egg. Serious impairment of hatching due to ecologically realistic levels of pH and Al are well documented in several species.^{42,70–72} Similarly, tadpole mortality increases significantly at pH below 5.0.^{73–76} Acute or episodic exposure to reduced pH and elevated Al, such as what might occur with a rapid snowmelt, tends to be more toxic than chronic exposure.⁷⁶ There is some evidence that amphibians may adapt physiologically or genetically to long-term exposure to reduced pH.⁷⁷ Hardly anything is known about the effects of pH or Al on adult amphibians.⁴⁸

Among the plethora of other contaminants, many occur in the environment at lethal concentrations as determined by laboratory LC₅₀ tests (Table 40.1). In this table, ambient concentrations for most of the chemicals come from Eisler.⁷⁸ However, organophosphorus, carbamate, and pyrethroid pesticides are not persistent, and environmental fate studies of these compounds often result in measurements below instrument detection levels. Thus, when measurable concentrations are detected, they may be a fraction of the maximum to which the amphibians were exposed. Because few reliable data exist, I used label application instructions⁷⁹ to derive a rough approximation for some of these; amount per area was converted to concentrations in water based on wetlands with average depth of 0.5 m, under the presumption that most amphibians lay their eggs in shallow water. Realized concentrations can vary considerably from these estimates due to actual depth of eggs masses, applicator deviations from label application rates, and additional pesticides entering a wetland through runoff or wind. Lethal toxicity data come from many sources including some recent reviews.^{80–82}

The table has several limitations and is intended only to illustrate that there are many compounds that potentially are found in the environment at higher than toxic concentrations. Limitations include the previously stated weaknesses in relying on laboratory toxicity tests to reflect natural exposures and differences in testing methodology among labs that may affect results. Life stages and duration of tests also are important because of differential sensitivity among stages and because length of exposure may greatly alter LC₅₀ values. Whereas many laboratory toxicity tests end after 24 or 96 h, free-ranging animals may be exposed for much longer durations or be subject to repeated exposures through time. Third, the table does not report the many instances of nondetects for specific contaminants. The relative frequency of nondetects is biased against totally anthropogenic and short-lived chemicals compared to molecules such as metals that are persistent and also naturally occurring. Fourth, the presence of a substance in sediment may not reflect its bioavailability; it may be bound to sediment particles. Fifth, acute lethality, as demonstrated by the LC₅₀ values, is the ultimate and strongest effect of contaminant exposure. Sublethal or chronic effects, which may reduce the survivorship or reproductive potential of an organism, can occur at concentrations much lower than those necessary for acute toxicity. In view of these caveats, perhaps the greatest value of the table is to clearly indicate the great need for ecologically relevant, cause-and-effect data on amphibian populations and contaminant exposure.

Despite these limitations, a few salient points may be developed:

- In contrast to the 75,000 chemicals manufactured in the United States each year, not including pesticides and the 3000 that are considered high-production-volume chemicals (> 1 million pounds produced),⁸³ toxicity data for amphibians are known for only a very, very small proportion.
- Relationships between ambient concentrations of conventionally used pesticides and effects are poorly known.
- Ambient concentrations are often several times greater than the lethal concentrations, as determined by lab tests, and this difference extends across all categories of contaminants for which there are data.
- Formulations can make a difference. For example, at a given concentration of azinphos-methyl, the formulation Guthion 2S may result in amphibian die-offs, whereas use of the alternative formulation Guthion might not.
- Different life stages of amphibians vary in their sensitivity to the same contaminant. For example, tadpole *Bufo arenarum* are more sensitive than embryos to parathion, and adult *R. pipiens* are less sensitive to TFM than either tadpoles or embryos.

Table 40.1 Median Lethal Concentrations (LC50s) for Various Contaminants in Amphibians that are Near Below Reported Concentrations in the Environment^a

Compound	Ambient Levels		Species	Stage	Dosage	Effect	Reference
	Matrix	Concentration					
Azinphos-methyl	Water	0.71 mg/L	<i>Rana catesbeiana</i>	Tadpole	1.8 kg/ha	100% mortality	165
As Guthion			<i>Hyla regilla</i>	Tadpole	8.7–9.7 mg/L	100% mortality	166
Guthion			<i>H. regilla</i>	Tadpole	4.14 mg/L	96 h LC ₅₀	166
As Guthion 2S			<i>H. regilla</i>	Tadpole	0.8–1.5 m/L	100% mortality	165
Guthion 2S			<i>H. regilla</i>	Tadpole	0.46–0.84 mg/L	96 h LC ₅₀	166
Guthion 2S			<i>Bufo woodhousei fowleri</i>	Tadpole	0.13 mg/L	96 h LC ₅₀	167
Guthion 2S			<i>Ambystoma gracile</i>	Larvae	1.67 mg/L	96 h LC ₅₀	168
Guthion 2S			<i>A. maculatum</i>	Larvae	1.9 mg/L	96 h LC ₅₀	168
Chlorpyrifos	Water	0.68 mg/L	<i>Rana tigrina</i>	Tadpole	10 µg/L	6 days LC ₅₀	169
Fenitrothion	Water	75.5 µg/L	<i>R. catesbeiana</i>	Tadpole	4 mg/L	field mortality	170
Parathion	Water	0.34 mg/L	<i>Bufo arenarum</i>	Embryos	20.2 mg/L	7d LC ₅₀	171
Parathion			<i>B. arenarum</i>	Tadpoles	4.5 mg/L	7d LC ₅₀	171
Temephos			<i>R. clamitans</i>	Tadpoles	4.24 µg/L	96 h LC ₅₀	100
Carbaryl	Water	0.45 mg/L	<i>R. tigrina</i>	Tadpoles	10 mg/L	MRT ^a 110 min.	172
Deltamethrin	Water	2.6 µg/L	<i>B. arenarum</i>	Tadpoles	4.4 µg/L	96 h LC ₅₀	173
Esfenvalerate	Water	1 µg/L	<i>R. blairi</i>	Tadpoles	7.29 µg/L	96 h LC ₅₀	174
Esfenvalerate			<i>R. sphenocephala</i>	Tadpoles	7.79 µg/L	96 h LC ₅₀	174
Atrazine	Water	0.1–480 µg/L	<i>R. pipiens</i>	Tadpoles	14.5–47.5 mg/L	96 h LC ₅₀	175
	Sediment	0–7.3 mg/L	<i>B. americana</i>	Tadpoles	10.7–26.5 mg/L	96 h LC ₅₀	175
Triclopyr		0.1 mg/L	<i>R. clamitans</i>	Tadpoles	2.4 mg/L	100% mortality	170
TFM			<i>Hyla versicolor</i>	Tadpoles	1.98 mg/L	96 h LC ₅₀	176
TFM			<i>R. pipiens</i>	Tadpoles	2.76 mg/L	96 h LC ₅₀	176
TFM			<i>R. catesbeiana</i>	Tadpoles	3.55 mg/L	96 h LC ₅₀	176
TFM			<i>R. pipiens</i>	Tadpoles	0.95 mg/L	96 h LC ₅₀	177
TFM			<i>R. pipiens</i>	Adults	12.99 mg/L	96 h LC ₅₀	177
TFM			<i>R. pipiens</i>	Embryos	1.0 mg/L	arrested development	177
Paraquat	Water	0.17 mg/L	<i>B. woodhousei fowleri</i>	Tadpoles	15 mg/L	96 h LC ₅₀	178
Paraquat			<i>Pseudacris triserata</i>	Tadpoles	28 mg/L	96 h LC ₅₀	178
Rotenone	Water	0.05 mg/L	<i>R. pipiens</i>	Tadpoles	5 µg/L	24 h LC ₅₀	179
Rotenone			<i>R. sphenocephala</i>	Tadpoles	30 µg/L	24 h LC ₅₀	179
Arsenic	Water	0–243 mg/L	<i>Adelotus brevis</i>	Tadpoles	55 mg/L	96 h LC ₅₀	180
Arsenic	Sediment	5–3500 ppm	<i>Ambystoma opacum</i>	Embryo	4.45 mg/L	8d LC ₅₀	181
Arsenic			<i>Gastrophyrne carolinensis</i>	Embryo	0.04 mg/L	7d LC ₅₀	181
Arsenic			<i>R. hexadactyla</i>	Tadpole	0.249 mg/L	96 h LC ₅₀	182

Table 40.1 Median Lethal Concentrations (LC₅₀s) for Various Contaminants in Amphibians that are near below Reported Concentrations in the Environment^a (Continued)

Compound	Ambient Levels		Species	Stage	Dosage	Effect	Reference
	Matrix	Concentration					
Boron	Water	0–0.3 mg/L	<i>B. woodhousei fowleri</i>	Embryo	123 mg/L	8d LC ₅₀	183
Boron	Sediment	10–500 ppm	<i>R. pipiens</i>	Embryo	130 mg/L	8d LC ₅₀	183
Cadmium	Water	0.5 µg/L	<i>G. carolinensis</i>	Embryo	0.04 mg/L	7d LC ₅₀	181
Cadmium	Sediment	0.16 ppm	<i>A. opacum</i>	Embryo	0.15 mg/L	8d LC ₅₀	181
Cadmium			<i>B. arenarum</i>	Tadpole	6.77 mg/L	96 h LC ₅₀	184
Chromium	Water	0–780 mg/L	<i>G. carolinensis</i>	Embryo	0.03 mg/L	7d LC ₅₀	181
Chromium	Sediment	1–25000 ppm	<i>R. hexadactyla</i>	Tadpole	10 mg/L	96 h LC ₅₀	182
Copper	Water	0.001–0.1 mg/L	<i>A. jeffersonianum</i>	Embryo	0.315 mg/L	96 h LC ₅₀	185

^a For empty ambient concentration cells use the preceding concentration for that compound.

- Amphibians are exquisitely sensitive to certain contaminants including chlorpyrifos, temephos, rotenone, silver, zinc, tributyltin, TFM, and endosulfan; laboratory toxicity tests for synthetic pyrethroids had indicated that they also are very toxic, but field trials that allowed for natural attenuation of pyrethroids indicate that the pesticides are less toxic than had been believed.
- For other contaminants, sediment toxicity may be more important than water toxicity due to concentrations in sediment; but very few studies have examined sediment toxicity in amphibians.

40.3.1.3 Do Criteria Developed from Fish Toxicity Data Protect Amphibians?

At present, there are no federal regulatory criteria on toxicants for amphibians. Instead, data from fish studies are often assumed to provide comprehensive coverage and safety. This implies that fish and amphibians are equally sensitive to the toxicants for which criteria have been established. Birge et al.⁸⁴ compared the toxicity of a variety of amphibians and organic compounds or metals to that of fish species commonly used in toxicity tests such as the rainbow trout (*Oncorhynchus mykiss*), fathead minnow (*Pimephales promelas*), and largemouth bass (*Micropterus salmoides*). Comparisons were standardized as much as possible including comparable life stages, water chemistry, and durations. Twenty-eight species of native amphibians from the families of Ambystomatidae, Microhylidae, Hylidae, Ranidae, and Bufonidae and the African clawed frog (*Xenopus laevis*) were included in these tests. Median lethal toxicity values for metals in amphibians varied by 100-fold in amphibians (e.g., Hg — 1.0 µg/L in *Gastrophyrne carolinensis* to 103 µg/L in *Ambystoma opacum*). In all, 50 metals and inorganics were tested, as were 13 organic compounds, for a total of 694 amphibian/fish comparisons. Their results showed that amphibians had lower LC₅₀ values than fishes in:

- 64% of all the tests
- 74% of the comparisons among the 15 most sensitive amphibian species and fishes
- 80% of the comparisons involving amphibians and warm-water fishes
- 66% of the 13 most metal-sensitive amphibians and rainbow trout, and
- 74% for all amphibian species vs. the fathead minnow

The researchers' overall conclusions were that there was great variation among amphibian species in their sensitivity to metal and organic contaminants, that amphibians generally were more sensitive than fish, and that water-quality criteria established for fish may not be protective of amphibians. From the perspective of population declines, these data also demonstrate that amphibian responses to contaminants may not be predictable from responses of fishes.

Bridges and Semlitsch⁸⁵ recently added another conundrum into the attempt to simplify understanding the effects of contaminants on amphibian populations. Through a well-designed study, they demonstrated that significant differences in sensitivity to contaminants such as the pesticide carbaryl can occur at all demographic levels — among closely related species, among populations of the same species (*R. sphenoccephala*), and even among families within the same population. Thus, using a standard toxicity value for amphibians as a whole can be very misleading.

40.3.2 Sublethal Effects and Interactions between Contaminants and Other Factors

Contaminants have a host of sublethal effects that, while not overtly killing an animal, may weaken it and make it more vulnerable to other factors. Thus, they interact with the other factors that have been related to amphibian population declines. Figure 40.3 graphically illustrates this. High concentrations of a chemical induce acute mortality. Lower concentrations, if sufficiently persistent in the environment or presented as episodic events, may induce mortality but over a longer period of time, often resulting in inconspicuous die-offs. At still lower concentrations, the effects of the contaminants may present themselves in one or more sublethal mechanisms (on the

Figure 40.3 Schematic demonstrating the decreasing direct effects of contaminants on amphibian populations and the increasing potential for interactions with other factors. At high exposure concentrations the potential for interactions is low because animals die quickly. As concentrations decrease death or ill effects take longer to manifest and the possibility of interactions with other limiting factors increases. Mechanisms through which sublethal effects and interactions take place are shown to the left of the chart.

left side of the chart) that can interact with other factors (bottom of chart) to induce population declines, often with ambiguous and confusing causes.

40.3.2.1 A Brief Synopsis of Sublethal Mechanisms in Amphibians

There is not sufficient space in this chapter to discuss all the ways contaminants may affect amphibians. Many of these effects are consistent with other, better studied species or are presented in more exhaustive reviews.¹⁵ This section briefly covers physiological effects, genetic damage, behavioral effects, problems with development including malformations and decreased energy efficiency.

40.3.2.1.1 Effects on Expected Physiological Pathways

Contaminants that have been studied in other vertebrates affect predictable physiological pathways. For example, organophosphorus and carbamate pesticides block cholinesterase and disrupt normal functioning of the nervous system, which results in loss of neural control. Overt signs of this disruption may include loss of coordination, listlessness, and convulsions. Available data show that amphibians are affected in similar ways as other vertebrates by these pesticides. Heavy metals chelate with enzymes to disrupt physiological pathways and cause histological damage in some organs;⁸⁶ low pH affects ion balance^{73,87} as does nitrate and ammonia compounds;⁸⁸ aluminum binds with phosphorus and prevents its uptake, resulting in rickets.⁸⁹ In these cases, the responses of amphibians should be qualitatively similar to those of other vertebrates, especially fish. In contrast to birds and particularly mammals, however, the mixed-function oxidase system of amphibians appears to be less developed and induction of P450 responses less pronounced.^{90,91} Mixed-function oxidases are involved in the metabolism of cellular toxins and the hydrolysis of some organic contaminants such as certain pesticides, PAHs, and PCBs. Because the degradates of these compounds may be more toxic than their parent form, diminished ability to metabolize the parent form may not necessarily be bad, and the responses of amphibians to these compounds may differ from that of homeotherms. In general, anurans have relatively low sensitivity to PCBs compared to other

vertebrates, especially mammals.⁸² In other cases, scientists can expect amphibians to respond to contaminants in ways similar to fish and birds, and existing knowledge of effects and bioindicators is transferable.

40.3.2.1.2 Genotoxicity

Organic contaminants can induce chromosomal and DNA mutations, at least in somatic cells.⁹² These mutations can alter cellular functioning and impair survival. Genotoxic effects in amphibians have been reported for herbicides,⁹³ other pesticides,⁹⁴ PCBs,⁹⁵ wastewater,⁹⁶ and PAHs.⁹⁷ The effects of some PAHs can be enhanced by 100-fold or more by irradiation by ultraviolet light^{98,99} (see Section 40.3.2.2.5, Photoenhanced Toxicity).

40.3.2.1.3 Effects on Behavior and Development

There are several laboratory studies that have shown a decrease in activity related to contaminants. For example, temephos, an organophosphorus insecticide, reduced the activity rate of *R. sphenoccephala* tadpoles and produced distinct diphasic activity cycles in relation to dose.¹⁰⁰ Maintenance of equilibrium in tadpole *R. catesbeiana* was upset by the pesticide malathion at the lowest concentration tested (500 µg/L).¹⁰¹ Development was also delayed in this species at 1000 µg/L. Chlorpyrifos (0.1 mg/L) reduced swimming speed and startle responses in *Hyla versicolor* when prodded; lethargy and abnormal feeding behavior were even more pronounced when low doses of atrazine (0.2 mg/L) and metolachlor (0.25 mg/L) were added to reflect a common exposure paradigm of herbicides and insecticides.⁵⁶ In a classical conditioning experiment, *R. catesbeiana* and *R. clamitans* avoidance–preference responses were impaired by exposure to 750 µg Pb/L for 120 h, indicating that tadpoles had poorer learning and retention when exposed to lead.¹⁰² The authors also noted increased variation in locomotor activity with animals at 625 µg Pb/L or more, demonstrating spontaneous spurts of activity not seen in controls.

Statistically slower developmental times, which could be caused by many physiological and behavioral factors, have been observed in response to atrazine in *H. versicolor*,¹⁰³ tiger salamanders (*Ambystoma tigrinum*),¹⁰⁴ and other species. Similarly, developmental effects occur with chromium,¹⁰⁵ triphenyltin,¹⁰⁶ dioxins,¹⁰⁷ acidification and aluminum,^{48,68} and a host of other contaminants.¹⁵ Reduced developmental rates may expose tadpoles to drying wetland conditions and may affect survival in other ways.^{108–110} Some contaminants such as the herbicide acetochlor may accelerate development, presumably by stimulating the thyroid or interacting with corticosterone.¹¹¹

Amphibians that undergo complete metamorphosis are potentially excellent candidates to study and screen for endocrine-disrupting chemicals, especially those that affect the thyroid.¹¹² Thyroid stimulating hormone (TSH) and tri-iodothyronine (T₃) are the overall regulators of the climax stage of metamorphosis,¹¹³ although their actions may be modified by other hormones.¹¹⁴ Because thyroid action can be affected by several contaminants,^{111,115} metamorphosis can be altered by exposure to these chemicals and can also serve as a useful endpoint in screening potential thyroid disruptors. Sex hormones also may be affected by contaminants in amphibians, as they are in other organisms,¹¹⁶ and these effects may directly impinge on reproduction. Recently, Hayes et al.²⁰⁰ showed that atrazine may be a potent endocrine disruptor; concentrations as low as 0.1 ppb significantly increase the incidence of ovitests in *Xenopus laevis*.

40.3.2.1.4 Contaminants and Amphibian Malformations

Considerable research attention has been given to amphibian malformations over the past few years because they have recently attracted public attention and become more widespread than when they were first seen by a group of students in 1995, but the problem does not appear to be a completely new phenomenon. In fact, malformations in amphibians have been described for more

than 300 years.¹¹⁷ Clearly, one cause of missing and supernumerary limbs and portions of limbs is parasitism from trematodes.¹¹⁸ However, parasitism does not explain all the incidents of high frequencies of malformations, and considerable evidence also points to waterborne chemicals as another cause.^{119–121} Although the malformations of greatest current interest primarily involve the hindlimbs, there are many different kinds of malformations including missing and supernumerary forelimbs, abnormal mouths, spinal problems, and internal abnormalities.¹¹⁷ Several contaminants have been linked to malformations including chlorinated hydrocarbon pesticides,^{122,123} boron,¹²⁴ atrazine,¹²⁵ ammonia,¹²⁶ coal ash effluent,^{127–129} methyl-parathion and pirimicarb,¹³⁰ methoprene derivatives,^{100,131} maneb,¹³² several pharmaceuticals and organic contaminants,^{133,134} and metals (see Reference 135 for review). Many of these compounds can cause malformations at environmentally realistic concentrations and decrease the survival of affected individuals. In a recent study, Kiesecker²⁰¹ found that environmentally realistic concentrations of malathion interacted with trematode infestations to significantly increase the incidence of malformations in native amphibians compared to trematodes alone. However, the malformations seen in the wetlands of Minnesota and elsewhere often differ in important details from the types of malformations produced in laboratories.

40.3.2.1.5 *Effects on Energetics*

Rowe et al.¹³⁶ found that *R. catesbeiana* tadpoles collected from wetlands contaminated by effluent from coal ash retaining ponds had standard metabolic rates that were 40–175% greater than similarly aged tadpoles collected from clean sites. Assuming that an organism's energy allocations are finite and divided among growth, storage, maintenance, and reproduction, higher metabolic rates could leave less energy for growth or reproduction. Alternatively, tadpoles would be required to spend greater time foraging and less time on other activities such as predator avoidance and resting.

Adult *R. ridibunda* that were exposed to 200 mg/L Cd in solution for 30 days showed signs of metabolic stress in the liver for the first 10 days, after which protective mechanisms, including the synthesis of metallothioneins and glutathione, were initiated; by 30 days of exposure, most liver parameters returned to normal.¹³⁷

An indirect relationship was developed between toxicity of carbaryl and metabolism in *R. clamitans* tadpoles.¹³⁸ Because amphibians are poikilothermic, barring behavioral changes, metabolic rate is directly related to ambient temperature. Carbaryl was significantly more toxic at 27°C than at 17 or 22°C. At 27°C, lethal concentrations approached expected ambient concentrations, whereas the concentration needed to significantly increase mortality at 17°C was appreciably higher than anticipated environmental levels. Mudpuppies (*Necturus maculosus*) living in streams contaminated with a variety of organochlorines including PCBs and pesticides had lower liver glycogen concentrations than those inhabiting cleaner streams; liver glycogen can be a major energy reserve for vertebrates and is influenced by corticosterone, which, in turn, was experimentally shown to be altered by PCB exposure.¹³⁹

40.3.2.2 *Evidence for Interactions between Contaminants and Other Factors Associated with Amphibian Population Declines*

Except in very simple ecosystems, it is very rare for only one factor to restrict the growth or survival of a population. Whereas a factor may be limiting for a certain period, through the course of time many constraints may affect a population, and their effects may be interactive. Thus, contaminants may cause added stress to individuals in a population, which makes them more vulnerable to parasites or disease. Similarly, a contaminant may alter behavior to make animals more vulnerable to predation or less competitive. Stress due to sublethal effects of an herbicide may increase metabolic demands at the same time the herbicide is decreasing food supply. Therefore, the actual causes of population declines may be difficult to discern. This section examines

the potential interaction of biological factors of disease, predation, and competition and nonbiological aspects of habitat composition and solar radiation with contaminants to negatively affect amphibian populations.

40.3.2.2.1 Interaction with Disease Agents

It is clear that disease is associated with amphibian population declines. Not clear, however, is why disease organisms, which presumably have been associated with amphibians for many years, should suddenly be significant in global declines of these animals. The possibility that contaminant-caused stress may reduce the immunological defenses of amphibians periodically has been raised.^{17,140} Unfortunately, the relationship between contaminants and immunosuppression in poikilothermic vertebrates has been studied very little.¹⁴¹ Captive, adult male Woodhouse's toads (*Bufo woodhousi*) were experimentally exposed to sublethal concentrations (0.001 and 0.011 mg/g) of commercial-grade, formulated malathion and the bacterium *Aeromonas hydrophila*, the organism responsible for red leg disease.¹⁴¹ No deaths occurred over the 30-day test period among controls injected with saline or among animals injected with the low dose of malathion alone. When toads were exposed only to *A. hydrophila*, mortality rose to 20%, and at the high rate of malathion alone it was 40%. Toads that were exposed to both *A. hydrophila* and malathion had 80% mortality at the low dose and 100% at the high. Moreover, occurrence of hepatomegaly (enlarged liver) went from 40% for the high dose of malathion alone (0% for control, low dose, and *A. hydrophila* alone) to 80 and 100% when both malathion and *A. hydrophila* were presented.

40.3.2.2.2 Interaction with Predation

Because of interspecific differences in sensitivity to contaminants, predator/prey relationships within a polluted wetland may be affected due to changes in species composition, to lethargy and impaired escape responses by prey, or to other factors. For example, fish species tend to be more sensitive to acidification than many invertebrates. Thus, a reduction in the abundance and species richness of fish may open a wetland for greater densities of predacious invertebrates. While reduction in the abundance of fish might seem of benefit to amphibians, many invertebrates, such as odonates, notonectids, corixids and dytiscids, are important predators on amphibian eggs and small larvae. Henrikson¹⁴² discussed the effects of a change from fish to large invertebrates as chief predators on amphibian eggs and early larvae and showed that the predator/prey relationships in acidified wetlands are complex. Insects tended to avoid eggs of *R. arvalis* because of a thick jelly. *Bufo bufo* eggs were avoided by insects with chewing mouth parts but not those with sucking mouth parts. Tadpole *R. arvalis* were readily depredated by insects and by the newt *Triturus vulgaris* but *B. bufo* were not because of lower palatability. Fish, on the other hand, might not be as particular in their selection of eggs.

Tadpole Columbia spotted frogs (*R. luteiventris*) that were exposed to water from an aquarium that held tadpole-eating fish sought cover more often and reduced movements compared to those exposed to water with fish that had not eaten tadpoles.¹⁴³ Reduced movements and seeking cover were considered as antipredator behaviors. When zinc (7.4 ppm), lead (0.11 ppm), or high levels of metal-laden soil taken from a Superfund site were added to the test chamber, tadpoles did not show antipredatory behavior. Simultaneous presentation of lead and zinc had greater effects on the tadpoles than either metal alone.

Coal ash, which is the by-product of coal combustion in energy production, is a common source of pollution in the United States.¹⁴⁴ Because all of the combustible carbon has been burned off, coal ash has high concentrations of inorganic metals and minerals. Typically, coal ash is pumped into basins where it settles, but the surface waters eventually enter natural waterways. Exposure to water coming from settling basins decreased movement and escape responses in *R. catesbeiana*

tadpoles. When exposed tadpoles were experimentally housed with a snapping turtle (*Chelydra serpentina*), their survival was only 6% after 3 days compared to 97–100% among controls.

Tadpole green treefrogs (*Hyla cinerea*) showed a higher mortality rate when aluminum was added to pH 4.5 water compared to controls or aluminum at pH 5.5; growth of the tadpoles was reduced at both pH levels.²⁰² When dragonfly nymphs were added to the test units, they depredated at a higher rate in water with 150 µg/L aluminum and pH 4.5 than without aluminum. The authors attributed the higher rate of predation to a slower growth rate of tadpoles, which kept them at a vulnerable size longer than controls.

A recent paper¹⁴⁵ clearly demonstrated both the longer-term effects of pesticide exposure in *H. versicolor* tadpoles and a relationship between predation and pesticide effects. The 96-hour LC₅₀ of carbaryl in amphibians ranges from 2.5 to 20.6 mg/L. However, after 10 days, 0.09 mg/L carbaryl resulted in 90% mortality and 0.05 mg/L in 60% mortality in laboratory tests. Moreover, at the lower dose, the presence of a caged larval salamander (*Ambystoma maculatum*), which is a predator on tadpoles, resulted in 100% mortality of *H. versicolor* tadpoles after 8 days. Activity and growth rates were also suppressed both by the low and high concentrations of carbaryl and by the presence of a predator under the low concentration. At the low carbaryl concentration, there was an interaction between presence of predator and chemical treatment. No predator effect was observed at the high concentration of carbaryl because the pesticide alone was sufficient to reduce growth and survival.

40.3.2.2.3 Interactions between Contaminants and Competition

As with predation, differences in sensitivity to contaminants among amphibian species and between amphibians and nonamphibian competitors may alter community composition and affect species richness. Poor, relatively tolerant competitors may outperform more sensitive species under polluted conditions. For instance, *R. clamitans* tadpoles, which did not show a response to acidification or the addition of aluminum in field tests, were more abundant in ponds that had been treated with aluminum and acid than in control ponds, possibly due to release from competition with other sympatric species that showed significant decreases in relative abundance to acidification.⁴⁶

As an example, *H. gratiosa* and *H. femoralis* are sympatric species in the southeast United States. Of the two, *H. femoralis* seems to be more acid-tolerant than *H. gratiosa*.¹⁴⁶ *H. gratiosa* also tends to show pronounced responses to intraspecific competition in that growth rates and age at metamorphosis are density-dependent. At circumneutral (6.0) pH, the presence of both species resulted in reduced growth and increased time to metamorphosis for *H. gratiosa*. At this pH, the survival rate of *H. gratiosa* was also lower when *H. femoralis* was present than when it was not. In general, *H. femoralis* tended to do better at low pH, where *H. gratiosa* may have been at a competitive disadvantage. Pehek¹⁴⁷ saw that competition between *H. andersonii* and either *R. sphenoccephala* or *H. versicolor* resulted in decreased survival and body mass of *H. andersonii*, but that pH (3.9 vs. 5.9–8.4) had no effect on any of the species or on competitive effects.

Heavy-metal concentrations may alter the competitive balance between snails and tadpoles, both of which feed on detritus and algae.¹⁴⁸ Snails (*Lymnaea pulustris*) were not measurably affected by the presence of zinc, cadmium, or lead, but tadpole *R. lutriventris* took longer to metamorphose. In the absence of heavy metals, the presence of tadpoles resulted in decreased snail recruitment. Competition between snails and tadpoles led to shifts in feeding locations and higher heavy-metal concentrations in tadpole tissues than when competition did not occur. Interspecies interactions were even more complex when a fish predator (*Lepomis macrochirus*) was added.

40.3.2.2.4 Interactions with Habitat Characteristics

Habitat characteristics for aquatic stages of amphibians include water chemistry and presence of multiple contaminants, food, and shelter, some of which have been discussed above. For terrestrial amphibians, habitat may involve landscape features such as travel lanes, juxtaposition and

interspersed of breeding ponds, forests, cropland, and other factors. The type of habitat a species occupies may provide clues to the types of contaminants it's likely to encounter. For example, amphibians inhabiting agricultural areas may be more subjected to pesticides than those inhabiting forested vernal pools. Amphibians such as *R. clamitans* or *R. catesbeiana* that breed in semipermanent or permanent ponds may be subjected to different forms of pollution than stream-breeding *Ambystoma* species or *R. sylvatica* that breed in vernal wetlands. The study of interactions among contaminant exposure, survival, and landscape features is in its infancy, but several researchers are beginning to work in this area.

Perhaps the most pertinent study of this kind to date was conducted by Bunnell and Zampella.¹⁴⁹ Using detrended-correspondence analysis and principal-component analysis, they found a primary gradient predicting the distribution of anurans in New Jersey that was formed by increasing pH and emergent herbaceous vegetation and decreasing specific conductance. The authors concluded that landscape patterns influence the distribution of adult anurans, whereas pond chemistry limited recruitment. Other studies have shown that movement patterns between water and terrestrial habitats are nonrandom,⁴¹ that there are important species differences in use patterns of aquatic and terrestrial habitats,¹⁵⁰ and that terrestrial habitat characteristics are important factors in predicting amphibian occurrence, even for highly aquatic species.^{151,152} Given that terrestrial and habitat landscape features are important to the distribution of amphibians, additional research on how contaminants interact with these habitat characteristics becomes critical.

40.3.2.2.5 Photoenhanced Toxicity

Recent findings on the interactions between ultraviolet radiation and contaminant toxicity raise very interesting and alarming possibilities. Most acute toxicity tests have occurred under laboratory conditions with artificial lighting. However, studies have shown that the toxicity of some chemicals, including pesticides and PAHs, may increase by 400 times in the presence of ultraviolet radiation, particularly UV-B.¹⁵³ Photoenhanced toxicity can occur either through photodegradation of parental forms of contaminants into more toxic degradates or through sensitizing organisms to contaminants.¹⁵⁴ Photodegradation can occur, for example, with several organic contaminants commonly found in petroleum such as PAHs.¹⁵⁵ Photoenhanced toxicity has been identified in fish, aquatic insects, and macrophytes.¹⁵⁶ Due to atmospheric depletion of ozone, some parts of the world are now exposed to greater ultraviolet radiation than they have been historically.¹⁵⁷ Thus, there could be an interaction between ultraviolet radiation and contaminant toxicity. This is particularly relevant to amphibians whose population declines are occurring in montane areas, where the strength of ultraviolet radiation is greater than at sea level.

The toxicity of at least one carbamate insecticide — carbaryl — is enhanced under UV-B exposure in frogs,¹⁵⁸ but most other pesticides have not been tested. Mortality and swimming activity of *H. versicolor* were reduced by exposure to either carbaryl and realistic doses of UV-B compared to controls, but when both were present, the effects increased dramatically. Without UV-B (but UV-A present) 96-hour mortality in *H. versicolor* embryos ranged from 0 to 76.7% after 4 days with carbaryl concentrations ranging from 0 to 15 mg/L. No mortality was observed with just UV-B and no carbaryl. When UV-B and carbaryl were combined, mortality soared to 93% after 2 days. Significant interactions between UV-B and carbaryl were also seen in *H. versicolor* tadpoles; for example, mortality increased from 20% after 4 days at 1.24 mg/L carbaryl alone to 93.3% after 2 days with the same amount of carbaryl and low (4 $\mu\text{W}/\text{cm}^2$) UV-B. Increased toxicity of carbaryl in *Xenopus laevis* tests appeared to be due more to photoactivation than to photosensitization in that pre-irradiated carbaryl was more toxic than nonirradiated carbaryl, and there was no difference in mortality between embryos that had been exposed to carbaryl and then irradiated and those that were not exposed to UV-B.

Larval *R. sphenoccephala* were exposed to water-soluble fractions of weathered petroleum distillates collected from an abandoned oil field and then either to UV-B or lighting without UV-B.¹⁵⁹

All of those that were exposed to both distillates and UV-B died within 4 days, even at 5% distillate concentration; in contrast, none of the animals died when exposed to the distillates without UV-B or with UV-B but no distillates.

The genotoxicity of PAHs, as determined by the frequency of micronucleated red blood cells, can increase by more than 100 times when UV-B is present. Mature amphibian red blood cells are nucleated and certain genotoxic chemicals result in small nuclei due to chromosomal breakage and loss. Benzo[a]pyrene, a common constituent of oil and incompletely combusted fuels, had no apparent toxicity in the newt *Pleurodeles waltl*, even at 500 ppb when UV-B was not present. When the newts were tested in daylight, however, significant increases in micronuclei frequency resulted at 500 ppb, and even at 25 ppb, with the addition of UV-A radiation. Photosensitization may have been the primary mechanism for this increased toxicity in that pre-irradiation of benzo[a]pyrene reduced the toxicity of the chemical, but animals that had been exposed to nonirradiated benzo[a]pyrene and then post-irradiated showed significant increases in toxicity compared to newts that did not receive post-irradiation. Photoenhancement of toxicity was also observed for benz[a]anthracene, 7,12-dimethyl-benz[a]anthracene and benz[a]anthraquinone.^{98,99} Similarly, UV-B-irradiated fluoranthene, a common PAH in sediments, is significantly more toxic to amphibian embryos and tadpoles than fluoranthene without UV-B.^{160,161}

Photoenhanced toxicity is potentially more important to amphibian population declines than direct effects of UV-B. Because most toxicity studies have occurred under laboratory conditions without the presence of UV-B and only low amounts of UV-A, published LC₅₀ values for chemicals that can be photoactivated or to which photosensitization occurs may be an order of magnitude or greater than lethal concentrations in the field. Pesticide concentrations in pristine areas of the Sierra Nevada,^{162,163} for example, were thought to be sublethal. If photoenhanced toxicity is occurring, the measured values may be well within the actual lethal range for the amphibians that are declining there. While tadpoles can alter behavior to avoid direct sunlight,^{36,38} avoidance of water contaminated with photoactivated chemicals may be more difficult. Also, some species of tadpoles have mechanisms to repair photodamaged cells¹⁶⁴ but might not have the ability to recover from chemical exposure.

40.4 CONCLUSIONS

Although there are no published studies that demonstrate beyond all doubt that contaminants are involved in long-term population declines of amphibians, there is ample evidence and reason to encourage active research and concern about effects. Many contaminants are lethal to amphibians at environmentally realistic concentrations. Acute mortality from these compounds may be difficult to detect because investigators would have to be present shortly after exposures. Chronic mortality may be masked by metapopulation phenomena, so that areas that serve as population sinks may be repeatedly recolonized and difficult to identify. Metapopulation dynamics also make it more difficult to define discrete populations. Contaminants also have many sublethal effects on behavior, energetics, malformations, and diverse effects on physiological pathways which by themselves might not lead to overt death but could alter reproduction or interact with other factors to result in gradual declines in populations. Scientific understanding of these interactions, and of the ecotoxicology of amphibians in general, is far behind what is known about birds, fish, and mammals, and research is desperately needed in this area. Some specific suggestions for critically needed research include:

- Determination of lethal concentrations of common contaminants — pesticides, PAHs, metals — under environmentally realistic conditions of light, temperature, and water chemistry
- Better understanding of the effects of long-term (weeks, months), low-concentration exposure of persistent pesticides and stable contaminants on amphibians

- Development and refinement of bioindicators in amphibians to use in monitoring and screening for potential effects of contaminants in declining amphibian populations
- Further studies on the interaction between contaminants and disease agents including immunosuppression in amphibians
- Additional research on the interaction between ultraviolet radiation — both UV-A and UV-B — and a broader range of contaminants
- Development of models to assess risk in amphibians as related to landscape factors and especially in the aquatic–terrestrial interface
- Population survival requires that organisms survive through their entire life cycle; to date, there have been no studies examining the responses of amphibians to contaminants in all phases (egg, embryo, larvae and adult) of their life cycles.

“... it is important to take genetics into account in understanding if and how chemical contaminants impact populations.”

Peter Calow¹

41.1 INTRODUCTION

“Understanding changes to the genetic apparatus of an organism exposed to contaminants in the environment is essential to demonstrating an impact on parameters of ecological significance such as population effects. That field of environmental science that attempts to (a) identify changes in the genetic material of natural biota that may be induced by exposure to genotoxicants in their environment and (b) the consequences at various levels of biological organization (molecular, cellular, individual, population, etc.) that may result from this exposure is termed genetic ecotoxicology.²

Within genetic ecotoxicology, it is critical to realize that there are two possible classes of effects. First, there are effects that occur in the somatic or reproductive tissues of an organism. These effects are the result of direct exposure to a genotoxicant and have the potential to lead to somatic or heritable (genotoxicological) disease states. Another class of effects results indirectly from contaminant stress on a population and leads to alterations in the genetic makeup of populations, a process termed evolutionary toxicology.³ These latter types of effects alter the inclusive fitness of populations, such as by the reduction of genetic variability, and can potentially have profound impact on biomarker studies.⁴ For example, populations inhabiting contaminated and reference sites might be adapted to different environmental conditions and thus respond differently than expected in such studies.

With respect to genotoxicology (“a” above), it is now possible to identify molecular targets of genotoxicants with extreme sensitivity and to determine how chemical modifications of these targets affect function at a precise molecular level.⁵ For several reasons, approaches and studies related to “b” above are not as far advanced. First, a major challenge has been to develop assays with the sensitivity to demonstrate those subtle changes in the genetic material of organisms exposed to genotoxicants that may be genetic markers of population effects.^{6,7} However, recent advances in the discipline of molecular biology may provide the experimental tools with which to investigate those key biological mechanisms at the genetic level that regulate and limit responses of ecological relevance.^{8,9} Second, most studies performed *in situ* are often burdened by complicating environmental factors. Individual genetic variability within a population, population size, and exposure to complex mixtures are just a few of the many problems that must be addressed in order to interpret data generated by the sophisticated methodologies currently in use.

This chapter is divided into three main sections. The importance of understanding contaminant-induced DNA damage and related effects in relation to population-level studies is covered in Section 41.2, Genetic Effects. Section 41.3, Environmental Population Genetics, focuses mainly on new methodologies applicable to population genetic studies. Finally, Section 41.4, Case Histories, details several different investigations that provide insight on how chemical contaminants may impact populations.

41.2 GENETIC EFFECTS

41.2.1 Introduction

Within a cell, the structural integrity of the DNA molecule is in a constant state of flux between a functionally stable double-stranded entity without discontinuity and some intermediate, unstable state. This latter state is a transient phenomenon triggered by normal cellular processes. However,

Table 41.1 Cellular Responses after Exposure to Genotoxicants

Biological Response	Expression in Cell	Temporal Occurrence ^a
Detoxication	Protein induction: P450 enzyme system and metallothionine	Early
DNA Structural Modification		
Adduct	Covalent attachment of genotoxicant to DNA	Early
Strand Breaks	Breakage of DNA phosphodiester linkages	Early
Base Modification	Hypomethylation and chemical modification of bases	Early/Middle
Repair	Induction of DNA repair enzymes	Early
Abnormal DNA	Apoptosis	Early/Middle
	Chromosomal aberrations, micronuclei, aneuploidy, mutations	Middle/Late
Pathological Conditions	Neoplasia, tumors, and protein dysfunction	Late

^a Temporal occurrence subsequent to exposure will depend on species of and type of genotoxicant. Early: hours to days; Middle: days to weeks/months; Late: weeks/months to years. (Source: From Shugart, L.R., *Ecotoxicology*, 9, 329, 2000. With permission.)

these processes can be disrupted when exposure to a genotoxicant occurs, often with the concomitant loss of structural integrity of the DNA molecule. Some of the cellular responses that may be expressed after exposure to genotoxicants are given in Table 41.1. The organism's inability (whether transient or permanent) to cope with loss of structural integrity provides the investigator the opportunity to detect environmental exposure to a genotoxicant. In addition, the occurrence of DNA damage provides a means to investigate the qualitative and quantitative relationships between the formation of DNA damage, subsequent DNA processing, appearance of deleterious lesions, and irreversible effects on reproduction and fitness. The reader is referred to the scientific literature for current reviews on this topic, in particular those of Shugart,¹⁰⁻¹² Shugart et al.,¹³ Dixon and Wilson,¹⁴ and Wirigin and Theodorakis.¹⁵

41.2.2 Types of DNA Modifications

A summary of some of the more common DNA structural modifications that occur when a genotoxicant becomes bioavailable and interacts with cellular DNA is recorded in Table 41.2. Two general classes of structural modifications can be inferred from the information contained therein. First, there are those modifications that identify the specific genotoxicant responsible for the structural modification. For example, ultraviolet light in the 290–300 nm range (UV-B) causes specific dimerization of pyrimidine bases within the DNA. Also, many chemicals, such as the polycyclic aromatic hydrocarbon (PAHs) and benzo[a]pyrene (BaP), can form an adduct with the

Table 41.2 DNA Structural Modifications Caused by Genotoxicants

Genotoxicant	Type of Modification	Mechanism
Physical	Thymine-Thymine Dimer	Dimerization of pyrimidine bases by UV-B light
	Strand Breakage	Breakage of phosphodiester linkages due to formation of free radicals by ionizing radiation
Chemical	Adduct	Covalent attachment of genotoxicant to DNA molecule
	Altered Bases	Chemical modification of existing bases
	Abasic Site	Loss of chemically unstable adduct or damaged base
	Strand Breaks	Breakage of phosphodiester linkages due to formation of free radicals and abasic sites
	Hypomethylated DNA Mutation	Improper postreplication Improper DNA repair

Source: From Shugart, L.R., *Ecotoxicology*, 9, 329, 2000. With permission.

DNA. After metabolic activation, the BaP becomes covalently attached to the DNA. In both examples, the structural modification represents a specific fingerprint of the responsible genotoxicant. Second, there are those structural modifications that, although not specific to a particular genotoxicant, nevertheless suggest that exposure has occurred (e.g., breakage of the phosphodiester backbone of the DNA molecule). Strand breakage of the DNA can result when a genotoxicant produces free radical or forms an abasic site or sites. Also, many genotoxicants are known to interfere with normal DNA processing activities such as replication, methylation, and repair, which in turn may result in mutations (e.g., base addition/deletion). The detection of nonspecific structural modification (e.g., strand breaks, abasic sites, hypomethylation and mutations) may imply genotoxicant exposure, especially if the level or degree of these types of modification to the DNA molecule is not what might be anticipated (e.g., when compared to controls).

41.2.3 Detection of DNA Modifications

41.2.3.1 DNA Adducts

Detection of structural damage to DNA such as adducts is not an easy task, for several reasons. First, environmental genotoxicants are usually present at low concentrations and once they become bioavailable are readily detoxified.¹⁶ Therefore, the potential for *in situ* DNA damage is not high, and the amount that is found is often on the order of one adduct per 10⁷ nucleotides or less. Second, until recently, the analytical technologies with the required selectivity and sensitivity to detect extremely low levels of DNA damage were not readily available. However, the application of modern techniques from the scientific disciplines of biochemistry and molecular biology has begun to alleviate this problem.^{5,14} In this regard, the possible application of DNA fingerprinting using PCR methodologies for the detection of structural DNA damaged, including adducts, caused by exposure to genotoxic environmental agents has been addressed.¹⁷

The adverse health effects of most environmental chemicals are the result of their covalent binding to physiologically important receptor molecules. Identification of the interactive products with DNA, especially adducts, can represent the most direct and biologically relevant indicator of exposure to a genotoxicant.¹⁸ Numerous analytical methods to detect and quantify DNA adducts are available,^{12,17} with the ³²P-postlabeling technique being the most used. The methodology is described in detail elsewhere.^{12,14,18} Because the salient features of this technique are sensitivity and selectivity, it is finding increased application in environmental monitoring studies where genotoxic contaminants exist.^{14,18,19} Lists of recent investigations that used the ³²P-postlabeling technique to screen for DNA adducts in organisms taken from contaminated environments are available.^{12,20} It should be noted, however, that this technique is subject to problems that may interfere with the interpretation of the data generated.²¹ Several laboratories from Europe and North America are currently participating in a project to determine the extent of variability with this technique.²²

41.2.3.2 DNA Strand Breaks

Because both physical and chemical genotoxicants have the potential to cause DNA strand breaks,¹² recent environmental studies have included this structural modification as an indicator of genotoxicant exposure. Several of the popular strand-break assays are based on the observation that under *in vitro* denaturation conditions of high pH, the rate of conversion of double-stranded DNA to the single-stranded moiety is proportional to the number of strand breaks in the DNA molecule.²³ Among these are the alkaline elution assay,²⁴ the alkaline unwinding assay,²⁵ the gel electrophoresis method,²⁶ and the comet assay.²⁷ A list of investigations where these techniques have been applied are found in Shugart.¹²

41.2.4 Cytogenetic Effects

DNA damage that is not corrected or is improperly processed may potentiate irreversible cellular events^{14,15} that result in the appearance after cell division of abnormally processed DNA (e.g., chromosomal aberrations, micronuclei, somatic mutations etc., Table 41.1.).

Such cytogenetic effects result in alteration of the chromosome structure or chromosome number. The traditional approach microscopically analyzes condensed chromosomes in metaphase cells to determine the karyotype (i.e., number and appearance of chromosomes). Less laborious and time consuming methods than karyological examination include micronucleus analysis and detection of variation of DNA content among cells by flow cytometry. Micronuclei result from acentric fragments of whole chromosomes that lag at anaphase and subsequently do not become incorporated into either daughter nuclei after cell division but form their own small nucleus.²⁸ Flow cytometry is used to measure the differences in total DNA content among cells that result from the unequal assortment of fragmented or rearranged chromosomal material after cell division.²⁹ Obviously, cytogenetic, micronucleus, and flow cytometric analyses are measuring related phenomena.

41.2.5 Mutations

In addition to cytogenetic effects, faulty repair of genotoxic-induced DNA damage can result in the occurrence of mutations in the DNA molecule (i.e., point mutations, additions/deletions, translocations, etc.). In somatic tissue, mutations in oncogenes and tumor suppressor genes have been associated with the initiation of chemical carcinogenesis. Because these genes are involved in the regulation of cell growth, differentiation, and DNA repair, mutational events in these genes can be correlated with aberrant cellular function, which can then be related to individual- and, it is hoped, population-level effects.^{2,9} Wirgin and Theodorakis¹⁵ discuss recent application of this approach in relation to somatic and heritable effects of environmental contaminants on fish.

41.2.6 Protein Induction

The genetic apparatus of an organism can interact with a genotoxicant in a variety of ways that may not result in structural modification to its DNA (Table 41.1.). The most common response is that which results in the induction of a protein, or sets of proteins, involved with cellular detoxication processes. For example, the organism may perceive⁷ the genotoxicant and modify its physiology, as is found with the induction of the P4501A1 detoxication system.^{15,16,30} The induction of the P4501A1 system can be detected by an increase in enzyme activity or enzyme protein, and the magnitude of induction provides a measure of the degree of interaction of the inducing agent with the aryl hydrocarbon hydroxylase receptor (Ah-receptor) in the cytoplasm of the exposed cell.

Metallothionein is a constitutive protein associated with the maintenance of homeostasis of the trace metals zinc and copper. It is known to play a role in the detoxication of the genotoxic metals cadmium and mercury, and upregulation of the metallothionein gene can serve as an early warning signal of metal-induced toxicity.^{15,16}

A wide range of genotoxic agents can act as inducers (see discussion below).

41.2.7 Genotoxic Agents

A variety of contaminants can induce genotoxic responses. Some chemicals, including PAHs and their nitrogenated or chlorinated derivatives, mycotoxins such as aflatoxins and related compounds, and vinyl chloride typically exert their genotoxicity via formation of bulky adducts.^{18,31-35} However, induction of oxidative damage may be a secondary mechanism of genotoxicity.³⁶ A second class is comprised of those genotoxic chemicals that cause derivatization of nucleotide bases via transfer of methyl or ethyl moieties and includes the potent carcinogens diethylnitrosamine and

methylnitrosourea.³⁷ Another class of genotoxic agents includes metals such as arsenic, cadmium, chromium, mercury, nickel, and lead.^{38,39} There are three possible mechanisms whereby metals may induce genotoxicity. First, some metals, chromium in particular, may adduct nucleotide bases.⁴⁰ Second, there is growing evidence that metals may inhibit repair of DNA damage induced by chemicals or endogenous metabolism.⁴¹ Third, metals may increase levels of oxidative stress via redox cycling and Fenton reactions.⁴² There are also many organic chemicals that can potentiate genotoxicity via oxidative stress induction, and these include cyclic or aliphatic chlorinated hydrocarbons and several classes of pesticides.^{43–46}

Besides chemical agents, there are physical agents that can also lead to DNA damage, most notably several types of radiation. For example, ionizing radiation in the form of high-energy photons (γ - and x-rays), electrons (β -rays), or helium nuclei (α -rays) may be genotoxic. One mechanism by which ionizing radiation can induce DNA damage is via direct interaction of the radioactive particles with the DNA molecule.⁴⁷ This can result in base alterations or breaks in the sugar phosphate backbone. Alternatively, the radioactive particles may interact with water or oxygen molecules, producing oxyradicals.⁴⁸ These radicals may also produce base alterations or DNA strand breaks. Another type of physical genotoxicant is ultraviolet radiation, specifically UV-B. Irradiation of DNA with UV-B may result in covalent attachment of adjacent pyrimidine bases, resulting in so-called cyclobutane dimers.⁴⁹ A secondary genotoxic effect of UV radiation is the production of oxyradicals.⁵⁰ There have been suggestions that other types of electromagnetic radiation (e.g., radio and microwaves) and magnetic fields may also produce genotoxic effects, but this research is equivocal.^{51,52}

41.3 ENVIRONMENTAL POPULATION GENETICS

41.3.1 Introduction

Chemical contamination can cause population reduction by the effects of somatic and heritable mutations as well as nongenetic modes of toxicity.^{2,3,9,16} Although the original damage caused by chemical contaminants may be at the molecular level, there are emergent effects at the level of populations, such as the loss of genetic diversity, that are not predictable based solely on knowledge of the mechanism of toxicity of the chemical contaminants. In this regard, population genetic diversity has been proposed as a bioindicator of a population's vulnerability to natural and anthropogenic stressors, as a record of genotypic variation in the population history and the effects of genotypic changes on the spatial distribution and abundance of populations in a geographic region.

Even though there is an extensive scientific literature in regards to classical Mendelian genetics, protein polymorphism, and DNA-marker studies in the field of population genetics, it is only recently that studies of the effects of pollution on population genetics have come to the forefront.^{53,54}

41.3.2 Genetic Markers

The oldest and most classical genetic marker is the *phenotype*, the visible traits or characters of individuals within a biological species. Phenotypic traits, such as mortality, developmental abnormalities, DNA strand breakage, physiology, and metabolism, stand as valid characters for population studies.

Another approach to population genetic analysis is to examine protein polymorphisms. An electrophoretic methodology, known as allozyme analysis, detects charge characteristics of enzymatic proteins produced by amino acid substitution. Allozyme analysis has been used in the past 20 years to assess the relationship between allozyme genotype and exposure to chemical compounds.⁵⁵ The importance of the methodology to population genetic studies has been reviewed.^{53–55}

Table 41.3 A Comparison of the DNA Marker Methods

Marker	Polymorphic Markers per Reaction	Markers per Genome	Marker Type
RFLP	1–2	1000	Co-dominant
RAPD	4–6	10,000	Dominant/Co-dominant
SSR	3–10	10,000	Co-dominant
AFLP	10–50	>100,000	Co-dominant/Dominant

Table 41.4 A Comparison of the Targets, Resolutions and Costs of Various Methods for Surveying Genetic Diversity in Natural Populations^a

Method	Target	Resolution	Cost (\$)	Development
Allozyme	Nucleus	Low	0.1	Low
Microsatellite	Nucleus	High	3.0	High
RAPD	Nucleus	High	3.0	Low
Single gene sequence	Nucleus	Low-High	30.0	High
RFLP	mtDNA	Medium	100.0+	Low
Single gene sequence	mtDNA	Low-High	30.0	Low
Single gene mutation screen	mtDNA	Low-High	0.5	Low

^a The costs are those involved in screening a single gene for variation, while development refers to the relative effort which must be expended before the collection of information on a new species.

Source: From Bickham, J.W., Sandhu, S., Hebert, P.D.N., Chikhi, L. and Athwal, R., *Mut. Res.*, 463, 33, 2000. With permission.

Recently, the application of DNA sequencing and the polymerase chain reaction (PCR)-based technologies has revolutionized the science of generating high-throughput genetic markers. New genetic-marker systems generated by the PCR methodology with applications to environmental genetics include RFLPs (restriction fragment length polymorphism), RAPD (random amplified polymorphic DNA), SSRs (simple sequence repeats such as mini- and microsatellites), and AFLP (amplified fragment length polymorphism).^{17,53,54} These PCR-derived methods provide the potential to encompass large genomic regions, both coding and noncoding. A limited comparison of the capabilities of the various types of genetic markers is given in Table 41.3.

Since the various methodologies discussed above target different segments of the genome, possess differing resolution (Table 41.3), and involve varied operating and developmental costs, there is no single optimal technique (Table 41.4). Instead, methodological selection for environmental population genetic studies is guided by the problem under investigation.⁵³

41.4 CASE HISTORIES

This section is not intended to review all relevant literature but rather to present several case histories to demonstrate and illustrate (a) the types of techniques and methodologies that were applied to a particular study (b) that exposure to environmental contamination is a possible or likely cause of the population impacts observed, and (c) the kinds of genetic alterations seen or suspected to have occurred.

41.4.1 Allozymes

Differences in allozyme allele frequencies between contaminated and reference sites have been found to occur in many species,^{56,57} and this may suggest that there is a selective advantage to certain genotypes over others in contaminated populations. For example, Gillespie and Guttman⁵⁶

reported that some allozyme alleles were present at a higher frequency in contaminated stoneroller (*Camptostoma anomalum*) populations than in reference populations. Fish with these alleles also had longer survival times when exposed to copper in the laboratory.⁵⁸ *In vitro* enzymatic assays indicated that the enzymatic activity of these particular alleles was less inhibited by copper than that of the alleles that were more prevalent in noncontaminated populations.⁵⁹ This not only linked genotype frequencies with survival (a component of selection) but also demonstrated a biochemical basis for differential susceptibility. On the other hand, selection may not act directly on the allozyme loci themselves, but rather these loci may be closely linked to other genes (e.g., detoxification enzymes, etc.) that impart a selective advantage.

In another series of studies, Newman et al.⁶⁰ found that survival time of eastern mosquitofish (*Gambusia holbrooki*) exposed to heavy metals was correlated with allozyme genotype, particularly glucose-phosphate isomerase (GPI) alleles. Mulvey et al. (1995) went on to find that reproductive performance (number of gravid females and developing embryos per female) in these fish exposed to mercury was dependant on GPI genotype. Such differences in reproductive performance were in accordance with differences in survival among GPI genotypes. However, there was no evidence that such differences in survival and reproduction were related to differential susceptibility among GPI genotypes to enzymatic inhibition by mercury, either *in vitro* or *in vivo*.^{62,63}

Correlations between laboratory exposures and natural populations are not necessarily straightforward. Diamond et al.⁶⁴ found that survival time of metal-exposed *G. holbrooki* was dependent upon allozyme genotype, but this pattern was not consistent among different populations or for fish collected from different years. Indeed, Lee et al.⁶⁵ argued that correlations among broods or other subunits of a structured population may influence observed differences between polluted and reference populations. Consequently, the effectiveness of demonstrating contaminant-induced selection using allozyme may depend on the life-history characteristics, behavior, or local population structure.

In order to address other variables besides contaminant selection, Newman and Jagoe⁶⁶ simulated mercury-driven selection for *G. holbrooki* GPI genotypes. They used simple and complex models to quantify the relative effects of viability selection, random genetic drift and migration on the GPI-allele frequencies, and sexual and fecundity selection. A simple suggested viability selection was a greater determinant than mortality-driven genetic drift, sexual selection, or fecundity selection. They also found that gene flow could abolish the effects of mercury selection on genetic differentiation among populations. In general, their model simulations indicated that changes in allele frequencies may reflect population-level effects of pollution, provided that the system under study is properly understood.

41.4.2 Puget Sound, Washington

It has been known for a long time that exposure to genotoxic agents may lead to neoplastic and preneoplastic lesions, and such patterns have been found in natural populations exposed to high levels of genotoxic contaminants, primarily in fish. Tumor incidence in fish and other aquatic organisms associated with exposure to genotoxic contaminants at a variety of sites throughout the United States including Boston Harbor,⁶⁷⁻⁷¹ the Hudson River,⁷² Elizabeth River, Virginia,⁷³ the Black River in Ohio, and the Great Lakes.⁷⁴ However, perhaps one of the best-studied systems is in Puget Sound, Washington, which includes Eagle Harbor, a site heavily contaminated with PAH-laden creosote.

This system has been found to be contaminated with high levels of PAHs, and PAH adducts were associated with hepatic carcinomas in populations of English sole *Pleuronectes vetulus*.^{75,76} In addition, levels of hepatic DNA adducts have corresponded with known sediment or tissue-contaminant concentrations. In laboratory experiments using sole exposed to sediment collected from Eagle Harbor, PAH adducts demonstrated a linear dose-response function for both PAH concentration and length of exposure.⁷⁷ In native fish populations, these adducts were associated with not only neoplastic lesions but also degenerative and preneoplastic lesions, and such lesions

have shown significant associations with other biomarkers of PAH exposure and effect such as elevated cytochrome P450 and biliary PAH metabolite levels.^{75,76} Additionally, Reichert et al.⁷⁶ have used a molecular epizootiological approach to provide definitive evidence that exposure to PAHs was the etiological agent in development of neoplasms. They found that levels of hepatic DNA adducts were a significant risk factor in the development of neoplasia in feral sole populations.

Further studies employ sequencing of the K-ras oncogene in order to study mutational events associated with neoplastic and preneoplastic lesions in this species.⁷⁸ Hepatic lesion frequencies as well levels of DNA adducts and other PAH-indicative biomarkers were lower in fish collected after the cessation of discharge than were historical data collected when contaminant-generating activities were ongoing. The site has been capped with uncontaminated sediment, and these biomarker and histological endpoints are being used to assess the efficacy of remediation activities of Eagle Harbor.⁷⁹

Besides PAH adducts, other measures of DNA damage have also been examined in English sole from Puget Sound. For example, Malins and Haimanot⁸⁰ found that oxidative DNA damage was highest in livers from sole that were tumorous from contaminated sites, least in sole livers from reference areas, and intermediate in tumor-free fish from contaminated sites. This method also exposed positive associations between levels of oxidized bases and severity of preneoplastic and nonneoplastic lesions in livers of fish from the same area.⁸¹

41.4.3 Sunfish

In 1987, the measurement of DNA strand breaks (see Section 41.2, Genetic Effects) in sunfish was implemented as a biological monitoring technique for environmental genotoxicity.^{82,83} Sunfish were initially collected and analyzed over a period of several years (1987–1992) from a contaminated stream (primarily mercury) and reference stream⁸⁴ as part of a Biological Monitoring and Abatement Program for the U.S. Department of Energy (USDOE) in Oak Ridge, Tennessee. Analyses for DNA strand breaks in sunfish inhabiting these same streams were performed again in 1994–1995 by Nadig et al.⁸⁵ and finally in 1997 by Theodorakis et al.⁸⁶ Data collected indicated that the DNA structural integrity of sunfish from the reference stream was good (few DNA strand breaks) and remained relatively constant over the entire 10-year sampling period. However, levels of DNA strand breaks of sunfish from the contaminated stream fluctuated and varied with time of sampling. DNA damage was high in 1987 but started to decline in 1988. By 1992, the levels of DNA strand breaks were comparable to that found in the sunfish from the reference stream. The data from the 1994–1995 sampling period⁸⁵ indicated a return to the high level of DNA strand breaks observed in 1987. However, by the 1997 sampling period,⁸⁶ no significant DNA strand breakage was noted.

These data, in conjunction with other indicators of stress and toxicity,⁸⁴ suggested that sunfish in the contaminated stream were being exposed to genotoxicants in a recurring manner. An improving aquatic environment, due to the effects of remedial actions implemented by the USDOE during the early years of sampling, was thought to be responsible for the diminution in DNA strand breakage that returned to normal levels observed in 1992. Subsequent release of contaminants into the stream after 1992 resulted in a return to the high levels of DNA strand breaks, which was documented in the 1994–1995 sampling period.⁸⁵ Correction of the problem saw a return to the low levels of DNA strand breaks in the sunfish during the 1997 sampling period.⁸⁶

Theodorakis et al.⁸⁶ extended the investigation of genetic effects in the sunfish to include both DNA strand breaks and chromosomal damage (measured by flow cytometry). In general, chromosomal damage in sunfish appeared to be correlated with mutagenicity of the sediment in the stream and was related to community-level responses (e.g., community diversity and percent pollution-tolerant species). Because responses at several levels of biological organization showed similar patterns of downstream effects, the authors suggested a causal relationship between contamination and observable biological effects.

The studies just described focused mainly on individual-level genetic effect (DNA strand breaks and chromosomal damage) from exposure of sunfish to contamination in their environment.

However, the studies of Nadig et al.⁸⁵ extended this investigation beyond genetic effects at the individual level and examined potential alteration of population genetics. Using DNA markers produced by the RAPD technique (see Section 41.3.2, Genetic Markers), specific and unique genotypes were identified. Two measures of genetic diversity — the band-sharing index and the nucleon diversity index — showed that the sunfish from the contaminated and reference sites were different. Difference in genetic distance between populations was attributed to selection pressure of contaminants. This conclusion was supported by the finding that frequencies of certain unique genotypes in sunfish from the contaminated site correlated with a downstream gradient of mercury.

Taken together, these several studies^{67–86} show that sunfish were experiencing genotoxic stress as a result of exposure to contaminants in their environment. Analysis of DNA structural integrity reflected the level of insult from exposure at the time of sampling, while chromosomal damage data revealed the occurrence of irreversible cellular events as a result of this exposure. The observation that genetic diversity was altered in sunfish populations from contaminated sites compared with those from reference sites suggests that genetic selection occurred in the resident population and was probably due to contaminant effects.

The USDOE Biological Monitoring and Abatement Program in Oak Ridge has collected and archived a wealth of scientific information over the years on such topics as contaminant effects on biological species, waste management, and risk assessment.⁸⁷ This program has, by design, the potential to advance our knowledge in the science of environmental population genetics, but to date it has been noticeably underutilized in this respect.

41.4.4 Mosquitofish

Beginning in 1992, a series of studies was initiated to determine the effects of ionizing radiation on DNA integrity and population genetics of western mosquitofish (*Gambusia affinis*) living in radionuclide-contaminated ponds on the Oak Ridge National Laboratory in Oak Ridge. In the first phase of these studies, DNA strand breakage was measured in mosquitofish exposed to ionizing radiation *in situ*.⁸⁸ This was done by examination of four populations of mosquitofish, two from sites contaminated with radionuclides (Pond 3513 and White Oak Lake) and two from clean sites (Crystal Springs and Wolf Creek). The results of this study⁸⁸ demonstrated that the double-stranded MML (median molecular length of DNA fragments detected by gel electrophoresis) of DNA of the fish from White Oak Lake and Pond 3513 was lower than from either of the two reference sites, indicating a higher degree of DNA strand breakage. Also, the single-stranded MML in the DNA of fish from Pond 3513 was lower than in any other population. It was also found that there was a direct correlation of DNA integrity (i.e., MML) with fecundity at least for single-stranded MML. There were no such relationships observed in the reference sites. These observations imply that resistance to DNA damage carries a fitness component, in that individuals that are better able to prevent or repair DNA damage are at a selective advantage in their environment. However, it could also be argued that this relationship is due to environmental factors. Therefore, the population genetics of these fish were examined to determine if this correlation had a genetic, rather than environmental, etiology.

In the next phase of these studies,⁸⁹ the RAPD technique was employed in order to determine if the certain genotypes could impart a selective advantage in contaminated environments. A total of 142 RAPD bands were identified, and of these 16 were found to be present at a higher frequency in the contaminated sites relative to the reference sites (“contaminant-indicative bands”). The differences in frequency of the contaminant-indicative bands between contaminated and reference populations suggests that these bands may be genetic markers of loci that provide some sort of selective advantage in radionuclide-contaminated habitats. If this were true, it should be reflected in some component of fitness. To test this hypothesis, fecundity was examined in fish from each of the four populations with and without the contaminant-indicative bands. It was found that for seven of the contaminant-indicative bands in Pond 3513 and White Oak Lake, females that displayed

these bands had a higher fecundity than those that did not. This was true for only one band in the Crystal Springs population.⁸⁹ Another component of fitness is survival. Thus, if there is differential fitness between genotypes, then survival should be dependent on genotype for those fish exposed to radiation. To test this hypothesis, mosquitofish were collected from a noncontaminated pond and caged in another noncontaminated pond or in Pond 3513. It was found that for nine of the contaminant-indicative bands, the percent survival of fish with the band was greater than that for fish without the band.⁹⁰

These data imply that the contaminant-indicative bands may be genetic markers of loci that confer some sort of selective advantage in contaminated populations, in this case a higher degree of relative radioresistance. If the amount of DNA damage is a reflection of relative radioresistance, then the relative amount of DNA damage should be dependent on RAPD genotype. Therefore, the MMLs were compared for individuals with and without the contaminant-indicative bands. In order to do this, three separate experiments were performed. The first experiment used fish collected from the four populations described previously and used in determination of band frequencies.⁸⁹ In the second experiment,⁹¹ 30 fish were collected from a noncontaminated pond and exposed to 20 Gy (approximately 12 min exposure time) of x-rays in the laboratory. The third experiment⁹⁰ used the fish from the caging experiment described above. The results from these experiments indicated that for many of the contaminant-indicative bands, the fish that displayed the bands had higher DNA integrity than fish that did not display the bands.

If these bands are indeed genetic markers of loci that confer relative radioresistance, then this should also be reflected in other species exposed to radionuclides. To test this hypothesis, samples of a closely related species, *G. holbrooki*, were collected from two radionuclide-contaminated and two reference sites on the USDOE Savannah River Site (SRS). The population genetic structure of these mosquitofish was examined by the RAPD technique, using the same primers as were used in the Oak Ridge studies.⁹² It was revealed that the frequency of three RAPD markers (i.e., PCR-amplified DNA fragments) was greater in the DNA of fish from contaminated than the reference sites, and the frequency of two markers was greater in the reference than in the contaminated sites. These DNA fragments were the same size and amplified by the same PCR primers used in the ORNL study. Southern blot analysis, using labeled *G. affinis* RAPD bands as probes, revealed that the SRS *G. holbrooki* contaminant-indicative markers were homologous to the ORNL *G. affinis* contaminant-indicative markers.

If these RAPD fragments are genetic markers of selective advantage to fish in contaminated habitats, then it is possible that they are being amplified from a physiologically important locus. Thus, their DNA sequences may be conserved across taxa. To test this possibility, probes were made from 3 of the *G. affinis* RAPD primers described above. They were then hybridized to RAPD amplification products obtained from human, herring gull (*Larus argentatus*), and sea urchin (*Strongylocentrotus droebachiensis*) DNA, using the same RAPD primers as were used to produce the *G. affinis* RAPD bands described above. Southern blot analysis revealed that these markers were conserved in DNA sequence and molecular length in all species examined. The *G. affinis* bands were also cloned and sequenced, but the results of DNA sequencing efforts did not provide definitive evidence as to the identity of these loci.⁹² Although the identity of these bands is still unknown, the high degree of conservatism suggests that these loci might play an important role in molecular processes such as DNA repair, fitness, and survival.

These studies are significant for two reasons. First, genetic differences between populations may suggest selection for specific genotypes, but to validate this hypothesis, differential fitness and possible biochemical/molecular mechanisms for differential responses to toxicants must be shown. Second, integration of genotoxic or other molecular biomarkers (e.g., DNA strand breakage) into population genetic analyses could provide valuable insight as to the etiology and consequences of population genetic alterations. The concordance of all these results indicates that radiation exposure selects for certain genotypes, and the contaminant-indicative bands are markers of genes or other elements that confer a selective advantage in contaminated environments.⁹³

Due to ongoing restoration activities at the Oak Ridge National Laboratory, Pond 3513 is scheduled for remediation. To facilitate future scientific research initiatives with mosquitofish from this contaminated environment, samples were taken and are currently being maintained in laboratory aquaria at the Environmental Sciences division. Also, some carcasses have been archived and preserved in liquid nitrogen. Interested investigators should contact Dr. Mark Greeley.⁹⁴

41.4.5 Kangaroo Rats

The Nevada Test Site (NTS) is a nuclear weapons testing facility operated by the USDOE. Between 1951 and 1963, there were 105 aboveground tests of atomic weapons conducted at the NTS or its associated bombing range. In some sites, towers were located upon which bombs were placed for detonation. These ground-zero, or T, sites were used multiple times, and the surrounding areas received considerable radioactive contamination.

Theodorakis et al.⁹⁵ conducted studies of the genotoxic effects of radiation from aboveground atomic bomb tests on Merriam's kangaroo rat (*Dipodomys merriami*) at two of the T sites (T1 and T4). Initially, they used flow cytometry and the micronucleus assay to detect the somatic effects of radiation. These studies were inconclusive because, although cytogenetic analysis suggested genotoxic effects (means were higher in the contaminated sites than in the control sites), the differences were not statistically different. This is in spite of the fact that previous studies of heteromyid rodents exposed to chronic low-level radioactivity had revealed ecological effects.⁹⁶ Theodorakis et al.⁹⁵ subsequently conducted molecular genetic analyses to better characterize the populations and search for population-level genetic effects.

Two molecular genetic analyses — RAPDs and mtDNA control-region sequences — were employed in their study. Although the nuclear RAPDs did not reveal any differences among the four localities (two reference, R1, R2, and two ground-zero sites, T1 and T4), the maternally inherited mtDNA showed significant differences among populations. This was interpreted to mean that males disperse at a greater rate than females; thus, the nuclear markers reflect panmixia, but the maternal markers show population differentiation. This is consistent with behavioral studies on kangaroo rats in which males have been shown to disperse at a greater rate than females.

It was found that some mtDNA haplotypes were shared among sites (potential migrant haplotypes), and others were restricted to only a single site (potential resident haplotypes). Theodorakis et al.⁹⁵ surmised that the unique haplotypes represented long-term residents and the shared haplotypes represented potential recent immigrants. To test this hypothesis, the flow-cytometry and micronucleus data were reanalyzed. It was found that when the animals with migrant haplotypes were excluded from the analysis, one of the contaminated sites had significantly increased DNA damage compared to one of the control sites. Furthermore, when animals from the contaminated sites were considered alone, individuals with resident haplotypes had significantly greater chromosome damage compared with animals with migrant haplotypes. This study shows that molecular genetic data can be used to better interpret biomarker data and that it is possible for genotoxic effects to be masked by high immigration from uncontaminated sites into contaminated sites. MtDNA is a potentially valuable genetic marker for differentiating among potential immigrants and residents.

The kangaroo rat data led Theodorakis et al.⁹⁵ to hypothesize a specific demographic pattern of movement among populations. Reference area 2 (R2) proved to be significantly different in the biomarker analyses from contaminated T4; R1 and T1 were not different. They hypothesized that R1 was more likely to be exchanging migrants with the contaminated sites than was R2. This could be investigated by long-term field studies using mark-recapture techniques, but such data would take several years to obtain. To test this hypothesis using the genetics data, they conducted a phylogenetic analysis of the haplotypes and plotted the localities at which each haplotype occurred. Using the method of Slatkin and Madison,⁹⁷ the hypothetical immigration events needed to explain the topology of the tree (which itself reflects the geneological history or genetic relatedness of the

haplotypes) was reconstructed. Using this analysis, Theodorakis et al.⁹⁵ found that 27 migration events were needed to explain the tree, for 23 of which the direction of migration could be determined. Of these, 13 migration events involved movement of animals from the reference areas into the contaminated areas, and 6 involved migration from the contaminated areas into the reference areas. This is consistent with their conclusion that the shared haplotypes represented migrant individuals. The greatest number of migration events involved animals migrating from R1 → T4 (n = 7) and R1 → T1 (n = 5).

Therefore, this analysis supports the hypothesis that R1 serves as a significant source of migrant individuals for the contaminated areas. Furthermore, it changed the perception of the ecology of the ground-zero sites. The data are suggestive that the ground-zero sites are in fact sinks that are populated with a relatively high proportion of migrant individuals. For purposes of ecological risk assessment and ecotoxicological studies using biomarkers, the population genetic data in this case proved critical in obtaining a clear assessment of effects.

41.4.6 Bank Voles

The meltdown at Chernobyl caused the worst nuclear power plant disaster, highly contaminating the area surrounding the reactor. Unfortunately, the impacts of this contamination upon wildlife remain largely undetermined. Two studies have been published, however, that shed light on the genetic effects of chronic exposure to radiation in natural populations near Chernobyl.

Matson et al.⁹⁸ studied genetic effects of radiation on the bank vole, *Clethrionomys glareolus*, because it exhibits the highest internal levels of ^{134,137}Cesium and ⁹⁰Strontium among rodent species living in this area. Samples were collected over time from two contaminated sites, Glyboke Lake and the Red Forest (which has the highest levels of radiation of any area studied). Samples were also taken from one reference area, Oranoe, located outside the 30-km restriction zone. From these samples, a 291-base-pair region of the highly variable mtDNA control region, the D-loop, was sequenced and used to identify haplotypes. This study showed significantly higher genetic diversity in contaminated sites in comparison to the reference site.

Baker et al.⁹⁹ continued the previous study, monitoring spatial and temporal dynamics of haplotype frequencies and genetic diversity. In addition to sampling the same reference and experimental sites used in Matson et al.,⁹⁸ two additional reference sites were added, Chista and Nedanchichy (which has the lowest levels of radiation of any area studied). Sequential sampling of populations consistently showed significantly higher genetic diversity in experimental sites as compared to the reference sites. However, based on these data alone, the cause of increased variation in animals from contaminated sites was not determined. Two possible explanations to explain this observation were offered. First, increased genetic diversity could have resulted from mutations induced by exposure to radiation. Alternatively, it could be that the populations of *C. glareolus* were extirpated as a result of the meltdown of the reactor, causing an ecological sink. Consequently, multiple founder effects of animals emigrating from different areas resulted in an increase in genetic diversity in this area. To distinguish between these two hypotheses, monitoring studies are now being conducted at these sites. These studies include establishing pedigrees for resident bank voles using microsatellite analyses and monitoring changes in genetic diversity through time. Such data should reveal if new variants are evolving within the populations or are introduced by immigration.

41.5 SUMMARY

Laboratory studies have identified as genotoxic a large number of chemicals that are commonly found in contaminated environments. The adverse health effects of genotoxic chemicals on organisms often result from the consequence of direct DNA damage. While the majority of chemical-induced alterations to DNA are repaired, some are either not repaired or improperly repaired,

leading to mutations and changes in the genetic make-up of affected individuals.¹³ Genetic alterations in somatic tissue of an individual may not only have a number of immediate effects on the cells involved, but they may also provide an important clue as to the nature of the stress experienced by a population. Nevertheless, the most profound and long-lasting environmental effects occur at higher levels of biological organization.³

When mutations occur in germ cells, they can potentially be passed to the offspring. Extrapolation of observations made at the somatic-cell level of biological organization to events occurring in germ cells in the same organism is difficult due to the inherent difference in sensitivity of these types of cells to genotoxicants. Individuals carrying harmful mutations are often eliminated from the population due to a strong selection against less fit and less well-adapted individuals.^{9,100} However, the main concern for induced heritable mutations is that they will lower the reproductive output of an affected population since affected individuals have relatively low viability and fertility.

In addition, toxic chemicals, which do not interact directly with DNA, can also cause genetic effects on a population due to the selection or elimination of resistance or sensitive individuals in a population. Thus, adaptation can result in a narrowing of genetic diversity, which in turn is exasperated by associated ecological influences such as genetic drift, bottlenecks, and inbreeding, as well as the risk of producing the fixation of deleterious alleles.³

Distinctive groups that differ genetically exist within natural wildlife populations. Variation in responses of organisms within these groups to toxic stress can be attributed in part to their genetic variations. In addition, contamination may influence the genetic composition of individuals within these populations and impose new or additional selection pressures. Stressed organisms are even more vulnerable to additional stressors, which may further jeopardize the survival of the population. Thus, the degree of genetic variation maintained by a population may be evidence of its capacity to survive future environmental alterations by tempering or modulating the stress-related effects of pollution. Genotypes that survive pollutant exposure may represent those individuals that are most tolerant to environmental stressors. For more detailed discussions on this topic, the reader should consult the scientific literature.^{2,3,9,53} The work of Belfiore and Anderson¹⁰⁴ on distinguishing between genetic alterations caused by natural processes and contaminants is especially relevant.

Genetic markers offer the most direct approach for measurement of genetic diversity. Two approaches pertaining to selection by anthropogenic stressors are found in the literature. The first is to identify genetic markers linked to either resistance or sensitivity to particular stressors or combination of stressors in select species, and the second is to employ a suite of genetic markers to examine population-level responses. Despite its limited resolution, allozyme analysis remains the simplest and most rapid technique for surveying genetic diversity in single-copy nuclear genes. The appeal of the PCR-based technologies is based on several factors including the simplicity of the procedure, the requirement for small amounts of DNA, and the potential to access many genetic loci. Employing genetic markers to assess genetic diversity of natural populations appears to be a promising and useful approach for determining the effects of environmental pollution on ecosystems.³

Since the more significant ecological effects of contamination usually occur at the population or higher levels of biological organization, monitoring changes in population genetic structure will become a valuable component of ecological risk assessments.¹⁰¹ Research efforts in genetic ecotoxicology that deal with the ecological significance of exposure are rapidly expanding, as evidenced by the publication of a Special Issue on Environmental Population Genetics¹⁰² in the scientific journal *Ecotoxicology*. This special issue is a compilation of several current scientific research endeavors employing different approaches including classical allozyme analysis and genetic markers for studying the diversity (genetic variation) of population. These studies describe approaches and methodologies for the detection of stressor-induced effects on genetic diversity of populations, and several of them detail important case studies that demonstrate the usefulness of a particular approach to a given environmental problem.

ACKNOWLEDGMENTS

Opinions expressed or implied in this chapter are solely those of the authors and are not those of any institution or federal agency that participated in or sponsored the studies described herein. LRS is president of LR Shugart and Associates, Inc., a consulting firm specializing in ecotoxicological issues. Funding for research on bank voles was provided in part by a contract (DE-FC09-96SR18546) between the United States Department of Energy (DOE) and the University of Georgia. One of the participants of the bank vole project, AMB, is supported by a Howard Hughes Medical Institute grant through the Undergraduate Biological Sciences Education Program to Texas Tech University. We thank R. J. Baker for his comments. JWB is presently funded by grant ES04917 from NIEHS. Studies of kangaroo rats and sunfish were funded in part by DOE under Cooperative Agreement No. DE-FC04-95AL85832. This chapter is contribution no. 103 of the Center for Biosystematics and Biodiversity at Texas A&M University.

42.1 INTRODUCTION

Achieving sustainable use of the planet will require a new view of the relationship between human society and the environment and a concomitant acceptance of responsibility by those now living to provide a quality life for their descendants for an indefinite period of time. Both industrial ecology and natural capitalism provide useful guidelines and case histories on how these two changes might be achieved. Industrial ecology is the study of the flows of materials and energy in the industrial environment and the effects of those flows on natural systems.^{1,2} Natural capitalism refers to the increasingly critical relationship between natural capital (i.e., natural resources), living systems and the ecosystem services they provide, and human-made capital.³

The idea of sustainability, which includes concepts from both industrial ecology and natural capitalism, regards the environment as an inclusive system that serves as the ecological life-support system upon which humans depend. Both industrial ecology and natural capitalism espouse mimicking natural cyclic phenomena so that wastes can be immediately reincorporated into natural systems in ways that benefit natural systems and preserve their integrity. The ecological life-support system upon which humans depend provides services, such as the maintenance of the atmospheric gas balance, that are frequently not replaceable by present technologies and that the present economic system does not value appropriately because they are “free.” However, since the most important ecosystem services cannot, at present, be replaced by technology and are essential to human survival, they are priceless. Both industrial ecology and natural capitalism advocate the preservation of natural capital (old growth forests, soils, biotic diversity from which many medicines are developed, etc.) so that it can continue to provide “interest” — i.e., ecosystem services.

These new approaches will require a global ethos or set of guiding values based on equity and fairness in the use and protection of natural systems, not only among members of the human species but in relationships with other species as well. These approaches are basically ethical constructs, so implementing them will require sound science that assures a relationship between human society and natural systems and that protects the health and integrity of natural systems and facilitates the accumulation, rather than the destruction, of natural capital. Since sound science is essential for implementation, ecotoxicologists have the opportunity to play a dominant role by determining how to reincorporate the wastes of human society into natural systems to the benefit of natural systems and to reduce or eliminate the stress that this process presently produces. Essentially, since natural systems cannot speak for themselves, ecotoxicology will provide the informational feedback loops that guide the new relationship between human society and natural systems.

Because both human society and natural systems are dynamic and multivariate, the future is inherently uncertain. As additional evidence accumulates, the uncertainty will be reduced, and precautionary measures will reduce risks of major catastrophes.

Natural capitalism and two of its subdisciplines — industrial and municipal ecology — are essential components in developing a sustainable relationship with natural systems and protecting both natural capital and the delivery of ecosystem services. The role of ecotoxicologists in this sustainability approach includes: (1) shifting goals and endpoints from an absence of harm to evidence of health, (2) increasing both temporal and spatial scales of ecotoxicological studies, (3) achieving a critical mass of qualified personnel, (4) including demographic change in ecotoxicological analysis and judgment, (5) developing new ecological thresholds, (6) being prepared for environmental surprises, (7) focusing on design for a quality environment, (8) using ecosystem services as endpoints in ecotoxicological studies, and (9) being prepared for climate change and other events that might destabilize the biosphere and require major adjustments to the process of ecotoxicological testing.

42.2 THE INHERENTLY UNCERTAIN FUTURE

McNeill⁴ in his excellent book comments that the 20th century qualifies as a peculiar century in environmental history because of the acceleration of so many processes that brought ecological change. In an era when sustainable practices are being widely discussed, although rarely implemented, McNeill⁴ notes that China had approximately 3000 years of unsustainable development. It then changed, not to sustainability, but to some new and different kind of unsustainability. In fact, economist Simon⁵ actually advocates changing from one unsustainable concept to another, although not expressing it the same way, i.e., resources are infinitely substitutable and the ultimate resources are human ingenuity, creativity, and technology. Thus, resources, including natural systems, can be utilized in an unsustainable way because, when they are depleted, substitutes will inevitably be found through human ingenuity. McNeill⁴ notes that imperial China was always adopting new food crops, new technologies, and shifting its trade relations with its neighbors. Thus, it was constantly adapting and then surviving crises. If change is necessary, why not move from an unsustainable system to a sustainable one?

The new factor is the appearance of globalization and increased unsustainable practices on a planetary scale. Even during that 3000-year period just mentioned, Chinese society suffered horrendous periods of starvation and mortality. At present, a different perception of human “rights” has surfaced, that is, the “right” to adequate nourishment, adequate housing, and freedom of assembly and expression. Exercising these rights requires not only an enlightened social contract respected by a substantial majority of persons in human society, but also an adequate resource base per capita that permits going beyond mere survival.

Yet compelling evidence indicates that crucial thresholds of ecological damage have already been crossed and are being crossed regularly at local levels in many parts of the planet. The field of restoration ecology^{6,7} will provide much useful information, as will books that cover a variety of ecological indicators.⁸

One major difficulty in using the information will be estimating the quality of the vast quantity of information that will be generated if industrial ecology and natural capitalism acquire even a modest-sized group of practitioners. Regrettably, some data generated will be considered proprietary and not made generally available, either because it might be harmful to the company that generated the information or because of general fears that the information might be used in some way against the organization in the future. Some information may come from unknown sources, from organizations or individuals not generally known to the ecotoxicological community, or from groups that do not have the methodology or other information depicted with sufficient detail for the reader to make an informed judgment on its quality, etc. Even information in peer-reviewed journals may not always be reliable if qualified reviewers cannot be found. Alternatively, high-quality information may suffer inordinate delays because one or more reviewers did not fulfill the professional responsibility of completing a review in a timely manner.

Those who feel that the present societal view is invulnerable would do well to read works that focus on the early empires.⁹ It is prudent, not subversive, to consider when a shift in approach is advisable and what the new approach should be. Changes in approach can be thrust upon society by catastrophic events such as the terrorist attacks of September 11, 2001 on the World Trade Center in New York City and the Pentagon in Washington, D.C. Alternatively, they might occur as a result of reason guided by intelligence and the desire to take precautionary measures despite uncertainty because the consequences of no action might well be severe. In the first case, events cause the change in approach. In the second, a management decision must be made despite some degree of uncertainty of the need because the scientific evidence is not yet robust. The National Academy of Engineering¹⁰ is one of a number of organizations that examine technological trajec-

tories to facilitate transitions from one stage to another. Ironically, it is often the cumulative impact of decisions that seem small in isolation from other decisions but, in the aggregate, exert a surprising tyranny over human lives.^{11,12}

The perfection of resource partitioning in natural systems is literally the result of millions of years of evolution. The extraordinary diversity of some ecosystems, usually accompanied by low numbers of individuals per species and infrequent dominance by any one species, illustrates how finely tuned this process can become. Keeping in mind that many of the species on the planet have yet to be named and that even those named have functional roles that are poorly understood, it is presumptuous, arguably arrogant, to assume that humans can couple their social system to natural systems in ways that enhance the integrity of both systems. Nevertheless, even modest improvements in this relationship between humans and natural systems should produce dramatic benefits, and the increased knowledge about complex ecosystems should lead to further improvements. As the President's Acid Rain Review Panel of the Office of Technology Assessment¹³ noted: "Recommendations based on imperfect data run the risk of being in error; recommendations for inaction pending collections of all the desirable data entail even greater risk of damage." But, as Likens¹⁴ points out, even when reasonably precise information is available, its interpretation can be strongly influenced by human value judgments. He gives the following example. A spokesperson for the proponents of a multimillion-dollar tourist and residential canal estate development stated: "... even though the development would mean the destruction of 53% of the wetland (in the Bateman's Bay area), that would be balanced by the construction of a wetlands education center to teach people of the need to protect wetlands!"

Haeckel's¹⁵ original definition of ecology, despite its focus on animals, is quite relevant today:

By ecology we mean the body of knowledge concerning the economy of nature; the investigation of the total relations of the animal both to its inorganic and to its organic environment; including, above all, its friendly and inimical relations with those animals and plants with which it comes directly or indirectly into contact.

Note Haeckel's use of the phrase "economy of nature," which gets to the heart of human society's present dilemma. Human society's economy is quite different from nature's economy.¹⁶ The materials that human society produces are all too frequently unsuitable for nature's economy and sometimes, arguably most times, a threat to its integrity.¹⁷ Industrial ecology as well as the quest for sustainable use of the planet is an attempt to develop a harmonious relationship between the relatively new human economy and the ancient economy of nature. After noting that human society's present course is unsustainable, Thompson¹⁸ states: "To reverse that course, we need to emulate the economics of nature. It's the straightest path toward stimulating the crucial changes needed to make sustainable development work."

42.3 ACKNOWLEDGING THE OBVIOUS AND ABANDONING DENIAL

Bartlett¹⁹ gives an elegant analysis of the "Hubbert curve,"²⁰ which empirically approximates the full cycle of the growth, peaking, and subsequent decline to zero of the "production" [(quantity/year) vs. year] of a finite, nonrenewable resource. Bartlett notes that each increase of one billion barrels in the size of the world estimated ultimate oil recovery beyond the value of 2.0×10^{12} bbl can be expected to result in a delay of approximately 5.5 days in the date of maximum production. Enormous uncertainties also exist in the amount of natural gas (which has been suggested as an alternative fuel for vehicles) remaining in the United States.²¹ The World Resources Institute²² scorecard shows that many of the important ecological life-support systems are declining in capacity, while some, such as forests, are increasing, and some, such as wood fuel production and coastal recreation, are unknown. Myers,²³ despite an acute awareness of the plethora of bad environmental

news, nevertheless feels that these unprecedented environmental problems also invoke opportunities of parallel scope! Myers²³ notes: “The vital question is not ‘How can we afford to do the necessary?’ it is ‘How can we afford not to do it?’ The biggest cost will not be to our pocketbooks; it will be to our philosophies.”

Aside from the obvious evidence of abused resources, there is also a strong element of denial. In the United States in spring of 2000, gasoline prices increased markedly, as did the number of gas-guzzling sport utility vehicles. An alternative hypothesis is that humans are not in denial; they have just decided that if they are “on the Titanic,” they might as well fulfill their dreams as long as there is time to do so. However, human society, although aware of the risks, may very well cross one or more crucial ecological thresholds and provoke a sudden nonlinear effect. In the past, such an event seemed unimaginable. For example, McNeill⁴ calls attention to the irony in the 1930 statement of American physicist and Nobel Prize winner Robert Millikan who stated that there was no risk that humanity could do real harm to anything as gigantic as Earth. In the same year, American chemical engineer Thomas Midgley invented chlorofluorocarbons, the chemicals now known to be responsible for thinning the stratospheric ozone layer. Midgley certainly had no idea of the profound global consequences of the widespread use of this new compound.

For ecotoxicologists, the prospect is daunting. New chemical compounds are being produced at an unprecedented rate, and the time permitted for testing has not lengthened, due in large part to intense global economic competition as well as the cost of lengthy testing. Furthermore, testing procedures and predictive modeling provide no absolute guarantees that events, such as eggshell thinning caused by some pesticides in some bird eggs, would be a threat, nor is it likely that ozone depletion would initially be predicted to have major effects. Such revelations require perfect hindsight. Even if the precautionary principle (which asserts that when an activity raises threats of harm to human health or the environment, precautionary measures should be taken, even if some cause-and-effect relationships are not fully established scientifically²⁴) is applied and is widely accepted in practice, there must be some persuasive, but not necessarily conclusive, evidence regarding the consequences that will result if precautionary measures are not taken. A substantial portion of the burden of the proof of likely consequences will certainly fall on ecotoxicologists, as it should. At present, political and judicial systems worldwide are simply not prepared to cope with scientific uncertainty, as is quite evident from discussions of global warming, stratospheric ozone depletion, and biotic impoverishment caused by the extinction of species. Clear and compelling evidence exists that human society has the ability to change the biospheric life-support system of the planet — for both better or worse.

42.4 INDUSTRIAL AND MUNICIPAL ECOLOGY

Allenby²⁵ discusses eight unifying themes concerning industrial ecology.

1. “... a globalized economy and society is evolving that will not necessarily be homogenous.”
2. “The earth is increasingly ... engineered” and “... human choice and technology determine the structure not only of human lives and environments, but ”...” other life forms as well.
3. “... reductionist science ...” must “... be augmented ... by more systems-based, comprehensive approaches.”
4. “Policy generally functions in the short term ...” temporally and a limited area spatially.
5. Modern institutions are “... changing in both unparalleled and little recognized ...” ways.
6. Both sustainability and sustainable development are ambiguous terms both “... because of a lack of knowledge ...” and “... because they involve social choice.”
7. “Evolution toward an economically and environmentally efficient economy will differentially favor certain industrial sectors and technological systems and disfavor others.”
8. Although “... environmental issues are occasionally framed in apocalyptic terms ... [w]hat is threatened from a human perspective ... is the stability of global economic and social systems.”

Graedel²⁶ notes that “technological resources should cycle just as nature’s resources do.” He gives a superb discussion of the basics of municipal ecology or, as Newcombe²⁷ names it, “the metabolism of a city.” Graedel²⁶ uses the term *ecocity* and maintains that cities be “... regarded as organisms, and analyzed as such, in an attempt to improve their current environmental performance and long-term sustainability.” This view provides a clear opportunity for ecotoxicologists since they are accustomed to determining response of complex systems to chemical and other stresses. However, it will require an array of methods, procedures, and endpoints suited to this new undertaking.

42.4.1 Mimicking Natural Cycles

Nature’s wastes are most often used by some other part of nature (e.g., dung by the African dung beetle),²⁸ and there are few waste products produced by any species that are not of immediate value to one or more other species. Some plants and animals produce particularly toxic materials, but they are not usually widely distributed and are not usually persistent. Other species have varied means of avoiding exposure, and, in fact, many toxics are produced in order to avoid predation. Industrial wastes, on the other hand, often have no value to other species or organisms and may be fatal to them.

Although some materials do accumulate, such as fossil fuels, most of nature keeps moving. Industrial ecology attempts to mimic natural cycles, which mostly keep materials moving in a way that does not disrupt the biosphere, and to modify industrial wastes so that they are more amenable to cycling in natural systems. The concept of industrial ecology or industrial symbiosis with natural systems is to model industrial systems after the cycles characteristic of natural systems. A more specific definition of industrial ecology is provided by Graedel and Allenby:²

Industrial ecology is the means by which humanity can deliberately and rationally approach and maintain a desirable carrying capacity, given continued economic, cultural and technological evolution. The concept requires that an industrial system be viewed not in isolation from its surrounding systems, but in concert with them. It is a systems view in which one seeks to optimize the total materials cycle from virgin material, to finished material, to component, to product, to obsolete product, and to ultimate disposal.

Similarly, municipal ecology proposes to model municipal systems (towns, cities, and other concentrations of human population)²⁶ after the cycles characteristic of natural systems. Both industrial and municipal systems should be designed to cycle materials in such a way that they are used serially, rather than in a once-through system in which raw materials are extracted from natural systems and transformed into products, and then ultimately both the product and the waste are discarded into natural systems without regard for the ability of the systems to assimilate and cycle them. Recycling is not an afterthought, as it now is in most human societies; but, rather, the concept is incorporated into all aspects of a cyclic process. It is not enough that the waste products do no harm to natural systems; rather, the essence of industrial and municipal ecology is that the wastes are amenable to incorporation into the natural systems in a way that will promote ecological integrity and health.

If the waste products of anthropogenic activities are not harmful to natural systems but of benefit to them, there is no justification for transporting the wastes considerable distances from the point of generation. If human society mimicked the economies of nature and produced wastes that are not dangerous to natural systems and a threat to their integrity but, rather, are beneficial to natural systems and improve their health and condition, there would be no need to transport such wastes or store them in containers for long periods of time. If wastes were indeed beneficial to natural systems, then producers of the wastes would be losing a valuable resource by exporting them. In fact, the only reason for exporting wastes is the recognition that they are harmful to human

health and the environment. The only justification for doing so is that the exporter is so exceptional that the health of its citizens and its environment are more important than the areas to which the wastes are being exported. The fact that other areas are willing, even eager, to accept these wastes does not in any way diminish the moral dilemma of the exporter.

Regrettably, this dumping of harmful wastes on others has been discussed in economic terms and not in ethical and moral terms, which should make the action unthinkable. Even for those favoring economic thinking, unethical and immoral practices are not good for either the exporter or the recipient. Resolving these ethical issues entails determining how to develop wastes that can be reintroduced into natural systems without harm to the natural systems or to human health. There is no moral or ethical dilemma if the wastes are effectively resources to the recipient. However, there is a dilemma if the wastes are harmful to the exposed organisms or effectively block access to essential resources.

All aspects of each industrial processing system must be examined in terms of its compatibility with natural systems wherever and whenever the two interface. Within this conceptual framework, industrial and natural processes are designed to be more compatible and, ultimately, symbiotic, rather than isolated from each other conceptually, as they now are. Human society must operate in such a way that its waste products are readily and beneficially reincorporated into natural systems. If a judgmental error is made in the ecosystem assimilative capacity for anthropogenic wastes, ecosystem stress should be apparent in one or more of a series of departures from the nominative state, such as ecological integrity, resilience,²⁹ biotic impoverishment,³⁰ and increased variability,³⁰ all of which are exceedingly difficult but not impossible to measure.

The example most often cited for industrial ecology is the Danish industries of Kalundborg.^{28,31} In this small city, the industries act as if they are an integrated system or a web linking the "metabolism" of one company with that of the others. For example, the "waste" energy in the form of spent steam from a power plant is used to heat the town, to heat fermentation vats for a pharmaceutical company, and to heat water for aquaculture. Thus, the spent steam does not become an environmentally harmful waste discharge, but rather an economic asset cycled through a system that consists of a web of previously isolated components.

On March 10, 2000, the Physicians for Social Responsibility (PSR) held a conference on drinking water entitled "Drinking water and disease: what every healthcare provider should know." The news media have given enormous attention to disease problems associated with poor drinking water, food processing, and the like. What has received less attention is the fact that chlorination for disinfection of drinking water supplies, although it has helped to control cholera and other diseases that once menaced much of human society, has a downside in that the chemical by-products formed as a result of chlorination may be associated with increased risk of bladder cancer, colorectal cancer, and adverse reproductive and developmental effects.³² The report also notes that anthropogenic pollutants contaminate ground and surface water that supply drinking water. Leaking underground storage tanks and hazardous waste sites, for example, can contaminate groundwater use for individual and community drinking water supplies. Agricultural and livestock production introduce pesticides, fertilizers, animal waste, and antibiotics into the hydrologic cycle. All sorts of contaminants have been identified in drinking water including trace amounts of caffeine.

Tests to identify complex chemicals with precision are costly and are well beyond the analytical capabilities of most water-treatment facilities, except possibly those of large metropolitan areas. In addition, even when the chemicals have been identified, targeting sources is still problematic because wastes are now moved considerable distances from their site of production to sites within the United States and to some other developed countries. Quality control monitoring of safety of underground storage sites has often been inadequate. Industrial ecology can do much to alleviate this problem by minimizing the production of wastes that are unsuitable for release into the environment and by treating wastes as valuable resources and reusing them in a variety of ways. Spreading wastes over wide areas throughout the environment primarily by means of the transportation system and faulty and poorly monitored long-term storage systems should be remedied.

42.4.2 Toxicants in Human Behavioral Problems

New research suggests that millions more children than previously thought might have lead-linked mental impairment,³³ while another study supports a strong link between that exposure and juvenile delinquency. Other such findings have also been reported elsewhere.³⁴

Suppose there is significant evidence that these contaminants are capable of producing behavioral changes, particularly in the young, and that they are ubiquitous in the environment. This scenario means, first of all, that reference specimens are impossible to obtain or, at best, are exceedingly rare. Even the investigators studying the problem are likely to have altered behaviors. In addition, if humans are as unique as some believe, tests on surrogate species, however scientifically reproducible, may not extrapolate well to the human species.

Even if the possibility of contaminant-altered behavior is remote (and it appears not to be), the precautionary principle requires that precautionary action be taken, especially when the means for such action, namely industrial ecology, shows considerable promise and has been tested to a significant degree.

Even if the principles, concepts, and procedures of industrial ecology are immediately implemented, the environmental concentrations of persistent chemicals and their various transformation products will remain for some time. Since these chemicals are numerous and likely to have at least some interactions, there are two quite obvious tasks for ecotoxicologists — determine routes of exposure and means to avoid them and determine the rates of degradation and the ways in which particularly important chemicals partition in the environment, which will provide both the means to avoid exposure and the possibility of *in situ* treatment of the highest concentrations.

42.4.3 Quality Control Monitoring

Environmental monitoring is carried out for the purpose of determining that previously established quality-control conditions have been met.³⁵ The quality-control conditions will be those developed by environmental scientists.³⁶ At the very least, monitoring should provide an early warning that quality-control conditions are not being met and provide a degree of validation of the predictive models developed from ecotoxicological testing. In the early development of this area, both false negatives and false positives are likely to be common, possibly even frequent, especially if multiple lines of evidence are not gathered because of cost-cutting measures. A false positive is a signal that quality-control conditions are not being met when in fact they are, and a false negative is an indication that no adverse effects are occurring when in fact they are. These false positives and negatives will be a source of frustration to the general public and its representatives if their ecotoxicological literacy is not raised well above present levels!

In order for quality control monitoring of ecosystem conditions to be effective, the information systems must, above all, be rapid and comprehensive. Decision makers will likely insist that monitoring systems also be economical, but, as is the case for preventative medicine, the cost of ignorance often far exceeds the cost of the preventative measures. The need for speed in effective biological monitoring systems has been recognized for years.^{37,38} Major problems will arise in spatial and temporal complexity at the landscape and larger levels; investigators may initially cope with these problems through the use of echelon analysis^{39,40} and various other types of system-level assessment.^{41,42} Although methods and procedures for the determination of ecosystem health are still in the early development stages, a considerable body of literature already exists.^{43–47}

In any widespread activity, the sampling methods, procedures, and protocols become standardized. There are organizations whose mission may be entirely or substantially devoted to such activities (such as the American Society for Testing and Materials, the American Public Health Association, the American Water Works Association, the European Island Fisheries Committee). When any activity becomes increasingly common, it is important to know how a particular number is derived and whether it is from a biological, chemical, or physical sampling. In addition, when

any activity becomes particularly common, measurements are made by persons with less formal training than research investigators. Even research investigators should be obliged to collect some data in the same way in order to facilitate comparisons between studies made in widely differing geographic areas or measurements made over considerable spans of time at the same place.

Researchers tend to be attracted to the latest methodologies and technologies; but for studies covering large temporal and spatial spans, consistency in making the measurements, especially in highly variable systems, results in a marked reduction in uncertainty. “Unknowns” in “round robin” testing evaluations are often used to determine the reliability of the laboratory or individual’s analytical procedure. It is often a shock to many environmental professionals when they first find how important standard methods are in courts of law. Courts of law are particularly fond of standard methods for three important reasons: (1) they usually represent a strong consensus by practitioners in a particular field as to how a particular measurement should be made; (2) each step of the analytic process is described in painstaking detail so that it is extraordinarily difficult to inadvertently deviate from the established methodology; and (3) because of their widespread use, especially in compliance to regulatory requirements, they are subjected to continual intense scrutiny, reevaluations, and descriptions of situations, which would produce spurious results.

Standard methods already exist for many chemical and physical parameters, and they already have a well-established role in many other areas that affect the daily lives of humans and the environment. Biological standardized methods exist, but they are not nearly as numerous as those in other categories. Before a methodology has achieved the status of a standard method, it is often termed a provisional method, which has less status than a standard method. However, the provisional method is already attracting more attention than would otherwise be the case had it not entered a standardization process. The disadvantage of standard methods is their extreme rigidity. Rigidity has notable advantages in replication, etc. but is often frustrating when adjustments must be made for conditions of a specific site, many of which are unique.

Protocols are produced by a consensus of carefully selected professionals and have a certain stature in courts of law. Even protocols are regularly revised and subcomponents of them explored in great detail. Standard methods and procedures give confidence to the general public, decision makers, and regulatory agencies that appropriate methods are being used. Modification of protocols gives confidence in the process of decision making, integration of information, and predetermining the normal state that, if not met, calls for immediate corrective action.

In historic times, environmental monitoring was practiced in an informal sense. The nobility in many countries, from India to many parts of Europe and, more recently, in parts of North America, had large nature preserves predominantly used for recreation, such as hunting. They employed gamekeepers, river wardens, and the like to keep a watchful eye on the condition of the preserve and also, especially if it was very large, to drive off poachers. The people charged with preserving the system often had little or no formal education and were definitely not acquainted with the complex ecological and statistical analyses at the system level. Nevertheless, these keepers had direct observation of the condition of the system based on a life-long association with it and an encyclopedic knowledge of its components and processes. If they used poor management skills, they suffered severely and, in some primitive cultures, often died. Today, when most inhabitants of the planet have only a fragmentary understanding of natural systems and very little personal involvement with them, society must rely upon rather complex assessments. In an era when many people have a distrust of science, communicating this complex information to the general public will indeed be a challenge. However, society will suffer if its relationship with natural systems is not managed skillfully.

Espousing keepers is in sharp contrast to most of this discussion. At worst, it might be construed as an argument against science and informed management. It does, however, recognize two realities: (1) there are, at present, insufficient professionals to implement these practices on a large scale and (2) even if they become available, many countries will be too poor to employ the professionals and provide them with adequate equipment. One hopes this situation will change; but, in the meantime,

it will probably be essential to implement some older practices that may alert management of the need to acquire, temporarily or permanently, more skilled professionals with better equipment.

42.4.4 Cessation of Production of Persistent, Non-Degradable Compounds

The most common justification for producing persistent chemicals, many of which are known to be toxic and all of which have the potential to be toxic or environmentally harmful, is that technology will be developed in the future that will transform them into nonpersistent, harmless chemicals. However, the existence of a need is not likely to create the funding necessary to develop this new technology unless there is evidence that the storage systems are not working. The monitoring costs to assure that storage systems are working are too high. There must be unmistakable, or at least persuasive, evidence that faulty storage sites present an immediate threat to human health or the environment before such practices are halted. The many proponents of a future technological solution never mention an alternative that is more attractive in terms of reducing risk. The alternative is to use human ingenuity, creativity, and technology to produce nonpersistent chemicals that need no storage and do not depend on the development of some future, unknown technology in order to be rid of them. In addition, society is running out of storage space because most people resist such sites in their backyard, near their groundwater supply, or near other aquatic ecosystems.

When the United States Congress developed legislation to identify and decontaminate hazardous waste sites (Toxic Substances Control Act), the number that already existed was startling to most people. The difficulty of determining who was responsible for the hazardous wastes was beyond the capability of the justice system in practically every instance. Instead of the allocated funds going toward cleanup of the storage sites, which would have reduced their potential for harm, most of the money went into legal fees, which regrettably have neither led to substantive reductions in risk nor identified a satisfactory means of addressing the problem. Scientists are the ones who must make the most critical judgments on risks to human health and the environment from toxic substances. Ecotoxicologists, of course, have a role to play, both in the development of nonpersistent chemicals and in the detoxification of persistent chemicals. Since there are no courts of science and technology that are comparable to courts of law, the work of ecotoxicologists is directed by, and all too often suppressed or ignored by, the legal system.

In one view, science is supposed to be value-free; however, personal values of scientists determine what research is carried out, how teaching is designed, and the choice of words and phrases in professional publications and presentations at professional meetings. Most scientists attempt to maintain objectivity, and some even carry the effort to the extreme limit of not expressing any opinion about even the possible extinction of their favorite species. The quest for objectivity is greatly assisted by the peer-review system, but even this rigorous quality control system permits value judgments to appear in many journals, even if they are not clearly labeled as editorials, commentaries, or speculations.

The quest for sustainable use of the planet is basically a value-laden goal. A central value is that it would be a good goal for human society to be able to use the planet indefinitely. Other species and the natural systems they inhabit are viewed as valuable as the ecological life-support system of human society and the source of natural capital upon which other forms of human capital depend. Those who use the term "sustainable development" add a further value, that is, development as it is now understood in human society is good and should never cease. Scientists have an ethical and moral responsibility to speak up when damage being done by toxicants to natural systems destroys or impairs the integrity of those systems. Using the excuse of scientific objectivity to avoid speaking out when systems are being destroyed is far worse than stating a value judgment that is clearly identified as such and based on evidence and reason. It is instructive to examine the litigation on the harmful effects of cigarette smoking to see how the public views the absence of ethical values.

42.4.5 Industrial Ecology Buffer Zones

The buffer-zone approach is applicable to both private and public structures and, when used in an ecological context, is appropriate when there is an interest in protecting the integrity of both natural and hybrid ecological systems from anthropogenic damage. Each buffer zone requires an array of quality-control conditions and a monitoring system to confirm that they are being met and to provide an early warning if they are not being met.

In the context of sustainable use of the planet, ecotoxicologists will be asked to design and monitor buffer zones around each industry or industrial complex. Ideally, aggregates of industries in which the waste products of one can be used beneficially by another²⁸ might have a single communal buffer zone. The advantage of this design is cost savings through shared ecotoxicological and monitoring resources. The disadvantage is that incompetent work in one industry may lead to problems for the entire group, particularly if the guilty industry is not willing to admit mistakes and errors. On the positive side, the costs of accidental-spill-contaminant teams for the entire complex could be shared, thereby reducing the cost and, perhaps, increasing the innovative approaches to spill containment.

For those industries willing to share a single group of equipment inspectors for such things as wiring, pump performance, and the like, cost could be substantially reduced. In addition, if an effective industrial-ecological buffer zone is designed, workers should be willing to live closer to their place of employment and, perhaps, in a very well designed buffer zone, even use portions of it for recreation. This design would significantly reduce commuting time, require less area for parking lots, and, since the workers would live closer to the industry, provide an additional incentive for environmentally compatible activities and better maintenance of equipment to prevent environmentally damaging accidental spills, etc. Four major advantages, other than the ones just briefly described, exist to establishing such buffer zones.

1. These zones would serve to validate and confirm models regarding the impact of waste products on ecosystems.
2. By maintaining ecological integrity, buffer zones would provide evidence of protection of adjacent ecosystems. Inevitably, instances would occur where failure to meet standards and criteria would be covered up due to fear of reprisals, fear of losing jobs, or fear of the consequences of poor professional performance. The fate of “whistle blowers” is already well known in society. Generally, their former colleagues turn on them, administrators punish them, and society forgets their courageous acts all too quickly. It is a tribute to human society that, given these daunting obstacles, people still continue to “blow the whistle” when it is abundantly clear that something is wrong. One safeguard against coverups would be to have all buffer-zone plans around industry become an integral part of a bioregional plan with professionals who would check the validity of the conclusions drawn, the interpretation of the data, and the adequacy of the data.
3. Buffer zones can provide an attractive workplace, i.e., a naturalistic setting. This concept is often dismissed as impractical, noncompetitive, and an unnecessary expenditure of capital funds. A Netherlands bank in southeastern Amsterdam, on a site chosen by the workers because of its proximity to their homes, is such a facility.³ Although a buffer zone is absent because of the highly urban location, this “organic” building integrates art, natural and local materials, sunlight, green plants, energy conservation, quiet, and order, all of which please the employees and did not cost one guilder more than the market average. The information on maintenance is even better since the money spent to put the energy-saving system in place paid for itself in the first 3 months. After an initial start-up period, the bank complex used 92% less energy than an adjacent bank constructed at the same time, representing a saving of 2.9 million guilders per year and making it one of the most energy-efficient buildings in Europe. The energy and time saved by employees because of the short distance to the workplace are additional benefits not included in the figures just mentioned. There are numerous other examples of resource savings. Large urban areas have cut traffic by using metro stations (subway and surface high-speed transport) as development foci. In addition, clustering of housing permits the preservation of substantial natural areas for hiking forest trails

or for footpaths. Residents in some areas do without an automobile by using inexpensive, communal transportation for shopping, cultural events, and the like. Cluster housing can work at an optimal level if a high level of civility and civic responsibility exists. However well cluster housing works in providing some respite to natural areas, it is unlikely to be popular in the United States due to individual choices and, therefore, even less likely for industrial choices. Nevertheless, the success in efforts to conserve resources through cluster housing and communal transportation in Europe, parts of South America, and parts of the United States indicates that one should not abandon hope.

4. Buffer zones provide sites for determining the threshold responses in complex systems. Inevitably, accidents will occur at some industrial sites such as equipment failures, spills, errors in the predictive models, and the like. Thus, any aggregate industrial ecology buffer zones will provide some sites for determining the threshold responses in complex ecosystems (or at least some naturalistic assemblages of plants and animals bearing some resemblance to natural ecosystems, thereby having some useful responses, particularly with regard to determining thresholds). These buffer zones are not great substitutes for natural systems, but there are limitations to the complexities that can be mimicked in laboratory tests, including micro- and mesocosms. One does not wish to place natural systems at risk by carrying out controlled experiments in them; and yet it is desirable to have some evidence of responses at this level of biological organization. While accidents are not to be welcomed, one could take full advantage of them when they happen. Therefore, any test should go well beyond normal routine monitoring so as to gather as much useful information as possible resulting from accidents.

42.5 NATURAL CAPITALISM

Hawken and colleagues³ note that

... natural capitalism recognizes the critical interdependency between the production and use of human-made capital and the maintenance and supply of natural capital. The traditional definition of capital deals with accumulated wealth in the form of investments, factories, and equipment.

They³ also note that

... in actual fact an economy needs four types of capital to function properly:

- Human capital, in the form of labor and intelligence, culture and organization
- Financial capital, consisting of cash, investments, and monetary instruments
- Manufactured capital, including infrastructure, machines, tools, and factories
- Natural capital, made up of resources, living systems, and ecosystem services

The present industrial system uses the first three forms of capital to transform natural capital into the materials that are currently taken for granted daily such as cars, highways, food, television sets, etc. Under the current concept of economic growth, which positions development of human artifacts at a much higher priority level than the preservation of natural systems, the ecological price, as is already becoming evident, is severe. The destruction and degradation of natural systems is occurring at a rate unprecedented in human history.

While stock markets boom worldwide and economic growth continues at rates as much as a 10-year doubling time, the natural capital upon which this economic prosperity depends is speedily declining. Natural capital includes resources that are so familiar that they are taken for granted; examples include water, a suitable atmospheric gas balance, minerals, forests, fisheries, soil, and models for pharmaceutical chemicals. All of these resources in the aggregate form the planet's biosphere, a "skin" on Earth's surface so thin that it cannot be detected from outer space. The biosphere has for all of human history been humankind's ecological life-support system. Only in relatively recent times has the technological life-support system been added that originated from

the agricultural revolution first and, subsequently, the industrial revolution. These two support systems have made possible the concomitant dramatic rate of increase in human population size and affluence. However, infinite growth on a finite planet is simply not possible, despite economic claims to the contrary. Common sense indicates that continued increases are simply not rational, and even if they were, they are not desirable. Natural capitalism demands that the supply of natural capital and the services it performs be given the same attention that has been given to the first three types of capital.

Hawken and colleagues³ note that what might be called “industrial capitalism” does not fully conform to its own accounting principles. It liquidates its capital and calls it income. It neglects to assign any value to the largest stocks of capital it employs, natural resources and living systems, as well as the social and cultural systems that are the basis of human capital. Valuing natural capital is a difficult and imprecise exercise at best,³ but the value of its services has been calculated as at least U.S. \$33 trillion, using 1994 dollars as a reference point.⁴⁸ This valuation is undoubtedly a conservative figure, given the fact that things human society cannot live without and cannot replace at any price transcend customary value systems. The Hope Diamond is unique and therefore irreplaceable, but still has value. However, there are many diamonds, none of which are an essential component of the ecological life-support system. Humans have benefited from the latter for their entire existence as a species. If it changed to a far less suitable set of conditions, human society would suffer — possibly even collapse. How does one value an essential life-support system? Arguably, it is undervalued at present.

From another perspective, humans are not an essential component of the ecological life-support system and, therefore, add little value to it. Natural systems functioned without humans for billions of years and, doubtless, would do so if *Homo sapiens* became extinct. How does one value such a system? Certainly it is in human society’s enlightened self-interest to take precautionary measures to protect its integrity.

Since the advent of the agricultural and industrial revolutions and the increasing concentration of humans into urban and suburban areas, society’s life-support system has become both technological and ecological.⁴⁹ When technological services are disrupted for even short periods of time by earthquakes, hurricanes, or snow and ice storms, humans are made well aware of their necessity, even if they take them for granted during normal times. Urban and suburban dwellers, and even those in rural areas, are far less sensitized to ecosystem services because these systems rarely fail so dramatically. Furthermore, damage to the technological system can be repaired much more quickly than damage to the ecological systems. Technological systems in Japanese and European cities that suffered enormous damage during WWII enjoyed rapid restoration. On the other hand, destruction of old-growth forests may require recovery times far longer than an individual human life span, and the recovery is not guaranteed to the extent that it is for technological systems.

Natural capitalism is an attempt to redesign technological systems so that they not only do not threaten ecological systems but actually enhance them and, therefore, increase natural capital. Some ecologists oppose the strategy of interfacing industrial product life cycles and ecological or biological assimilative capacity of natural systems for this purpose.⁵⁰ Assimilative capacity is defined as the ability of natural systems to absorb and transform anthropogenic waste without damaging the system’s integrity. All of these strategies are based on (1) the assumption that human society’s life-support system is both technological and ecological and (2) the abundant evidence that the technological system as presently designed threatens the ecological system, while the reverse is true only to a minor extent. Thus, sustainable use of the planet requires achieving a balance between the technological and ecological systems since the ecological systems are being destroyed and degraded at a rate greater than they are being repaired, and technological systems and other human artifacts are constantly encroaching on the physical space utilized by ecological systems.

Natural capital must be accumulated and preserved. The role of preservation is not a new one, but the accumulation of natural capital requires that ecosystems be moved closer to optimal condition than they now are. For badly degraded or moderately stressed systems, of which there

are many on the planet, this restoration is comparatively easy; when conditions begin to approach optimum more closely, much professional judgment and additional knowledge will be required.

42.6 NEW ROLES FOR ECOTOXICOLOGISTS

In the context of establishing sustainable use of the planet through emphasis on industrial ecology and natural capitalism, the current roles or activities of ecotoxicologists will probably be abandoned. Furthermore, it is virtually certain that most of these areas of activity will continue to be developed and refined. Major changes and additions that will accommodate industrial ecology and natural capitalism will dramatically enlarge the activities of ecotoxicologists.

42.6.1 Shift from Absence of Harm to Presence of Health

A shift from a concentration on absence of harm to a focus on presence of health will probably follow the developments in the field of human health, which has moved from symptoms of disease and malfunction to attributes of well-being and health. Even so, symptoms of ill health and malfunction will continue to be extremely important, just as they presently are in human medicine. Literally billions of humans on the planet are malnourished, afflicted by one or more diseases, or need substantive improvement in their health. Similarly, many of the world's ecosystems are in comparably poor condition and desperately need remedial action. So, the first shift for ecotoxicologists will be in endpoints from those whose presence shows harm or degradation to those whose presence affirms good condition and well-being. Some of these shifts have already occurred at the species level in ecotoxicological testing.

The concept of "health" in ecology, whether at the individual, population, or ecosystem level, necessarily involves value judgments.⁵¹ As Nielsen⁵² states: "In the final analysis, what is considered healthy must be reasonable from biological, physical, ethical, and aesthetic points of view, as determined by people." Therefore, health is not a scientific determination per se but a social construct, and its defining characteristics will evolve with time and circumstances.

Ecosystems are more than aggregations of individual species. At each level of biological organization, starting from subcellular levels on up to communities and ecosystems, new properties not apparent at lower levels emerge at each level. These emerging attributes will require much developmental effort in the field of ecotoxicology. However, the search will not be random, and it should not be based on the personal preferences of individual investigators or on those attributes most easily measured and amenable to standardization.

The "interest" from natural capital is ecosystem services, which collectively make up the planet's ecological life-support system. Therefore, natural systems cannot merely continue to exist; they must be in condition for optimal and reliable delivery of these services. More important, each natural system is delivering not one but, typically, a long list of services that ultimately must be assessed in the aggregate. So it has been for human health and so it must be for ecosystem health.

42.6.2 Increased Temporal and Spatial Scales

Another change for ecotoxicologists will occur in increased testing at higher levels of biological organization.⁵³ Tests at levels of biological organization higher than single species, for example, in microcosms, mesocosms, and field enclosures, will continue to be extremely valuable because investigators identify good indications of response thresholds and patterns and can subject test systems to a degree of stress that would be unacceptable in natural systems.

Micro- and mesocosms are used in monitoring complex systems; they are not miniature ecosystems but are constructs that replicate significant cause-and-effect pathways of natural systems. The process of developing an ecosystem-based capability for ecological risk assessments has been

described to illustrate how such units can furnish useful information as well as other sources of system-level information.⁵⁴ Ecological function and resilience have been espoused as important criteria for environmental impact assessment and ecological risk analysis.⁵⁵ Microcosms need not be inordinately expensive, especially if naturally derived microbial communities are used as receptors in toxicity testing.⁵⁶ The uncertainties associated with extrapolating from toxicological responses in laboratory systems to the responses of natural systems have also been described.⁵⁷ A key issue in this context is the correspondence of a microscale toxicity test to responses to toxicants in natural systems. Various endpoints and thresholds in the field of ecotoxicology are useful in this regard.⁵⁹ These preliminary developments need to be expanded rapidly and the robustness of the methods and procedures confirmed and validated since this is a key issue for ecotoxicologists in both industrial ecology and natural capitalism.

It seems abundantly clear that, while ecotoxicologists may continue the types of testing already developed, they must be prepared to move outside the laboratory and beyond field enclosures to engage in bioregional assessment and planning. However, for sustainable use of the planet,⁶⁰ the physical and biological basis for the services provided by nature should not be systematically diminished. To achieve sustainability, the life-support system's integrity cannot be impaired. At the very least, the ability of natural systems to assimilate societal wastes without themselves being degraded or damaging their ecological integrity must be used but not abused.

Ecological integrity has been defined as the maintenance of the structure and function characteristic of a locale.⁶¹ Meeting this condition requires that assimilative capacity be quantified and that human society adjust its waste disposal into natural systems so that they remain healthy and suitable for sustained use. An ecological landscape usually consists of a mosaic of habitat types that are interactive and dynamic. Dynamic means that they are constantly changing and they most likely have cyclic behaviors dependent on climate cycles and the like. Ecotoxicologists must, therefore, incorporate more ecological principles into their activities than they presently do, and ecologists must be more aware of this need and the frames of reference used by toxicologists in general. Details on recognizing needs in increased temporal and spatial scales must also be considered.⁶²⁻⁶⁴

42.6.3 Achieving a Critical Mass of Qualified Personnel

When the military produces a new tank or plane, it also takes great pains to ensure that appropriate personnel are available to run it, maintain it, repair it, and use it as part of a larger strategic plan. If a public consensus existed for implementing suggestions for ecological restoration and made funds available for doing so, an adequate number of prepared professional personnel would still be lacking.⁶⁵ The educational system is still a series of petty fiefdoms and tribal units that are often excellent for quality control and teaching activities of specialized disciplines but not for the integration of disparate types of information of the type needed for both ecotoxicology and sustainable use of the planet. Educational courses are often taught and disciplines operate as if each were the only flower facing the sun, and students are badly underprepared for the integration of a wide variety of social, physical, and biological sciences, not to mention economics, engineering, law, and the like. Even major research universities are not particularly aware of designing for quality environments where their interactions with natural systems are concerned. This disparity definitely needs to be changed.

A survey of environmental management systems at North American universities⁶⁶ has been conducted by considering two components: (1) key areas and major challenges and (2) the posture and behavior of environmental management systems toward environmental issues. Interestingly, only 50 responses were received from an initial mailing of 269, although 18 of these were returned as undeliverable. This figure alone shows how unaware of, or indifferent to, the environmental crisis these institutions are. Alternatively, one might also assume that many North American universities are quite dependent on extramural funding from sources that might be offended by

almost any strong environmental position taken by the university. Responses on the areas of posture and behavior were divided into four major components:

1. Environmental leaders: these people feel that environmental problems do affect the university, and they know where the problems are; as a consequence, they have developed the necessary programs and performance to mitigate environmental problems.
2. Environmental strugglers: these people feel that environmental problems do not affect the university, and they are not sure where the problems are until they arise; as a consequence, they are struggling to develop an effective environmental management system.
3. Accidental "greens": these people do not see environmental management systems as a necessary tool because they are not aware of the environmental problems that affect the university; as a consequence, they have not yet considered preventative programs.
4. Environmental dinosaurs: these people feel that environmental issues do not affect their institutions, and they are therefore not aware that there are environmental problems; they do not see environmental management systems or any other environmental program as necessary.

Although the survey is more extensive than reported here, these survey responses do not inspire confidence that university graduates will be as prepared as they should be for facing environmental management issues.

An international conference was held in December of 1997 in Thessaloniki, Greece to celebrate the 20th anniversary of the Tbilisi Doctrines and to reorient education for *sustainability* (italics mine) in the 21st century.⁶⁷ The culmination of this event was a Thessaloniki Declaration — a charter for the future of education for sustainability. In only two of the 29 statements made in the Declaration was the term *environmental education* mentioned. One of those references suggested that environmental education be referred to as education for environment and sustainability. Scant use of the term *environmental education* indicates that the term is finding decreasing support in the international community.⁶⁷ It is noteworthy that *sustainability* is the word of choice in this Declaration, rather than *sustainable development*.

Despite the call for total integration of environmental education into all subject areas, few holistic approaches can be found in the United States.^{67,68} Criticisms⁶⁹ include assertions that environmental education (1) is based on emotionalism rather than facts, (2) tends to be issue driven rather than information driven, and (3) is politically motivated. The public perception of the environmentalists and environmental education is too frequently associated with emotional activism rather than reasoned argument. People must become better informed about environmental issues and become more literate.

42.6.3.1 Professional Certification

Scientists will almost certainly have an increased role in the societal decision-making processes as long as they use reason and information, even when major catastrophes occur. Professionals must insist that those who label themselves ecotoxicologists must have appropriate credentials. The process of certification is long overdue! Societies must begin the process of certifying professionals in every country at the earliest possible time. As a preliminary step, one might consider three levels of certification: (1) gathering data, (2) grouping data and carrying out quality control practices, and (3) interpreting and analyzing data and making professional judgments, together with design for investigative projects intended to furnish information useful in the decision-making process. Those sufficiently skilled to carry out particular experiments, especially using standard methods, may not have the background for making professional judgments, especially in areas where extrapolations are necessary and much professional knowledge is required.

The task of assembling, integrating, and condensing all the information needed for both industrial ecology and natural capitalism is unprecedented. For routine measurements, production of standard methods with the usual great detail required by such organizations as the American Society

for Testing and Materials will be extremely helpful. However, most ecosystems and ecological landscapes are mosaics and will require different mixtures of standard methods and different temporal and spatial units. Finally, each system will have some unique properties for which standard methods are inappropriate. For these situations, certification of the organizations or individuals generating the information will reduce the uncertainty about its quality. If the certification process is as rigorous as it should be, relatively few individuals and organizations will qualify, certainly not enough to generate the masses of information that now seems necessary.

42.6.3.2 *Obtaining Hands-On Experience*

The educational system should provide the formal courses necessary in chemistry, statistics, biology, and the like. However, the practical operational experience should be in a laboratory certified in the field of ecotoxicology staffed by experienced professionals in that field. This step is a practice of some other professions and would provide the necessary hands-on experience under supervision. Funding agencies could assist this process by providing fellowships, grants-in-aid, etc. for students who aspire to become ecotoxicologists.

42.6.3.3 *Funding*

At present, it appears extremely unlikely that the average person would be willing to pay the costs of ensuring that healthy ecosystems exist to provide the services upon which human society depends. An environmental catastrophe might well be the only means of causing such a massive shift.

The areas of industrial ecology, natural capitalism, and other terms referring to the same concepts have two major components: (1) preserving the planet's ecological life-support system and its services to human society and (2) maintaining and preserving natural capital, which is the source of the planet's economic and societal well-being and which is responsible for the life-support services. Once the need for preserving the planet's ecological life-support system is recognized and ecotoxicology and other necessary fields are given the respect that is justified by the enormity of this undertaking, funding will become available. The exact means of doing so will be a function of the perceived urgency, which will, in turn, be closely related to the size of the catastrophe that results from crossing the threshold. In the meantime, prudence dictates allotting more significant funding to education at all levels so that the basics of science, engineering, and other necessary fields are well established in the generations to come.

42.6.4 *Demographic Change*

Demographers expect the human population to grow to at least 9 billion by 2050, and resource depletion is inevitable unless restoration of natural capital becomes a major societal goal globally. Ecotoxicologists are more accustomed to preventing damage than repairing ecological damage, but now they must have their mission increased to encompass both activities. Ecotoxicology studies the effects of stress and restoration ecology rehabilitation after stress; thus, the two fields of study have more in common than is initially apparent.

Even if human society embraces the quest for sustainable use of the planet to the degree that (1) major behavioral changes occur in the use of energy and the establishment of a robust energy policy, (2) demographic transition to lower fertility is hastened, and (3) less per-capita resource use is embraced, ecotoxicologists will still be challenged to estimate what is likely to happen before it is too late to do anything about it. On a more positive note, present methodology, predictive modeling, validation of predictive models, and determination of ecotoxicological effects at the ecosystem and landscape level can clearly be vastly improved. These improvements will substantially reduce but not eliminate uncertainty, but they will not occur until those politicians who control research budgets understand that these efforts require long-term, consistent funding and

interdisciplinary research teams accustomed to working together and able to do so for long periods of time. Finally, it is worth reemphasizing that although the present system of higher education has made remarkable strides toward multidimensional integration of knowledge, students are still woefully unprepared for the new challenges they will encounter after graduation.

42.6.5 Ecological Thresholds

The goal of natural capitalism is sustainable use of the planet. Industrial ecology also has a sustainability goal, but it is focused primarily on industrial systems, which will play an important role in achieving sustainability. Toxicologists in general and ecotoxicologists in particular have long recognized that the only way to determine a precise threshold is to cross it. Most laboratory toxicity tests are designed with this determination in mind, so that a range of concentrations producing a 100% effect (e.g., death or mortality) to 0% effect (e.g., 100% survival) are customary. This strategy is also designed to find the critical range for more complicated test systems, such as micro- and mesocosms. However, the biosphere is a complex, multivariate system not amenable to the type of testing with which ecotoxicologists are familiar. Societal decisions on the use of fossil fuels and the like are the equivalent of a major global experiment in which human society is a part of the test system.

In a statement that will be all too familiar to ecotoxicologists, but less so to politicians and citizens, Costanza⁷⁰ has written: “The problem is that one knows one has a sustainable system only after the fact.” Stated in terms more familiar to ecotoxicologists, researchers can estimate these thresholds and, using the precautionary principle, attempt to avoid approaching them too closely. Although the precautionary principle has been endorsed by the United Nations, Germany, and a number of other political entities, it has not been widely implemented. Arguably, the most probable reason for this lack of implementation is that it is viewed as an obstacle to economic growth; as a consequence, the most probable scenario is that the various biospheric thresholds will be found only by crossing them. Crossing some of these thresholds is likely to be catastrophic; crossing others may cause minor, local, or regional damage.

Illustrative examples can be taken from history of crossing sustainability thresholds.⁷¹ One key lesson from history is that most irrigation-based civilizations fail. Irrigation is a cornerstone of present-day agriculture and has been a major force in human advancement for at least 6000 years. Will these systems escape the fate of their defunct antecedents?⁷¹ In addition to this example, other interesting information has been gathered about the ecological collapse of ancient civilizations.⁷²⁻⁷⁴ Such information should alert human society to the dangers of overconfidence.

42.6.6 Environmental Surprises

In the present enlightened state of computer technology, the Internet, and global communications, will there be environmental surprises? Do not count on political leaders to be saviors rather than managers! As historian Edward Gibbon⁹ stated at the end of the first volume of *Decline and Fall of the Roman Empire*: “The people became indifferent or inured to the Emperor’s debauches so long as he paved the roads and remitted taxes.” If everyone were interested in both natural capitalism and industrial ecology, would there be any environmental surprises likely to push the environment across a crucial threshold? Bright⁷⁵ discusses three types of environmental surprises:

1. A *discontinuity* is an abrupt shift in a trend or previously stable state; the abruptness is not necessarily apparent on a human scale; what counts is the time frame of the processes involved.
2. A *synergism* is a change in which several phenomena combine to produce an effect that is greater than would have been expected from adding up individual or separate effects.
3. An *unnoticed trend*, even if it produces no discontinuities or synergisms, may still do a surprising amount of damage before it is discovered.

As a consequence, there is a high probability, almost a certainty, that one or more crucial environmental thresholds will be crossed, even if the precautionary principle is implemented to a much greater degree than it is now. Ecotoxicologists must be prepared to detect evidence that a threshold has been crossed — not in a laboratory, but in natural systems. This role is quite different from the one most ecotoxicological professionals now assume. Natural systems are generally characterized by considerable variability, and one must be able to distinguish between normal variability and the onset of a new trend. In addition, when there is persuasive evidence that a threshold has been crossed, one must use all the evidence available to estimate the probable location of the threshold.

Ecotoxicologists must be prepared to detect the crossings of such thresholds at every level, from local to global, and must also be prepared to give some advice about how the system may be brought below the adverse response threshold. Ecotoxicologists might justifiably complain that this responsibility is a huge expansion of their present role, which will bring them into an area in which there is even higher uncertainty than the present range of responsibilities. They can also properly claim that they are presently unprepared for this new role and need much time to do so. No professional group is well prepared for this particular role, even though ecotoxicologists are particularly well prepared for thresholds involving ecosystems. Arguably no other group, even classical ecologists, is so well acquainted with stress thresholds, especially those involving hazardous chemicals and other comparable stressors. Collaboration with those working at the systems (rather than the single-species) level is definitely advisable.

42.6.7 Design for Quality Environment

For the past 100 years, both human population growth and economic growth have accelerated, and, although the former shows some signs of moderating (but by no means stopping, with 81 million additional living persons annually), economic growth with increased consumption of resources is accelerating even further with globalization. The dimensions of these changes are difficult even for the environmentally literate to comprehend, and for the affluent, life is good and change unthinkable. The world's millions who are living in poverty, who are ill-housed and ill-fed, have insufficient political clout or resources to initiate the major changes required. Still, there are grounds for cautious optimism as a consequence of industrial ecology, natural capitalism, and the moderate portions of the green environmental movement.

Society would do well to reflect on who or what will drive the engines of change from the present practices to the new sustainability paradigm. Lemann⁷⁶ discusses power elites, and in his concluding statement, he notes that rapid economic change and concentration of power have provoked strong, unpredictable reactions. People feel left out and try to use politics and government to slow down the pace of change and to build intermediate structures that will protect them. However, the economic boom, by so profoundly streamlining America's operations, is creating propitious conditions for a powerful counter reaction. Alternatively, severe economic crisis, such as droughts in North America's grain-producing areas, total depletion of surface water and groundwater for agricultural purposes, salinization of soils, or some other environmental changes, may produce consequences so severe that human society's relationship with natural systems is reexamined and restated. In some cases, citizens' groups have filed lawsuits to delay or halt environmental destruction. If the consequences of environmental damage reach catastrophic levels in the minds of enough people, then gross environmental damage, and even moderate environmental damage, may become taboo,⁷⁷ as is the case with nuclear weapons. If this aversion to nuclear weapons can grow in strength and become locked into military doctrine, without being fully appreciated or even acknowledged by society, the possibility exists for a comparable situation with regard to environmental damage. Scientists would do well to note both existing trends and highly probable trends because they often indicate that much more time should be spent raising "grass roots" literacy about both environmental matters and ecotoxicology than they are now doing.

42.6.8 Ecosystem Services

Ecosystem services can be used as toxicological endpoints,⁷⁸ and the effects of toxicants on ecosystem services must be considered.⁷⁹ Abundant literature exists on ecosystem services themselves⁸⁰ and their astonishing value,⁴⁸ but very little has been written about the effect of toxicants on their delivery. Some of the services will be global in importance, such as maintaining atmospheric gas balance, and others will be highly site-specific, such as the protection of specific endangered species. Reduced to its essence, however, the problem becomes: what effect does a toxicant have upon a particular function? The challenge is to first identify breakpoints or thresholds in natural systems or in micro- and mesocosms and then find the point at which toxicants approach or cross the threshold.

42.6.9 Climate Change

The probability of significant global climate change is fairly high, although the rate and amount of change are uncertain. Not only does temperature often affect toxicity, particularly in cold-blooded organisms, but it affects chemical reactions, partitioning, and transformation of various chemicals as well. Finally, climate change will of itself affect communities of organisms and habitat conditions — sometimes in the same ways that a toxicant does. For example, climate change may adversely affect some species that are sensitive to either increases or decreases in temperature and, thus, increase the dominance of those that either are or are not favored by the newer temperatures. When natural systems are under multidimensional stress effects, separating the effects of one particular stress from the others will not be easy. As a consequence, the role of microcosms and mesocosms will increase dramatically since they provide the opportunity of controlling the variables in a way that might lead to separating their effect. Industrial/ecological hybrid systems will also play an important role because they are multidimensional, but they will be of necessity less amenable to deliberate exposure to drastic stress.

Possibly one of the most important effects of climate change, if it occurs gradually, will be the expansion or contraction of the ranges of many species, alteration in cyclic events, and interactions between species. For example, a flowering plant may produce flowers primarily in response to temperature changes, while the pollinators, such as hummingbirds, might be more affected by photoperiod. As a result, a temperature change without a corresponding photoperiod change would disrupt the synchronization that has developed over a substantial period of time. Both pollinator and pollinated would suffer, and the effects would have nothing to do with whatever toxicants are present.

42.7 SUMMARY

The trends described here seem almost inevitable if sustainable use of the planet is to be achieved. The world ecological crisis is of sufficient dimensions that the rate of change for ecotoxicologists will make the rapid growth of recent years seem as if it had occurred at a snail's pace. Because of the need of human society to interface in an enhancing way with ecosystems, general principles will have to be modified for each locale, because no two ecosystems are alike, although there will be areas of correspondence in basic structure and function. Furthermore, although microcosms and mesocosms — now the primary tools for evaluating effects on complex systems — are dynamic, they are not nearly as dynamic as natural systems. Since they are controlled, to a significant degree, they are not as likely to be vulnerable to such disruptions as invasion by exotics, which may be especially likely to occur when natural systems are weakened by toxicants and their resistance to invasion diminished.

These trends will almost certainly become so powerful, because they involve the planet's life-support system, that if scientists do not accept these new responsibilities and challenges, they will undoubtedly be accepted by other, often less qualified, people. Disciplines exist in isolation from each other, although the degree of isolation is far less than it was a decade ago. Both industrial ecology and natural capitalism require a far greater degree of interaction between disciplines than presently exists. The benefits of any interactions will not fully be realized until the needs described in this chapter are recognized by funding organizations and implemented by developing new funding initiatives. Furthermore, an entirely new funding approach must be developed. Since many, if not all, of the applications will be highly site-specific, local responsibility from business, political units, and the citizenry needs to be developed. Environmental activists and industries must work together and avoid the polarization that now exists. Political leaders and legislatures will need to be held more accountable for their election-campaign rhetoric and their failure to follow through. Sufficient examples of successful interactions exist, which indicate that all of these goals can be achieved. Successful implementation of sustainable use of the planet requires that all groups benefit, including industries. Natural capitalism shows that environmental sensitivity can go hand in hand with substantial profits.

There are enough case histories to illustrate that both industrial ecology and natural capitalism are feasible and workable. There is persuasive evidence that there will be a shift to these new ideas in the first half of the 21st century. There is also persuasive evidence that many of human society's present practices are unsustainable for multigenerational time spans. The past century has shown a remarkable array of changes, and it seems probable that there will be even more in the next century. Paradigm shifts often occur suddenly as a result of episodic events for which human society was either unprepared or initially reluctant to accept. But a major paradigm shift is essential before future needs can be met!

ACKNOWLEDGMENTS

I am indebted to Eva Call for transcribing the dictation of the first draft of this manuscript and for subsequent alterations. My editorial assistant, Darla Donald, provided her usual exemplary assistance in preparing the manuscript for publication. I am indebted to Alan Heath, B. R. Niederlehner, and David Orvos for comments on an early draft of this manuscript and to B. R. Niederlehner for assistance in collecting some references. Correspondence with Peter Leigh provided some very useful insights for parts of this manuscript. The Cairns Foundation paid for the transcription and processing costs for this manuscript.

43.1 INTRODUCTION AND HISTORICAL BACKGROUND

43.1.1 Wildlife Declines

In recent decades, there has been growing concern that many species of wildlife inhabiting farmland are in severe and widespread decline throughout much of Europe and North America. The best-documented evidence comes from bird data collected in Britain¹⁻⁴ and throughout Europe.⁵ In North America, birds classified as those found nesting in grasslands, including those found in

small-grain cereals, have also shown widespread steep declines over wide areas of their range since the 1960's.^{6–10} This was considered to be a loss greater than that measured for neotropical migrants.¹¹ However, declining trends in other wildlife groups are also apparent including butterflies,¹² beneficial insects,^{13,14} annual arable wildflowers,¹⁵ and amphibians.¹⁶ The intensification of agriculture over the last 50 years, and especially the more widespread use of pesticides, is often regarded as being responsible for the decline in wildlife. Reports on the direct effects of pesticides on wildlife are numerous, but the indirect effects are also considered to be substantial, although the link to declining wildlife is more difficult to detect.

Among species of farmland birds, the grey partridge (*Perdix perdix*) has been one of the best-studied species, and this has led to its description as the barometer of countryside change in Britain. Its decline has been documented, the population dynamics of this species are well understood, the precise mechanisms responsible for its decline have been identified, and recovery programs to reverse declines and restore former distributions and abundance have been recommended.^{17–21}

This review will focus on field-based studies examining the indirect effects of pesticides on farmland wildlife, although some groups of pesticides, because of their persistence and dispersal in the food chain and water, accumulate in environments far beyond agricultural areas.

43.1.2 The Intensification of Agriculture

The spatial and temporal declines in farmland wildlife have coincided with changing patterns of agricultural development. There has been intense speculation as to the causes of these declines, but a consensus has developed that associates them with the increased production of food.^{5,22} Such intensification has been expressed in many ways, but all have led to more intensively managed farming systems involving increased inputs, simplified rotations and monoculture cropping, and the polarization of specific farming enterprises in distinct areas of production.²³ For example, in Britain, mixed farming has been largely replaced by specialist areas of livestock production or arable farming.²⁴ In addition, noncropped cover, such as hedgerows and fence lines, has been removed to increase field size,²⁵ thereby removing habitat used for foraging, nesting, and escape cover.²⁶

Agrochemical inputs have also increased. Average levels of nitrogen fertilizer applied to crops of winter wheat and spring barley in Britain have increased by 900 and 500%, respectively, since the early 1950s.^{27,28} This followed a massive improvement in plant-breeding technology that produced cereal varieties that would produce yield responses to inorganic fertilizers.²⁹

The use of pesticides has also increased. In the United Kingdom, the number of pesticide active ingredients approved for use increased from 11 to 105 between 1957 and 1995 (Figure 43.1). Use of pesticides expressed as tonnage applied has fallen, but when expressed as area treated, the increase was from 1,931,000 ha sprayed in 1974 to 16,590,000 ha in 1998 (Table 43.1). Also, over a similar time period, the spectrum of activity of the herbicides, expressed as the number of weed taxa classified as susceptible to herbicides, increased from 22 in 1970 to 38 in 1995.³⁰ Similar increases in the use of pesticides occurred in North America. In the United States herbicide usage has increased by 180% in the period 1971–1987,³¹ with 96% of pesticide-treated areas receiving a herbicide and 30% insecticides.³² In Canada from 1971 to 1986, there was a threefold increase in herbicide use, while insecticide use increased fivefold, resulting in 1986 in 34 and 7% of total farmland being treated with herbicides and insecticides, respectively.³³ In addition, the spiralling cost of developing and registering new pesticides has led manufacturers to concentrate their efforts on broad-spectrum products for use in a world market at the expense of more selective ones that offer environmental benefits through the preservation of some nontarget species but that may have more limited markets.

These many changes in agricultural production systems are now considered responsible for the decline in much of farmland wildlife. However, individual factors alone cannot often be identified as the cause because the functioning of agroecosystems is relatively complex, and thus a number of interacting factors will be responsible.⁴ The response of the grey partridge provides one of the best researched examples, but the principles apply to a much wider range of wildlife.

Figure 43.1 The number of active pesticide ingredients approved for use in U.K. cereal fields by decade.

Table 43.1 The Use of Pesticides on Winter Wheat in England and Wales 1974–1998

	1974	1977	1982	1988	1990	1992	1994	1998
Total area grown (x 10 ³ ha)	1139	1025	1620	1780	1895	2067	1811	2045
Area of crop treated (x 10 ³ ha)								
Insecticides	44	491	345	1004	1952	1585	1462	2068
Fungicides	94	367	3274	4815	6044	7016	6145	8053
Herbicides	1793	1647	4161	4385	4297	4608	4879	6469

43.1.3 The Decline of the Grey Partridge in the United Kingdom

As a hunted species, the grey partridge represents a valuable source of historical data for bird numbers stretching back many decades because of the bag data (hunting records) it generates. In the United Kingdom, bag records reveal that about 2 million birds were killed annually on a sustainable basis between 1870 and 1930.³⁴ Between 1940 and 1990, the same source of bag data showed a decline of about 85%³⁵ (Figure 43.2). As a result of this national decline, The Game Conservancy Trust began an intensive study of grey partridges on farmland in southern England in 1968, and it was still collecting data in 2002.³⁶ Details of this Sussex study may be found

Figure 43.2 Mean annual number of grey partridges shot per km² from 12 estates in southern and eastern England for which records extend back to 1900. (From: Aebischer, N.J., in *Conservation and the Use of Wildlife Resources*, Chapman & Hall, London, 1997. With permission.)

elsewhere.³⁷ Monitoring this study area showed that in the late 1960s, spring pair density on the 62-km² study area was 20 pairs/km². This has fallen to less than five pairs in recent years (Figure 43.3). This trend is very similar to the national situation provided by the British Trust for Ornithology's database whose index of abundance for the grey partridge declined between 1962 and 1994 by 90%.³⁵ (Figure 43.4).

43.1.4 The Impact of Pesticides

If pesticide use is implicated in this decline of a once common and widespread farmland bird in the United Kingdom, then a mechanism for such a decline must be identified, a hypothesis formulated as to its impact and then tested in the field.

Table 43.2 Incidence of Mortality in Gamebirds in Britain

Decade	DNOC (Herbicide)	Cyclodienes (Mainly Dieldrin)	Other Insecticides	Total
1950s	31	>85	34	>150
1960s	0	228	26	254
1970s	1	18	13	32
Total	32	>330	73	>436

43.1.4.1 Direct Effects

In the early 1950s, many birds were found dead on farmland in the U.K. The use of DDT and cyclodiene insecticides like aldrin and dieldrin caused nationwide declines in numbers of sparrow hawks (*Accipiter nisus*) and peregrine falcons (*Falco peregrinus*)^{38,39} and killed large numbers of graminivorous birds.⁴⁰ For partridges and pheasants, a similar trend emerges whereby deaths attributable to the herbicide DNOC, the cyclodiene insecticides, and other insecticides were recorded in the 1950s, 1960s, and 1970s.¹⁷ (Table 43.2). These peaked in the 1960s but declined after reductions in use following government-imposed regulatory restrictions. Although the amounts of pesticides used have increased since the 1950s, the rate of increase was greatest after this period, when direct toxicity was a problem. Furthermore, those products available during the 1950s (e.g., organochlorines), although generally less toxic than those used in the 1970s and more recently (e.g., carbamates and organophosphates), they were more likely to bioaccumulate.

The withdrawal of these products, which began in the mid 1960s, greatly reduced the exposure, so that today this direct effect is not considered to play a major role in the decline of farmland birds in the United Kingdom.⁴¹ Moreover, raptors, which were especially vulnerable to bioaccumulation, have recovered in those countries where organochlorines are no longer used.^{1,5,42} In Spain, however, levels of DDT and lindane are present at a sufficient level to pose a threat to the survival of red-legged partridges (*Alectoris rufa*).⁴³ Unfortunately, banned⁴⁴ or poor-quality products containing contaminants⁴⁵ are still made available in developing countries⁴⁶ and as a consequence can be detected in species feeding in agricultural areas such as raptors⁴⁷ and neotropical migrants.⁴⁸ The persistence of organochlorines in the soil has also enabled them to accumulate in higher organisms, leading to secondary poisoning. In Canadian orchards, DDT is still being detected in American robins (*Turdus migratorius*) 20 years after the last application at levels sufficient to cause mortality or reproductive effects.⁴⁹ This has occurred through the food chain, as the robins feed predominantly on earthworms, which readily accumulate DDT.

Direct mortality may still occur with modern insecticides. When the toxicological appraisal as given on the product label of 100 commonly used pesticides was examined, a relatively high proportion of the insecticides and other products (principally rodenticides and molluscides) were classified as very toxic to birds (Table 43.3). Pesticide incidents involving birds are still frequently recorded in the U.K. via routes described as following approved or unspecified uses.⁵⁰ Species routinely involved include gamebirds, ducks, corvids, geese, pigeons, gulls, and birds of prey. Recent concern has been expressed over mortality rates among owls found dead from residues of rodenticides; their deaths are thought to have been caused by secondary poisoning.⁵¹ Similarly, buzzards (*Buteo buteo*) were dying from feeding on earthworms in sugar beet fields treated with carbofuran.⁵²

Granular insecticides and nematicides may also cause direct mortality because they are readily consumed by ground-feeding birds.^{53,54} For these birds, the method of application may reduce exposure. In a comparison of liquid vs. granular applications of the organophosphorus insecticide diazinon, survival of bobwhite quail (*Colinus virginianus*) was only reduced by the granular form.⁵⁵ In the same experiment, gray-tailed voles (*Microtus canicaudus*) were unaffected, indicating that quail feeding habits increased their susceptibility. However, some liquid formulations can still

produce mortality among birds. Numerous examples can, however, be found in the literature concerning bird mortality caused by modern pesticides from either direct consumption or secondary transfer. For example, the consumption of prey debilitated by insecticides can also increase the risk of consuming toxic doses of pesticides, and this has been shown to occur with insectivorous and vermivorous raptors.⁵⁶ However, the data show that many pesticide-related mortalities go undetected or are not reported. Moreover, the exposure–effect relationship may be difficult to detect if multiple stressors are involved.⁵⁷

43.1.4.2 Sublethal Effects

Many insecticides can adversely affect birds without killing them, for example by increasing their susceptibility to disease or predation, by lowering their productivity, the hatchability of their eggs, the viability of their chicks or by altering their behavior patterns. There has been no evidence, however, to suggest that sub-lethal effects are important in the partridge decline. Recent research with red-legged partridges has shown that some pesticides may increase a bird's susceptibility to later applications of other pesticides. Two separately harmless pesticides suddenly became toxic when used together or in rapid succession. The same synergistic effect has been detected in pigeons, but not in starlings.^{58,59} However, these effects have not yet been demonstrated outside the laboratory.

There has been a failure, so far, to detect large-scale lethal or sublethal effects of pesticides on partridges at a level that would equate to the estimated millions of birds⁶⁰ represented by the scale of the loss (85%) over the last four decades. This is the reason why gamebird research in the United Kingdom has concentrated on the indirect effects following the reduction of weeds and insects on gamebird chick food chains.

43.1.4.3 Indirect Effects

Earlier studies^{61,62} had found that the key factor causing changes in a grey partridge population in southern England was chick survival (Figure 43.5); in addition, those studies had clearly linked the observed national decline with the availability of sufficient quantities of the preferred insects that are essential in the diet of young chicks^{17,63} (Figure 43.6). Moreover, it has been shown that pesticides appeared to be a major factor reducing populations of preferred insects. These insects include a group of Coleoptera (Chrysomelidae, small diurnal Carabidae and Curculionidae), caterpillars of Lepidoptera and Tenthredinidae (sawflies: especially species of the genus *Dolerus*), and many members of the Heteroptera (bugs) especially species of the genus *Calocoris*.⁶⁴ The data

Figure 43.5 Annual chick survival rate (to 6 weeks) of grey partridge in Sussex, 1953–1990, corrected for weather and releasing of hand-reared birds. The thick line indicates the long-term trend; the dotted horizontal line is the minimum chick survival rate required to maintain the population. (From: Aebischer, N.J., in *Conservation and the Use of Wildlife Resources*, Chapman & Hall, London, 1997. With permission.)

Figure 43.6 Relationships between grey partridge chick survival (to 6 weeks) and chick-food insects. Annual survival rates in Sussex in relation to abundance indices of chick-food insects sampled in cereals in mid-June (time of peak chick hatch) 1970–1992. (From: Aebischer, N.J., in *Conservation and the Use of Wildlife Resources*, Chapman & Hall, London, 1997. With permission.)

supporting the importance of insects to grey partridge chicks were reviewed in 2000.⁶⁵ Many of these preferred insects were found to be more abundant at the edges of cereal fields, where grey partridge broods preferentially foraged.⁶⁶

43.2 CONSTRUCTING THE HYPOTHESIS FOR THE INDIRECT EFFECTS OF PESTICIDES

There is now an enormous amount of data documenting that various types of pesticides can reduce the numbers of nontarget chick-food insects that are crucial in the diet of young gamebird chicks in their first two weeks of life.

43.2.1 The Impact of Pesticides

43.2.1.1 Insecticides

The use of insecticides has been shown to significantly reduce densities of chick-food insects in cereal crops at the time chicks hatch and actively begin foraging for food. Such studies have either compared groups of commonly used insecticides,^{67,68} or they have focused on particular groups of insecticides like the organophosphates^{69–73} or the pyrethroids.^{74,75} There was evidence from feeding trials that some insecticides can cause taste aversion in birds, which would ultimately have the same impact as invertebrate mortality because the food resource were made unavailable.⁷⁶ This remains to be proven for birds foraging under natural conditions. Alternatively, the direct impact of insecticides to chick-food insects⁷⁷ has been reported and specifically for the sawflies (Hymenoptera: Tenthredinidae)⁷⁸ and the Heteroptera (Hemiptera).⁷⁹

All these studies document short-term reductions of invertebrates following insecticide application. With respect to chick survival, such reductions are crucial as a continual supply of food is required; lack of food, even for relatively short periods, in combination with inclement weather may be sufficient to cause mortality or adversely influence development. However, long-term trends are also important, as demonstrated in the link between declining chick-food invertebrates and the grey partridge. The declines found for many insect groups in Sussex¹³ have also been mirrored elsewhere, although they are not always so clearly demonstrable.⁸⁰ In Germany, a 50 to 81% reduction in the activity/density of carabids and formicids was found over a 30-year period, with a 48 to 85% decrease in species numbers.¹⁴ Similarly, an 81% decrease in carabid beetle trapping rates and a 90% decrease in biomass were found from 1971–1974 compared to 1978–1983.⁸¹ Indeed, monitoring conducted within the LINK Integrated Farming System project in the U.K. from 1992–1997 on six farms revealed that the numbers and diversity of invertebrates were very low at half of the sites, suggesting that intensive arable farming was having adverse effects.⁸² Species dominance may also change,^{83,84} which can also alter food availability for birds. In general, invertebrate species with the poorest dispersal power have declined the most.⁸⁵

Whether an insecticide has an impact on invertebrates may vary, depending on a complex of interacting factors such as the insecticide's characteristics, the invertebrate species and its associated biology, the application technique, and environmental conditions.^{86,87} Consequently, the impact on individual invertebrates in the crop will vary considerably. Taking many of these factors into consideration by calculating a hazard index, insects inhabiting the top of the crop were found to be most vulnerable to insecticides.⁶⁷ Moreover, the duration of the effect will depend on the chemical's persistence and the capacity for reinvasion from untreated refuges, which again will be species-dependent.⁷¹ The speed of recovery appears to be inversely related to the size of the treated area.⁸⁸ Thus, the impact on species dependent on invertebrates as a food resource will vary considerably, the extent of effect varying with their foraging range, the scale of the insecticide application, and weather conditions. In addition, insecticides may also influence the breeding condition of insectivorous birds: those with lower fat reserves as a result of poorer feeding conditions produce fewer broods and are less successful with each one, although there is only evidence for this with respect to granivorous birds and seed availability (see below).

43.2.1.2 Fungicides

The use of fungicides has also increased in U.K. cereal fields, and the insecticidal properties of these fungicides and their impact on chick-food insects have also been reported.^{68,89,90} Modern fungicides are, however, still relatively harmful to invertebrates (Table 43.3) and may also decrease food availability for saprophytic species; this may explain the decline in the Sussex study of *Tachyporus* species (Coleoptera: Staphylinidae), a group of fungal-feeding rove beetles.¹³

43.2.1.3 Herbicides

Herbicides have only rarely been shown to cause direct mortality of farmland arthropods, other soil organisms, birds, or mammals, especially under field conditions,⁹¹⁻⁹³ although some are classified as very toxic (Table 43.3). However, they influence the density, distribution, and composition of weeds present in cropped fields. These provide foliage and seeds for phytophagous and polyphagous species, influence the microclimate and thereby soil moisture, and govern the degree of physical protection from predators.⁹³ Thus, the environment created after herbicide applications will favor xerophobic or euryhygric species, which prefer more open habitat, while phytophagous, xerophilic species will be confined to weedy patches and field margins.⁹⁴ Arable weed abundance and diversity have declined in the long-term with the intensification of agriculture and in particular the use of more efficient herbicides,¹⁵ which is considered to be important in the decline of invertebrates.^{30,93}

Many chick-food insects are also phytophagous or associated with high densities of weed cover.⁹⁵⁻⁹⁸ The use of herbicides has also been an important factor in the dynamics of grey partridge chick survival because of their ability to remove weeds that are the host plants of many of these phytophagous beneficial insects.^{63,96,99-101} Weed seeds are also an important dietary component of many adult farmland birds, especially in autumn and winter when they feed upon cereal stubbles.^{26,41} Low seed availability during this period as a result of intensive herbicide use in the preceding crop may lead to a situation in which birds start breeding with lower fat reserves and consequently have a lower reproductive capability. Evidence that spring seed supplies are insufficient was demonstrated with ring-necked pheasants. Supplementary feeding increased their breeding success.¹⁰² Similarly, the number of clutches produced by Turtle doves (*Streptopelia turtur*) has declined since the 1960s from 2.9 to 1.6 because their preferred food, the broad-leaved weed common fumitory (*Fumaria officinalis*), is not sufficiently available.¹⁰³

43.2.2 The Hypothesis

As partridge numbers declined, the annual rate of chick survival, governed by the availability of their chick-food insects, also fell. At the same time, herbicide and insecticide use increased. Experimental evidence proved the powerful impact of insect-host-plant removal by herbicides as well as the impact of nontarget-insect removal by insecticides. Routes of exposure that would produce direct toxicities to partridges were discounted, and sublethal impacts provided no plausible explanation for the magnitude of the observed declines. Therefore, in the early 1980s in the United Kingdom, The Game Conservancy Trust developed the hypothesis that the grey partridge decline was caused by the use of insecticides killing insects and herbicides removing host plants, both of which reduced chick-food insects.

43.3 TESTING THE HYPOTHESIS

A series of large-scale, replicated experiments was set up in the mid-1980s to test this hypothesis. A large farming estate (about 3000 ha) was divided into three areas or beats and each area divided into two blocks. The six trial plots contained a total of 37 cereal fields. In each field, in one block of land in each area, a 6-meter-wide strip of the cereal crops was not sprayed with pesticides after January 1. Fields in the other block of land per area were fully sprayed right up to the crop edge. The delineation between blocks of land either sprayed or with unsprayed edges was chosen to coincide with natural barriers to partridge movement such as woods, shelter belts, and blocks of break crops such as oilseed rape known to minimize movement of broods between spray treatments. Details of the experiment, the cropping, and the pesticide regime are described elsewhere.²⁰ After

Table 43.4 Mean Grey Partridge Brood Sizes (\pm SE) on Blocks of Cereal Fields with Sprayed and Selectively Sprayed Headlands in Southern and Eastern England (Sample Sizes in Parentheses)

Grey Partridge, Mean Brood Size				
Study Area	Year	Sprayed Headlands	Selectively Sprayed Headlands	P
Principal study	1983	4.7 \pm 1.1 (39)	8.4 \pm 1.2 (29)	<0.01
Farm	1984	7.5 \pm 0.8 (34)	10.0 \pm 0.6 (34)	<0.01
Southern England	1985	3.3 \pm 0.7 (9)	5.7 \pm 0.6 (34)	<0.05
	1986	5.9 \pm 1.6 (17)	6.2 \pm 1.0 (21)	NS
Eastern England	1984	4.7 \pm 0.4 (71)	7.8 \pm 0.6 (57)	<0.001
	1985	2.7 \pm 0.4 (19)	4.0 \pm 0.7 (19)	<0.05
	1986	4.8 \pm 0.6 (32)	8.7 \pm 1.5 (6)	<0.001

harvest, field counts of partridges were made from vehicles at dawn and dusk, when family parties or coveys of partridges were actively feeding.

After 1984 in southern England, the cereal crop edge pesticide recommendation changed from no sprays after January 1 to a selective spray regime whereby certain autumn-applied insecticides, noninsecticidal fungicides, and certain graminicides were used. These selectively sprayed edges became known as Conservation Headlands and were selected for practical agronomic reasons. However, such a spray regime still withheld all spring and summer insecticides and all broad-leaved weed herbicides, the group of plants most used as insect host plants. Between 1984 and 1986, a series of experiments was set up on eight farms in eastern England to further test this hypothesis.

Without herbicides, weeds grew in the unsprayed and, later, the Conservation Headlands. Individual weed densities, total numbers of species, total biomass, and percent weed cover were all found to be significantly higher in crop edges with reduced or no herbicides compared to those fully sprayed.^{100,101,104,105} The numbers of chick-food insects were also significantly increased by the provision of host plants provided by the absence of herbicides. Two- and threefold increases in density were recorded both between fields⁶⁸ and within a field.¹⁰⁵

In response to increased densities of chick-food insects in areas of crops not receiving full inputs of pesticides, mean grey partridge brood sizes were significantly greater compared to brood sizes in areas of farmland that were fully sprayed^{20,21,106,107} (Table 43.4).

Using radiotelemetry with broods foraging in spring barley fields, survival rates to 21 days of age and mean distances between successive roost sites were significantly higher and lower, respectively, in unsprayed headlands compared to those that were fully sprayed. Home range sizes were smaller for broods in fields with unsprayed edges, but the proportion of the 6-meter-wide crop edge in their home range was significantly greater for such broods.²¹

From these studies it has been concluded that grey partridge declines in the United Kingdom have been caused primarily by the indirect effects of pesticides acting on food chains.^{41,108} The Conservation Headland hypothesis was similarly tested in the United States. The density and diversity of plants were increased with associated increases in arthropods. The improved food availability and habitat modification subsequently increased densities and diversity of small mammals. Gamebirds were also expected to be encouraged by the mechanism given for grey partridge.¹⁰⁹ Further evidence is now appearing that this scenario is occurring elsewhere. Poor chick survival along with poor hen survival during the breeding period were identified in France as being responsible for the decline of grey partridge.¹¹⁰ In South Africa, decline of helmeted guinea fowl (*Numida meleagris*) was linked to a reduction in insect and seed food and loss of nesting habitat in intensive agricultural areas.¹¹¹ The grey partridge, however, is likely to be one of the bird species most vulnerable to indirect pesticide effects because it resides year round within agricultural fields, feeding predominantly within crops. Similarly, birds feeding predominantly within orchards may similarly suffer because of the high number of insecticide applications and the extended period over which applications occur. Thus, the birds are more exposed to direct toxicity through ingestion

of treated prey and indirectly by removal of their food.¹¹² Indeed, avian abundance and diversity was lower in conventional compared to organic orchards but no mechanisms was identified.¹¹³ Most other species make some use of noncrop areas within agricultural areas or utilize other habitats during the year and are consequently at lower risk of contamination.^{112,114} Even so, in Canada, those species that spent more time within crops showed population declines.¹¹² The other changes associated with intensive agriculture may, however, also be contributing to their decline.

Other changes in agriculture and game management have also contributed to the decline of the grey partridge and other farmland wildlife. Some of these changes act synergistically with pesticide effects, leading to more rapid and extensive reductions. These key factors include removal or damage of edge habitat, which is used for foraging and serves to supplement that available in the field. This also provides essential cover for nesting and escape from predation.^{17,115} The deliberate or misapplication of herbicides leading to herbicide drift can damage the functioning of such habitats.^{116,117} Finally, the level of mammalian and avian predator control has shown to be important for many farmland bird species,¹¹⁸ and an interaction exists with noncrop habitat. Poor cover appears to increase the chance that nests, chicks, or adults will be predated and may lead to premature nest abandonment.^{115,119} In addition, the time spent foraging is a function of prey availability and consequently the time exposed to predation.^{17,115}

43.4 INDIRECT EFFECTS OF PESTICIDES ON OTHER FARMLAND WILDLIFE

43.4.1 Benefits of Conservation Headlands for Other Farmland Wildlife

Evidence for the indirect effects of pesticides on grey partridges can be readily extended to declines of other farmland species of wildlife. Certainly, in our large-scale experiments in southern and eastern England, other species of gamebirds responded to the presence of increased food resources provided in cereal crop edges where pesticide regimes were modified. Although not in decline, the red-legged partridge also responded to the increased food resource. Mean brood sizes were generally larger with increased chick-food insect densities, but differences become statistically significant between treatment only when data from all study areas were pooled.²¹ The benefits of Conservation Headlands have been similarly demonstrated for a wide range of species, not just in the United Kingdom but also in Sweden¹²⁰ and The Netherlands.¹²¹ Mean brood sizes of ring-necked pheasant (*Phasianus colchicus*) also increased significantly in the presence of crop edges receiving reduced levels of pesticides.^{21,106}

Data on the effects of Conservation Headlands on other species of birds are more variable. In an extensive survey of passerine birds in hedgerows and adjacent crops during the breeding season, the presence of three species of bird — greenfinch (*Carduelis chloris*), robin (*Erithacus rubecula*), and song thrush (*Turdus philomelos*) — was lower in hedgerows adjacent to autumn-sown cereals, which had received pesticides, compared to the presence of those species adjacent to autumn crops which were fully sprayed. Most other species showed similar, but insignificant, differences. However, most species showed a tendency towards higher incidences in hedgerows adjacent to spring-sown cereals with reduced pesticide inputs than in those adjacent to fully sprayed spring-sown crops. There was no manipulative or experimental aspect to this study, and no comment as to mechanisms involved was made.¹²² Insecticide drift into hedgerows poses a threat to birds, both directly as found for nesting great tits (*Parus major*) and also indirectly through the removal of invertebrate food.¹²³ In the Netherlands, Conservation Headlands were used in preference to standard crop edges by the insectivorous bird, *Motacilla flava flava*,¹²⁴ probably because phytophagous insect densities were higher. However, skylarks (*Alda arvensis*), which feed on plants as well as insects at ground level, avoided the Conservation Headlands, probably because of their extensive weed growth.¹²⁴

In another survey of the use made by a farmland bird in an arable farmland habitat, it was found that corn buntings (*Miliaria calandra*), a species in steep decline in the United Kingdom,

also responded to the use of pesticides and the density of insect chick-food items thereby produced.¹²⁵ Adults preferentially foraged in areas of high chick-food-insect density, and density was negatively correlated with the number of insecticide applications made that season. Low chick-food-insect abundance close to nests resulted in greater distances travelled from the nest by foraging parents and longer trip durations. Nestling weight was positively correlated with insect abundance. Finally, the probability of nest survival was negatively correlated with the abundance of chick-food insects close to the nest, apparently as a result of increased predation.¹²⁵

During the course of the experiments on crop margins, the recommendations for pesticide use changed from a no-spray moratorium after January 1 to a selective regime called Conservation Headlands, whereby broad-leaved weed herbicides and summer insecticides were restricted. At this time, the study on nongame species began. Benefits of Conservation Headlands to butterflies (Lepidoptera) started in the mid-1980s with some simple censuses using standard techniques. Over a 5-year period, significantly more individuals representing 13 species were found in Conservation Headlands compared to headlands that were fully sprayed. When pesticide use was reduced, Lepidoptera numbers increased.^{126–128}

Detailed observations of butterfly behavior in the two headland treatments have shown that flight speed and duration were lower in Conservation Headlands.¹²⁹ Activity patterns also changed, with some species showing different behaviors between spray management regimes. Small white (*Pieris rapae*) males spent almost all of their time in flight in field margins that had fully sprayed headlands, with little time devoted to either feeding or resting. In field margins with Conservation Headlands, the proportion of time spent in flight was radically reduced, with a much higher proportion of time spent in feeding and resting.¹²⁹ *Pieris rapae* males observed in fully sprayed field margins also spent most of their time in the hedgerow area, whereas the hedgerows were virtually ignored in field margins where there were Conservation Headlands.

For many species of strongly flying butterflies (Pieridae and Nymphalidae), the nectar provided by weeds such as charlock (*Sinapsis arvensis*), field pansy (*Viola arvensis*), and creeping thistle (*Cirsium arvense*) attracted them into Conservation Headlands. The larval host plants of some of the Pieridae (*S. arvensis* and rape, *Brassica napus*) were found in Conservation Headlands¹²⁶ and were exploited as larval food plants. Increased numbers of such species as green-veined white (*Pieris napi*), *P. rapae* and orange tip (*Anthocharis cardamines*) may also have been caused by their presence. However, the host plants of the Satyridae, Hesperiiidae, Nymphalidae, and Lycaenidae were not found in the Conservation Headlands. Indeed, those of the satyrids and hesperiids (*Graminea*) were selectively controlled using herbicides. This was fortunate, as any eggs laid in Conservation Headlands could constitute lost reproductive effort following destruction by harvest and tillage.

For some species, it was not possible to make sufficient observations in fully sprayed headlands because of low numbers. However, such an explanation cannot be applied to all species recorded on farmland in southern England. No such speculation of time spent between the sprayed and selectively sprayed headland treatments could be found for meadow brown (*Maniola jurtina*) males,¹²⁹ while other species such as the gatekeeper (*Pyronica tithonus*) spent their time in the hedgerow regardless of the spray regime in the adjacent cereal crop edge. However, the abundance of both these species was clearly greater adjacent to Conservation Headlands,¹²⁶ despite our inability to explain these differences in terms of their behavior. It may have been that when hedgerow nectar was scarce, unsuitable, or unavailable, headland nectar was used to “top-up,” or act as the major nectar source.

Another possible explanation for the increased abundance of hedgerow species could be the reduced pesticide drift into field boundaries where the spray boom was switched off 6 m away from the field edge. Conservation Headlands may be acting as buffer zones, protecting hedgerows from summer insecticides and broad-leaved residual herbicides throughout the year. The amount of pesticide deposition into field boundaries adjacent to Conservation Headlands and fully sprayed crop edges has been measured in both the autumn and summer. The crop in the Conservation

Headland buffer zone absorbed a significant amount of pesticide before it reached the noncropped area of the field boundary, thereby reducing spray drift.¹³⁰ Levels of mortality of *P. brassicae* larvae exposed to grass upon which insecticide deposits had drifted from fully sprayed and selectively sprayed crops were significantly different. Very high mortality (100%) was found in larvae exposed to vegetation collected from fully sprayed sections of crop compared to much lower levels of mortality of larvae (18%) exposed to vegetation collected from vegetation adjacent to a nonsprayed headland.¹³⁰ Conservation Headlands were also shown to reduce pesticide drift by 95%, and thus contamination of watercourses and risk to aquatic wildlife decreased.¹²¹

So, for the Lepidoptera, evidence for both direct and indirect routes of exposure to pesticides was found. Longer-term trends in relative abundance have been established on the study farm over a 5-year period and comparisons made with data derived from the U.K.'s National Butterfly Monitoring Scheme. For two satyrid species (*M. jurtina* and *P. tithonus*), populations were either maintained or increased relative to 1984 levels at the study farm. This compares with the south-southeast region of the National Butterfly Monitoring Scheme (many of the incorporated sites being National Nature Reserves), where these species showed declines over the same period.¹²⁶

Other groups of beneficial insects, including the stenophagous and polyphagous natural enemies of cereal pests, may also benefit from the resources provided in Conservation Headlands or from the degree of exclusion of the adverse effects of pesticides that they provide. Reinvansion of a dimethoate-treated field by epigeal invertebrates was quicker and more extensive in the half surrounded by unsprayed outer 6-m border compared to areas fully sprayed.⁷¹ The authors concluded that this was because the margins from which the reinvading arthropods originated were protected from spray drift. Indeed, arthropod abundance is usually greatest at the field edges, declining into the field.^{94,131} Preliminary work has also shown how some economically important species of hover fly (Diptera: Syrphidae) such as *Episyrphus balteatus* made use of the nectar and pollen of flowering weeds in Conservation Headlands such as *S. arvensis*, *Matricaria* spp., and *C. arvensis*.^{132,133} Similarly, bumblebees made use of the pollen resources provided by arable weeds in Conservation Headlands.¹³⁴ Again, analysis of the behavior of adult flies showed that they were retained in the weedy strips because they were foraging on the weeds.¹³⁵

Overall numbers and, in some years, diversity of carabid beetles were higher in unsprayed edges; this was especially true of the spermophagous species, which were responding to the greater abundance of weeds.¹³⁶ Microclimate will change if weed cover increases, and this may influence species composition, as carabids differ in their environmental requirements.¹³⁷ Polyphagous species, such as the carabid beetles *Pterostichus melanarius* and *Agonum dorsale* were also better fed (i.e., a significantly higher proportion of males, gravid females, and nongravid females had all four portions of their digestive tracts full of solid food remains) in Conservation Headlands compared to individuals from fully sprayed crop edges. It is possible that the greater prey availability (larger numbers and more diverse alternative prey items) may increase predator numbers through improved diet and fecundity.¹⁰⁰ For all these groups of nontarget insects, there is evidence of benefit from the increased provision of food resources (pollen, nectar invertebrates) as a result of the reduced use of pesticides.

43.4.1.1 Farmland Birds

In a recent review of the indirect effects of pesticides on birds, the authors concluded that many species of birds fed on a varied diet of plant and invertebrate species found on farmed land. In most groups of farmland birds, populations are either declining or stable and increasing, but in two — the thrushes and the buntings — all species are in decline.⁴¹ The authors conclude from the available data that their food items are also in decline on U.K. farmland. They found that in the majority of studies, the use of pesticides resulted in short-term reductions in the abundance of bird food items and that such effects could persist for weeks or months after initial applications.⁴¹ Many cite these short-term reductions as being unimportant and of little impact on breeding success of

birds. For example, when the impact of two insecticides, Deltamethrin and Furadan, on the chestnut-collared longspurs (*Calcarius ornatus*), which feeds predominantly on grasshoppers, were compared, both insecticides decreased grasshopper populations by more than 90%, but the number of grasshoppers in nestling diets was only decreased in nests within the deltamethrin-sprayed plots.¹³⁸ However, the insecticide spraying did not decrease the total biomass of arthropods delivered to the nestlings, and nestling weight and size were unaffected. In this case, birds overcame the effect of the insecticide spraying by foraging further, although previously this was shown not to occur. Instead, their diet changed.¹³⁸ In contrast, another species present, the Baird's sparrow (*Ammodramus bairdii*), abandoned many of its nests in plots treated with the other insecticide, Furadan.¹³⁸ This difference between species occurred because the design of experiments, the pesticides, and bird species involved can all influence the outcome of field based studies.¹³⁹ Thus, the timing of such insect reductions during the stage when nestlings need feeding could be crucial.

Strong temporal associations between the start of the declines and the widespread use of pesticides in cereals were also found.⁴¹ Strong associations (more than 50% of cereals treated at the beginning of the population decline) of 11 bird species to the use patterns of herbicides were cited. For fungicides, the researchers found associations with six species but no associations for insecticides or molluscicides. For these two pesticide groups, they only refer to probable associations where between 10 and 50% of cereals were treated. However, for 11 out of 12 species, they identify the year the decline started, and those were during a period of increasing pesticide use.⁴¹

For other declining species, there is evidence, but not experimental proof, that the cause is related to pesticide use and the resulting reductions of bird food, both plant and insect material, in the summer to feed chicks and as seeds to feed birds over the winter. However, for these species, other hypotheses linking the declines to changing agriculture practices are equally compelling to explain these declines in the United Kingdom and Canada.^{41,93}

Where pesticides use is eliminated, as in organic production, the benefits would be expected to be greatest. A survey of farms in the United Kingdom revealed higher numbers of birds on organic compared to conventional farms.¹⁴⁰ However, the organic farms were characterized by smaller fields with a greater proportion of hedgerows and more diverse crop rotations, and the effect of eliminating pesticide use could consequently not be separated out as the determining factor in the bird increases. Invertebrate food sources for birds have been found to be higher in Danish organic cereal fields,¹⁴¹ but the differences were lower at the edge compared to the field center, which explains why fewer differences were found between organic compared to conventional cereal fields in the United Kingdom, where only edge samples were taken.¹⁴² In Canada, birds typical of wetland areas were more abundant in the wetland areas on organic farms and in wild areas compared to on conventional farms or those using conservation tillage.¹⁴³ Overall differences in avifaunal density and diversity between the farming systems were small in comparison to differences between farms and wild sites, again emphasizing the importance of noncrop habitats.

43.4.1.2 Other Wildlife

Evidence for the direct and indirect effects of pesticides on other wildlife is less comprehensive than for birds and invertebrates. The pyrethroid insecticides commonly used in temperate farmland areas are not regarded as toxic to mammals,¹⁴⁴ but organophosphorus insecticides are highly toxic and can also reduce activity levels.¹⁴⁵ Insecticides have also been shown to directly reduce the reproductive ability of small mammals, the impact varying between species leading to a change in their competitive ability.¹⁴⁶ As a consequence, the duration of effect lasted longer than the insecticide (diazinon) persisted in the environment.

Amphibians are in worldwide decline, but the causes behind these declines are complex,¹⁴⁷ although pesticides are considered to be the most important factor in agricultural areas.¹⁶ Insecticides originating from intensive agricultural areas were responsible for the decline in riverine amphibian populations,¹⁴⁸ and this may occur through direct toxicity¹⁴⁹ or morphological changes that reduce

survival.^{16,150} The herbicide atrazine has also been shown to cause morphological changes.¹⁵¹ However, there is no evidence that indirect effects through reduced food availability or habitat modification are contributing to these declines, although this is a possibility.

43.5 SUMMARY

Many species of farmland birds are in decline in the United Kingdom, and there is considerable evidence that the indirect effects of pesticides are the cause. Of the 24 species listed as in decline in the United Kingdom, pesticides were thought to have a possible link to 19 species, 11 with reasonably good evidence. For three species, it was thought there was no evidence, but for only one — the grey partridge — was there conclusive evidence for the indirect effect of pesticides.⁴¹ For the grey partridge, survival of chicks is strongly correlated with pesticide use, including insecticides, insecticidal fungicides, and herbicides, which have all been shown to reduce the insect foods of a partridge chick.¹⁷ The timing of the partridge decline coincides with the increased use of pesticides, and the effects of pesticides have not been changed by the effects of other changes to farming practice. Changes to chick survival drives the population size of the grey partridge,¹⁷ and it was concluded that the timing and magnitude of changes in population size and chick survival are consistent with the increased use of pesticides as the cause.⁴¹ However, the experimental manipulation of pesticides alone (the Conservation Headlands experiments), when all other variables remained constant, showed a clear link between the indirect effects of pesticides and the decline of this once common U.K. farmland bird.

Indirect effects are also likely to impact a wide variety of farmland wildlife that are dependent on the same food chain as the grey partridge, and evidence of this is starting to appear for some passerines. Small mammals and amphibians may similarly suffer from a decline in their food and the creation of simplistic habitats through the creation of monocultures. Wildlife may also decline if pesticides cause sublethal effects, for example, by changing reproductive success or by altering behavior. However, these are seldom investigated in the field because their impact may be confounded by other factors. Insects especially have been shown in the laboratory to exhibit a range of sublethal effects,⁸⁷ which may then be exacerbated through an interaction with other species, habitat, or the environment.

The development of more efficient pesticides combined with intensive farming methods has allowed farmers to substantially increase yields, to such an extent that set-aside was introduced to control production in the U.S. and in the European Union (EU). This has provided an opportunity to provide areas of habitat able to support a greater abundance of wildlife than could ever be achieved in a crop, however low the inputs. Moreover, the areas under set-aside are massive in comparison to nature reserves, and, because they are located in farmed areas, they have the potential to create a diversity not previously possible. The debate over whether widespread use of extensive farming systems or intensive production with a higher proportion of noncrop areas has yet to be resolved. There is no doubt that set-aside, if sympathetically managed, can support a diverse wildlife.¹⁵² Unfortunately, in the past, the management options for set-aside were restricted by regulation or expense, and the full potential has not been realized. Evidence is now available that wildlife can recover using conventional pesticide inputs, if set-aside along with predator control is managed to provide food and cover for wildlife.¹⁵³ Further evidence on the benefits of set-aside were revealed in an ornithological survey comparing set-aside with arable crops and pasture.¹⁵⁴ Nonpasserines, passerines, insectivores, and granivores all exhibited a preference for rotational set-aside over any farmed crops, probably because of better foraging.

The alternative approach of using more extensive farming systems utilizing lower inputs of pesticides through the greater use of natural control mechanisms has been studied extensively in the EU¹⁵⁵ and in the United States.³⁰ Their impact on wildlife, however, has often been limited to studies of invertebrates because of the resources available or the limitations of scale. Whether the

response was direct or indirect was also not ascertained. The results from these studies have been variable, with some reporting increases in arthropod numbers and diversity where lower inputs of pesticides were used¹⁵⁶⁻¹⁶⁴ but others finding no clear benefit. One of the earliest of these studies, the Boxworth project,¹⁶⁵ also examined the overall impact of conventional and lower-input approaches on small mammals and farmland birds. There was, however, no conclusive evidence of an overall effect of the pesticide regimes on the breeding performance of the most common bird species.¹⁶⁶ Pesticide use has declined considerably in the U.K. since the project finished (Table 43.1), with conventional inputs now being comparable to the lower-input approach used, and consequently the impact on wildlife should be lower.

Pesticides have been identified as contributing to the decline of farmland wildlife, although the impact is often exacerbated by other farm practices associated with intensive agriculture. Their impact may, however, often not be detected because the direct and indirect effects of pesticides are complex and have been studied in detail for only a few species. Costs will inhibit further detailed studies such as those conducted on the grey partridge, but if key indicators can be identified from the grey partridge studies that relate to the population response of other species, then it may be possible to predict the impact of pesticide applications. The abundance of chick-food insects may be one such variable.

44.1 INTRODUCTION

Nutrition of test animals is one of the most important variables in any biological experiment. Animals with poor nutrition can be physiologically abnormal, which can result in biased results in experiments.¹ In the environment, natural feeds typically supply essential vitamins, minerals, trace elements, and other nutrients needed by fish and wildlife to maintain homeostatic functions. However, when fish and wildlife species are cultured and used in experiments, they must have adequate artificial nutrition to ensure survival and growth and, in some experiments, reproductive success including survival and growth of young. Much effort has been expended to document the essential vitamin, mineral, and other nutritional requirements of fish^{2,3} and wildlife.^{4,5} Deficiencies of vitamins, minerals, and other nutrients in prepared fish foods can result in skeletal deformities, cataracts, histological lesions, abnormal behavior, and many other abnormalities; in addition, excessive amounts of vitamins and minerals have also resulted in abnormalities.² Similar findings have been reported in wildlife species in response to nutrient deficiencies and excesses.⁴⁻⁶ Even in routine fish and invertebrate culture activities, monocultures of live foods such as brine shrimp nauplii can vary in their nutritional quality due to genetics, amino acids, fatty acid composition, caloric content, carotenoids, and residues of chlorinated hydrocarbons and inorganic elements.⁷

The quality of commercial or experimentally prepared diets used in fish toxicology studies can influence the acute and chronic toxicity of test compounds.⁸ Mehrle et al.⁸ showed that a high-protein (45%) diet increased a fish's tolerance of a test chemical compared to a low-protein (23%) diet. Furthermore, the type of protein incorporated in a diet can influence a fish's tolerance to toxicants, i.e., protein sources casein and gelatin resulted in a greater tolerance of a test chemical than fishmeal and soybean meal as protein sources. Phillips and Buhler⁹ and Hilton¹⁰ also reported

that diet quality was an important consideration in interpreting experimental results in fish studies. As with prepared fish diets, live diets can influence the results of toxicity tests with fish. For example, the geographical source of the brine shrimp can alter the toxicity exhibited by fish exposed to test compounds.^{11,12}

Several studies have compared the uptake of inorganic elements from water and food either simultaneously or within a series of experiments.^{13–19} Although exposures were generally in the $\mu\text{g/L}$ range for water and in the $\mu\text{g/g}$ range for food, body burdens of toxicant were mostly derived from food exposures. Thus, the nutrition and dietary content of trace elements can play an important role in the culture and use of fish and wildlife in research activities.

44.1.1 Overview of Trace Elements Essential to Fish and Wildlife Nutrition

Trace elements, considered essential micronutrients in most animals, include arsenic, cobalt, copper, iron, manganese, molybdenum, selenium, vanadium, and zinc.^{5,6,20,21} For these elements, there are three levels of biological activity: trace concentrations are required for normal growth and development, moderate concentrations can be stored without disrupting homeostatic functions, and elevated concentrations can result in toxic effects. Numerous other trace elements are not considered essential and at elevated environmental concentrations can result in toxic effects. Human industrial and agricultural activity has hastened the release of inorganic elements from geologic sources and made them available to fish and wildlife in aquatic and terrestrial ecosystems around the globe.

Uptake of essential trace elements can be from water or diet. Uptake of water-soluble trace elements by fish can be either by gills or epidermis. However, dietary exposure of fish to inorganic elements is usually the dominant pathway of uptake because fish are typically at higher trophic levels in the aquatic food web,^{22,23} as are birds and mammals that feed in aquatic ecosystems.

44.1.2 Overview of Trace Elements Toxic to Fish and Wildlife

Reviews of trace elements in human health have been reported by Goyer.²¹ For fish, Leland and Kuwabara²⁴ reviewed the effects of copper, lead, mercury, and zinc, and Sorensen²⁵ reviewed the effects of arsenic, cadmium, copper, lead, mercury, selenium, zinc, and mixtures of elements. Since the publication of those two studies, many additional dietary toxicity studies with fish have been conducted. The effects on wildlife of arsenic, boron, cadmium, chromium, copper, iron, mercury, lead, manganese, molybdenum, nickel, selenium, silver, tin, and zinc have been reviewed by Klasing⁵ and Eisler.⁶ Further reviews of effects of lead, mercury, and selenium are provided within other chapters of this book. Ohlendorf et al.²⁶ reported on the uptake and potential interaction in wildlife of selenium with arsenic, boron, and molybdenum from food chain organisms in areas in central California impacted by agricultural irrigation activities.

Diet is recognized as a highly relevant route of inorganic element uptake, especially in chronically exposed feral fish.^{27–30} Dallinger et al.²³ coined the phrase “the food chain effect” to describe the movement of trace elements along the food chain in polluted aquatic environments to fish and the resulting adverse effects. They noted that two factors affect the food chain effect: (1) high concentrations of contamination of the food and (2) the reduction of species diversity that occurs when susceptible species are eliminated and metal-tolerant food organisms become dominant. The dominance of the dietary pathway for uptake of inorganic elements in fish is particularly true for bioaccumulative elements like selenium. For example, fish species have disappeared from aquatic ecosystems due to food chain contamination by selenium at Belews Lake in North Carolina,^{31,32} Martin Lake in Texas,^{33,34} and Kesterson Reservoir in California.^{35,36}

Few trace elements have been studied in aquatic food chains, but there is some information on arsenic, cadmium, vanadium, and mercury and a substantial amount of literature on selenium. Chen and Folt³⁷ reported that arsenic was not biomagnified to fish in an arsenic- and lead-contaminated

aquatic ecosystem. Biomagnification is defined as the processes of both bioconcentration (uptake from water) and bioaccumulation (uptake of a contaminant from both water and dietary sources) that result in increased tissue concentrations of a contaminant as it passes through two or more trophic levels. Devi et al.³⁸ reported that cadmium was bioaccumulated in a simple aquatic food chain comprised of duckweed (*Lemna minor*) and red swamp crayfish (*Procambarus clarkii*). The information on vanadium is mostly for marine ecosystems because vanadium is an element of concern in seawater. Reports by Unsal³⁹ and Miramand and Fowler⁴⁰ showed that vanadium bioaccumulates in marine food chains, and it was assumed by the authors that a similar bioaccumulation occurred in freshwater ecosystems. Suedel et al.⁴¹ report that methylmercury and possibly inorganic mercury biomagnify in aquatic ecosystems. Cherry and Guthrie⁴² reported that selenium and zinc biomagnified in an aquatic ecosystem contaminated with coal ash. Suedel et al.⁴¹ acknowledged that dietary uptake of inorganic elements was an important route of exposure in higher trophic levels.

Several papers document and review selenium in aquatic food chains from various viewpoints such as those of an aquatic toxicologist,⁴³ wildlife toxicologists,^{44,45} an ecologist,⁴⁶ a research chemist,⁴⁷ a modeler,⁴⁸ a national selenium expert,⁴⁹ and other experts.^{25,50,51}

Bioaccumulation of trace elements in food chain components such as aquatic invertebrates and fish has been documented in aquatic ecosystems contaminated with mixtures of elements. Cherry and Guthrie⁴² examined contaminated food chains in settling basins for coal ash and reported that several elements were elevated in higher trophic levels including arsenic, copper, manganese, selenium, and zinc. These elements were biomagnified by at least one biotic component compared to sediment concentrations of the elements. They reported that aquatic plants had high concentrations of arsenic, manganese, mercury, and titanium; invertebrates had biomagnified concentrations of arsenic, cadmium, chromium, cobalt, copper, and mercury; and fish had biomagnified selenium and zinc.⁴²

Furr et al.⁵² also examined contaminated food chains in coal-ash-settling basins and reported that aluminum, cobalt, europium, iron, lanthanum, lutetium, samarium, selenium, and titanium were elevated in biota from a fly-ash pond compared to a reference pond. They concluded that, from a toxicological standpoint, selenium was the only element of concern to biota. Patrick and Loutit⁵³ also showed accumulation of chromium, copper, iron, lead, manganese, and zinc in fish fed tubificid worms, which in turn had ingested inorganic-enriched heterotrophic bacteria. Dallinger and Kautzky²² concluded that uptake of inorganic elements in fish in a polluted river in Italy was primarily from food organisms because the waterborne concentrations of elements were low, which suggested to the authors that absorption through the gills was of secondary importance.

Of course, not all trace elements accumulate in fish and wildlife primarily from dietary exposure. For example, Suzuki et al.⁵⁴ reported that dietary exposure was the primary route for manganese and zinc, water exposure was the primary route for strontium and rhodium-ruthenium, and diet and water had equal roles in the accumulation of cesium, cobalt, and cerium-praseodymium in yellowtail (*Seriola quinqueradiata*).

There is a substantial database of information on the toxicity of dietary selenium in fish and wildlife but a more limited database on the dietary toxicity of other elements. Consequently, the following sections emphasize selenium and interactions with selenium. The paucity of information on the dietary toxicity of other elements should not be misinterpreted to mean that they are not important environmental considerations.

44.2 TOXICITY OF SELENIUM TO FISH AND ITS EFFECTS

Several early dietary studies with selenite and rainbow trout (*Oncorhynchus mykiss*) were published in the early 1980s by Canadian researchers.⁵⁵⁻⁵⁹ These investigations were not apparently connected to the fish population disappearances in Belews Lake, North Carolina, which were

believed to be due to selenium toxicity.³¹ This same group of researchers also conducted two waterborne studies with selenite and rainbow trout to complement their dietary studies.^{14,60} These early selenium studies explored dietary requirements, elimination and uptake rates from water and diet sources, the minimum dietary requirement for rainbow trout (between 0.15 and 0.38 $\mu\text{g/g}$ in dry feed) for maximal storage, half-life period, influence of dietary carbohydrate, and toxic concentrations in water and diet. It was shown that plasma glutathione peroxidase homeostasis was maintained at up to 1.25 $\mu\text{g/g}$ dry-feed activity; toxicity occurred at 13 $\mu\text{g/g}$ dry feed, but the authors speculated that dietary concentrations in excess of 3 $\mu\text{g/g}$ in dry feed over long time periods might be toxic; liver and kidney were the primary tissues of storage; and excess dietary carbohydrate enhanced dietary selenium toxicity in rainbow trout. Channel catfish (*Ictalurus punctatus*) have similar responses to dietary selenium (requirement between 0.1 and 0.5 $\mu\text{g/g}$ and toxicity at 15 $\mu\text{g/g}$) to those of rainbow trout.⁶¹

Two other early investigations of dietary selenite toxicity to rainbow trout were conducted by the Colorado Division of Wildlife.^{62,63} Their investigations were prompted, in part, by two field investigations in Colorado and Wyoming that concluded selenium toxicity was occurring in fish via the food chain.^{64,65} Barnhart⁶⁴ was the first publication to suggest that selenium in the food chain was causing fishery problems in Sweitzer Lake in western Colorado. It is interesting to note that these publications and those of the Hilton group⁵⁵⁻⁵⁹ did not mention selenium problems in Belews Lake, North Carolina, which was occurring during the same time period. Goettl and Davies⁶³ reported that dietary selenium toxicity occurred between 5 and 10 $\mu\text{g/g}$ dry diet, which is remarkably close to that reported by the Hilton/Hodson group and also to later dietary studies conducted with selenomethionine and other fish species in the late 1980s.

Sandholm et al.⁶⁶ were the first to show that selenium accumulation in fish was greater from dietary sources such as phytoplankton or zooplankton than from water. They also showed that there was little difference in fish accumulation of selenite or selenomethionine in the food chain. Besser et al.⁶⁷ further reported that selenate and selenite were accumulated in fish primarily via the food chain, whereas selenomethionine was accumulated via both aqueous and food chain uptake. Kleinow and Brooks⁶⁸ reported that selenite and selenate were efficiently absorbed from the gastrointestinal tract of fish, thus resulting in a high assimilation efficiency.

In general, dietary studies with selenomethionine have reported that toxic responses in fish were similar to those in fish fed diets containing naturally incorporated selenium compounds such as fishmeal made from western mosquitofish (*Gambusia affinis*)⁶⁹ or zooplankton.⁷⁰ However, Bell and Cowey⁷¹ reported that the digestibility and availability of selenium to Atlantic salmon (*Salmo salar*) were the least for fishmeal (source not given) and followed the order from greatest to least: selenomethionine > selenite > selenocystine > fishmeal. The comparability of selenium-laden fishmeal diet and a selenomethionine-fortified diet in three studies with chinook salmon (*Oncorhynchus tshawytscha*)⁶⁹ compared to differential digestibility reported in Atlantic salmon⁷¹ may reflect species differences or fishmeal differences. In the study by Hamilton et al.,⁶⁹ the authors noted in both their freshwater and brackish-water studies with chinook salmon that fish growth was significantly reduced at lower concentrations and in shorter exposure periods in fish fed the diet made with the western mosquitofish fishmeal compared to the selenomethionine diet, which contained a comparable amount of clean fishmeal from western mosquitofish. They suggested that the slightly greater toxic effect in fish fed the fishmeal diet could have been caused by three factors: (1) additional toxic elements accumulated in the western mosquitofish inhabiting the San Luis Drain, (boron, chromium, and strontium); (2) other forms of organoselenium such as selenocystine present in the western mosquitofish; or (3) differential uptake, distribution, or elimination of the protein-bound organoselenium in the fish fed the western mosquitofish fishmeal diet compared to fish fed the free amino acid selenomethionine diet that contained a comparable amount of clean fishmeal.

Due to the similarity between selenomethionine and naturally selenium-laden food organisms, selenomethionine-fortified diets have been used in studies with bluegill (*Lepomis macrochirus*) to

determine toxic effects on reproduction.^{72–74} The study by Woock et al.⁷² incorporated a waterborne exposure to 10 µg/L selenite and reported that larvae survival was reduced in the adult dietary exposure to 13 µg/g diet. The Cleveland et al.⁷³ study with juvenile fish reported effects at some of the lowest whole-body selenium residues (~4–5 µg/g, wet weight) that have been linked to adverse effects in fish. The Coyle et al.⁷⁴ study incorporated a 10 µg/L waterborne selenium exposure and reported adverse effects on fry when adults were exposed to 33 µg/g in the diet. Ogle and Knight⁷⁵ conducted a reproduction study with adult fathead minnow (*Pimephales promelas*) and progeny exposed to a dietary mixture of selenate, selenite, and selenomethionine. They reported reduced growth of adults exposed to 20 µg/g selenium after 56, 70, 84, and 96 days of exposure, but no effects on progeny.

As was reported with selenomethionine, Bryson et al.⁷⁰ reported that selenocystine incorporated into a fish food diet also produced adverse effects comparable to selenium-laden zooplankton. Bryson et al.⁷⁰ and Woock et al.⁷² reported that diets incorporating selenite were not as toxic to fish as diets incorporating selenomethionine. This finding may be related to those of Lorentzen et al.⁷⁶ who reported that at low dietary selenium concentrations (~1–2 µg/g), dietary selenite was accumulated primarily in liver, whereas dietary selenomethionine accumulated primarily in whole body and muscle. This differentiation of storage compartments for different selenium compounds may influence the toxic effects observed.

Studies conducted in experimental outdoor streams at the U.S. Environmental Protection Agency's Monticello Research Station have demonstrated adverse effects on reproduction of fathead minnow and bluegill exposed for about a year to a selenite concentration of 10 µg/L.^{77–79} Although these studies did not measure selenium concentrations in the food chain, selenium was rapidly accumulated during the growing season (i.e., May–September) in sediments and emergent, floating, and submerged aquatic plants in wetlands that comprised a portion of the experimental streams.⁸⁰ Consequently, accumulation of selenium in food organisms no doubt occurred and contributed to a dietary exposure of the fish.

Several dietary selenium studies have been conducted with food organisms collected from selenium-contaminated environments. Woock⁸¹ demonstrated in a cage study with golden shiners (*Notemigonus crysoleucas*) that fish in cages with access to bottom sediments accumulated more selenium than fish held in cages suspended about 1.5 m above the sediments. This study showed that effects in fish were linked to selenium exposure via sediment, benthic organisms, detritus, or a combination of sediment compartments. A similar finding was reported by Barnhart⁶⁴ who reported that “numerous species of game fish” lived at least 4 months when held in a livebox, which limited access to food organisms and sediment, but fish lived less than 2 months when released in selenium-contaminated Sweitzer Lake, Colorado. The highly toxic nature of benthic organisms from selenium-contaminated Belews Lake, North Carolina was shown by Finley⁸² in an experiment where bluegill-fed *Hexagenia* nymphs died in 17 to 44 days. In another study, selenium-contaminated red shiner (*Notropis lutrensis*) collected from Belews Lake, North Carolina were highly toxic to striped bass (*Morone saxatilis*).⁸³ In a series of experiments with the endangered razorback sucker (*Xyrauchen texanus*), larvae were fed selenium-laden food organisms from sites in the upper Colorado River and the Green River, both in the upper Colorado River basin.^{84–86} Larvae consistently showed adverse effects at 4–5 µg/g in the diet (zooplankton collected from backwater areas).

Another important aspect influencing the toxic effects in fish resulting from dietary selenium exposure is season.⁸⁷ The toxicity to bluegill of combined low dietary (5.1 µg/g) and low waterborne (4.8 µg/L) selenium at low water temperature (4°C) resulted in significantly increased mortality of fish.⁸⁸ The combination of a stress-related elevated energy demand from selenium exposure and reductions in feeding due to cold temperature and short photoperiod led to a severe depletion of stored body lipid and an energetic drain that resulted in the death of about a third of the fish tested. Heinz and Fitzgerald⁸⁹ also suggested that stress from winter conditions might have increased the harmful effects of dietary selenium in adult mallards (*Anas platyrhynchos*).

44.3 INTERACTIONS OF SELENIUM WITH OTHER TRACE ELEMENTS IN FISH

Selenium interacts with several trace elements in fish, birds, and mammals.^{25,90–92} These interactions can be additive, antagonistic, or synergistic, and in some cases the interaction was reversed, i.e., antagonism changed to synergism. In general, selenium toxicity was alleviated by antimony, arsenic, bismuth, cadmium, copper, germanium, mercury, silver, and tungsten,^{90–93} whereas chromium, cobalt, fluorine, molybdenum, nickel, tellurium, uranium, vanadium, and zinc apparently have no effect on selenium toxicity.^{94,95} Dietary studies conducted with fish have assessed the interaction between selenium and arsenic, copper, and mercury, as discussed below.

44.3.1 Arsenic Interaction with Selenium

An arsenic interaction with selenium seems to have occurred in a toxicity test conducted with endangered larval razorback sucker (Table 44.1).⁸⁵ The study involved exposing larvae to several food treatments and water treatments at locations near Grand Junction, CO. This discussion will be limited to one water treatment and two food treatments: nauplii of brine shrimp (reference food) or natural zooplankton collected from a low-selenium wetland (termed HTEW: Horsethief east wetland) located near the Colorado River, but up-gradient from irrigation activities.

Selenium residues in razorback sucker larvae after 10 days of exposure were 6.3–6.7 $\mu\text{g/g}$ in the brine shrimp treatment and 6.1–7.0 $\mu\text{g/g}$ in the HTEW treatment. However, survival was very different between the two food treatments: 87% in the brine shrimp treatment, but 15–20% in the HTEW treatment. The difference may have been due in part to the selenium concentrations in food at 10 days of exposure because the brine shrimp treatment had lower selenium concentrations (3.2 $\mu\text{g/g}$) than the HTEW treatment (5.0 $\mu\text{g/g}$). Nevertheless, selenium concentrations in both food treatments were above the selenium dietary toxic threshold (3 $\mu\text{g/g}$),^{96,97} and whole-body residues in larvae from both food treatments were above the whole-body adverse effect threshold (4 $\mu\text{g/g}$).^{55,69,73,75,88,98–101}

The same scenario occurred at day 30 in razorback sucker larvae fed the brine shrimp treatment, where whole-body residues were 5.2 $\mu\text{g/g}$, and in larvae fed the HTEW treatment, where whole-body residues were 8.2 $\mu\text{g/g}$. Survival of larvae was different between the food treatments: 81–83% in the brine shrimp treatment, but 0–10% in the HTEW treatment. Considering that the whole-body residues were somewhat similar, and selenium concentrations in food were relatively close, but survival was very different between the food treatments, it seems that the selenium residue in larvae fed the brine shrimp treatment was somehow inactivated from having a toxic effect, whereas in the HTEW treatment no inactivation occurred.

Hamilton et al.⁸⁶ discussed the potential confounding factors, such as difference between zooplankton and nauplii of brine shrimp (i.e., caloric content, nutrition value, trace element content, suitability as fish food), and concluded that an interaction probably occurred between arsenic and selenium in the brine shrimp treatment. Arsenic concentrations in brine shrimp nauplii were 24 $\mu\text{g/g}$, and in the HTEW treatment they were 6 $\mu\text{g/g}$. Arsenic concentrations in brine shrimp nauplii were not elevated sufficiently to cause dietary toxicity¹⁰² but may have ameliorated the toxic stress of dietary selenium. Arsenic compounds have been shown to protect against the toxicity of a variety of forms of selenium including selenite, selenocystine, and selenomethionine.⁹³ The protective effect of arsenic has been observed in rats, dogs, swine, cattle, and birds.⁹³ In general, arsenic exposure in water or diet protected against dietary selenium toxicity,^{103–110} but combined arsenic and selenium waterborne exposure did not.^{111,112} Dubois et al.¹⁰⁴ and Klug et al.¹⁰⁵ reported that the toxicity of selenite, selenomethionine, selenocystine, and seleniferous grain was reduced in rats by exposure to arsenic as either arsenite or arsenate, but not as arsenic sulfides. Klug et al.¹⁰⁶ exposed rats for 12 weeks to arsenic in water and selenium in the diet and reported that arsenic protected against selenium-induced mortality, reduced growth, and reduced feeding, even though selenium residues were increased in liver (28%), kidney (141%), and muscle (52%) compared to exposure to only

Table 44.1 Interactive Effects of Nutritional Factors and Other Elements on Selenium Toxicity in Fish

Species, Age	Form of Se, Dietary (Conc.)	Interactive Factor	Observation Period	Effects	Ref.
Rainbow trout, juvenile	Sodium selenite (5 or 10 ppm)	Low (0.8%) vs. elevated (24%) carbohydrate	Juvenile through 16 weeks	Excess dietary carbohydrate enhanced selenium toxicity (reduced body weight, enlarged glycogen-filled livers, food avoidance)	57
Chinook salmon, swim-up larvae	Diets with clean fishmeal fortified with seleno-D,L-methionine vs. fishmeal using selenium-laden western mosquitofish (5.3–9.6 ppm)	Organic forms of selenium or trace elements or nutritional factors	Swim-up through 90 days	Fish growth reduced at slightly lower selenium concentrations and in shorter exposure period fed diets with fishmeal using selenium-laden western mosquitofish compared to clean fishmeal fortified with seleno-D,L-methionine	69
Razorback sucker, larvae	Natural zooplankton from selenium-contaminated sites vs. brine shrimp from a commercial source (6–7 ppm)	Elevated arsenic in nauplii of brine shrimp (24 ppm) vs. low arsenic in zooplankton (6 ppm)	5-day-old through 30 days	Elevated arsenic in brine shrimp counteracted selenium to prevent toxic effects, whereas low arsenic in zooplankton did not. Similar selenium residues in larvae but greatly different effects	86
Atlantic salmon, fry	Organic selenium in fish (unknown)	Dietary copper (500 ppm)	Fry through 12 weeks	Reduced growth, depleted energy stores, and selenium-copper antagonism	115, 116
Pearl dace (adult) Yellow perch (~2 g) Northern pike (~35 g)	Natural zooplankton exposed to waterborne selenium (6, 100 ppb)	Mercury-contaminated lakes	3, 6, and 8 weeks	Dietary selenium, but not waterborne selenium, reduced mercury uptake in fish; at elevated concentrations, selenium reduced survival of yellow perch but not pearl dace	118–120
Yellow perch (adult) Northern pike (adult)	Selenite uptake in the food chain (5 ppb in water)	Mercury-contaminated lakes	Adults for 1–2 years	Reduced mercury residues below level of human health, but selenium reduced fish survival and reproduction	122–125

selenium in the diet (no arsenic exposure). Klug et al.¹⁰⁶ concluded that arsenic counteracted selenium toxicity in some way other than increasing selenium elimination. Levander and Argrett¹⁰⁷ also showed that arsenic protected against selenosis in rats and that selenium residues were increased in carcass over animals in the selenium-only exposure. Others have concluded that arsenic exposure increased the elimination of selenium in bile in short-term (1–10 h) injection experiments.^{90–93} In a reciprocal manner, selenium has been reported to reduce arsenic-induced teratogenic deformities in hamsters.¹¹³

Considering that (1) the whole-body residues of larvae were elevated in the brine shrimp and HTEW dietary treatments, (2) selenium concentrations in both diet treatments were above the selenium dietary toxicity threshold, (3) arsenic concentrations in the brine shrimp treatment were elevated (24 µg/g) and in the HTEW treatment were low (6.0 µg/g), (4) survival was high in the brine shrimp treatments but low in the HTEW treatment, and (5) no confounding factors seemed to be present between the two dietary treatments such as caloric content, nutritional value, trace element content (other than arsenic), and suitability as fish food, it seems likely that arsenic interacted with selenium in the fish larvae and inhibited mortality in larvae fed the brine shrimp treatment but did not inhibit mortality in the HTEW treatment.⁸⁶ These results were similar to observations of Klug et al.¹⁰⁶ and Levander and Argrett.¹⁰⁷

44.3.2 Copper Interaction with Selenium

Lorentzen et al.¹¹⁴ and Berntssen et al.^{115,116} both reported that elevated dietary copper reduced concentrations of selenium in liver of Atlantic salmon. Lorentzen et al.¹¹⁴ suggested that reduced selenium concentrations were due to the formation of insoluble copper–selenium complexes in the intestinal lumen, reducing selenium bioavailability or the excretion of copper–selenium complexes from the liver through the bile. Berntssen et al.¹¹⁶ reported that dietary copper exposure significantly reduced selenium concentrations in intestine and liver, which in turn reduced glutathione concentrations (selenium is a component of glutathione). However, dietary copper did not affect antioxidant glutathione peroxidase enzyme activity. In contrast, Hilton and Hodson⁵⁷ reported that increasing dietary selenium exposure of rainbow trout significantly increased copper concentrations in liver. They speculated that dietary selenium interfered with copper transport or excretion.

44.3.3 Mercury Interaction with Selenium

Perhaps one of the most published interactions between inorganic elements is that between mercury and selenium. Pelletier¹¹⁷ reviewed the literature for aquatic organisms and concluded that many authors reported simultaneous bioaccumulation of mercury and selenium, but there was no evidence of natural joint bioaccumulation of mercury and selenium in fishes, crustaceans, and mollusks. He noted that many results were unrelated and sometimes contradictory.

A series of experiments by Rudd, Turner, and others^{118–120} investigated the ability of selenium to ameliorate the toxic effects on fish inhabiting a mercury-contaminated lake in the English-Wabigoon River system in Ontario, Canada. They conducted enclosure experiments in the lake and reported that selenium additions reduced mercury accumulation in fish. Selenium interfered with mercury mobilization through the food web rather than mercury accumulation directly from water. They cautioned that selenium amelioration of mercury should be approached with caution because selenium readily and efficiently accumulated in the food organisms and fish, especially through the food chain, and recommended that selenium additions be limited to 1 µg/L. Klaverkamp et al.¹²¹ reported that exposure of northern pike (*Esox lucius*) to waterborne selenium at 1 µg/L reduced mercury accumulation in carcass, but exposure to 100 µg/L selenium increased mercury accumulation in carcass.

Another series of experiments in mercury-contaminated lakes in Sweden also tested the ameliorating effects of selenium.^{122–124} Like the studies by Rudd, Turner, and others, these studies also

confirmed that selenium readily reduces mercury accumulation in fish, but selenium bioaccumulated in fish via the food chain if waterborne selenium concentrations were $> 3\text{--}5\ \mu\text{g/L}$. Fish kills of yellow perch (*Perca flavescens*) occurred in 4 of the 11 lakes in their study, which prompted Lindqvist et al.,¹²⁵ who reviewed mercury concerns in the Swedish environment, to recommend against the use of the selenium amelioration technique in mercury-contaminated lakes.

44.4 EFFECTS OF TOXIC DIETARY TRACE ELEMENTS (OTHER THAN SELENIUM) TO FISH

44.4.1 Aluminum

Dietary-aluminum studies with fish showed that aluminum accumulated in fish, but apparently did not result in toxic effects.^{126–128} Interestingly, Poston¹²⁶ reported no effects on growth, survival, or feed conversion in Atlantic salmon fed up to $2000\ \mu\text{g/g}$ dietary aluminum. These studies contrast with waterborne studies that showed that, under acid rain conditions (i.e., low pH), certain aluminum species can be toxic to fish, although they did not seem to accumulate substantially.¹²⁸ Poston¹²⁶ reported that trace amounts of aluminum had some nutritional benefits to Atlantic salmon, thus suggesting that aluminum may be an essential inorganic element and most likely metabolically regulated.

44.4.2 Arsenic

Dietary inorganic arsenic compounds (arsenic trioxide [AT] and disodium arsenate heptahydrate [DSA]) were more toxic to rainbow trout than organic arsenic compounds (dimethylarsinic acid [DMA] and arsanilic acid [AA]).¹²⁹ The NOEC (no-observed-effect concentration) for inorganic arsenic was between 1 and $137\ \mu\text{g/g}$ for DSA, between 1 and $180\ \mu\text{g/g}$ for AT, and at least $1497\ \mu\text{g/g}$ for DMA and AA. In a more detailed dietary-arsenic study with rainbow trout, Cockell et al.¹⁰² reported adverse effects in fry at $33\ \mu\text{g/g}$ of pentavalent arsenic as DSA. In another dietary arsenic study with rainbow trout exposed to trivalent arsenic (sodium arsenite), Oladimeji et al.¹³⁰ reported adverse effects at 20 and $30\ \mu\text{g/g}$, thus suggesting that the dietary toxicity of trivalent and pentavalent forms of arsenic were similar. However, in aquatic ecosystems, arsenic does seem to biomagnify in invertebrates but not in fish.⁴² Chen and Folt³⁷ reported that in the arsenic- and lead-contaminated Aberjona Watershed of Massachusetts, arsenic accumulated in lower food-chain components such as algae and zooplankton, but not in upper trophic levels including fish. Woolson¹³¹ also reported that although arsenic was bioconcentrated from water to aquatic plants, it was not biomagnified to invertebrates or fish. Although arsenic bioaccumulated in plants and zooplankton,^{37,42} no biological effects were measured in fish.^{37,42,131} Furthermore, Chen and Folt³⁷ noted that although arsenic was bioaccumulated in lower trophic levels from the arsenic-contaminated site, fish from that site had tissue arsenic concentrations similar to reference areas.

44.4.3 Cadmium

There is a controversy as to the importance of exposure route in the accumulation of cadmium in fish. Studies have reported that (1) a greater proportion of cadmium was accumulated from food than from water,^{19,22,132} (2) about equal amounts of cadmium were accumulated from diet or water exposures,¹³³ or (3) more cadmium was accumulated from water than dietary exposures.^{134–136} Several studies have reported cadmium concentrations in food that were related to adverse effects. Handy¹³⁷ reported that dietary cadmium at $10\ \text{mg/g}$ caused increased mortality of subadult rainbow trout in a 28-day study. Hatakeyama and Yasuno¹³⁸ reported that the reproduction of the guppy (*Poecilia reticulata*) was adversely affected, i.e., the cumulative number of fry produced was reduced

by exposure to 210 $\mu\text{g/g}$ in midge used as a food source. Kumada et al.¹³⁵ reported that 100 $\mu\text{g/g}$ cadmium as cadmium stearate in the diet caused liver and kidney damage in rainbow trout. Sublethal dietary concentration of 10 $\mu\text{g/fish/day}$ fed to tilapia (*Oreochromis mossambicus*) resulted in disruption of plasma calcium, magnesium, and phosphate concentrations, which was ameliorated somewhat by high waterborne calcium concentrations.¹³⁹ Crespo et al.¹⁴⁰ reported that sublethal exposure of rainbow trout to dietary cadmium concentrations of 5 $\mu\text{g/g}$ resulted in morphological disorders in the middle and posterior intestine, which the authors concluded would impair intestinal absorption of nutrients. Lundebye et al.¹⁴¹ also reported intestine damage in Atlantic salmon exposed to dietary cadmium. In a comparison of the toxicity of cadmium and copper to rainbow trout, Handy¹³⁷ reported that dietary cadmium was more toxic than dietary copper, which is an essential element to animals.

In the extensive review of cadmium in food webs by Kay¹⁴² and the review by Handy,³⁰ the authors cited several studies that reported cadmium concentrations to be generally higher in aquatic invertebrates than in fish, thus suggesting that cadmium was not biomagnified through the food web. Nevertheless, the authors concluded that food, as a source of cadmium, might be relatively more important in nature than implied from laboratory studies. Dallinger and Kautzky²² and Dallinger et al.²³ also concluded that dietary exposure of fish to cadmium was especially important in aquatic ecosystems where waterborne cadmium concentrations were low, but sediment concentrations could cycle cadmium into the food chain.

Harrison and Curtis¹⁴³ compared natural foods to commercial diets fortified with cadmium and reported that five times more cadmium was accumulated by fish from natural foods than from a fortified commercial diet. This observation is the opposite of Merlini et al.¹⁴⁴ and Pentreath,¹⁴⁵ who reported that zinc was more efficiently accumulated from a prepared diet than from a natural food. This difference between cadmium and zinc accumulation from different types of foods may be due to the fact that zinc is an essential element to animals, whereas cadmium is not. Likewise, fish mortality in dietary cadmium exposures may not be due exclusively to direct dietary cadmium toxicity because investigators have reported disruption of copper and zinc metabolism that may have contributed to the observed mortality.^{137,146}

A concern raised in dietary-cadmium studies reviewed by Kay¹⁴² was that a major problem in cadmium-treated artificial diets was the use of soluble chloride and nitrate forms of cadmium, which could rapidly leach from the diet, thus resulting in a partial aqueous cadmium exposure. He further noted that rapid-exchange flow-through exposure systems and immediate removal of uneaten food were only partial solutions to the problem of waterborne exposure. These two concerns — soluble trace elements added to diets and rapid flushing or rapid removal — apply to any study where a trace element or other toxic is added to a prepared diet.

44.4.4 Cesium

Aoyama et al.¹⁴⁷ reported that predator fish accumulate cesium from prey fish. The cesium concentration in predator fish increased with ration size, but altering the feeding interval did not influence the accumulation of the trace element. Fish growth, however, diluted the body residue when the dietary concentration of cesium was constant.

44.4.5 Chromium

One study investigated the effects of dietary chromium in fish using trivalent chromium.¹⁴⁸ Rainbow trout did not accumulate chromium in carcass, fin, vertebrae, skin, gill, muscle, or intestine, even at the highest concentration tested (8.2 $\mu\text{g/g}$). Nevertheless, chromium apparently caused reduced growth at this concentration. These results were consistent with those of Patrick and Loutit⁵³ and Dallinger and Kautzky,²² who investigated aquatic ecosystems contaminated with a mixture of inorganic elements and reported that chromium in the food chain accumulated less in fish than

other elements such as cadmium, copper, lead, and zinc. Part of the reason for a lack of adverse effects from chromium may be due to its metabolic regulation as an essential element in animals.

44.4.6 Cobalt

Baudin and Fritsch¹⁴⁹ investigated the relative contribution of cobalt from food and water with common carp (*Cyprinus carpio*) in a 63-day exposure. They concluded that the uptake and accumulation of cobalt, which is an essential element for plants and animals, was greater from water exposure than from food. However, the exposure concentrations were very low (0.2 µg/L in water and 0.13 µg/g in food), which resulted in low accumulation in fish (total cobalt 0.0033 µg/g). Suzuki et al.⁵⁴ reported that cobalt accumulated about equally in fish exposed by either waterborne or dietary routes of exposure.

44.4.7 Copper

The dietary concentration of copper that was toxic to rainbow trout as reported by Lanno et al.¹⁵⁰ was 664 µg/g. This elevated toxic concentration, relative to the lower toxic dietary concentrations of arsenic, cadmium, and mercury that cause adverse effects in fish, may be due, in part, to copper being an essential inorganic element to fish and other animals. Miller et al.¹⁵¹ reported that rainbow trout exposed to dietary copper as high as 684 µg/g showed no adverse effects on survival, growth, condition factor, or food conversion efficiency, but they noted that diet seemed to be the dominant source of copper in their water and dietary exposure study. Similarly, Handy et al.¹⁵² reported no effects on survival or growth of rainbow trout exposed to 490 µg/g of dietary copper, but lipids were reduced in liver, and swimming activity was altered. Berntssen et al.¹¹⁵ reported adverse effects on growth and whole-body energy stores of protein and glycogen in Atlantic salmon fed 500 µg/g or greater copper in the diet. Lundebye et al.¹⁴¹ also reported that growth was reduced in Atlantic salmon exposed to dietary copper at concentrations of 700 µg/g or greater. Most investigators hypothesized that biochemical regulation of copper prevents toxic effects at low concentrations (i.e., < 100 µg/g) because copper is an essential element to fish and other animals. In a comparison of the toxicity of copper and cadmium to rainbow trout, Handy¹³⁷ reported that dietary copper was less toxic than dietary cadmium. This differential toxicity probably reflects the regulation of copper and the limited regulation of cadmium via metallothionein.^{137,146}

44.4.8 Lead

Hodson et al.¹⁵³ reported that dietary lead was not accumulated by rainbow trout, although the highest concentration tested in the diet was only 1 µg/g. Chen and Folt³⁷ reported that elevated lead concentrations in the arsenic- and lead-contaminated Aberjona Watershed of Massachusetts were accumulated in lower food-chain components, such as algae and zooplankton, but not in upper trophic levels including fish. Leland and McNurney¹⁵⁴ also reported that the highest lead concentrations were in periphyton and macrophytes, and lead was not biomagnified through the aquatic food chain. They showed that lead accumulation in fish was lowest in piscivores, intermediate in predators of macroinvertebrates, and highest in grazers or detritus feeders. Patrick and Loutit⁵³ and Dallinger and Kautzky²² investigated aquatic ecosystems contaminated with a mixture of inorganic elements and reported that lead was accumulated in fish through the food chain, but to a lesser extent than other important elements such as copper and zinc. Nevertheless, a dietary lead concentration of 10 µg/g fed to rainbow trout caused morphological disorders in the middle and posterior intestine and altered chlorine and sodium fluxes and sodium-potassium ATPase activity.¹⁴⁰ Vighi¹⁵ reported that more lead was accumulated via the food chain than from water in an algae-daphnia-guppy food-chain exposure. However, the accumulation factors showed high accumulation in algae, lower concentrations in daphnia, and still lower in fish. Exposure of rainbow trout to very elevated

dietary lead (7 mg/g) caused a 12% incidence of black-tail, a well-established symptom of lead toxicosis in fish.¹⁵⁵

44.4.9 Manganese

Manganese accumulates in fish primarily from dietary sources.^{54,145} Dallinger and Kautzky²² studied a trace-element-contaminated (copper, cadmium, chromium, lead, manganese, nickel, zinc) river ecosystem and reported that rainbow trout accumulated a substantial amount of manganese from dietary sources. No one has reported adverse effects in fish associated with dietary manganese exposure.^{22,54,145}

44.4.10 Mercury

Mercury has no known essential function in vertebrate organisms.¹⁵⁶ Diet was the primary route of methylmercury uptake by fish and methylmercury the dominant mercury form in fish.¹⁵⁶

For example, Phillips and Buhler¹³ reported that 70% of dietary methylmercury was assimilated fish, whereas only 10% of waterborne methylmercury was assimilated. Handy³⁰ and Wiener and Spry¹⁵⁶ noted that the trophic transfer of mercury to fish has received a substantial amount of attention because of mercury poisoning in humans from consumption of contaminated fish. However, there is limited information on dietary mercury toxicity to fish. Dietary mercury exposure of fish to about 20–40 µg/g resulted in adverse effects such as gastrointestinal damage and inhibition of enzymes in the gut.³⁰ Zhou and Wong¹⁵⁷ reported a fourfold difference in mercury accumulation from the diet in six species of fish due to differences in feeding behavior.

44.4.11 Vanadium

One study investigated the toxicity of vanadium in the diet to fish.¹⁵⁸ Vanadium concentrations of 10.2 µg/g and greater in the diet of rainbow trout reduced growth and feeding responses. It was concluded that rainbow trout were extremely sensitive to dietary vanadium, and dietary vanadium toxicity was similar to that of dietary selenium toxicity. In contrast, waterborne exposure of fish to vanadium in freshwater ecosystems does not seem to be of major concern.¹⁵⁹ Hamilton et al.⁸⁴ suggested that elevated vanadium residues in aquatic invertebrates fed to larval endangered razor-back suckers in an on-site toxicity test contributed to the mortality of larvae. Vanadium is one of the least-studied trace elements from a dietary-toxicity standpoint but could potentially be a very important dietary contaminant. Most research with dietary vanadium has been done to determine its essentiality.¹⁶⁰

44.4.12 Uranium

One dietary study has been conducted with uranium in which lake whitefish (*Coregonus clupeaformis*) exposed for 100 days to 100 µg/g of dietary uranium had concentration- and duration-dependent histopathologies in liver and posterior kidney.^{161,162} Those effects were chemotoxic rather than radiotoxic because α -radiation rates were negligible.

44.4.13 Zinc

In a comparison of waterborne vs. dietary uptake of zinc, Merlini et al.¹⁴⁴ reported a two- to fourfold greater uptake in pumpkinseed (*Lepomis gibbosus*) of zinc from food than from water. Likewise, Willis and Sunda¹⁷ compared waterborne vs. dietary uptake in western mosquitofish and spot (*Leiostomus xanthurus*) and reported that 78 to 82% of the accumulated zinc came from the dietary uptake. Investigations have reported that zinc was more efficiently accumulated from

surfacially incorporated prepared diets than from zinc incorporated into live foods.^{144,145} However, others have reported that zinc proteinate (i.e., a chelated amino acid complex of zinc) accumulated to greater concentrations in fish than did dietary zinc supplemented as unbound zinc as zinc sulfate.^{163–165} Wekell et al.¹⁶³ reported that exposure of rainbow trout to up to 1.7 mg/g dietary zinc did not cause effects on growth or survival, which was similar to Brafield and Koodie,¹⁶⁵ who found no effects in common carp exposed to up to 5 mg/g dietary zinc. These results were probably due to the fact that zinc is an essential element to animals and is efficiently regulated in fish from a dietary exposure route.¹⁶ However, exposure of rainbow trout to very elevated dietary zinc (8.2 mg/g) has been reported to reduce growth, which may have been due to feed avoidance.¹⁵⁵ In general, waterborne exposure to zinc seems to lead to greater toxic effects than from dietary exposure.^{18,166} Elevated concentrations of calcium or phosphorus in the diet can cause a functional zinc deficiency in fish.³⁰ Similarly, Satoh et al.¹⁶⁷ reported that fishmeal diets deficient in zinc reduced growth of rainbow trout.

44.4.14 Mixtures of Inorganic Elements

It is rare in the aquatic environment that one inorganic contaminant stands out alone as the sole source of pollutant stress on fish, with the possible exceptions of mercury and selenium. Rather, a mixture of contaminants is often present at generally low concentrations in water but elevated concentrations in sediment and food organisms.^{22,23,53} Woodward, Farag, and coworkers have reported two good examples of mixtures of elements contaminating food organisms and the resulting adverse effects in fish in the Clark Fork River of Montana^{168–172} and the Coeur d'Alene River of Idaho.^{170,173,174} Both rivers were Superfund sites contaminated by wastes from mining activities and have depressed trout populations. The Clark Fork River is contaminated dominantly by copper and the Coeur d'Alene River by lead.

Food organisms from the Clark Fork River contained elevated concentrations of arsenic, cadmium, copper, lead, and zinc and when fed to brown trout (*Salmo trutta*) or rainbow trout resulted in adverse physiological, metabolic, behavioral, and histopathological effects.^{168–172} Woodward et al.¹⁷¹ reported that dietary exposure to the mixture of trace elements was more important than waterborne exposure in causing reduced growth and survival of fish. One interesting aspect of these studies was that the benthic invertebrates collected from the Clark Fork River and used in the experimental diets were either homogenized and refrozen for later feeding or pasteurized and supplemented with vitamins and minerals. Fish growth was reduced in fish fed either the unsupplemented diet or the supplemented diet. However, survival was reduced in fish fed the unsupplemented diet but not in those fed the supplemented diet, which suggested that either pasteurization (eliminated diseases in the wild caught invertebrates) or addition of vitamins and minerals (which may have produced healthier fish) may have enabled the fish to better withstand stresses from the dietary inorganic elements. A large number of studies were conducted as part of the Clark Fork River investigations including chemistry studies of terrestrial and aquatic abiotic and biotic components; ecological and population studies of terrestrial and aquatic organisms; and *in situ*, laboratory, and field studies of organisms. The weight of evidence in the risk assessment gave great weight to the findings in the fish studies with dietary exposure to inorganic elements.¹⁷⁵

One interesting study conducted as part of the Clark Fork River investigation was a dietary study with nauplii of brine shrimp. Nauplii were enriched with cadmium, copper, lead, and zinc, individually and as a mixture including arsenic, then fed to rainbow trout fry for 60 days starting at 11-days post swim-up.¹⁷⁶ Fish exposures also included simultaneous exposure to a mixture of waterborne elements at sublethal concentrations. Nauplii were exposed to aqueous element concentrations for about 24 h before hatch and about 24 h post hatch to achieve residues close to those in invertebrates from the Clark Fork River; then they were fed to fish. No adverse effects on survival or growth of fish were observed. In citing this study, Woodward et al.¹⁷² noted that the duration of the brine shrimp exposure was short; thus, the elements were probably attached to the

external surfaces of the nauplii and in the free form instead of incorporated protein, as in the studies by Woodward et al.^{171,172} and Farag et al.^{168,169} They also noted that ionic inorganic elements were not absorbed as efficiently in the gut and may not be as toxic as elements bound to proteins.^{143,165,170,177} Farag et al.¹⁷⁰ reported that inorganic elements incorporated naturally into invertebrates collected from the Clark Fork River were processed differently during digestion by cutthroat trout (*Oncorhynchus clarki*) than those from diets made up of brine shrimp nauplii exposed to a mixture of elements in the laboratory for ~24 h, as was done by Mount et al.¹⁷⁶ They cautioned that the results from studies that incorporate inorganic elements into live foods as part of a dietary exposure may result in toxicological effects different than those using natural foods with elevated inorganic elements.

Results similar to those in the Clark Fork River studies were found in the Coeur d'Alene River studies, where the elements of concern included arsenic, cadmium, copper, lead, mercury, and zinc.^{170,173,174} In general, inorganic elements were highest in sediments and *aufwuchs*, intermediate in invertebrates, and lowest in fish. Although the elements did not biomagnify, they were bioavailable and did biotransfer to fish. Fish fed diets incorporating benthic invertebrates collected from contaminated sites in the Coeur d'Alene River had reduced survival, growth, and feeding activity and increased histopathological abnormalities.¹⁷⁴ One interesting aspect reported by Farag et al.¹⁷³ was that smaller invertebrates accumulated greater concentrations of elements than larger invertebrates, which the authors hypothesized would expose early life stages of fish to larger doses of elements than adults.

44.5 INTERACTIVE EFFECTS OF NUTRITION AND OTHER ELEMENTS ON SELENIUM TOXICITY IN BIRDS

Fewer trace element/nutrition interaction studies have been conducted with wildlife species than with fish. Most of these studies have been conducted with birds and virtually none with wild mammals. This most likely is due to the fact that the human health effects literature, as well as human and agricultural nutrition literature, is abundant with interaction studies conducted with laboratory rodents as well as with other species of domestic mammals that are viewed by some as surrogate species for mammalian wildlife. Most of the studies conducted with avian wildlife species appear to fall into three categories: (1) those related to interactions between selenium, nutritional factors, and other trace elements; (2) those related to interactions between lead, nutritional factors, and other trace elements; and (3) a smaller number of studies related to interactions among other trace elements. The findings from studies in these three categories are summarized and discussed below for selenium and in subsequent sections for lead, other trace elements, and field studies.

Agricultural drainwater, sewage sludge, fly ash from coal-fired power plants, and mining of phosphates and metal ores are all sources of selenium contamination of the aquatic environment.^{178,179} High concentrations of selenium from agricultural drainwater accumulated in the aquatic food chain at the Kesterson National Wildlife Refuge in the San Joaquin Valley of California. These included mean selenium concentrations of 73 µg/g in submerged rooted aquatic plants and over 100 µg/g in aquatic insects consumed by ducks and other aquatic birds.⁴⁴ Similar problems of elevated selenium have been reported elsewhere in the western United States in at least a dozen different locations⁴⁵ but most notably in the Tulare Basin in California.¹⁸⁰ Resulting adverse biological and physiological effects of exposure have included avian mortality, impaired reproduction and teratogenesis, and histopathological lesions with alterations in hepatic glutathione metabolism and oxidative stress.¹⁸¹⁻¹⁸⁴ As a consequence of these findings, a series of laboratory studies was conducted primarily with mallards to help interpret the potential toxicity of different forms of selenium, dietary sources of selenium, and interactions with other dietary components including methionine, protein, and various trace elements that might be encountered in nature.

44.5.1 Different Dietary Forms of Selenium and Comparative Effects

The form of selenium in the diet was found to play an important role in the subsequent uptake and resulting toxicity. Selenomethionine is a major form of selenium found in wheat and soybean protein and may be a major form of selenium in other plants.^{185,186} This form of selenium is presumably an important exposure source for wild aquatic birds since the toxic thresholds in eggs for decreased hatching success and teratogenicity from lab studies with mallards proved to be nearly identical to those derived from field studies.¹⁷⁹ Selenomethionine becomes particularly embryotoxic and teratogenic when it exceeds 4 ppm Se in the laboratory diet of mallards. At higher concentrations, it becomes toxic to other stages of the mallard life cycle.

44.5.1.1 Reproductive Effects in Mallards

Findings from reproductive studies have indicated that selenium as selenomethionine is considerably more teratogenic and generally more embryotoxic than sodium selenite or selenocystine, due to much higher accumulation in eggs when provided in this form in the diet. When mallards were fed 10 ppm selenium as selenomethionine, 25 ppm as sodium selenite was required to produce a similar decrease of 40–44% in the total number of eggs that hatched compared to controls.^{187,188} Furthermore, 10 ppm Se as selenomethionine was more teratogenic than sodium selenite at 25 ppm, and resulted in an incidence of 13.1% malformations that were often multiple, whereas sodium selenite (10 and 25 ppm Se) resulted in 3.6 and 4.2% malformations. The teratogenicity of selenomethionine was confirmed in a second experiment in which mallards received 1, 2, 4, 8, or 16 ppm Se as selenomethionine, resulting in 0.9, 0.5, 1.4, 6.8, and 67.9% malformations, respectively.¹⁸⁹ Selenocystine at 16 ppm in the diet did not impair reproduction or result in significant malformations. In a subsequent reproductive study with mallards, seleno-DL-methionine and seleno-L-methionine were found to be of similar toxicity, and both forms were more toxic than selenium derived from selenized yeast, which is most likely due to the presence of less toxic forms of selenium in the yeast.¹⁹⁰

44.5.1.2 Survival and Growth in Mallard Ducklings

Selenium as selenomethionine resulted in generally greater oxidative stress than did selenium as selenite in the diet of mallard ducklings, as reflected by effects on hepatic glutathione metabolism and lipid peroxidation.¹⁹¹ These findings reflect the much greater accumulation of selenium in the liver and other organs as dietary selenomethionine than as selenite. However, both forms of selenium reduced duckling growth and survival.¹⁹² When day-old ducklings were fed 10, 20, or 40 ppm Se as seleno-DL-methionine or sodium selenite for six weeks, selenium from selenomethionine accumulated in a dose-dependent manner in the liver. Hepatic and plasma GSH peroxidase activity was initially elevated at 10 ppm Se as selenomethionine, whereas GSSG reductase activity was elevated at higher dietary concentrations of selenium. A decrease in the concentration of hepatic-reduced glutathione (GSH) and total hepatic thiols (SH) at 20 ppm Se in the diet was accompanied by an increase in the ratio of oxidized glutathione (GSSG) to GSH and an increase in thiobarbituric acid reactive substances (TBARS) concentration as evidence of lipid peroxidation.¹⁹¹ Selenium from selenite accumulated in the liver to an apparent maximum at 10 ppm in the diet, resulting in an increase in hepatic GSH and GSSG, accompanied by a small decrease in hepatic total SH. Sodium selenite resulted in increased hepatic GSSG reductase activity at 10 ppm and in plasma GSSG reductase activity at 40 ppm. A small increase in lipid peroxidation occurred at 40 ppm.

44.5.1.3 Subchronic Effects on Immune Function and Hepatotoxicity in Adult Mallards

The subchronic effects of selenomethionine and sodium selenite were compared with respect to several immunologic, hematologic, and serologic parameters in adult male mallards, using

concentrations in drinking water of 0, 0.5, or 3.5 mg/L Se as sodium selenite or 2.2 mg/L Se as selenomethionine for 12 weeks.¹⁹³ A battery of *in vivo* and *in vitro* immunologic assays was performed on each bird throughout the study. The selenomethionine-treated birds displayed an impaired delayed-type hypersensitive (DTH) response to tuberculin (*M. bovis*), as measured by the number of positive reactions present 24 h post purified protein derivative (PPD) challenge. This group also exhibited increased serum alanine aminotransferase (ALT) and plasma GSH peroxidase activities. The selenium concentration in the liver and breast muscle was significantly elevated 4- and 14-fold, respectively, over controls. Sodium-selenite-treated birds did not display any detectable differences in immune function or selenium accumulation in tissues above that of controls. Serum ALT activity was increased in the 3.5 mg/L group, although to a lesser extent than in selenomethionine-treated birds. Concentrations of selenium as sodium selenite did not affect the immune system, whereas low concentrations of selenomethionine (2.2 mg/L Se) appeared to suppress certain aspects of the mallard immune response.

44.5.1.4 Nutrition of Diet, Source of Selenium, and Bioavailability

Since the composition of the diet of wild ducklings may vary considerably in selenium-contaminated environments, a study was conducted to compare seleno-DL-methionine (DL, previously used in many lab studies), seleno-L-methionine (L, a form found in nature), selenized yeast (Y), and selenized wheat (W).^{194, 195} Day-old mallard ducklings received an untreated diet (controls) containing 75% wheat (22% protein) or the same diet containing 15 or 30 ppm Se in the above forms for 2 weeks (Table 44.2). All forms of selenium caused significant increases in plasma and hepatic glutathione peroxidase activities. Selenium as L at 30 ppm in the diet was the most toxic form, resulting in high mortality (64%) and impaired growth (> 50%) in survivors and the greatest increase in ratio of hepatic GSSG:GSH. Selenium as both L and DL decreased the concentrations of hepatic GSH and total thiols. Selenium as Y accumulated the least in liver (approximately 50% of other forms) and had less effect on GSH and total thiols. In contrast, when a different and commercially based basal diet, rather than the 75% wheat diet, was provided, survival of ducklings was not affected by 30 ppm Se. Again, selenium as selenized yeast was found to be less toxic than seleno-D,L-methionine, seleno-L-methionine, or selenized wheat, as reflected by the fewer effects on growth, plasma alkaline phosphatase activity, and hepatic oxidative stress. Here, greater oxidative stress for DL and L diets was manifested by significant decreases in hepatic GSH and total SH. This may be related, in part, to the nearly double tissue accumulation of selenium from selenomethionine diets than from selenized yeast.

44.5.1.5 Dietary Methionine and Protein

Since both quantity and composition of dietary protein for wild ducklings may vary in selenium-contaminated environments, several studies were conducted to examine effects of methionine and protein concentration on selenium toxicity. Findings from these studies have shown the potential for antagonistic effects of selenium, methionine, and protein on duckling survival and oxidative stress.

In one study, day-old mallard ducklings received one of the following diets containing 22% protein: unsupplemented controls, 15 ppm Se (as selenomethionine), 60 ppm Se, methionine-supplemented controls, 15 ppm Se with methionine supplement, or 60 ppm Se with methionine supplement for 4 weeks.¹⁹⁶ In a second concurrent experiment, the above sequence was repeated with a protein-restricted (11%) but isocaloric diet. In a third concurrent experiment, protein was increased to 44% with 0, 15, or 60 ppm Se added. With 22% protein and 60 ppm Se in the diet, duckling survival and growth were reduced, and histopathological lesions of the liver occurred. Antagonistic interactive effects occurred between supplementary methionine and selenium including complete to partial alleviation of the following selenium effects: mortality, hepatic lesions, and altered glutathione and thiol status.

Table 44.2 Interactive Effects of Nutritional Factors and Other Elements on Selenium Toxicity in Birds

Species, Age	Form of Se, Dietary (conc., ppm)	Interactive Factor	Observation Period	Effects	Ref.
Mallard, duckling	Compared these forms: seleno-D,L-methionine (DL), seleno-L-methionine (L), selenium from yeast (30 ppm)	Wheat diet vs. standard diet	Day-old through 2 weeks	With wheat diet: L was most toxic with respect to mortality, decreased growth, and increased oxidative stress With standard diet: all forms of Se less toxic than with the wheat diet	194, 195
Mallard, duckling	Seleno-D,L-methionine (15 ppm) (60 ppm)	Dietary methionine (0.42% added)	Day-old through 4 weeks	Methionine decreased Se-related histopathological lesions and oxidative stress Methionine decreased Se-related mortality, histopathological lesions, and oxidative stress	196
Mallard, duckling	Seleno-D,L-methionine (15 ppm) (60 ppm)	Restricted dietary protein (7 or 11% vs. 22% protein controls)	Day-old through 4 weeks	Restricted dietary protein increased Se-related toxicity with respect to growth, plasma chemistries, hepatic Se accumulation, and oxidative stress Se caused complete mortality in combination with restricted dietary protein	110, 196 197
Mallard, duckling	Seleno-D,L-methionine (15 ppm) (60 ppm)	Excess dietary protein (44 vs. 22% protein controls)	Day-old through 4 weeks	Excess dietary protein increased Se-related toxicity with respect to growth and oxidative stress Excess dietary protein increased Se-related toxicity with respect to mortality, growth, hematocrit, hemoglobin, plasma chemistries, and oxidative stress	196
Mallard, embryo through post-hatching (reproduction study)	Seleno-D,L-methionine (10 ppm)	Sodium arsenate (25, 100, or 400 ppm As)	Embryo through 14 days post-hatching	Sodium arsenate decreased the accumulation of Se in liver and egg, and Se-related hatching failure, and teratogenesis	198
Mallard, duckling	Seleno-D,L-methionine (15 ppm) (60 ppm)	Sodium arsenate (200 ppm As)	Day-old through 4 weeks	Sodium arsenate decreased Se-related oxidative stress Sodium arsenate decreased Se-related mortality, impaired growth, histopathological lesions, hepatic Se concentration, and oxidative stress	110

Mallard, embryo through post-hatching (reproduction study)	Seleno-D,L-methionine (7 ppm)	Dietary B (boric acid) (900 ppm B)	Embryo through 14 days post hatching	No interactive effects observed	199
Mallard, duckling	Seleno-D,L-methionine (15 ppm)	Dietary B (boric acid) (1000 ppm) with and without restricted dietary protein	Day-old through 4 weeks	With normal protein (22%) diet, B and Se in combination decreased liver weight and altered several plasma chemistries With restricted protein (7%) diet, B and Se in combination increased mortality and increased hepatic Se accumulation	197
	(60 ppm)			With normal protein (22%) diet B and Se in combination decreased liver weight and altered several plasma chemistries With restricted protein (7%) diet Se alone caused complete mortality	
Japanese quail, chicks	Sodium selenite (5 or 8 ppm)	Methylmercury chloride (20)	23 days	Se protected from Hg effects including mortality and tremors	200, 201
Japanese quail, embryos and chicks (reproductive study)	Sodium selenite (6 or 12 ppm)	Methylmercury chloride (15)	Through hatching	Se and Hg were mutually protective from adverse reproductive effects including decreased egg productivity, hatching success, and teratogenesis	202
Mallard, adult	Seleno-D,L-methionine (10 ppm)	Dietary methylmercury (10 ppm Hg)	10 weeks	Se protected from Hg effects including mortality, paralysis of the legs, and oxidative stress	203, 204
Mallard, embryo (reproductive study)	Seleno-D,L-methionine (10 ppm)	Dietary methylmercury (10 ppm Hg)	Embryo through 7 days post hatching	Combined Se and Hg was more toxic than either alone with respect to teratogenesis and duckling production	203

With 11% protein, selenium toxicity was greater than with 22% protein; growth of controls was less than that with 22% protein, selenium (60 ppm) caused 100% mortality, and methionine supplementation, although protective, afforded less protection than it did with 22% protein. Two other studies also reported similar interactive effects between selenium and restricted dietary protein (7%) including mortality, impaired growth, and hepatic oxidative stress.^{110,197}

With 44% protein in the diet, ducklings experienced oxidative and renal stress, and selenium was more toxic than with methionine-supplemented diets containing 22% protein.

44.5.2 Other Trace Elements

44.5.2.1 Arsenic and Selenium

High concentrations of arsenic (As) may be found in combination with selenium in aquatic food chains associated with irrigation drainwater. Studies with mallard ducklings examined the potential for interactive effects between Se and As on duckling survival, growth, and oxidative stress.¹¹⁰ Day-old ducklings received diets containing 22% protein as an untreated diet (controls) or diets containing 15 ppm Se (as selenomethionine), 60 ppm Se, 200 ppm As (as sodium arsenate), 15 ppm Se with 200 ppm As, or 60 ppm Se with 200 ppm As for 4 weeks. With 22% protein and 60 ppm Se in the diet, duckling survival and growth was reduced, and livers had histopathological lesions. However, when selenium was provided with arsenic in the diet, antagonistic interactive effects occurred and included complete to partial alleviation of the following selenium effects: mortality, impaired growth, hepatic lesions, and oxidative stress. In another study, 99 pairs of breeding mallards were fed diets supplemented with arsenic (sodium arsenate) at 0, 25, 100, or 400 ppm in combination with selenium (seleno-DL-methionine) at 0 or 10 ppm in a replicated factorial experiment.¹⁹⁸ Ducklings that hatched from parents on the various diets were placed on the same treatment combination as their parents. Arsenic accumulated in adult livers and eggs, reduced adult weight gain and liver weight, delayed the onset of egg laying, decreased whole-egg weight, and caused eggshell thinning. Arsenic did not affect hatching success and was not teratogenic. In ducklings, arsenic accumulated in the liver and reduced body weight, growth, and liver weight. Arsenic decreased overall duckling production. Selenium accumulated in adult liver and eggs, was teratogenic, and decreased hatching success. In ducklings, selenium accumulated in the liver and reduced body weight and growth, and increased liver weight. Selenium increased duckling mortality and decreased overall duckling production. When selenium and arsenic were combined, antagonistic interactions between arsenic and selenium occurred, where arsenic decreased the accumulation of selenium in liver and egg and alleviated the effects of selenium on hatching success and embryo deformities.

44.5.2.2 Boron and Selenium

Boron (B) and selenium sometimes occur together in high concentrations in the environment and can accumulate in plants and invertebrates consumed by waterfowl. A reproductive study with mallards examined toxicity and interaction between boron and selenium in the diet.¹⁹⁹ This study demonstrated that boron and selenium can individually affect mallard reproduction and duckling growth, but with apparent minimal interaction between the two. Breeding mallards were fed diets supplemented with boron (as boric acid) at 0, 450, or 900 ppm, in combination with selenium (as seleno-DL-methionine) at 0, 3.5, or 7 ppm, in a replicated factorial experiment. Ducklings hatched received the same treatment combination as their parents for 2 weeks. Boron and selenium accumulated in adult livers, eggs, and duckling livers. In adults, boron and selenium caused weight loss, and boron decreased hemoglobin concentration, egg weight, and egg fertility. Both boron and selenium reduced hatching success and duckling weight, and boron reduced duckling growth and duckling production and caused several alterations in duckling liver biochemistry, including

increased lipid peroxidation (TBARS), and decreased total thiol and protein concentrations, but with few apparent interactive effects.

Another study examined boron and selenium for effect on duckling survival and growth for a longer duration of 4 weeks.¹⁹⁷ Day-old mallard ducklings received diets containing 22% protein as an untreated diet (controls) or diets containing 15 ppm Se (as selenomethionine), 60 ppm Se, 1000 ppm B (as boric acid), 15 ppm Se with 1000 ppm B, or 60 ppm Se with 1000 ppm B for 4 weeks. This same study was repeated, but with only 7% protein in the diet. With 22% protein and 60 ppm Se in the diet, duckling survival and growth was reduced and histopathological lesions of the liver occurred. Boron alone caused some reduction in growth. Several interactive effects occurred between boron and selenium; the combination decreased liver weight and affected several plasma chemistries. However, with a restricted protein (7%) diet, boron and selenium (15 ppm) in combination increased mortality and increased hepatic selenium accumulation. These findings suggest the potential for more severe toxicological effects of selenium and boron independently and interactively on duckling survival and development when dietary protein is diminished.

44.5.2.3 Mercury and Selenium

Earlier studies have shown that selenium as selenite was protective against the effects of methylmercury to quail; day-old Japanese quail (*Coturnix coturnix*) fed 5 or 8 ppm Se as sodium selenite and 20 ppm Hg as methylmercury chloride were protected from mercury effects including high mortality and tremors.^{200,201} In another study, the addition of 3 or 6 ppm Se as sodium selenite reduced the toxicity of 20 ppm Hg as methylmercury hydroxide to young Japanese quail, even though brain levels of mercury were higher when sodium selenite was included in the diet.²⁰² Selenium levels in the brain were also higher, suggesting that selenium was somehow protecting the brain from methylmercury damage. Mercury and selenium in these forms were mutually protective to reproduction; mercury alone reduced egg production and hatchability, but the addition of selenium lessened these effects, whereas selenium alone reduced hatchability and increased the incidence of deformed embryos, but the addition of mercury reduced these effects.

Recent findings with environmentally relevant forms of mercury and selenium have also shown that mercury and selenium may be antagonistic to each other in adult mallards but synergistic to the reproductive process and embryos. In one study, the effects of selenium (seleno-D,L-methionine) and mercury (methylmercury chloride) were examined separately and in combination.²⁰³ Mallard drakes received one of the following diets: untreated feed (controls), or feed containing 10 ppm Se, 10 ppm Hg, or 10 ppm Se in combination with 10 ppm Hg for 10 weeks. One of 12 ducks fed 10 ppm Hg died, and eight others suffered paralysis of the legs. However, when the diet contained 10 ppm Se in addition to the 10 ppm Hg, none of these effects were apparent. The presence of methylmercury in the diet greatly enhanced the storage of selenium in tissues. The livers of males fed 10 ppm Se contained a mean of 9.6 ppm Se, whereas the livers of males fed 10 ppm Se plus 10 ppm Hg contained a mean of 114 ppm Se. However, selenium did not enhance the storage of mercury. The following clinical and biochemical alterations occurred in response to the mercury exposure: hematocrit and hemoglobin concentrations decreased; activities of the enzymes glutathione (GSH) peroxidase (plasma and liver), glutathione-S-transferase (liver), and glucose-6-phosphate dehydrogenase (G-6-PDH) (liver and brain) decreased; hepatic oxidized glutathione (GSSG) concentration increased relative to reduced glutathione (GSH); and lipid peroxidation in the brain was evident as detected by increased TBARS.²⁰⁴ Effects of selenium alone included increased hepatic GSSG reductase activity and increased brain TBARS concentration. However, selenium in combination with mercury partially or totally alleviated the effects of mercury on GSH peroxidase, G-6-PDH, and GSSG. It was concluded that since both mercury and excess selenium can affect thiol status, measurement of associated enzymes in conjunction with thiol status may be a useful bioindicator to discriminate between mercury and selenium effects. The ability of selenium to restore the activities of G-6-PDH, GSH peroxidase, and GSH status involved

in antioxidative defense mechanisms may be crucial to biological protection from the toxic effects of methylmercury.

In contrast to the protective effect of selenium against mercury poisoning in adult mallards, selenium plus mercury was worse than selenium or mercury alone for some measurements of reproductive success.²⁰³ Both selenium and mercury lowered duckling production through reductions in hatching success and survival of ducklings, but the combination was worse than either mercury or selenium alone. Controls produced an average of 7.6 young per female, females fed 10 ppm Se produced an average of 2.8 young, females fed 10 ppm Hg produced 1.1 young, and females fed both mercury and selenium produced 0.2 young. Teratogenic effects were notably greater for the combined treatment; deformities were recorded in 6.1% of the embryos of controls, 16.4% for those fed methylmercury chloride, 36.2% for those fed selenomethionine, and 73.4% for those fed methylmercury chloride and selenomethionine.

44.6 EFFECTS OF NUTRITION AND OTHER ELEMENTS ON LEAD TOXICITY IN BIRDS

44.6.1 Diet and Lead Shot Ingestion in Waterfowl

Jordan²⁰⁵ concluded after controlled experiments with mallards, lesser scaup (*Aythya affinis*), and Canada geese (*Branta canadensis*) that diet was the most important variable modifying the toxic effects of ingested lead-shot pellets. A corn diet resulted in 50% mortality and 34% net weight loss by 25 days, following a dose of four No. 6 lead shot (Table 44.3). However, commercial duck food in the form of pellets was the most effective in lessening these toxic effects, followed by aquatic plants and grains. Corn is deficient in essential minerals, including calcium, several vitamins, and low in protein, hence enhancing the effects of lead. However, the author concluded that these nutritional factors alone were not entirely responsible. The size and hardness of the diet was also a factor. The physical form of the diet appeared to determine the rate of food intake of captive waterfowl, where commercial duck pellets were taken in greatest amounts, followed by small grains and wild seeds, with rice more so than mixed grains, and corn the least. The smaller softer feeds, including duck pellets, which essentially became mash after ingestion, were more easily reduced to a softer form in the gizzard and hence passed along more readily to the intestine, hastening the rate of elimination of lead. Thus, both nutritional benefits and movement of a greater volume of food are likely to facilitate the elimination of lead removed from the surface of ingested lead shot. Others have also reported greater toxicity of lead-shot ingestion in conjunction with a corn diet.^{206, 207}

44.6.2 Calcium and Lead Shot Ingestion

Carlson and Nielsen²⁰⁸ studied the role of dietary calcium on lead-shot poisoning in adult mallards. In this study, there were three dietary groups consisting of: Group I, fed pelleted calcium-supplemented corn (1.2% Ca); group II, fed a pelleted commercial duck ration with 1.2% Ca; and Group III, fed cracked corn (0.03% Ca). Ten ducks from each group were given four No. 4 lead shot via an esophageal tube, and five ducks from each group were kept as pair-fed controls. Anorexia and weight loss were most severe in the lead-shot-dosed Group III ducks. Group III had a maximum reduction in food consumption of 87%, followed by a slight improvement in appetite but a loss of 35% of the initial body weight. Group I treated ducks had a reduction in food consumption of 64% that eventually returned to the quantities consumed at the start of the experiment; Group I ducks lost 18% of their initial body weight. Group II treated ducks maintained healthy appetites during the experiment and had a weight gain of 2% of their initial body weight. The number of ducks that became moribund and were euthanized differed significantly among the treated groups, with 100% of Group III, 50% of Group I, and 0% of Group II treated ducks becoming moribund.

Table 44.3 Interactive Effects of Nutritional Factors and Other Elements on Lead Toxicity in Birds

Species, Age	Form of Pb, Dose or Dietary Concentration	Interactive Factor	Observation Period	Effects	Ref.
Mallard, Lesser scaup Canada goose (adults)	Four No. 6 lead shot pellets	Commercial feed vs. corn and other diets	25 days post dosing	Lead-shot ingestion most toxic with corn diet and least toxic with softer diets with respect to mortality and weight loss	205–207
Mallard, adult	Four No. 4 lead shot pellets	Dietary calcium supplementation	9 weeks	Calcium supplementation of a corn diet decreased lead-related mortality by one half and decreased weight loss as well as histopathological lesions	208
Mallard, adult	Lead contaminated mining sediment (1000 ppm Pb in diet)	Ground corn diet vs. commercial diet	15 weeks	Ground corn diet containing lead sediment resulted in 80% mortality, greatest weight loss, lowest hemoglobin concentration, and threefold greater hepatic lead accumulation than with commercial diet containing lead sediment	209
Mallard, ducklings	Lead contaminated mining sediment (830 ppm Pb in diet)	Two thirds ground corn/one third commercial diet mixture vs. commercial diet	6 weeks	Ground corn diet mixture containing lead sediment resulted in highest blood lead concentration, reduced growth, most oxidative stress, and increased prevalence of acid-fast inclusion bodies in the kidney compared to commercial diet containing lead sediment	210–212
Japanese quail, young adults	Lead acetate in drinking water at 100 or 400 µg/mL	Poultry feed vs. ground corn	7 days	Corn diet resulted in lead-related mortality, greatest weight loss and suppressed antibody-mediated immunity	214
Zebra finch	10 µg/mL of lead as lead acetate and of cadmium as cadmium chloride in drinking water	0.3 vs. 3% calcium	51 days	Low dietary calcium enhanced hepatic and renal accumulation of lead (~400%) and cadmium (~200%), increased metallothionein production, and inhibited ALAD the most compared to controls	215
Ringed turtle dove	50 ppm of lead as lead acetate, 20 ppm cadmium as cadmium chloride, and 1500 ppm aluminum as aluminum sulfate	0.4 vs. 2% calcium	6 months	Low dietary calcium enhanced the accumulation of lead and cadmium but not aluminum, increased metallothionein production, and inhibited ALAD the most compared to controls	215

All three groups of treated ducks had increased protoporphyrin IX concentrations compared with controls. Groups I and III lead-treated ducks had significant reductions in erythrocyte counts, PCV, hemoglobin concentrations, and mean corpuscular hemoglobin concentrations as compared with controls. Group II had reduced hemoglobin concentration and mean corpuscular hemoglobin concentration compared with controls. However, none of the above changes differed statistically among the three dietary groups of lead-poisoned ducks. Gross pathologic lesions of treated ducks (pectoral muscle atrophy and green discoloration of gizzard mucosa) were most pronounced in Group III, followed by Group I and Group II, in that order. Histopathologic lesions consisting of neuropile vacuolization, intranuclear inclusion bodies, neuronal degeneration, and myocardial and pectoral muscle degeneration, necrosis, and atrophy occurred most frequently in the Group III treated ducks, less in the Group I treated ducks, and least in the Group II treated ducks. These findings suggested that the addition of calcium to the corn diet had an ameliorating effect, but other nutrients found in the Group II commercial duck diet were also important in mollifying lead absorption and metabolism in mallard ducks.

44.6.3 Diet and Lead-Contaminated Mining Sediment in Waterfowl

A series of experiments was conducted to measure the toxicity of lead-contaminated mining sediment from the Coeur d'Alene River basin (CDARB) in Idaho to waterfowl, including mallards, Canada geese, and mute swans (*Cygnus olor*), under optimal and less-than-optimal nutritional conditions.

44.6.3.1 Adult Mallards

In adult mallards, mortality of 80% occurred from lead poisoning within 15 weeks when fed a less than optimal diet of ground corn containing 24% CDARB sediment (with 3954 $\mu\text{g/g}$ lead in this sample of sediment), but none died when 24% CDARB sediment was mixed into a nutritionally balanced commercial duck diet.²⁰⁹ Birds fed the corn diet containing 24% CDARB sediment lost weight. Mallards fed 24% CDARB sediment in the commercial diet and corn diet had elevated levels of protoporphyrin (424 and 689 $\mu\text{g/dl}$) compared to controls fed the commercial diet and corn diet (45 and 25 $\mu\text{g/dl}$). Four of five mallards fed 24% CDARB sediment in a commercial diet and all five fed the contaminated sediment in a corn diet had renal intranuclear inclusion bodies. Lead accumulation was higher in the livers of mallards fed 24% lead-contaminated sediment in the corn diet (38 $\mu\text{g/g}$) than in the commercial diet (13 $\mu\text{g/g}$). These laboratory findings with mallards demonstrated that ingestion of realistic amounts of sediment from the Coeur d'Alene River Basin caused lead poisoning in waterfowl, as had been reported in the field, and a less-than-optimal diet such as corn could severely intensify many aspects of these effects.

44.6.3.2 Duckling Growth and Survival

Other studies were conducted to assess the effects of the same sediment on posthatching development of mallard ducklings for 6 weeks.²¹⁰⁻²¹² Day-old ducklings received untreated control diet, clean-sediment-supplemented (24%) control diet, or CDARB-sediment-supplemented (3449 $\mu\text{g/g}$ lead) diets at 12% or 24%. The 12% CDARB diet resulted in a blood lead concentration of 1.4 ppm (wet weight) with over 90% depression of red blood cell ALAD activity and over a threefold elevation of free erythrocyte protoporphyrin concentration. The 24% CDARB diet resulted in blood lead of 2.6 ppm with over sixfold elevation of protoporphyrin. In this group, the liver lead concentration was 7.9 ppm (wet weight), and there was a 40% increase in hepatic reduced glutathione concentration. The kidney lead concentration in this group was 8.0 ppm and acid-fast inclusion bodies were present in the kidneys of four of nine ducklings. When ducklings were on a less-than-optimal diet (two thirds corn and one third standard diet), CDARB sediment was more

toxic; blood lead levels were 1.7-fold higher, body growth and liver biochemistry (TBARS) were more affected, and the prevalence of acid-fast inclusion bodies increased.

In addition, significant effects on the brain were seen due to lead accumulation and included oxidative stress, altered metabolites, and decreased brain weights.^{211,212} Significant increases in brain-reduced glutathione (GSH), calcium, and triglyceride concentrations occurred, with significant decreases in brain protein, ATP, and brain weights. Nutrient level of the diets significantly affected brain GSH, triglyceride, inorganic phosphorus, and protein concentrations, acetylcholinesterase activity, and brain and body weights. Nutrient levels marginally affected lead accumulation in the brain. The incidence and duration of ten behaviors was recorded (resting, standing, moving, drinking, dabbling, feeding, pecking, preening, bathing, and swimming). Contaminated sediment significantly affected the proportion of time spent swimming yet did not significantly affect any of the other recorded behaviors. There were also signs of disruption of balance and mobility. Nutrient level affected the amount of time spent in water-related behaviors.

44.6.3.3 Mute Swans

In another study with captive mute swans, CDARB sediments were combined with either a commercial avian maintenance diet or a less optimal diet of ground rice and fed to captive mute swans for 6 weeks.²¹³ Experimental treatments consisted of maintenance or rice diets containing 0, 12 (no rice group), or 24% lead-contaminated (3950 $\mu\text{g/g}$ lead) sediment or 24% uncontaminated (9.7 $\mu\text{g/g}$ lead) sediment. Swans fed the less optimal rice diet containing 24% lead-contaminated sediment were the most severely affected, experiencing a 24% decrease in mean body weight, including three birds that became emaciated. All birds in this treatment group had significant reductions in hematocrit and hemoglobin concentrations, nephrosis, and abnormally dark, viscous bile. This group also had the greatest mean concentrations of lead in blood (3.2 $\mu\text{g/g}$), brain (2.2 $\mu\text{g/g}$), and liver (8.5 $\mu\text{g/g}$). These birds had significant increases in mean plasma ALT, cholesterol, and uric acid concentrations and decreased plasma triglyceride concentrations. This study revealed that mute swans consuming environmentally relevant concentrations of CDARB sediment developed severe sublethal lead poisoning and that toxic effects were more pronounced when the birds were fed lead-contaminated sediment combined with rice, which closely resembles the diet of swans in the wild.

44.6.4 Diet and Acute Lead Exposure on Immunity of Quail

Grasman and Scanlon²¹⁴ investigated the interacting effects of acute lead exposure and different diets on antibody and T-cell-mediated immunity in 9-week-old male Japanese quail. The treatments were: (1) a positive control group fed 20 $\mu\text{g/g}$ corticosterone, (2) a negative control group given no lead or corticosterone, (3) a low-lead group, and (4) a high-lead group. The low- and high-lead groups received 100 and 400 $\mu\text{g/mL}$ lead as lead acetate in drinking water for 7 days. The two diets were poultry feed and ground corn. Control quail fed corn lost 13–14% of initial body mass, but lead-dosed quail fed corn lost 23–24%. All quail fed poultry feed gained body mass. On the corn diet, three high-lead and one low-lead quail died of lead poisoning. Corn increased the percentage of heterophils in white blood cells and decreased lymphocytes and monocytes. There was marginal evidence that lead increased the heterophil/lymphocyte ratio in corn-fed quail. Corticosterone suppressed this response more than lead. In corn-fed quail, lead suppressed the primary total antibody response to immunization with chukar partridge (*Alectoris graeca*) erythrocytes. However, lead suppressed antibody-mediated immunity only at dosages that also caused clinical lead poisoning.

44.6.5 Interactive Effects of Calcium on Lead, Cadmium, and Aluminum in Finches and Doves

Scheuhammer²¹⁵ examined the influence of low dietary calcium on the accumulation and effects of dietary lead, cadmium, and aluminum in zebra finches (*Taeniopygia guttata*) and ring doves

(*Streptopelia risoria*). In zebra finches fed a diet containing low Ca (0.3%), the hepatic and renal accumulation of lead was enhanced approximately 400% and of cadmium about 150–200%, compared to birds fed a 3.0% Ca diet. Low dietary calcium also caused bones of female finches to lose an average of about 60% of their normal calcium content. Loss of bone-calcium was also observed in male finches but was less than in females. In reproductively active ring doves, low (0.4%) dietary calcium enhanced the accumulation of lead and cadmium but not of aluminum, compared with accumulation in doves consuming a 2.0% Ca diet. Enhanced accumulation of lead and cadmium was accompanied by an increased synthesis of the metal-binding protein metallothionein and by a greater inhibition of delta-aminolevulinic acid dehydratase activity. These results indicated that under conditions of reduced dietary calcium availability, such as can occur in acid-impacted environments, wild birds risk increased uptake of certain toxic metals more rapidly.

44.7 OTHER INTERACTIVE EFFECTS OF NUTRITIONAL FACTORS AND TRACE ELEMENTS IN BIRDS

44.7.1 Calcium, Phosphorus, and Aluminum in Waterfowl and Passerines

Acidification may alter the species composition and abundance of aquatic organisms that serve as food, reduce caloric content of aquatic insects, or elevate metal levels in food.²¹⁶ Calcium-rich taxa such as snails and freshwater clams are usually scarce in acidified waters, and calcium deficiencies may limit the distribution of certain aquatic birds. In order to further test this hypothesis, Sparling^{217,218} fed day-old black ducks (*Anas rubripes*) and mallards diets varying in calcium, phosphorous, and aluminum for 10 weeks. Ducklings on low-calcium, low-phosphorus diets experienced the greatest problems with elevated aluminum. At the highest level of aluminum (5000 µg/g), all ducklings died within 2 weeks and mortality exceeded 60% for those on 1000 µg/g Al. In contrast, no mallards died and mortality did not exceed 30% for black ducks on normal levels of calcium and phosphorus or on low-calcium, high-phosphorus diets, regardless of aluminum diet. Femur and liver aluminum levels correlated highly with dietary aluminum. Many of the differences among treatments diminished or disappeared by 10 weeks of age. It was concluded that rapidly growing young birds may have greater problems coping with elevated aluminum than adult birds, especially when high aluminum is combined with low levels of calcium and phosphorous. Because acidified lakes and streams often have higher aluminum and lower calcium levels than circumneutral surface waters, the possibility of aluminum toxicity in aquatic birds should not be dismissed.

Miles et al.²¹⁹ fed adult European starlings (*Sturnus vulgaris*) diets varying in levels of calcium, phosphorous, and aluminum to determine if aluminum interacted with the other elements to affect reproductive capability.

Starlings on normal levels of calcium and phosphorous but with elevated levels of aluminum (1000 or 5000 ppm) laid significantly more eggs than those on a control level (200 ppm) of aluminum. Reduced levels of calcium, however, resulted in smaller clutch sizes than the normal level. Low-calcium and low-phosphorus reduced food consumption and body weights of the adult starlings. Mortality was higher in adults on low-calcium and low-phosphorus and normal levels of these nutrients when aluminum concentrations were increased, but differences were not statistically significant. Eggshells of starlings on elevated aluminum were thicker but not stronger than those on low aluminum. Eggshell and bone characteristics were affected more by calcium and phosphorus levels in the diets than by aluminum levels.

44.7.2 Arsenic and Dietary Protein in Mallards

Day-old mallard ducklings received untreated diets of either 22% protein (controls) or restricted dietary protein (7%), with or without 200 ppm As (as sodium arsenate).¹¹⁰ With restricted dietary

protein, arsenic was considerably more toxic with respect to effects on survival, growth, histopathological lesions, and oxidative stress. Plasma LDH and GSSG reductase activities were elevated. Greater accumulation of arsenic in the liver occurred, with greater oxidative stress recorded as increased hepatic TBARS.

44.7.3 Boron and Dietary Protein in Mallards

Day-old mallard ducklings received untreated diets of either 22% protein (controls) or restricted dietary protein (7%), with or without 1000 ppm B (as boric acid).¹⁹⁷ With restricted dietary protein, boron had a greater negative effect on duckling growth than with adequate dietary protein.

44.7.4 Mercury and Vitamin E in Quail

Mercury as methylmercury chloride at 30 ppm in the diet of day-old Japanese quail caused mortality and signs of mercury toxicity, decreased growth rate, hematocrit, and bone calcification, whereas the addition of varying amounts of supplemental vitamin E significantly decreased these effects.²²⁰ The effects of vitamin E and five synthetic antioxidants, including ethoxyquin, BHT, DPPD, Antabuse and BHA, were examined on methylmercury-induced mortality in day-old Japanese quail.²²¹ At 0.5% in the diet, both ethoxyquin and DPPD reduced mercury-related mortality. However, vitamin E was equal or superior to all synthetic antioxidants tested in alleviating mercury-related toxicity.

44.7.5 Mercury, Lead, and Cadmium in Pekin Ducks

Adult female Pekin ducks (*Anas platyrhynchos*) were fed diets with no metals added (controls), 8 mg of methylmercury chloride/kg feed, 80 mg of lead acetate/kg feed, 80 mg of cadmium chloride/kg of feed, or all combinations of two and three of the above metals for 13 weeks.²²² Cadmium, when administered alone or in combination, caused a 60-fold increase in kidney metallothionein levels. A combination of lead and mercury significantly increased the concentration of lead in kidney above that of lead alone. Cadmium, when administered alone or in combination, caused an increase in the levels of zinc and copper in kidney. Administration of cadmium alone or in combination caused degenerative changes in kidney proximal tubules. However, the severity of the degenerative changes increased when cadmium was administered with the other metals.

44.8 FIELD STUDY INTERACTIONS OF TRACE ELEMENTS IN WILDLIFE

In field studies, interactions between trace elements and between other nutritional factors and trace elements are harder to demonstrate due to a lack of controlled conditions and due to the presence of often multiple variables including trace elements themselves. However, in both wild birds and mammals, significant correlations between mercury and selenium levels in tissues have been shown, and high levels of inorganic mercury are found in tissues such as liver and kidney in an apparently bound form with mercury. Mercury and selenium concentrations in the livers of wild mammals, particularly piscivorous and carnivorous ones, are often highly correlated in a molar ratio of 1:1.^{178,223–225} The relationship between total mercury and selenium concentrations was found to be more variable for wild aquatic birds, depending on the species.^{226–229} However, more recent studies that were able to differentiate between methylmercury and demethylated mercury in livers of aquatic birds have revealed that demethylated mercury exists as inorganic mercury protectively sequestered with selenium and correlates in a molar ratio of 1:1 with selenium.^{230,231}

When Moller²³² compared the concentrations of Al, As, B, Ba, Be, Cd, Cr, Cu, Fe, Pb, Li, Mg, Mn, Hg, Mo, Ni, Se, Ag, V, and Zn in aquatic bird liver, fish liver, whole bivalves, insects, and waters in several aquatic ecosystems in northern California, there was evidence of *in vivo* and environmental interactions including the observation of manganese as a possible cofactor or indicator in selenium bioaccumulation. The nearest neighbor selenium correlation in aquatic bird liver tissue that resulted was Cd-Mn-Se-Hg-As. The correlation of liver selenium to manganese *in vivo*, and the finding that the majority of the variance in liver selenium concentration was contained in the manganese term of the regression model relating selenium to cadmium, manganese, and mercury was new knowledge in the study of aquatic birds. A linear relationship between liver selenium and environmental manganese (water and sediment) suggested a water-chemistry compartmentalization or activation of toxicants, or, alternatively, the hepatic concentrations of selenium, manganese, and iron suggested induction of enzymes in response to oxidative stress.

The possibility that aluminum may reach toxic levels in the foods of aquatic birds nesting near acidified ponds was first raised in Sweden.²³³ Scheuhammer reviewed and studied the effects of acidification on wildlife inhabiting aquatic or semiaquatic environments, with particular reference to the possibility of increased dietary exposure to mercury, cadmium, lead or aluminum and decreased availability of essential dietary minerals such as calcium.^{234,235} It was concluded that: (1) piscivores risk increased exposure to dietary methylmercury in acidified habitats, with concentrations in prey becoming potentially high enough to cause reproductive impairment in birds and mammals; (2) piscivores risk minimal increased exposure to dietary cadmium, lead, or aluminum because either these metals are not increased in fish due to acidification or increases tend to be trivial from a toxicological perspective; (3) insectivores and omnivores may, under certain conditions, experience increased exposure to toxic metals in some acidified environments. However, of greater impact on these species is the decrease in availability of dietary calcium due to the pH-related extinction of high-calcium aquatic invertebrate taxa (molluscs, crustaceans). Egg laying and eggshell integrity in birds and the growth of hatchling birds and neonatal mammals are all highly dependent upon calcium. Acidification-related changes in the dietary availability of other essential elements, such as magnesium, selenium, and phosphorus, have not been established and require further investigation; and (4) herbivores may risk increased exposure to aluminum and lead, and perhaps cadmium, in acidified environments because certain macrophytes can accumulate high concentration of these metals under acidic conditions. The relative importance of pH in determining the metal concentrations of major browse species and the toxicological consequences for herbivorous wildlife are not well established and require further study. A decreased availability of dietary calcium is also likely for herbivores inhabiting acidified environments.

44.9 CONCLUDING REMARKS AND FUTURE RESEARCH NEEDS

It is clear from a review of the literature that there is only limited information on the effects of foodborne trace elements and other nutritional factors on fish and wildlife. There is an extensive database on foodborne selenium toxicity to a variety of fish species compared to information available for other trace elements. Yet, the information on dietary-selenium toxicity to fish is incomplete because few of the possible interactions of selenium with nutritional factors or with other trace elements have been examined. In comparison, the single dietary toxicity test with one species of fish and vanadium, which was thought by researchers to have dietary toxicity comparable to that of selenium, is a glaring information gap that would hinder a hazard assessment where vanadium might be a potential contributor to stresses in the aquatic ecosystem. The few dietary tests with other elements, such as arsenic, cesium, chromium, cobalt, lead, mercury, and uranium, and limited tests with cadmium, copper, and zinc are also major information gaps in need of research.

Adequate hazard assessments must incorporate information from not only waterborne exposures, but also dietary exposures. In-depth studies with foodborne mixtures of trace elements, such

as those conducted by Woodward, Farag, and coworkers in the Clark Fork River and Coeur d'Alene River, provide valuable information about specific ecosystem hazard assessments. However, dietary studies gave conflicting results when fish were fed nauplii of brine shrimp briefly exposed to a mixture of trace elements in an effort to simulate trace-element concentrations in food organisms in the Clark Fork River. This latter study shows the need for careful experimental design if environmental conditions are to be adequately simulated in laboratory studies.

The emphasis in aquatic toxicology over the past few decades has been on waterborne exposures. Consequently, national water-quality standards have been propagated based on a waterborne approach. Recent studies have shown that single-element criteria do not account for interactions with other waterborne factors such as other trace elements or water characteristics. Limited information from dietary studies with trace elements, especially selenium, show that diet can be an important contributor to toxic effects observed in contaminated ecosystems, yet water-quality standards do not consider potential effects from dietary exposures. Incorporation of dietary criteria into national criteria for trace elements will occur only after a sufficient database of information is generated from dietary toxicity studies.

Fewer trace element/nutrition interaction studies have been conducted with wildlife species than with fish, and most of these studies have been conducted with avian wildlife. Nearly all of the studies conducted with birds fall into three categories: (1) selenium-related interactions between nutritional factors and other trace elements, (2) lead-related studies of nutritional factors including trace elements, and (3) only a few studies with other trace elements such as aluminum. Recent findings with environmentally relevant forms of mercury (methylmercury) and selenium (selenomethionine) in birds have shown that mercury and selenium may be antagonistic to each other in adult birds but synergistic to the reproductive process in embryos. Therefore, further investigations in birds are warranted to compare the interactions of various forms of mercury and selenium, particularly with respect to effects on reproduction and teratogenesis. The ability of selenium to restore the activities of G-6-PDH, GSH peroxidase, and GSH status involved in antioxidative defense mechanisms may be crucial to biological protection from the toxic effects of methylmercury in adults. Further studies are needed to examine the relationship between selenium and other trace elements that may be toxic by compromising cellular antioxidative defense mechanisms.

Virtually no trace element/nutrition interaction studies have been conducted with mammalian wildlife, probably because the human-health-effects literature and the agricultural-nutrition literature are abundant with interaction studies conducted with laboratory rodents as well as other species of domestic mammals, which are viewed by some as surrogate species for mammalian wildlife. However, there are many unique species of wild mammals with varied sensitivities to certain classes of contaminants including trace elements, as reviewed by Shore and Rattner.²³⁶ Therefore, there is a need for comparative interaction studies in these species, particularly with respect to locations where multiple trace-element contaminants exist and other nutritional conditions may be suboptimal.

45.1 INTRODUCTION

During the last 100 years, human activities have contributed to an extinction rate rivaling the meteor strike that ended the dinosaur era. The speed, severity, and taxonomic diversity of declining species is a major concern of the world's ecologists.¹ Extinctions are taking place at a rate of approximately 100 species per day.² In 1989, Wilson³ projected the loss of species at more than 20% of the planet's total biodiversity in 20 years.

The Nature Conservancy compiled a list of 20,481 plants and animals within the United States and estimated, within arbitrary parameters, the persistence of each species.⁴⁻⁶ There were 4325 animals on the list: 2524 vertebrates and 1801 invertebrates. Seventy-five percent (1893) of the vertebrates and 61% (1098) of the invertebrates were secure or apparently secure and could be expected to persist. The remaining animal species (1334) are likely to go extinct. This chapter discusses the role of contaminants/pollution in the decline of species. A subset of the pertinent information represented by recovery plans and listing packages provides data on species response and contaminant impact.

45.1.1 What Is Threatened and Endangered: Definitions

The U.S. Endangered Species Preservation Act of 1966 granted authorization to protect listed species and their habitat and gave approval to acquire land for imperiled species. The Endangered Species Conservation Act of 1969 broadened the law to include international species, prohibited importation of listed species, and called for an international convention on the conservation of endangered species.

Outside the United States, the protection of threatened and endangered species is ambiguous and poorly defined. Legislation that formally lists and protects species moves slowly along many legislative pathways. Ray and Ginsberg⁷ evaluated the status of protective legislation in Australia, Canada, and the European Union. In this chapter, we will use their evaluations on the status of species protection and legislative turmoil. The Australian Endangered Species Protection Act of 1992 allows the designation of endangered communities and the remediation of activities that could threaten designated communities. Progress in Canada has been slow, especially at the national level, where the legislation that has passed has been weakened significantly, apparently reflecting a lack of interest by the federal government in assuming a leadership position.⁷ The European Union is handicapped by the cultural and linguistic differences of its member states. Consequently, they rely on a disparate set of national endangered species legislation and regional environmental laws that may have provisions for species protection. A unified approach to endangered species protection appears unlikely within the European Union. The most probable legislation will deal with the question on a subregional level.⁷

45.1.1.1 *The Convention on International Trade in Endangered Species of Wild Fauna and Flora and the Endangered Species Act (U.S.)*

In 1973, a convention was developed on the worldwide conservation of endangered species. More commonly known as CITES, the Convention on International Trade in Endangered Species of Wild Fauna and Flora restricts international commerce in plant and animal species harmed by trade or believed to be harmed by trade. The United States' 1973 Endangered Species Act (ESA)

Table 45.1 Listing and Recovery Plans (as of June 2002)

	Endangered		Threatened		U.S. Species with Recovery Plans
	U.S.	Foreign	U.S.	Foreign	
Mammals	65	251	9	17	53
Birds	78	175	14	6	75
Reptiles	14	64	22	15	32
Amphibians	11	8	9	1	12
Fishes	71	11	44	0	95
Snails	21	1	11	0	27
Clams	62	2	8	0	56
Crustaceans	18	0	3	0	12
Insects	35	4	9	0	29
Arachnids	12	0	0	0	5
Total	387	516	129	39	396

was established to provide protection for threatened and endangered species (nationally and internationally) and their habitats (nationally). The ESA stands as the most powerful law in the United States, perhaps the world, protecting flora and fauna.

The U.S. Fish and Wildlife Service⁸ lists 1071 animal species (516 in the United States, 555 foreign species) under the ESA as endangered or threatened as of June 2002 (Table 45.1). By definition, a species under ESA includes any species or subspecies of fish, wildlife, or plant; any variety of plant; and any distinct population segment of any vertebrate species that interbreeds when mature. Excluded from the ESA are any species of the class Insecta determined to be pests whose protection would present an overwhelming and overriding risk to humans. A species is classified as *endangered* when it is in danger of extinction within the foreseeable future throughout all or a significant portion of its range. A determination of *threatened* is made when the plant or animal so designated is likely to become endangered within the foreseeable future throughout all or a significant portion of its range.

4.5.1.1.2 Listing Packages and Recovery Plans

Listing packages describes the process as well as the documents required under ESA to declare a species threatened or endangered. The determination of status is made based only on the biological and trade information, with no consideration of economic impact or other possible impacts. Criteria for listing are quite specific:

- The present or threatened destruction, modification, or curtailment of habitat or range (pollution events figure prominently here).
- Overutilization for commercial, recreational, scientific, or education purposes.
- Disease or predation.
- The inadequacy of existing regulatory mechanisms. Biocides are regulated, but the full range of their impacts are poorly understood and rarely mentioned or included.
- Other natural or human-made factors affecting a species' continued existence. Human-made problems such as depletion of groundwater, infiltration of contaminants, and careless handling of chemicals create additional hazards that could have been avoided.

The proposed rule is published in the Federal Register, opening a comment period of 6 months. Within 1 year (1) a final listing rule must be published, (2) the proposal must be withdrawn, or (3) a determination may be made to extend the comment period for up to 6 months. Once the proposed rule has been approved, recovery planning starts. Causes of the species' decline must be identified and a recovery plan developed. The recovery plan may be developed by a panel of experts or a knowledgeable consultant but remains the responsibility of the Fish and Wildlife Service or National Marine Fisheries Service. The recovery plan describes and prioritizes the tasks essential to the

species recovery. A public review period takes place prior to finalizing the plan and the final approval of the regional director. Approval of the plan does not insure funds are available to carry out the plan, and years may go by before the priority tasks are addressed.

45.1.2 Factors Driving Species Decline

Multiple factors contribute to the decline of a species. Habitat destruction is the primary factor that threatens species^{1,9–15} and is listed as a significant factor affecting 73% of endangered species.^{16–17} The second major factor causing species decline is the introduction of nonnative species.^{15,17} This affects 68% of endangered species.^{16,17} Pollution and overharvesting were identified as impacting 38% and 15% of endangered species, respectively.^{13,15–18} Other factors affecting species decline include hybridization, competition, disease, and other interspecific interactions.^{15,17}

Although frequently espoused, environmental pollution as a significant cause of the initial decline is problematic. Effects of DDE/DDT on avian reproduction are well documented; that a major contaminant also bioaccumulated, biomagnified, and targeted an enzyme system universal to birds (eggshell formation) was unexpected and unanticipated. No other contaminant has impacted animal survival to such an extent, and DDT remains one of the few examples of pollution actually extirpating animal species over a significant portion of their range.

However, once a species is reduced to a remnant of its former population size and distribution, its vulnerability to catastrophic pollution events increases, frequently exceeding or replacing the factors responsible for the initial decline. Large-scale environmental events, such as global warming, acid rain, and sea-level rise, attract considerable attention as speciation events — both good (species numbers increase) and bad (species numbers decrease).

45.2 CHARACTERISTICS OF POLLUTION

The terms *pollution* and *contamination* remain ambiguous, even in the scientific community. For example, in the literature reviewed, each study started the same way — by defining terms. Definitions were applied and derived from a publication with different definitions or categories of pollution for each study. In general, authors need to move toward a universal definition. We classify pollution in two main categories: physical pollution and chemical contamination.

45.2.1 Physical Pollution

Physical pollution is most frequently caused by habitat modification such as channelization, dredging, dam and impoundment construction, urbanization, logging, and agricultural operations.^{19–21} Aquatic fauna are extremely sensitive to environmental variations, especially pollution and contamination.^{10–12,14,22} Habitat destruction was ranked the first and pollution the second most important factor affecting species decline for aquatic animals including amphibians, fish, mussels, crayfish, dragonflies, and damselflies.¹⁵ Lakes, streams, rivers, and freshwater ponds across the nation are adversely affected by various forms of pollution and contamination.

The effects of physical pollution include siltation, sedimentation, altered thermal regimes, altered water-flow regimes, changes in water depth, altered oxygen availability, and changes in pH, salinity, and erodability. Altered hydrologic regimes affected 34% of all species historically and currently affect 28% of all organisms.²² Channel modification results from flood-control devices, improper agricultural practices, grazing, logging, and mining operations; these activities remove the substrate that organisms live in and lead to increased siltation.^{23,24} Siltation is the most important water-quality problem across 45% of U.S. river miles and 28% of U.S. stream miles.¹⁹ Siltation covers spawning sites for fish and destroys benthic food sources.²⁵ Freshwater clams and other

bottom-dwelling filter feeders suffocate when covered by a layer of silt because they are relatively immobile as adults.^{24,26}

Water development projects, including dams, impoundments, river channelization, navigational barriers, and agricultural diversion, contribute to the decline of 30% of all threatened and endangered species. Over 91% of endangered freshwater fish and 99% of freshwater mussels are affected by water development.¹⁵ Large, multiple impoundments are the most prominent factor affecting freshwater mussels in any given watershed.²⁷ These watershed changes are estimated to impact 36% of the species affected by this class of habitat damage.²² Damming dramatically alters substrate composition, water chemistry, water temperature, and the amount of dissolved oxygen in the water.^{24,28,30} Altering free-flowing water contributes to erosion, modifies the transport of organic matter and sediment, changes the temperature regimes, and destabilizes bankments.^{12,31} Dams degrade fish-spawning habitat, leading to decreased densities and species richness of fish communities.^{29,31} Larval freshwater mussels depend on a host fish to attach to, so they are indirectly threatened by human actions that affect host-fish populations,²⁴ as are many benthic organisms. The benthic community, especially mussels, is most likely affected indirectly.

45.2.2 Chemical Contamination

Chemical contamination includes wastewater discharge, agricultural runoff, nutrient enrichment, pesticide/herbicide use, heavy metals, and organic chemicals. Contaminants originate from both point and nonpoint sources including municipal, industrial, and agricultural runoff and discharges.¹⁹ Over 17,365 waterways in the U.S. have been altered by a multitude of point- and nonpoint-source discharges of pollutants.³² Approximately 37% of U.S. rivers are affected by nutrient pollution, which is followed by pathogen indicators (27%), pesticides (26%), and organic enrichments combined with low dissolved oxygen (24%). Agricultural practices impact 72% of streams, followed by municipal point-source pollution (15%), urban runoff (11%), resource extraction (11%), and industrial point-source pollution (7%).¹⁹

45.3 SOURCES OF POLLUTION

Venues that allow pollutants to enter the environment are numerous, and articles listing all the potential contaminants are frequent. Basically, all of the factors are derivatives of three sources.

1. Agricultural
2. Municipal
3. Industrial

The path is twisted and contains many false trails, but eventually one or more of these three sources cover the introduced/anthropomorphic-derived pollutants. Compounds derived from municipal and industrial sources are difficult to separate. Frequently, industrial-derived pollutants are discharged into municipal treatment plants, from where they pass on into the environment. Rather than try to follow the trail to its source, industrial and municipal will be treated as a single category.

45.3.1 Agricultural

Agricultural practices are ranked as the most influential factor affecting water quality for rivers, streams, and lakes.^{19,22,29,33} Nonpoint agricultural pollutants, such as silt, nutrients, farm waste, and fertilizers, are detrimental to aquatic species.^{15,22,25,29} Commercial fertilizer is the primary agricultural nonpoint source of nitrates and phosphates,³³ which serve as catalysts for the development of anoxic water, toxic algal blooms, and the eutrophication of plant production. Organic nutrients

enter waterways via municipal, industrial, and agricultural pathways including feedlot and pasture runoff.¹⁹ Nitrogen is a common contaminant also released from industrial activities, transportation sources, sewage, and atmospheric acid deposition.²⁰ Breakdown of accumulated toxic nutrients uses up large quantities of dissolved oxygen. This results in low levels of dissolved oxygen in the water, rendering the habitat unsuitable for many aquatic species.¹⁹

Agricultural runoff also contains pesticides/insecticides and herbicides. Agricultural pollution is most likely to cause sublethal toxic effects in a species, affecting hormone regulation, reproduction, and embryonic development.^{25,29,34–38} Pesticides affect not only aquatic species larval development, but also adult immune systems, rendering organisms more susceptible to disease. With fewer healthy adults in the breeding population, fewer young will be produced, and of those produced, more offspring will not develop normally.⁸ Constant pesticide applications that affect immune system development can only suppress an already small population characterized by an endangered or threatened species.

Herbicides produce a wide range of detrimental effects in endangered species. Common herbicides are Atrazine, Paraquat, Diquat, Alachlor, Protham, and Barban.^{36,38} Most effects are indirect, such as the loss of plants that act as food sources and provide shelter from predators.³⁷ Most endangered and threatened species are habitat specialists, and alteration of their habitat may reduce their chances of survival.

45.3.2 Municipal and Industrial Pollution

Many of the same pesticides and nutrients used in large-scale agricultural practices are also used by municipal entities including urban and rural households. Runoff from fertilized lawns, household termite control, and organic nutrients from grass clippings may alter the soil makeup and can render a habitat unsuitable for certain plant and animal species.¹⁹ Such municipal sources produce substantial amounts of runoff that is discharged into surface waters, serving as the largest source of pollution for rivers, streams, and estuaries. Municipal discharges affect 16% of rivers and streams, 17% of lakes and reservoirs, and over 35% of estuaries. Runoff from city streets, construction sites, storm sewers, household waste, and leachate from septic tanks and landfills alters the sediment load in aquatic systems and deposits contaminants directly into surface- and ground-water sources.

Industrial sources of pollution include plants, steel mills, paper mills, mining establishments, and chemical manufacturers, whose effluent is usually categorized as point-source pollution. In the U.S., over 160,000 industrial facilities discharge 92,000 metric tons of hazardous wastes into municipal treatment plants annually, and as much as 18% of that remains untreated when it is discharged into surface water.³⁹ Municipal and industrial effluents carry toxic organic chemicals, toxic nutrients, heavy metals, salts, and pathogens.¹⁹ Runoff and discharges from municipal and industrial effluents eliminate opportunities for threatened species to recolonize local populations, destroy benthic food sources for aquatic species, and isolate populations resulting in lower genetic variability and, ultimately, viability.³⁹

Polycyclic aromatic hydrocarbons (PAHs) are one of the more toxic human-generated wastes. PAHs are carcinogens generated by the steel and iron industries, heating and power generation, and fossil fuel production and use.^{36,37} PAHs are released into the environment through petroleum spills, sewage effluents, and other accidental spills and are strongly implicated in the formation of liver neoplasms and tumors in fish and amphibians.^{36,37,40} PAHs are particularly hazardous to small, isolated, at-risk populations because spills high in PAHs are highly toxic.

A major group of contaminants associated almost exclusively with human activities is the heavy metals. They have been implicated in negative impacts affecting over 48% of U.S. lakes and reservoirs, 15% of rivers and streams, 10% of estuaries.¹⁹ Sources of toxic heavy metals and metalloids include atmospheric deposition, industrial activities, mining leachate, and stormwater runoff.^{19,20} Aquatic organisms exposed to high levels of metals in their environment suffer from a

decreased metabolic rate and a decreased ability to siphon for food.^{41,42} Aquatic organisms like freshwater mussels are sedentary and cannot move from an environment that is becoming increasingly toxic from the deposition of heavy metals. Exposed mussels ingest metals during their siphoning activities and concentrate metals until their metabolic rate is decreased to a level where they cannot siphon for food any longer. Some of the most common pollutants found in municipal and industrial runoff are copper, lead, zinc, mercury, aluminum, and cadmium.^{19,37} Mercury and lead are the most studied, but others, such as cadmium and selenium, are known hazards, even if they do require more research before their true impact can be accurately predicted. The dynamics of how each metal affects an organism depends on pH, alkalinity, organic enrichment, water movement, and biomagnification in the food web.³⁷ For example, mercury enters the environment through its use in mining, paints, fungicides, batteries, and thermometers. Metallic mercury is easily methylated by microorganisms in the environment to form methylmercury or dimethyl mercury, which are hazardous to aquatic animals.²⁰ Methylmercury attacks an organism's central nervous system but is not excreted from organisms readily because it is fat soluble, so it tends to bioaccumulate in the food chain.^{20,37} The process of mercury methylation is enhanced by the rate of decomposition of organic matter and the availability of organic nutrients, and it remains a consistent problem in newly flooded reservoirs.

45.4 CASE HISTORIES

Only 75% (n = 396) of the species listed in the United States have approved recovery plans, ranging from a low of 42% for arachnids to a high of 86% for reptiles (Table 45.1). Using the recovery plans as our data source, we tallied by taxonomic category (Table 45.1) the number of contaminants or pollution identified as a cause of the decline, contributed to the decline, or potentially posed a threat. Although incomplete because it only utilizes a portion of the listed species and none of those proposed for listing, this approach suffices for illustrative purposes.

45.4.1 Terrestrial Organisms

There were 194 terrestrial species with recovery plans. This corresponds roughly to mammals, birds, reptiles, insects, and arachnids (Table 45.1). These species had 400 cumulative threats listed in recovery plans (Figure 45.1). Municipal sources were listed most frequently (n = 105), followed by industrial sources (n = 100), agricultural sources (n = 80), waterway/navigation (n = 51), industrial/municipal (n = 42), and agriculture/municipal/industrial combination (n = 22). The main stressors affecting terrestrial species were discharges and effluents (n = 129), pesticides and poisons (n = 112), hydrologic modifications (n = 99), heavy metals (n = 25), and waste runoff (n = 14) (Figure 45.2). The following species are offered as case-history examples.

45.4.1.1 *American Burying Beetle, *Nicrophorus americanus* (USFWS 1991)*⁴³

Listed as endangered with a recovery plan approved in 1991, this coleopteran has a disjunct population, with subpopulations in Rhode Island and Oklahoma.⁴³ Estimated total population is less than 1000 individuals. Initial declines are believed to be due to the extensive use of DDT in agriculture, although there is historical evidence that populations were decimated by disease. However, extensive habitat alteration, habitat loss, and conversion to other uses have resulted in severe habitat fragmentation. In all likelihood, DDT in combination with habitat losses/alteration caused the decline and now inhibits the surviving populations from reoccupying habitat. Additionally, pesticides and herbicides present a severe threat to the beetle because a significant portion of the population could be killed in a single incident.

Sources of Contaminants

Figure 45.1 Sources of contaminants affecting U.S. endangered and threatened species.

Stressors Affecting Terrestrial Species

Figure 45.2 Contaminant and pollution stressors affecting U.S. endangered and threatened terrestrial species.

45.4.1.2 Desert Tortoise (*Mojave Population*), *Gopherus agassizi* (USFWS 1994)⁴⁴

Populations of this reptile occur in California, Nevada, Arizona, and Utah. Throughout their range, tortoises are being impacted by similar problems, but the impact is most acute in the six Mojave subpopulations, especially those in California. The Mojave segment was listed as threatened in the most recently approved recovery plan (1994).⁴⁴

Overgrazing by exotics (horses and burros) and off-road-vehicle use has reduced the undisturbed and undamaged desert scrub preferred by tortoises. Compounding these population-wide threats is

the proliferation of roads and urbanization, putting more tortoises in harm's way from vehicles, domestic pets (especially dogs), and the large commercial and amateur pet trade.

The widespread occurrence of a lung disease appears to affect populations already stressed. A new issue is raven predation. Supported by the proliferation of dumps and landfills, raven populations are increasing; a recently learned behavior involves dropping juvenile tortoises from high altitude onto hard-surface roads to crack the shell, kill and consume the tortoise.

45.4.1.3 Florida Panther, *Felis concolor coryi* (USFWS 1995)⁴⁵

The second revision of the recovery plan for this endangered feline was approved in 1995.⁴⁵ Before it was extirpated through most of its range, it occupied most of the southeast from Texas to North Carolina. It now consists of a highly inbred population of 20–30 animals in a single location within Florida.

Isolated from contact with other mountain lion populations, gene flow has been eliminated, and the remnant population suffers the fate of all limited gene pools — disease and parasitism take their toll as do stochastic events such as road kills, fires, and inbreeding depression. Human presence continues to increase, with more panther habitat being converted to uses detrimental to the panther's well-being.

Tissues from panthers and their prey items show mercury levels that may be toxic as well as constitute a reproductive hazard.⁴⁶ Sugar cane is a major crop in the area utilizing substantial amounts of pesticides; maintenance of habitat as grasslands for cattle grazing contributes to these hazards. Runoff from these fields exposes the panther to a suite of biotoxins, which may or may not have an effect.

45.4.1.4 Eastern Brown Pelican, *Pelecanus occidentalis carolinensis* (USFWS 1979)⁴⁷

Listed as endangered in 1979, this subpopulation was delisted in 1985. The wild population nested along the Gulf coast from Mexico to Florida, then along the Atlantic coast, from Florida north.⁴⁷ The brown pelican's decline on the east coast bore little resemblance to that of the Pacific coast. On the Pacific coast, the decline was much slower and could be explained by the shell thinning and subsequent reproductive failure attributed to DDE/DDT. On the east and Gulf coasts, the decline started in the 1930's and was attributed to a combination of factors including weather, predation, starvation, disturbance, vandalism, and DDE/DDT. Louisiana's breeding population disappeared between 1957 and 1961, leaving a remnant population in Texas, none along the Gulf coast until Florida, and South Carolina, where 20,000–30,000 pelicans (mostly in Florida) continued to breed with no apparent problem. This precipitous decline suggests a toxicant rather than failure to produce viable young. Louisiana lost 40% of a population it was seeking to reestablish from an endrin spill, and oil spills pose a constant and familiar hazard. Brown pelicans nationwide have benefited from the reduction of organochlorine pesticide use.

45.4.1.5 California Condor, *Gymnogyps californianus* (USFWS 1996)⁴⁸

The California condor was listed as an endangered species in 1967, but did not have a recovery plan until 1975; the current plan was approved in 1996 and represents the third revision.⁴⁸ Historically (1700–1800), the California condor was believed to have been a common species along the Pacific coast from Baja California, Mexico, to British Columbia, Canada, where they fed on marine mammals washed up on shore. Their distribution during the Pleistocene was apparently continent-wide. With a wingspan approaching 3 m, this wide-ranging soaring scavenger depends on its vision to locate primarily mammal carcasses in grasslands and other open environments. Ridgelines and hilltops are especially liked because they make it easier for the condor to resume flight from a

running start. The declines in marine mammals hurt condor populations, as did the conversion of the Central Valley from marshes and grasslands to agriculture and the subsequent loss of Tule elk, mule deer, and pronghorn antelope. As agriculture expanded in the valley floor, both the condors and the cattle industry retreated into the surrounding foothills and mountains of the Coast range, Transverse range, and Sierra Nevada.

The causes of the decline may never be completely understood, but some aspects of the decline are obvious. Loss of foraging range and declines in the primary food sources made foraging more difficult, as the birds searched for carcasses that were increasingly less common. Assembling personal natural-history-specimen collections was quite popular during the Victorian era and carried on into the 1900s; eggshell collecting was one of the more popular themes. Consequently, condor eggs were much sought after and 'hundreds were taken from the wild for formal collections as well as for amateur collections. Also known to have killed condors are power transmission lines, compound 1080, radiator fluid, cyanide, and lead. Elevated organochlorine residues are reported from eggs in the 1980s, although no evidence of significant shell thinning was found.

Despite conservation efforts, the species was in decline throughout the 1900s, culminating in the removal from the wild of the last condor in April 1987. The decision to move the entire population into captivity was the result of the losses incurred by the wild population during the winter of 1984–1985. Four of the five pairs suffered losses, three pairs had one member disappear, and the fourth pair vanished. Faced with a situation in which half of the wild population vanished, bringing the wild population into captivity and planning to restore this population through the release of captive-reared birds appeared to be the only available tactic.

Lead poisoning appears to be a significant problem. Four out of the last five condors recovered after death had died of lead poisoning. Elevated blood-lead levels and mortality have been reported in all of the released condor populations including those from the remote Arizona site. All the evidence indicates that the source of the lead causing raptor mortality is not organic, biologically incorporated, or derived from sediments, but is metallic lead in the form of shot or fragments from expanding bullets.

45.4.2 Aquatic Organisms

Aquatic organisms serve as excellent indicators of environmental quality because they are often specialized for such restricted habitats. Freshwater environments are susceptible to degradation caused by changes in biogeochemical processes and changes in the local watershed including the surrounding terrestrial habitat.²⁵ For example, because mussels are relatively immobile and their reproductive cycle is fairly complex, they are exposed to changes in a watershed at various stages of their life cycle. Good water quality is critical for survival, making mussels extremely sensitive to environmental pollution. Mussels ingest and concentrate heavy metals, contaminants, and pesticides from water, making their absence or presence an indication of water quality and chemical contamination.^{24,29}

Freshwater aquatic organisms comprise a substantial number of threatened species listed under the ESA.⁴ Aquatic fauna are proportionately more threatened than terrestrial species.^{4,13,21} Freshwater mussels, crayfish, amphibians, and fish have the largest numbers of species at risk. More than 60% of freshwater mussels and crayfish are at risk of endangerment or extinction.¹³ Various scientists have developed similar values estimating species imperilment. Approximately 37% of freshwater fish and 35% of amphibians are imperiled.²¹ Over 20% of the world's fish species are either extinct or endangered,^{17,25} and one third of all U.S. fish species are threatened or endangered.¹² Of all freshwater organisms, mussels are the most rapidly declining group,²⁷ with estimates as high as 10% extinction in the past century.²¹

There were 202 aquatic species that had recovery plans, divided into the categories of amphibians, fish, clams, and crustaceans (Table 45.1). Recovery plans for aquatic species totaled 1089 contaminant and pollution threats (Figure 45.1). Waterway navigation was the main source of

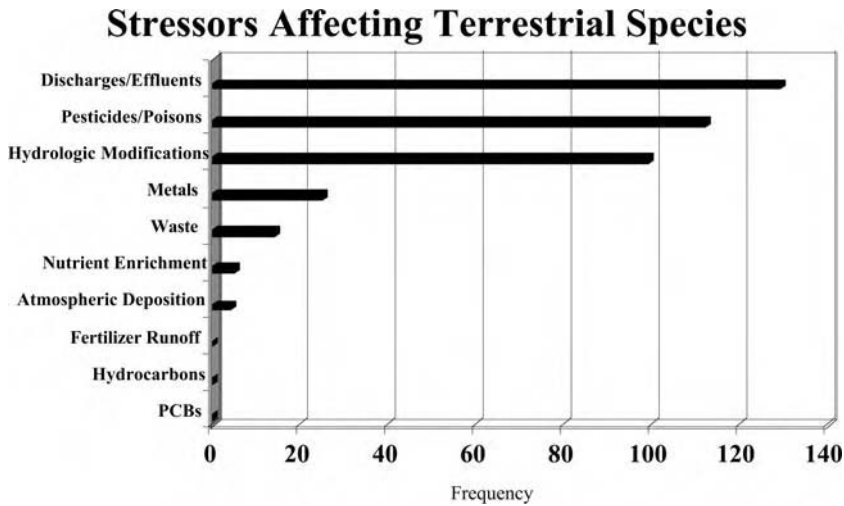

Figure 45.3 Contaminant pollution stressors affecting U.S. threatened and endangered aquatic species.

contaminant and pollution threats affecting aquatic species ($n = 326$), followed by industrial sources ($n = 318$), municipal sources ($n = 151$), agricultural sources ($n = 131$), industrial/municipal sources ($n = 117$), and agricultural/municipal/industrial combinations ($n = 46$). The stressors listed most frequently were hydrologic modifications ($n = 548$), discharges and effluents ($n = 344$), poisons and pesticides ($n = 80$), heavy metals ($n = 56$), and nutrient enrichment ($n = 39$) (Figure 45.3). The following species are offered as case history examples.

45.4.2.1 *San Diego Fairy Shrimp, Branchinecta sandiegonensis* (USFWS 1998)⁴⁹

This endangered freshwater crustacean had its recovery plan approved in 1998.⁴⁹ Found only in small, shallow ephemeral ponds in southern California, this fairy shrimp numbers less than 1000 individuals. Historically, these vernal pools were subjected to the impacts of overgrazing, trampling, and waste dumping (industrial, municipal, and agricultural). A significant number of pools were lost when they were inundated by reservoirs created for flood control and domestic water supply.

Since the shrimp can tolerate only minimal changes in water quality, maintaining suitable aquatic habitat is the main issue they face. Joining cattle as a significant degrader of habitat quality are off-road vehicles. Runoff from agricultural fields, highways, and urban areas degrades water quality and further threatens this native shrimp.

45.4.2.2 *Utah Valvata Snail, Valvata utahensis* (USFWS 1995)⁵⁰

The endangered Utah valvata snail, whose recovery plan was approved in 1995, is restricted to cold-water springs in Utah and Idaho.⁵⁰ Although numbering about 12,000 individuals, its specialized and unique habitat requirements make it quite vulnerable to extirpation from acute pollution events. It is known to occur at four sites.

It has been severely impacted by impoundments intended for power generation. The loss of critical habitat and the severe habitat fragmentation have isolated populations with large stretches of still, hostile impounded water. The remaining populations are threatened by water-quality issues including runoff from feedlots and farm fields as well as excessive water withdrawals that expose critical habitat to dessication and increased water temperatures. The restricted distribution makes the remaining populations quite vulnerable to catastrophic pollution events.

45.4.2.3 Wyoming Toad, *Bufo hemiophrys baxteri* (USFWS 1991)⁵¹

The Wyoming toad was classified as endangered in its 1991 recovery plan.⁵¹ It is a relic population of a species that was widespread when the climate was wetter but is now reduced to a single population of 100–150 animals inhabiting the wetlands around Laramie, Wyoming.

Climate has been the major cause of the decline, reducing the toad's preferred habitat to wetlands associated with the widely scattered rivers and creeks of the high plains short grass prairies. The result was isolated subpopulations that could not interact and had no suitable habitat for expansion. These are also the areas that have been converted to homesteads, pastures, and agricultural lands. Virtually all of these areas lie in private ownership and are used as pastures and hay meadows, with irrigation and mowing schedules impacting the toad to varying degrees. Populations disappeared without notice until the species was reduced to a single population.

The surviving population is further threatened by disease, predation, development, and ongoing agricultural practices. Of particular concern has been the use of fenthion as a mosquito-control agent. Efforts to reduce mosquito populations are the greatest hazard the toad population faces, with extinction in a single spray event possible, depending on the toxicity, persistence, and exposure levels the population experiences.

45.4.2.4 Blue Pike, *Stizostedion vitreum glaucum* (USFWS 1975)⁵²

The blue pike was a very popular food fish and quite abundant at one time throughout the Lake Huron/Lake Erie/Lake Ontario ecosystem. The recovery plan was signed August 1975, designating the blue pike as an endangered species.⁵² The dramatic drop in the commercial and recreational catch year to year warned of the problem, but it was not addressed soon enough to save the blue pike. Further surveys failed to find any fish, and it was declared extinct. The primary factors leading to extinction were over-fishing by commercial and recreational users in concert with a rapidly increasing level of pollution that led to severe oxygen depletion. The introduction of smelt accelerated the downturn because smelt exploited the same food resources as the blue pike and were more tolerant of the deteriorating conditions. As the population levels declined, hybridization became more prominent as individuals failed to find conspecifics and mated with related but nonconspecifics.

45.4.2.5 Devil's Hole Pupfish, *Cyprinodon diabolus* (USFWS 1980)⁵³

Listed as endangered in July 1980, the Devil's hole pupfish is one of many pupfish found in the southwestern U.S. with a restricted range — relics of a wetter, cooler climate.⁵³ As the climate changed, pupfish populations become isolated and evolved into separate species. The Devil's Hole pupfish are restricted to one water-filled limestone cavern in Nevada. The maximum population estimate was 300–400 fish. Additionally, they are also restricted by the shallow shelf that provides the only source of plant and invertebrate resources for the entire population. Water depletion, particularly falling groundwater, jeopardizes the species through loss of its foraging habitat.

Groundwater depletion has been the most immediate concern. Runoff from adjacent fields into the Devil's Hole watershed and groundwater has raised concerns that toxic substances would move into the cavern. Pesticides pose an immediate threat to the fish, as herbicides do to the plants growing on the foraging rock shelf. The influx of surface water also carries silt and nonpoint-source contaminants into the cavern with unknown effects. Finally, the limited habitat and small population places the species in immediate threat of extinction. Any perturbation of the system, any spill that flows into the cavern or reduces water flow into the system, is capable of driving the Devil's Hole pupfish to extinction.

45.4.2.6 Curtis' Pearly Mussel, *Epioblasma florentina curtis* (USFWS 1986)⁵⁴

The Curtis' pearly mussel was listed as an endangered species at the time the recovery plan was approved in February 1986.⁵⁴ This freshwater mussel historically occurred in the basins of the White and St. Frances Rivers in Missouri and Arkansas. Present distribution is 6.1 mi of the Little Blue River and 7 mi of the Castor River, all in Arkansas. Like so many of its endangered cousins, the Curtis' pearly mussel requires stable substrates of sand, gravel, cobble, or boulder in riffles and runs of moderate water volume.

Much of its habitat has been covered by impoundments, destroying its suitability to this riverine species. Channelization and gravel dredging has destroyed additional miles of stable river habitat. Impoundments have also impacted downstream water quality, altering water chemistry, temperatures, and flow regimes. Encroaching agricultural fields and building construction degrades water quality by releasing nutrients, pesticides, herbicides, and sediments. The sediments clog occupied habitat, suffocating adult mussels and driving host fish from the area. From the agricultural fields also come low levels of a variety of agricultural chemicals of unknown toxicity or sublethal effects. Finally, the restricted distribution makes the surviving populations vulnerable to spills that might sterilize the river system.

45.5 SUMMARY AND CONCLUSIONS

Multiple factors contribute to the decline of species. Habitat destruction is the primary factor that threatens species, affecting 73% of endangered species. The second major factor causing species decline is the introduction of nonnative species, affecting 68% of endangered species. Pollution and overharvesting were identified as impacting, respectively, 38 and 15% of endangered species. Other factors affecting species decline include hybridization, competition, disease, and other inter-specific interactions.

Once a species is reduced to a remnant of its former population size and distribution, its vulnerability to catastrophic pollution events increases, frequently exceeding or replacing the factors responsible for the initial decline. Small, isolated populations are particularly vulnerable to catastrophic loss by an acute event, such as a chemical spill or pesticide application. However, when it comes to surviving a single disaster, widespread subpopulations of a species are far more resilient and ensure genetic survival. Hypothesizing theoretical concerns of potential factors that could affect an endangered species could predispose the scientific and political communities to jeopardizing threats.

The user of recovery plans as a data source must be aware of the bias within the data set. These data should be used with the caveat that the source of information in recovery plans is not always based on scientific research and rigorous data collection. Over 58% of the information identifying species threats is based on estimates or personal communication, while only 42% is based on peer-reviewed literature, academic research, or government reports. Many recovery plans were written when a species was initially listed in the 1970s or 1980s. Politics, human disturbance, and habitat demand issues evolve over a 20- to 30-year period, leaving much of the threats facing endangered species outdated and inadequate. These data are most valuable when used to facilitate reviews of Section 7 consultations and environmental impact statements, review permit applications, conduct environmental risk assessments, prioritize research needs, and identify limiting factors affecting species health. These data are also useful in identifying potential threats to species' health. Without properly identifying threats to endangered species based on sound, scientific research, there is little hope to successfully recover an endangered species.
