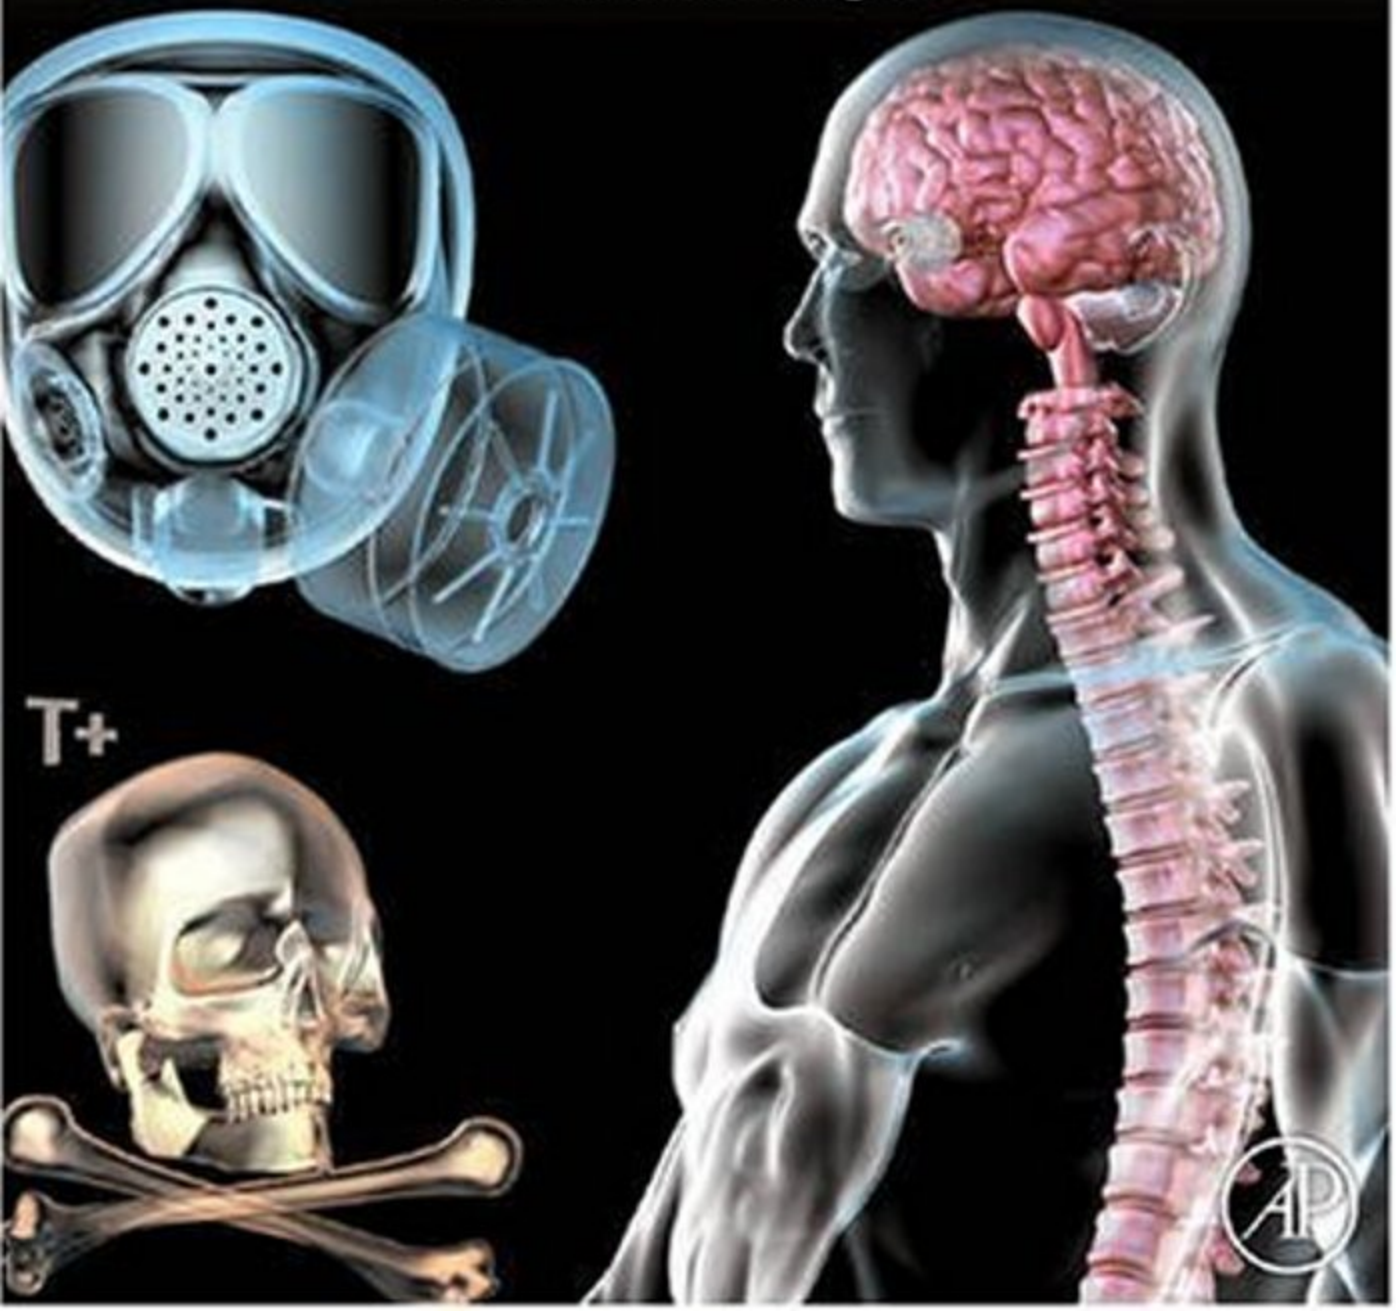
Handbook of Toxicology of Chemical Warfare Agents

EDITED BY

Ramesh C. Gupta



Academic Press is an imprint of Elsevier
32 Jamestown Road, London, NW1 7BY, UK
30 Corporate Drive, Suite 400, Burlington, MA 01803, USA
525 B Street, Suite 1900, San Diego, CA92101-4495, USA

First edition 2009

British Library Cataloguing in Publication Data
A catalogue record for this book is available from the British Library

Library of Congress Cataloging-in-Publication Data
A catalog record for this book is available from the Library of Congress

ISBN: 978-0-12-374484-5

This book is dedicated to my beloved wife Denise, daughter Rekha,
and parents the late Chandra and Triveni Gupta

List of Contributors

ARTURO ANADÓN, DVM, PhD, DipECVPT, Professor, Departamento de Toxicología y Farmacología, Facultad de Veterinaria, Universidad Complutense de Madrid, 28040-Madrid, España

JAIME ANDERSON, DVM, PhD Lieutenant Colonel, Veterinary Corps, US Army, Chief, Analytical Toxicology Division, US Army Medical Research Institute of Chemical Defense, 3100 Ricketts Point Road, APG-EA, Maryland 21201-5400, USA

JUN-ICHI ANZAI, PhD Graduate School of Pharmaceutical Sciences, Tohoku University, Aramaki, Aoba-ku, Sendai 980-8578, Japan

MICHAEL ASCHNER, PhD Departments of Pediatrics and Pharmacology, Center in Molecular Toxicology and Kennedy Center for Research on Human Development, Vanderbilt University School of Medicine, Nashville, TN 37212, USA

PETER AVDONIN, MSc N.K. Koltzov Institute of Developmental Biology, Russian Academy of Sciences, ul.Vavilova #32, Moscow, Russia

VLADIMIR BABAKOV, PhD Research Institute of Hygiene, Occupational Pathology and Human Ecology, Bldg 93, p.o.Kuzmolovsky, Saint-Petersburg, 188663, Russia

MICHAEL C. BABIN, DVM, PhD Toxicologist, Battelle Biomedical Research Center, 505 King Avenue, Columbus, OH 43201-2693, USA

DEBASIS BAGCHI, PhD, FACN, CNS InterHealth Research Center, 5451 Industrial Way, Benicia, CA, USA and Creighton University Medical Center, 2500 California Plaza, Omaha, NE, USA

MANASHI BAGCHI, PhD, FACN InterHealth Research Center, 5451 Industrial Way, Benicia, CA, USA

JIRI BAJGAR, MD, CSD Department of Toxicology, Faculty of Military Health Sciences, University of Defense, Trebesska 1575, Hradec Kralove, Czech Republic

KULBIR BAKSHI, PhD Retired, Program Director, Committee on Toxicology, Board on Environmental Studies and Technology, National Research Council, Washington, DC, USA

FRANK BALSZUWEIT, PhD Bundeswehr Institute of Pharmacology and Toxicology, Neuherbergstr. 11, 80937 Munich, Germany

ATRAYEE BANERJEE, PhD Post Doctoral Research Fellow, Missouri University of Science and Technology, Rolla, Missouri 65401, USA

CHERYL BAST, PhD, DABT Toxicology and Hazard Assessment Group, Environmental Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN, USA

VAL R. BEASLEY, DVM, PhD, DABVT, Professor, Department of Veterinary Biosciences, College of Veterinary Medicine, University of Illinois, Urbana, IL, USA

R. BHATTACHARYA, Sci E Division of Pharmacology and Toxicology, Defence Research and Development Establishment, Jhansi Road, Gwalior - 474 002, MP, India

WHITNEY BURROWS, MD Thoracic Surgeon, Greenebaum Cancer Center, University of Maryland Medical Center, 22 S. Greene St, Baltimore, MD 21201-1595, USA and Assistant Professor of Surgery, University of Maryland School of Medicine, 655 W. Baltimore St, Baltimore, MD 21201-1559, USA

ROBERT P. CASILLAS, PhD Vice President, Biomedical Science and Technology, Battelle Memorial Institute, 505 King Ave, 7-2, Columbus, OH 43201, USA

SYLVAIN CHEMTOB Department of Pharmacology, Pediatrics and Ophthalmology, University of Montreal, Quebec, Canada

EDWARD D. CLARKSON, DABT, PhD Medical Toxicology Branch, Analytical Toxicology Division, US Army Medical Research Institute of Chemical Defense, 3100 Ricketts Point Road, APG-EA, MD 21010-5400, USA

Foreword

TETSUO SATOH, PHD, FATS

A highly toxic chemical intended to harm, kill, incapacitate, or control adversaries in warfare is called a chemical warfare agent (CWA). Throughout the world, some 70 different chemicals have been developed and produced, and many of them have been stockpiled as CWAs or chemical weapons of mass destructions (CWMD) during the 20th and 21st centuries. The use of biotoxins (botulinum toxin, ricin, saxitoxin, anthrax, etc.) is also sometimes referred to as chemical warfare.

Although the use of CWAs dates back to the 5th century BC, modern CWAs were not used at full scale until World War I. Since then, a variety of CWAs have been developed and deployed in many wars, conflicts, terrorist attacks, hostage crises, and riots. These chemicals came into the limelight particularly due to Gulf War Syndrome (aftermath of Gulf War I, 1991) and the Tokyo Subway terrorist attacks in 1994 and 1995. In the present world situation, the intentional use of highly toxic chemicals as CWAs/CWMD is a growing concern for government officials and civilians alike in developing as well as industrialized countries. The terrorist attacks in New York City on September 11, 2001 led to an increased awareness of protecting national monuments, landmarks, federal and state buildings, and workplaces, in addition to civilians, as possible terrorist targets.

Performing a comprehensive analysis of the inadequate database on chemical warfare agents is often a highly demanding task for toxicologists, risk assessors, regulatory agencies, and policy and decision makers at both state and federal levels. Due to the lack of adequate control, legislation, regulations, and knowledge, the term ''chemical warfare'' is often misunderstood or misused. In the recent past, in order to protect people and educate them about terrorist attacks, a variety of Standards and Exposure Guidelines have been made available, and on January 23, 2008, the U.S. Department of Labor published ''Safety and Health Topics, Chemical Terrorism''.

Handbook of Toxicology of Chemical Warfare Agents is the first book on chemical warfare agents that provides a plethora of knowledge on the historical perspective, epidemiology, detailed toxicology profile of CWAs/CWMD, target organ toxicity, analytical methodologies, biosensors, biomarkers, prophylactic and therapeutic countermeasures, and decontamination and detoxification procedures. In addition, the book serves as a significant source of information for nuclear and biological warfare agents. Therefore, this book appears to be an extremely useful reference source for academicians and regulatory authorities for risk and safety assessment, and management of chemical terrorism. The information provided in this book will draw immense attention from federal and state agencies, as well as political decision makers.

The editor, contributors, and publisher faced tremendous challenges in order to cover comprehensively all possible aspects of the toxicology of CWAs. Presently, there are at least two dozen chemicals that can be used as CWAs. Organophosphate (OP) nerve agents and mustards have been most frequently used and are most likely to be used in the future by terrorists and dictators throughout the world, because of their easy access and delivery systems. As a result, these chemicals have been extensively studied, and books, monographs, reviews, and papers are widely published. Recently, Academic Press/Elsevier published a most comprehensive book entitled *Toxicology of Organophosphate and Carbamate Compounds*, and *Handbook of Toxicology of Chemical Warfare Agents* appears to be unique in providing a thorough assessment of all possible aspects of toxicology, risk assessment, and remedial measures of CWAs in humans, animals, and wildlife.

The contributors of this book from around the globe are leading scientists and internationally recognized for their expertise in particular areas of toxicology of CWAs/CWMD and countermeasures. The book is divided into nine sections that deal with different aspects of CWAs. Section I deals extensively with the historical perspective, epidemiology and global impact of CWAs. Section II covers the broad array of chemical agents that can be weaponized and deployed as CWMD. In this section, toxicity profile, mechanism of action, risk assessment, and prophylactic/therapeutic measures of the individual chemicals are described in an in-depth manner. Section III provides an exhaustive coverage of target organ toxicity, which is indeed a novel aspect of this book. Several chapters on special topics about OP nerve agents, including molecular/

cellular mechanisms and neuropathological modulations, are discussed in section IV. Section V describes the risks to animals and wildlife associated with CWAs and chemicals of terror contaminating feed and water reservoirs, which can have a serious impact on human and animal health and the environment. Section VI deals with the metabolism, toxicokinetics and physiologically based pharmacokinetics of CWAs. A novel section (VII) is introduced with six chapters that provide discussion of analytical methodologies, biosensors, and biomarkers of CWAs. These topics will aid researchers in determining the extent of human/animal exposure, risk/safety assessment of CWAs, and management of poisoning. Section VIII covers extensively the unique approaches and strategies involved in prophylactic and therapeutic management and countermeasures. Many novel topics are included in this section, such as medical management of not only military personnel but civilians (more importantly the pediatric population), physiologically based pharmacokinetic modeling in countermeasures, catalytic and non-catalytic bioscavenging enzymes, and novel oximes. Prophylaxis and therapeutics for other CWAs are discussed in section II dealing with individual CWAs. The final section (IX) deals with information on decontamination and detoxification of CWAs.

In essence, this book is a landmark publication in the field of toxicology of CWAs/CWMD, as it provides comprehensive coverage of these chemicals and emphasizes current and novel issues that have not previously been addressed. It is hoped that this book will aid not only academicians but lay persons in community preparedness at local, state, and federal levels to protect civilians, military personnel, animals, wildlife, and the environment from chemical attacks by terrorists, dictators, and other adversaries. This book will be an invaluable source of information for homeland security, the Department of Defense, the Department of Veteran Affairs, the Department of Defense Research Establishment, diagnostic labs, poison control centers, federal, state and local authorities, forensic scientists, pharmacologists, toxicologists, chemists, biologists, environmentalists, teachers, students, and libraries.

CHAPTER 1

Introduction

RAMESH C. GUPTA

For centuries extremely toxic chemicals have been used in wars, conflicts, terrorists', extremists' and dictators' activities, malicious poisonings, and executions. One of the earliest forms of chemical warfare agents (CWAs) were natural toxins from plants or animals, which were used to coat arrowheads, commonly referred to as ''arrow poisons''. Ancient use of some CWAs and riot control agents (RCAs) dates back to the 5th century BC, during the Peloponnesian War, when the Spartans used smoke from burning coal, sulfur, and pitch to temporarily incapacitate and confuse occupants of Athenian strongholds. The Spartans also used bombs made of sulfur and pitch to overcome the enemy. The Romans used irritant clouds to drive out adversaries from hidden dwellings. In the 15th century, Leonardo da Vinci proposed the use of a powder of arsenic sulfide as a chemical weapon. Modern use of CWAs and RCAs or incapacitating agents dates back to World War I (WWI).

With advancements in science and chemistry in the 19th century, the possibility of chemical warfare increased tremendously. The first full-scale use of chemical warfare agents began in April of 1915 when German troops launched a poison gas attack at Ypres, Belgium, using 168 tons of chlorine gas, killing about 5,000 Allied (British, French, and Canadian) soldiers. During WWI, the deployment of CWAs, including toxic gases (chlorine, phosgene, cyanide, and mustard), irritants, and vesicants in massive quantities (about 125,000 tons), resulted in about 90,000 fatalities and 1.3 million non-fatal casualties. The majority of the deaths in WWI were a result of exposure to chlorine and phosgene gases. During the Holocaust, the Nazis used carbon monoxide and the insecticide Zyklon-B, containing hydrogen cyanide, to kill several million people in extermination camps. Poison gases were also used during the Warsaw Ghetto Uprising in 1943. Again, in November 1978, religious cult leader Jim Jones murdered over 900 men, women and children with cyanide.

Prior to, during, and after World War II, anticholinesterase organophosphate (OP) nerve agents/gases were developed in Germany, the USA, the UK, and Russia, and produced in large volumes in many other countries. They were maximally produced and stockpiled during the ''Cold War'' period. These nerve agents have been used in wars and by dictators, extremists, cult leaders, and terrorist groups as chemical weapons of mass destruction (CWMD) on many occasions. In 1980, Iraq attacked Iran, employing mustard and OP nerve gases. During the period of the Iraq and Iran conflict (1980–1988), Iran sustained 387 attacks and more than 100,000 troops were victims along with significant numbers of civilians. Thousands of victims still suffer from long-term health effects. Shortly after the end of the Iraq–Iran war in 1988, the brutal dictator of the Iraqi regime, Saddam Hussein, used multiple CWAs against the Kurdish minorities in Halbja village, killing more than 10% of the town's 50,000 residents. To date, mustards have been used in more than a dozen conflicts, killing and inflicting severe injuries in millions of military personnel and civilians.

During the Persian Gulf War, exposure to OP nerve agents occurred from the destruction of munitions containing 8.5 metric tons of sarin/cyclosarin housed in Bunker 73 at Khamisyah on March 4, 1991, and additional destruction of these nerve agents contained in rockets in a pit at Khamisyah on March 10, 1991. Although exposure levels to nerve agents were too low to produce signs of acute toxicity, the serving veterans in and around the Khamisyah area still suffer from long-term adverse health effects, most notably ''Gulf War Syndrome''. In 1996, about 60,000 veterans of the Persian Gulf War claimed to suffer from ''Gulf War Syndrome'' or ''Gulf Veterans' Illnesses'', possibly due to low-level exposure of nerve agents, mustard, pyridostigmine bromide and pesticides. Exposed veterans had an increased incidence of chronic myelocytic leukemia and increased risk of brain cancer deaths compared to unexposed personnel.

In the mid-1990s, two terrorist attacks by a fanatic religious cult Aum Shinrikyo (Supreme Truth), known as Aleph since 2000, took place in Japan (Matsumoto, 1994 and Tokyo Subway, 1995). In both incidents, the OP nerve agent sarin was used as a CWA. An estimated 70 tons of sarin was manufactured by Aum Shinrikyo in Kamikuishiki, Japan. Although the total fatality count involved not more than 20 civilians, injuries were observed in more than 6,000 and millions were terrified. These acts of chemical terrorism were unprecedented and the impact propagated not only throughout Japan, but the entire world. In the past few decades, many incidents have also occurred with biotoxins such as ricin and anthrax. Publicity surrounding frequent recent use due to easy access, and

copycat crimes increase the possibility of future use of these chemicals and biotoxins, which warrants advancement in emergency preparedness planning at the federal, state, and local government levels.

It is interesting to note that toxic chemicals have been used by governmental authorities against rebels, or civilians. In 1920s, Britain used chemical weapons in Iraq ''as an experiment'' against Kurdish rebels seeking independence. Winston Churchill strongly justified the use of ''poisoned gas against uncivilized tribes''. The Russian Osnaz Forces used an aerosol containing fentanyl anesthetic during the Moscow theater hostage crisis in 2002. RCAs were frequently used in the USA in the 1960s to disperse crowds in riot control.

At present, more than 25 countries and possibly many terrorist groups possess CWAs, while many other countries and terrorist groups are seeking to obtain them, due to their easy access. Some of these agents are stockpiled in enormous quantities and their destruction and remediation are not only expensive but associated with significant health risks. There is also the possibility of accidental release of CWAs or CWMD at the sites of their production, transportation, dissemination, and deployment. The intentional or accidental release of highly toxic chemicals, such as nerve agent VX (Dugway Proving Ground, Utah, 1968), Agent Orange (Vietnam, 1961–1972), PBB (Michigan, USA, 1973), dioxin (Seveso, Italy, 1976), and methyl isocyanate (Bhopal, India, 1984), has caused injuries in more than a million people, and deaths in several thousands. A 1968 accident with VX nerve gas killed more than 6,000 sheep in the Skull Valley area of Utah.

After September 11, 2001, the chances are greater than ever before for the use of CWMD by extremist and terrorist groups like Al Qaeda, which presents great risks to humans, domestic animals, and wildlife in many parts of the world. On 26 November 2008, Pakistani Islamic terrorists attacked Mumbai city in India at 10 different sites, including two luxury hotels, a Jewish center, a train station, and hospitals and cafes. Approximately 200 innocent people died and about 300 people were injured by bullets and fire smoke. It is more likely that these terrorist groups may use toxic industrial chemicals (agents of opportunity) either as such or as a precursor for more deadly CWMD. At present, many countries have established Defense Research Institutes with two major missions: (1) to understand the toxicity profile of CWAs/CWMDs, and (2) to develop strategic plans for prophylactic and therapeutic countermeasures. By the turn of the 21st century, the USA established the Department of Homeland Security. Many other countries also developed similar governing branches and agencies at the state and national level to protect people and properties from terrorist attacks. Among chemical, biological, and radiological weapons, the possibility of CWMD is more likely because of their easy access and delivery system. It is important to mention that understanding the toxicity profile of CWAs/CWMD is very complex, as these chemical compounds are of a diverse nature, and as a result, treatment becomes very difficult or in some cases impossible.

In the past, many accords, agreements, declarations, documents, protocols, and treaties have been signed at the international level to prohibit the development, production, stockpiling, and use of CWAs, yet dictators and terrorists produce and/or procure these chemicals to harm or kill enemies, create havoc, and draw national and international attention. In 1907, The Hague Convention outlawed the use of chemical weapons, yet during WWI, many countries used these chemicals. The first international accord on the banning of chemical warfare was agreed upon in Geneva in 1925. Despite the General Protocol, the Japanese used chemical warfare against China in 1930. In 1933, the Chemical Weapon Convention banned the development, possession, and use of CWAs. The document was signed and implemented by more than 100 countries. Yet, during WWI many chemicals of warfare were developed, produced, and used by many countries. In 1993, another global convention banning the production and stockpiling of chemical warfare agents was signed by more than 100 countries.

In the present world situation, it is highly likely that these agents will be used in wars, conflicts, terrorist attacks, and with malicious intent. In such scenarios, these extremely toxic agents continuously pose serious threats to humans, animals, and wildlife.

This *Handbook of Toxicology of Chemical Warfare Agents* was prepared in order to offer the most comprehensive coverage of every aspect of the deadly toxic chemicals that can be used as CWAs/CWMD. In addition to the chapters on radiation, several chapters are included on deadly biotoxins (ricin, abrin, strychnine, anthrax, and botulinum toxins) that can be weaponized in chemical, radiological, and biological warfares. Many special and unique topics are offered that have not been covered in previous books. This is the first book that offers detailed target organ toxicity in this area of toxicology. In every chapter, all factual statements are substantiated with appropriate references.

This book meets the needs not only of academicians but lay persons as well. The format employed is user friendly and easy to understand. Standalone chapters on individual chemicals, target organ toxicity, biosensors and biomarkers, risks to man, animal and wildlife, and prophylactic and therapeutic countermeasures are just a few of the many novel topics covered in this book. The chapters are enriched with the historical background as well as the latest information and up-to-date references. With more than 70 chapters, this book will serve as a reference source for toxicologists, pharmacologists, forensic scientists, analytical chemists, local/state/federal officials in the Department of Homeland Security, Department of Defense, Defense Research Establishments, Department of Veterans Affairs, physicians at medical and veterinary emergency care units of hospitals, poison control centers, medical and veterinary diagnostic

labs, environmentalists and wildlife interest groups, researchers in the area of nuclear, chemical, and biological warfare agents, and college and university libraries.

Contributors of the chapters in this book are the most qualified scientists in their particular areas of chemical and biological warfare agents. These scientists are from around the globe and regarded as authorities in the field of pharmacology, toxicology, and military medicine. The editor sincerely appreciates each author for his/her dedicated hard work and invaluable contributions to this volume. The editor gratefully acknowledges Robin B. Doss and Kristie A. Rohde for their technical assistance, Alexandre M. Katos for cover design and Denise M. Gupta for indexing. Finally, the editor remains indebted to Renske Van Dijk, Rebecca Garay, and William Brottmiller, the editors at Elsevier, for their immense contributions to this book.

CHAPTER 2

Historical Perspective of Chemical Warfare Agents

NATHAN H. JOHNSON, JOSEPH C. LARSEN, AND EDWARD MEEK

The opinions or assertions contained herein are the private views of the authors, and are not to be construed as reflecting the views of the Department of Defense, the Defense Threat Reduction Agency, or the US Air Force.

I. INTRODUCTION

The employment of chemicals in warfighting has a long history (Silvagni *et al.*, 2002; Romano *et al.*, 2008). Just as the utilization of chemicals brought about tremendous advances in society, the concept of using chemicals as a contributing factor in winning wars has been pursued for centuries (Joy, 1997; Smart, 1997). There are many examples of the exploitation of chemicals in warfare and conflict dating back to antiquity. Primitive man may have been the first to use chemical compounds in hunting and in battle. The use of smoke from fires to drive animals or adversaries from caves may have been the earliest use of chemical weapons. Natural compounds from plants, insects, or animals that were observed to cause sickness or death were likely used by our distant forefathers in attempts to gain or maintain superiority (Hammond, 1994). Natural toxins from plants or animals on arrowheads or the poisoning of water or food could increase casualties and cause fear in opposing military forces or civilian populations. These early uses of chemicals would pave the way for more lethal chemical weapons. For example, in the fourth century BC, smoke containing sulfur was used in the war between Sparta and Athens (Joy, 1997). Chinese manuscripts indicate arsenical-based compounds were used in conflict (Joy, 1997). A few hundred years later, toxic smoke was used by the Romans in Spain (Coleman, 2005). During the second siege of Constantinople, the Byzantine emperor Leo III used ''Greek fire'' in his quest for military victory (Coleman, 2005). During the ensuing years, there were many instances of the limited and attempted use of chemicals and toxins on the battlefield. Many of these examples may have been influenced by the intentional poisonings occurring in civilian settings (Joy 1997; Smart, 1997; Newmark, 2004; Coleman, 2005). The earliest known treaty to ban poisons in warfare was signed between the French and Germans in the 17th century (Smart, 1997). In the siege of Groningen, incendiary devices were used by European armies to release belladonna, sulfur, and other compounds. This led to the Strasbourg Agreement in 1675 (Coleman, 2005). This agreement prohibited poison bullets (Smart, 1997).

As science and chemistry advanced in the 19th century, the possibilities of chemical warfare increased exponentially. Advancements were made in industrial applications of sulfur, cyanide, and chorine (Joy, 1997). In addition, the concept of chemicals in projectiles was introduced. During the Crimean War, the British refused to use cyanide-based artillery shells against the Russians on the grounds that it was a ''bad mode of warfare'' (Smart, 1997). This was an early example of the ethical questions surrounding chemical use in warfare that continued into the 20th century (Vedder and Walton, 1925). During the American Civil War, both the Northern and Southern armies seriously considered using various chemicals in their pursuit of operational victories (Smart, 1997). Early attempts at international treaties were met with mixed results. The USA prohibited any use of poison in the Civil War. The Brussels Convention on the Law and Customs of War of 1874 prohibited poisons or poison-related arms (Smart, 1997). The first Peace Conference at The Hague prohibited projectiles filled with asphyxiating or deleterious gases (Smart, 1997). Some countries, including the USA, were not signatories to this agreement. The employment of chemicals as asphyxiating warfare agents was vigorously discussed at The Hague convention (Joy, 1997). Arguments were again made against chemicals based on moral grounds. However, counterarguments were made based on the assumption that chemicals lead to a death devoid of suffering (Vedder and Walton, 1925; Joy, 1997; Coleman, 2005). Individuals who advocated chemicals did not see their use as an unfair advantage; rather, it was just one in a series of technological advances, which if mastered could provide strategic, operational, and tactical advantages on the battlefield. The second Peace Conference at The Hague 8 years later prohibited poisons or poisoned weapons (Smart, 1997). The British use of picric acid-filled shells during the Boer War and the Japanese use

of arsenical rag torches in the Russo-Japanese War further illustrate that chemical warfare was considered by some a legitimate form of warfare at the turn of the 20th century (Smart, 1997). During the early 20th century, technological advancements in the chemical industry made the possibility of sustained military operations using chemicals a realistic possibility. The murder of Archduke Francis Ferdinand at Sarajevo set the stage for what would become the first widespread use of chemical weapons to date (Harris and Paxman, 2002).

II. THE FIRST SUSTAINED USE OF CHEMICALS AS AGENTS OF WARFARE

The talk and rhetoric of the late 19th century should have prepared the countries involved in World War I for chemical warfare. However, that was not case (Smart, 1997). World War I clearly demonstrated the deadly and destructive nature of chemicals in modern warfare. Both alliances in the war experimented with novel forms of warfare, to include chemical weapons, and followed the lead of their advisory (Hay, 2000). It is little wonder this war is known as the ''chemist's war'' (Fitzgerald, 2008). Initially, the French used gas grenades with little effect and were followed by the German use of shells filled with tear gas (Joy, 1997). The Germans, capitalizing on their robust chemical industry, produced shells filled with dianisidine chlorosulfate (Smart, 1997). These shells were used in October of 1914 against the British at Neuve-Chapelle but had little effect. In the winter of 1914–15, the Germans fired 150 mm howitzer shells filled with xylyl bromide (Smart, 1997). The xylyl bromide shells were fired on both the eastern and western fronts with disappointing effects. Despite the inauspicious start of chemical warfare on both fronts, efforts were continued to develop new uses. It would soon be evident that chemical warfare would be devastating on the battlefield (Coleman, 2005; Tucker, 2006). Fritz Haber, a German scientist who later won the Nobel prize in Chemistry, had proposed the possibility of releasing chlorine gas from cylinders (Joy, 1997). Chemical warfare was attractive to Germans for two reasons: the shortage of German artillery shells and the ability to defeat the enemy trench system (Smart, 1997). After consideration and debate, the Germans released chlorine in April 1915 at Ypres, Belgium (Coleman, 2005). The German military was not prepared for the tremendous operational advantage the chlorine release provided. It did not take long for the British and French forces to respond in kind to the German offensive (Vedder and Walton, 1925; Joy, 1997; Smart, 1997; Coleman, 2005). In the fall of 1915, a British officer, William Livens, introduced a modified mortar (Figure 2.1) that could project gas-filled shells of chlorine or phosgene, the two agents of choice at that time (Joy, 1997). Both chlorine and phosgene caused extreme respiratory problems to those soldiers who were exposed (Vedder and Walton, 1925; Joy, 1997; Smart, 1997; Coleman, 2005; Hurst *et al.*, 2007) (Figure 2.2).

As the USA entered the war in the spring of 1917, an obvious concern of the military command was the effect of chemical warfare on standard operations. Chemistry departments at universities were tasked with investigating and developing novel chemical agents (Joy, 1997). Protective equipment (Figure 2.3) and basic studies of the biological effects of chemical agents were assigned to the US Army Medical Department (Joy, 1997). In the fall of 1917, the Army began to build an industrial base for producing

chemical agents at Edgewood Arsenal, Maryland (Joy, 1997). As the effects of chlorine and phosgene became diminished by the advent of gas masks (Figure 2.4), the Germans turned to dichlorethyl sulfide (mustard) at Ypres against the British (Joy, 1997). As opposed to the gases, mustard remained persistent in the area and contact avoidance was the major concern (Joy, 1997). It is worth noting that almost 100 years after it was first used on the battlefield, mustard still has no effective treatment and research continues for effective therapeutics (Babin and Ricketts *et al.*, 2000; Baskin and Prabhaharan, 2000; Casillas and Kiser, 2000; Hay, 2000; Schlager and Hart, 2000; Hurst *et al.*, 2007; Romano *et al.*, 2008). It has been estimated that there were over one million chemical casualties (Figure 2.5) of World War I with almost 8% being fatal (Joy, 1997). The Russians on the eastern front had a higher percentage of fatalities when compared with other countries in the war, primarily due to the later introduction of a protective mask (Joy, 1997). The relatively low mortality rate of chemical casualties in World War I demonstrated the most insidious aspect of their use, the medical and logistical burden it placed on the affected army. The eventual Allied victory brought a temporary end to chemical warfare. In 1919, the Treaty of Versailles prohibited the Germans from production and use of chemical weapons.

III. INITIAL COUNTERMEASURES

The conceptualization of a protective mask dates back over 500 years to Leonardo da Vinci (Smart, 1997). By the mid-19th century, protective masks were proposed in the USA and Europe for both industrial and military use. The modern ''gas mask'' was developed by the Germans with sodium thiosulfate and bicarbonate soaked pads and used in World War I (Joy, 1997). The French and English soon followed with their own versions of gas masks (Joy, 1997). In 1916, the Germans introduced a mask that incorporated a canister through which the soldiers breathed (Joy, 1997). Initially, the American forces in World War I used gas masks obtained from allies already fighting in the war (Smart, 1997). In 1918, the Americans introduced their RFK mask, a modified version of the British mask. Masks were also developed for the animals that supported the war fighting efforts. Decontamination efforts during World War I were rudimentary and included chemical neutralization and aeration of clothing and equipment. Although the need for

FIGURE 2.4. World War I soldier and horse wearing gas mask. *Source*: National Archives and Records Administration (http://commons.wikimedia.org/wiki/Image:Gasmask_for_man_and_horse.jpeg)

detection of chemical agents was clearly identified, very little progress was made during World War I. Medical treatment included removal of the patient from the source, decontamination, and palliative care (Smart, 1997).

IV. EVENTS AFTER WORLD WAR I

At the conclusion of World War I, the world had been introduced to chemical warfare on an unprecedented level. While there were groups that thought that humanity had learned a lesson from the cruel nature of chemical warfare, others prudently went to work on improved chemical defense (Vedder and Walton, 1925). The thoughts of many professional military officers were that future wars would be fought under the new paradigm of chemical warfare (Vedder and Walton, 1925; Vedder, 1926; Smart, 1997). New gas masks were developed and training in chemical environments was introduced (Vedder and Walton, 1925; Vedder, 1926; Joy, 1997). Textbooks and manuals, such as those written by US Army Colonel Edward B. Vedder (Figure 2.6), were introduced to the military medical community (Vedder and Walton, 1925). In addition, the civilian medical community gained valuable insight into toxicology and animal models from the events of World War I (Vedder, 1929; Johnson, 2007). Despite the first-hand experience with chemical warfare, some countries, including the USA, struggled to adequately fund their offensive and defensive programs during demobilization (Smart, 1997). It did not take long for chemical warfare to appear in other conflicts. Chemical agents were used to subdue rioters and suppress rebellions. The British used chemical agents to suppress uprisings in Mesopotamia by dropping bombs in cities throughout the area in the early 1920s (Coleman, 2005). The Soviet Union used chemical agents to quell the Tambov rebellion in 1921, and France and Spain used mustard gas bombs to subdue the Berber rebellion during the 1920s (Werth *et al.*, 1999). Italy and Japan used mustard in small regional conflicts (Joy, 1997). The Italian conflict in Ethiopia was noteworthy because

FIGURE 2.5. British soldiers temporarily blinded by tear gas awaiting treatment at the Battle of Estaires, April 1918. Photo by 2nd Lt T.L. Aitken.

FIGURE 2.6. Captain Edward Vedder, ''the father'' of USAMRICD. Photo courtesy of Mrs Martha Vedder.

mustard was sprayed and dropped from planes and the agent's use was considered by some to be significant to the Italian victory (Smart, 1997). This use demonstrated the contemporary thought that allowed chemicals to be viable alternatives to traditional combat. The Japanese also used chemical weapons during the 1930s against regional foes. Mustard gas and the vesicant Lewisite were released on Chinese troops and were also used in South East Asia (Coleman, 2005). Lewisite is an arsine which was usually produced as an oily brown liquid that was said to have the odor of geraniums (Spiers, 1986; Hammond, 1994). It was developed in the USA by Winford Lee Lewis in 1918 and was found to be effective at penetrating clothing. The USA produced approximately 20,000 tons of Lewisite but only used small quantities of the chemical in World War I (Coleman, 2005). Dimercaprol, more commonly called British anti-Lewisite, was developed as an effective treatment for the vesicant (Goebel, 2008). In the inter-war period, mustard was a key concern in defensive planning (Coleman, 2005). New stores of mustard were produced in many countries. Work continued on many fronts to improve protective equipment. For example, the US Chemical Warfare Service introduced the M1A2 mask, an improvement of the M1 mask (Smart, 1997). In the Geneva Protocol of 1925, 16 of the world's major nations pledged never to use gas as a weapon of warfare; it was not ratified in the USA until 1975 (Hammond, 1994). There has long been vigorous debate on the merits of treaties with nations balancing the military needs versus the potential irrational concept of chemical warfare (Vedder, 1926).

V. WORLD WAR II

In the lead up to World War II, the Germans forever changed chemical warfare with the discovery of the organophosphorus nerve agents (Goebel, 2008). These organophosphorus-containing nerve agents inhibit cholinesterase enzyme in the nerve synapse responsible for the breakdown of the neurotransmitter acetylcholine (ATSDR, 2008). This results in the accumulation of the neurotransmitter in the synapse and overstimulation of the nervous system. This can result in subsequent respiratory failure and death (ATSDR, 2008).

In 1936, Gerhard Schrader, a German chemist working on the development of insecticides for IG Farben, developed a highly toxic organophosphate compound which he named ''tabun'' (Hersh, 1968; Hammond, 1994). Schrader and an assistant became a casualty of their discovery when a drop of the neurotoxicant was spilled in the lab exposing both of them (Tucker, 2006). Had the amount of tabun spilled been greater both researchers would have certainly succumbed to the effects of the poison. Tabun was the first member in a series of compounds termed ''nerve gases'' (Coleman, 2005). The correct terminology is ''nerve agents'' as these agents are not gases, but liquids dispersed as fine aerosols. Tabun was extremely toxic in small amounts and invisible and virtually odorless (Tucker, 2006). The compound could be inhaled or absorbed through the skin. These characteristics made it too dangerous to be used as an insecticide by farmers. German law required that any discovery having military application be reported to military officials (Tucker, 2006). Schrader was not overly excited about producing chemical agents for the military; however, the Germans placed him in a secret military research facility with the emphasis on producing these nerve agents and discovering new agents (Tucker, 2006). Subsequently, Schrader and his team of researchers discovered a more lethal organophosphate compound similar to tabun, which he named ''sarin'' in honor of the team members: Schrader, Ambrose, Rudriger, and van der Linde (Coleman, 2005).

At the onset of World War II, both the Allies and the Germans anticipated chemical agents would be deployed on the battlefield (Tucker, 2006). This expectation intensified research into the development of new agents, delivery systems, and methods of protection (Figures 2.7 and 2.8). The Allied forces were unaware of the Germans' new nerve agent, tabun, at the beginning of the war. The rapidly advancing German army offered very little opportunity to use chemical agents, as it could prevent the rapid movement of the German troops into an area after being released (Tucker, 2006). Nevertheless, the Germans produced and stockpiled large amounts of nerve agents throughout the war (Spiers, 1986). The production of these organophosphate agents was complex, required custom equipment, and was hazardous to those involved in production (Tucker, 2006). If exposed, the workers would be dunked in a bath of sodium bicarbonate (Harris and Paxman, 2002; Goebel, 2008). It is also interesting to note that some members of the German workforce were given rations containing higher percentages of fat (Harris and Paxman, 2002). This was done because

FIGURE 2.7. Gas mask production – Detroit, Michigan, 1942. *Source*: Library of Congress.

FIGURE 2.8. World War II: a private trains using protective gear. Photo courtesy of the US Army Medical Research Institute of Chemical Defense.

authorities observed that workers with higher quality rations seemed protected against exposure to low levels of tabun. Many detainees were used in the manufacture and testing of chemical agents in Germany (Harris and Paxman, 2002; Tucker, 2006). It is not known how many chemical casualties there were in prisoners of war due to their forced labor in nerve agent production, but documented fatalities were recorded. The discovery of tabun and sarin was followed by the discovery of soman by Richard Kuhn and Konrad Henkel at the Kaiser Wilhelm Institute for Medical Research in 1944 (Tucker, 2006). This class of nerve agents is collectively termed ''G'' agents; the G is for German, since German researchers discovered this class of compounds. A second letter is included as the specific identifier of each compound: GA (tabun), GB (sarin), GD (soman), and GF (cyclosarin) (ATSDR, 2008). These agents were mass produced by the Nazi regime throughout the war but were not used (Tucker, 2006). There has been considerable debate questioning why the Germans did not employ their chemical weapons in World War II. While it may never be conclusively known, several potential reasons include a lack of intelligence regarding the German superiority in chemical weapons discovery, fear of retaliation, and Adolph Hitler's personal exposure to chemical agents on the battlefield in World War I (Harris and Paxman, 2002; Tucker, 2006).

Other chemical agents that had been produced during and following World War I were still being produced. On December 2, 1943, German planes sank several American ships off the coast of Italy and at least one of the ships contained mustard that was to be used as a retaliatory response if the Germans unleashed a large-scale chemical weapons attack (Tucker, 2006). Casualties resulted from exposure to the mustard, some of which were inflicted on civilian merchant seamen (US Navy, 2008). The presence of the agent on the ship was classified and resulted in incorrect treatment of many of the exposed by physicians (Tucker, 2006).

VI. POST-WORLD WAR II

By the conclusion of World War II, both the Allies and Germany had stockpiled large amounts of chemical agents (Tucker, 2006). The Allied forces divided up the stockpiles of agents discovered in German facilities. Following the end of the war, many of the Allied countries continued to conduct research on the German nerve agents. The rise of the Soviet Union as a power and adversary prompted the USA and other countries to continually search for novel chemical and biological warfare agents (Tucker, 2006). The research and resources that were allotted for these efforts were not trivial even though they were often overshadowed by the research and development of thermonuclear weapons (Hersh, 1968; Goebel, 2008).

The post-World War II era ushered in the nuclear age. Some felt the age of chemical warfare was past (Smart, 1997). Events would prove this to be a hasty conclusion. In the USA, research of the G-series agents and medical countermeasures against these agents was accomplished by

the late 1940s. Research and intelligence gathering was further hastened by the impressive gains the Soviet Union made in chemical warfare capability in the years after World War II. By the early 1950s, production of sarin had been initiated in the USA (Smart, 1997). At nearly the same time, Ranajit Ghosh, a chemist at the British Imperial Chemical Industries plant, developed a new organophosphate compound as a potential insecticide (Tucker, 2006). Like Gerhard Schrader before him, this compound was deemed too toxic to be used in the field as a pesticide. The compound was sent to researchers in Porton Down, England, synthesized and developed into the first of a new class of nerve agents, the ''V'' agents (Goebel, 2008). Like the ''G'' agents the ''V'' agents also have a second letter designation: VE, VG, VM, and VX (Coleman, 2005). Of these agents, VX was the most commonly produced. The ''V'' series of agents are generally more toxic than the ''G'' agents (ATSDR, 2008). In a deal brokered between the British and US governments, the British traded the VX technology for thermonuclear weapons technology of the USA (Tucker, 2006). The USA produced and stockpiled large quantities of VX (Hersh, 1968; Hammond, 1994).

Throughout the 1950s and 1960s, advancements were made in production and delivery of chemical weapons to include sarin and VX (Smart, 1997). While work on improved masks continued, a renewed concern was the inability to detect nerve agents. Several prototypes were developed in the mid-1950s. Great advancements were made in therapeutics of agents that inhibited the enzyme acetylcholinesterase (Gupta, 2006; Taylor, 2006; Klaassen, 2008). Atropine was introduced in the early 1950s. Oximes were added as an adjunct to speed up reactivation of the enzyme (Smart, 1997). The autoinjector was developed to overcome user fear of self-injection of atropine. Major advances were made in utilization of chemical weapons in artillery (Figure 2.9). For example, the USA developed both short and long range rockets filled with chemical agent. The USA disposed of stockpiles of its chemical weapons in the late 1960s in an operation termed CHASE (cut holes and sink em) in the sea (Coleman, 2005). In 1969, nerve agent stockpiles were discovered in US depots in Japan after several US military servicemen became ill while doing maintenance (Tucker, 2006). This stockpile had been kept secret from the Japanese and created an uproar that resulted in the later disposal of the agents in the Johnston Atoll in the Pacific Ocean.

Defensive equipment such as improved field alarms and drinking tubes for gas masks were introduced in the 1960s (Smart, 1997). Great strides were also made in collective protection in the 1960s and 1970s. Although not used extensively since World War I, chemical agents have nonetheless been used for military purposes. The Egyptians allegedly used mustard and possibly nerve agents in the Yeman civil war (Joy, 1997; Smart, 1997). This was the first reported use of nerve agent in armed conflict. There were allegations that chemical agents were used by the Vietnamese in Laos and Kampuchea in the late 1970s (Coleman, 2005). In the Vietnam War, the USA used defoliants and tear gas (Joy, 1997). The Soviet Union was accused of using chemical agents in their war in Afghanistan (Joy, 1997).

VII. INCAPACITANTS AND TOXINS

Incapacitating agents have long been considered an intermediate between chemical and traditional warfare. The Germans investigated the military use of lacrimators in the 1880s followed shortly thereafter by the French (Smart, 1997). The English and French considered using lacrimators in World War I (Smart 1997). Japanese forces used tear gas against the Chinese in the late 1930s. The US Army used riot control agents and defoliants in the Vietnam War (Smart, 1997). The defoliant ''Agent Orange'' was later potentially linked to several forms of cancer (Stone, 2007). During the 1950s and 1960s, the USA had an active incapacitant program (Smart, 1997). These agents were thought of as more humane than traditional chemical agents because the intent was not lethality. These agents were designated ''K-agents'' and included tetrahydrocannabinol and lysergic

acid (Smart, 1997). One of the most extensively studied incapacitating agents was 3-quinuclidinyl benzilate, designated BZ by the US Army (Ketchum, 2006). Like many incapacitating agents, BZ was not adopted due to difficulty producing reproducible effects, unwanted side effects, latency to produce effects, and difficulty in producing a dissemination that was free of smoke (Smart, 1997; Ketchum, 2006).

There have been multiple attempts to use the toxins from plants and living organisms to develop viable weapon systems. Two that are noteworthy are ricin and botulinum toxin. Ricin has been recognized as a potential biological weapon since World War I. While the British were developing the V agents, US military researchers patented a procedure for purifying ricin, a very potent toxin from the castor bean plant (Harris and Paxman, 2002). The development of a method of dissemination of ricin as a chemical weapon proved problematic thus making its use very limited. In 2003, ricin was detected on an envelope processed in a Greenville, South Carolina, postal facility. Postal workers did not develop symptoms of ricin exposure and the individual who mailed the letter remains at large (Shea, 2004). The development and use of botulinum neurotoxin as a biological weapon was initiated at least 60 years ago (Smart, 1997; Arnon, 2001). In the 1930s, during occupation of Manchuria, the Japanese biological warfare group, Unit 731, purportedly fed cultures of *Clostridium botulinum* to prisoners causing human lethality. The US Army biological weapons program produced botulinum neurotoxin during World War II in response to Germany's biological weapons program (Coleman, 2005). In fact, more than 100 million toxoid vaccine doses were prepared and forward positioned in time for the D-Day invasion of Normandy (Arnon, 2001).

VIII. RECENT EXPERIENCES

The 1980s proved to be very significant in the employment of chemical weapons on the battlefield. In 1980, Iraq invaded Iran (Smart, 1997). The Iraqi armed forces, who were advised by the Soviet Union, possessed chemical agents and were trained in their use. The war was unequivocally barbarous and neither side gained an advantage. In many ways, this war had similarities to World War I. By 1983, Iran formally protested to the United Nations about the Iraqi use of chemical agents. The general consensus was that Iraq used mustard agent and possibly tabun in this war (Figure 2.10). It is estimated that 5% of Iranian casualties, totaling approximately 45,000, can be attributed to chemical warfare agents (Smart, 1997). The same author also reported that the Iraqi Army used chemical agents against the Kurdish minority in northern Iraq. Lybia was also suspected of using chemical agents when Chad was invaded in 1986 (Smart, 1997).

FIGURE 2.10. Aftermath of Iraqi chemical weapon attack (1980s). Photo by Sayeed Janbozorgi; image used under the terms of the GNU free documentation license (http://en.wikipedia.org/wiki/Image:Chemical_weapon2.jpg).

The late 1980s also saw improvements in defensive equipment such as the M40 gas mask developed by the USA (Smart, 1997). Other advancements were made in collective protection, decontamination, and detection. In 1984, US President Ronald Reagan issued a statement calling for an international ban on chemical weapons (Tucker, 2006). Subsequently, on June 1, 1990, President George H.W. Bush and Soviet Union leader Mikhail Gorbachev signed a treaty banning the production of chemical weapons and initiated the destruction of the stockpiles of both nations (Tucker, 2006). In 1993, the Chemical Weapons Convention was convened and signed. It was implemented in 1997 (Hammond, 1994). As of 2008, the vast majority of United Nations member states have joined the Chemical Weapons Convention (OPCW, 2008).

In 1990, the Iraqi Army invaded neighboring Kuwait. Subsequently, the USA and eventually a coalition sent forces to the area at the request of Saudi Arabia (Smart, 1997). Because of the broad knowledge of Iraqi chemical use on the battlefield in the 1980s, coalition forces were the largest force to operate in a potential chemical environment since World War I. Forces moved into the area of operation were provided with atropine autoinjectors, an acetylcholinesterase reactivator, and a nerve agent pretreatment (pyridostigmine bromide). Fortunately, chemical weapons were not apparently used in this conflict, although multiple false alarms were reported. The failure of the Iraqi military to use chemical weapons could be attributed to fear of retaliation, breakdown of communication, changing wind patterns, the surprising speed of the coalition attack, or the fact that Iraqi chemical infrastructure was attacked during the initial portion of the conflict. There have been many coalition veterans who report a myriad of symptoms that

have been commonly referred to as ''Gulf War Syndrome''. The etiology of this syndrome is unclear despite multiple epidemiological studies (Coleman, 2005).

IX. TERRORIST USE

One of the reasons why chemical weapons have been used relatively infrequently in combat over the past century is the fear of retaliation by opposing countries. In less organized asymmetrical conflicts, the fear of retaliation is of less concern. The potential exploitation of chemical weapons by terrorists is of great worldwide concern. The appeal of these weapons to terrorists is centered on the fact that many of the chemical agents are cheap and relatively easy to produce, transport, and release. These characteristics, along with the fear associated with the idea of a chemical attack, make chemicals an ideal weapon for creating terror (Romano and King, 2001). In 1974, Muharem Kurbegovic attacked several public buildings with firebombs in California and claimed to have developed sarin and some other nerve agents (Tucker, 2006). The search of his home resulted in the discovery of various precursor materials for chemical agents and a large amount of sodium cyanide. In 1994, the Aum Shinrikyo, a Japanese religious cult, carried out several attacks using sarin produced by the cult's members (Tucker, 2006). The attacks included a residential and subway exposure. A total of 19 people were killed and over 6,000 sought medical attention. Some of those seeking medical attention may be attributed to a fear of exposure. Psychological stress is a common aftermath of a chemical or biological attack (Romano and King, 2001). In the 21st century, formerly used chemicals of military interest have reemerged as contemporary threats. In the fall of 2006, Al Qaeda and associated groups used chlorine combined with traditional car and truck bombings to spread panic in Iraq (Garamone, 2007). These attacks were followed by similar attacks in the subsequent months.

X. CONCLUDING REMARKS AND FUTURE DIRECTION

As long as there are legitimate uses for chemicals in our society, the risk of chemical agents in conflict and terrorist activity will always be present. Research across the globe continues for better detection, protection, and treatment of chemical warfare agents. While many countries have denounced and are signatories to various treaties to limit the use and production of chemical warfare agents, non-state and terror organizations are under no such restrictions. Luckily, chemical weapon use has been limited in warfare and conflict. As we progress into the 21st century, the use of established chemical warfare agents is a real possibility. The potential use of legitimate industrial chemicals (e.g. the Iraqi burning of petroleum fields in the first Gulf War) and the potential synthesis of new agents should also be recognized. History has demonstrated that chemicals have been used in both organized and asymmetrical conflicts and preparations for defense and therapy for such encounters is prudent. Chemicals represent a unique force multiplier that simply cannot be ignored in the 21st century.

CHAPTER 3

Global Impact of Chemical Warfare Agents Used Before and After 1945

JIRI BAJGAR, JOSEF FUSEK, JIRI KASSA, KAMIL KUCA, AND DANIEL JUN

I. INTRODUCTION

The threat of chemical weapons (CWs), used either by States or Parties to the Chemical Weapons Convention (Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and on their Destruction) or by terrorists, has never attracted so much public attention as in the past 10 years. In spite of the existing legal documents dealing with prohibition of CWs, e.g. Geneva Protocol 1925, and Chemical Weapons Convention (CWC), some incidents of the use of CWs in different conflicts and terroristic attacks have been observed. Moreover, alleged use of CWs was noted during the period from 1925 to the present time. It must be emphasized that the theoretical and practical basis for production, storage, and employment of CWs still exists. Also, it must be clearly stated that CWs are applicable at any time, in any place, and in large quantities.

CWs consist of the chemical warfare agents (CWAs) and the means to deliver to the target. They are characterized by high effectivity and large targets and are known as area weapons or silent weapons. They are relatively low cost and with their use it is possible to achieve destruction of everything that is living but avoid destruction of materials and buildings. They are also called the nuclear weapons of poor countries – ''poor man's nuclear weapon''. It should be pointed out that the use of CWs is connected with the use or release of toxic chemicals, thus, chemical warfare can be considered part of generally observed situations where toxic chemicals are used or released and influence the environment and humankind.

There exist a number of causal reasons for these events but apart from accidents connected with the release of toxic chemicals from a natural source (e.g. volcanoes), the factors shown in Figure 3.1 or their combinations can be involved.

For military purposes, a number of chemicals were tested, but only a small number are contained in military arsenals. However, according to the definition contained in the CWC, any toxic chemical intended for military use must be considered a chemical weapon, i.e. the aim is to limit the designation of the compound in question for use as a CW. On the other hand, all toxic chemicals of high toxicity can be chosen by terrorists.

II. BACKGROUND

The use of toxic chemicals against humankind is as old as any warfare conflict. The use of the poisoned arrow against man – not animal – can be considered as the beginning of chemical warfare and would be characterized as the intentional use of chemicals.

At the very beginning, chemical warfare was more closely connected with fire. ''Greek fire'' was an excellent naval weapon because it would float on water and set fire to the wooden ships. There are other examples from history: for example, toxic smoke was used in in China in 2000 BC. In Thucydides' *History of the Peloponnesian War*, the 5th century BC war between Athens and Sparta, we find the first description of chemical warfare – the formation of toxic sulfur oxide by burning sulfur. In the year 184 BC, Hannibal of Carthage used baskets with poisonous snakes against his enemy. Both Socrates and Hamlet's father were poisoned with koniin. Aqua Toffana containing arsenic was also a known poison in ancient Italy. Leonardo da Vinci proposed a powder of arsenic sulfide in the 15th century. There are many more examples of the use of chemical warfare agents (Bajgar *et al.*, 2007b). Modern history shows us that terrorists have used other chemicals, such as ricin (Bulgarian G. Markov was poisoned in 1978) or dioxin (the President of Ukraine Viktor Andriyovych Yushchenko was poisoned in 2004).

In a region of Bohemia, a ''form'' of CW was used as early as 600 years ago. It was in the year 1422 when the castle of Karlstein, the property of King Charles IV, was beseiged and 1,822 kegs containing the cesspools of the streets of Prague were hurled into the castle. Allegedly, the stench in the castle was unbearable. According to historical sources, the castle defenders were probably intoxicated with hydrogen sulfide released from the contents of the cesspools, therefore showing typical symptoms of poisoning (Bajgar, 2006).

Necessary condition: existence of toxic agent
production, processing, stockpiling, transport
(both for intentional and unintentional use)
↓
USE, RELEASE
↓ ↓
intentional/unintentional
military or local conflicts, unrestrained catastrophes, incidental events
terrorism or sabotage, failure of human factor or techniques

FIGURE 3.1. Possible reasons for a release/use of toxic chemicals.

There were some attempts to prohibit CWs by international agreement or law. Most of the early attempts were bilateral or unilateral agreements directed at the use of poisons. These included the 1675 agreement between France and Germany, signed in Strasbourg, to ban the use of poison bullets.

The first international attempt to control chemical and biological weapons took place in Brussels in 1874, when the International Declaration was signed and included a prohibition against poison and poisoned arms. In spite of the Brussels and Hague Conventions – first and second – (1899 and 1907 – signatories agreed not to use projectiles that could spread asphyxiating or deleterious gases), the world witnessed the application of chemicals in warfare to an unprecedented extent during World War I (WWI). A brief summarization of the events connected with the use/release of toxic chemicals is given in Table 3.1.

III. MILITARY USE OF CWs

The intentional use of CWs for military purposes can be found in both global and local conflicts. A typical example is the warning ''Gas! Gas!'' This was common in WWI and it is well known from the E.M. Remarque novel *All Quiet on the Western Front* where Remarque suggestively describes a chemical attack with chlorine.

During WWI, many chemicals were used including mustard, asphyxiating and irritant agents. About 45 types (27 more or less irritating and 18 lethal) of toxic chemicals were used. During the latter part of 1914, irritants were used by Germany and France; the effect was insubstantial. In late 1914, Nobel prize winner Fritz Haber of the Kaiser Wilhelm Physical Institute in Berlin (chemical synthesis of ammonium in 1918) came up with the idea of creating chlorine, although this idea of using toxic chemicals in war was expressed by Admiral Dundonald as early as 1855. Chemical warfare really began in 1915, when German troops launched the first large-scale poison gas attack at Ypres, Belgium, on April 22, using 6,000 cylinders to release 168 tons of chlorine gas, killing 5,000 British, French, and Canadian soldiers. The date is recognized as ''the birthday of modern chemical warfare'' and thereafter the belligerent parties frequently used chemical gases against each other. Phosgene was introduced by Germany late in 1915. Shortly after the first chlorine attack, the Allies had primitive emergency protective masks. In May 1916, the Germans started using diphosgene, while the French tried hydrogen cyanide 2 months later and cynogen chloride the same year. The first time mustard gas was used by German troops was July 12, 1917, and after its use near Ypres it was also called yperite.

By the end of the WWI, some 124,200 tons of chemical warfare agents (chlorine, phosgene, mustard, etc.) had been released, causing at least 1.3 million casualties of which more than 90,000 were fatal. The threat of the use of CWAs led to the development of protective means not only for humans, but also for horses and dogs. The effectivity of CWs in comparison with classic munition was evident: 1 ton of classic explosives caused 4.9 casualties; 1 ton of chemical munition caused 11.5 casualties; and 1 ton of yperite caused 36.4 casualties (Bajgar, 2006).

IV. THE PERIOD BETWEEN WWI AND WWII

The terrible casualties of CWs used during WWI, and the dangerous consequences on humans and the environment, led to the signing in June 17, 1925 of the ''Geneva Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous and other Gases and Bacteriological Methods of Warfare''. This is recognized as one of the unique and famous international treaties on the prohibition of CWs. However, it neither comprises provisions for effective verification nor prohibits development, stockpiling, and transfer of CWs. Moreover, no definition of CWs was included. Despite the provisions of the Geneva Protocol, in 1935–1936 Italian troops employed CWs during their invasion of Abyssinia (Ethiopia). This first major use of CWs after WWI came after October 3, 1935, when Mussolini launched an invasion of this country. Despite the Geneva Protocol (Italy had ratified in 1928) the Italians used mustard gas with horrible effects. Later, CWs were used between Japan and China in 1937–1945. The Japanese attacked Chinese troops with mustard gas and lewisite. The Japanese, in adition to their biological program, had an extensive CWs program and were producing agent and munitions in large quantities by the late 1930s.

V. WWII

Despite the storing and stockpiling of CWs by the great powers engaged in WWII, these fatal weapons were not practically used (except small examples) during WWII (probably because of the fear of massive retaliatory use of CWs). An example of intentional use but not in military conflict was the killing of prisoners in concentration camps in Nazi Germany. The agent first used in the camps was

TABLE 3.1. Some milestones related to the use/release of CWs and toxic chemicals

Year(s)	Event
2000 BC	Toxic smoke in China inducing sleep
4th century BC	Spartacus – toxic smoke
184 BC	Hannibal – baskets with poison snakes
1168	Fustat (Cairo) – use of ''Greek fire''
1422	Bohemia region – cesspools (H_2S)
1456	Beograde – rats with arsenic
19th century	Admiral Dundonald – proposed the use of chemicals in war
1914–1918	WWI – start of chemical war
1918–1939	Development of new CWs and protective means
June 17, 1925	Geneva Protocol
December 23, 1936	Lange and Kruger – synthesis of tabun
1940–1945	Concentration camps – cyanide
1943	Synthesis of sarin
1943	Hoffmann and Stoll – synthesis of LSD-25
1945	Kuhn – synthesis of soman
1950	V agents are begun
1961–1968	Production of VX
1961–1971	Vietnam War – herbicides (impurity dioxin)
1962	BZ was introduced into military arsenals
1970	Bicyclic phosphates considered as potential CWAs
1976	Seveso – release of dioxin
1980	Some rumors on intermediate volatility agent
1984	Bhopal incident – release of methyl isocyanate
1985	Decision on production of binary CWs
1986, 1987	Demonstration of USA CWs (Tooele) and Soviet Union CWs (Shikhany) to the CD in Geneva
1987	Production of binary CWs
1988	Halabja – use of mustard
1980–1990	Rumors of new nerve agent Novichok
1989	Conference on chemical disarmament, Paris
1991	Persian Gulf War – veteran's syndrome
1992	BZ military stocks of the USA were destroyed
1992	Finalization of the rolling text of the CWC at the CD – Geneva
1993	Signing CWC in Paris
1993	Preparatory Commission on OPCW
1994	CWs of Iraq were destroyed
1994	Aum Shinrikyo – sarin attack in Matsumoto
1995	Aum Shinrikyo – sarin attack in Tokyo
April 29, 1997	CWC – entry into force; establishment of OPCW in The Hague
2000	Research on nonlethal weapons intensified
2002	Moscow theater – Fentanyl derivatives used against terrorists
April 29, 2012	CWs of the State Parties to the CWC will be destroyed but will be prolonged

carbon monoxide, followed by the more ''effective'' hydrogen cyanide released from Zyklon B. Some experiments with aconitine-impregnated shells and some other toxic compounds including biological agents were tested on prisoners.

However, during WWII, an important step in the preparation of the most dangerous CWA was observed in Germany. In Schrader's group, organophosphates (OPs) were synthesized, primarily with the aim of obtaining more effective insecticides. Between 1934 and 1944, Schrader's team synthesized approximately 2,000 OPs including two well-known OP compounds, parathion and paraoxon. As early as 1935, the government of Nazi Germany insisted that Schrader switch the primary aim from OP insecticides to CWAs. At present, OPs are widely used in agriculture, medicine (human and veterinary), and industry. These compounds also include nerve agents (the most toxic compounds of the OP group). Nerve agents such as sarin, tabun, soman, and VX are the main compounds of CWAs. The Germans were also the greatest producers of nitrogen mustard and produced about 2,000 tons of HN-3.

Tabun was synthesized in 1936, followed by others (sarin, at the end of WWII, followed by soman) and production of these agents for the military in large quantities and their stockpiling were recognized after WWII in Dyhernfurth, Poland (e.g. stocks of tabun and some quantities of sarin). The technology was subsequently transferred to Russia and research and development of new OP nerve agents was continued. During this period British and American scientists were evaluating the toxic properties of DFP.

VI. THE PERIOD AFTER WWII AND THE COLD WAR

At the end of WWII, many Allied nations seized the chemical weapons. Most of the CW manufacturing plants in Germany were taken over and moved to Russia to new sites, e.g. the military area of Shikhany. This ''takeover'' prompted other states to begin even more research on CWs. Despite the Allies' own research into CWs, very important technologies and ''know how'' were obtained from Nazi Germany for both the USA and the former Soviet Union.

The interest in CW technology was probably one reason for the change of the future border: according to Churchill's history of WWII the proposed future boundary between Poland and Germany had been primarily agreed to consist in part of the Oder river flowing to the Baltic Sea, and its tributary, the Neisse river. Before their confluence, the Neisse consists of two branches, the East Neisse and the West Neisse. The East Neisse should be the boundary, resulting in slightly more territory for Germany. Stalin held for the West Neisse and progress was delayed. No one knows why Stalin was so insistent in this matter. The reason was probably very simple: the small town of Dyhernfurth (now Brzeg Dolny), a few kilometers north of Breslau (Wroclaw) in the disputed territory and a factory for the production of nerve agents. It was estimated that when Dyhernfurth was captured it contained stockpiles of 12,000 tons of tabun, 600 tons of sarin, and an unknown amount of soman. Presumably, the factory was dismantled, and along with their stockpiles, transported to the Soviet Union (Koelle, 1981). It has been documented that the Soviets were ready to conduct a chemical attack and their research and development of CWs was very intensified.

In the USA, during the 1950s, the chemical corporations concentrated on the weaponization of sarin. At the same time, they became interested in developing CWs that incapacitated rather than killed the targets. Mescaline and its derivatives were studied but without practical output. Five years later, a new project ''Psychochemical Agents'' (later K-agents) was established. The objective was to develop a nonlethal but potent incapacitant. Nonmilitary drugs like LSD-25 and tetrahydrocannabinol were also examined. None of these agents were found to be of military importance. The first and only incapacitant was BZ, developed in 1962; however, its stocks were destroyed in 1992 as declared by the US delegation to the Conference on Disarmament in Geneva (Document of CD, 1991). These agents, intended not to kill but to induce incapacitance, are covered under the class of nonlethal weapons (Hess *et al.*, 2005).

In the former Soviet Union, as a whole in 1940–1945 approximately 110,000 tons of first generation toxic chemicals were produced and most of them were yperite and lewisite, and irritating agents. Second generation CWs were composed of nerve agents such as sarin, soman, V agents, and to a lesser degree tabun. The development of new CWs of the third generation comprised traditional and nontraditional CWs, e.g. blister and irritant agents, and nerve gases including new types, e.g. Novichok 5, whose exact chemical structure is unknown though some assessments have been made (Bajgar, 2006); it could be a nerve agent having high toxicity. Its effects are difficult to treat using common antidotes.

An example of the unintentional use of CWs has also been observed. In March 1968, thousands of dead sheep were discovered in the Skull Valley area, Arizona, USA. This area was adjacent to the US Army's Dugway open-air testing site for CWs. Nerve gas had drifted out of the test area during aerial spraying and killed the sheep. One year later, on July 8, 1969, the Army announced that 23 US soldiers and one civilian had been exposed to sarin in Okinawa during the clearing of sarin-filled bombs (Sidell and Franz, 1997).

There are a number of examples of localized conflicts where CWs have been intentionally used but cannot be verified: e.g. in 1951–1952 in the Korean War; in 1963 the Egyptians used mustard bombs against Yemeni royalists in the Arabian peninsula; in the Indo-China War (see Vietnam War); in 1970, in Angola antiplant agents were almost certainly used; and in former Yugoslavia, there were rumors of the use of psychotomimetic agents.

A. Iraq–Iran and Afghanistan War

On September 22, 1980, Iraq launched its invasion against Iran. There has been mention of the large-scale use of CWAs in the Iran–Iraq war. In November 1983, Iran informed the United Nations that Iraq was using CWs against Iranian troops. Soon after, the use of CWs was unleashed. In addition, mustard and tabun were used. It is well known that the Iraqi Government used these agents against its own citizens, more conspicuously at Halbja in March 1988. The CWs attack was the largest against a civilian population in modern times. More than 100,000 Iranians were poisoned with CWAs; sulfur mustard was the most frequently used and has induced a number of delayed complications in Iranian veterans (pulmonary, dermal, ocular, immune system depression, reproduction, malignancy, etc.) (Afshari and Balali-Mood, 2006). Other localized conflicts involving alleged use of CWs are described in detail in an extensive review (Robinson, 1971).

The Soviet Union probably used mustard (and nerve gas) in Afghanistan. The Afghanistan war was considered the Soviet Union's ''Vietnam''. The use of CWs was described by Sidell and Franz (1997). The use of CWs by Soviet forces was also significant and has been confirmed against unprotected subjects. Despite the use of CWs, the withdrawal of Soviet troops from Afghanistan was realized at the beginning of 1989.

B. Vietnam War

After WWII, the main employment of CWs is recorded in 1961–1972 when the US Army used defoliants. The herbicide Agent Orange was used during the Vietnam War and led to the injury of more than one million Vietnamese and Americans. Agent Orange (a mixture of 2,4-dichlorophenoxy acetic acid and 2,4,5-trichlorophenoxy acetic acid) contained the chemical contaminant dioxin as an impurity which caused many deaths on both sides. There were other herbicide mixtures such as Agent White (2,4-D and picloram) and Agent Blue (cacodylic acid). The biological effects of dioxin were described by Sofronov *et al.* (2001). The first major operation of this type was conducted over the Ca Mau peninsula in September–October 1962. The area sprayed with defoliants during 1965 had been five times larger than in 1965 and in 1967 ten times larger. The scale of the use of defoliants was roughly in proportion to the overall involvement of US troops. In 1970, herbicides and defoliants were used in tens of tons, especially 2,4,5-T. The area sprayed enlarged from 23 km^2 in 1962 to 22,336 km^2 in 1969. The area exposed to spraying was assessed to be 58,000 km^2 and the number of people exposed was assessed to be more than one million including more than 1,000 deaths. In addition to defoliants used to destroy vegetation concealing the North Vietnamese, the USA used tear gas for clearing tunnels and bunkers. The irritants CS, CN, and DM were reported to be used. The total CS procured was approximately 7,000 tons from 1963 to 1969.

C. Development of VX Agent

VX was synthesized in the 1960s on the basis of the results of Tammelin and Aquilonius (Aquilonius *et al.*, 1964; Tammelin, 1957). The manufacturing of VX began in the USA in 1961. Construction of the USA's VX agent production plant at Newport, Indiana, was completed in 1961, when the first agent was produced. The production facility only operated for 7 years, and was placed on standby in 1968 (Smart, 1997).

During the same period, Soviet scientists developed the so-called Russian VX (VR, RVX, R 033) (Kassa *et al.*, 2006; Kuca *et al.*, 2006). The chemical structure of VX was unknown for a long time. Therefore some attempts to resolve this question have been made (Bajgar, 1968). Because of these ambiguities and difficulties in synthesis, model V agent [EDMM, *O*-ethyl *S*-(2-dimethylaminoethyl) methylphosphonothioate] was initially used in the Eastern Block to study antidotal treatment. Another structural analog of VX known as Chinese VX (CVX) was also developed and studied (Eckert *et al.*, 2006).

A very important step in the development in CWs has been the production of ''binary munition'', in which the final stage of synthesis of the agent from precursors is carried out in the munition (bomb, shell, or warhead) immediately before or during delivery to the target. In the 1950s, armed forces had begun looking at binary weapons. Until this time, CWs were unitary, i.e. the toxic agent was filled in the munition and then stored ready to be used. The binary concept – mixing or storing two less toxic chemicals and creating the nerve agent within the weapon – was safer during storage. The production of binary projectiles began on December 16, 1987 at the Pine Bluff Arsenal, Arkansas, USA.

D. Persian Gulf War

On August 2, 1990, Saddam Hussein sent Iraqi troops into Kuwait – allegedly in support of Kuwaiti revolutionaries who had overthrown the emirate. Iraq was known to have a large stockpile of CWs during its conflict with Iran and confirmed that they would use CWs.

President George Bush ordered US forces to be sent to Saudi Arabia at the request of the Saudi Government (Operation Desert Shield) – this was the buildup phase of the Persian Gulf War. As a consequence, in 1996, almost 60,000 veterans of the Persian Gulf War claimed certain medical problems related to their war activities, some caused by exposure to nerve agents (released after the bombing and desctruction of the sarin production facility). Unexplained ''Gulf War Syndrome'' with low-dose exposure to CWAs was suggested as a possible cause. Extensive research failed to find any single case of the problem.

However, some health effects, including alterations to the immune system 3 months after the exposure to low concentrations of sarin, were demonstrated (Kassa *et al.*, 2001, 2003). In the desert, during the fall and winter of 1990–1991, the threat of chemical warfare became very real to allied military personnel. It was demonstrated by the UN Commission that major Iraqi agents were mustard, tabun, sarin, and cyclosarin. Mustard agent was relatively pure but nerve agents were a complex mixture of the agent and degradation products. Over the period from June 1992 to June 1994, the Commission's Chemical Destruction Group destroyed 30 tons of tabun, 70 tons of sarin, and 600 tons of mustard, stored in bulk and in munitions.

Suddenly, it became clear to the whole world that there were countries that have CWs and biological weapons, and there were other countries that might obtain or produce them.

VII. UNINTENTIONAL USE OF TOXIC CHEMICALS

There are two main accidents connected with the release of toxic chemicals. In July 1976, in Seveso, Italy, more than 40,000 people were exposed to dioxin, a persistent and highly toxic chemical. The first signs were skin lesions appearing on children, and after some months there was evidence of chloracne. Health consequences have been observed from that time to the present. The Seveso accident was possibly the most systematically studied dioxin contamination incident. A similar contamination of one building of the Spolana company in Neratovice (a town in the former Czechoslovakia) was also observed (Bajgar *et al.*, 2007a). Another example, the Bhopal accident, is probably the greatest industrial disaster in history. On the night of December 2–3, 1984, water inadvertently entered the methylisocyanate storage tank (containing about 40 tons of this chemical). As a result, methylisocyanate was released into the sorrounding area. There was no warning. Many people who inhaled high concentrations of toxic gas were asphyxiated because of extensive lung damage. About 150,000 people were intoxicated (50,000 seriously poisoned) and more than 2,500 people died (Bajgar, 2006).

VIII. TERRORIST USE OF CW

Terrorists have expressed an interest in nerve agents and have deployed them in attacks on unprotected civilians (Rotenberg and Newmark, 2003). A Japanese religious cult, Aum Shinrikyo, independently manufactured numerous chemical and biological agents. The first such attack with sarin occurred in Matsumoto in 1994 and the Tokyo subway in 1995. Thousands of people were affected and dozens of people died (Nagao *et al.*, 1997; Ohtomi *et al.*, 1996; Okumura *et al.*, 1998; Yokoyama *et al.*, 1998). In Matsumoto (1994), 600 people were poisoned and hospitalized, and seven died (Morita *et al.*, 1995; Nakajima *et al.*, 1997; Yoshida, 1994). The attack in the Tokyo subway (1995) resulted in 5,500 people seeking hospital evaluation and 12 deaths (Bajgar, 2006). An interesting terroristic act was described by Tsuchihashi *et al.* (2005) – a fatal intoxication with VX administered percutaneously.

Nerve agents belong to the group of OPs. These compounds in the form of pesticides are commercially available, and are used in agriculture which can lead to professional, suicidal, or accidental intoxication. The mechanism of action, diagnosis, and treatment of intoxication with OP pesticides and nerve agents is a very hot topic at present. Moreover, some principles of the effects, diagnosis, and therapy are very similar for OP and highly toxic nerve agents, and therefore the principle of action and effective treatment can be applied in general for the civilian sector too.

The use of these chemicals was observed in Moscow in 2002. The Moscow theater hostage crisis was the seizure of a crowded theater on October 23, 2002 by about 40 armed Chechen militants who claimed allegiance to the separatist movement in Chechnya. They took 850 hostages and demanded the withdrawal of Russians from Chechnya and an end to the Chechnya war. The leader of the terrorists was 22-year-old Movsar Baraev. After two and half days of waiting, Russian forces used an unknown gas pumped into the ventilation system. Officially, 39 terrorists and at least 129 of the hostages (nine of them foreigners) were killed. Some estimates have put the civilian death toll at more than 200. It was thought that the security services used an aerosol of a chemical warfare agent, first assessed as BZ, but later it was specified that an aerosol anesthetic of the Fentanyl type was used (Bajgar and Fusek, 2006).

In the hospitals, the survivors were cut off from any communications with the outside and their relatives were not allowed to visit them. An incorrect list of hospitals for victims was released. The main problem was the lack of information about those dealing with the identification and characterization of the chemical used and the unavailability of known antidotes (e.g. naloxon) by medical staff treating the victims (Bajgar *et al.*, 2007a). It appeared from this event that there were compounds not explicitly enumerated in the CWC and therefore not controlled by this Convention. Fentanyl can be considered as a nonlethal weapon (a group of so-called calmatives) and these chemicals can also be used to incapacitate animals; of course, its use against humans is not excluded (Bajgar, 2006; Hess *et al.*, 2005).

IX. NEGOTIATIONS

Though the Cold War was continuing, the political situation led to increased activities in international negotiations. At the Conference on Disarmament in Geneva, some attempts to negotiate a ban of CWs was begun, first as the Ad hoc

Working Group, and later as the Ad hoc Committee on Chemical Weapons with the mandate to negotiate the text of a convention banning CWs.

The discussions in Geneva were more intensive from 1987 and, in 1992, the elaboration of the so-called rolling text of future CWCs was finished. During these negotiations, the text of future Conventions (''rolling text'') was enlarged: the final report (CD/342) of February 2, 1983 contained 23 pages; the same report of August 23, 1985 (CD/636) had 46 pages; and CD/952 of August 18, 1989 contained 134 pages. Simultaneously with the Geneva negotiations, in September 1989, the Memorandum of Understanding between the Governments of the United States and USSR regarding a bilateral verification experiment, data exchange related to prohibition of CWs otherwise known as the Wyoming, MT, started negotiations between two main possessors of CWs. These countries also contributed to the negotiations in Geneva: they demonstrated their CWs to the Conference on Disarmament in the USA in November 1986 (Tooele) and the USSR in October 1987 (Shikhany). The final document of the Convention is approximately 200 printed pages. The Convention was then agreed in New York at the UN General Assembly and signed in Paris in 1993. The CWC (Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and on their Destruction) entered into force on April 29, 1997, 180 days after the deposit of the 65th instrument of ratification of the Convention by Hungary. At this time, 87 countries ratified the CWC and became original States Parties to the Convention. Simultaneously, the Organization for Prohibition of Chemical Weapons (OPCW) in The Hague started its work of supervising the destruction of CW stocks and monitoring the world's chemical industry to prevent future misuse. There are many activities of the OPCW, e.g. training of the inspectors for control of destruction of CWs including their medical protection, research, and supported activities, solving problems due to practical implementation of the CWC, control of chemical and military facilities and other activities. Russia and the USA are unlikely to meet the final stockpile destruction deadline of April 29, 2012. By the middle of 2008, 183 Signing States and 194 recognizing States had adhered to the Convention (Davey, 2008). However, there are still States nonsignatories to the Convention. CWs have a long and ancient history. A lack of CW employment in WWII suggested that ''gas warfare'' had ended. However, further development and the utility of chemicals in Vietnam and in terrorist attacks have maintained a military interest in chemical weapons.

It is clear that the use (incidental or otherwise) of toxic chemicals has impacts in different spheres of human existence such as state structures and infrastructure, economics, psychic and public behavior, and the environment. Toxic chemicals are a great consumer of natural sources, both renewable and nonrenewable. They also consume raw materials and energy, and as a consequence cause pollution of the environment and lead to deficiency of raw materials throughout the world and therefore an unequal distribution of the world's natural sources. The impact on the psychology of humankind is also important, following either chemical wars (both global and local) or use of these chemicals by terrorists. The development of new technologies is equally important because they influence positively and negatively further human development. Research in this direction can not only contribute to ''improvement'' of chemicals to obtain more effective CWAs but also improve our knowledge in basic sciences (toxicology, neuropharmacology, etc.) and allow us to better understand physiological functions in general. It is appropriate to recall the history of cholinesterases and their inhibitors. The existence of cholinesterases was predicted by H.H. Dale in 1914, i.e. 14 years before acetylcholine was demonstrated as a natural constituent of animal tissues. This research approach was changed during WWII and cholinesterases acquired a special significance in the context of chemical warfare and nerve agents (Silver, 1974). Another publication in this area (Koelle, 1963) can be considered as the first to deal with anticholinesterase agents including CWAs – nerve agents. One can only hope that in the future the only physiological and pharmacological research will be performed in a nonmilitary framework, but that may not be the case.

X. CONCLUDING REMARKS AND FUTURE DIRECTION

The threat of the use (either military or terroristic) of CWAs (and other toxic chemicals) still exists. The military use of these agents is limited but their terroristic use is unlimited. The spectrum of these agents is very large and the ability to be prepared against the use of toxic chemicals is necessary.

CHAPTER 4

The Tokyo Subway Sarin Attack: Toxicological Whole Truth

TETSU OKUMURA, KENJI TAKI, KOUICHIRO SUZUKI, AND TETSUO SATOH

Humankind has not yet experienced a full-scale sarin attack in a major modern city.

I. INTRODUCTION

The Tokyo subway sarin attack occurred in 1995, following the Matsumoto sarin attack, and served as a ''wake-up call'' for anti-NBC (nuclear, biological, and chemical) terrorism policy throughout the world. In the 10 years since the attack, efforts to combat NBC terrorism have focused on rapid and effective measures to respond to attacks employing nerve agents such as sarin.

II. SARIN TOXICITY AND MECHANISM OF ONSET

Sarin is an organophosphate compound. Within the context of chemical weapons, organophosphates are collectively referred to as ''nerve agents'', of which sarin, tabun, soman, and VX are examples. Organophosphates inhibit the enzyme acetylcholinesterase (AChE), which degrades acetylcholine (ACh), a neurotransmitter substance that acts locally on nerve synapses. Once the organophosphates bind to and phosphorylate AChE to inhibit its activity, ACh accumulates at nerve terminals, resulting in enhanced ACh activity at receptor sites. ACh effects can be functionally classified based on their site of action and can have muscarinic, nicotinic, and central nervous system (CNS) effects. These effects cause the major symptoms associated with an acute organophosphate toxicity. Muscarinic effects increase parasympathetic nerve activity and cause miosis, visual disturbances (accommodation disorder), increased salivary and bronchial secretions, bronchospasm, bradycardia, and increased gastrointestinal peristaltic activity (e.g. abdominal pain, nausea, vomiting, and diarrhea). Nicotinic effects, due to hyperstimulation of neuromuscular junctions, cause fasciculations, muscle weakness, and respiratory paralysis, and increased sympathetic nerve activity leads to miosis, sweating, tachycardia, and hypertension. CNS effects due to ACh, when severe, include anxiety, headaches, excitement, ataxia, somnolence, disorientation, coma, and seizures.

Well-known symptoms of sarin toxicity include ''miosis'', ''hypersecretion'', ''bradycardia'', and ''fasciculations''. However, the mechanism of organophosphate toxicity seems to involve conflicting actions. For example, mydriasis or miosis, and bradycardia or tachycardia may occur. Acute respiratory insufficiency is the most important cause of immediate death. Early symptoms include (1) tachypnea due to increased airway secretions and bronchospasm (muscarinic effect), (2) peripheral respiratory muscle paralysis (nicotinic effect), and (3) inhibition of respiratory centers (CNS effect), which all lead to severe respiratory insufficiency. If left untreated at this stage, death will result. Cardiovascular symptoms may include hypertension or hypotension. In more severe cases, hypotension and shock develop. Various arrhythmias can also occur, and caution is required when the QT interval is prolonged. In particular, if hypoxemia is present, fatal arrhythmias may occur with intravenous administration of atropine sulfate, which means that this drug should be given intramuscularly to victims of sarin poisoning in the ''field''. Common gastrointestinal symptoms include nausea, vomiting, and diarrhea.

An ''intermediate syndrome'' lasting 1–4 days after sarin exposure is said to exist. This is due to prolonged AChE inhibition and is associated with acute respiratory muscle paralysis, motor nerve paralysis, and cervical flexor and proximal muscle paralysis. Recumbent patients who have difficulty raising their head and neck require particular care. However, the intermediate syndrome has not been reported with nerve agent toxicity in animals or humans (Sidell, 1997), and some experts even doubt that an intermediate syndrome actually exists (De Bleecker, 1992). Others believe that the cause may be due to oral toxicity or inadequate treatment (intestinal decontamination, antidote administration, and respiratory management). In organophosphate-induced delayed neuropathy (OPIDN), seen two to three weeks after exposure, and characterized by distal muscle weakness without fasciculations, the pathophysiology is not well understood. OPIDN was first reported in the 1930s due to

contamination of Jamaican ''ginger jake'' by organophosphates. This incident (so-called ''ginger paralysis'') caused lower limb paralysis in about 20,000 victims. OPIDN symptoms have also recently been reported in Matsumoto and Tokyo subway sarin victims (Himuro *et al.*, 1998; Sekijima *et al.*, 1997). Inhibition of neuropathy target esterase (NTE) plays a role in OPIDN, but despite several basic research studies, the detailed pathophysiology has not yet been established, thus making OPIDN difficult to treat.

III. OVERVIEW OF THE TOKYO SUBWAY SARIN ATTACK

The attack took place during the morning rush hour, about 8:00 am, on March 20, 1995, the day before a holiday. The attack was carried out by members of Aum Shinrikyo to distract police from carrying out a raid on the cult's headquarters. The terrorist target was government buildings in Kasumigaseki in the heart of Tokyo. Most offices in Kasumigaseki open for business at 9:30 am, but the early morning rush hour was heavy because this was a Monday. Some believe that the time of 8:00 am was because some cult members had inside information about the government offices. The police, based on an undercover investigation, suspected that Aum Shinrikyo was manufacturing sarin for use in a terror attack, but few people, even within the police department, were aware of this. The police did not have personal protective equipment (PPE), which meant that they had to borrow PPE and receive training on use of the equipment from the Self-Defense Forces. Members of the Self-Defense Forces were alerted to some of Aum Shinrikyo's planned activities, but the general public, including healthcare providers and fire department personnel, knew nothing about their activities.

According to a subsequent police report, the terrorists placed sarin in five subway trains. Approximately 600 grams of sarin at a concentration of 33% was mixed with hexane and *N*, *N*-diethylaniline and placed in a nylon/polyethylene bag. Five terrorists then wrapped the bags in newspaper, punctured the bags with the tips of their umbrellas and left the bags on the subways. In this way the sarin seeped out of the bags and vaporized, but no other active means of dispersal were used, and in this sense, the Tokyo subway sarin attack was not really a ''full-scale'' attack.

Thus, the way in which we use the lessons learned from this attack will affect our ability to adequately deal with future terrorist attacks using sarin, which could be even greater and more serious with respect to the number of victims. Can we really assume that only 12 of the approximately 5,500 victims died because the Japanese medical system was particularly well prepared for such an eventuality? Probably not. It is more likely that the relatively low number of fatalities was due to the low concentration of sarin and passive means of dispersing it. From this perspective, the Matsumoto sarin attack one year previously was more aggressive than the Tokyo subway sarin attack. In a trial after the Matsumoto incident, it was revealed that a 70% concentration of sarin was actively volatilized using an electric heater and dispersed using an electric fan. Seven victims died and 660 were injured, giving a fatality rate of 1%. In other words, if the Tokyo subway sarin attack had been conducted using the same means as those employed in the Matsumoto sarin attack, the number of fatalities may have risen to 50 or 60. Fortunately, only 12 victims died, but this suggests that the Tokyo subway sarin attack was not a full-scale attack. In other words, mankind has not yet experienced a full-scale sarin attack in a major city.

Of the bags of sarin used in the attack, two bags were not punctured. These bags were returned to the police laboratory for analysis. At one of the subway stations on the

FIGURE 4.1. Scene from a sarin attack at Tsukiji station.

Chiyoda line, Kasumigaseki, two station employees collapsed and died on the platform after they cleaned and removed the as yet unidentified object using gloves. The actual number of victims varies depending on the source, but all confirm that 12 people died in the attack and it is generally believed that at least 5,500 victims suffered mild to serious injuries; fire fighting agencies estimate 5,642 victims, and the police, 3,796 victims. Official figures released by the subway company put the total number of victims at 5,654. This includes the 12 who died (ten passengers, two employees), those hospitalized (960 passengers, 39 employees), and those treated for minor injuries (4,446 passengers, 197 employees).

This incident was the first chemical terrorist attack in a large city. There were few first responders who could even have conceived of such an attack and would have been prepared to rapidly evacuate victims from the subway station premises. Many passengers who had difficulty walking rushed out of the trains and onto the subway platform and fell down, which in effect would have increased their exposure to sarin in the subway station. In addition, the site to which many of the victims were finally evacuated at ground level where they could lie down was in close proximity to an air exhaust vent from the subway below.

Cult members arranged to puncture all the bags containing sarin at 8:00 am, and the first call for an ambulance came at 8:09 am with the first report of a ''victim with seizures at Kayabacho Station''. After 8:15 am, the reports of victims started to increase. Around this time, the fire department received a report from Tsukiji Station stating that ''an explosion occurred and several people were injured''. Calls for ambulances eventually came from 19 subway stations, and after 8:30 am, victims, either by walking or being picked up by passing vehicles, began to pour into local clinics and hospitals. According to the Tokyo Fire Department, 5,493 people were treated at 267 medical institutions in Tokyo, 17 people were treated at 11 medical institutions outside Tokyo, and among the victims, 53 were seriously injured (Ieki, 1997). Another source states that a total of 6,185 people were treated at 294 medical institutions (Chigusa, 1995). The discrepancy in the number of victims reported by different agencies attests to some of the confusion at the time. St Luke's Hospital received the largest number of victims (640 on the day of attack). The reason for this was because of its close proximity to the Hibiya line, where there were many victims, and because of a report on television which stated that ''St Luke's Hospital has the antidote for treatment''.

IV. EMERGENCY TREATMENT OF SARIN TOXICITY

In victims of the Tokyo subway sarin attack, endotracheal intubation was not difficult. The Japanese medical literature describes the standard treatment for sarin toxicity as (A) maintain the airway, (B) assist breathing, and (C) support circulation. However, in the Matsumoto sarin attack, endotracheal intubation was more difficult in many victims because of airway hypersecretion and bronchospasm. This difference in symptoms is attributable to the higher 70% concentration and active means by which the sarin was dispersed at Matsumoto, as opposed to the 33% concentration and passive means of dispersal employed in Tokyo. Dr Fredrick Sidell (now deceased), an expert on chemical terrorism in the USA, advocated decontamination, drugs, airway, breathing, and circulation (DDABC) as the basic treatment for nerve agent poisoning. Even if the so-called ABCs of emergency treatment are followed, initial efforts to achieve adequate ventilation may be in vain. Efforts to achieve adequate ventilation should be made after at least initial administration of atropine to control airway secretions and bronchoconstriction (Sidell, 1997). If healthcare professionals learn from the Matsumoto attack, they can better recognize early parasympathetic nervous symptoms, including miosis, hypersecretion, and rhinorrhea as common symptoms of chemical terrorism due to nerve agents and institute appropriate treatment with antidotes. In large-scale disasters with many victims, treatment is often deferred in those with cardiopulmonary arrest (so-called ''black tag''). However, at St Luke's Hospital, one in three persons with cardiopulmonary arrest and two patients with respiratory arrest made a full recovery and were discharged. This high rate of recovery and return to the community is unlike that seen in other types of disasters. Therefore, if medical resources are available, all victims of a sarin attack should be aggressively treated, including cardiopulmonary resuscitation (CPR) when necessary.

The global standard for the treatment of sarin toxicity is the administration of: (1) atropine, (2) an oxime agent like PAM, and (3) diazepam (Medical Letter, 2002).

Recommended doses of atropine are 2 mg in patients with mild symptoms, primarily ocular, but without respiratory symptoms or seizures; 4 mg in patients with moderate symptoms, including respiratory symptoms such as dyspnea; and 6 mg in patients with severe symptoms, including seizures and respiratory arrest, the standard administration route for which should be intramuscular. As mentioned previously, intravenous administration of atropine in the setting of severe symptoms such as hypoxemia can induce ventricular fibrillation; thus, intramuscular administration is advised. Oxime agents such as PAM (pralidoxime methiodide, or 2-formyl-1-methylpyridinium iodide oxime) should also be given. The recommended dose for PAM in moderate and severe cases of inhalation, or for liquid exposure to a nerve agent, is 1 g by intravenous infusion over 20 to 30 min. Further continuous administration of 500 mg per hour may also be required in severe cases. Since the rate of aging of nerve agent–enzyme bond is correlated with time until administration of PAM, if the aging half-life of sarin is 5 h, then PAM must be administered before this time. The oxime of choice for sarin and VX is PAM, but HI-6 should be used

FIGURE 4.2. Sarin victims at St Luke's International Hospital.

for soman and obidoxime for tabun. Seizures are treated with diazepam. This three-drug combination, atropine, PAM, and diazepam, is the global recommendation for sarin toxicity and autoinjectors are available in several countries (Vale *et al.*, 2006).

After the Tokyo subway sarin attack, St Luke's Hospital, which treated 640 victims, used about 700 ampules of PAM and 2,800 ampules of atropine (Okumura *et al.*, 1998). This calculates out to 550 mg of PAM and 2.2 mg of atropine for each victim. The route of administration was intravenous in all cases with a total dose of atropine in severe cases 1.5 mg to 9 mg (Okumura *et al.*, 1996); doses which reflect the low concentration and passive means of sarin dispersal used in the Tokyo attack.

However, in Tokyo, no one was saved by administration of PAM, and conversely, no one died because they did not receive PAM. In other words, if ''living or dying'' was the endpoint, there was no clinical evidence that PAM was effective. The only reported finding was a more rapid return of plasma pseudocholinesterase levels to normal in some patients who received PAM as compared to those who did not. But in terms of long-term prognosis, this does not rule out the effectiveness of oxime therapy. Ideally, detailed studies are needed to evaluate the efficacy of PAM, including for long-term prognosis, but there was no sophisticated study designed in victims of the Tokyo subway sarin attack.

One piece of evidence supporting the efficacy of PAM in sarin toxicity has been the clinical benefit associated with PAM in toxicity due to organophosphorous agrochemicals. However, some experts now doubt whether such a benefit really exists. For example, Peter *et al.* (2006), using meta-analytic techniques, reevaluated the effects of oxime therapy in organophosphate poisoning. Not only did they find no beneficial effects, they also reported possible adverse effects. The Cochrane reviews for clinical evidence-based medicine reported no risk/benefit evidence for the use of oxime agents in organophosphate poisoning, but they did conclude that further detailed investigations are necessary (Buckley *et al.*, 2005).

Based on the experience of Iranian physicians who treated sarin toxicity during the Iran–Iraq war (Newmark, 2004), PAM was not available on the front lines and atropine alone was used for treatment. The doses of atropine used were considerably higher than those used in the Tokyo subway sarin attack, or that are generally recommended in the USA (Medical Letter, 2002). The Iranian protocol called for initial administration of 4 mg intravenously. If no atropine effects (improvement in dyspnea or decrease in airway secretions) were seen after 1 to 2 min, 5 mg was then administered intravenously over 5 min while heart rate was monitored. A rise in heart rate of 20 to 30 beats per min was regarded as an atropine effect. In severe cases, 20 mg to 200 mg was given. Regardless of dose, the key to saving lives, in their opinion, was how soon the atropine was administered.

Thus, treatment without the use of an oxime agent is possible. Of course, ideally, in countries where this is economically possible, treatment should use the three recommended drugs: (1) atropine, (2) an oxime agent like PAM, and (3) diazepam, and the use of autoinjectors for administration is also helpful. Unfortunately, terrorist attacks using sarin are also carried out in less economically developed countries and even if the drugs are available, considerations related to cost performance need to be considered. In this sense, preference should be given to the availability of atropine and diazepam. In other words, unless it is economically feasible, funds should be used to obtain atropine and diazepam, rather than oxime agents, whose cost–benefit ratio is still inconclusive.

V. ACUTE AND CHRONIC SYMPTOMS OF SARIN TOXICITY

Based on available data from 627 victims treated at St Luke's Hospital, symptoms in order of occurrence were: miosis 568 (90.5%), headache 316 (50.4%), visual darkness 236 (37.6%), eye pain 235 (37.5%), dyspnea 183 (29.2%), nausea 168 (26.8%), cough 118 (18.8%), throat pain 115 (18.3%), and blurred vision 112 (17.9%) (Okumura *et al.*, 1998). Cases were defined as severe for seizures or respiratory arrest requiring mechanical ventilation, moderate for respiratory distress or fasciculations, and mild for eye symptoms only. Of 640 cases reported by St Luke's Hospital, degree of intoxication was severe in five, moderate in 107, and mild in 528 victims with nicotinic effects observed in those with moderate or severe symptoms.

In the Tokyo subway sarin attack, decontamination was not performed on site, and first responders and healthcare workers initially did not wear personal protective equipment (PPE). As a result, of 1,364 fire department personnel, 135 (9.9%) became secondary victims. Official reports for police department personnel were not released, but the number of secondary exposure victims was probably similar. At St Luke's Hospital, 23% of the hospital staff became secondary victims (Okumura *et al.*, 1998). The percentage of secondary victims by hospital occupation was: nurse assistants (39.3%), nurses (26.5%), volunteers (25.5%), doctors (21.8%), and clerks (18.2%). Thus, increased contact with a primary victim increased the risk of becoming a secondary victim, with the percentage of secondary victims by hospital location being the chapel (45.8%), ICU (38.7%), outpatient department (32.4%), general ward (17.7%), and the emergency department (16.7%). The high rate of secondary victims in the chapel was attributed to poor ventilation and the large number of victims sheltered there. Because it was during the winter, victims entered the chapel fully clothed. When they removed their coats, and every time they moved, some of the sarin trapped inside the clothing probably escaped, causing secondary exposure. Fortunately, none of the secondary victims died. However, in the event that a higher concentration of sarin and more effective means of dispersion had been employed in the Tokyo attack, such as that used in Matsumoto, for example, then it is likely that fatalities would have been encountered among secondary victims.

Within the context of risk communication, the so-called ''worried-well'' patients who are concerned about having been exposed to the nerve agent, and those complaining of symptoms, even though actual exposure was unlikely, also flock to hospitals seeking treatment (Bloch *et al.*, 2007). Among patients treated at St Luke's Hospital on the day of the attack, 90.5% (568/627) had miosis (pupillary constriction), an objective finding due to sarin exposure. The remaining 9.5% were considered to be ''worried-well'' patients. As days passed by, the number of ''worried-well'' patients appeared to increase, but no actual data for this is available.

The reason for the small number of ''worried-well'' patients in the Tokyo subway sarin attack is unclear. Given the extensive coverage by the news media who mentioned that victims were flocking to St Luke's Hospital, persons without definitive symptoms, or those who were unsure whether they had been exposed but who did not want to add to the confusion, avoided going to St Luke's Hospital creating a kind of natural selection process. In addition, the target of the attack was the government buildings in Kasumigaseki at heart of Tokyo, which would have meant that many of the victims were well educated. This may also have contributed to the small number of ''worried-well'' patients. Conversely, unfamiliarity with sarin and toxic gases in general may also have contributed to the low number of ''worried-well'' patients. In either case, these observations should be reviewed from the perspective of risk communication.

Fortunately, only one victim from the Matsumoto and Tokyo subway sarin attacks has still not regained consciousness and remains in a vegetative state due to anoxic brain damage (Yanagisawa *et al.*, 2006). Sarin victims treated at St Luke's Hospital were regularly followed for the development of chronic symptoms. One year after the incident a survey was conducted, and 303 of 660 victims responded (Ishimatsu *et al.*, 1996). Forty-five percent of the respondents reported that they still experienced symptoms. Regarding physical symptoms, 18.5% of the victims still complained of eye problems, 11.9% of easy fatigability, and 8.6% of headaches. Regarding psychological symptoms, 12.9% complained of fear of subways, and 11.6% still had fears related to escaping the attack. In another survey after 3 years, 88% of the respondents reported several sequelae (Okumura *et al.*, 1999). Unfortunately, these surveys may lack objectivity and may suffer from bias. For example, the response rate may have been higher among victims still complaining of symptoms.

Murata *et al.* (1997) performed a controlled comparison study in victims 6 to 8 months after the attack, with evaluations of event-related and visual-evoked potentials (P300 and VEP), brainstem auditory evoked potentials, electrocardiographic R-R interval variability (CVRR), and scores on a posttraumatic stress disorder (PTSD) checklist. In the sarin victims, P300 and VEP (P100) latencies were significantly prolonged, and the CVRR was abnormal, indicating depression of cardiac parasympathetic nervous activity. The findings suggested persistent effects of sarin in the higher and visual nervous systems. In another study, Yokoyama *et al.* (1998a) reported a delayed effect on the vestibulocerebellar system induced by acute sarin poisoning. Yokoyama *et al.* (1998b) also reported a chronic effect on psychomotor performance. In addition, Miyaki *et al.* (2005) described the chronic effects associated with psychomotor and memory function up to 7 years after exposure.

As mentioned previously, two victims with OPIDN were reported (Sekijima *et al.*, 1997; Himuro *et al.*, 1998).

As part of a series of scientific studies sponsored by the Japanese Ministry of Health, Labor, and Welfare, Matsui *et al.* (2002) conducted two studies 7 years after the sarin attack. The first study was a case control study comparing victims treated at St Luke's Hospital with a control group. Statistical analysis showed significantly higher rates of chest pain, eye fatigue, presbyopia, eye discharge, nightmares, fear, anxiety, difficulty concentrating, and forgetfulness in the victim group. Moreover, in the victim group, there were even significantly higher rates of visual blurring, myopia, problems with focal convergence, abnormal eye sensations, flashbacks, fear of returning to the attack site, and not wanting to watch news about the attacks. The rate of PTSD, as evaluated by several diagnostic criteria, was also higher in the victim group. The second study was a cohort study comparing a group who required medical intervention after the attack with a group who did not. For lethargy, diarrhea, myopia, presbyopia, problems with focal convergence, eye discharge, and apathy, there were no significant differences between the groups, but for other evaluated parameters, scores were significantly higher in the nonintervention group. Comparison of PTSD incidence based on whether intervention was received showed that the nonintervention group had a significantly higher rate of masked PTSD. There was a higher incidence of eye symptoms in the victim group than in the nonvictim group, but there was no difference between the intervention group and nonintervention group. Thus, eye symptoms are probably long-term physical sequelae of sarin exposure. In some Matsumoto cases, persistent EEG changes without seizure activity have been reported up to 5 years (Yanagisawa *et al.*, 2006).

The results of these studies suggest some long-term effects of sarin toxicity and careful follow-up and observation are indicated in these victims.

VI. LABORATORY FINDINGS IN SARIN TOXICITY

According to inpatient records from St Luke's Hospital, the most common laboratory finding related to sarin toxicity was a decrease in plasma cholinesterase (ChE) levels in 74% of patients. In patients with more severe toxicity, plasma ChE levels tended to be lower, but a more accurate indication of ChE inhibition is measurement of erythrocyte ChE, as erythrocyte ChE (AChE) is considered ''true ChE'' and plasma ChE is ''pseudo ChE''. However, erythrocyte ChE is not routinely measured, whereas plasma ChE is included in many clinical chemistry panels; thus, it can be used as a simple index for ChE activity. In both the Matsumoto and Tokyo subway sarin attacks, plasma ChE served as a useful index of sarin exposure. In 92% of hospitalized patients, plasma ChE levels returned to normal on the following day. In addition, inpatient records from St Luke's Hospital showed an elevated creatine phosphokinase (CPK) and leukocytosis in 11% and 60% of patients, respectively. In severe cases in the Matsumoto attack, hyperglycemia, ketonuria, and low serum triglycerides due to toxicity of sarin on the adrenal medulla were observed (Yanagisawa *et al.*, 2006).

VII. CONCLUDING REMARKS AND FUTURE DIRECTION

This chapter has discussed sarin toxicity based on experiences of the attacks in Matsumoto and the Tokyo subway, and also the Iran–Iraq war. This section provides some conclusions drawn from the toxicological issues related to sarin.

Given the low concentration and means of dispersal, the Tokyo subway sarin attack can be referred to as a ''passive'' attack. The implication of such an assumption is therefore that mankind has not yet witnessed a ''full-scale'' sarin attack in any major city. While valuable information can certainly be gained from the Tokyo subway sarin attack, the experience obtained from the more aggressive Matsumoto sarin attack and the Iran–Iraq war should also be considered when developing initiatives directed at dealing with a potential ''full-scale'' attack in the future where the effects will be more serious.

Importantly, reliable epidemiologic data is lacking regarding the long-term effects of sarin toxicity, whether low dose exposure to sarin has any long-term effects, and specific effects on children, pregnant women, and fetuses (Sharp, 2006). The sporadic and limited epidemiologic surveys undertaken to date suggest that some long-term effects are present. Thus, well-designed international epidemiologic studies should be conducted in victims exposed to sarin in Japan, Iran, and during the Persian Gulf War.

There are several issues regarding treatment that need to be resolved. Before the Tokyo subway sarin attack in 1995, treatment of chemical weapons victims was exclusively regarded as a military issue; however, since then, the deliberate release of nerve agents against the general public has become a serious public safety issue. Treatment of chemical weapon injuries in a military setting assumes that one is dealing with healthy males, who have received basic and ongoing training, and who are wearing PPE. In an attack on the general public, however, we are dealing with a heterogeneous population from different backgrounds, and the victims will include women, pregnant women, children, and persons who are elderly, sick, and disabled. Furthermore, the public is defenseless against chemical weapons because of their lack of knowledge of dangerous chemical substances, or lack of experience with wearing PPE. Taken together, there is thus the potential to have thousands of victims in the event that there is a deliberate release of nerve agents against ordinary citizens.

Therefore, the medical treatment required for responding to a chemical terrorist attack on the general public will require a different strategy than that employed for such attacks in a military setting. This is because, even though there are numerous lessons that can be learned from military experience, there will be measures that may not be applicable to an attack on the public. An important issue is the means by which appropriate drugs can be safely and reliably supplied to a large number of victims. In addition, it is unrealistic to expect that first responders wearing PPE will be able to establish intravenous lines in large numbers of victims at the scene of a terrorist attack and the use of autoinjectors for intramuscular or intraosseous access is more realistic (Ben-Abraham *et al.*, 2003). In this regard, what is needed are not standardized autoinjectors issued to military personnel, but rather, a variety of autoinjectors that are uncomplicated and easy to use by victims. Research on the drugs used to treat chemical terrorism victims crosses the military/private sphere and is being conducted in several countries. However, unlike drugs that are designed for treating diseases, clinical trials cannot be performed in humans due to ethical concerns. Conducting a randomized control study is also difficult because of an insufficient number of cases of organophosphate poisoning to establish a reliable sarin toxicity model. A prime example is the oxime agent HI-6. Despite being developed more than 10 years previously, considerable time elapsed before its widespread use. From the standpoint of international security, collaborative research on drugs for treating chemical terrorism and a global agreement on standard treatment are needed. These are important issues in clinical toxicology that require international collaboration.

Acknowledgments

We wish to thank the many people who have devoted their lives to research of chemical weapons treatment since the Tokyo subway sarin attack and who provided valuable advice in preparing this chapter. This chapter is dedicated to the memory of Dr Frederick Sidell at the United States Army Medical Research Institute.

CHAPTER 5

Epidemiology of Chemical Warfare Agents

LINDA A. McCAULEY

I. INTRODUCTION

While chemical warfare agents have been used for decades in military conflict, it is only in the last two decades that increasing attention has been placed on the acute and chronic health effects associated with exposure to these agents. The Gulf War of 1991 and the subsequent reports of ill-defined illnesses in the veterans of that conflict, followed by the 1995 sarin terrorist event in the Japanese subway system, placed increased attention on the capacity of deliberate or accidental exposure to chemical warfare agents resulting in significant human death and subsequent disability.

Epidemiological studies of chemical warfare agents have suffered problems in determining exposure. Other than epidemiological investigations following the Japanese terrorist event, little objective epidemiological evidence is available. In this chapter, the major studies that have been conducted on populations exposed to the chemical warfare agents are discussed and methodological issues summarized.

II. PRE-WORLD WAR II

The first full-scale deployment of chemical warfare agents was during World War I in 1915, when the Germans used chlorine gas against French, Canadian, and Algerian troops. Deaths were light, though casualties relatively heavy. A total of 50,965 tons of pulmonary, lachrymatory, and vesicant agents were deployed by both sides of the conflict, including chlorine, phosgene, and mustard gas. Official figures declare about 1,176,500 nonfatal casualties and 85,000 fatalities directly caused by chemical warfare agents during the course of the war (Heller, 2005). In 1925, 16 of the world's major nations signed the Geneva Protocol, pledging never to use gas in warfare again; however, there were subsequent reports of its use. In 1935 Italy used mustard gas during the invasion of Ethiopia in the Second Italo-Abyssinian War with 15,000 chemical casualties reported. In this military conflict and subsequent wars in which chemical agents were used, no systematic attempt was made to accurately describe the epidemiology of the exposures, nor were any accurate data established to follow the health of exposed populations after the acute exposure.

Concern regarding potential long-term effects of these exposures continued to be an issue and in 1975 a longitudinal follow-up study of the mortality experience of three samples of World War I veterans was conducted to determine if a single exposure to mustard gas with respiratory injury was associated with increased risk of lung cancer in later life (Norman, 1975). Rosters of men born between 1889 and 1893 [2,718 exposed to mustard gas, 1,855 hospitalized with pneumonia in 1918, and 2,578 with wounds of the extremities (controls)] were traced via the Veterans Administration's death records. The 4,136 deaths reported were 95% of that expected. Observed deaths from lung cancer numbered 69, or 2.5%, for the mustard-gas group as compared to 33, or 1.8%, for the pneumonia group and 50, or 1.9%, for the controls. The risk of death from lung cancer among men gassed relative to that for the controls was estimated as 1.3, with 95% confidence limits of 0.9–1.9.

III. WORLD WAR II

In 1938, the chemical structure of sarin nerve gas was discovered by the Germans, followed by the discovery of the nerve agent soman in the spring of 1944 (Schmaltz, 2006), but chemical warfare was not extensively used by either side due in part to fear of a devastating Allied retaliatory attack. There was one account of an exposure to mustard gas among Allied troops when several American ships were sunk by the Germans in 1943, including one carrying mustard gas intended for use in retaliation by the Allies if German forces initiated gas warfare. Because the presence of the gas was highly classified, authorities ashore, treating casualties, had no idea that they were seeing the effects of mustard gas and prescribed improper treatment. This incident was not uncovered for many years and military records account that 69 deaths were attributed in whole or part to mustard gas, out of 628 mustard gas military casualties (US Naval Historical Center, 1943). The due impact of the gas exposure to military and civilian populations was not accurately reported due to the high secrecy regarding the exposure and the difficulty discerning the effect of gas exposure from other types of injuries.

During the Holocaust, the Nazis used the insecticide Zyklon B containing hydrogen cyanide to kill several

million people in extermination camps and reportedly used poison gases during the Warsaw Ghetto Uprising in 1943. Human experiments were conducted on concentration camp prisoners using mustard gas and phosgene.

In 1994 a United States Senate Report, entitled ''Is military research hazardous to veterans health? Lessons spanning a half century'' reported that US military personnel were used as human subjects in the 1940s to test the chemical agents mustard gas and lewsite. This testing was done to determine how to best protect military troops from the effects of chemical warfare agents (Pechura and Rall, 1993).

During the war, the US military conducted a secret research program aimed at determining how best to protect military personnel against the effects of mustard gas and a similar compound, lewisite (Pechura and Rall, 1993). Up to 4,000 men took part in the program which required participants to wear gas masks and clothing that had been treated in an attempt to block the gas from reaching the skin. Men were required to remain in the sealed test room from 1 to 4 h. Some men were tested in the field where they were required to stay in an area that had been bombed with mustard gas anywhere from 1 h to 3 days. In 1992, the US Department of Veterans Affairs (VA) began to allow compensation for seven conditions that can result from mustard gas exposure: laryngitis, chronic bronchitis, emphysema, asthma, chronic conjunctivitis, chronic keratitis, and corneal opacities. Following publication of a report by the National Academy of Sciences (Pechura and Rall, 1993), the VA extended the list to include respiratory cancers (nasopharyngeal, laryngeal, and lung except for mesothelioma), skin cancer, chronic obstructive pulmonary disease, and acute nonlymphocytic leukemia.

In 2000, Bullman and Kang (2000) reported a 50-year mortality follow-up study of veterans exposed to low levels of mustard gas. They conducted a retrospective mortality follow-up study of World War II Navy veterans who received low-level nonlethal exposures to mustard gas while participating in mustard gas chamber tests at Bainbridge, Maryland, between 1944 and 1945. These veterans were exposed to mustard gas while wearing protective clothing and masks. Control veterans consisted of 2,663 Navy veterans who served at the same location and time as the exposed, but did not participate in chamber tests. The investigators found no excess of any cause-specific mortality associated with varying levels of mustard gas exposures that were sufficient to cause skin reactions. A significant strength of this study was that the length of time in the exposure chamber, the dose of exposure, and documentation of any observative acute effect were available for each of the exposed subjects so that a dose–response analysis could be done.

In a 2000 report, Schnurr *et al.* (2000) reported on the prevalence of current post-traumatic stress disorder (PTSD) associated with participation in these secret military tests of mustard gas exposure. Using the registry established by the VA, 363 male military veterans were randomly sampled and found to have a current prevalence of 32% for full PTSD and 10% for partial PTSD. Prevalence of PTSD varied as a function of risk and protective factors, including volunteering, physical symptoms during the tests, and prohibited disclosure. Veterans with full PTSD reported poorer physical health, a higher likelihood of several chronic illnesses and health-related disability, greater functional impairment, and higher likelihood of healthcare use than those with no PTSD. Veterans with partial PTSD also had poorer outcomes than did veterans with no PTSD in a subset of these domains.

Schnurr *et al.* (1996) postulate that these exposures involved elements of ''contamination stressors'' in which information about the exposure is the stressor rather than the tangible event. The late disclosure of the dangerous nature of these tests served as an additional stressor for many of the exposed men. Lack of information during the test, leaning to vague or diffuse fear with unknown consequences, could also contribute to the development of PTSD. The contamination stressor led to a future orientation; a worry about what problems will develop as a result of the previous exposure.

IV. POST-WORLD WAR II

Development of other agents such as the VX nerve agent continued during the 1950s and in 1961 the USA was producing large amounts of VX and performing its own nerve agent research. In 1952 the US Army patented a process for developing the powerful toxin ricin.

In 1969, 23 US servicemen and one US civilian stationed in Okinawa, Japan, were exposed to low levels of the nerve agent sarin while repainting the depot's buildings. When the exposure was publicized, the USA moved the weapons in 1971 to Johnston Atoll. Between 1951 and 1969 at the Dugway Proving Ground, various chemical and biological agents were tested. From 1962 to 1973 more than 5,800 military personnel participated in a series of tests on the vulnerability of warships to biological and chemical attacks. Only some of the involved military personnel consented to the tests. Many of the tests used chemical warfare simulants, thought at the time to be harmless. The results of the tests were reported in classified documents (SHAD report). In 2000, the Department of Defense released the names of the participants and information about the testing that occurred. In 2002 the Institute of Medicine agreed to undertake a scientific study of potential long-term health effects associated with these exposures. The IOM assembled a comparable control group and conducted a telephone health survey. Mortality records were also examined. The primary outcomes of interest were mortality, general health, and medical conditions. The SHAD participants were divided into four groups:

- Group A consisted of 3,000 participants whose exposure was limited to either *Bacillus globigii* (BG) or methylacetoacetate (MAA);
- Group B consisted of 850 participants whose only potential exposure was to trioctyl phosphate (TEHP or TOF) and contained a large number of marine participants;
- Group C consisted of 720 participants who were in tests where active chemical warfare agents were used;
- Group D consisted of 850 subjects potentially exposed to simulants who were not in groups A, B, or C.

Control groups were assembled for each of the exposed groups. Of the nearly 12,500 Navy and Marine subjects, 9,600 were assumed alive and were surveyed. The response rate for the SHAD participants was 60.8% and 46.6% for controls. No differences were observed in all-cause mortality between SHAD participants and controls, although the SHAD participants had a statistically significant higher risk of death due to heart disease. Lack of cardiovascular risk factor data makes this difference difficult to interpret. SHAD participants also reported statistically significantly worse health than controls, but no specific patterns of illness were found. Group C, the only group with potential exposure to active chemical or biological agents, reported the smallest differences in overall health compared to controls. Small differences in memory and attention as well as somatization were observed and SHAD participants had higher levels of neurogenerative conditions. SHAD participants also reported higher rates of symptoms, thought to be related to reporting bias. There were no significant differences in self-reported hospitalizations.

This report was significant in that it was the first epidemiological investigation of a military population with documented exposure to chemical agents or stimulants. The survey was conducted, however, 30 years after the exposure and with the exception of mortality records was limited to self-reported measures of health.

V. IRAN–IRAQ WAR

Saddam Hussein received chemical weapons from many countries, including the USA, West Germany, the Netherlands, the UK, France and China (Lafayette, 2002). In 1980 Iraq attacked Iran and employed mustard gas and tabun with 5% of all Iranian casualties directly attributable to the use of these agents. Iran sustained approximately 387 chemical attacks during the eight-year war (Shemirani *et al.*, 1993). About 100,000 Iranian solders were chemical warfare victims along with significant numbers of civilians. Nerve gas agents killed about 20,000 Iranian soldiers immediately. Shortly after the war ended in 1988, the Iraqi Kurdish village of Halabia was exposed to multiple chemical agents resulting in the death of 10% of the town's 50,000 residents. Hashemian *et al.* (2006) reported on the results of a cross-sectional randomized survey of 153 civilians in three towns exposed to military conflict in northwestern Iran; Oshnaviveh (low-intensity conventional warfare), Rabat (high-intensity conventional warfare), and Sardasht (both high-intensity conventional warfare and chemical weapons). The surveys measured full or partial PTSD diagnosis, anxiety symptoms, and depressive symptoms. The authors reported a 93% response rate from respondents (mean age of 45 years) and all were of Kurdish ethnicity. Compared with individuals exposed to low-intensity warfare, those exposed to high-intensity warfare and chemical weapons were at a higher risk for lifetime PTSD [odds ratio (OR), 18.6; 95% confidence interval (CI), 5.8–59.4], current PTSD (OR, 27.4; 95% CI, 3.4–218.2), increased anxiety symptoms (OR, 14.6; 95% CI, 6.0–35.6), and increased depressive symptoms (OR, 7.2; 95% CI, 3.3–15.9). Exposure to high-intensity warfare but not to chemical weapons was also significantly associated with lifetime PTSD (OR, 5.4; 95% CI, 1.7–17.6), compared with those in the low-intensity warfare group. Further, compared with individuals exposed to high-intensity warfare alone, those exposed to both high-intensity warfare and chemical weapons were at higher risk for lifetime PTSD (OR, 3.4; 95% CI, 1.5–7.4), current PTSD (OR, 6.2; 95% CI, 2.0–20.1), increased anxiety symptoms (OR, 5.6; 95% CI, 2.5–12.6), and increased depressive symptoms (OR, 3.7; 95% CI, 1.8–7.2).

This study was the first epidemiological study to document the long-term negative mental health sequelae of exposure to war and chemical weapons among civilians. The authors argue that exposure to chemical weapons is an extreme traumatic event that can result in acute helplessness and anxiety, loss of perceived safety, and chronic physical disabilities. The study had a number of limitations including the reliance on self-reported data; however, self-reported chemical exposure was verified with medical records.

VI. GULF WAR 1991

Given the past use of chemical weapons of Iraq on its own citizens, there was much concern that Saddam Hussein would again employ these weapons during the conflict against coalition forces. The only known exposure to anticholinesterase chemical warfare agents during the Gulf War was the destruction of munitions containing 8.5 metric tons of sarin/cyclosarin housed in Bunker 73 at Khamisyah, Iraq, on March 4, 1991, and additional destruction of sarin/cyclosarin rockets in a pit at Khamisyah on March 10, 1991. The US Department of Defense (DOD) reported that the exposure levels were too low to activate chemical alarms or to cause symptoms at the time of the detonation; however, several studies have been conducted to assess long-term health effects associated with this exposure. The DOD conducted modeling of the air plume that resulted from the detonation and estimated the extent of troops potentially exposed to the plume.

McCauley *et al.* (1999) conducted a computer-assisted telephone survey of 2,918 Gulf War veterans from Oregon, Washington, California, North Carolina, and Georgia to evaluate the prevalence of self-reported medical diagnoses and hospitalizations among this potentially exposed population and among comparison groups of veterans deployed and nondeployed to the Southwest Asia theater of operations. Troops reported to be within 50 km of the Khamisyah site did not differ from other deployed troops on reports of any medical conditions or hospitalizations in the nine years following the Gulf War. Hospitalization rates among deployed and nondeployed troops did not differ. Deployed troops were significantly more likely to report diagnoses of high blood pressure (OR = 1.7); heart disease (OR = 2.5); slipped disk or pinched nerve (OR = 1.5); PTSD (OR = 14.9); hospitalization for depression (OR = 5.1); and periodontal disease (OR = 1.8) when compared to nondeployed troops. There was a trend for deployed veterans to report more diagnoses of any cancer (OR = 3.0).

Smith *et al.* (2003) investigated postwar morbidity for Gulf War veterans, contrasting those who may have been exposed to low levels of nerve agents at Khamisyah and those unlikely to have been exposed. Cox regression modeling was performed for hospitalizations from all causes and hospitalizations from diagnoses within 15 categories during the period March 10, 1991 through December 31, 2000, for the duration of active-duty status. Veterans possibly exposed to nerve agents released by the Khamisyah demolition were not found to be at increased risk for hospitalizations from most chronic diseases nearly 10 years after the Gulf War. Only two of 37 models suggested that personnel possibly exposed to subclinical doses of nerve agents might be at increased risk for hospitalization from circulatory diseases, specifically cardiac dysrhythmias.

In 2005, Bullman *et al.* (2005) reported the results of a mortality study of troops exposed to chemical warfare agents based on the air plume models that were developed after the detonation. The cause-specific mortality of 100,487 exposed veterans was compared with that of 224,480 unexposed US Army Gulf War veterans. The risks for most disease-related mortality were similar for exposed and unexposed veterans. However, exposed veterans had an increased risk of brain cancer deaths (relative risk = 1.94; 95% CI = 1.12, 3.34). The risk of brain cancer death was larger among those exposed 2 or more days than those exposed 1 day when both were compared separately to all unexposed veterans.

This same team of investigators also conducted a study to examine the association of exposure to the Khamisyah plume with subsequent self-reported morbidity (Page *et al.*, 2005). The study sample included 1,056 deployed Army Gulf War veterans who responded to the 1995 National Health Survey of Gulf War Era Veterans and who were resurveyed in 2000. One-half of the subjects had been notified of potential exposure to chemical warfare agents and one-half had not. Comparing notified and nonnotified subjects, there were no statistically significant differences with respect to bed days, activity limitations, clinic visits, or hospital visits. Among 71 self-reported medical conditions and symptoms, there were five statistically significant differences, four of which were for lower rates of illness among notified subjects.

Page and colleagues also published a similar study undertaken to investigate whether possible chemical warfare exposure was associated with morbidity among Army Gulf War veterans using morbidity data for 5,555 Army veterans who were deployed to the Gulf region (Page *et al.*, 2005). Responses to 86 self-assessed health measures, as reported in the 1995 Department of Veterans Affairs National Health Survey of Gulf War Era Veterans, were evaluated. They found little association between potential exposure and health, after adjustment for demographic variables. The investigators concluded that potential exposure to sarin or cyclosarin at Khamisyah did not seem to have adversely affected self-perceived health status, as evidenced by a wide range of health measures.

More recently, Heaton examined the association between modeled estimates of sarin/cyclosarin exposure levels and volumetric measurements of gross neuroanatomical structures in 1991 Gulf War veterans with varying degrees of possible low-level sarin/cyclosarin exposure (Heaton *et al.*, 2007). Twenty-six GW-deployed veterans recruited from the Devens Cohort Study participated. Magnetic resonance images of the brain were acquired and analyzed using morphometric techniques, producing volumetric measurements of white matter, gray matter, right and left lateral ventricles, and cerebrospinal fluid. Volumetric data were analyzed using exposure estimates obtained from refined models of the 1991 Khamisyah presumed exposure hazard area. No differences were observed in the 13 ''exposed'' veterans when compared to 13 ''non-exposed'' veterans in volumetric measurements of discrete brain tissues. However, linear trend analyses showed a significant association between higher levels of estimated sarin/cyclosarin exposure and both reduced white matter (adjusted parameter estimate = 4.64, $p < 0.0001$) and increased right lateral ventricle (adjusted parameter estimate = 0.11, $p = 0.0288$) and left lateral ventricle (adjusted parameter estimate = 0.13, $p < 0.0001$) volumes. These findings suggest subtle but persistent central nervous system pathology in Gulf War veterans potentially exposed to low levels of sarin/cyclosarin.

This investigative team also compared previous neurobehavioral performance results collected prior to notification of veterans who were potentially exposed in the Khamisyah detonation (Proctor *et al.*, 2006). They hypothesized the exposure to sarin and cyclosarin would be associated with poorer performances on objective neurobehavioral tasks in specific functional domains (particularly in visuospatial abilities and psychomotor functioning) in a dose-dependent manner. They found that sarin and cyclosarin exposure was significantly associated with less

proficient neurobehavioral functioning on tasks involving fine psychomotor dexterity and visuospatial abilities 4–5 years after exposure. They concluded that the findings suggest a dose–response association between low-level exposure to sarin and cyclosarin and specific functional central nervous system effects 4–5 years after exposure.

VII. TERRORISM

Two terrorist attacks with the nerve agent sarin affected populations in Matsumoto and Tokyo, Japan, in 1994 and 1995 killing 19 and injuring more than 6,000. Morita *et al.* (1995) described the acute effects including instantaneous death by respiratory arrest in four victims in Matsumoto. In Tokyo, two died in station yards and another ten victims died in hospitals within a few hours to 3 months after poisoning. Six victims with serum cholinesterase (ChE) below 20% of the lowest normal were resuscitated from cardiopulmonary arrest (CPA) or coma with generalized convulsion. Five recovered completely and one remained in a vegetative state due to anoxic brain damage. EEG abnormalities were observed for up to 5 years in certain victims. Miosis and copious secretions from the respiratory and gastrointestinal tracts (muscarinic effects) were common in severely to slightly affected victims. Weakness and twitches of muscles (nicotinic effects) appeared in severely affected victims. Neuropathy and ataxia were observed in a small number (less than 10%) of victims, in which findings disappeared between 3 days and 3 months. Leukocytosis and high serum CK levels were common. Hyperglycemia, ketonuria, low serum triglyceride, and hypopotassemia were observed in severely affected victims, in which abnormalities were attributed to damage of the adrenal medulla.

The Matsumoto Japanese government assembled a committee of city government, local hospitals and physicians from Shinsu University to monitor the immediate and long-term effects of the exposure, resulting in the most comprehensive epidemiological studies of acute and residual effects of exposure to chemical warfare agents. Three weeks after the attack, community residents ($n = 2{,}052$) residing in an area within 1,000 to 850 m of the attack were surveyed and categorized as severely affected (admitted to the hospital), moderately affected if treated in outpatient clinics, and slightly affected if they had symptoms but did not seek medical attention. At the time of this follow-up survey, 28% of the affected residents remained symptomatic (69% of the severely affected, 42% of the moderately affected, and 14% of the slightly affected). The most frequent persisting symptoms were fatigue, dysesthesia of extremities, and ocular pain. Visual problems continued in about 10% of severely affected victims (Yanagisawa *et al.*, 2006).

In the Tokyo subway attack, 640 victims were seen within hours of the incident. Five were critically injured and required mechanical ventilation. One hundred and seven were moderately injured with systemic symptoms and signs of respiratory, digestive, and/or neurological systems in addition to ocular signs. The large majority ($n = 528$) had only eye signs or symptoms and were released after several hours of observation (Yanagisawa *et al.*, 2006).

There have been a number of investigations of the health of the survivors of the Tokyo subway attack. Yokoyama *et al.* (1998) conducted a study of 18 victims 6–8 months after the attack. At that time the mean plasma ChE was 72.1, lower than the ''normal'' range of 100–250 IU/l. In neurobehavioral testing at that time, sarin cases had significantly lower scores on the digit symbol test than the control group. Scores on the General Health Questionnaire and fatigue were significantly higher in the victims and PTSD scores were also increased. Postural balance was also different in victims suggesting that integration of visual input might have been impaired. P300 and VEP (P100) latencies in the sarin cases were significantly prolonged compared with the matched controls (Murata *et al.*, 1997). In the sarin cases, the CVRR was significantly related to serum ChE levels determined immediately after exposure; the PTSD score was not significantly associated with any neurophysiological data despite the high PTSD score in the sarin cases. These findings suggest that asymptomatic sequelae to sarin exposure, rather than PTSD, persist in the higher and visual nervous systems beyond the turnover period of ChE.

The National Police Academy (1999) conducted a survey of 1,247 residents who reported to the Police Department that they had contact with sarin at the incident. More than half complained of physical symptoms, such as asthnopia and decrease in visual acuity. Seventeen percent reported psychological trauma from the event with 14% still unable to ride on subways 3 years after the incident.

There continued to be follow-up studies indicating the residual effects of the attack. Ohtani *et al.* (2004) followed 34 victims 5 years after the attack. Not only PTSD but also nonspecific mental symptoms persisted in the victims at a high rate. A total of 11 victims were diagnosed with current or lifetime PTSD. Victims with PTSD showed higher anxiety levels and more visual memory impairment.

Yamasue *et al.* (2007) conducted a 5 year follow-up study to identify persistent morphological changes subsequent to the attack. Thirty-eight victims of the sarin attack, who had been treated in the emergency department for sarin intoxication and 76 matched health control subjects underwent weighted and diffusion tensor magnet resonance imaging. ChE values were compared to levels immediately after the attack. The voxel-based morphometry exhibited smaller than normal regional brain volumes in the insular cortex and neighboring white matter, as well as in the hippocampus in the victims. The reduced regional white matter volume correlated with decreased serum cholinesterase levels and with the severity of chronic somatic complaints related to interoceptive awareness.Voxel-based

analysis of diffusion tensor magnetic resonance imaging further demonstrated an extensively lower than normal fractional anisotropy in the victims. These findings suggest that sarin intoxication might be associated with structural changes in specific regions of the human brain.

Rescue and safety workers have also been studied. Nishiwaki *et al.* (2001) studied 27 male rescue team staff and 30 police officers, 3–45 months after the event. The study subjects showed decreased performance on the digit span test; however, no effects on stabilometry and vibration perception threshold were found. Li *et al.* (2004) followed 27 male firefighters and 25 male police officers three years after the attack for genotoxic effects. They found an elevated frequency of sister chromatid exchanges in lymphocytes of the victims which were related to the percentage of ChE inhibition observed just after the attack.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

This chapter described the major epidemiological studies of populations who have been exposed to chemical warfare agents. Many of the studies of military populations have suffered from inaccurate exposure assessment and lack of clinical data. The studies in the past decade of the survivors of the sarin terrorist attacks provide the most comprehensive data to date on the scope of health outcomes associated with these exposures. These reports point to the need for long-term follow-up studies of victims following such events. The data from the terrorist events and the Gulf War when many troops believed they were exposed to chemical agents point to the prevalence of PTSD associated with real or threatened exposure.

CHAPTER 6

Organophosphate Nerve Agents

ANNETTA WATSON, DENNIS OPRESKO, ROBERT YOUNG, VERONIQUE HAUSCHILD, JOSEPH KING, AND KULBIR BAKSHI

I. INTRODUCTION

The chemical warfare (CW) nerve agents primarily addressed in this chapter include the anticholinesterase nerve agents tabun (GA), sarin (GB), soman (GD), cyclosarin (GF), and VX, all of which are, or have been, part of the US domestic munitions inventories (Carnes, 1989; NRC, 1999; Opresko *et al.*, 1998). Russian VX (often represented as VR) will be evaluated in the following chapter by Radilov *et al.* (2009). Other, less well-characterized nerve agents such as compound GE, VG (Amiton™) or V_x will be evaluated as data allow.

These agents are potent anticholinesterase compounds deliberately formulated to induce debilitating effects or death during wartime hostilities and have been used by military authorities of several nations to develop munitions (e.g. Germany during the Nazi era, the USA, the former Soviet Union). US military stockpiles of CW munitions manufactured as a Cold War deterrent decades ago await demilitarization at designated stockpile sites and have been the subject of extensive emergency preparedness and response planning. Additional planning has been necessary at other current and formerly used military sites where containers, buried munitions, etc., have been inventoried (the ''nonstockpile'' sites) (NRC, 2003, 1999; Opresko *et al.*, 1998). More recent global events have focused attention on the potential threat of chemical terrorism, especially at transportation hubs (Tucker and Raber, 2008). The deliberate release of nerve agent sarin at lethal concentrations in the Japanese cities of Matsumoto (1994) and Tokyo (1995) by a Japanese domestic terrorist group has illustrated that such attacks can be a reality and require advance emergency preparedness planning (Morita *et al.*, 1995; Okumura *et al.*, 1996, 2007; Sidell, 1996; Yangisawa *et al.*, 2006; Cannard, 2006; Tu, 2007).

Information provided on agent toxicity, risk assessment, treatment options, and other related topics will be useful to communities and facilities developing and updating emergency preparedness plans for accidental or intentional release of nerve agents; this information can also be used to support environmental decision-making where nonstockpile materiel - military gear has been found. In response to various Public Laws and international agreements such as the Chemical Weapons Convention (PL 99-145, 1986; PL 102-484, 1993; CWC, 1997), existing emergency guidance and military policy documents currently reflect the identified criteria and information (e.g. CSEPP, 2003, 2006a, b; NRT, 2008; OASA, 1999).

While there are different applications for the information provided in this evaluation, in general the toxicological focus for emergency preparedness and response applications is that of acute exposures associated with a one-time release. Typically, the scenarios considered include a single-source airborne release either from an intentional terrorist attack or accident involving an agent container or munition from a military site. It is widely recognized that vapor inhalation is the exposure route of greatest concern for such an event (ATSDR, 2007; Sidell, 1997). In contrast, the toxicological focus of environmental site remediation plans for military installations and formerly used defense sites where buried chemical warfare agent residues may occur requires consideration of long-term release and potential incidental ingestion of media such as soil particles or water with relatively low levels of contamination. To reflect these critical applications and information needs, the current evaluation will also primarily focus on

- single-source, one-time nerve agent releases and exposure routes involving agent vapor inhalation or direct ocular vapor exposures, and
- long-term (chronic or subchronic) exposure from residual nerve agent contamination.

It is acknowledged that there exists a rich and valuable body of repeat-exposure studies employing serial vapor or serial injection exposures for the nerve agents soman (GD), sarin (GB) and VX (please see recent excellent reviews and analyses in Shih *et al.*, 2006; McDonough and Romano, 2008 as well as recent experimental studies by Dabisch *et al.*, 2005, 2007a); the interested reader is encouraged to examine these and related resources, as the current evaluation does not highlight experiments that apply serial exposure protocols.

II. BACKGROUND

A. Development of Organophosphate Formulations as Chemical Warfare Agents

The G-series nerve agents evaluated are all toxic ester derivatives of phosphonic acid containing either a cyanide

(GA) or fluoride (GD, GE, GF) substituent and are commonly termed ''nerve'' agents as a consequence of their anticholinesterase properties as well as their effects on both the peripheral nervous system (PNS) and central nervous system (CNS). The ''G'' series military nomenclature used by NATO member nations has historically been considered to be an abbreviation for ''German'', with the second letter of the code (''A'', ''B'', etc.) identifying the order in which these compounds were found and analytically identified by Allied forces investigating materials found in captured German military facilities at the close of WWII (Sidell, 1997). Agent VX, a phosphonic acid ester with a sulfur substituent, was industrially synthesized in the United Kingdom in the early 1950s; the code letter ''V'' is a reported reference to ''venom'' (Sidell, 1997). Other, less well-characterized V-series compounds include V_x, VE, VM, and VG (trade name Amiton™ when commercially introduced as a miticide in the mid-1950s).

As Cold War deterrents, nerve agents began to be manufactured and weaponized by the USA in the 1950s. When the US chemical warfare agent production program was terminated by the Nixon presidential ''Statement on Chemical and Biological Defense Policies'' of November 1969 (National Security Decision Memorandum 35), the US stockpile of unitary munitions included bulk (''ton'') containers, underwing spray tanks, projectiles, rockets, bombs, land mines, and rockets (Carnes, 1989; Sidell, 1997). Nerve agent unitary munitions contained either GA, GB, or VX. The US chemical warfare agent munition stockpile is obsolete, and is presently undergoing destruction and disposal by the US Army Chemical Materials Agency (see www.cma.army.mil) at each of the several unitary stockpile sites for compliance with the Chemical Weapons Convention (CWC) and to eliminate the risk of continued storage for these aging CW munitions; current nerve agent stockpile sites are located in Alabama, Arkansas, Indiana, Kentucky, Oregon, and Utah. In December 2008, the US Army Chemical Materials Agency announced that 58% of the US unitary chemical munitions stockpile had been successfully destroyed.

B. Physical and Chemical Properties of Nerve Agents

The G-agents are all viscous liquids of varying volatility (vapor density relative to air between 4.86 and 6.33) with faint odors (''faintly fruity'', or ''spicy'', ''odor of camphor''). Agent VX is an amber-colored liquid with a vapor density of 9.2, and is considered odorless. Thus, nerve agent vapors possess little to no olfactory warning properties (Table 6.1).

The vapor pressures and acute toxicity of these agents are sufficiently high for the vapors to be rapidly lethal. Within the G-series, GB is considered to present the greatest vapor hazard (order of vapor hazard approximates GB > GD > GF > GA). Agent VX was deliberately formulated to possess a low volatility; VX is approximately 2,000 times less volatile than nerve agent GB (DA, 1990a, b). As a consequence, agent VX is considered a persistent, ''terrain denial'' military compound with the potential to be a contact hazard or generate off-gas toxic vapor concentrations over a period of days following surface application particularly under cold weather conditions or when bulk-release quantities of liquid agent are involved. While not readily volatile, VX vapors (if allowed to accumulate) are nevertheless considered more acutely potent than those of agent GB or the other G-series agents (Mioduszewski *et al.*, 1998).

As a consequence of the volatilities exhibited by G-series nerve agents (Table 6.1), the most likely exposure route (and source of primary hazard) is via direct vapor exposure to the eyes and upper respiratory tract tissues, and vapor inhalation (with consequent systemic absorption) (Dabisch *et al.*, 2008a; Cannard, 2006); G-agents are considered ''nonpersistent'' as per definitions employed by the US Department of Defense (DOD, 2008). Nerve agent VX is widely considered to present a greater threat from the percutaneous exposure route (when compared to the G-series agents) as well as a vapor inhalation threat at elevated ambient temperatures (e.g. >40°C; Benton *et al.*, 2005, 2006a; Craig *et al.*, 1977; Sidell, 1997).

Nerve agent V_x exhibits volatility (76.4 mg/m^3 at 25°C) intermediate to that of agents GA and VX, and a vapor density (7.3) intermediate to that of agents GF and VX; V_x is also considered ''persistent''. There are few data from which to characterize nerve agents VE (*O*-Ethyl-*S*-[2-(diethylamino) ethyl]ethylphosphonothioate, CAS No. 21738-25-0) or VM (*O*-Ethyl-*S*-[2-(diethylamino)ethyl]-methylphosphonothioate, CAS No 21770-86-5).

III. MECHANISM OF ACTION

All of the nerve agents under consideration are anticholinesterase compounds and induce accumulation of the neurotransmitter acetylcholine (ACh) at neural synapses and neuromuscular junctions by phosphorylating acetylcholinesterase (AChE). Depending on the route of exposure and amount absorbed, the PNS and/or CNS can be affected and muscarinic and/or nicotinic receptors may be stimulated. Interaction with other esterases may also occur, and direct effects to the nervous system have been observed.

Exposure to acutely toxic concentrations of nerve agents can result in excessive bronchial, salivary, ocular and intestinal secretions, sweating, miosis, bronchospasm, intestinal hypermotility, bradycardia, muscle fasciculations, twitching, weakness, paralysis, loss of consciousness, convulsions, depression of the central respiratory drive, and death (Grob and Harvey, 1953; Grob, 1956; Marrs, 2007; Sidell, 1997; Yanagisawa *et al.*, 2006; many others). Minimal effects observed at low vapor concentrations

include miosis (contraction of the pupils of the eye, with subsequent decrease in pupil area), tightness of the chest, rhinorrhea, and dyspnea (Dunn and Sidell, 1989; Dunn *et al.*, 1997). Pupillary contraction, resulting in varying degrees of miosis characterized by measures of pupil diameter, is consequent to local inhibition of ocular AChE activity with pupillary sphincter contraction (Dabisch *et al.*, 2007b, 2008a, b).

Reactivation of inhibited cholinesterase by dephosphorylation is not possible once the nerve agent–cholinesterase complex undergoes ''aging'', which is thought to be the consequence of the loss of an alkyl or alkoxy group. Agent GD ages very rapidly when bound to red blood cell cholinesterase (RBC–ChE), with a $t_{1/2}$ (time required for 50% of the enzyme to become resistant to reactivation) of 1.3 min (Harris *et al.*, 1978). The aging half-time for agent GA with RBC–ChE is 46 h (calculated; De Jong and Wolring, 1978), and the $t_{1/2}$ for agent GB with RBC–ChE is 5 h (Sidell and Groff, 1974). The complex formed between RBC–ChE and agent VX does not age significantly (half-life of approximately 48 h) (Sidell and Groff, 1974; Dunn *et al.*, 1997).

A. Direct Nervous System Effects

Although nerve agents exert toxic effects on the CNS and PNS indirectly through AChE inhibition (Koelle, 1975, 1981), nerve agents may also affect nerve impulse transmission by additional mechanisms at neuromuscular junctions (see reviews by Somani and Husain, 2001; Marrs, 2007) and at neurotransmitter receptor sites in the CNS. Rao *et al.* (1987) reported that VX caused an increase in ACh release at neuromuscular junctions in the frog by an interaction with the nicotinic ACh receptor–ion channel complex. Aas *et al.* (1987) reported alterations in muscarinic receptors in rat bronchi and lung tissue after subacute inhalation exposures to agent GD. In the CNS, nerve agents may act directly on muscarinic, nicotinic, and glutamate receptors in manners unrelated to cholinesterase inhibition (Bakry *et al.*, 1988; Chebabo *et al.*, 1999; Lallement *et al.*, 1991a, b; Rocha *et al.*, 1998, 1999). Chebabo *et al.* (1999) reported that 0.3–1 nM of agent GB reduced the amplitude of GABA-mediated postsynaptic currents (GABA; neurotransmitter γ-aminobutyric acid), but had no effect on the amplitude of glutamatergic-mediated postsynaptic currents; this selective reduction in action potential-dependent release of GABA might account for GB-induced seizures. Lallement *et al.* (1991a, b) had earlier suggested that GD-induced overstimulation of glutamatergic receptors contributed to maintenance of seizures.

Although these electrophysiological data indicate that nerve agents may have direct effects on the nervous system unrelated to AChE inhibition, the data do not provide a means of determining a dose conversion to an integrative whole-body endpoint such as lethality or qualitative/quantitative comparisons directly relevant to adverse effects.

It should be further noted that the effects of nerve agents on GABAergic transmission in the CNS may have implications for behavioral effects in laboratory animals and humans, and may also contribute to the induction of convulsions at higher doses (Bakshi *et al.*, 2000). Nevertheless, given the present undefined application of non-cholinergic data to whole-body estimations, reliance on the primary assumption of AChE action is consistent with recognized opinion (Bakshi *et al.*, 2000).

B. Binding with Blood Cholinesterases

The activity of red blood cell cholinesterase (RBC–ChE), as well as that of plasma cholinesterase (plasma–ChE, BuChE or butyrylcholinesterase), has been used to monitor exposure to, and recovery from, anticholinesterase pesticides as well as nerve agents. There is some historical evidence that RBC–ChE can be as sensitive as brain–ChE to the anticholinesterase effects of nerve agents; Grob and Harvey (1958) reported that *in vitro* concentrations producing 50% activity depression of brain–ChE and RBC–ChE were equivalent in the case of GA (1.5×10^{-8} mol/l), and comparable in the case of GB (3.0×10^{-9} vs 3.3×10^{-9} mol/l). The *in vivo* animal studies conducted by Jimmerson *et al.* (1989) disagree, which is further supported by the fact that blood ChE activity may not always be correlated with exposure or with signs and symptoms of toxicity (Holmstedt, 1959; Sidell, 1992, 1997) (Table 6.2). This was also observed during clinical treatment of cases following the Matsumoto and Tokyo chemical terrorist incidents of GB exposure to the public (Yanagisawa *et al.*, 2006; Nozaki *et al.*, 1997).

It is generally considered that systemic effects in humans following acute nerve agent exposures are likely when RBC–ChE is inhibited by 75–80% (e.g. to 20–25% of normal activity levels) (Sidell, 1992). Nevertheless, it is well known that local signs and symptoms of the eye and nose in humans and animals (e.g. miosis, rhinorrhea) can occur in the absence of any measurable change from baseline ChE activity in the blood following vapor or aerosol nerve agent exposure (Harvey, 1952; Craig and Woodson, 1959; Sidell, 1992) and are attributable to the local and direct effects of agent on tissues of the eye and upper respiratory tract (Grob, 1956; Dabisch *et al.*, 2008a) (Table 6.2). When systemic exposure (e.g. other than direct ocular or direct nasal) occurs, miosis and rhinorrhea are not usually observed as first noticeable effects (Dabisch *et al.*, 2008a; NRC, 2003).

EPA science policy guidelines regarding use and application of cholinesterase activity inhibition data generally consider blood ChE activity inhibition to be an imperfect measure, and there appears to be no fixed percentage of blood ChE activity change that can distinguish adverse from nonadverse effects (USEPA, 2000; Storm *et al.*,

2000). A number of investigations have noted the poor association between blood (RBC and plasma) cholinesterase activity and nerve agent intoxication (Koelle, 1994; Sidell, 1992, 1997; Rubin and Goldberg, 1957; Mioduszewski *et al.*, 2002a; Yanagisawa *et al.*, 2006; Cannard, 2006); minimal blood ChE activity has been observed in association with normal tissue function (Sidell, 1992). In a clinical situation, measurement of blood ChE activity has forensic utility and is helpful as a measure of recovery, but is not a quantitative measure of absorbed dose (Cannard, 2006).

C. Binding with Other Enzymes

Nerve agents also interact with detoxification enzymes such as carboxylesterases (CarbE) and A-esterases (e.g. arylesterase and paraoxonase), and the degree of such interaction can alter the magnitude and extent of the toxic cascade following AChE inhibition (Pope, 1999; Pope and Liu, 2002; Fonnum and Sterri, 2006) as well as species-specific characteristics. Observed spontaneous reactivation of soman-inhibited plasma CarbE in the rat indicates that ''aging'' does not occur for the GD–plasma CarbE complex (in contrast to that observed for GD and RBC–ChE; Dunn *et al.*, 1997) and further suggests that endogenous plasma CarbE may be a principal functional scavenger for agent GD (Maxwell and Brecht, 2001). Recent studies indicate that full characterization of the OP-protective capabilities of CarbEs requires assessment not only of the amount, but also of the affinity exhibited by CarbEs for the inhibitor, as well as the total CarbE activity unlikely to be inhibited (inhibitor resistant esterase activity, or IRE) (Chanda *et al.*, 2002). The detoxification potential of CarbEs is multifaceted, and is an area requiring further experimental characterization (Fonnum and Sterri, 2006).

IV. TOXICITY

A. Effects

Nerve agents are toxic anticholinesterase compounds by all routes of exposure, and exhibit a steep dose–response. Detailed descriptions of nerve agent toxicity may be found in reviews by Bakshi *et al.* (2000), NRC (1999, 2003), Mioduszewski *et al.* (1998), Marrs (2007), Opresko *et al.* (1998), Sidell (1997), Somani and Husain (2001), Munro *et al.* (1994), and others.

Anticholinesterase effects of nerve agent exposure can be characterized as muscarinic, nicotinic, or CNS. Muscarinic effects occur in the parasympathetic system and, depending on the amount absorbed, can be expressed as conjunctival congestion, miosis, ciliary spasm, nasal discharge, increased bronchial secretion, bronchoconstriction, anorexia, emesis, abdominal cramps, sweating, diarrhea, salivation, bradycardia, and hypotension. Nicotinic effects are those that occur in somatic (skeletal/motor) and sympathetic systems, and can be expressed as muscle fasciculations and paralysis. CNS effects may be manifested as confusion, reflex loss, anxiety, slurred speech, irritability, forgetfulness, depression, impaired judgment, fatigue, insomnia, depression of central respiratory control, and death (Sidell, 1992, 1997; Sidell and Groff, 1974; Opresko *et al.*, 1998; Bakshi *et al.*, 2000). Minimal effects observed at low concentrations in human subjects include miosis, a feeling of ''tightness'' in the chest, rhinorrhea, and dyspnea (Dunn and Sidell, 1989) (Table 6.2).

While RBC–ChE inhibition in the blood is considered an operationally acceptable surrogate for CNS inhibition, plasma ChE is more labile and is a less reliable reflection of enzyme activity change at neuro-effector sites (USEPA, 2000; Young *et al.*, 1999).

In the whole-body agent vapor exposure studies of Mioduszewski *et al.* (2002a; SD rat single exposures to GB vapor) and Benton *et al.* (2006a; SD rat single exposures to VX vapor), miosis was usually not correlated with or accompanied by reductions of circulating AChE, BuChE, or CarbE. For the VX vapor exposure study of Benton *et al.* (2006a) and among those rats exhibiting only one sign (either whole-blood AChE activity inhibition or miosis), miosis developed in the absence of blood AChE activity depression ''90% of the time''. The findings of Mioduszewski *et al.* (2002a) for SD rats are consistent with those for human volunteers exposed to GB vapor in the study of Rubin and Goldberg (1957). These results further document the fact that miosis alone, and in the absence of signs such as ChE or CarbE activity inhibition, is a local effect, and reflects an exposure much less than that required for generation of systemic clinical effects. Thus, consideration of a local effect such as miosis as a critical endpoint for decision criteria and exposure guideline determination allows a useful margin of protection against the potential for agent exposures sufficiently large so as to generate systemic effects.

B. Minimal Potential for Delayed Neuropathy

A continuing area of public concern regarding nerve agent exposure is the possibility of chronic neurological effects, particularly delayed neuropathy, given that neuropathic effects have been observed following high levels of occupational exposure to the lipophilic agricultural pesticides. Exposure to some OP anticholinesterase compounds results in delayed neurotoxic effects (ataxia, distal neuropathy, paralysis), which are collectively described as organophosphate-ester induced delayed neuropathy (OPIDN). OPIDN is characterized by myelin sheath and axon degeneration and was once thought to be the consequence of inhibition and aging of neuropathy (or neurotoxic) target esterase (NTE) (Abou-Donia, 1993; Ehrich and Jortner, 2002). With greater knowledge and recent data pointing out that NTE-knockout mice may also develop OPIDN

TABLE 6.2. Human experimental data for single exposures to GB vapor[a]

Concentration (mg/m^3)	Exposure duration	Ct ($mg\text{-}min/m^3$)	Signs and symptoms	Reference
0.05	20 min	1	Headache, eye pain, rhinorrhea, tightness in chest, cramps, nausea, malaise	Harvey (1952)
0.05	20 min	1	Threshold (<1 mm pupil diameter decrease) to mild (1–2 mm pupil diameter decrease) miosis[b] in test subjects	Johns (1952)
0.06	20 min	1.2	No reported effects	McKee and Woolcott (1949)
0.06	40 min	2.4	Miosis; slight tightness in chest ($n = 4$)	McKee and Woolcott (1949)
0.3	0.5 min	0.15	Rhinorrhea in 16/16; chest tightness in 7/16	Fairley and Mumford (1948)
0.5	30 min	15.0	Miosis, dyspnea, photophobia, 40% inhibition of RBC–ChE, subclinical SFEMG[c] changes	Baker and Sedgwick (1996)
0.6	1 min	0.6	Miosis and slight tightness in chest	McKee and Woolcott (1949)
2	2 min	4	Miosis ''moderate''; no other signs of ChE inhibition	Rubin *et al.* (1957)
NA	10 min to 5 h	3.13	50% pupil area decrement	Callaway and Dirnhuber (1971)
NA	10 min to 5 h	13.85	90% pupil area decrement	Callaway and Dirnhuber (1971)
4.19 (average)	2 min	8.38	Average 47% inhibition of RBC–ChE; no other effects (breathing rate 5.6–8.4 l/min through nose or mouthpiece)	Oberst *et al.* (1968)
20.7 (average)	2 min	41.4	Average 49% inhibition of RBC–ChE; no other effects (breathing rate 47–65 l/min through nose or mouthpiece)	Oberst *et al.* (1968)
2.8–4.3	1–2.25 min	4.5–5.0	Miosis of unprotected (unbandaged)[d] eyes of 10 military servicemen; min pupil size of 1.8 mm	Sim (1956)
4.0–4.5	2–2.25 min	8.3–9.8	Miosis of unprotected (unbandaged)[d] eyes of 22 military servicemen; min pupil size of 1.6 mm	Sim (1956)
9.5	1 min, 3 s	10	Miosis of unprotected (unbandaged)[d] eyes of 12 military servicemen; min pupil size of 1.7 mm	Sim (1956)
5.5–7.6	1.75–2.5 min	13.1–15.4	Miosis of unprotected (unbandaged)[d] eyes of 54 military servicemen; min pupil size of 1.5 mm	Sim (1956)
12.8–15.3	1–1.2 min	14.4–15.0	Miosis of unprotected (unbandaged)[d] eyes of 38 military servicemen; min pupil size of 1.5 mm	Sim (1956)

[a]Adapted from NRC (2003) with permission by the National Academy of Sciences, courtesy of the National Academies Press, Washington DC
[b]Mild miosis defined by Johns (1952) as ''decrease of 1 to 2 mm'' in pupil diameter; reversible within 24 h.
[c]Single fiber electromyography (SFEMG)
[d]Note that a similar experimental exposure protocol employed by Sim (1956) for subjects with bandaged eyes (''protected'') resulted in no clinical miosis in any subject

(Abou-Donia, 2003; Winrow *et al.*, 2003; O'Callahan, 2003), the NTE theory has been replaced with one involving a noncholinergic, proteolytic mechanism involving cytoskeletal proteins found in neurofilaments (De Wolff *et al.*, 2002). The resulting proteolysis, accompanied by perturbed ionic gradients, cellular edema, and myelin debris, can generate neuropathy.

A number of well-conducted studies employing USEPA guidelines for experimental determination of delayed neurotoxicity (USEPA, 1998) have been performed for the G-agents and agent VX (Gordon *et al.*, 1983; Willems *et al.*, 1984; Goldman *et al.*, 1988; Wilson *et al.*, 1988). The USEPA protocol requires toxicological testing with the domestic hen, an OPIDN-sensitive laboratory animal. In general, exposure to the standard threat nerve agents (e.g. GA, GB, GD, GF, VX) is not considered neuropathic in humans (Marrs, 2007) given that (1) agent VX is not neuropathic in standard challenge tests with hens and (2) G-agent concentrations necessary to induce OPIDN would be supralethal, and human survival would be highly unlikely.

C. Evaluation of Other Potential Effects

Animal data from vapor, oral, and injection exposure studies for the G-series nerve agents and agent VX indicate that these agents do not induce reproductive or developmental effects in mammals (Denk, 1975; LaBorde and Bates, 1986; LaBorde *et al.*, 1996; Bucci *et al.*, 1993; Bates *et al.*, 1990; Schreider *et al.*, 1984, 1988; Goldman *et al.*, 1988; Van Kampen *et al.*, 1970). Incidental data from the Tokyo subway incident (Ohbu *et al.*, 1997) documenting the birth of healthy children to women who had received exposures to toxic GB concentrations at 9–36 weeks' gestation support this finding.

Neither agent GB nor agent VX was genotoxic in a series of microbial and mammalian assays (Goldman *et al.*, 1987, 1988; Crook *et al.*, 1983), while agent GA has been reported to be weakly mutagenic in similar cellular assays (Wilson *et al.*, 1994). Experimental results indicate that agents GB, GA, and VX have no carcinogenic potential (Weimer *et al.*, 1979; Bucci *et al.*, 1992a, b; Goldman *et al.*, 1988).

D. Inhalation/Ocular Toxicity in Human Subjects

It is noted that the most complete experimental data set for the nerve agents evaluated in all species is that for agent GB; the following analysis reflects that emphasis (Table 6.2). Human study reports evaluated have been previously judged by the US Environmental Protection Agency National Advisory Committee for Acute Exposure Guideline Levels for Hazardous Substances and the National Research Council (NRC) Committee on Toxicology to be consistent with acceptable criteria and procedures regarding informed consent and appropriate clinical supervision (NRC, 2001, 2003).

1. Agent GB

Fairley and Mumford (1948) exposed 16 male volunteers to 0.3 mg GB/m^3 for 0.5 min. Nine of the test subjects reported that they could detect the agent by smell; seven reported tightness of the chest and 16 reported rhinorrhea.

McKee and Woolcott (1949) evaluated the effects of low concentrations of agent GB on 14 male volunteers. A single exposure to 0.6 mg GB/m^3 for 1 min, or 0.06 mg GB/m^3 for 40 min resulted in miosis and slight tightness of the chest; within 24 h, signs and symptoms resolved in subjects exposed for 1 min, while more than 48 h was required for resolution in subjects exposed for 40 min.

In a study reported by Harvey (1952), 128 adult male volunteers were exposed in a chamber to GB concentrations ranging from 0.05 to 3.0 mg/m^3 for 2 to 20 min. The corresponding cumulative exposures ranged from 1.0 to 6.0 mg-min/m^3. The most common signs and symptoms resulting from the GB exposures were headaches, eye pain, rhinorrhea, tightness in the chest, cramps, nausea, and concentration difficulties.

When evaluating data from the Harvey (1952) study, Johns (1952) reported on the occurrence of miosis in exposed individuals. Regression analysis of 150 observations, including 55 controls, indicated that the concentration at which a 50% decrease in pupil diameter would be attained was approximately 4.1 mg-min/m^3, with 90% confidence limits of about 2.7 and 5.7 mg-min/m^3. Johns (1952) defined ''mild miosis'' as a ''decrease of 1 to 2 mm'' in pupil diameter, which usually disappeared within 24 h. While mild miosis as defined above was observed in some subjects at the lowest Ct tested (Ct = 1.0 mg-min/m^3), other subjects exhibited mean maximal pupil decreases of <1 mm, indicating attainment of a response threshold at this level of exposure. Untreated controls exhibited a pupil diameter decrease of ≥ 0.33 mm; Johns (1952) attributed this difference to observer bias and pointed out that there was still a relative difference between the control group and the exposed groups.

Oberst *et al.* (1968) conducted inhalation studies in which 125 volunteers were exposed to low concentrations of GB vapor in order to measure levels of GB retention and changes in RBC–ChE activity. In one series of tests in which resting subjects were exposed to GB for 2 min, the calculated retained dose was 3.4–3.8 µg/kg and the percent inhibition of RBC–ChE activity was 39–63% (average 49%). In a second series of tests, in which exercising men were exposed to GB for 2 min, the calculated retained dose was 3.2–4.0 µg/kg and the percent inhibition of RBC–ChE activity was 29–58% (average 47%). The reported 2 min ChE_{50} dose for all 125 subjects (grouped data) was 3.95 µg GB/kg. From these data, the 2 min EC_{50} for cholinesterase inhibition can be estimated as approximately 21 mg/m^3 for resting men breathing about 7 l/min and about 4 mg/m^3 for exercising men breathing about 50 l/min.

Baker and Sedgwick (1996) exposed eight human volunteers to 0.5 mg GB/m^3 for 30 min in a chamber; test subjects walked at a rate of 96 paces per minute while breathing normally. The exposure resulted in a 60% inhibition of RBC–AChE activity; subjects exhibited miosis, some photophobia and mild dyspnea. Respiratory symptoms resolved within minutes and the ocular effects within 48 h post-exposure. There were no clinical neuromuscular signs or symptoms; however, small and non-clinical changes in single fiber electromyography (SFEMG) of the forearm were measured at 3 h and 3 days post-exposure; SFEMG changes were not detectible 15–30 months post-exposure.

The results of agent GB vapor exposure studies conducted with human volunteers indicate that the threshold for miosis and other minimal toxic effects falls in the range of 0.05–0.5 mg/m^3 for 10–30 min exposures (see Table 6.2 and summaries above).

Rubin *et al.* (1957) evaluated the effects of agent GB on the visual threshold of three adult volunteers. The test individuals were exposed to 2 mg GB/m^3 for 2 min with the eyes exposed or protected. With the eyes unprotected, the exposure resulted in moderate miosis with no other obvious signs of cholinesterase activity inhibition, but with a significant elevation of the absolute visual threshold in the dark-adapted eye.

Callaway and Dirnhuber (1971) evaluated the ''miotogenic potency'' of GB vapor in humans (62 miosis responses in 26 human volunteers). Exposure time periods ranged from 10 min to 5 h. Callaway and Dirnhuber reported 50% and 90% decrements in pupil area (Table 6.2). There are acknowledged weaknesses in the protocol and data of Callway and Dirnhuber (1971), such as limited 1970s-era capabilities for measuring agent vapor concentrations, semi-subjective protocols for measuring miosis in human eyes, and incomplete documentation of miosis incidence.

Based on human and animal data, McNamara and Leitnaker (1971) estimated that the EC_{50} for miosis in humans would be 0.0083 mg/m^3 for 8 h exposure duration or 0.0028 mg/m^3 for 24 h exposure duration. McNamara and Leitnaker (1971) did not expect miosis to occur at 0.001 mg/m^3 for 8 h or 0.0003 mg/m^3 for 24 h.

2. Agents VX and V_x

No experimental data are available for direct characterization of acute VX vapor toxicity in humans following inhalation exposure. Based on lethality data for several animal species, Bide and Risk (2000, 2004) estimated the 10 min LCt_{50} value for a VX aerosol to be 7 mg-min/m^3 for a 70 kg man breathing 15 l/min for 10 min.

One of the few experimental attempts to evaluate human exposure to VX vapor for durations greater than a few minutes is the historically important study of Bramwell *et al.* (1963) in which eight individuals were exposed to VX vapor concentrations ranging from 0.23 mg/m^3 to 5 mg VX/m^3 for durations ranging from 2.25 s to 24 min (Cts = 0.7 to 25.6 mg-min/m^3). The Bramwell *et al.* (1963) study is not considered credible because of its seriously flawed exposure protocol; both C and t were varied (resulting in no replicate cumulative exposures), and the organic solvent benzene was used to help disperse the agent in the exposure (carrier solvent may have altered agent absorption) (Reutter *et al.*, 2000).

Koon *et al.* (1959) evaluated the minimum odor detection limits of VX in 16 volunteers. Each subject sniffed the agent both in the morning and afternoon on two successive days (presumably only one sniff at each time point). The estimated total doses for the four exposures ranged from 0.01 to 0.13 μg/kg. No significant changes in RBC or plasma ChE activity were observed in the test subjects. Three subjects reported headaches the evening of the last test, and three other subjects reported slight chest tightness, dryness of the mouth, and nasal irritation for 30 min following the test.

Recent multiservice (Army, Marine Corps, Navy, and Air Force) guidance on agent-specific exposure limits estimates the VX ECt_{50} for mild toxicity in humans (miosis, rhinorrhea) to be 0.10 mg VX-min/m^3 for 2–360 min exposures (DA, 2005). The inhalation/ocular ECt_{50} for severe effects in humans (i.e. muscular weakness, tremors, breathing difficulty, convulsions, paralysis) was estimated to be 10 mg-min/m^3 for 2–360 min exposures for a respiratory minute volume of 15 l/min (DA, 2005).

Agent V_x is considered toxic via inhalation exposure or direct contact with the eye and/or skin (DA 2005), but has been poorly studied. Due to lack of data suitable for analysis, DA (2005) has determined that no toxicity estimates for V_x can be developed at this time.

E. Inhalation/Ocular Toxicity in Laboratory Species

1. G-Series Agents

a. Lethal Levels

There are considerable data on the acute lethality of G-series agents for short-term exposures (Table 6.3; see also NRC (2003) for a detailed review).

In studies conducted by Mioduszewski *et al.* (2001, 2002a), acute lethality of agent GB to male and female SD rats was evaluated for time periods of 10, 30, 60, 90, 240 and 360 min in a whole-body dynamic chamber. GB concentrations ranged from about 2 to 56 mg/m^3, and lethality was assessed at 24 h and at 14 days post-exposure. Female rats were reported to be significantly ($p < 0.01$) more sensitive than males to GB vapor toxicity over the range of exposure concentrations and durations studied.

In studies conducted by Bide and Risk (2004), male CD-1 strain mice were exposed whole body to GB for time periods ranging from 20 to 720 min. LC_{50} values for 3–12 h were progressively higher (toxicity lower) than that predicted by either Haber's rule or the Ten Berge relationship (Ten Berge *et al.*, 1986). In studies conducted by Anthony *et al.* (2004), male and female SD rats were exposed whole

body to agent GF for 10, 60 or 240 min, and lethality was assessed 24 h and 14 days post-exposure (Table 6.3). Females were more sensitive than males.

Hulet *et al.* (2006b) exposed male and female Göttingen minipigs whole body to lethal concentrations of agent GF vapor for 10, 60, or 180 min (Table 6.3). No significant gender differences were observed in the GF lethality values.

In the latter years of WWII, agent GE underwent acute inhalation toxicity characterization at a number of research facilities managed by the Office of Scientific Research and Development (National Defense Research Committee). These results, for which the research protocols and exposure concentrations are not available for comparison, were summarized by Gates and Renshaw (1946) and are provided in Table 6.3 as LCt_{50} values.

b. Sublethal Levels

A consistent endpoint for sublethal effects determination is miosis; this information is summarized in Table 6.4.

Van Helden *et al.* (2003, 2004a, b) exposed male and female marmosets (*Callithrix jacchus*, Harlan, UK) (whole body) to mean GB vapor concentrations of 0.27–0.91 μg/m^3 and male Dunkin–Hartley guinea pigs to 0.02–0.43 μg/m^3 for 5 h. The lowest cumulative exposure at which the internal dose became measurable (based on fluoride-regenerated GB from blood BuChE) was 0.04 ± 0.01 mg-min/m^3 in marmosets and 0.010 ± 0.002 mg-min/m^3 in guinea pigs.

Miosis, EEG effects, and visual evoked response (VER) were examined following 5 h exposures at concentrations ranging from 7.5 to 150 μg GB/m^3. Significant miosis (as measured by the ratio of pupil diameter to iris diameter; $p < 0.05$) was attained for marmosets and guinea pigs (Table 6.4) (Van Helden *et al.*, 2003; 2004a). Significant ($p < 0.05$) threshold change in EEG parameters for marmosets occurred at 0.2 mg-min/m^3, while significant threshold VER changes occurred at 25 mg-min/m^3 (Van Helden *et al.*, 2004b).

Mioduszewski *et al.* (2002a, b) exposed young adult (8–10 week) male and female Sprague–Dawley (SD) rats whole body to GB vapor concentrations of 0.01 to 0.48 mg/m^3 for three exposure periods of 10, 60, and 240 min in a dynamic airflow inhalation chamber. Rat pupil diameters were assessed and blood samples were also collected for RBC–AChE, butyrylcholinesterase (BuChE), and plasma carboxylesterase (CarbE) activity determinations. Animals were also observed for development of clinical signs during a 7-day post-exposure period; EC_{50} values for miosis were reported (Table 6.4; miosis EC_{50} points defined as the statistical concentration required for post-exposure pupil diameters of 50% or less of the pre-exposure pupil diameter in 50% of the exposed population) (Mioduszewski *et al.*, 2002a, b). Gender differences (females more susceptible) were observed. Whole-body exposure to GB vapor did not result in significant activity inhibition for any blood enzyme monitored (RBC–AChE, plasma–BuChE, or CarbE) for any GB vapor concentration and duration tested. Mioduszewski *et al.* (2002a, b) concluded that clinical signs associated with whole-body GB vapor exposure were limited to miosis.

Kassa *et al.* (2001) exposed male albino Wistar rats for 60 min in an inhalation chamber once, or repeatedly to GB concentrations of 0.8, 1.25, or 2.5 mg/m^3. Animals exposed to the lowest concentration (Level 1) were asymptomatic based on clinical and laboratory measurements. Animals exposed to the second concentration (Level 2) were asymptomatic based on clinical signs, but experienced significant inhibition of RBC–AChE activity (by 30%). The highest test concentration (Level 3) was reported to be a nonconvulsive symptomatic exposure. Three months following exposure, control and exposed animals were evaluated for GB-induced effects using biochemical, hematological, neurophysiological, behavioral, and immunotoxicological methods. None of the exposed animals showed any clinical signs of intoxication; their body weight did not differ significantly from control values, and there were no changes in hematological or biochemical parameters, including blood and brain cholinesterase activity. The only significant effect ($p < 0.05$) observed in rats exposed once to 1.25 mg GB/m^3 (Level 2) was an increase in stereotypical behavior. In a continuation of these studies, Kassa *et al.* (2004) reported that at 3 months after exposure, the Level 3 animals showed significant increases in two biochemical markers of stress, plasma corticosterone, and liver tyrosine aminotransferase activities. The latter was also significantly increased in Level 2 test animals. In spatial discrimination tests, animals tested at all three GB concentrations showed significant increases in reaction time up to 2 h after exposures. In the Level 3 animals, the effects lasted for 3 weeks.

Walday *et al.* (1991) exposed male Wistar rats to 0.05 or 0.2 mg GD/m^3 for a single 40 h period. No clinical signs of toxicity were seen during the exposures. AChE, BuChE, and CarbE activities were significantly inhibited in airway and lung tissue at both doses. Brain BuChE and CarbE activity exhibited significant effects at either dose; brain AChE activity did not significantly change from baseline at 0.05 mg GD/m^3, but did so at 0.2 mg GD/m^3.

Genovese *et al.* (2004) evaluated cognitive and general performance effects of GB on adult male SD rats. The test animals received a single whole-body exposure for 60 min once to 1.7–4.0 mg GB/m^3. Cognitive and behavioral performance testing began 48 h after inhalation exposure, and were conducted during 55 sessions occurring over approximately 11 weeks following exposures. Single exposures did not significantly affect performance and no delayed performance onset was observed.

Genovese *et al.* (2008) characterized the miosis EC_{50} for sarin in a nonhuman primate (African green monkey; *Chlorocebus aethiops*) after 10 min exposures (Table 6.4). Evaluation of potential behavioral change by performance on a serial probe recognition test indicated no change from baseline for all subjects. No other clinical sign was observed.

[a]Data for T2715 (2-methylcyclohexyl methyphosphonfluoridate) analog for agent GF
m = male, f = female

Genovese *et al.* (2006) also evaluated cognitive and general performance effects of GF on adult male SD rats using the same protocol as that for GB. The test animals were exposed for 60 min to 0, 1.6, 3.7, or 5.2 mg GF/m^3. The highest test concentration resulted in a significant decrease in the response rate in the behavioral task for the first two post-exposure sessions; however, the deficit was not persistent as recovery occurred rapidly. None of the exposures to GF caused a significant effect on completion time in the maze (cognitive) task.

In tests conducted by Allon *et al.* (2005), freely moving male albino SD rats were exposed whole body to 34.2 ± 0.8 µg GB/L for 10 min, after which electrocardiograms (ECG) of exposed and control animals were monitored every 2 weeks for 6 months. One and 6 months post-exposure, rats were challenged with epinephrine under anesthesia and the threshold for cardiac arrhythmia was determined. Surviving, treated, rats displayed agitation, aggression, and weight loss compared to nonexposed rats and about 20% experienced sporadic convulsions. GB-challenged rats with severe signs demonstrated QT segment prolongation during the first 2–3 weeks after exposure. Epinephrine-induced arrhythmias (EPIA) appeared at a significantly lower blood pressure in the treated group in the first month after exposure, and lasted for up to 6 months.

Callaway and Dirnhuber (1971) evaluated the miotogenic potency of GB vapor in rabbits exposed to GB under goggles (43 miosis responses in ten albino rabbits). Exposure time periods ranged from 10 min to 5 h (Table 6.4).

Bartosova-Sevelova and Bajgar (2005) exposed rats to agent GB vapors for 4 h at four different concentrations (0.30, 0.43, 0.58, and 0.82 mg/m^3) in a whole-body exposure chamber. Convulsions and hypersalivation were observed in one animal exposed to 0.82 mg/m^3. There was a significant decrease in blood AChE activity in all but the low-dose test groups and the control. AChE activity in the brain was significantly decreased only in animals exposed to 0.58 mg/m^3, and only in the pontomedullar area. No significant alterations in AChE activity were seen in the frontal cortex or in the basal ganglia. AChE activity in the pontomedulla was lowest at the greatest dose (0.82 mg/m^3), but the data were too variable for statistical significance.

Sekowski *et al.* (2004) evaluated gene and protein level changes in the brain of male and female SD rats exposed to low-level doses (0.004–0.033 mg/m^3) of aerosolized agent GB and GF via whole-body inhalation for 4 h. Preliminary results indicate that exposure to nerve agent results in differential expression of a number of neuronal genes, including a group that affects cellular processes critical to neurological injury and regeneration, and gender-associated differences in the level and type of gene expression response were significant.

Whalley *et al.* (2004) exposed adult male and female SD rats whole body to a series of agent GF vapor concentrations for 10, 60, or 240 min. Miosis (defined as a 50% reduction in pupil area compared to baseline) measured approximately 30 min after exposure indicates that females were significantly more sensitive than males ($p < 0.05$) (Table 6.4).

In studies conducted by Hulet *et al.* (2006a, c, 2007), male and female Göttingen minipigs were exposed whole body to agent GB or GF for 10, 60, or 180 min (Table 6.4). Male minipigs were significantly ($p = 0.022$) more sensitive to the effects of GF exposure than females.

Conn *et al.* (2002) exposed male F344 rats to 0, 0.2, or 0.4 mg GB/m^3 for 1 h/day for one or more days. Animals were maintained at either 25°C or 32°C to evaluate the effects of heat stress. Body temperature and activity were monitored by telemetry continuously during exposure and for one month following the exposures. Although RBC–ChE activity was reduced in the exposed animals (quantitative data not provided), the test protocol did not significantly alter temperature regulation or locomotive activity of the rats.

2. Agent VX

a. Lethal Levels

Benton *et al.* (2006b, 2007) experimentally determined the LCt_{50} and LC_{50} in male and female adult SD rats exposed whole body to VX vapor for 10, 60, and 240 min in a dynamic exposure chamber (Table 6.3); study protocol was similar to that for agent GB in the studies conducted by Mioduszewski *et al.* (2001, 2002a). Experiments testing the role of decontamination less than 24 h post-exposure provided clear evidence for percutaneous toxicity induced by whole-body vapor exposure to the persistent nerve agent VX. For severe and lethal VX vapor exposure effects, females were not more susceptible than males for the exposure durations examined.

Bide and Risk (2000) exposed outbred male CD1 (SD) BR rats, outbred male CD1 (ICR) BR mice, and outbred male (HA) BR guinea pigs to NaCl aerosols containing entrained VX in a nose-only inhalation system for an exposure time of 12 min. Observed LCt_{50} values are summarized in Table 6.3.

Bide and Risk (2000, 2004) also cite several earlier studies in which LCt_{50} values for mice, guinea pigs, rabbits, hamsters, and dogs were reported (Table 6.3).

For exposure to VX vapors, Koon *et al.* (1960) reported 10 min LCt_{50} values for mice exposed either whole body or head only, as well as for goats. Carroll *et al.* (1957) also reported female mouse LCt_{50} values for nose-only and whole-body protocols. However, Carroll *et al.* (1957) reported that the concentration of VX in the exposure chamber was not measured directly but was estimated from the mortality level which was correlated with the LD_{50} for IV injection.

b. Sublethal Level

Benton *et al.* (2005, 2006a, 2007) have characterized miosis as well as severe effects (severe tremors and/or prostration, convulsions and/or gasping) in male and female SD rats exposed whole body to VX vapor (0.00037 to 0.016 mg VX/m^3) under study protocols similar to those for agent GB in

the studies conducted by Mioduszewski *et al.* (2001, 2002a). Miosis EC_{50} endpoints were derived for VX vapor exposure durations of 10, 60 and 240 min (Table 6.4). At the highest VX concentrations tested for each exposure duration, significant (>99.9% confidence) differences between control and experimental whole-blood AChE activity were observed; no other signs (e.g. tremors, salivation, etc.) were observed and delayed pupil effects were minimal. For the miosis endpoint, female rats are considered more susceptible than males to VX vapor exposure.

For severe effects (tremors, prostration, etc.), the ECt_{50} values (mg-min/m^3) reported by Benton *et al.* (2007) were as follows: 10 min, 40.9 (female) and 35.2 (male); 60 min, 30.0 (female) and 31.2 (male); 240 min, 31.5 (female) and 29.9 (male). EC concentrations were not reported.

Following single 60 min VX vapor exposures in the range of 0.016 to 0.45 mg VX/m^3, Genovese *et al.* (2007) examined blood AChE activity, dose estimation by regeneration assay, transient miosis, and behavior parameters in adult male SD rats. Behavioral evaluation included a radial maze task and a variable-interval schedule-of-reinforcement task. At all concentrations tested, transient miosis and AChE activity inhibition were observed and some subjects exhibited transient ataxia and slight tremor. Following 3-month post-exposure evaluations of behavior, the authors concluded that performance deficits were minor and transient at these concentrations. Further, no delayed effects were observed.

V. RISK ASSESSMENT

Application of standard risk assessment methods by numerous authorities and agencies to the toxicological data summarized above has generated exposure guidelines that provide objective and health-based foundations for responsible and efficient response following nerve agent release as well as a basis for site recovery and decontamination decision criteria. The health-based nerve agent exposure guidance summarized here has been derived in an open and transparent manner and judged scientifically valid and protective (NRC, 1999, 2001, 2003; Krewski *et al.*, 2004, Opresko *et al.*, 1998, 2001; Watson *et al.*, 2006a, b; see also www.epa.gov/oppt/aegl/). While initially developed to facilitate disposal of the US stockpile of CW munitions and to support remediation or closure at sites where CWs were historically processed, nerve agent exposure guidance became a subject of interest for homeland defense applications after the events of September 2001.

For reasons described earlier, the air exposure pathway has been a primary focus of risk assessment activity for nerve agents (NRC, 2003; ATSDR, 2007; Cannard, 2006; Dabisch *et al.*, 2008a; others). In situations where long-term agent release is a concern, and where agent residuals may be found, potential exposure to relatively low levels of ingested agent is a priority.

In all cases, it is important to appropriately safeguard public health without defaulting to overly conservative actions (e.g. to ''nondetect'') that would divert limited resources without significant benefit. The following sections summarize toxicological support and developmental rationale for the two primary criteria of interest to community decision-makers managing response to an intentional or accidental release of nerve agent(s) to the environment.

A. Acute Exposure Guideline Levels (AEGLs)

Credible short-term nerve agent exposure limits designed to aid state and local government agencies in developing emergency response plans in the event of accidental or deliberate atmospheric release have been derived. These short-term values have also proved useful in deployed force health protection and in establishing health-based CWA performance goals for detection system development (USACHPPM, 2004, 2008).

Acute Exposure Guideline Levels (AEGLs; expressed in units of mg/m^3 or ppm) are vapor exposure guideline values for numerous hazardous compounds (primarily toxic industrial compounds) that have been published by the National Academy Press (e.g. NRC, 2003, 2007). For each hazardous compound, guideline levels are developed for vapor exposure durations of 10 and 30 min, 1 h, 4 h, and 8 h as well as for three gradations of toxic effect severity. AEGL-1 concentrations are the mildest effect category while AEGL-3 concentrations represent the most severe effect category (NRC, 2001). The point above the AEGL-3 concentration at which ''Level-3'' effects would initiate for any given human exposure duration is not identified in the AEGL assessment protocol.

Typically, the AEGL concentration established for any given effect level is often less than the known experimental concentration at which such toxicological effects occur. This protective nature of the AEGL process and values was demonstrated for each of the nerve agents, where observed human thresholds for reversible effects occur at air concentrations greater than AEGL-1 levels (Watson *et al.*, 2006a, b).

Selection protocols for critical effects and studies, AEGL derivation, time scaling, use and selection of uncertainty and modifying factors, and a description of the lengthy and deliberative review process employed are all described in NRC (2001) as well as in recent papers by Krewski *et al.* (2004) and Bruckner *et al.* (2004). Development of AEGL values includes consideration of uncertainty factors as well as the need for any modifying factors. Because exposure–response data are usually not available for each AEGL-specific exposure duration (NRC, 2001), temporal extrapolation is employed in the development of values for some AEGL-specific time periods. The concentration–exposure time relationship for many systemically acting vapors and gases may be described by $C^n \times t = k$, where the exponent n ranges from 0.8 to 3.5 (Ten Berge *et al.*, 1986;

NRC, 2001). Some investigators refer to the Ten Berge extrapolation as the ''toxic load model'' and *n* as the ''toxic load exponent'' (Dabisch *et al.*, 2008a; Sommerville *et al.*, 2006). The excellent data collected by investigators at Edgewood Chemical Biological Center (Aberdeen Proving Ground, MD) characterizing nerve agent vapor exposure miosis and lethality endpoints for multiple agents and species has allowed agent-specific determination of *n* (summarized in Dabisch *et al.*, 2008a). In the case of swine exposed to G-agents and rats exposed to VX, the experimentally determined *n* values for these endpoints are $\leq$1.6, less than the *n* of 2 assumed during AEGL development for these same compounds in 2001–2003 (NRC, 2003), and based on then-available data for SD rats exposed to agent GB (Mioduszewski *et al.*, 2002a, b). It thus appears that G-agent and VX dose response for the miosis and lethality endpoints are less steep than previously indicated and that the published nerve agent AEGL values (Table 6.5) are more protective than originally considered (NRC, 2003; Watson *et al.*, 2006a, b).

For comparison, it is useful to consider other common guideline sources applicable to short-term nerve agent release events. The US Department of Energy, in their development of 1 h Protective Action Concentrations/Temporary Emergency Exposure Levels (PAC/TEELS), has chosen to replicate the published nerve agent-specific 1 h AEGL-1, -2, and -3 values as Tier 1, Tier 2, and Tier 3 PAC/TEEL values, respectively (see http://hss.energy.gov/HealthSafety/WSHP/chem_safety/teel.html).

1. Application of AEGL Values

The AEGL process does not include specific implementing or application guidance, and specific approaches for using the values are left to the discretion of risk managers and appropriate authorities (NRC, 2001). Nevertheless, AEGL application is already broad, and continues to expand.

The utility of AEGL values for chemical warfare agent emergency preparedness planning was recognized by the Chemical Stockpile Emergency Preparedness Program (CSEPP) when FEMA and Army representatives adopted final nerve agent AEGL concentrations to replace previous agent toxicity criteria for emergency response decision-making (CSEPP, 2003). As of February 2003, standing CSEPP policy guidance for each of the communities hosting agent demilitarization facilities in the US recommends application of AEGL-2 concentrations as the protective action level for evacuation or shelter-in-place, and AEGL-1 concentrations as notification levels (CSEPP, 2003). Since publication of final AEGL levels by NRC (2003) and enactment of the above CSEPP Policy Paper (CSEPP, 2003), multiple stockpile states and counties have incorporated the Policy Paper recommendations into their individual community emergency response plans and employed them in making regulatory decisions permitting agent munition disposal operations (CSEPP, 2006a, b).

In February 2008, the US National Response Team (NRT) posted *Quick Reference Guides* for the G-series nerve agents and VX for public access on its website (www.nrt.org) (NRT, 2008). These *Quick Reference Guides* are useful summaries of agent characteristics and advisories, and are provided as national guidance. While acknowledging that site-specific cleanup decision criteria will be the result of multi-agency agreements and site-specific factors, the NRT considers that attainment of agent-specific air concentrations $<$8 h AEGL-1 is an acceptable criterion for verification of site decontamination.

In general, agent concentrations $<$AEGL 2 are considered to be in a range that poses relatively negligible health consequences for acute exposures.

Other AEGL applications performed or recommended include use as hazard assessment plume modeling criteria for the US Non-Stockpile Chemical Material Program and Homeland Defense scenarios, as testing criteria for personal protective equipment intended for use by first responders in a single weapon-of-mass-destruction scenario, as detection performance goals for advanced equipment acquisition and development, and as a tool for assessing potential exposures during military missions such as peacekeeping (USACHPPM, 2008).

B. Estimated Oral Reference Doses (RfD_e)

Development of nerve agent-specific reference dose estimates is critical to remediation and restoration at existing and closing military sites, which is a priority activity for DOD (Opresko *et al.*, 1998, 2001).

A reference dose (RfD; mg/kg/day) was originally designed for estimating noncancer health risks at CERCLA (Comprehensive Environmental Response, Compensation, and Liability Act of 1980) Superfund sites (USEPA, 1989). As such, it is an essential component of the site risk assessment used to assess potential long-term exposures to contaminated media such as soil, where RfDs address the pathway of incidental ingestion of soil particles (see Dourson, 1994; Cicmanec *et al.*, 1996; Abernathy *et al.*, 2004; USEPA, 1989).

Methods used to derive oral RfDs for nerve agents follow standard USEPA protocols (USEPA, 1989; Dourson, 1994), employ appropriate toxicological data and uncertainty factors, and have undergone review for consistency by the National Research Council (NRC, 1999; Bakshi *et al.*, 2000; Opresko *et al.*, 1998, 2001). Because EPA has not officially verified the derived values for nerve agents, they are identified as estimated RfDs (RfD_e) (Table 6.6).

These criteria are selected by the Office of the Army Surgeon General as the most appropriate oral toxicity reference values for use in environmental risk assessments, and represent the Army's position (Opresko *et al.*, 2001). The RfD_e values have been input to USEPA risk models along with accepted chronic vapor exposure limits (as cited in Watson and Dolislager, 2007) to generate agent-specific

TABLE 6.5. Summary of AEGL values for G-series nerve agents and VX (mg/m^3)[a]

Health Based Environmental Screening Levels (HBESLs). These HBESLs are endorsed by military policy as criteria to assess potentially contaminated soils (Table 6.6) (USACHPPM, 1999; OASA, 1999; Watson and Dolislager, 2007).

VI. TREATMENT

A. Critical Role of Decontamination

Prior to discussion of antidotes and treatment regimens, it is noted that affected individuals should be removed from the site of agent exposure as quickly as possible and undergo rapid decontamination to remove potential for continued personal exposure and to prevent secondary exposure to responders, healthcare workers, medical transport vehicles, and treatment facilities (Okumora *et al.*, 2007, Cannard, 2006; ATSDR, 2007; Sidell, 1997; Pulley and Jones, 2008). Decontamination of CW agents is discussed more fully by Gordon (2009) in a later chapter of this volume.

B. Signs and Symptoms Guiding Medical Management

Depending on concentration and duration of exposure, cases of nerve agent intoxication can exhibit a dose-dependent ''constellation'' of clinical signs and symptoms representing a variety of parasympathetic effects, functional change at neuromuscular junctions, and altered CNS function (Cannard, 2006). As a consequence, critical care personnel and others responsible for developing and administering treatment protocols should take into account the totality of the case presentation. A good example is drawn from observations made by medical personnel treating subway passengers presenting at Tokyo area hospitals and clinics on Day 1 of the sarin release incident. In decreasing order of frequency, the following clinical signs and symptoms were noted: miosis (observed in most patients), headache, dyspnea, nausea, vomiting, muscular weakness, cough, rhinorrhea, chest oppression, muscular fasciculations, and psychological disturbances such as anxiety (Lillibridge, 1995). Similar distributions were observed among subway passengers treated at St Luke's International Hospital (Okumura *et al.*, 1996, 2007) as well as residents affected in the Matsumoto incident of 1994 (Yanagisawa *et al.*, 2006), and are consistent with classic descriptions of nerve agent intoxication (Sidell, 1997; Leikin *et al.*, 2002; Cannard, 2006). Miosis was found to be a more responsive exposure index than RBC–ChE activity inhibition (Nozaki *et al.*, 1997) or serum cholinesterase activity (Yanagisawa *et al.*, 2006) in cases of sarin vapor exposure during the Tokyo and Matsumoto incidents, respectively.

Yanagisawa *et al.* (2006) classified individuals exhibiting a pupil diameter >3.0 mm as without miosis and not affected by nerve agent vapor exposure given that simultaneous serum ChE activity measurements taken during treatment of the Matsumoto cases displayed no inhibition (e.g. largely $\geq 100\%$ of normal serum ChE activity with two cases exhibiting activity $<90\%$ of normal). This, and additional miosis data from Matsumoto, can be employed in determining appropriate treatment for individuals without known or confirmed nerve agent vapor exposure (Yanagisawa *et al.*, 2006; Cannard, 2006); for these individuals, examination, observation without treatment, and discharge are appropriate actions and were successfully implemented during medical responses to the Tokyo subway incident (Lillibridge, 1995).

TABLE 6.6. Estimated reference doses (RfD_e), RfD uncertainty factors, and health-based environmental screening levels for nerve agents[a]

Nerve agent	RfD_e (mg/kg/day)	Composite uncertainty	Residential soil preliminary remediation goal (mg/kg)	Industrial soil preliminary remediation goal (mg/kg)
VX	6E-7	100	0.042 (est.)	1.1 (est.)
GA	4E-5	3,000	2.8 (est.)	68.0 (est.)
GB	2E-5	3,000	1.3 (est.)	32.0 (est.)
GD	4E-6	3,000	0.22 (est.)	5.2 (est.)

C. Nerve Agent Antidotes

The choice of appropriate treatment for nerve agent intoxication depends on the agent as well as extent and route(s) of exposure. Very mild exposure to nerve agent vapor may necessitate only decontamination and observation; severe exposure to vapor or liquid requires immediate decontamination, antidote administration, artificial respiration, monitoring, and supportive therapy over hours to multiple days (ATSDR, 2007; Sidell, 1997; Vale *et al.*, 2007; Pulley and Jones, 2008). Convenient triage classifications have been developed by ATSDR (2007) in collaboration with the US Army Medical Research Institute of Chemical Defense.

In cases of massive inhalation exposure, immediate care is vital to prevent death from respiratory failure and because the agent–AChE complex becomes resistant to reactivation by oxime-type antidotes. ''Aging'' is compound-specific; aging half-times range from minutes (agent GD) to days (agent VX) (Sidell and Groff, 1974; Sidell, 1997). Standard antidotes clinically available in the US are atropine (anticholinergic) and pralidoxime (Protopam or 2-PAM-Cl). In addition, CNS active drugs such as diazepam (Valium) are strongly recommended if convulsions occur; anticonvulsant treatment is critical for protection against lethality and brain pathology (Shih *et al.*, 2003).

Individuals exposed to vapor and exhibiting miosis only or miosis and rhinorrhea only do not usually require antidote treatment and will resolve without medical intervention (ATSDR, 2007; Cannard, 2006), but should be observed. If rhinorrhea is problematic in these vapor-only cases, ATSDR (2007) advises atropine IM (0.05 mg/kg pediatric; 2.0 mg adult) to relieve signs, followed by patient discharge. If eye pain/headache or nausea is problematic in vapor-only cases, ATSDR (2007) further advises administration of topical atropine or homatotropine to the eye for relief, eye protection from bright light, and discharge.

If liquid/droplet exposure is known or suspected in an individual exhibiting miosis only or miosis and rhinorrhea only, it is recommended that the individual receive no antidote treatment but be closely observed for at least 18 h given that toxic effects of liquid percutaneous exposure may not manifest for several hours (Sidell, 1997; Cannard, 2006). Toxic effects from vapor-only exposure usually occur quickly (within minutes; Sidell, 1997). Current medical management guidelines and recommended medication protocols are summarized in ATSDR (2007), Pulley and Jones (2008) and Vale *et al.* (2007). The ATSDR antidote treatment protocol for civilian emergency management is summarized in Table 6.7.

D. Ongoing Antidote Development

Given that termination of seizure activity protects against development of neuropathological lesions (especially neuronal necrosis) in brain tissues of experimental animals (Marrs and Sellström, 2007; Martin *et al.*, 1985; Shih *et al.*, 2003), focus on anticonvulsant therapy is critical. Reduced potential for permanent brain damage in human cases by preventing or limiting the duration of *status epilepticus* is a primary goal. In challenge tests against multiple LD_{50} doses of agents GA, GB, GD, GF, VX, and VR in guinea pigs, the anticonvulsants midazolam and trihexyphenidyl were more effective than diazepam for seizure control with midazolam the most rapidly effective (Shih *et al.*, 2003). The diazepam pro-drug avizafone is also effective (Lallement *et al.*, 2000, 2004) and is available via autoinjector administration (as is diazepam). For more rapid seizure control during acute treatment phases, Marrs and Sellström (2007) recommend midazolam administered IM due to its more rapid intramuscular absorption.

While pralidoxime is an effective and well-tolerated reactivator, it is not very potent. Search has thus continued for oximes that would combine high reactivator effectiveness against nerve agents with low toxicity and good chemical stability; several promising drugs (the oxime HI6; trimedoxime, or TMB-4; and obidoxime, or LüH-6) have emerged, but are not equally effective against all agents and forms of exposure (Dawson, 1994; Eyer and Worek, 2007; Marrs *et al.*, 2006; Wetherell *et al.*, 2007; Antonijevic and Stojiljkovic, 2007). Marrs *et al.* (2006) point out that, in the absence of pyridostigmine pretreatment, there are at present ''no clinically important differences'' between the standard oxime pralidoxime and the alternative oximes HI-6 and obidoxime in the treatment of nerve agent intoxication.

As a combinatorial drug with atropine, galantamine has been effective and safe in counteracting lethal GD and GB doses in the guinea pig (Albuquerque *et al.*,

2006; Pereira *et al.*, 2008); galantamine also protects against neurodegeneration at $\geq LD_{50}$ doses in the guinea pig, and shows promise as a pretreatment prior to GD or GB exposures.

Lethality was prevented by treatment with nasal atropine (atropine methyl nitrate) and post-exposure treatment with atropine methyl bromide instillation in combination with pulmonary therapeutic surfactants or liquevents in guinea pigs exposed to approximate LC_{50} concentrations of VX aerosol (Nambiar *et al.*, 2007); this concept shows promise for operational application in emergency response.

E. Pretreatment When Exposure is Likely

In certain military deployment settings when threat of nerve agent exposure exists, pretreatment with an anticholinesterase carbamate compound has been fielded to protect personnel. The pretreatment carbamate of current choice, pyridostigmine bromide (PB), reversibly sequesters (and thereby protects) a fraction of AChE from bonding with circulating nerve agents; the carbamate moiety spontaneously hydrolyzes from the AChE molecule within hours and allows AChE to again become available for normal physiological function. Such a pretreatment concept and drug enhances the effectiveness of atropine and oximes in treating lethal doses of GA, GB, and VX (Gall, 1981; Inns and Leadbeater, 1983). US combat units already supplied with atropine and pralidoxime have been equipped with 30 mg PB tablets for oral administration every 8 h; the current maximum pretreatment period is 21 days (Sidell, 1997; Scott, 2007).

A related carbamate, physostigmine, has been shown to protect animals against not only nerve agent lethality, but also incapacitation (Leadbeater *et al.*, 1985). When co-administered with hyoscine, physostigmine effectively reduced incapacitation and prevented death in guinea pigs exposed to agent GD (Wetherell, 1994) and prevents lethality and reduced/prevented incapacitation in guinea pigs exposed to GA, GB, GD, GF, and VX (Wetherell *et al.*, 2002). Transdermal patch administration of physostigmine and hyoscine, or physostigmine alone, in the guinea pig has protected against GD intoxication (Meshulam *et al.*, 1995).

Other developmental pretreatment options include pre-exposure loading with an excess of circulating ChE or BuChE (Van der Schans *et al.*, 2008; Bajgar *et al.*, 2007; Saxena *et al.*, 2008; Lenz *et al.*, 2008; Podoly *et al.*, 2008) or CarbEs (Maxwell *et al.*, 1987) to bind nerve agent before the agent can reach tissue AChE sites.

VII. CONCLUDING REMARKS AND FUTURE DIRECTION

A good deal of nerve agent toxicity research performed and published since the mid-1990s has served to bring a more widespread awareness of the knowledge that detectable (either by means of devices or manifestation of signs) low-level nerve agent exposures under a variety of scenarios are

TABLE 6.7. Recommended antidote protocol for emergency nerve agent exposure therapy[a]

	Antidotes		
Patient age	**Mild/moderate signs and symptoms[b]**	**Severe signs and symptoms[c]**	**Other treatment**
Infant (0–2 yr)	Atropine: 0.05 mg/kg IM or 0.02 mg/kg IV 2-PAM-Cl: 15 mg/kg IV slowly	Atropine: 0.1 mg/kg IM or 0.02 mg/kg IV 2-PAM-Cl: 15 mg/kg IV slowly	Assisted ventilation as needed Repeat atropine (2 mg IM or 1 mg IM for infants) at 5–10 min intervals until secretions have diminished and breathing is comfortable or airway resistance has returned to near normal Phentolamine for 2-PAM induced hypertension (5 mg IV for adults; 1 mg IV for children) Diazepam for convulsions (0.2 to 0.5 mg IV for infants up to 5 yr; 1 mg IV for children >5 yr; 5 mg IV for adults)
Child (2–10 yr)	Atropine: 1.0 mg IM 2-PAM-Cl: 15 mg/kg IV slowly	Atropine: 2.0 mg IM 2-PAM-Cl: 15 mg/kg IV slowly	
Adolescent (>10 yr)	Atropine: 2.0 mg IM; 2-PAM-Cl: 15 mg/kg IV slowly	Atropine: 4.0 mg IM 2-PAM-Cl: 15 mg/kg IV slowly	
Adult	Atropine: 2.0–4.0 mg IM 2-PAM-Cl: 15 mg/kg (1 g) IV slowly	Atropine: 6.0 mg IM 2-PAM-Cl: 15 mg/kg IV slowly	
Elderly, frail	Atropine: 1.0 mg IM 2-PAM-Cl: 5–10 mg/kg IV slowly	Atropine: 2.0 mg IM 2-PAM-Cl: 5–10 mg/kg IV slowly	

[a]Contents reproduced from ATSDR (2007) (public domain)
[b]Mild/moderate signs and symptoms include localized sweating, muscle fasciculations, nausea, vomiting, weakness, dyspnea
[c]Severe signs and symptoms include unconsciousness, convulsions, apnea, flaccid paralysis

both sublethal and also potentially without significant long-term adverse health impact. Although such points are also inherent in the development of LD_{50}s and related values, much of the original focus of nerve agent toxicological work was, not surprisingly, on lethal or severe toxicological endpoints. To the extent that it adds detail and rigor to the estimation of exposure levels for nonlethal effects as well as insightful information on specifics of the mechanisms of nerve agent action, the more recent research has been highly useful in validating past conclusions on the subject. These recent data also further direct attention towards responsible consideration of the consequences for transient presence of residual, low-level agent concentrations in a number of scenarios. Having a transparent, robust and strongly data-based framework within which to evaluate likely consequences of potential low-level nerve agent exposures will greatly aid in planning and evaluating response operations and reducing the magnitude of disruption to affected communities and facilities.

It is hoped that additional species and agents will be evaluated under comparable experimental protocols for the endpoints of miosis and lethality as well as for more intermediate toxicological endpoints.

Standard treatment and pretreatment guidance is also summarized, as well as consideration of novel antidote development and promising approaches. Additional clinical trials will assist in developing protocols and practices for expanding available treatment options. Fielding of improved seizure management drugs and protocols should be expedited. The detoxification potential of CarbEs is multifaceted and is an area that would benefit from further characterization.

Acknowledgments

Analysis contained in this evaluation was originally prepared for two agencies of the US Department of the Army: the US Army Center for Health Promotion and Preventive Medicine under Interagency Agreement 2207-M135-A1 and the US Army Environmental Command under Interagency Agreement 2134-K006-A1. The Oak Ridge National Laboratory (ORNL) is managed and operated by UT-Battelle, LLC, for the US Department of Energy under contract DE-AC05-00OR22725.

The critical advice of our colleagues Dana Glass and Robert Ross (Leader, Toxicology and Hazard Assessment Team, Environmental Sciences Division, ORNL) in the preparation of this chapter is thankfully acknowledged.

The views expressed in this chapter do not necessarily represent official Federal agency position or policy. Mention of trade names or commercial products does not constitute endorsement or recommendation of use.

I. INTRODUCTION

One of the most abundant and most toxic chemical warfare agents in the chemical arsenals of the USA and Russia is VX and Russian VX, respectively, whose development in the middle of the 20th century signified the peak of warfare chemistry. V-gases are low-volatile liquids with high boiling points and, therefore, they are much more persistent than higher volatility organophosphorus (OP) agents of the G-series, such as sarin, soman, or tabun. V-series compounds are more toxic that OP nerve agents of the G-series. For example, in comparison with sarin (GB), VX is estimated to be approximately twice as toxic by inhalation, ten times as toxic by oral administration, and approximately 170 times as toxic after skin exposure (Munro *et al.*, 1994). V-series nerve agents are quite effective when exposed through skin contact, especially as tiny drops, and commonly cause death. Poisoning occurs irrespective of route of exposure; specifically inhalation, ingestion of vaporous and liquid agents through intact or injured skin or eye mucosa, and on contact with contaminated surfaces. This chapter describes in detail the chemistry, analysis, toxicity, monitoring and regulatory hygiene, and therapy of Russian VX nerve agent.

II. BACKGROUND

The arbitrary name VX relates to a group of *O,S*-diesters of methylphosphonic acid $ROPO(CH_3)S(CH_2)_2N(R1)_2$. *O*-Isobutyl *S*-2-(diethylamino)ethyl methylphosphonothioate (R = *i*Bu, R1 = Et), produced since 1972 exclusively in the former Soviet Union, was generally referred to as Russian VX or RVX (CAS #159939-87-4). The synonyms are: VR; VA; phosphonothioic acid methyl-, *S*-[2-(diethylamino)ethyl] *O*-(2-methylpropyl) ester; *O*-isobutyl *S*-2-(diethylamino)ethyl methylthiophosphonate; *O*-isobutyl *S*-(*N,N*-diethylaminoethyl) methylphosphonothioate; and Russian V-gas. The brutto formula of RVX is $C_{11}H_{26}SNPO_2$ (MW 276.37). The structural formula of RVX is presented in Figure 7.1.

RVX is a colorless transparent liquid resembling glycerol in mobility, boiling point 300.0°C, melting point 35.0°C, ρ^{20}1.0083 g/cm^3, and volatility C_{max}^{20} 0.0105 mg/dm^3. The agent is poorly soluble in water (less than 5% at 20°C) and readily soluble in organic solvents. Technical product can be colored from yellow to dark brown and the odor is fried sunflower seeds.

Research into environmental behavior of highly toxic chemicals is an important branch of analytical toxicology. We take the word ''behavior'' to mean persistence, mechanisms of possible transformation, composition of such transformation products and their toxicity. Among known toxicants, V-series compounds, in view of their unique structure, tend to undergo perhaps the most diverse transformations. Possessing a high reactivity on the one hand and polyfunctionality on the other, these compounds incorporated in multicomponent matrices are capable of concurrently reacting with several components. The reactions may involve different active centers in one and the same molecule. The routes and results of such reactions cannot be predicted in advance. The situation is complicated by the fact that active components of a natural or technogenic matrix are not always known. In view of this, research aimed at identifying transformation products of VX in various media is of particular importance. The degradation of such compounds is suggested to be initiated by electron addition to phosphorus via reaction with anionic nucleophiles (Yang, 1999), such as hydroxide ion, water, alcohols, amines, or unsaturated organic compounds. The problem of determination of RVX in complex matrices and identification of RVX transformation products is still more complicated by the scarcity of available reference information.

Cholinesterases (ChE) are well-known targets for organophosphates (OPs), and RVX is no exception. Much less information is available about other enzymes that could be primary targets upon exposure to low doses of OP, and on biochemical markers of possible delayed effects of OP intoxication when the level of ChE activities is the same as the control. However, this problem is very important due to various reasons, among which is fulfillment of chemical weapon agents (CWAs) nonproliferation conventional programs and inherent possibility of accidental exposure of

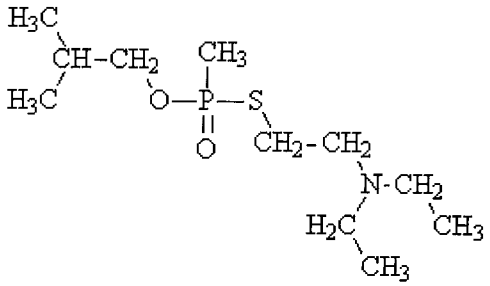

FIGURE 7.1. Structural formula of Russian VX.

personnel to RVX, as well as the chronic effects of subsymptomatic concentrations of RVX that could arise from the stockpiles of chemical agents. Among other reasons, the terrorist threat is a well-recognized problem relevant to the scope of our concern.

A. Ambient Monitoring and Environmental Persistence of Russian VX

The composition of VX degradation products and admixtures has been studied in detail by hybrid chromatography–mass spectrometry methods. The objects of admixture studies were the contents of containers in which VX had been stored for a long time. Dozens of admixtures and stabilizers could be identified. There has been much work on identification of admixtures in VX and its degradation products. A systematic review of VX transformation products is presented by Munro *et al.* (1999). There are no such systematic data for RVX. The degradation of RVX in various media always produces complex mixtures of products that commonly contain dozens of both volatile and nonvolatile organic compounds. The prevalent volatile products are phosphorus-free alkyl diethylaminoethyl mono- and polysulfides. The electron impact (EI) mass spectra of these compounds are quite similar to each other and most commonly contain a single strong peak at *m/z* 86, formed by the $[(Et)_2NCH_2]^+$ ion. Among phosphorus-containing products, methylphosphonic acid (MPA) and its mono- and diisobutyl esters (iBuMPA and iBu_2MPA) are almost always detected in certain quantities. These compounds are also present as admixtures in technical RVX samples in varied contents (from tenths of a percent to several percent). The P–S bond cleavage in RVX forms diethylaminoethanethiol and iBuMPA. The latter slowly hydrolyzes to form MPA. Conditions favoring P–O bond cleavage to form the highly toxic *S*-2-(diethylamino)ethyl methylphosphonothioic acid are unknown.

The most hazardous known VX hydrolysis products are persistent bis[2-(diisopropylamino)ethyl] disulfide, and highly toxic and persistent *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate. The decomposition of RVX gives rise to structural analogs of the above products: bis[2-(diethylamino)ethyl] disulfide and *S*-[2-(diethylamino)ethyl] methylphosphonothioate. The latter is commonly called by its trivial name ''monothiol''. Systematic data on the behavior of these products in the environment, as well as on their acute and chronic toxicity to humans and mammals and ecotoxicity, are lacking. Components of the complex mixture of RXV decomposition products feature as low-informative EI mass spectra and, therefore, these compounds are hardly possible to identify on the basis of mass spectral data solely. Chemical-ionization (CI) mass spectra are much more characteristic, but CI mass spectra, in view of their irreproducibility and lack of databases, are of limited use for identification. Russian VX, like VX, does not possess a strong electron-acceptor center favoring decomposition, but still is not a complete analog of VX in this respect. In dilute aqueous solutions, RVX proved to be much more persistent: half-life 12.4 days against 4.8 days for VX (Crenshaw *et al.*, 2001). The mechanism of the neutralization of VX and RVX with an equimolar amount of water was first described by Yang *et al.* (1996). It was found that autocatalytic hydrolysis is possible exclusively in V-series nerve agents, since it should involve the protonated amino group.

We performed experimental research on stability assessment of RVX and identification of its transformation products under the action of equimolar or excess amounts of water. The method for analysis was GC-EIMS. In a dilute aqueous solution (10 mg/ml) in the presence of 5% phosphoric acid, the concentration of RVX after exposure for 20 days at room temperature without stirring was 2.7 mg/ml or 27% of the initial amount. Since among RVX hydrolysis products both volatile and nonvolatile compounds could be expected, we chose three schemes for sample preparation: (a) evaporation to dryness followed by silylation; (b) organic solvent extraction; and (c) silylation of the extract obtained by procedure (b).

Table 7.1 lists the principal products of RVX hydrolysis with excess water in an acid medium, with specified analytical fractions with the highest contents of each compound. It should be noted that even after 100-day exposure we could detect in the solution 1% of the initial amount of RVX, which implied a fairly uniform hydrolytic degradation.

Experiments on RVX hydrolysis with an equimolar amount of water were performed as follows. A mixture of 74 µl of RVX and 5.6 µl of water was exposed at room temperature for 3.5 months without stirring. An ash-gray thick uniform material formed after hydrolysis and completely dissolved in 5 ml acetonitrile. The solution was diluted 100 times with acetonitrile and analyzed by GC-EIMS (sample D). An aliquot of this sample was mixed with an equal volume of bis-trimethylsilyltrifluoroacetamide (BSTFA), and the mixture was heated at 70°C for 30 min and then analyzed by GC-EIMS (sample E). The autocatalytic hydrolysis of RVX was almost complete by the end of the experiment, since the RVX content in the sample was no more than 0.01%. Qualitatively, the reaction mixture in the latter case was much poorer than in the hydrolysis with

TABLE 7.1. Products of RVX hydrolysis with excess water in an acid medium

excess water. Among the volatile hydrolysis products, the following were detected by GC-EIMS in sample D: 2-(diethylamino)ethanethiol (4%), diisobutyl methylphosphonate (2%), bis[2-(diethylamino)ethyl] sulfide (2%), RVX (<0.01%), and bis[2-(diethylamino)ethyl] disulfide (80%). Of nonvolatile products in sample E, methylphosphonic acid (MPA) (3%) and isobutyl ester of MPA (isobutyl MPA) (96%) were identified as trimethylsilyl ester. Isobutyl MPA which catalyzes RVX degradation was detected as the major components of the reaction mixture. As the second most abundant component we expected, according to Yang *et al.* (1996), 2-(diethylamino)ethanethiol but found that it almost completely converted into bis[2-(diethylamino)ethyl] disulfide. This result seems feasible, since once the autocatalytic degradation of RVX was complete nothing would prevent thiol from being converted into disulfide. In a dilute aqueous solution of RVX, this conversion occurs less rapidly, and even after 100 days the solution contains much less 2-(diethylamino)ethanethiol than bis(2-diethylaminoethyl) disulfide.

The Convention requires Signatory States to completely destroy not only their stockpiled chemical weapons, but also the corresponding industrial facilities, including buildings and other constructions. Toxicity and hazard assessment of demolition wastes of former VX production facilities is quite a challenging problem in view of the high absorption capacity of building materials for VX-series agents. Whether V-series agents are possible to detect in one or another material is difficult to predict because of the paucity of data on their persistence in various media. An ion-trap secondary ionization mass spectrometry study showed that VX undergoes complete degradation when in contact with concrete surfaces (Groenewold *et al.*, 2002). The process follows first- or pseudo-first-order kinetics, and the half-life of VX is about 3 h. Affinities and persistence of VX in certain materials was studied by Love *et al.* (2004). The test materials included powdered activated charcoal, as well as natural iron and aluminum oxyhydroxide minerals: goethite (yellow ochre) and montmorillonite (clay), respectively. It was shown that VX has a high affinity for charcoal, a moderate affinity for montmorillonite, and a very low affinity for goethite. The adsorption on goethite was increased in the presence of dissolved organic matter. VX degraded more rapidly on dry goethite than in the presence of water. We performed experiments with RVX applied on soil, concrete, bricks, and a polymeric material (polyisobutylene used in hydroinsulation) at concentrations over the range 10^{-6}–10^{-5} mg/kg which corresponded to the tentative maximum allowable concentrations accepted in the Russian Federation. Conditions for effective extraction of RVX could not be found for any of the materials tested. The extremely low recoveries of RVX from materials of various nature can be explained by both irreversible sorption and degradation. The problem of simulating the behavior of V-series nerve agents, including RVX, in various materials is complicated by the fact that such factors as the presence of water and/or organic compounds strongly affect both RVX sorption and degradation kinetics. In any case, in alkaline materials (concrete, cement, plaster, or lime) RVX undergoes fast degradation, especially in the presence of water, whereas in organic hydrophobic media (polymers, lubricants) it can persist for a long time.

During operation of an RVX production or destruction facility, its inner surfaces might have been treated with various reagents, and it is therefore quite difficult to predict the transformation routes and degradation products of the toxic agent. These products may include previously unknown toxic compounds. We faced such problems in

assessing toxicities and hazards of samples, specifically wall and ceiling fragments, from a former RVX production facility (Radilov *et al.*, 2007). This research was required for developing technical regulations for demolition of the facility. Table 7.2 lists compounds isolated from the samples of building materials, taken in working areas of the former RVX production facility, which might have contacted RVX. Aqueous and organic extracts of the samples were prepared according to the Organization for the Prohibition of Chemical Weapons (OPCW) Recommended Operational Procedures (Rautio, 1994). Analysis was performed by GC-MS in the electron impact and positive chemical ionization (reactant gas methane) modes. According to the procedures, aliquots of all extracts were subjected to BSTFA silylation and diazomethane methylation.

Along with RVX transformation products, the samples contained more than 100 organic compounds which are matrix components of building materials, solvents, plasticizers, reaction products of degassing agents with matrix components, etc. In brick and concrete samples we detected, in high concentrations (up to 10 g/kg), so-called fyrols, components of foam fire-extinguishing compositions. In terms of chemical composition, fyrols are mixtures of tris(dibromoalkyl) phosphates with phosphoric acid. Among the RVX transformation products in Table 7.2, components with RI 1685, 1888, and 2241 were relatively abundant (up to 5 mg/kg) and were assigned two almost equally probable structures (printed in bold). Such products could not be expected in advance and, as a result, were not detected by target analysis. However, their detection can be considered as evidence that the samples in hand were contaminated with RVX in the past.

B. Biomonitoring and Toxicokinetics of Russian VX

1. GC-MS and HPLC-MS Analyses of Russian VX Metabolites

Identification and quantitative assessment of toxic chemicals and their metabolites in biomedical samples can be performed by the following scenarios: (1) establishment of the fact and factor of exposure of humans and animals to chemical accidents; (2) clinical diagnosis of poisoning; (3) forensic expertise; and (4) biomonitoring of people who deal with highly toxic chemicals. RVX, like other highly toxic readily metabolizing chemicals, is difficult to detect in body fluids and tissues even a very short time after exposure. Successful identification and quantitative assessment of the toxicity factor in biomedical samples is possible under the following conditions (Savelieva *et al.*, 2003): right choice of biological matrix (object for analysis); right choice of a biomarker pertinent to the level and nature of exposure; measurable biochemical or biological effect; availability of a reliable and sufficiently selective and sensitive analytical procedure; availability of reference compounds and criteria for correct data interpretation. Analytical procedures applied to diagnosis and retrospective verification of exposure to OP include (Worek *et al.*, 2005): (1) biochemical determination of ChE activity; (2) identification of unbound OP; (3) identification of decomposition products; (4) fluoride-induced reactivation of inhibited ChE, followed by analysis of the inhibitor; and (5) analysis of phosphyl–protein adducts after tryptic digestion of the protein. The last procedure is regarded to be the most specific and sensitive, but has the drawback of being strongly dependent on the analysis of butyrylcholinesterase (BChE), the most abundant plasma serine esterase with a half-life of about 16 days.

It is well known that hydrolysis is the major metabolism pathway of G-series agents (DeFrank *et al.*, 1993; Beck and Hadad, 2008). The enzymatic hydrolysis of these agents primarily involves phosphorylyl phosphatases and produces *O*-alkyl methylphosphonic acids (*O*-alkylMPA). V-series agents (VX, RVX) are not typical substrates for phosphorylyl phosphatases, which probably explains the higher persistence of these agents in the organism. Free *O*-alkyl methylphosphonic acids formed by hydrolysis of OP agents can be detected in body fluids and tissues and are used as markers of exposure to these agents. The final hydrolysis product is MPA, but its fraction is smaller compared to *O*-alkylMPA. The low-molecular RVX hydrolysis products are actively excreted within the first days after intoxication and can serve as suitable targets for retrospective analysis for no longer than 2–3 weeks. However, 2–3 days after exposure the body levels of *O*-alkylMPA and MPA become much more demanding in terms of detection sensitivity. We have developed a series of procedures for identification and quantitative assessment of *O*-isobutyl MPA as a marker of exposure to RVX, in urine and blood plasma. Characteristics of the procedures are presented in Table 7.3.

The GC-MS procedure involves sample deproteinization, purification, evaporation to dryness, *tert*-butyldimethylsilylation of redissolved dry residue, and GC-EIMS analysis in the SIM mode. The solid-phase microextraction (SPME)-GC-MS procedure involves extraction of *O*-alkyl MPA from urine on microfiber, their *tert*-butyldimethylsilylation directly on microfiber, and thermodesorption of the resulting derivatives in a GC injector. SPME of *O*-alkyl MPA on microfiber is an effective approach for urine, since it allows one to avoid the stage of sample desalination associated with inevitable losses of target compounds. However, SPME is much less effective with plasma because of its high protein content. The HPLC-MS procedure involves sample centrifuging, solid-phase extraction on Diapak C16M cartridges, elution with an acidic (pH 3.0–4.0) methanol, evaporation and redissolution of the eluate, and HPLC-MS analysis in the chemical ionization mode at atmospheric pressure with registration of negative ions (Rodin *et al.*, 2006, 2007). The latter procedure has been used in toxicokinetic experiments for measuring the concentration of *O*-alkyl MPA in rat plasma 1, 6, 24, and 48 h after

intramuscular injection of OP agents at a dose of $0.8 \times LD_{50}$ (0.0144 mg/kg). The toxicokinetic curve for *O*-isobutyl MPA is presented in Figure 7.2.

The HPLC-MS (quadrupole analyzer) and HPLC-MS-MS (medium-class ion-trap analyzer) procedures for the determination of OP metabolites in blood plasma were found to be comparable in terms of sensitivity, accuracy, and performance, but HPLC-MS is preferred in terms of availability and cost of equipment and maintenance.

2. MS/MS Analysis of Human Albumin

Albumin has been demonstrated to be an OP hydrolase (Erdos and Boggs, 1961; Sogorb *et al.*, 1998). Bovine albumin binds diisopropylfluorophosphate (DFP) in equimolar proportions (Murachi, 1963), and binding of DFP to Tyr was shown simultaneously (Sanger, 1963). Mass spectrometry identified the active site to be Tyr410 for bovine albumin and Tyr411 for human albumin (Schopfer *et al.*, 2005; Li *et al.*, 2007). A characteristic feature of this Tyr is a low pKa near 8, in contrast to pKa near 10 for other tyrosines (Means and Wu, 1979), which is believed to be due to a pocket with nearby basic residues Arg410 and Lys414 in human albumin (Sugio *et al.*, 1999; Li *et al.*, 2007). Various warfare agents were shown to readily bind to Tyr411, though VX needs more time and a higher concentration for this chemical binding, which is explained by a lower potential of the $SCH_2CH_2N(iPr)_2$ substituent in VX to leave in a noncatalyzed reaction, as compared with F^- or CN^- (Williams *et al.*, 2007).

In order to find out the specificity of RVX binding with albumin, we first obtained a mass spectrum of human albumin after *in vitro* incubation of blood serum of one of the authors (V.B.) with RVX (Figure 7.3). The shift in the spectrum of about 400 Da suggested two to four sites of RVX binding to albumin.

To search for the sites we incubated RVX with commercially available human albumin (Sigma), and then digested it with trypsin to obtain MS/MS peptide spectra. Two sites of binding RVX to human albumin were revealed, one of them being the well-known Tyr411 (not shown here).

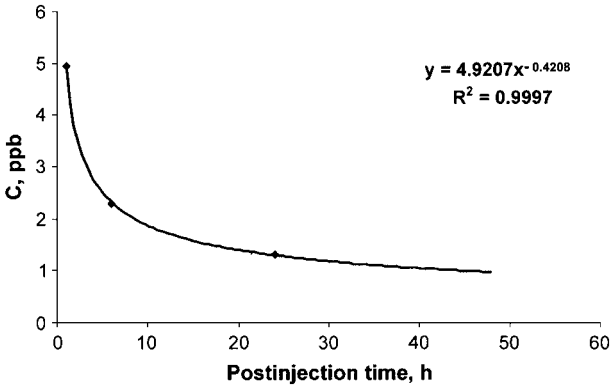

FIGURE 7.2. Concentration of *O*-isobutyl MPA in blood plasma versus time after intramuscular injection of RVX in rats at a dose of $0.8 \times LD_{50}$.

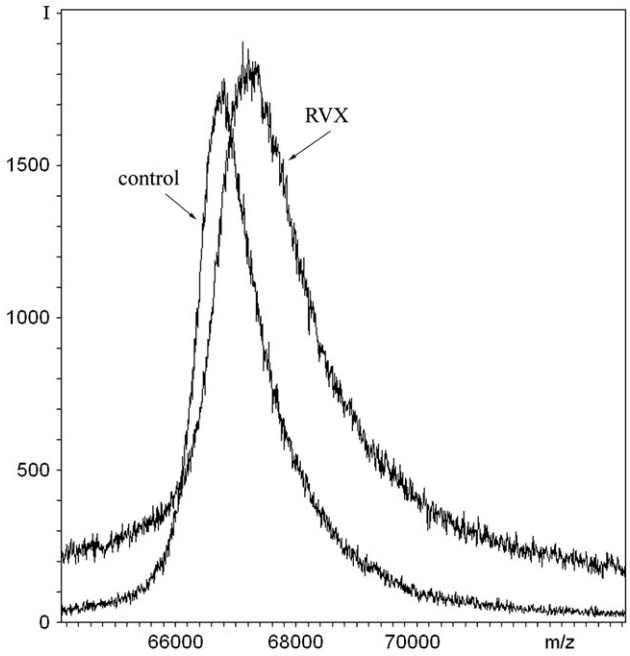

FIGURE 7.3. Mass spectrum of human blood serum albumin in linear mode after *in vitro* incubation with 0.1 mg/ml RVX at 37°C for 1 h.

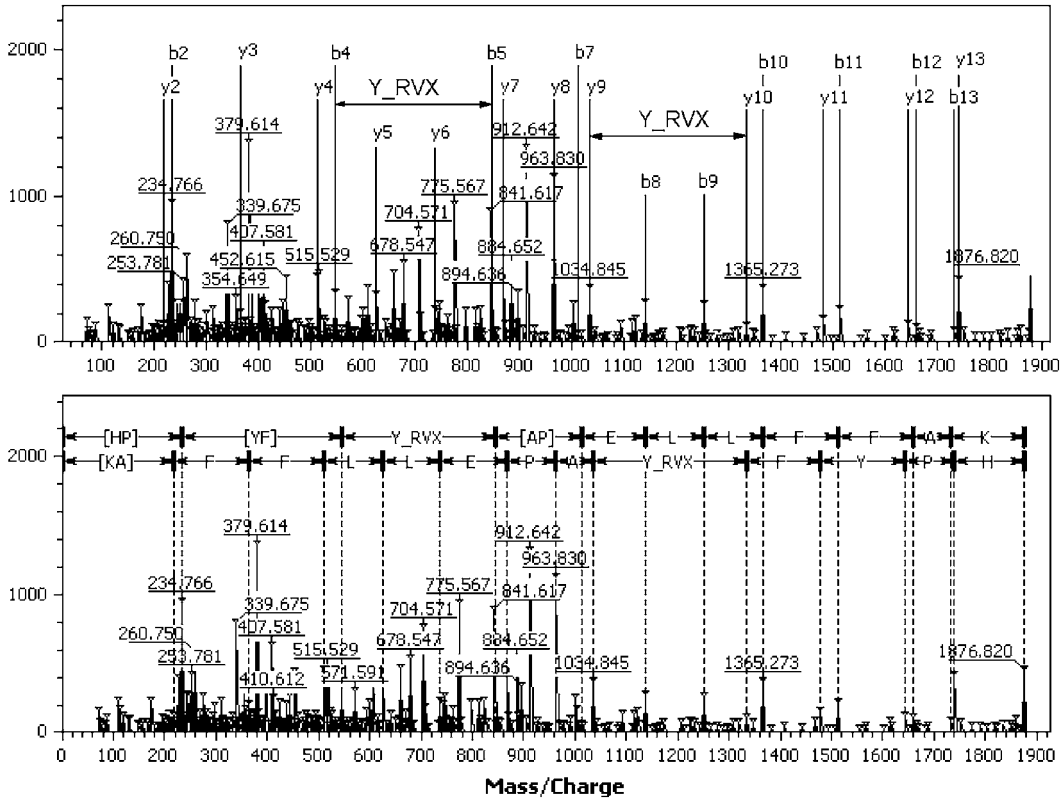

FIGURE 7.4. MS/MS spectrum of peptide HPYFYAPELLFFAK with phosphonylated Tyr150, obtained after trypsinolysis of human albumin incubated *in vitro* with RVX 0.1 mg/ml at 37°C for 1 h. The parent ion has MH+ 1876.820. Ions y and b (up) and deciphered sequence of the peptide (bottom). Tyr150 of the phosphonylated RVX is designated (Y_RVX).

The second site was an unexpected Tyr150 (Figure 7.4). Taking into consideration that 144–160 amino acids in human albumin are RRHPYFYAPELFFAKR (http://myhits.isb-sib.ch/cgi-bin/motif_scan), we suggest that Tyr150 could be activated by positively charged RRH and KR, which could serve to lower its pKa. However, these data and suggestion need *in vivo* experimental evidence.

III. MECHANISMS OF ACTION AND TOXICITY

Three types of damage induced by OPs have been identified: acute poisoning, the so-called intermediate syndrome (IS), and OP-induced delayed polyneuropathy (OPIDP) (Ray, 1998). The IMS symptoms and signs usually occur after apparent recovery from the acute cholinergic syndrome but before OPIDP is developed (Karalliedde *et al.*, 2006). OPIDP also occurs almost exclusively in patients with preceding acute cholinergic toxicity related to severe acute exposure to an OP compound; neuropathy target esterase (NTE) is considered to be the principal molecular target for OPIDP (Lotti, 1991; Ehrich and Jortner, 2001; Lotti and Moretto, 2005). However, there is no data to indicate that VX has any potential at high or low doses for the induction of OPIDP in its classic manifestation in human beings or other species either with acute or long-term exposure. The reason could be that the ability of VX to inhibit NTE is near 1000-fold less than that of GB (Vranken *et al.*, 1982; Gordon *et al.*, 1983). Single intramuscular, injections of VX at 5 × LD_{50} in atropine-protected chickens did not produce inhibition of NTE and histological or behavioral evidence of OPIDP (Wilson *et al.*, 1988a). There was no ability of VX at subchronic exposure (0.04 mg/kg for 90–100 days) to induce OPIDP in antidote-protected chickens (Wilson *et al.*, 1988b). According to other data, NTE activity in brain areas and soleus muscle of rats was significantly depressed after they were subacutely exposed to VX in the absence of supporting therapy for 14 days at doses at the LD_{50} level and higher, and surviving animals exhibited muscle myopathy in the soleus muscle (Lenz *et al.*, 1996). Blood AChE activity was depressed to zero throughout the experiment, so there is no contradiction on the lack of clear OPIDP signs under severe intoxication with VX.

Thus, molecular mechanisms of delayed and chronic effects of VX are still poorly understood, and scientific data on these effects under RVX intoxication is much scarcer. It seems that chronic intoxication should be a separate type of damage with OPs. The problem requires a search for new criteria of intoxication. One should differentiate at least two aspects of this problem: molecular and functional. The former concerns revealing new molecular targets of OP

action. For instance, plasma and liver carboxylesterases (CarbEs) may be more sensitive targets compared to AChE in cases of chronic action of OP low concentrations (Ray and Richards, 2001). Since CarbEs are responsible for the metabolism of a variety of xenobiotics, this fact has been ignored over a long period of time. Another esterase is involved in testosterone biosynthesis metabolizing cholesterin esters in the testis (Jewell and Miller, 1998), one more (surfactant convertase) is also involved in cholesterin metabolism in the lung (Krishnasamy *et al.*, 1997), and a number of brain CarbEs and other hydrolases are also sensitive to OPs (Poulson and Aldridge, 1964; Chemnitius and Zech, 1983; Richards *et al.*, 2000; Nomura *et al.*, 2005). Various OPs are potent inhibitors of fatty acid amide hydrolase and monoacylglycerol lipase (Quistad *et al.*, 2001, 2006), the principal enzymes of the endocannabinoid system.

The second (functional) aspect of this problem concerns the development of pathologic symptoms, the molecular causes of which are not due to AChE inhibition. One of the first cases of OP nonanticholinesterase effects (when the association between the OP molecular target and the functional disturbance has been proved) involved inhibition of kinurenin formamidase of the hen egg yolk sac membrane responsible for teratogenic effects (Seifert and Casida, 1978). Another example of OP teratogenic effect is abnormal development of the conjunctival tissue of *Xenopus* embryos due to inhibition of lysyloxidase and incomplete post-translational modification of collagen (Snawder and Chambers, 1993).

A. Acute Intoxication with RVX

A contributing factor to the high toxicity of VX may be its preferential reaction with AChE. Moreover, unlike the G agents, VX depresses AChE activity significantly more than BChE in humans (Sidell and Groff, 1974); the result is that more VX is available to react specifically with the target enzyme, AChE. At the same time, indirect primary (connected with AChE inhibition) and secondary (not connected with AChE inhibition) effects of RVX have also been described. Development of after-intoxication immunodeficient or immunotoxic states relates to the first group of effects (Germanchuk and Zabrodskii, 2005). In experiments with rats that were administered RVX at a dose $0.75 \times LD_{50}$ a suppression of immune reactions was found: Th-1 cells significantly lost their functions, and T-dependent immune reactions were depressed. In addition, an optimal balance of cAMP and cGMP in lymphocytes necessary for their proliferation and differentiation was disturbed (Zabrodskii *et al.*, 2003, 2007). On the other hand, after a severe intoxication with RVX of laboratory rats ($2 \times LD_{50}$ with therapeutic treatment) there was no after-effects concerning the capability of the central nervous system to produce conditioned reflex reactions, either in early post-intoxication period (2 weeks) or at remote terms (1–6 months) (Novikova *et al.*, 2007). Four different effects of RVX were ascribed to the second group (Prozorovskii and Chepur, 2001): (1) sensitization and desensitization of cholinoceptors to acetylcholine (ACh) that is characteristic for M-cholinoceptors; (2) influence on ACh release by nerve terminals: an inhibition under stimulation of M- and facilitation under stimulation of N-cholinoceptors; (3) direct interaction with cholinoceptors, mainly with nicotinic ones, leading to either their activation or inactivation; and (4) interaction with ionic channels, mainly with that of N-cholinoceptors.

Hypoxic syndrome is one of the principal clinical manifestations under acute intoxication with RVX. It is triggered by disturbance of ventilation, which in its turn is caused by bronchospasm, bronchorrhea, convulsions, and central deregulation of respiration. A series of pathological mechanisms leads to reduction of circulating blood volume, decrease of blood vessel tone, and deregulation of vessel wall permeability. Abnormalities of blood rheology, caused by the loss of body fluids (salivation, bronchorrhea, etc.), and aggregation of blood cells significantly increase dynamic viscosity of blood and aggravate disturbances of microcirculation. Disturbances of oxygen transport and its delivery to tissues induce secondary metabolic disorders and involvement in pathological process of related biological systems which provide oxygen utilization by the tissues (Shestova and Sizova, 2005). Imbalance of electrolytes has also been described: in blood plasma under acute intoxication there was a decrease of sodium and potassium, the latter being more expressed than the former (Rybalko *et al.*, 2005). Indirect secondary effects of OP agents including RVX can be induced by excessive amounts of ACh in blood, with its action on cells having no cholinergic innervations. This can lead to deformation of red blood cells and endothelial cells, activation of basophils, and degranulation of mast cells (Prozorovskii and Chepur, 2001). In this context, one should keep in mind that endothelial cells have all the attributes of autonomic cholinergic regulation. Not only M- but also N-cholinoceptors have been revealed (Hsu *et al.*, 2005), as well as activity of AChE (Carvalho *et al.*, 2005; Santos *et al.*, 2007), the system of synthesis of acetylcholine (choline acetyltransferase), and vesicular system of ACh transport out of the cells (Kirkpatrick *et al.*, 2001, 2003).

B. Chronic and Subchronic Intoxication with RVX, and Delayed Effects

In the context of realization of the conventional programs for chemical weapon (CW) destruction, chronic effects of subsymptomatic concentrations of RVX are of particular interest, since risk of exposure of personnel of the CW destruction facilities to chemical agents cannot be completely ruled out. In addition, members of the rescue service engaged in the decontamination process are regarded as a group at high risk of exposure. The difficulty of diagnosis of delayed effects and chronic intoxication with RVX relates to polymorphism of the clinical manifestations

(Savateev *et al.*, 2001). Long-term monitoring of personnel staff engaged in production of RVX revealed slowly progressing signs of chronic intoxication (Gur'eva *et al.*, 1997). The clinical signs of this may consist of functional and organic disorders of the central nervous system together with vegetative dysregulations, such as peripheral angiodystonic syndrome, vegetosensory polyneuropathy or complex motor-sensory-vegetative pathology of axonopathic or myelinopathic type. Neuromuscular affects, visual and gastrointestinal disorders, immunodeficiency and metabolic disorders have also been described (Gur'eva *et al.*, 1997; Yanno *et al.*, 2000). Cessation of contact with RVX does not lead to involution of the clinical picture of chronic intoxication. Along with nervous, gastrointestinal, and motor disorders, there can be visual and cardiovascular diseases. Moreover, the chronic occupational pathology of the former workers of the facilities may develop in 3–6 years even though they were exposed to no more than tenfold the maximum permissible concentrations of RVX and had no acute intoxications in their anamneses (Filippov *et al.*, 2005).

Experimental results were reported on exposing male and female rats to VX (0.00025, 0.001, or 0.004 mg/kg, s.c.) daily for 30, 60, and 90 days (Goldman *et al.*, 1988). RBC-AChE activity was significantly depressed in rats at all VX doses for 30, 60, and 90 days. BChE was significantly depressed in rats given 0.001 mg/kg VX for 30 days and in both genders of the high-dose group at all exposure periods. No dose-related changes were reported in clinical chemistry and histopathology. The authors concluded that VX exposure sufficient to significantly depress RBC-AChE activity produced no subchronic toxic effects.

Taking into consideration these clinical manifestations of delayed and chronic effects of RVX, an experimental search was undertaken to seek new possible mechanisms of the pathogenesis and novel functional signs of intoxication (Goncharov *et al.*, 2001, 2002, 2003; Mindukshev *et al.*, 2005b). To model chronic intoxication in experiments with animals, RVX was dissolved daily in drinking water to concentrations of 5×10^{-8}, 5×10^{-7}, and 5×10^{-6} g/100 ml. A group of five rats consumed 20 ml of RVX aqueous solution daily. So, during the 3 month test, animals of the first group consumed daily RVX with drinking water in a dose 10^{-5} mg (**I**), animals of the second group 10^{-4} mg (**II**), and those of the third group 10^{-3} mg (**III**) per 1 kg body weight. Measurement of AChE activity in red blood cells (RBC-AChE) was performed by Ellman's method (Ellman *et al.*, 1961). The functional activity of platelets was investigated by a novel method of low angle light scattering that allows all stages of the platelet transformation to be assessed (Mindukshev *et al.*, 2005a, b). Investigation of monosynaptic miotatic reflex and conduction rate through the peripheral nerve fiber was conducted with N. tibialis.

Comparative analysis of biochemical and physiological parameters studied is indicative of the complete absence of significant changes of RBC-AChE activity in rats of all three groups relative to the control, after exposure to the RVX doses given above (not shown here). On the contrary, platelets of test animals exposed to RVX differed from the control by their pronounced instability, an indication of which was development of their spontaneous activation and aggregation (Figure 7.5).

After 3 months of intoxication, kinetic parameters of aggregation – normalized maximal rate U_{max} and effective concentration EC_{50} – were significantly increased (in groups **II** and **III**). Two months after cessation of the chronic intoxication with RVX (rehabilitation period) significant differences of both kinetic parameters were found only for group **III**. Groups **II** and **I** showed significant increases of EC_{50}, but only a tendency ($p < 0.1$) to increase U_{max}. The final estimation of kinetic parameters of aggregation made after 6 months of rehabilitation showed significant decrease of U_{max} in group **III** and increase of EC_{50} in all three

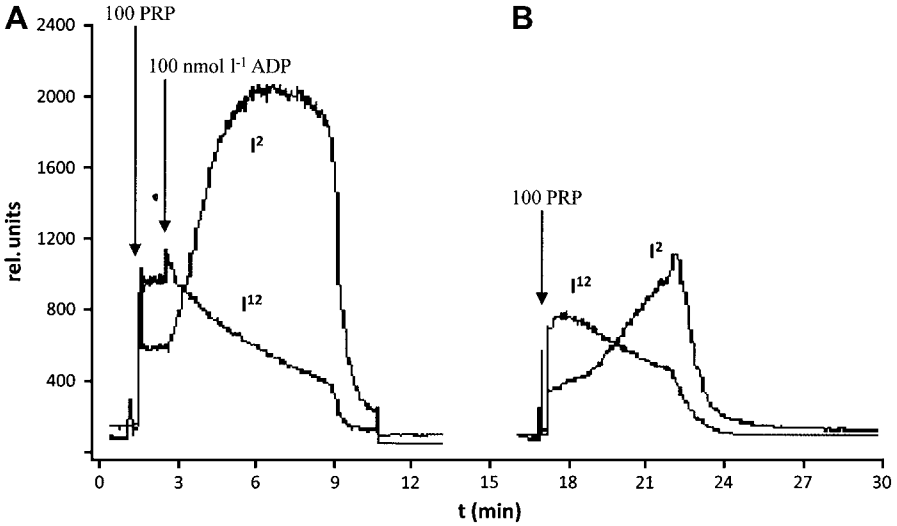

FIGURE 7.5. (A) ADP-induced activation and aggregation of blood platelets of control rats. (B) Spontaneous activation and aggregation of rat blood platelets immediately after 3 months' RVX exposure at a dose of 10^{-4} mg/kg. 100 PRP = 100 µl of Platelet-Rich Plasma; I^{12} and I^{2} indicate low angles of 12° and 2° at which light-scattering was recorded. intoxicated groups (Figure 7.6). Significant increase of U_{max} suggests the sensitization of platelets with the primary activation of signaling ways via protein kinases, the action of which tends to increase the expression of GPIIb/IIIa receptors (Geiger *et al.*, 1994; Shattil *et al.*, 1998). The increase of the EC_{50} parameter with further elevation of U_{max} points to a partial desensitization of $P2X_1$ and $P2Y_1$ receptors, as does the growing activity of the above-mentioned kinases.

Stimulation of the peripheral nerve trunk of intact animals leads to generation of muscle action potentials of three types. According to the duration of latent periods, they fall into the following order: M-response (the result of the direct stimulation of α-motor neuron axons), H-response (the monosynaptic response), and polysynaptic responses with the variable latent period from 8–12 up to about 40 ms. In test animals of the **III** group, the changes of temporal parameters refer mainly to the latent period and duration of M-response (Table 7.4). Polysynaptic responses occur at all intensities of excitation and have a more pronounced character than in intact rats. A marked level and more distinct differentiation of the peaks of the complex action potential were noted.

The results obtained after examining rats of **II** group differ from the control more significantly. Along with normal action potentials (of the ''spike'' type) there were slow waves of depolarization of up to 30 ms duration. Another significant difference is the absence of the ''subthreshold border'', that is, graduation of the increase of the amplitude of the action potential when the irritation stimulus enhances (Figure 7.7). Such an event can usually take place in newborn animals and is caused by slight differentiation of motorneurons (Bursian, 1983). The latent period of M-response, the rate of rising action potentials, and their duration increased significantly. The results of testing the rats of group **I** did not differ from the control. At the same time, some animals had the entire spectrum of pathologic reactions observed in rats of the **II** and **III** groups: fasciculations, the presence of slow (local, depolarized) potentials, and paradoxical discharges. The opposite character of the changes in velocity of nerve impulse conduction within **III** and **II** groups could be caused by different intensity of demyelinization of nerve fibers with different diameters.

E-5, E-4, and E-3 relate to doses of RVX ($1*10^{-5}$, $1*10^{-4}$, and $1*10^{-3}$ mg/kg) consumed by rats daily with drinking water. After Mindukshev *et al.* (2005b). Reprinted from *Spectroscopy Int. J.* **19**: 247–57. Copyright (reprinted with permission from IOS Press).

Earlier, there were contradictory functional disorders under exposure to OPs described, for which no appropriate interpretations were suggested from the point of view of molecular sources. For example, daily administration of DFP to rats for 20 days at a dose of 17% of LD_{50} caused an increase of velocity of nerve impulse conduction (Anderson and Dunham, 1985), though dimethoate or dichorvos treatment at subsymptomatic doses for at least 8 weeks caused reduction of peripheral nerve conductivity (Desi and Nagimajtenyi, 1999).

C. Studies of Peptide Fractions in Blood Plasma After Subchronic Exposure to RVX

To further clarify the pathogenesis of RVX chronic intoxication, and to seek new approaches to monitoring and estimating the effects of exposure of living organisms to RVX, we focused our efforts on analysis of the peptide fraction of blood plasma. In the past few years, a field of proteomics named peptidomics has been actively developed (Richter *et al.*, 1999; Villanueva *et al.*, 2006). Investigations in this field are focused on biomarkers of various pathological states mainly in oncology, and we have suggested that this scientific methodology could be of value in case of intoxication with OPs. A set of low molecular weight peptides is regarded as a ''molecular imprint'' of the state of an organism, or its molecular ''signature''. The pattern of peptide spectrum (''peptidome'', ''degradome'') reflects the state of certain proteins–enzymes, whose activity or even very existence is extremely hard to measure by direct biochemical methods (Villanueva *et al.*, 2006). With regard to specificity and sensitivity, the most convenient method for peptidome analysis should be mass spectrometry, and when considering a cohort analysis the most appropriate method should be matrix assisted laser desorption/ionization-mass spectrometry (MALDI-MS).

The mass spectra analysis of peptides was performed on an Ultraflex-TOF-TOF instrument (Bruker Daltonics, Germany) with a MALDI source equipped with UV laser (337 nm) operated with positive ion detection (*m/z* 700–2,000) and in reflection mode. The spectra were processed using Flex Analysis 2.4 software. A SwisProt database search was performed using the MASCOT program package (Matrix Science, UK). The exact monoisotope masses and

isotope distributions were obtained using the MassPro program, and MS/MS data were represented by means of the Sequence Viewer 2.0 program (Institute of Analytical Instrument Making, Russian Academy of Sciences). For procedure development and testing, the whole venous blood from healthy donors was taken into vacuum tubes charged with EDTA (Becton Dickinson). The low-molecular fraction of rat blood plasma peptides was obtained by precipitating plasma proteins with a 1:2 mixture of acetonitrile and 2% acetic acid for 30 min at 4°C followed by centrifuging at 10,000*g* for 30 min. The precipitate was then dissolved in 0.1% TFA, and the undissolved fraction of proteins unprecipitated at the preceding stage was removed by centrifuging at 10,000*g* for 10 min. The sample was desalinated with a membrane with a cross-linked C18 phase, placed in a microcolumn, after which the peptides retained by the membrane were eluted onto a target with a 60% solution of acetonitrile in 0.1% TFA, containing α-cyano-4-hydroxycinnamic acid (10 mg/ml).

The analysis undertaken revealed that several components of the peptide spectrum grew to become the major ones (Figure 7.8, right). Moreover, during the process of identification all the major peptides were referred to fibrinopeptide A that was truncated at the N-end. A new peptide GEGDFLAEGGGVR (MH^+ 1263.6 Da) came into the picture, which also had a fibrinogenic nature being characterized by the absence of three amino acids as compared to human fibrinopeptide ADSGEGDFLAEGGGVR.

A subchronic intoxication was then conducted by administration of aqueous solutions of RVX at doses $1/100LD_{50}$, given to rats with drinking water every day for 3 weeks. The period of exposure was followed by a 1 month recovery period during which further analyses were carried out. Activities of AChE and BChE in whole blood and plasma were measured according to Ellman *et al.* (1961), and activity of NTE was measured according to Johnson (1969). There were no significant changes in activity of AChE, BChE, and NTE under our experimental conditions (data not shown). Comparing the peptide spectra, we found no qualitative difference between the peptide pools in the mass range of 700–2000 Da. At the same time, several signals which were not notable in the control spectra became major ones in the spectra of intoxicated animals (Figure 7.9, right). Moreover, a new signal arose corresponding to peptide with MH^+ 1452.77 Da, which was absent in control spectra. For every peptide relating to these signals MS/MS analysis was carried out, which revealed that all of them originated from the N-end truncated fibrinopeptide A.

Thus, characteristic changes can be revealed in the low molecular weight fraction of blood plasma, and these could serve as a new molecular marker of intoxication with RVX and other OPs. The peptides of rats and humans begin with Gly from the N-end, and the preceding truncated amino acid is a neutral and hydroxyl-bearing one (Thr in rat fibrinopeptide and Ser in human fibrinopeptide) (Table 7.5).

It seems that under exposure to RVX an inhibition of some exopeptidases (aminopeptidases) takes place, resulting in a shift of the quantitative ratio of the low molecular weight peptide components of blood plasma. Specifically, an enhancement of the fibrinopeptide fragments' signaling occurs as compared to other signals in the spectrum, as well as the appearance of novel peptides related to fibrinogen. Thus, in addition to the above-mentioned peptide with MH^+ 1263.6 Da, another peptide with MH^+ 1616.6 Da emerged in the samples of human blood plasma exposed to RVX. According to the MS/MS analysis this signal was also due to fibrinopeptide A, though phosphorylated at a serine residue. Fibrinopeptide A is a peptide cut off from fibrinogen by thrombin during activation of blood clotting system (Blomback, 1967), and changes in the peptide spectra of fibrinogen origin signify a possible impact of RVX on blood vessels and hemostasis.

In addition, we have discovered another peptide SFSYKPRAPSAEVEMTAYVL that was present in plasma of control rats, but absent in plasma of subchronically intoxicated rats just after intoxication and 1 month after cessation of the subchronic intoxication (Figure 7.10). Identification of the peptide revealed that it was a part of

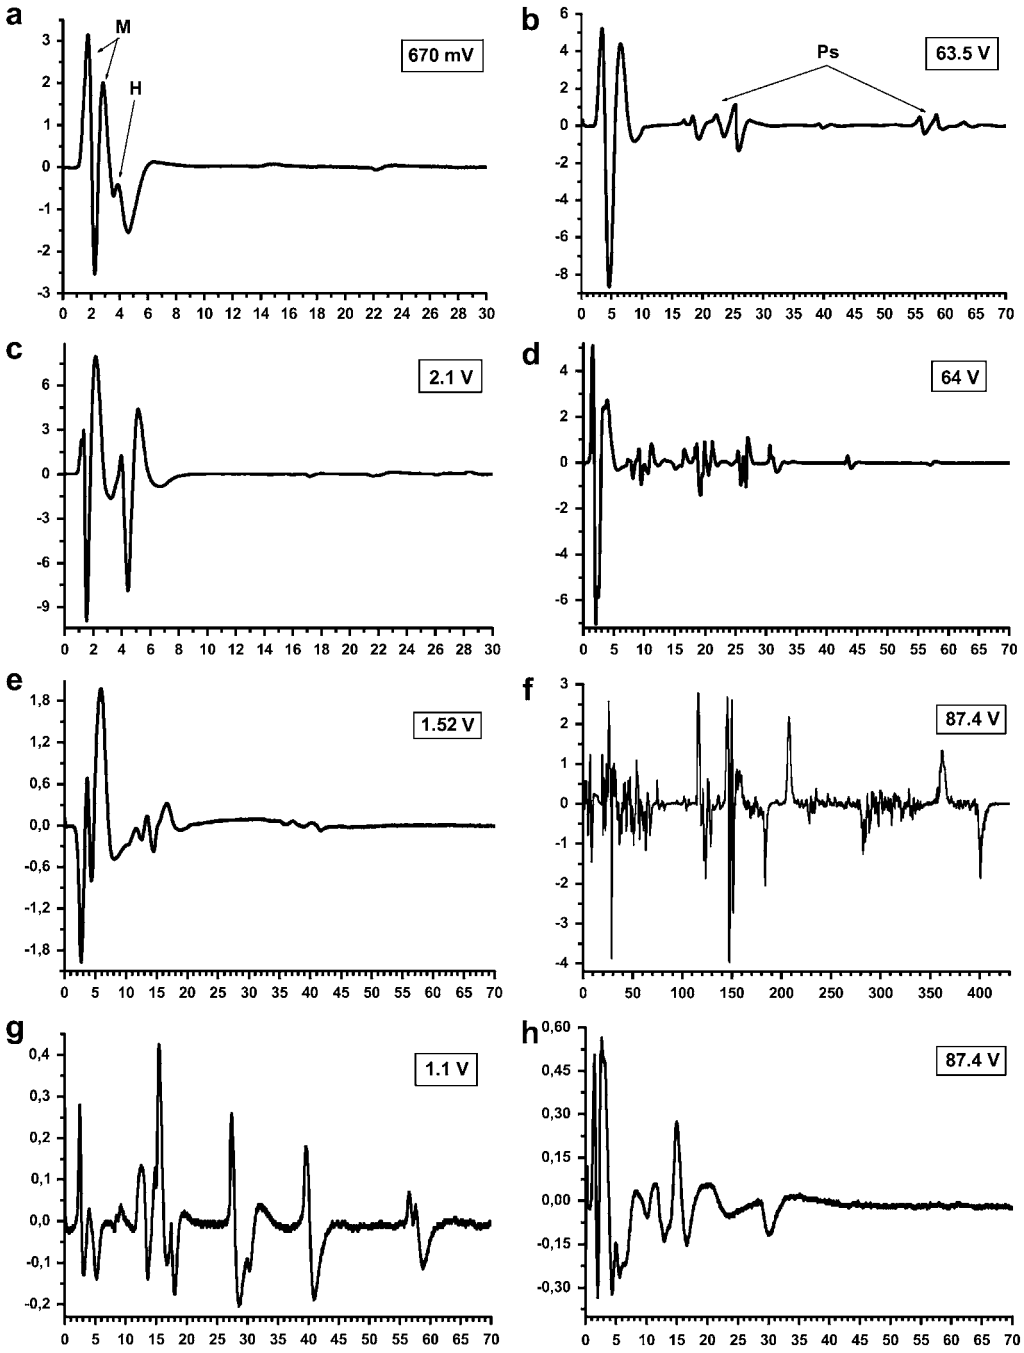

FIGURE 7.7. Action potentials of the rat gastrocnemius muscle under stimulation of N. tibialis: effect of direct stimulation of the muscle (M-response, M), mono- (H-response, H) and polysynaptic (Ps) responses of control rats (a, b), rats of group III (c, d), II (e, f), and I (g, h). Ciphers within frames indicate value of the stimulus. *x*-axis shows time of registration, msec; *y*-axis shows amplitude of action potential, mV.

alpha-1-macroglobulin of rat plasma. Furthermore, some other peptides were found that could arise from chymotryptic activity of proteinases of rat blood plasma and which could be fragments of alpha-1-macroglobulin (not shown here). As for possible sources of chymotryptic activity in blood plasma, several chymotrypsin-like proteinases have been described, the most common of which are chymase and cathepsin G (Schoenberger *et al.*, 1989; Bisaro *et al.*, 2005). Their targets have been shown to be C1-inhibitor, angiotensin I, extracellular matrix, TGF-beta1, IL-1beta, and alpha-2-macroglobulin (Schoenberger *et al.*, 1989; Doggrell and Wanstall, 2004; Bisaro *et al.*, 2005; Bacani and Frishman, 2006). Considering data obtained in experiments with rats, one should keep in mind that alpha-1-macroglobulin is the main macroglobulin in rat blood plasma or serum, its concentration being at the level of 2–4 mg/ml, whereas the concentration of alpha-2-macroglobulin is less than 50 μg/ml (Lonberg-Holm *et al.*, 1987; Sottrup-Jensen, 1989). In human plasma, alpha-1-macroglobulin is completely absent (Lonberg-Holm *et al.*, 1987), but the concentration of human alpha-2-macroglobulin is similar to that of rat alpha-1-macroglobulin, and it has been suggested that these two macroglobulins have similar functions in humans and rats (Tsuji *et al.*, 1994).

D. Embryotoxicity, Gonadotoxicity, Mutagenesis, and Carcinogenesis

To study the embryotoxicity of RVX, it was administered to pregnant female rats perorally at a dose $1/100LD_{50}$ (Kiryukhin *et al.*, 2007). RVX had a toxic effect in the females judged by decrease of their RBC-AChE activity; at the same time, AChE activity in tissues of fetoplacental complex complied with age-specific control levels. These results may be regarded as evidence for impossibility or low probability of transplacental transfer of RVX from maternal organism to fetus. However, manifestation of intoxication symptoms by pregnant rats indicates that RVX can induce an embryotoxic effect, which is apparent from disorders of

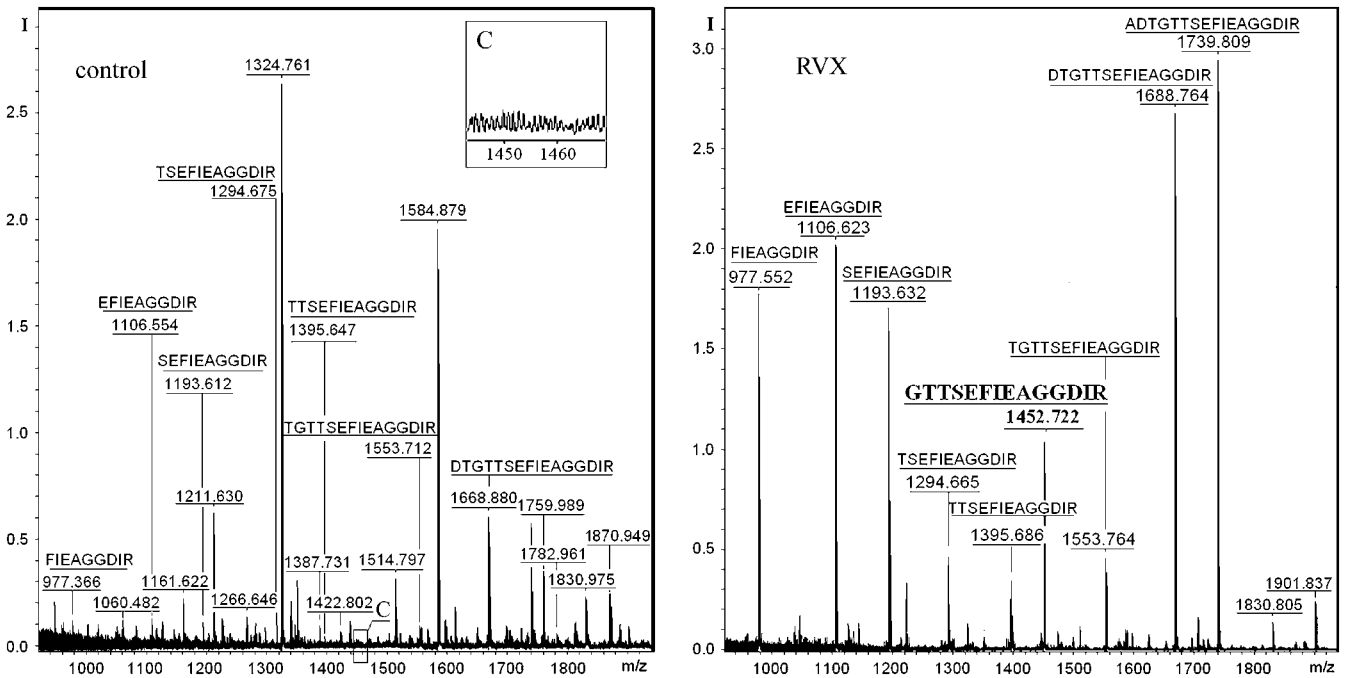

FIGURE 7.9. Mass spectra of peptide fraction of blood plasma of control rats (left) and that of rats after subchronic exposure to RVX (right). Lack of peptide with MH+ 1452.77 Da is demonstrated on the spectrum of control rats (C).

pre-natal and post-natal ontogenesis (Tochilkina and Kiryukhin, 2007). It should be mentioned that embryotoxicity of VX to rat fetuses was also shown after single LD_{50} doses to the mother (Guittin, 1988), and after repeated doses of 0.005 mg/kg (near $1/5LD_{50}$) at varying times during fetal development (Guittin *et al.*, 1987). On the other hand, no teratogenic potential of VX was found in sheep, rats, and rabbits (Van Kampen *et al.*, 1970; Goldman *et al.*, 1988).

Gonadotoxicity of RVX was investigated in chronic experiments for different ways of introduction. Dermal exposure of male rats to RVX demonstrated that general toxic effects were the governing factor of gonadotoxicity. There were no gonadotoxic effects at the level of threshold dose, which was estimated to be $4*10^{-6}$ mg/kg (Maslennikov and Kiryukhin, 2003). Other research has not revealed changes in weight parameters of left and right testicles and epididymis, nor as their total and specific weight parameters (Shabasheva *et al.*, 2007). It has been concluded that RVX poses no danger concerning development of specific disorders of male reproductive function, and this is in agreement with available data on VX: neither acute nor chronic VX exposure had deleterious effects on reproductive potential (Van Kampen *et al.*, 1970; Goldman *et al.*, 1987).

Studies of mutagenicity of RVX in the Ames test revealed no point mutations in the indicative bacteria. However, studies conducted by a micronuclear test have

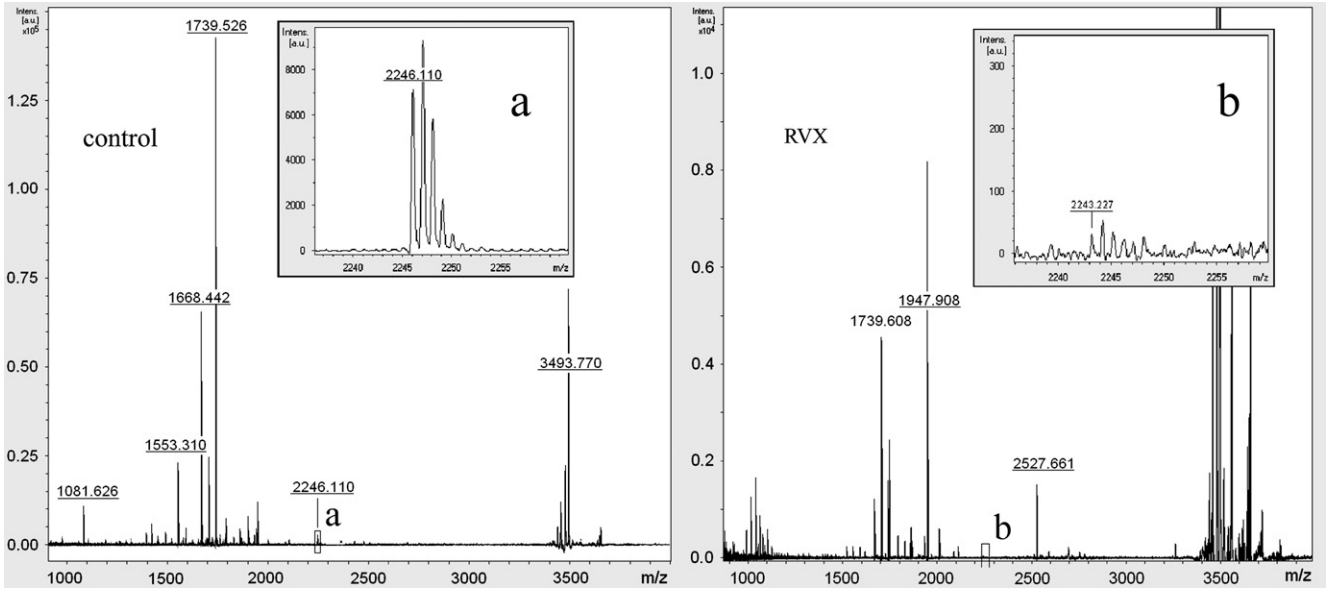

FIGURE 7.10. Peptide SFSYKPRAPSAEVEMTAYVL. (a) Blood plasma of control rats, (b) Blood plasma of rats after subchronic exposure to RVX.

demonstrated that a single intragastric introduction of RVX at a dose $1/10LD_{50}$ stimulated in rats an enhancement of frequency of polychromatophilic erythrocytes with extranuclear inclusions. In the case of absence of the cytotoxic effects, these alterations could be interpreted as being of a mutagenic nature (Maslennikov and Ermilova, 2005). At the same time, the threshold dose of general toxic effect of RVX did not have mutagenic as well as embryotoxic and gonadotoxic effects. Therefore, the delayed effects of RVX can appear at doses exceeding those that induce general toxic effects, indicating nonspecific character of its action.

In studies involving bacteria or yeast, VX was tested both with and without metabolic enzyme activation to determine if VX metabolites might be mutagenic; the results were negative (Crook *et al.*, 1983; Goldman *et al.*, 1988). In addition, negative results were obtained for VX in the *Drosophila* mutagenicity assay (Crook *et al.*, 1983), and VX was considered to be a nonmutagen in a test with mouse lymphoma cells (Goldman *et al.*, 1988).

In the available literature, we could not find experimental data on carcinogenicity of RVX. Nevertheless, epidemiologic data on tumor and pre-tumor diseases of the people who were engaged in production of RVX did not reveal an increase of oncological morbidity as compared to control humans (Fedorchenko *et al.*, 2003). In agreement with this, McNamara *et al.* (1973) reported that there was no increase in cancer in personnel working daily with VX.

IV. TOXICOMETRY AND HYGIENIC REGULATIONS

In countries dealing with destruction of chemical warfare agents, control limits for exposure via surface contact of drinking water are needed, as are detection methods for their low levels in water, soil, or foodstuffs. Some of the toxicity parameters of RVX for humans and animals are available in the text *A Book of Instructions and Technical Documentation on the Problem of Chemical Weapon Destruction* (Anon, 2001), and are given in Table 7.6.

In the event of contact of human skin with the fabric of a protective suit, there have been toxicometric parameters of RVX experimentally estimated with laboratory rats (Zhukov *et al.*, 2007): $LD_{50} = 0.55 \pm 0.09$ mg/kg, or $6.9*10^{-3}$ mg/cm^2; Lim ac (integr.) $= 0.056 \pm 0.001$ mg/kg, or $7.0*10^{-4}$ mg/cm^2; Lim ac (sp) $= 0.0051 \pm 0.001$ mg/kg, or $6.4*10^{-5}$ mg/cm^2; Lim ch $= 4.75*10^{-5}$ mg/kg, or $5.9*10^{-7}$ mg/cm^2. The maximum concentration limit of RVX for the fabric of protective suits has been estimated to be $3.1*10^{-8}$ mg/cm^2, taking into consideration the reserve coefficient, an average body weight, and total area of the skin.

For the purposes of sanitary regulations, it has been estimated that RVX within the range of concentrations 0.01–1.0 mg/l has no negative influence on the natural purification of aquatic reservoirs, on growth and decay of saprophytic and pathogenic microflora, and on nitrification processes; the noneffective dose of RVX has been estimated to be $1*10^{-7}$ mg/kg, the threshold dose $1*10^{-6}$ mg/kg, and the effective dose $1*10^{-5}$ mg/kg (Maslennikov and Ermilova, 2006). Studies on RVX effects on the soil microflora have revealed that actinomyces and micromycetes proved to be the most vulnerable, whereas *Nitrobacteria* was the least vulnerable species (Gorbunova and Maximova, 2003). The hygienic regulations for RVX are presented in Table 7.7.

V. PRINCIPLES OF THERAPY

Acute toxicity of OPs in general and RVX in particular has been much more extensively investigated than chronic toxicity, so it is not surprising that an effective therapy has been developed for acute intoxications only. The most effective antidote complex for treating acute intoxications with RVX consists of an antagonist of M-cholinoceptors, a reversible inhibitor of cholinesterase, and a reactivator of cholinesterase; in addition, anticonvulsants can be used in cases where convulsions occur. In experiments with guinea pigs, they were pretreated with pyridostigmine (0.026 mg/kg, i.m.), then immediately after RVX intoxication ($2 \times LD_{50}$) animals were given pralidoxime chloride (25 mg/kg, i.m.) and atropine sulfate (2, 8, or 16 mg/kg, i.m.); diazepam (5 mg/kg, i.m.) was administered to animals that displayed seizures and convulsions (Chang *et al.*, 2002). It was also

TABLE 7.6. Parameters of RVX toxicity for animals and humans

Parameter	Route of exposure	Dose
LCt_{50} (human)	Inhalation	0.04 mg/min/l
CL_{50} (mouse)	Inhalation	$1.8–4.5*10^{-5}$ mg/kg
LCt_{50} (mouse)	Inhalation	0.011 mg/min/l
LD_{50} (rabbit)	Percutaneous	0.014 mg/kg
LD_{50} (cat)	Percutaneous	0.01 mg/kg
LD_{50} (dog)	Percutaneous	0.0157 mg/kg
LD_{50} (mice)	Percutaneous	0.016 mg/kg
LD_{50} (human)	Percutaneous	0.1–0.01 mg/kg

TABLE 7.7. RVX safety standards in the Russian Federation (Uiba *et al.*, 2007)

MAC for working air (mg/m^3)	$5*10^{-6}$
MAC for reservoir water (mg/m^3)	$2*10^{-6}$
ASEL for ambient air (mg/m^3)	$5*10^{-8}$
MPL for equipment surface (mg/dm^2)	$2*10^{-6}$
MPL for human skin (mg/dm^2)	$3*10^{-8}$
MAC for soil (mg/kg)	$5*10^{-5}$
MEL for ambient air (mg/m^3)	
after 1 h	$1.6*10^{-5}$
after 4 h	$4.1*10^{-6}$
after 8 h	$2.0*10^{-6}$
after 24 h	$6.6*10^{-7}$

Abbreviations: MAC – Maximal Allowable Concentration
ASEL – Approximate Safety Exposure Level
MPL – Maximal Permissible Level of Contamination
MEL – Maximal Emergency Level

shown that in case of acute intoxication with RVX, higher doses of atropine should be administered as compared to those for VX, and of several oximes (pralidoxime, obidoxime, HI-6) the most effective was HI-6, as it was in the case of VX, sarin, cyclosarin, or soman poisonings (Kassa *et al.*, 2006).

Looking for therapy to treating chronic low-dose intoxication, one should keep in mind that the VX-AChE complex has been found to undergo a significant degree of spontaneous reactivation in humans (at a rate of about 1%/h over the first 70 h after i.v. administration of VX); another feature of VX toxicity is the lack of aging or stabilization of the VX-AChE complex and the relative ease of reactivation of VX-poisoned enzyme by oxime antidotes in humans (Sidell and Groff, 1974). Because there are no major differences in the reactivation process of both VX and RVX-inhibited cholinesterase (Kuca *et al.*, 2006), natural inactivation with plasma and liver paraoxonase (PON1) of RVX, VX, and other warfare agents could play a bigger role in prophylactic therapy of acute and chronic intoxications and their delayed effects (Li *et al.*, 1993; Costa *et al.*, 2005). PON1 is a catalytic bioscavenger, in contrast to stoichiometric bioscavenger BChE. A constituent of red wine, resveratrol, has been shown to be a natural and rather effective up-regulator of PON1, and it has good potential for protecting living cells against chemical warfare agents (Curtin *et al.*, 2008).

VI. CONCLUDING REMARKS AND FUTURE DIRECTION

The ambient monitoring and biomonitoring of RVX and its destruction products within the areas of chemical weapon storage and destruction facilities is an important task for the State Sanitary Inspection Units of the Russian Federation. In this regard, development of chemical analytical and bioanalytical methods and procedures should be among the main purposes of applied sciences. At the same time, estimation of probability of exposure to RVX and other warfare agents calls for fundamental problems of molecular and functional diagnostics of the pathogenesis to be solved, as well as development of effective therapy or prophylaxis.

In this chapter, we presented the principal products of RVX hydrolysis with excess water in an acid medium. It has been shown that after the 3 months' exposure, close to 1% of the initial amount of RVX in the solution could be detected. According to data on RVX hydrolysis with an equimolar amount of water, the autocatalytic hydrolysis of RVX was almost completed after 3 months, since the RVX content in the sample was no more than 0.01%. Moreover, the reaction mixture was much poorer than in the case of hydrolysis with excess water. Isobutyl MPA, which catalyzes RVX degradation, was detected as the major component of the reaction mixture. Yang *et al.* (1996) found 2-(diethyl amino)ethanethiol as the second major component of the mixture, but in our experiment it was almost completely converted into bis[2-(diethylamino)ethyl]disulfide.

We have not found conditions for effective extraction of RVX in experiments with its application on soil, concrete, bricks, and polyisobutylene at concentrations of 10^{-6}–10^{-5} mg/kg. The extremely low recoveries of RVX from materials of various natures can be explained by both irreversible sorption and degradation. A summarized list of compounds isolated from samples of building materials was presented, which were taken from some areas of a former RVX production facility and might have contacted RVX. RVX degradation products were found, along with organic components of building materials, solvents, plasticizers, reaction products of degassing agents with matrix components, etc. High concentrations of fyrols were detected in some brick and concrete samples.

Procedures for identification and quantitative assessment of *O*-isobutyl MPA (a marker of exposure to RVX) in urine and blood plasma have been developed, and toxicokinetic experiments conducted to measure *O*-alkyl MPA in rat plasma after intramuscular injection of RVX at a dose of $0.8 \times LD_{50}$. In addition, we have obtained a mass spectrum of human albumin after *in vitro* incubation of blood serum with RVX. Incubation of commercially available human albumin with RVX with subsequent trypsinolysis and MS/MS analysis has revealed two sites of binding RVX to human albumin, Tyr 411 and Tyr150. These data could contribute to development of sensitive and specific diagnostic methods.

Having analyzed our own experimental data and available scientific literature we came to the conclusion that the toxicological features of RVX were not properly studied. On the one hand, pathogenesis of acute intoxication has been described, and toxicometric parameters and hygienic regulations have been developed. On the other hand, mechanisms of nonspecific effects and chronic intoxication, and the pathogenesis of delayed manifestations, need further

clarification. This is why there is a lack of effective prophylactic and therapeutic means of treating the delayed effects of RVX (and many other OPs) that cannot be reduced to development of OPIDP. The search for non-cholinesterase targets is still far from its final stage and not all the functional consequences of an OP exposure have been revealed. Various OPs can covalently bind to tyrosine residues of tubulin, near the GTP binding sites or within loops that interact laterally with protofilaments (Grigoryan *et al.*, 2008), and this could partly explain an impairment of fast axonal transport and neuropsycological effects of low-dose chronic exposure to OPs (Stephens *et al.*, 1995; Terry *et al.*, 2007). Previously, assumptions have been made about a direct influence of OPs on the humoral components of hemostasis and the complement system in terms of abundance of serine proteases in these systems (O'Neill, 1981; Ray, 1998). An interrelation of hemostasis and neuromuscular conduction is of undoubted interest considering the low percentage of endoneural capillaries in the structure of nerve fibers, and dependence of the trophism of any tissue upon the integrity of the endothelial monolayer and upon adequate functioning of hemostatic mechanisms. An idea about dependence of the trophism of nerve fibers upon the vascular bed comes from data on their ratio: the volume of capillaries amounts to just 2–4% of the total volume of nerve fiber (Odman *et al.*, 1987). Moreover, peripheral nerves have no lymphatic vessels, which could provide an effective outflow of the capillary infiltrate and prevent development of edema (Low, 1984; Olsson, 1984).

Our data support suggestions on a key role of nonsynaptic mechanisms of developing effects under chronic exposure to RVX. The morphofunctional changes at the level of the microcirculatory bed that influence the functional state of platelets may prove to be significant factors in the etiology of delayed effects of chronic intoxication. Since the life span of blood platelets is about 10 days (Stuart *et al.*, 1975), the changes observed are likely to reflect multiple micro-angiopathies, when clinically pronounced manifestations are prevented by compensatory mechanisms, such as receptor desensitization, endothelial and plasmatic proteases, and molecular effectors providing the feedback regulation.

It is well known that OPs cause inhibition of several major enzymes, and this fact can be easily proved by simple methods of laboratory and clinical biochemistry. On the other hand, diagnostics of a low-dosed chronic action of OPs, or their delayed effects after subacute intoxication, is a big problem because of lack of inhibition or recovery of the enzymes' activity. Determination of a peptide spectrum of blood plasma or serum could serve as an alternative and more sensitive method for diagnosing the intoxications. We have shown with MS/MS analysis that peptide components of plasma or serum affected by RVX are represented by fragments of fibrinopeptide A, and this fact could signify an inactivation of exopeptidases (aminopeptidases) under exposure to RVX. It is interesting that earlier an N-acyl-peptide hydrolase was found in brain that was covalently bound with some OP pesticides in subsymptomatic concentrations (Richards *et al.*, 2000). Various aminopeptidases relevant to our research field have been found in plasma or serum. Aminopeptidase A (L-alpha-aspartyl-(L-alpha-glutamyl)-peptide hydrolase, EC 3.4.11.7) hydrolyzes only acidic amino acid derivatives (Asp and Glu in rat and human fragments of fibrinopeptide A) (Lalu *et al.*, 1986). Aminopeptidase N (CD13/APN, EC 3.4.11.2) is a multifunctional protein and the principal aminopeptidase in plasma; it is present as a membrane-bound enzyme on myeloid cells including mature monocytes and neutrophils (Favaloro *et al.*, 1993). It is also expressed on epithelial cells, fibroblasts, and endothelial cells; angiogenic growth or signaling factors induce CD13/APN expression (Pasqualini *et al.*, 2000; Bhagwat *et al.*, 2001; Bauvois and Dauzonne, 2006). On the other hand, alphastatin, a 24-amino acid peptide derived from the amino terminus of the α-chain of human fibrinogen, has been found to possess the anti-angiogenic activity that was originally observed to be present in fibrinogen degradation product E (Staton *et al.*, 2004). Numerous other proteolytic degradation products have been shown to be endogenous inhibitors of angiogenesis (Van Hinsbergh *et al.*, 2006). The MS/MS analyses conducted in our laboratories have revealed another enzyme activity affected by RVX, and it is likely to be a chymotrypsin-like activity. We certainly have to directly measure cathepsin G and chymase activities to prove our hypothesis; moreover, it is interesting in view of the fact that cathepsin B can be activated with cathepsin G to further enhance angiogenesis (Van Hinsbergh *et al.*, 2006).

An adequate interpretation of the experimental data would lead to a proper understanding of the therapeutic approaches, which could prevent or even reverse development of delayed effects of RVX and other warfare or pesticide OPs. Resveratrol is now being extensively studied in different laboratories as a possible remedy, being an effective up-regulator of PON1 (Curtin *et al.*, 2008). In view of our understanding of the pathogenesis of delayed effects, it is important to mention another property of resveratrol as a protector of endothelial progenitor cells, which contribute to renovation of injured blood vessels (Gu *et al.*, 2006; Xia *et al.*, 2008).

In conclusion, we outline some present and future directions in the studies on analytical chemistry, biochemistry, and toxicology of RVX:

- Improvement of the methodology of chemical and biochemical monitoring in environmental objects and human organisms;
- Development of prognostic modeling for probable risk assessment in case of elevation of the allowable levels of RVX in various media;
- Studies on the quantitative relations ''dose-effect'', ''time-effect'', and ''dose-time-effect'' for cholinesterase and noncholinesterase effects at both acute and chronic exposure to RVX;
- Studies on novel molecular and functional effects under acute and chronic exposure to RVX;

- Studies on mechanisms of development of delayed effects after intoxication with RVX;
- Development of novel effective means for prophylaxis and treatment of delayed effects of intoxications with RVX.

We believe that fulfillment of these studies would surely contribute to fundamental and applied knowledge far beyond the toxicology of RVX.

CHAPTER 8

Mustards and Vesicants

ROBERT A. YOUNG AND CHERYL BAST

I. INTRODUCTION

In the simplest terms, vesicants are chemicals that cause tissue blistering. Their toxic activity is, however, not limited to the skin and their mode of action is complex. These cytotoxic alkylating agents were initially developed as chemical weapons used to induce ocular, dermal, and respiratory damage resulting in immediate casualties, reduction in fighting efficiency, and demoralization. Depending on the exposure, injury may be local or systemic. This chapter will focus on sulfur mustards, nitrogen mustards, and lewisite. Although occasionally classified as a vesicant due to its action as a skin, eye, and respiratory tract irritant, phosgene oxime (CX) is more appropriately considered an urticant or nettle agent and is not discussed in this chapter. Extensive information regarding the chemistry and toxicology of vesicants is available in several publications (Papirmeister *et al.*, 1991; Somani, 1992; USACHPPM, 1996; ATSDR, 2003; Romano *et al.*, 2008). In response to a request by the Department of Veterans Affairs, a panel of experts extensively reviewed and evaluated the medical and scientific literature on mustard agents and lewisite, and the military testing programs relative to these agents (IOM, 1993).

The sulfur mustards include distilled mustard [bis(2-chloroethyl)sulfide; HD, SM], Levenstein mustard (H), agent HT [a mixture of HD and bis(2-chloroethylthioethyl)ether], a sulfur mustard–lewisite mixture (HL), and sesqui mustard (Q). Distilled mustard (HD) is relatively pure (97%) bis(2-chloroethyl) sulfide and results from the vacuum distillation of HD. Generic reference to sulfur mustard usually implies HD. Levenstein mustard (H) is a mixture of HD and sulfur impurities (generally in a 70:30 ratio) and, as its name implies, was produced by the Levenstein process involving reacting ethylene with sulfur chloride. Agent H may contain sulfur impurities imparting a yellowish color and sweet garlic-like odor.

Agent HT is generally a mixture of 60% HD and 40% bis(2-chloroethylthioethyl)ether (T), although this ratio may vary. Agent HL is a mixture of sulfur mustard (HD) and lewisite (L) that was developed for cold weather or high-altitude use due to its lower freezing point. Sesqui mustard (Q) is 1,2-bis(2-chloroethylthio) ethane and is considered a more potent vesicant than HD but its very low vapor pressure limits its effectiveness as a warfare agent, a condition remedied by combining it with HD to form agent HQ. Removal of one chlorine from sulfur mustard results in ''half-mustard'' (2-chloroethyl ethyl sulfide; CEES), a monofunctional sulfur mustard analog. Although retaining some alkylating properties, half-mustard is not as highly regulated as is sulfur mustard and is frequently used in sulfur mustard research. Most of the discussion of sulfur mustards in this chapter will be in reference to distilled sulfur mustard (HD).

Nitrogen mustards include HN1 [bis(2-chloroethyl) ethylamine], HN2 (2,2′-dichloro-*N*-methyldiethylamine), and HN3 [tris(2-chloroethyl)amine hydrochloride]. As will be discussed later, some of these found application in therapeutic arenas rather than in warfare.

Lewisite [L or L-1; dichloro(2-chlorovinyl) arsine] is an arsenical vesicant developed early in the 20th century. Lewisite occurs as *cis*- and *trans*-isomers; the typical ratio being 10:90. Several impurities including *bis*(2-chlorovinyl) chloroarsine (L-2) and *tris*(2-chlorovinyl)arsine (L-3) are typically present. The chemical and physical properties of the *cis*- and *trans*-isomers are similar.

A. Sulfur Mustards

Sulfur mustards are chemical vesicants capable of causing severe skin and eye damage at very low concentrations. The chemical name, synonyms, identification codes, chemical formula, and structural formula for sulfur mustard are shown in Table 8.1.

Although frequently referred to as ''mustard gas'', the chemical is a liquid at normal ambient temperatures. Due to its oily consistency and low aqueous solubility, sulfur mustard is persistent in the environment. Information on the half-life of HD in air is unavailable. As previously noted, impurities may impart a garlic-like odor to sulfur mustard. Odor thresholds ranging from 0.15 to 0.6 mg/m^3 have been reported for sulfur mustard (Dudley and Wells, 1938; Bowden, 1943; Fuhr and Krakow, 1945; Ruth, 1986).

Watson and Griffin (1992) have summarized information on the distribution of unitary chemical weapon stockpiles in the USA. The chemical and physical properties of sulfur mustard (agent HD) are shown in Table 8.2.

The water solubility of sulfur mustard has been reported as 0.092 g per 100 g water at 22°C (DA, 1974), and

TABLE 8.1. Nomenclature, chemical formulae, and chemical structure of sulfur mustard

Sulfur mustard (HD)	
Synonyms	*bis*(2-chloroethyl)sulfide; 1,1′-thiobis(2-chlorethane); 1-chloro-2-(2-chloroethylthio)ethane; SM; distilled mustard; agent HD; mustard gas; yperite; yellow cross
CAS No.	505-60-2
Chemical formula	$C_4H_8Cl_2S$
Chemical structure	C_2H_4-Cl / S \ C_2H_4-Cl

5×10^{-3} M at room temperature (MacNaughton and Brewer, 1994). In dilute aqueous solutions sulfur mustard hydrolyzes almost completely to thiodiglycol and hydrochloric acid (Papirmeister *et al.*, 1991). For dissolved HD, the hydrolysis half-life ranges from about 4 to 15 min for temperatures of 20–25°C. Bulk HD may persist in water for up to several years (Small, 1984). It has been estimated that it would take 15 days for the mass of a 1 cm droplet of HD in quiescent water to decrease by one half (Small, 1984). The Henry's law constant for HD has been estimated to be 2.1×10^{-5} atm m^3/mol (MacNaughton and Brewer, 1994), indicating a moderate potential for evaporation from water.

The persistence of sulfur mustard in soil depends on the soil type, pH, moisture content, and whether the agent is at the soil surface or buried. Small (1984) reported that HD applied to the soil surface volatilized and would likely be the main route of HD loss (half-life about 30 min). However, if the soil was wet, hydrolysis would be the primary loss pathway. When sprayed onto soil, a vesicant action may persist for about 2 weeks but when the agent continually leaks into the soil vesicant action may be present after 3 years (DA, 1974). Rosenblatt *et al.* (1995) state that the persistence of sulfur mustard in soil is due to the formation of oligomeric degradation products that coat the surface of the mustard agent and that are resistant to hydrolysis. This may greatly enhance the environmental persistence of sulfur mustard. Sulfur mustard has a log K_{ow} of 1.37 and a K_{oc} of 133, indicating that binding to soil organics would limit transport through soil to groundwater (MacNaughton and Brewer, 1994). MacNaughton and Brewer (1994) also calculated a leaching index of 7.2 for HD (i.e. the number of leachings required to reduce the HD soil concentration to one-tenth of the original amount, assuming that for each leaching one kilogram of soil is in equilibrium with one liter of water).

TABLE 8.3. Nomenclature, chemical formulae, and chemical structures of nitrogen mustards

HN-1	
Synonyms	ethyl-*bis*(2-chloroethyl)amine; *bis*-(2-chloroethyl)ethylamine
CAS No.	538-078
Chemical formula	$(ClCH_2CH_2)_2NC_2H_5$
HN-2	
Synonyms	methyl-bis(-chloroethyl)amine; 2,2′-dichloro-*N*-methyldiethylamine; ''S''; mechlorethamine
CAS No.	51-75-2
Chemical formula	$(ClCH_2CH_2)_2NCH_3$
HN-3	
Synonyms	*tris*(-chloroethyl)amine; [*tris*(2-chloroethyl)amine hydrochloride]
CAS No.	555-77-1
Chemical formula	$N(CH_2CH_2Cl)_3$

B. Nitrogen Mustards

Nitrogen mustards are tertiary *bis*(2-chloroethyl)amines with vesicant activity (NDRC, 1946). All are active alkylating agents. The nomenclature, chemical and physical properties of HN1, HN2, and HN3 are summarized in Tables 8.3 and 8.4. Due to their toxicity and various

physical–chemical properties, initial interest in these chemicals as warfare agents came about shortly before or during World War II. Although HN2 and HN3 were specifically developed as military agents, HN1 was originally developed as a pharmaceutical. HN2 (mechlorethamine) later found use as an antineoplastic agent. Nitrogen mustards and derivatives such as melphalan, chlorambucil, and cyclophosphamide are alkylating agents used as cancer therapeutic agents (Somani, 1992).

TABLE 8.5. Nomenclature, chemical formulae, and chemical structure of lewisites

C. Lewisite

Lewisite is composed of *cis*- and *trans*-isomers in the ratio of 10:90 and several impurities including *bis*(2-chlorovinyl)chloroarsine (L-2) and *tris*(2-chlorovinyl)arsine (L-3) (Rosenblatt *et al.*, 1975). The chemical and physical properties of the *cis*- and *trans*-isomers are similar. The nomenclature and chemical and physical properties of L-1, L-2, and L-3 are presented in Tables 8.5 and 8.6, respectively. In pure form, lewisite is colorless and odorless but usually occurs as a brown oily liquid with a distinct geranium-like odor. Gates *et al.* (1946) reported an odor threshold of 14–23 mg/m^3 for lewisite.

Information regarding the atmospheric tranformation of lewisite is limited. MacNaughton and Brewer (1994) reported that some photodegradation may take place and that hydrolysis may also occur in the gas phase. Lewisite is only sparingly soluble in water; 0.5 g/l (Rosenblatt *et al.*, 1975). Hydrolysis of lewisite results in the formation of lewisite oxide and HCl, and may occur rapidly. The hydrolysis of lewisite is complex and includes several reversible reactions (Epstein, 1956; Rosenblatt *et al.*, 1975; Clark, 1989; MacNaughton and Brewer, 1994). Under slightly acidic conditions, lewisite initially undergoes rapid and reversible conversion to dihydroxy arsine, 2-chlorovinyl arsine oxide and two equivalents of hydrogen chloride:

$$Cl{-}CH{=}CH{-}AsCl_2 + 2H_2O \;\Omega\; Cl{-}CH$$
$${=}CH{-}As(OH)_2 + 2HCl$$

The production of two equivalents of chloride occurs within 3 min at 20°C; at 5°C the reaction is 90% complete within

TABLE 8.6. Physical and chemical properties of lewisite

	Value	Reference

Freezing point	−18°C; varies ∀ 0.1°C depending on purity	Watson and Griffin (1992)
Vapor pressure (mmHg)	0.34 mm Hg at 25°C; 0.22 mm Hg at 20°C	USACHPPM (1996)
Water solubility (g/l)	0.5 g/l in water; soluble in most organic solvents	USACHPPM (1996)

2 min, and the completion of the reaction requires several hours. The hydrolysis rate constant is reported as 1 min^{-1} at 20°C. Hydrolysis of 2-chlorovinyl arsine oxide is slower, resulting in lewisite oxide (chlorovinyl arsenous oxide) and polymerized lewisite oxide:

$$\mathrm{Cl{-}CH{=}CH{-}As(OH)_2\ \Omega\ H_2O + Cl{-}CH{=}CH{-}AsO + (Cl{-}CH{=}CH{-}AsO)_n}$$

The forward reaction is favored because lewisite oxide and polymerized lewisite oxide are insoluble. In a basic solution, the *trans*-lewisite isomer is cleaved by the hydroxyl ion to give acetylene and sodium arsenite; this reaction may occur even at low temperatures (Rosenblatt *et al.*, 1975; Clark, 1989). *Cis*-lewisite heated to over 40°C reacts with sodium hydroxide to yield vinyl chloride, sodium arsenite, and acetylene (Rosenblatt *et al.*, 1975). In aqueous solution, the *cis*-isomer undergoes a photoconversion to the *trans*-isomer (Rosenblatt *et al.*, 1975). Epstein (1956) reported that the toxic trivalent arsenic of lewisite oxide in standing water is converted to the less toxic pentavalent arsenic.

Lewisite in soil may rapidly volatilize or may be converted to lewisite oxide due to moisture in the soil (Rosenblatt *et al.*, 1975). The low water solubility suggests intermediate persistence in moist soil (Watson and Griffin, 1992). Both lewisite and lewisite oxide may be slowly oxidized to 2-chlorovinylarsonic acid (Rosenblatt *et al.*, 1975). Possible pathways of microbial degradation in soil include epoxidation of the C=C bond and reductive dehalogenation and dehydrohalogenation (Morrill *et al.*, 1985). Due to the epoxy bond and arsine group, toxic metabolites may result. Additionally, residual hydrolysis may result in arsenic compounds. Lewisite is not likely to bioaccumulate. However, the arsenic degradation products may bioaccumulate (Rosenblatt *et al.*, 1975).

II. HISTORY AND BACKGROUND

A. Sulfur Mustards

Sulfur mustard was developed in Germany and initially used as a warfare agent (as Levenstein mustard) during World War I. More recent use occurred in Middle East conflicts. Its oily nature makes it persistent on surfaces it contacts. Because sulfur mustard exerts toxic effects following dermal, ocular, and inhalation exposure, its use necessitated full body protection which, in turn, required the development of protective clothing and significant changes in warfare operations.

Minute quantities of sulfur mustard are used by various military and contract laboratories for defense research purposes, and for verification of Chemical Weapons Convention compliance. Bulk quantities of sulfur mustard are no longer manufactured in the USA. Military stockpiles of sulfur mustard are awaiting destruction or are in the process of being destroyed. Some sulfur mustard may also be found buried or abandoned at former defense sites. Sulfur mustard was frequently loaded into artillery shells and aerial bombs (often with lewisite). Various quantities of sulfur mustard also exist in other countries. Large amounts of sulfur mustard have been disposed of at sea.

Outside of military conflicts, exposure to sulfur mustard has occurred or may occur in work environments associated with chemical weapon materiel (e.g. storage depots, demilitarization facilities, research laboratories), during emergency response operations or remediation and decontamination activities, or during treaty verification activities in support of the Chemical Weapons Convention. Chemical weapons such as the vesicants are still considered potential military threats and terrorist targets. The most likely route of exposure to sulfur mustard is via aerosol/vapor exposure of the skin, eyes, and respiratory tract.

B. Nitrogen Mustards

Due to their toxicity and various physical–chemical properties (they are structurally similar to sulfur mustard), initial interest in nitrogen mustards as warfare agents came about shortly before or during World War II. Like sulfur mustard, all are alkylating agents. This document is limited to the nitrogen mustards referred to as HN1, HN2, and HN3, selected chemical and physical properties of which are summarized in Tables 8.3 and 8.4. Although HN2 and HN3 were initially investigated as military agents, HN1 was

originally developed as a pharmaceutical. HN2 (mechlorethamine) later found use as a pharmaceutical. Nitrogen mustards and derivatives such as melphalan, chlorambucil, and cyclophosphamide are alkylating agents used as cancer therapeutic agents (Somani, 1992). HN1 and HN3 are among the chemical agents found in Chemical Agent Identification Sets (CAIS) which are considered a component of nonstockpiled material. Generally, the nitrogen mustards have not had the interest or high profile associated with sulfur mustard and lewisite.

C. Lewisite

Lewisite, an organoarsenic compound, was developed in an attempt to create a more effective blister agent than sulfur mustard. Its development is generally credited to Winford Lewis at the Catholic University, Washington DC, and is based upon a thesis by Julius Nieuwland who described the synthesis of lewisite from arsenic trichloride, acetylene, hydrochloric acid, and mercuric chloride. Early on, the compound was frequently referred to by the vividly descriptive term, ''Dew of Death''. Like sulfur mustard, it is both a vesicant and systemic poison with target tissues not limited to the skin. In an attempt to develop an antidote to lewisite, British Anti-lewisite (BAL; dimercaprol) was developed (Peters *et al.*, 1945) which later became invaluable in the treatment of arsenic poisoning. Late in World War I and into World War II, large quantities of lewisite were manufactured by Germany, the US, Italy, the Soviet Union, and Japan (reviewed by Trammell, 1992). Large amounts of lewisite were manufactured (up to 2 tons/day by Japan) and stored prior to and during World War II (Tanaka, 1988; Trammell, 1992). Lewisite was frequently a component (often mixed with sulfur mustard) in artillery shells and aerial bombs. Like sulfur mustard, there are reports of large amounts of the compound being disposed of at sea (Spiers, 1968). With the possible exception of its use against Iranian soldiers during the Iraq–Iran conflict (Perera, 1985), there has been little or no use of lewisite in battle situations. Goldman and Dacre (1989) have reviewed the chemistry and toxicology of lewisite.

III. TOXICOKINETICS

A. Sulfur Mustards

With its high lipophilicity, toxicologically relevant amounts of sulfur mustard are absorbed into epithelial tissue (Papirmeister *et al.*, 1991). Dermal absorption is dependent on the thickness of the epidermis and on the presence of moisture, which enhances penetration. Absorption tends to be greater at the base of hair shafts and in the hair follicle where the epithelial tissue is thinner than the surrounding surface area (Papirmeister *et al.*, 1991). Approximately 20% of sulfur mustard applied to skin may be rapidly absorbed while 12–50% of this may react and remain at the application site (Somani and Babu, 1989). About 12% of that absorbed remains at the contact site and the remaining 88% enters the circulation (Renshaw, 1947). Renshaw (1947) noted that the rate of penetration is 1–4 μg/cm^2/min at 75°F.

For dermal exposure, penetration rates over 2–8 h ranged from 2.9 to 6.7% and rates of absorption from 1.2 to 4.0% following application of 400 μg of radiolabeled sulfur mustard per cm^2 of isolated perfused porcine skin (Riviere *et al.*, 1995). The average total recovery of the radiolabel was 9.3% (3.8–17.7%) suggesting substantial loss due to volatilization.

Relative to dermal absorption, little is known about absorption in the respiratory tract. Cameron *et al.* (1946) calculated the absorption of sulfur mustard vapor in the noses of rabbits and rhesus monkeys. The concentration of the agent in the nasal passages was 10–30% of the chamber concentrations (40, 100, and 500 mg/m^3), implying an absorption of approximately 70–90%.

Several studies using radiolabeled sulfur mustard have shown that sulfur mustard and its metabolites may be widely distributed in the body after percutaneous or intravenous exposure. Maximum levels of radioactivity were detected in the kidney, lungs, and liver of rabbits following intravenous administration (Boursnell *et al.*, 1946). At 15 min following percutaneous exposure of rats, sulfur mustard derived radioactivity was found in all examined tissues except the eyes (Young *et al.*, 1944). Similarly, Clemedson *et al.* (1963) noted uniform distribution of radioactivity in mice after either percutaneous or intravenous exposures, with most radioactivity occurring in the nasal region, kidneys, liver, and intestine. Hambrook *et al.* (1993) reported on the uptake and distribution of radiolabeled sulfur mustard in the skin and blood of rats after cutaneous application. It was found that much of the agent entering the blood binds to hemoglobin and, to some extent, with glutathione. Results of studies with rabbits showed that sulfur mustard concentrated in the cornea and to a lesser extent in the iris, lens, and conjunctiva within 5 min after application (Axelrod and Hamilton, 1947).

The biotransformation of sulfur mustard after intravenous or intraperitoneal injection of radiolabeled compound in rats has been examined. Following intravenous injection, the major urinary metabolite was glutathione-bis-chloroethyl sulfide conjugates (45% of total urinary radioactivity) and smaller amounts of sulfone conjugates (7%) and thiodiglycol and its conjugates (14.4%) (Davison *et al.*, 1961). Roberts and Warwick (1963) found the major urinary product of cysteine-bis-(β-chloroethyl)sulfone after intraperitoneal injection of sulfur mustard in rats. Papirmeister *et al.* (1991) concluded that hydrolysis to thiodiglycol and reaction with glutathione are the most important routes of detoxification. This is supported by human data showing that thiodiglycol is present in the urine for one week or more after exposure (Wils *et al.*, 1987).

B. Nitrogen Mustards

The effects of time, temperature, and humidity on the vapor penetration of HN1 and HN3 into the forearm skin of human male volunteers were reported by NDRC (1945). Results of this work showed similar effects of temperature and humidity as observed for sulfur mustard, e.g. greater absorption with increased temperature and humidity. The penetration of HN1 and HN3 was found to be linear with time (5 to 20 min for HN1 and 30–60 min for HN3). At 71–72°F and 50–52% relative humidity, HN1 penetration rate was 2.8 μg/cm^2/min and for HN3 was 0.18 μg/cm^2/min at 72–73°F and 45–48% relative humidity. At 86–87°F and 47–49% relative humidity, HN1 penetration rate increased to 5.2 μg/cm^2/min and HN3 penetration rate increased to 0.3 μg/cm^2/min at 85°F and 47–48% relative humidity. Excretion via the urine is likely a major route of elimination, especially due to the water solubility of the immonium ion (see section IV).

C. Lewisite

Little information is available regarding the toxicokinetics of lewisite. Lewisite is readily absorbed by mucous membranes and, because of its lipophilicity, dermal absorption is significant (HSDB, 2004). Dermal absorption is reportedly more rapid than for sulfur mustard (Hurst and Smith, 2008). Axelrod and Hamilton (1947) reported that radiolabeled (^{74}As) lewisite applied to a 0.43 cm^2 area of human skin was primarily fixed on the epidermis and that very little was found in the dermis; most was detected in hair and hair follicles. In experiments with guinea pigs, histological examination revealed that lewisite applied to skin entered epidermis within 2 min and penetrated into the dermis within 10 min (Ferguson and Silver, 1947). Only trace amounts were detectable in the dermis at 24 h post-application.

IV. MECHANISM OF ACTION

A. Sulfur Mustards

The mechanism of action of sulfur mustard is multifaceted and complex, and has been reviewed in some detail by Papirmeister *et al.* (1991), Hurst and Smith (2008), and Smith *et al.* (2008). Efforts to understand the mechanisms of sulfur mustard toxicity are ongoing. Basically, sulfur mustard disrupts the interface of the epidermis and basement membrane causing blistering between the epidermis and dermis. Both immediate (immediate cell membrane damage) and delayed phases (secondary effects resulting from inflammatory responses, DNA damage, vascular leakage) have been described for sulfur mustard-induced dermal effects (Somani and Babu, 1989). Many of the toxic effects of sulfur mustard can be attributed to oxidative stress.

Among the most studied mechanisms of sulfur mustard toxicity are thiol depletion resulting in intracellular calcium imbalance and subsequent cell death, alkylation of DNA and other cellular macromolecules, lipid peroxidation resulting from sulfur mustard-induced gluthathione depletion, and induction of an inflammatory response. The overall mechanism of sulfur mustard toxicity likely involves an interlinking of the aforementioned processes which are briefly described below.

A key component of sulfur mustard toxicity is the formation of a sulfonium ion and resulting episulfonium intermediate which may react with sulfhydryl-containing macromolecules. Damage may include Ca^{2+} translocases (Ca^{2+}-stimulated, Mg^{2+}-dependent ATPase) which are dependent on thiol groups to maintain cellular Ca^{2+} homeostasis, and microfilamentous proteins. The resulting increase in intracellular calcium levels ultimately causes a decrease in cellular integrity and induction of apoptosis. Oxidative stress in sulfur mustard toxicity has been reviewed by Smith *et al.* (2008).

The role of DNA alkylation and the poly(ADP-ribose) polymerase (PARP) hypothesis theory for sulfur mustard toxicity has been reviewed by Papirmeister *et al.* (1991). In this mechanism, DNA is the initial target of the mustard agent. Alkylated DNA purines are enzymatically depurinated creating apurinic sites which are cleaved by apurinic endonucleases resulting in DNA strand breaks. The accumulation of DNA breaks leads to activation of the chromosomal enzyme PARP, which utilizes NAD^+ causing severe lowering of cellular NAD^+. Depletion of NAD^+ results in the inhibition of glycolysis, and stimulation of the nicotinamide adenine dinucleotide phosphate ($NADP^+$)-dependent hexose monophosphate shunt, ultimately resulting in the induction and secretion of proteases and subsequent cellular changes.

In the review by Papirmeister *et al.* (1991), it was noted that sulfur mustard-induced cytotoxicity is dose dependent and that DNA appeared to be more sensitive to mustard-induced alkylation than are other cellular constituents. The low-dose effects of sulfur mustard are characterized by genotoxicity and inhibition of mitosis. The loss of cellular reproduction may be due to bifunctional alkylation that ultimately prevents normal DNA replication. It was hypothesized that monofunctional DNA damage might be responsible for low-dose mutagenic and possibly carcinogenic effects.

Sulfur mustard-induced lipid peroxidation is a function of glutathione (GSH) depletion. For this mechanism, depletion of GSH results in an accumulation of reactive oxygen species via hydrogen peroxide-dependent processes (Miccadei *et al.*, 1988). The oxygen radicals react with membrane phospholipids forming lipid peroxides that alter membrane structure resulting in membrane breakdown.

Recent work has focused on the identification of possible biomarkers of sulfur mustard exposure and injury (Buxton *et al.*, 2000, 2001; Danne *et al.*, 2000). More recently, the role of metalloproteinases and collagen degradation (Gerecke *et al.*, 2005), platelet activating factor (Clark *et al.*, 2005, 2006), and interaction with cytochrome P450

processes (Brimfield and Hodgson, 2005; Brimfield *et al.*, 2006; Mancheco and Brimfield, 2006) are being investigated relative to the mechanism of action of sulfur mustard.

B. Nitrogen Mustards

A key component of nitrogen mustard toxicity is analogous to that of sulfur mustard: the formation of a cyclic onium cation. This occurs in the presence of polar solvents such as water (Somani, 1992). The immonium ion may react with nucleophiles such as nitrogen in the base components of nucleic acids and with sulfhydryl groups in proteins and peptides. The precise mechanism of nitrogen mustard activity is unclear but several have been proposed: DNA/RNA alkylation and resultant effects, effects on glutathione, membrane effects (protein cross-linking, ion transport effects), and cytoplasmic effects (release of lysosomal enzymes). The possible mechanisms of nitrogen mustard have been reviewed by Gray (1989). Results of preliminary work by Elsayed and Omaye (2006) in mice given HN2 intraperitoneally showed pulmonary alterations indicative of oxidative stress and impaired detoxification processes which are consistent with the aforementioned mechanisms.

C. Lewisite

Dermal or intravenous exposure to lewisite leads to local skin edema and pulmonary edema due to increased capillary permeability. The increased capillary permeability results in blood plasma loss and resultant physiological responses collectively referred to as ''lewisite shock''. Lewisite shock may be likened to shock observed in severe burn cases. It has been hypothesized that functional changes in the lungs, kidneys, respiratory tract, cardiovascular, and lymphatic systems may be the result of a disturbance of osmotic equilibrium (Goldman and Dacre, 1989).

Lewisite-induced vesicant and systemic toxicity are likely due, in part, to interactions with thiol groups (Goldman and Dacre, 1989). The interaction with enzyme sulfhydryl groups may cause inhibition of enzyme by the formation of stable cyclic structures with arsenic. These thiol interactions result in energy depletion leading to cell death (Young, 1999).

V. TOXICITY

A. Sulfur Mustard

The toxic effects of sulfur mustard in humans and animals have been extensively reviewed by ATSDR (2003), Sidell and Hurst (1992), Somani (1992), Watson and Griffin (1992), IOM (1993), NRC (2003), and Romano *et al.* (2008).

Sulfur mustard affects the skin, respiratory tract, and eyes. The acute effects include edema, ulceration, and necrosis of epithelial tissue. Systemic toxicity may also occur and is characterized by nausea and vomiting, fever, and malaise. There is evidence of systemic toxicity (gastrointestinal tract) following dermal exposure only (Dacre and Goldman, 1996). Delayed effects include conjunctivitis and blindness following ocular exposure and chronic bronchitis following inhalation exposure. Affected tissues may have an increased susceptibility to secondary infections, and possibility of carcinogenicity of the skin and respiratory tract.

Ambient temperature and humidity govern the degree of toxicity of sulfur mustard; in hot and humid conditions, lower mustard concentrations are required to produce debilitating effects. The severity of sulfur mustard effects is also greater in areas of the body with greater moisture (e.g. axilla, groin, eyes). Information regarding the toxic effects of long-term exposure to low levels of sulfur mustard that are not acutely toxic is limited.

Available data suggest that the location and severity of damage resulting from exposure to sulfur mustard are concentration dependent and a function of the highly reactive nature of sulfur mustard (Papirmeister *et al.*, 1991). The eyes are generally considered to be the most sensitive and rapidly responding target (Reed, 1918; Reed *et al.*, 1918; Anderson, 1942). For low exposures, sulfur mustard-induced injury appears to be limited to the upper respiratory tract (Eisenmenger *et al.*, 1991) and eyes (Reed, 1918; Reed *et al.*, 1918; Guild *et al.*, 1941; Anderson, 1942). In work with informed volunteer subjects, Anderson (1942) reported that Ct values of 60–75 mg-min/m^3 would result in conjunctivitis, photophobia, and ocular irritation, while Ct values of 75–90 mg-min/m^3 would cause a high proportion of casualties as determined by more severe ocular damage requiring several weeks of treatment. At higher concentrations, pulmonary effects would be expected (Eisenmenger *et al.*, 1991). Regardless of the target tissue, there is a latency period between initial exposure and development of effects. The eyes and respiratory tract appear to have the shortest latency period with effects appearing within hours depending on the exposure level.

In addition to the acute toxic effects on the eyes, skin, and respiratory tract, both acute and longer-term neuropsychiatric effects (e.g. depression, anxiety, neurasthenia, insomnia, post-traumatic stress syndrome) have been documented for individuals exposed to sulfur mustard (Romano *et al.*, 2008). Many of these effects have been documented for individuals exposed during noncombat (e.g. munitions plant workers) activities and are not always the result of high-level exposure that result in serious overt effects. Longer-term effects such as chronic bronchitis have been associated with occupational exposures that included episodes of acute toxicity, and delayed or recurrent keratitis may occur 8–40 years after a severe vapor exposure. Sulfur mustard-induced immunosuppression resulting in greater susceptibility to infections has also been reported.

TABLE 8.7. Acute lethality of sulfur mustard in laboratory species following inhalation exposure

Species	Lethality value	Concentration (mg/m^3) and exposure duration (min)	Reference
Rat	2 min LCt_{50}: 1512 mg-min/m^3 30 min LCt_{50}: 990 mg-min/m^3 60 min LCt_{50}: 840 mg-min/m^3	756 mg/m^3 (2 min) 33 mg/m^3 (30 min) 14 mg/m^3 (60 min)	Fuhr and Krakow (1945) (not verified)
Mouse	2 min LCt_{50}: 4140 mg-min/m^3 30 min LCt_{50}: 1320 mg-min/m^3 60 min LCt_{50}: 860 mg-min/m^3	2070 mg/m^3 (2 min) 44 mg/m^3 (30 min) 14.3 mg/m^3 (60 min)	Fuhr and Krakow (1945) (not verified)
Mouse	60 min LCt_{50}: 42.5 mg/m^3	42.5 mg/m^3 (60 min)	Vijayaraghavan (1997)
Monkey	10 min LCt_{50}: 800 mg-min/m^3	80 mg/m^3 (10 min)	Rosenblatt *et al.* (1975)
Dog	10 min LCt_{50}: 600 mg-min/m^3	60 mg/m^3 (10 min)	Rosenblatt *et a*l. (1975)
Cat	10 min LCt_{50}: 700 mg-min/m^3	70 mg/m^3 (10 min)	Rosenblatt *et al.* (1975)
Goat	10 min LCt_{50}: 1900 mg-min/m^3	190 mg/m^3 (10 min)	Rosenblatt *et al.* (1975)
Guinea pig	5 min LCt_{50}: 800 mg-min/m^3 10 min LCt_{50}: 1700 mg-min/m^3	160 mg/m^3 (5 min) 170 mg/m^3 (10 min)	Langenberg *et al.* (1998) Rosenblatt *et al.* (1975)

Acute lethality data in animals are summarized in Table 8.7. Based upon the animal data, interspecies variability in the lethal response to sulfur mustard vapor is less than an order of magnitude. For nonlethal effects, the animal data suggest that test species exhibit signs of toxicity that are qualitatively similar to humans when acutely exposed to sulfur mustard vapor. Ocular and respiratory tract irritations are clearly evident in studies using dogs, rats, mice, rabbits, and guinea pigs.

Effects of orally administered sulfur mustard in rats were studied by Sasser *et al.* (1996a). Repeated gavage administration of sulfur mustard in sesame oil produced epithelial hyperplasia of the forestomach at the highest dose tested but no deaths and no other treatment-related pathological lesions or changes in clinical chemistry or hematological parameters.

Results of a multigeneration study in rats given sulfur mustard by gavage showed no significant adverse effects on reproductive parameters at any dose level, but revealed dose-related lesions of the squamous epithelium of the forestomach (acanthosis and hyperplasia). It is likely that the forestomach lesions were a function of the treatment regimen whereby the bolus dose in an oil vehicle (sesame seed oil) would enhance the direct-contact effects of the sulfur mustard on the forestomach tissue. Studies by Hackett *et al.* (1987) in which rabbits were gavage dosed with sulfur mustard were equivocal regarding reproductive/developmental effects due in part to the dose regimen and overt maternal toxicity.

Studies in animals have shown that sulfur mustard may induce developmental and reproductive effects (reviewed in NRC, 1999, 2003). Acute exposures resulting in systemic uptake may have effects on reproductive organs, including inhibition of spermatogenesis. Fetal anomalies were observed in tests with rats given sulfur mustard during gestation but only at maternally toxic doses.

The genotoxicity of sulfur mustard is well documented. It is known to produce DNA cross-links, mutations following replication or repair errors, chromosomal breaks, and chromosomal aberrations. Occupational exposures have been associated with increased frequencies of somatic cell mutations, sister chromatid exchanges, and chromosome abnormalities. Studies with rats indicate that subchronic inhalation or oral exposures can produce dominant lethal effects.

The carcinogenicity of sulfur mustard in animals has been reviewed in IARC (1975), Watson *et al.* (1989), IOM (1993),

NRC (1999), and USACHPPM (2000). McNamara *et al.* (1975) studied the potential carcinogenicity of sulfur mustard in rats, mice, rabbits, guinea pigs, and dogs exposed via inhalation for up to one year. No tumors were detected in the mice, rabbits, guinea pigs, or dogs, but skin tumors (basal and squamous cell carcinomas, trichoepitheliomas, and keratoacanthomas) were associated with sulfur mustard exposure at the highest exposure tested (0.1 mg sulfur mustard/m^3 for 6.5 h followed by 0.0025 mg sulfur mustard/m^3 for 17.5 h/day, 5 days/week). An increased incidence of pulmonary tumors in Strain A mice was observed following intravenous injections (four doses over 2 days) of sulfur mustard (Heston, 1950), and an increase in injection site tumors in mice given subcutaneous injections of sulfur mustard over a 6-week period (Heston, 1953).

A study of the Iranian military veterans exposed to sulfur mustard under battlefield conditions during the Iran–Iraq conflict at levels sufficient to cause severe signs of toxicity indicated a potential increased incidence of chronic myelocytic leukemia (CML). In several earlier studies on WWI veterans who had been exposed to sulfur mustard, leukemia was not identified as a possible effect, although it is unclear if examination for CML had ever occurred in those populations. Confounders, such as exposure to benzene or radiation which complicate the analysis, have not yet been ruled out in the ongoing epidemiologic study of Iranian veterans. Two cases of CML were reported for Japanese workers exposed to sulfur mustard (Shakil *et al.*, 1993) but the incidences of CML in the entire population of sulfur mustard-exposed workers and in an unexposed control population were not reported. Studies in animals provide supporting evidence for the carcinogenicity of sulfur mustard although the results of some studies are compromised by insufficient exposure durations and injuries resulting from caging situations.

B. Nitrogen Mustards

Information regarding the toxicity of nitrogen mustards is not as extensive as that for sulfur mustard. Limited lethality data in animals are summarized in Table 8.8. Like sulfur mustard, exposure to nitrogen mustards may cause skin blistering as well as respiratory tract injury and ocular damage. Response data from tests with informed human volunteer subjects (NDRC, 1944) suggested a relative potency of HN3 > HN1 > HN2 for vesicant effects, although the differences were minor. Like sulfur mustard, dermal effects were enhanced by moisture (as from sweating). Estimated thresholds for skin blistering and ocular injury are summarized in Table 8.9. Ocular injury (irritation resulting in compromised operational effectiveness of military personnel) was detected at exposures much lower than those causing dermal effects. All of the toxic effects of nitrogen mustard appear to involve a latency period of several hours for ocular responses and several days for dermal blistering. Nitrogen mustards are alkylating agents with known mutagenicity, but there are no animal cancer bioassays and no human carcinogenicity data.

Nitrogen mustard and its hydrochloride salt have been shown to be teratogenic in mice and rats. Intraperitoneal administration of HN2-hydrochloride/g to mice during gestation resulted in serious teratogenic effects (Danforth and Center, 1954). Haskin (1948) and Murphy *et al.* (1958) reported similar findings in rats given HN2-hydrochloride/kg subcutaneously during gestation.

Nitrogen mustards are bifunctional alkylating agents that produce a carcinogenic response (primarily lung tumors and lymphomas) in mice following subcutaneous, intraperitoneal, and intravenous administration as well as by skin painting (IARC, 1987). Intravenous administration of nitrogen mustard to rats produced tumors in multiple organs (IARC,

TABLE 8.8. Lethality of nitrogen mustard (HN2)

Route	Species	Dose (mg/kg)	Exposure time	Effect	Reference
Oral	rat	10–85	–	LD_{50}	NDRC (1946)
	mouse	10–20	–	LD_{50}	Fox and Scott (1980)

TABLE 8.9. Estimated effects thresholds in humans exposed to nitrogen mustard vapors

HN1	HN2	HN3	Effect
–	0.012 mg-min/m^3	–	No observable effect level during therapeutic use of HN2 (Van Vloten *et al.*, 1993)
90 mg-min/m^3	70 mg-min/m^3	42 mg-min/m^3	Moderate but reversible ocular effects (Porton Report, 1942a, b, 1943a, b, c, d; US Army Med. Div., 1945a, b; NDRC, 1946)
>21,170 mg-min/m^3	5,800 mg-min/m^3	1,800 mg-min/m^3	Median blistering Ct (10 min or 20 min exposure) for normal skin
		1,300 mg-min/m^3	Median blistering Ct (20 min exposure) for sweating skin (NDRC, 1944)

1987). Information in humans is limited to reports of squamous cell carcinomas of the skin following therapeutic application of nitrogen mustard in the treatment of mycosis, fungoides, and psoriasis (IARC, 1987).

C. Lewisite

The toxicology of lewisite has been reviewed by Goldman and Dacre (1989), Watson and Griffin (1992), Trammell (1992), and Hurst and Smith (2008). Its characteristic geranium-like odor is detectable at 14–23 mg/m^3 (Gates *et al.*, 1946). Lewisite may be lethal in humans following inhalation, dermal, or oral exposure. It is reportedly immediately highly irritating at estimated concentrations of 6–8 mg/m^3. Gates *et al.* (1946) estimated an LC_{50} of 3,300 mg/m^3 for 30 min for lewisite vapor absorption through the bare skin and an inhalation LC_{50} of 120 mg/m^3 for 10 min and 50 mg/m^3 for 30 min. Inhalation of 10 mg/m^3 lewisite for 30 min may result in severe intoxication and incapacitation lasting for several weeks, and inhalation of 10 mg/m^3 for 15 min caused inflammation of the eyes and swelling of the eyelids (Franke, 1977). Like sulfur mustard, moist tissues are particularly sensitive to lewisite. The eyes exhibit the greatest sensitivity (IOM, 1993).

The vesicant properties of lewisite result from direct contact with the skin. Signs of dermal toxicity (pain, inflammation) may be experienced within a minute after exposure. Acute lethality is usually the result of pulmonary injury. Ocular exposure may result in corneal necrosis. Due to its lipophilicity, percutaneous absorption of lewisite is rapid and, at a sufficient exposure, may be associated with systemic toxicity characterized by pulmonary edema, diarrhea, agitation, weakness, hypothermia, and hypotension (IOM, 1993). The threshold for severe systemic toxicity in humans following dermal exposure to lewisite has been estimated at 10 mg/kg (9.1–13.4 mg/kg) (Sollman, 1957).

Eldridge (1923) conducted tests on human volunteers to assess the effects of dermal exposure to lewisite vapor. The arms of men (one to seven men with previously determined average sensitivity to lewisite) were exposed to varying concentrations of lewisite vapor for periods ranging from 10 min to 3 h for the purpose of determining the concentration of lewisite required for blistering. The resulting dermal responses ranged from reddish discoloration to a clear watery blister over the entire burned area, accompanied by reddening, swelling, and hardening of the surrounding skin. The burns reached maximum severity in 36–48 h, and healing was complete in 6 days to 2 weeks. The men reported that the healed skin remained sensitive for several weeks after the healing was complete.

It has been hypothesized that fatalities following dermal exposure to lewisite may be due to blood plasma loss resulting from extensive capillary damage (lewisite shock) (Cameron *et al.*, 1946). Sollman (1957) estimated that an oral dose of as little as 2 ml in an adult human (equivalent to 37.6 mg/kg) may be fatal within several hours. The target tissues and organs for systemic toxicity of lewisite include the liver, gall bladder, urinary bladder, lung, and kidneys (Cameron *et al.*, 1946; Snider *et al.*, 1990). Generally, there is a data deficiency regarding definitive exposure–response data for lewisite.

In studies with rats, Silver and McGrath (1943) found little difference in the acute lethality of *cis*- or *trans*-lewisite exposed for 10 min. Ten-minute mouse LC_{50} values for the *cis*- and *trans*-isomers were 190 and 200 mg/m^3, respectively. All mice exposed to 240 mg/m^3 lewisite for 10 min died. Clinical signs in dogs exposed for 7.5 or 15 min included immediate continual eye blinking, followed by excessive nasal secretion, lacrimation, and sneezing (Armstrong, 1923). Ocular inflammation and vomiting also occurred in some dogs by the end of the 7.5- and 15-min exposures. Dogs exposed for 30 min or longer exhibited frequent retching, vomiting, extreme salivation, labored breathing, and inflammation of the entire respiratory tract. Necropsy revealed a thick membrane in the nostrils, larynx, and trachea, which was accompanied by purulent bronchitis, hemorrhage, pneumonia, edema, and congestion of the lungs.

Similar to the work on sulfur mustard, Sasser *et al.* (1989a) conducted experiments in rats given lewisite by gastric intubation (in sesame oil) at doses of 0.01, 0.1, 0.5, 1.0, or 2.0 mg/kg, 5 days/week for 13 weeks. A dose-related response was observed for lethality (deaths in the three

highest dose groups) and frequency and severity of forestomach lesions. The forestomach lesion incidence and severity were due, at least in part, to the bolus of dosing and the sesame oil vehicle.

Multigeneration reproductive studies in rats (Sasser *et al.*, 1989b) and teratology studies in rats and rabbits (Hackett *et al.*, 1987) given lewisite by gastric intubation were negative or compromised by concurrent maternal toxicity.

The carcinogenic potential of lewisite is not well understood. In a long-term follow-up study, Krause and Grussendorf (1978) reported the formation of a malignant lesion at the site of contact 8 years following a single, acute dermal exposure of a German soldier accidentally exposed to liquid lewisite on his lower right leg in 1940. Eight years later the lesion was diagnosed as malignant. Thirty-eight years after exposure, the area of contact remained ulcerated and diagnosed as Bowen's disease (an intradermal squamous cell carcinoma). Bowen's disease was also diagnosed in workers at a Japanese lewisite production facility (Inada *et al.*, 1978). Findings in these workers were not conclusive due to concurrent exposure to diphenylcyanoarsine and sulfur mustard. Furthermore, no quantitative estimates of dose or exposure rates were available (Inada *et al.*, 1978).

Increased incidences of cancer mortality (respiratory tract: 14%; digestive tract: 9.6%) in workers from the Okuno-Jima poison gas factory were reported by Wada *et al.* (1968). When cancer rates were correlated with job classification, the frequency of respiratory and gastrointestinal tract neoplasms was highest in the workers who were involved in the production of sulfur mustard or lewisite, followed by those who worked indirectly with sulfur mustard or lewisite. The lowest frequency occurred in the group having no direct contact with the vesicant agents (Yamakido *et al.*, 1985). Similar to the Bowen's disease findings, the cancer incidences were confounded by the fact that workers were also exposed to sulfur mustard, hydrocyanic acid, diphenylcyanoarsine, chloroacetophenone, and phosgene.

VI. RISK ASSESSMENT

A. Sulfur Mustards

1. Noncancer

Various standards and guidelines have been developed for sulfur mustard. These values are applicable to occupational exposures, emergency planning and response efforts, and remediation efforts. Airborne exposure limits (AELs) and health-based environmental screening levels (HBESLs) for sulfur mustard have been developed by the US Army (USACHPPM, 1999, 2000). Most health-based criteria for sulfur mustard vapor exposure are based upon protection of the eyes and respiratory tract which are the most sensitive targets.

Acute Exposure Guideline Levels (AEGLs) for sulfur mustard have been developed for emergency planning and emergency response applications (NRC, 2003). The AEGLs represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h.

Reference doses (RfDs), an estimate of a daily dose to humans that is likely to be without appreciable risk of deleterious health effects during a lifetime, have also been developed for sulfur mustard (NRC, 1999).

The various guidelines and standards for sulfur mustard have been summarized by ATSDR (2003).

2. Cancer

The International Agency for Research on Cancer (IARC) classified sulfur mustard as a Group 1 carcinogen (carcinogenic to humans) (IARC, 1987). The National Toxicology Program (NTP) considers ''mustard gas'' as a substance ''known to be a human carcinogen'' (DHHS, 1998). These assessments are based upon human and animal data.

Studies of occupational exposures to sulfur mustard indicate an elevated risk of respiratory tract and skin tumors following long-term exposure to acutely toxic concentrations. Overall, several factors are important regarding the assessment of the carcinogenicity of sulfur mustard. Increased cancer incidence in humans appears to be associated only with exposures that caused severe acute effects, and occupational exposures tended to involve repeated exposures and repeated injury of the same tissues. Because the therapeutic use of the sulfur mustard analog nitrogen mustard is associated with an increased incidence of CML, the reports of CML in HD-exposed individuals appear to be relevant to the carcinogenicity of sulfur mustard.

Cancer slope factors and unit risk values for sulfur mustard have been summarized by ATSDR (2003).

B. Nitrogen Mustards

1. Noncancer

Very few standards and guidelines are available for nitrogen mustards. AEGL values for the nitrogen mustards, HN1, HN2, and HN3, have been developed and are based upon ocular irritation in human volunteers (AEGL-2) and lethality in rodents (AEGL-3). Data were insufficient for derivation of level AEGL-1 values. The AEGL values are currently awaiting finalization. The US Army (USACHPPM, 1996, 2004) has developed Worker Population Limit (WPL) values and General Population Limit (GPL) values for nitrogen mustard (USACHPPM, 1996, 2004).

2. Cancer

Data are not available with which to quantitatively assess the cancer risk from nitrogen mustards, although IARC (1987) considers nitrogen mustard a Group 2A carcinogen based upon limited evidence in humans and sufficient evidence in animals.

C. Lewisite

1. Noncancer

The US Army has developed HBESLs for lewisite (USACHPPM, 1999). Additionally, a chronic oral reference dose (RfD) is available (NRC, 1999; USACHPPM, 1999), as are inhalation and dermal RfDs (USACHPPM, 1999). Interim Acute Exposure Guidelines values (AEGLs) have been developed for lewisite.

2. Cancer

Data regarding the potential carcinogenicity of lewisite are anecdotal and insufficient for a quantitative assessment. Although quantitative data are lacking, the position maintained by CDC (DHHS, 1988) is that some evidence suggests that lewisite may be a carcinogen. For environmental exposure and remediation concerns, the arsenic component and/or arsenic-containing degradation products are, however, relevant.

Although the carcinogenicity of lewisite is equivocal and a quantitative assessment not feasible, several lewisite degradation products are known carcinogens. Combustion products of lewisite include the inorganic arsenicals, arsenic trichloride, arsenic trioxide, and vinyl chloride. Inorganic arsenic is carcinogenic in humans and animals and is classified as a Group A carcinogen by the US EPA (2008). Arsenic trioxide and vinyl chloride are both considered Group A carcinogens by the US EPA (US EPA, 1984) and Group 1 carcinogens by IARC (IARC, 1987).

VII. TREATMENT

A. Sulfur Mustard

Medical management of sulfur mustard exposure begins with prevention of exposure. As previously noted in this chapter, the military use of sulfur mustard necessitated full-body protection. As a result, considerable effort has been expended in the development and evaluation of protective clothing and equipment (Schier and Hoffman, 2005). In general, these include respirators (air-purifying and atmosphere-supplying), and chemical-protective clothing (e.g. chemical and vapor impermeable coverings, clothing treated with adsorbing or neutralizing chemicals). Following exposure, rapid decontamination is essential and may include removal of contaminated clothing and removal/neutralization of the agent. Ocular exposure will necessitate rapid removal of the agent from the eyes by irrigating with water. Vapor exposure may necessitate respiratory support. Because there are no antidotes for sulfur mustard poisoning, medical management must rely on prevention, decontamination, and palliative treatment of signs and symptoms. The use of possible antidotes (e.g. antioxidants) has been reviewed by Smith *et al.* (2008) and polyurethane sponges containing detoxification additives are currently being developed and evaluated for decontamination/detoxification (Gordon *et al.*, 2006). The medical management of sulfur mustard (and other vesicant agents) has been reviewed by Munro *et al.* (1990) and Keyes *et al.* (2005).

B. Nitrogen Mustards

Medical management of nitrogen mustard exposure is similar to that for sulfur mustard and involves prevention of exposure and, where exposure has occurred, decontamination and support therapy. The use of antioxidants in the treatment of nitrogen mustard toxicity is currently under investigation (Hardej and Billack, 2006).

C. Lewisite

Similar to the mustard agents, exposure prevention is the first line of defense against lewisite. Rapid decontamination is especially relevant to lewisite exposure due to the rapid development of pain (1–2 min) associated with lewisite exposure. Unlike other vesicants, an effective antidote for lewisite toxicity exists in the form of British anti-lewisite (BAL; 2,3-dimercaptopropanol) which binds with arsenicals, thereby countering the lewisite-induced damage. Such chelation therapy is associated with notable side effects (e.g. renal effects) and requires careful medical management. More effective analogs of BAL have been developed with less significant side effects.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

As chemical warfare agents, vesicants have received considerable attention over the last two decades due to concerns regarding destruction of agent stockpiles, remediation of contaminated sites, the documented and speculated use of these agents in regional conflicts, and possible use in subversive/terrorist activity. This elevated interest profile has resulted in summaries of older toxicological data, generation of new data, and a greater understanding of the effects of these agents on biological systems. Application of these data have been invaluable in the development of various health-based criteria, standards, and guidelines for use in remediation efforts, risk planning, and emergency response activities.

Future directions appear to focus on acquiring additional in-depth understanding of the mechanism of action of these agents through the development of experimental models for vesicant-induced injury, and an application of this information in the development of therapeutic measures for the prevention and treatment of vesicant-induced injury.

CHAPTER 9

Arsenicals: Toxicity, their Use as Chemical Warfare Agents, and Possible Remedial Measures

SWARAN J.S. FLORA, GOVINDER FLORA, AND GEETU SAXENA

I. INTRODUCTION

Arsenic is a metalloid (semi-metal) member of group V elements of the periodic table having oxidation states of +3 (As III) and +5 (As V), in which the former (As III) is more toxic than the latter (As V) (Aposhian *et al.*, 2003). Both species occur in organic as well as inorganic compounds. Arsenic combines chemically with most nonmetals to form a variety of both inorganic and organic compounds. Organoarsenic compounds with trivalent arsenic were produced as pesticides as well as chemical warfare agents in the first half of the 20th century (Aposhian *et al.*, 2003; Li *et al.*, 2005). A number of organic arsenicals have been developed for use as chemical warfare agents. These arsenic-containing substances in the chemical weapon's program are of human and ecotoxicologic relevance. The story of arsine and lewisite encapsulates the key elements of the history of chemical weapons and their continuing power (Kunz, 1994; Stanek, 1991; Sugden, 2008). Although information about arsenic and its inorganic and organic derivatives is well documented, there is very little literature available on their role as chemical warfare agents. This chapter provides readers with updated information about the organic arsenicals as chemical warfare agents and also gives a comprehensive account of toxicity due to inorganic arsenicals. Arsenic poisoning has recently assumed an alarming proportion in some nine districts of West Bengal, India, so much so that it has been earmarked as ''the biggest arsenic calamity in the world''. In view of the rapid spread of various diseases arising out of arsenic contamination (e.g. arsenical dermatosis, melanosis, keratosis, edema, gangrene) in different areas of West Bengal and also in adjoining areas of Bangladesh, there is a need to provide the reader with information about the modes and sites of action following exposure to environmentally relevant levels of arsenicals and to determine the effects of arsenicals in susceptible populations.

II. BACKGROUND

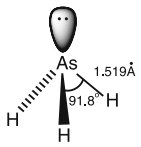
Arsenic is well known as an insecticide in the form of lead arsenate, arsenic acid, etc., and in pharmacy, especially in the form of salvarsan and neosalvarsan. Arsenic derivatives are also of value from the point of view of chemical warfare agents (Stanek, 1991; Wexler, 2004). World War I marked a new era in the modern warfare as persistent rumors were circulated in the early part of the war that the Germans were to use arsine (Szinicz, 2005; Thomas and Young, 2001). These rumors led to the use of sodium permanganate in the canister, but no arsine was actually used. Another suggestion which received considerable attention was the use of arsenide, which might decompose under the influence of atmospheric moisture with the liberation of arsine (Henriksson *et al.*, 1996; McManus and Huebner, 2005). However, calculation of the amount of arsenide required to establish a lethal concentration of arsine suggests no possibility of using the material in the field. Organic arsenic derivatives are the most important compounds from a military point of view. The first substance used was diphenylchloroarsine, a white solid, which readily penetrated the canister and caused sneezing. This was used alone, and in solution in diphenylchloroarsine. Later, methyl and ethyl dichloroarsines were introduced (Beckett, 2008).

Arsine, the most toxic form of arsenic, exhibits some characteristics that may make it useful as a chemical warfare (CW) agent. Arsine is a colorless, odorless, nonirritating gas and is 2.5 times denser than air (Henriksson *et al.*, 1996; Pullen-James and Woods, 2006; Thomas and Young, 2001). At concentrations above 0.5 ppm, a garlic-like odor may be noted, but arsine is toxic at much lower concentrations. Acute arsine poisoning due to inhalation of arsine gas (AsH_3) is rare but has no known antidote. It is the most acutely toxic form of arsenic causing rapid and severe hemolysis immediately on exposure. The mechanisms of hemolysis are not completely understood. Arsine has a short half-life (27–96 h) and is converted to various arsenic derivatives. Although it

has been investigated as a CW agent, arsine has no recorded battlefield use. During and prior to World War II, the British studied this agent and rejected its use in the field. They concluded it was more than ten times less toxic than phosgene (CG). In addition, it is difficult to manufacture and is highly flammable. Although it was determined that arsine was not a useful battlefield CW agent, it may still be useful as a small-scale weapon of assassination or terror. A number of other arsine-derived organoarsenic compounds have been developed and used as CW agents, including lewisite (L), methyldichloroarsine (MD), diphenylchloroarsine (DA), and ethyldichloroarsine (ED) (Ishizaki *et al.*, 2005).

Arsenicals are considered a threat, not so much from large nation states but from smaller, less developed nations and/or by terrorist organizations. The relative ease of production coupled with their effectiveness against an unprotected population make organic arsenicals a continued threat in the 21st century. This chapter describes the human health aspects of arsine, organic arsenicals, and inorganic arsenic, and the current status of development of suitable therapeutic measures.

III. ARSINE



Arsine (AsH_3) is a colorless, extremely flammable gas with a garlic-like odour. The most common synonyms for arsine are arsenic hydride, arsenic trihydride, hydrogen arsenide, and arsenous hydride. The relative molecular mass of arsine is 77.95. Its boiling point is −62°C and vapor pressure at 20°C is 1043 kPa. Arsine is a strong reducing agent, deposits arsenic on exposure to light and moisture, and is easily transformed into other oxidized arsenic forms [e.g. As (III) and As (V)]. The arsine gas is colorless, odourless, and 2.5 times denser than air (Table 9.1). Arsine is a class of organoarsenic compounds of the formula $AsH_{3-x}R_x$, where R = aryl or alkyl (Fowler and Weissber, 1974).

Possible sources of occupational exposure are many and include the semiconductor industry during microchip production and other industries in which workers are involved in galvanizing, soldering, etching, and lead plating (Landrigan *et al.*, 1983). It also can be produced inadvertently by mixing arsenic-containing insecticides and acids (Pullen-James and Woods, 2006). In humans and animals, arsine is metabolized to trivalent arsenic as well as pentavalent arsenic. Arsenic (III) is methylated to monomethylarsonate (MMA) and dimethylarsinate (DMA). Arsine metabolites are mainly excreted via urine (Apostoli *et al.*, 1997).

Arsine is supposed to be the most toxic form of arsenic. The acute toxicity of arsine is high in different species including humans. The target organ of arsine is the hematopoietic system and, in particular, the erythrocytes (Blair *et al.*, 1987). Inhaled arsine gas is distributed rapidly and causes massive red blood cell hemolysis that can potentially lead to cellular hypoxia (Apostoli *et al.*, 1997; Hatlelid et al., 1995, 1996; Peterson and Bhattacharyya, 1985). The mechanisms of action involved in hemolysis are not elucidated fully, but studies (Hong *et al.*, 1989; Winski *et al.*, 1997) reveal: (1) arsine causes a nonspecific disruption of ion gradients, leading to cell membrane instability, (2) sulfhydryl groups in cell membranes are probable targets of arsine toxicity, and (3) hemoglobin is an important subcellular target of arsine toxicity.

TABLE 9.1. Physical and chemical properties of arsine

Molecular formula	AsH_3
Molar mass	77.95 g/mol
Appearance	Colorless gas
Density	4.93 g/l, gas; 1.640 g/ml (−64°C)
Melting point	−117°C (157 K)
Boiling point	−62.5°C (210 K)
Solubility in water	0.07 g/100 ml (25°C)
Molecular weight	77.95

Arsine poisoning can lead to acute renal tubular necrosis and ultimately to oliguric/anuric renal failure (Rogge *et al.*, 1983). Renal failure can be attributed to (1) direct effect of arsine on renal tissue, (2) heme-pigment nephropathy, or (3) renal hypoxia secondary to massive hemolysis and decreased oxygen carrying capacity of the blood.

Effects of long-term exposure to low levels of arsine are not well documented; however, most of the reported deaths are believed to be secondary to acute renal failure. Exposure to other arsenic compounds to which arsine is metabolized can induce lung, bladder, kidney, and skin cancer in humans (Kleinfeld, 1980; Lenza, 2006).

A. Synthesis of Arsine

Arsine is formed whenever nascent hydrogen is released in the presence of arsenic or by the action of water on a metallic arsenide. The formation of arsine can be described with the help of the following reaction (Anthonis *et al.*, 1968a, b; Bellama and Macdiarm; 1968; Coles *et al.*, 1969; Jenkins *et al.*, 1965):

$$3\ H_2 + HAsO_2 \rightarrow AsH_3 + 2\ H_2O$$

AsH_3 is also prepared by the reaction of As^{3+} sources with H^- equivalents (Bellama and Macdiarm, 1968):

$$4\ AsCl_3 + 3\ NaBH_4 \rightarrow 4\ AsH_3 + 3\ NaCl + 3\ BCl_3$$

Alternatively, sources of As^{3-} react with protonic reagents to produce arsine:

$$Zn_3As_2 + 6\ H^+ \rightarrow 2\ AsH_3 + 3\ Zn^{2+}$$

B. Sources of Exposure

The main anthropogenic sources of arsine include its accidental formation, particularly in the chemical and nonferrous (like zinc, copper, and cadmium) metallurgical industries, production or use of the gas itself during manufacture of semiconductors as a doping agent (Aposhian, 1997; Winski *et al.*, 1997) and in battery production as an alloy with lead (Wald and Becker, 1986).

Arsine is extensively used in the semiconductor industry for epitaxial growth of gallium arsenide (GaAs) and as a dopant for silicon-based electronic devices (Sheehy and Jones, 1993). Arsine is also used in organic synthesis (Lewis, 1993), as an agent in the manufacture of light-emitting diodes, and for manufacturing certain glass dyes (HSDB, 1999).

C. Human Arsine Exposure

Occupational sources where exposures to arsine at levels sufficient to cause acute arsine intoxication have occurred include copper smelting and refinery (Pinto *et al.*, 1976), bronzing process (Clay *et al.*, 1977), a chemical company cleaning a clogged drain (Parish *et al.*, 1979), transistor industry (Kleinfeld, 1980), and burnishing of metals (Romeo *et al.*, 1997). Many processes including electrolyte refining, galvanizing, soldering, etching, lead plating, metal smelting, and extraction may expose workers to toxic concentrations of arsine. Workers in the electronics industry using GaAs to manufacture GaAs optoelectronic, microwave, and integrated circuit products are potentially exposed to arsine (Chein *et al.*, 2006; Sheehy and Jones, 1993). Unintentional formation of arsine can occur principally in the metallurgical industry as a result of arsenic contamination of many ores, such as zinc, lead, copper, cadmium, antimony, gold, silver, and tin (Braman, 1977; Fallenti *et al.*, 1968).

D. Metabolism of Arsine

1. Animal Studies

Levvy (1947) reported that an average of 64% of inhaled arsine was absorbed in mice exposed by inhalation route at concentrations of 25–2500 mg/m^3 for periods ranging from 0.40 min to 24 h. Blair *et al.* (1990b) measured the arsenic content in liver after exposure of rats to variable arsine concentrations (0.08, 1.6, and 8.1 mg/m^3 for 6 h/day for 90 days). Arsenic concentration in liver increased with airborne arsine concentration and was higher in females than in males. The arsenic level in 3–4 days after a 90 day exposure at a concentration of 8.1 mg/m^3 was 6–8 µg/g (compared with approximately 1.5 µg/g in controls).

The main route of arsine excretion is via urine after metabolism. Levvy (1947) studied the elimination of arsenic in arsine-exposed mice and compared it with the animals exposed to sodium arsenite. Arsenic was excreted exponentially in intravenously arsenite-administered mice and after 24 h, less than 10% of the dose remained. On the other hand, arsenic arising from inhalation exposure to 180 mg arsine/m^3 for 120 min was excreted more slowly and after 24 h about 45% of arsenic remained in the exposed mice. Buchet *et al.* (1998) exposed rats to 4–80 mg arsine/m^3 for 1 h; the major metabolites determined in urine were As (III) and As (V), MMA and DMA. When the exposure exceeded 60 mg/m^3, the proportional urinary excretion also showed an increase, indicating saturation of arsine/arsenic binding.

2. Human Studies

Arsine is rapidly absorbed into blood through the respiratory tract (Venugopal and Luckey, 1978). Arsenic can be detected in blood after a few days of exposure. The highest quantities of arsenic were found in liver, kidney, and spleen, and smaller amounts of arsenic were also found in the hair of workers occupationally exposed to arsine (Romeo *et al.*, 1997). Apostoli *et al.* (1997) detected the presence of arsenic in tissues, blood, and urine of workers in the petroleum industry who were poisoned with arsine. In a fatal case of arsine poisoning, arsenic was found in the liver at a concentration of 11.8 mg/g, spleen at 7.9 mg/g, kidneys at 3.2 mg/g, brain at 0.6 mg/g, and in the urine at 0.6 mg/ml. Trace amounts were also found in the blood (Apostoli *et al.*, 1997).

Inhaled arsine was rapidly dissolved in body fluids and oxidized to As (III) (Apostoli *et al.*, 1997). Part of As (III) is further oxidized to As (V), as indicated by the appearance of As (V) in urine of humans exposed to arsine 1–2 days following exposure. Trivalent arsenic is methylated to MMA and DMA (Romeo *et al.*, 1997).

E. Mechanism of Toxicity

After inhalation of arsine gas it causes rapid destruction of red blood cells leading to hypoxia and renal failure. The mechanism of toxicity and modes of action of arsine in humans and animals have not been fully studied. Two mechanisms have been proposed for arsine poisoning, (1) reaction with sulfhydryl groups (Blair *et al.*, 1990b; Waters *et al.*, 2004; Winski *et al.*, 1997) and (2) oxidative stress (Blair *et al.*, 1990a, b; Hatlelid *et al.*, 1996; Hatlelid and Carter, 1997). Besides these two mechanisms nonspecific disruption of ion gradient leading to cell membrane instability and lysis of red blood cells have also been proposed as mechanisms for the toxic effects of arsine (James and Woods, 2006). Hatlelid and Carter (1997) postulated that the hemolytic activity of arsine is related to oxidative stress through the formation of hydrogen peroxide and arsine adducts with hemoglobin, according to the following reaction:

$$H_2As - H + HbO_2 \rightarrow H_2As^* + 2\ Hb - O_2 - H$$

These products may then react to form methemoglobin and arsine peroxide, or, alternatively, the reaction may

produce hydrogen peroxide and arsenic adduct such as H_2As-H or H_2As-heme:

$$H_2As^* + 2\ Hb - O_2 - H \rightarrow adduct + H_2O_2$$

Such an adduct may probably damage hemoglobin molecules, leading to the rapid denaturation and precipitation of the proteins (Hatlelid and Carter, 1997).

Some studies have suggested that the sulfhydryl groups of glutathione (GSH) prevented hemoglobin oxidation and in this manner are essential for the maintenance of intact erythrocyte structure (Blair *et al.*, 1990b). In an *in vitro* study, a decrease in reduced GSH concentration in human RBCs was found to correlate with the hemolytic action of arsine (Pernis and Magistretti, 1960). Blair *et al.* (1990a) recorded a 60% decrease in reduced GSH level in erythrocytes exposed to arsine *in vitro*. However, later studies by Hatlelid *et al.* (1995) showed that the depletion of reduced GSH in RBCs in dogs neither preceded nor coincided with hemolysis.

According to the hypothesis of the sulfhydryl-dependent mechanism of arsine toxicity (Levinsky *et al.*, 1970), arsine reacts with the sulfhydryl group of Na^+/K^+-ATPase, causing an impairment in the sodium–potassium pump which subsequently causes red cell swelling and hemolysis. The affinity of trivalent arsenic for the sulfhydryl group is well known. Winski and co-workers reported profound abnormalities in membrane ultrastructure and in red blood cell volume (Winski et al., 1997), which were manifested by potassium leakage, sodium influx, and increases in hematocrit in arsine-exposed red cells, although no change in ATP and ATPase was observed following exposure to arsine. Hemolysis in arsine exposed RBCs was dependent on membrane disruption caused by arsine-hemoglobin metabolites, the ultimate toxic species (Winski *et al.*, 1997).

F. Effects on Humans

The data on arsine concentration in the workplace atmosphere are relatively scant. Toxicity of arsine to humans was first demonstrated in 1815 when a German chemist accidentally inhaled arsine vapor during an experiment. He became ill and soon died. A case report indicated that exposure to arsine by inhalation for a few hours at a concentration of 10–32 mg/m^3 might induce symptoms of poisoning, whereas exposure to 810 mg/m^3 for 30 min might be fatal (Romeo *et al.*, 1997). It has been reported that concentrations of 23–970 mg arsine/m^3 were associated with fatalities (Morse and Setterlind, 1950).

G. Acute Arsine Poisoning

Most patients report little or no discomfort at the time of exposure. Although a garlic-like odor may be noted with higher ambient arsine concentrations, serious toxicity may result from clinically nondetectable exposures. Following exposure, a dose-dependent latent period ensues, lasting up to 24 h (Apostoli *et al.*, 1997; Lenza, 2006; Levvy, 1947; Song *et al.*, 2006; Thomas and Young, 2001; Young *et al.*, 2003). Symptoms following sublethal arsine exposure may include abdominal pain, hematuria, and jaundice (Figure 9.1).

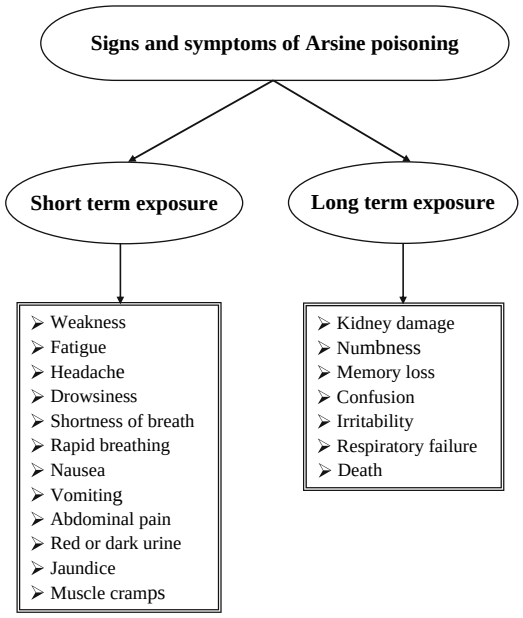


FIGURE 9.1. Signs and symptoms of arsine poisoning.

1. Physical Signs

Physical signs and their severity depend on the concentration of arsine gas and the duration of the exposure (Apostoli *et al.*, 1997; Lenza, 2006; Levvy, 1947; Song *et al.*, 2006; Thomas and Young, 2001; Young *et al.*, 2003).

- Vital signs – hyperthermia, tachypnea, tachycardia, hypotension.
- Head, ears, eyes, nose, and throat (HEENT) – discoloration of conjunctivae (red, orange, brown, or brassy; reportedly distinct from hyperbilirubinemia), scleral icterus, garlic odor to breath (possible).
- Pulmonary – rales from acute respiratory distress syndrome (ARDS) in severe exposure
- Gastrointestinal – abdominal tenderness, hepatomegaly.
- Genitourinary – costovertebral angle tenderness, colored urine (red, brown, or green from hemoglobinuria and/or methemoglobinuria).
- Extremities – possible paresthesias and Mees lines with chronic arsenic toxicity from arsine exposure.

2. Causes

- Arsine gas is used in the semiconductor industry when depositing arsenic on microchips. Exposure also may occur from producing, cleaning, or reclaiming GaAs wafers (Carter *et al.*, 2003; Chein *et al.*, 2006).

- Arsine is released during the production of hydrogen in an acid medium in contact with arsenic-contaminated metals (Braman, 1977).
- Arsine might be a potential chemical warfare agent (Lenza, 2006).

H. Immediate Effects

Clinical manifestation of arsine intoxication appears within 24 h of exposure (usually within a few hours). The period of latency depends on concentration and time of exposure. The initial symptoms include headache, malaise, weakness, dyspnoea, dizziness, abdominal pain, nausea, and vomiting. The urine might be dark red, usually 4–6 h following exposure, and jaundice of the skin and mucous membranes might appear usually 24–48 h after exposure. In some cases, hepatomegaly and splenomegaly with tenderness of costovertebral angle, fever, tachycardia, and tachypnea occur. Information on the concentration of arsine in the air or on the duration of the exposure in relation to the effects observed is mostly not available (Kleinfeld, 1980).

Hemolytic anemia is the most consistent clinical finding in humans. Massive hemoglobinuria may lead to anuria, which, if untreated, is often the cause of death. Both central and peripheral nervous systems may also be affected. Toxic pulmonary edema and acute circulatory failure have also been reported as the cause of death in arsine poisoning (Hatlelid *et al.*, 1996; Winski *et al.*, 1997).

I. Late Effects

Late consequences of acute arsine poisoning include chronic renal damage, hematological changes, polyneuritis, and neuropsychological symptoms (e.g. irritation, confusion, memory losses, agitation, and disorientation). Morphological changes in the kidneys of a truck driver with arsine-induced anuria have been reported earlier (Muehrcke and Pirani, 1968). Six months after arsine poisoning, the patient showed anemia and azotemia. Twenty-three months after recovery from acute renal failure, interstitial fibrosis was focal, and severe nephrosclerosis with renal insufficiency was present. Gosselin and co-workers described reversible polyneuritis of the upper and lower extremities that was observed 3 months after exposure. Peripheral neuropathy was still present 6 months after exposure (Gosselin *et al.*, 1982). Extreme restlessness, loss of memory, agitation, and disorientation occurred several days after exposure and lasted about 10 days in two patients heavily exposed to arsine. An increase in total cell count and macrophages in bronchoalveolar lavage was observed in an arsine-exposed worker. Progressive improvement in diffusing capacity of lungs was observed only after 2 months of treatment. Pinto and co-workers reported that electrocardiographic (ECG) changes in one case lasted for 10 months. Vertical white lines on the nails were observed in many cases 10 days to 3 weeks following arsine exposure (Pinto *et al.*, 1976). Hepatitis in an arsine-poisoned patient on the 20th day after the acute hemolysis has also been reported (Mora *et al.*, 1992).

J. Long-Term Exposure

Long-term exposure may cause symptoms similar to those observed in acutely poisoned individuals. The main differences from acute poisoning were in a delay in onset and development of peripheral neuritis, development of gastrointestinal tract involvement, and development of hemolysis and renal impairment (Risk and Fuortes, 1991; Watson and Griffin, 1992). Lowered hemoglobin levels were found in zinc ore smelting workers exposed to arsine for long periods and who had urinary arsenic concentration below 0.2 mg/liter. These urinary concentrations were estimated to correspond to air arsine concentrations below 0–16 mg/m^3. Once a special ventilation system had been installed, the hemoglobin levels in the workers gradually returned to their normal values (Risk and Fuortes, 1991; Watson and Griffin, 1992).

K. Diagnostic Tests

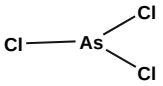
1. Laboratory Studies

- Complete blood count
  - o Hemolytic anemia – may be severe and rapidly developing, with pink serum resulting from free hemoglobin
  - o Elevated white blood cell count – may be seen early
- Methemoglobinemia
- Urinalysis
  - o Hemoglobinuria
  - o Proteinuria
  - o Serum chemistry panel
  - o Hemolysis can cause hyperkalemia, elevated lactate dehydrogenase, and hyperbilirubinemia
  - o Renal failure can cause elevated creatinine and blood urea nitrogen (BUN) levels
  - o Hepatic transaminases may be elevated
- Arsenic levels
  - o Blood and urine arsenic levels are elevated acutely
  - o A 24-h urine arsenic may help in monitoring chronic, low-level arsine exposures
- Electrocardiogram
  - o Peaked T waves from hyperkalemia may be seen
  - o Nonspecific ST segment and T wave abnormalities have been reported
  - o QT interval prolongation is possible from arsenic toxicity
- Imaging studies
  - o No routine imaging studies are indicated
  - o Chest radiography is indicated to detect acute respiratory distress syndrome (ARDS) in patients with pulmonary symptoms

2. Complications

- Hemolytic anemia
- Renal failure
- Hyperkalemia
- Death
  - o Overwhelming exposures cause rapid death from massive hemolysis
  - o Most deaths occur from renal failure in patients who survive acute exposure
- Chronic arsenic toxicity – patients surviving acute arsine exposure may develop chronic arsenic toxicity, including anemia and peripheral neuropathy.

IV. ORGANIC ARSENICALS



The arsenicals are a series of blister agents based around a chloroarsine ($AsCl_3$) molecule in which one of the chlorine atoms is replaced by an organic radical.

These chloroarsines are effective cytochrome oxidase destroyers, or blood agents. Arsenic seeks to replace calcium in the bones, thus causing bone marrow destruction as the endocrine system is concurrently attacked (Styblo and Thomas, 1997). Many organic radicals penetrate human skin, carrying their compounds with them (Cohen *et al.*, 2006).

A. Background

Interest in organic arsenicals dates back to the mid-19th century. Chemists discovered that an arsenic-chloride compound (chloroarsines) in which one of the chlorine atoms is replaced by an organic radical tends to be harmful both to insects and to human tissue (Bartelt-Hunt *et al.*, 2008; Beckett, 2008; Kunz, 1994; McManus and Huebner, 2005; Vilensky and Redman, 2003). The trench warfare stalemate during World War I created a tactical need for a chemical weapon that was both short acting (e.g. nonpersistent, volatile) and lethal (Stephenson, 2006). To fill this need, first weaponized organic arsenical, methyldichloroarsine (MD), was delivered. Two additional organic arsenicals, diphenylchloroarsine (DA) and ethyldichloroarsine (ED), soon augmented MD. A fourth organic arsenical named lewisite was discovered by US Army Medical Corps but was never deployed in World War I (Bartelt-Hunt *et al.*, 2008; Beckett, 2008; Kunz, 1994; McManus and Huebner, 2005; Vilensky and Redman, 2003).

B. Mechanism of Toxicity

The exact mechanism for the toxic effects of organic arsenicals is unknown. DNA alkylation and/or inhibition of glutathione-scavenging pathways are two postulated mechanisms (Nesnow *et al.*, 2002). On contact with arsenicals a blistering reaction occurs on skin, eye, or pulmonary tissues. The onset of symptoms after arsenical exposure occurs in seconds as compared to 4–8 h for mustard exposure. Either a liquid or vapor can cause toxicity. The organic arsenicals tend to have high volatility at room temperature and thus pose a significant vapor threat following exposure (Carter *et al.*, 2003; Cohen *et al.*, 2006; Devesa *et al.*, 2006; Gao and Burau, 1997; Kojima *et al.*, 2006) (Figure 9.2).

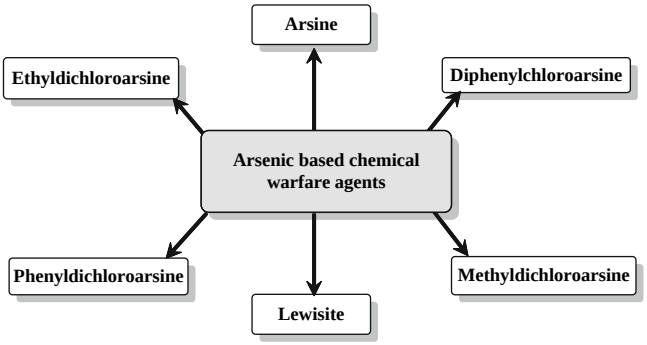


FIGURE 9.2. Arsenic-based chemical warfare agents.

Animal data and limited human trials suggested that organic arsenicals readily penetrate the skin. Within seconds of contact, the chemical fixes itself to the epidermis and dermis. Pain is immediate followed by destruction of subcutaneous tissue. The separation of dermis from epidermis together with capillary leakage causes fluid-filled vesicles (McManus and Huebner, 2005; Noort *et al.*, 2002).

C. Symptoms

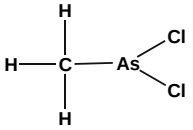
- Vapor contact with the conjunctiva may be the victim's first symptom. Severe conjunctival irritation and blepharospasm result upon eye contact leading to loosening of corneal epithelial cells and swelling and edema of the cornea.
- The respiratory tract's mucosa and submucosa are susceptible to vapor exposure. Mucosal damage starts in the nose and descends down the respiratory mucosa in a dose-dependent fashion. Immediate pain, lacrimation, and irritation accompany the damage. Damaged respiratory mucosa slough off, filling the airways with debris. Damage to the lung parenchyma causes the secretion of blood and mucus that, with the pseudomembranes, can cause asphyxiation.
- The gastrointestinal tract is also susceptible. DA vapor in particular produces a phenyl radical that causes vomiting. Vomiting usually develops within 1–2 min after exposure to DA.

The immediate onset of symptoms following exposure makes severe or systemic toxicity to organic arsenical unlikely. However, prolonged contact may lead to multi-organ involvement (Kinoshita *et al.*, 2007; Kojima *et al.*, 2006). Blood-borne arsenicals can trigger increased

permeability of capillaries throughout the body (Naranmandura and Suzuki, 2008). Leakage of proteins and plasma then can cause third space fluid shifts, hypovolemia, and shock. It may result in intravascular hemolysis of erythrocytes with subsequent hemolytic anemia (Wu *et al.*, 2003).

Organic arsenicals cause immediate signs, whereas signs of mustard exposure appear after a latent period of several hours. An erythematous rash appears within 15–30 min. This is followed by the development of fluid-filled vesicles. A lewisite skin lesion has more actual tissue destruction (but less surrounding erythema) than a mustard lesion. Compared to distilled mustard, lewiste is gram-for-gram more toxic. The LD_{50} (lethal dose for 50% of the population) of lewisite is 2.8 g on the skin.

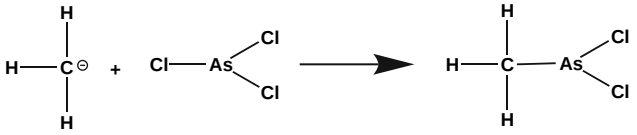
D. Methyldichloroarsine (MD)



Methyldichloroarsine was apparently used by the Germans in 1917. Methyldichloroarsine is a colorless liquid of powerful burning odor, which boils at 132°C. It is somewhat soluble in water and is soluble in organic solvents. The specific gravity is 1.838 at 20°C. The vapor pressure at 25° was found to be 10.83 mm Hg. Not only is the material toxic but it has remarkable vesicant properties, comparing favorably with mustard gas in this respect (Bennett and Dill, 1994).

1. Structure

The structure of MD consists of a trichloroarsine ($AsCl_3$) molecule combined through catalyzation with a methyl (CH_3) group.



2. Pathology

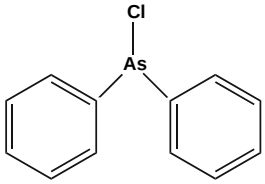
Chlorine bonds in MD give it its blistering qualities. The methyl group simply aids in its assimilation into the human body. Chlorine reactivity causes severe respiratory pain and damage to the membranes of the lungs. The methyl arsenic group readily penetrates the skin as a liquid and its prolonged exposure leads to systemic damage through bone calcium displacement and subsequent bone marrow destruction. Vapor concentration in open areas, given MD's high volatility, is not enough to cause Cl^--induced blistering although liquid contamination will give rise to blistering similar to that of distilled mustard within several hours. ''Dry-land drowning'' can occur as the lungs flood with water and mucus and the victim dies of a combination of blood poisoning and asphyxiation (Pitten *et al.*, 1999).

3. Physical and Chemical Properties

TABLE 9.2. Physical and chemical properties of methyldichloroarsine (MD)

Chemical formula	CH_3AsCl_2
Molecular weight	160.86
Freezing point	−55°C
Boiling point	133°C with decomposition
Flash point	No imminent hazard of explosion or fire
Liquid density	1.836 g/cc at 20°C
Median lethal dose (LCt_{50})	3,000 mg-min/m^3
Median incapacitating dosage (ICt_{50})	25 mg-min/m^3 (inhalation)
Vapor density	5.5 times as heavy as air
Vapor pressure	2.17 mm Hg at 0°C; 7.76 mm Hg at 20°C
Rate of detoxification	Sublethal dosages are rapidly detoxified, although arsenic poisoning may be accumulative if untreated
Persistency	Very short duration in humid climates due to high volatility and rapid hydrolysis. In dry, cold climates MD can persist up to several hours
Skin toxicity	Exposure of skin to liquid MD will cause blistering similar to that of HD within several hours. Vapor exposure in unlikely to cause blistering as sufficient concentration in unlikely in open areas
Eye toxicity	Exposure to even the slightest amount is highly irritating. At exposures above 30 mg-min/m^3 permanent corneal damage occurs
Latent heat of vaporization	49 calories/gm
Volatility	74,900 mg/m^3 at 20°C
Decontaminants	Bleaches and alkaline solutions such as sodium hydroxide (NaOH)
Rate of hydrolysis	Rapid
Hydrolysis products	Hydrochloric and methyl arsenic acids
Effect on metals and other materials	None on ferrous alloys. Slight oxidation to copper-based alloys

E. Diphenylchloroarsine

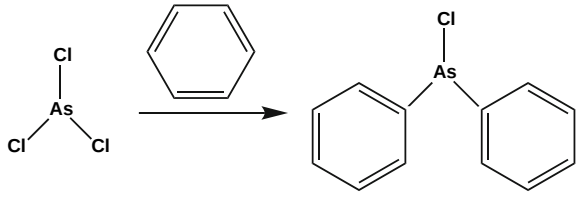


Diphenylchloroarsine (DA) is an irritating substance which was developed in 1918 for use in a smoke generator known as the M-device. The researchers described DA as having ''a very powerful irritant action on the mucous membranes of the eyes and nose, causes painful blistering of the skin, and is very dangerous for those working with it, since its vapor causes respiratory embarrassment, faintness, and long-lasting paralysis and anesthesia of the extremities''. However, after the entry of mustard (a far superior blister and casualty agent), DA proved to be less attractive as a chemical weapon (Ishii *et al.*, 2004; Kato *et al.*, 2007).

As DA and related compounds cause intense effects on the nasal and upper respiratory passages, they are referred to as ''sneeze gases'' (sternutators). Like other arsenicals, DA is a white solid, and was originally produced as both a casualty gas and a mask breaker during World War I. Military doctrine in World War I involving the use of DA counted on its being able to force soldiers to remove their protective masks, thus making them vulnerable to it or other chemical agents (Ishii *et al.*, 2004; Pitten *et al.*, 1999). Only very low concentrations of DA are needed to cause severe irritation of the nose and throat, approximately 0.0005 mg per liter of air (Hanaoka *et al.*, 2005). The median incapacitating dose (ICD_{50}) of DA is approximately 12 mg-min/m^3, while the median lethal dose (LD_{50}) is estimated at 15,000 mg-min/m^3. Due to the availability of other compounds with greater activity, however, less importance is attached to DA as a chemical weapon threat nowadays.

1. Structure

DA is prepared from trichloroarsine ($AsCl_3$):



Two chlorine ions are replaced by benzene groups, forming a stable compound which may be safely stored under all field conditions.

2. Effects

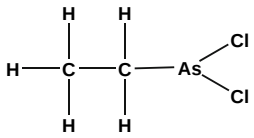
The immediate effects of DA are those associated with tear gas compounds: severe irritation to the eyes, nose, and throat. Severe headache and the feeling of tightness of the chest and bowels occur within a minute of inhalation of this compound. The headache rapidly develops into a general nausea which results in vomiting within 3 min. In closed or confined spaces DA can produce fatalities through first causing unconsciousness and then asphyxiation (Ochi *et al.*, 2004).

3. Physical and Chemical Properties

TABLE 9.3. Physical and chemical properties of diphenylchloroarsine (DA)

Chemical formula	$(C_6H_5)_2AsCl$
Molecular weight	264.5
Boiling point	333°C with decomposition
Decomposition point	300°C
Flash point	350°C
Median lethal dose (LCt_{50})	15,000 mg-min/m^3
Median incapacitating dosage (ICt_{50})	12 mg-min/m^3 (over 10 min)
Vapor density	Forms no significant vapor mass
Vapor pressure	0.0036 mm Hg at 45°C
Rate of detoxification	The human body will detoxify DA inhaled in brief exposures within 1 to 2 h
Persistency	Short duration
Skin toxicity	Irritating, nontoxic in open areas or in short exposures
Volatility	48 mg/m^3 at 45°C
Latent heat of vaporization	56.6 calories/gm
Eye toxicity	Irritating. Nontoxic in open areas or in short exposures
Decontaminants	Bleaches or caustic soda
Rate of hydrolysis	Slow in open container. Rapid when disseminated (in gaseous form)
Hydrolysis products	Hydrochloric and diphenylarsenous acids
Effect on metals and other materials	None when dry

F. Ethyldichloroarsine

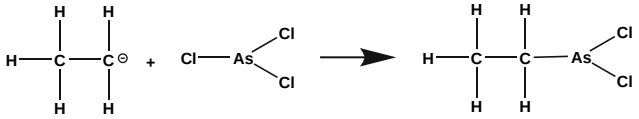


Ethyldichloroarsine (ED) was the third, and last, of the three blistering arsenicals developed in late 1917 to early 1918. Despite serious efforts made to weaponize this compound, little literature exists on the effectiveness and history of its use. Fast acting – compared to mustard or phosgene – ED is

a colorless liquid that smells like rotting fruit and has multiple effects on the body (Henriksson *et al.*, 1996). ED poses a significant vapor threat to exposed personnel. Within seconds of contact with the skin, the agent fixes itself to the epidermis and dermis causing immediate pain. The agent penetrates deeper into the skin layers causing the destruction of subcutaneous tissue. Fluid-filled blisters are formed only after prolonged exposure. Inhalation can cause pulmonary edema or ''dry-land drowning''. A lethal exposure, however, depends upon the period of exposure. A dose of 3,000 to 5,000 mg-min/m^3 is generally lethal.

1. Structure

The structure of ED consists of the trichloroarsine ($AsCl_3$) molecule combined through catalyzation with the ethyl (C_2H_5) group.



Production of ED is similar to that of MD, involving the ethylation of a chlorinated arsenite or arsenate salt, or reductions of arsenious oxide, As_4O_6, a naturally occurring compound (Bartelt-Hunt *et al.*, 2006).

2. Effects

Chlorine bonds in ED giving its blistering, lachrymatory, and harsh respiratory effects. Dosages as low as 5 mg-min/m^3 may cause severe discomfort to the eyes and throat. Sublethal dosages are detoxified by the body. ED's ethyl arsenic group may cause systemic damage to bone marrow and to the digestive and endocrine systems.

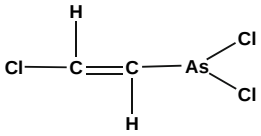
Blisters may appear within 2 to 4 h following skin redness or rash. However, like the mustards, ED actively attacks lung tissue. Damage to lung tissue is permanent to its survivors and presents a hazard area for future infections and tumors. ED is also highly toxic to the eyes. It may cause permanent corneal damage.

3. Physical and Chemical Properties

TABLE 9.4. Physical and chemical properties of ethyldichloroarsine (ED)

Chemical formula	$C_2H_5AsCl_2$
Molecular weight	174.88
Boiling point	156°C
Melting point	−65°C
Decomposition point	156°C
Flash point	No immediate hazard of fire or explosion
Median lethal dose (LCt_{50})	Between 3,000 and 5,000 mg-min/m^3
Median incapacitating dosage (ICt_{50})	5 to 10 mg-min/m^3
Vapor density	Six times as heavy as air
Vapor pressure	2.09 mm Hg at 20°C
Persistency	Short duration
Rate of action	Immediate effects on eyes and respiratory tract. Skin rash leads to blistering within 1 to 2 h
Rate of detoxification	Rapid for nonlethal dosages
Volatility	6,500 mg/m^3 at 0°C; 20,000 mg/m^3 at 20°C
Skin toxicity	Rapid advent of blistering (within 1 h of exposure to high concentrations of ED)
Latent heat of vaporization	52.5 calories/gm
Eye toxicity	Highly irritating. Splashed liquid may cause permanent corneal damage
Decontaminants	Bleaches and other oxidizers and strong alkaline such as NaOH
Rate of hydrolysis	Rapid
Hydrolysis products	Hydrochloric acid and ethylarsenous oxide
Effect on metals and other materials	Very destructive to rubber and plastics. No effect on ferrous alloys

G. Lewisite



The formulation of lewisite (chlorovinyldichloroarsine) as a war gas was achieved by W. Lee Lewis in 1918 (Goldman and Dacre, 1989). It is a colorless, oily liquid at room temperature with a faint ''geranium-like'' odor (Table 9.5). It is more volatile than sulfur mustard and, therefore, can be used as a vapor over greater distances. It was considered an alternative to sulfur mustard, which had become the main chemical warfare agent. Lewisite is a potent blistering agent. Like other blistering agents, it not only produces casualties but also restricts use of terrain, hampers troop movements, and requires cumbersome protective gear (Somani, 1992). To achieve greater effectiveness in combat, lewisite has been mixed with sulfur mustard. Because of its freezing point, lewisite is effective over a wider temperature range than sulfur mustard. Lewisite dissolves very slowly in water. The dissolved lewisite hydrolyzes rapidly to hydrochloric acid and lewisite oxide (Daniels *et al.*, 1990).

TABLE 9.5. Physical and chemical properties of lewisite

Boiling point	190°C
Freezing point	18 to 0.1°C (purity and isomer dependent)
Vapor pressure	0.394 mm Hg at 20°C
Vapor density	7.1 (compared to air)
Volatility	4,480 mg/m^3 at 20°C
Decomposition temperature	>100°C
Hydrolysis rates	Degrades under humid conditions
	Vapor – rapid
	Dissolved – rapid
Hydrolysis products	HCl and chlorovinyl arsenous oxide; alkaline hydrolysis destroys blister properties

In high concentrations, lewisite produces irritation and blistering of the skin and injury to the eyes and lungs promptly after exposure while, at lower levels, the effects resemble exposure to tear gas, with irritation of skin, eyes, and respiratory tract. Chronic exposure may lead to development of chronic bronchitis and predispose to Bowen's squamous cell intraepithelial cancer of the skin.

1. History and Background Information

Lewisite (also known as Agent L) is no longer considered a state-of-the-art chemical warfare agent (Franke, 1967; Goldman and Dacre, 1989). Lewisite is relatively simple and inexpensive to produce (Franke, 1967).

Lewisite acts promptly on exposure, persists with moderate potency, and is easily mixed with other chemical agents to augment toxic effects. Lewisite can be most effective when mixed with nerve agents. Once absorbed, lewisite induces vomiting, precluding the use of protective masks and making personnel vulnerable to other, more toxic chemicals. Lewisite is a significant threat to unprotected personnel and causes prompt incapacitation from eye injuries and respiratory irritation, coupled with long-term incapacitation from skin burns, pulmonary injury, and systemic illness (Sidell *et al.*, 1997; Wachtel, 1941). Large munitions expenditures were required to achieve effective concentrations in the field (Pechura and Rall, 1993).

Although the use of lewisite was suspected at times during the Iran–Iraq War, it was never proved present in the munitions studied (DIA, 1997; Dunn *et al.*, 1997; UN, 1984) and no elevated levels of arsenic were found in the blood and tissues of Iranian casualties treated in Europe (Heyndrickx, 1984). There is some human exposure experience from accidental exposure to lewisite (Pechura and Rall, 1993). The levels of exposure that resulted from accidents in occupational workers are not known.

Lewisite is easy to manufacture, and storage stability problems can be overcome. It can be dispersed by aerial spraying, shells, or bombs. Lewisite persists for 6 to 8 h on the ground in sunny weather. Its decomposition products are toxic, making decontamination difficult. Munitions containing lewisite may contain toxic stabilizers. Lewisite is effective as vapor, aerosol, or liquid (Boronin *et al.*, 1996; Goldman and Dacre, 1989).

Lewisite is reported to possess a characteristic (geranium-like) odor in the range of 0.8 mg/m^3 to more commonly cited 14–23 mg/m^3 median detection (Pechura and Rall, 1993). US forces have detectors for lewisite-paper and kits (M7 and M9A). Other forensic techniques for soil and material analysis already exists (e.g. gas chromatography). In biological tissues, increased arsenic levels are a surrogate for lewisite (Haddad and Wincester, 1983).

2. Toxicity and Mechanism of Action

Lewisite causes painful blistering of the skin and eyes. If decontamination does not occur within 1 min, lewisite produces severe damage to the cornea, and permanent loss of sight can result. Reddening of the skin begins within 30 min, and blistering appears about 13 h after exposure. As a vesicant, lewisite is about four times as fast acting as mustard and is much less persistent (Somani, 1992). Effects of lewisite are similar to those of sulfur mustard, except that it is absorbed through the skin and acts as a systemic poison. Exposure to lewisite leads to pulmonary edema, diarrhea, restlessness, weakness, subnormal temperature, and low blood pressure. Prolonged exposure leads to severe pain in the throat and chest (Bartelt-Hunt *et al.*, 2008; USDHHS, 1988).

Trivalent arsenic is considered the component of lewisite that is primarily responsible for its vesicant and systemic toxicity; thus, field drinking-water standards for lewisite are expressed in terms of the arsenic fraction (Aposhian *et al.*, 2003). Trivalent arsenic exerts its toxic effect by binding to sulfhydryl-containing proteins, especially enzymes, thus inhibiting pyruvate oxidation – a critical step in carbohydrate metabolism (Black, 2008). The lipid solubility of lewisite also contributes to its toxic effects; trivalent arsenic readily penetrates skin, exerting its toxic action systemically and causing painful localized blistering. As a systemic toxicant, lewisite produces pulmonary edema, diarrhea, restlessness, weakness, subnormal temperature, and low blood pressure. Vascular damage, induced by lewisite, is partly responsible for effects such as blistering, tissue perforation, and hemorrhaging. Edema and hemorrhaging associated with lewisite exposure can lead to shock and death (Flora *et al.*, 2007b, c).

Human data concerning the toxicity of lewisite via the oral route of exposure are not available. However, there are limited toxicity data on lewisite ingestion from animal studies. In animals, ingestion of lewisite can produce acute inflammation of the mucous membrane of the stomach or intestine, which is characterized by hemorrhage, necrosis of the epithelium, and submucous edema. Developmental effects have been reported in pregnant rats and rabbits

exposed to lewisite by intragastric intubation. A no-observed-adverse-effect-level (NOAEL) of 0.016 mg/kg/day in rabbits and 1.5 mg/kg/day in rats was identified (Daniels *et al.*, 1990; Goldman and Dacre, 1989). The NOAEL of 0.016 mg/kg/day in rabbits was selected for developing the proposed field drinking-water standards for lewisite. There are no data on chronic toxicity resulting from the ingestion of lewisite.

Lewisite, as an arsenical, might be carcinogenic, although no specific studies were found in which the carcinogenicity of lewisite was evaluated. There is evidence that arsenic might act as a co-carcinogen and promote the carcinogenic process. It is capable of producing DNA damage; however, direct tests of its mutagenic potential have been inconclusive (Datta *et al.*, 2007).

Given the limited epidemiological data, the proposed drinking-water standards for lewisite (Daniels *et al.*, 1990) were derived from three animal studies – a sparse database. The shortcomings of the animal studies for predicting the effects in humans exposed to lewisite in water, and in particular in military personnel exposed to field drinking water, have been clearly recognized (Daniels *et al.*, 1990). However, there are major data gaps on the toxicity of lewisite, and the usefulness of most of the studies is limited by the lack of a satisfactory animal model. Little information exists on the reaction of lewisite with biologically important molecules, although it is reasonable to assume that, as with sulfur mustard, DNA is a major target (IOM, 1996). There are no adequate data on the acute effects of lewisite following dermal exposure. Very little is known about its specific effects on skin, and data on its absorption, disposition, and excretion following dermal exposure are minimal. Microscopic examination of affected skin has not been pursued extensively. The proposed Army standards for exposure to lewisite in field drinking water were derived from a rabbit study, in which the NOAEL was estimated to be 0.016 mg/kg/day (Daniels *et al.*, 1990). Whether the rabbit is the species most sensitive to lewisite is not known, and the applicability of the rabbit data to the human situation requires further evaluation.

Neurological effects following acute exposure to lewisite have not been documented in animals. Acute exposure to high concentrations of lewisite leads to a shock syndrome that is thought to result from increased capillary permeability (Goldman and Dacre, 1989). No direct evidence exists that lewisite might cause neurological problems in humans, although arsenic is considered a neurotoxin and peripheral neuropathy has been reported in humans following a single arsenic exposure (Moore *et al.*, 1997).

3. Toxicokinetics

Lewisite is a local and pulmonary irritant, a vesicant, and a systemic poison. When ingested with food, it produces severe gastrointestinal irritation. The eyes, respiratory tract, and skin are the most likely sites of exposure when lewisite is used as a chemical warfare agent. The agent is lipophilic and readily penetrates intact skin. The approximate lethal dose (LD_{50}) is 35–40 mg/kg, an amount present in 2 ml of liquid agent (NATO, 1973). Lewisite toxicity resembles other trivalent arsenicals that produce peripheral and central neurotoxicity, hepatotoxicity, and epithelial damage. Death may result from fluid loss and hypovolemia secondary to capillary leakage – the so-called ''lewisite shock'' (Sidell *et al.*, 1997; Snider *et al.*, 1990; Watson and Griffin, 1992).

The cellular poisoning effects are attributed to the inhibition of cellular enzyme systems (Pechura and Rall, 1993; Watson and Griffin, 1992), especially as a result of arsenic complexing with sulfhydryl groups of proteins and enzymes. This agent affects many sulfur-containing enzymes, including amylase, lipase, cholinesterase, some adenosine triphosphate (ATP) enzymes, creatine phosphokinase, and of central importance (Snider *et al.*, 1990), the pyruvate oxidase system. Two mechanisms have been proposed for the above-mentioned effects (Sidell *et al.*, 1997): (1) reactions with glutathione leading to loss of protein thiol status, loss of calcium ion homeostasis, oxidative stress, lipid peroxidation, membrane damage, and cell death, and (2) reactions with sulfhydryl groups on enzymes leading to inhibition of pyruvate dehydrogenase complex, inhibition of glycolysis, loss of ATP, and cell death.

4. Clinical and Pathological Findings

There are few published case reports of human lewisite poisoning. Signs and symptoms of acute lewisite exposure include the rapid onset of irritation to the eyes and mucous membranes of the upper respiratory tract (lachrymation and rhinitis). In more serious cases of vapor intoxication, chest pain, nausea, vomiting, headache, weakness, convulsions, hypothermia, and hypotension occur (Katos *et al.*, 2007; NATO, 1973; Sidell *et al.*, 1997; USDHHS, 1988). The pathology literature is largely limited to serious acute exposures. Laboratory tests of the blood of persons exposed may show hemoconcentration; animal studies suggest elevated liver enzymes, including lactate dehydrogenase (LDH) (King *et al.*, 1994, 1992; Sasser *et al.*, 1996, 1999). The following subsections describe the effects on specific body sites.

a. Skin

Exposure of the skin to vapor causes immediate itching or stinging within 1 min, followed by erythema over 10 to 30 min. Mild exposures resemble sunburn with pain decreasing over 24 to 48 h. More intense exposures, including liquid contact, produce intense stinging and the formation of small vesicles over the next 24 h, with later enlargement of the vesicles with accumulation of a nontoxic fluid (McManus and Huebner, 2005). Systemic illness is more likely to occur if heavy exposures are to the liquid form, with later development of vomiting, pulmonary edema, or shock (Arroyo *et al.*, 2004; Kato *et al.*, 2007; King *et al.*, 1992).

b. Eye

Immediate eye pain and blepharospasm result from lewisite exposure, followed by conjunctival and lid edema. Severe exposures can produce necrotic injuries of the iris with depigmentation, hypopion, and synechia development. In contrast, very low levels may only involve the conjunctivae (McManus and Huebner, 2005). The eye lesions produced by lewisite are particularly serious: blindness will follow contamination of the eye with liquid lewisite unless decontamination is prompt.

c. Respiratory System

Mild respiratory exposures resemble upper respiratory infections, with sneezing, coughing, rhinitis, and mucous membrane erythema, possibly progressing to retrosternal pain, nausea, and malaise. More severe exposures cause lower respiratory effects, with continuous coughing, laryngitis, and aphonia (McManus and Huebner, 2005; Sasser *et al.*, 1996; Telolahy *et al.*, 1995).

d. Nervous System

Neurological findings are inconsistent despite reports of convulsions and coma with severe exposures (McManus and Huebner, 2005). Neurologic complications after mild exposures have not been described. Edema and hemorrhage in the brain are rare but no reports of degeneration of peripheral nerves were found.

e. Cardiovascular System

Bradycardia, dyspnea, hypotension, and hemoconcentration have been reported in severe intoxication. These effects are mediated by vasodilatation and increased capillary permeability (Watson and Griffin, 1992). Dilation of the right side of the heart in severe poisoning in animals has been reported.

f. Other Systems

Human ingestion experience is not documented (NAS, 1997), but would be expected to produce severe abdominal pain and bloody diarrhea. Nausea and vomiting occur from respiratory or dermal exposure (Fang, 1983). In human and animals vomiting is associated with retching (Sidell *et al.*, 1997). There is no documentation of liver effects from chronic lewisite exposure. There are no specific musculoskeletal findings, although weakness has been observed. There is little clinical information about effects on bone marrow and the immune and endocrine systems. Renal disorders, although theoretically possible, are not described. There is also no substantial evidence that lewisite is carcinogenic, teratogenic, or mutagenic (Sidell *et al.*, 1997).

V. INORGANIC ARSENIC

Arsenic is a metalloid belonging to group VA of the periodic table. It exists in three oxidation states: metalloid (0), trivalent (−3 or +3), and pentavalent (+5). The most common inorganic trivalent arsenic compounds are arsenic trioxide, sodium arsenite, and sodium trichloride. Pentavalent inorganic arsenic compounds are arsenic pentaoxide, arsenic acid, and arsenate, e.g. lead arsenate and calcium arsenate. In general, the toxicity of arsenic compounds is in the following order:

arsine > arsenites > arsenates > organic > elemental.

A. Sources and Uses

1. Uses

Current uses of arsenic are in pesticides, cotton desiccants, and wood preservatives. Arsenic is also used as a bronzing and decolorizing agent in the manufacture of glass, and in the production of semiconductors (Tanaka, 2004), as a desiccant and defoliant in agriculture, and as a byproduct of the smelting of nonferrous metals, particularly gold and copper, from coal residues (Hall, 2002).

2. Exposure

Arsenic exposure occurs from inhalation, absorption through the skin, and primarily by ingestion of arsenic contaminated drinking water. The exposure to arsenic may come from natural sources (groundwater, arsenic containing mineral ores), industrial processes (semiconductor manufacturing, wood preservatives, metallurgy, glass clarification, smelting, and refining of metals and ores), commercial products (pesticides, herbicides, fungicides, fire salts), food (sea food, kelp, wine, and tobacco), and medicines (antiparasitic drugs and folk medicines) (Kosnett, 1990). Acute arsenic poisoning is only limited to homicidal or suicidal attempts.

B. Absorption, Distribution, and Excretion

Respiratory absorption of arsenic is a two-stage process, involving deposition of the particles on to airway and lung surfaces, followed by absorption of arsenic from deposited particulates. Absorbance of inorganic arsenic from the gastrointestinal tract depends on the solubility and composition of arsenic compound. Both human and animal data show that over 90% of an ingested dose of dissolved inorganic arsenic is absorbed from the gastrointestinal tract to the bloodstream and distributed to organs/tissues after first passing through the liver. Trivalent and pentavalent inorganic arsenic have been reported to cross the placenta in laboratory animals and humans (Bollinger *et al.*, 1992). Following absorption by the lungs or the gastrointestinal tract, arsenic is transported via the blood to other parts of the body. Inorganic arsenic is rapidly cleared from the blood in both humans and common laboratory animals. In rats, absorbed arsenic is accumulated in the red blood cells due to its binding with hemoglobin. Recent studies indicate that the main form of arsenic bound to rat hemoglobin is

dimethylarsinic acid (DMA), the primary metabolite of inorganic arsenic (Lu *et al.*, 2004).

In humans as well as in most animal species, exposure to either arsenite or arsenate leads to an initial accumulation in the liver, kidneys, and lungs (Fujihara *et al.*, 2004). The clearance from these tissues is, however, rather rapid, and a long-term retention of arsenic is seen in hair, skin, squamous epithelium of the upper gastrointestinal tract, epidymis, thyroid, lens, and skeleton (Huges *et al.*, 2003). Two to four weeks after exposure ceases, most of the arsenic remaining in the body is found in keratin-rich tissues, such as skin, hair, and nails. Inorganic arsenic can cross the human placenta (Tabacova *et al.*, 1994). Arsenic metabolism is characterized by two main types of reaction: (1) reduction of the pentavalent arsenic to trivalent arsenic – this conversion of pentavalent arsenic species to trivalent arsenic species is catalyzed by arsenate reductase (Radabaugh and Aposhian, 2000; Radabaugh *et al.*, 2002), and (2) oxidative methylation reactions in which trivalent forms of arsenic are sequentially methylated to form mono-, di- and trimethylated products using *S*-adenosyl methionine (SAM) as the methyl donor and GSH as an essential co-factor (Vahter, 2002). Pentavalent arsenic has been reported to be less toxic than inorganic trivalent arsenic. The metabolic methylation had historically been considered as a detoxification process. Recently, it has been established that trimethylated arsenicals, particularly monomethylarsinous acid [MMA(III)] and dimethylarsinous acid [DMA(III)], exist as intermediates in the metabolic methylation process of inorganic arsenic in humans (Le *et al.*, 2000; Mandal *et al.*, 2001) and are more active than the parent inorganic arsenic for enzymatic inhibition (Styblo *et al.*, 1997), cytotoxicity (Petrick *et al.*, 2001), and genotoxicity (Nesnow *et al.*, 2002). The major route of excretion following exposure to inorganic arsenic is via the kidneys (Csanaky and Gregus, 2005). Only a few percent are excreted in feces (Mann *et al.*, 1996).

C. Biochemical and Toxic Effects

1. Hematopoietic

The hematopoietic system is affected by both short- and long-term arsenic exposure. Arsenic is known to cause a wide variety of hematological abnormalities like anemia, absolute neutropenia, leucopenia, thrombocytopenia, and relative eosinophilia – more common than absolute esinophilia, basophilic stippling, increased bone marrow vascularity, and rouleau formation (Rezuke *et al.*, 1991). These effects may be due to a direct hemolytic or cytotoxic effect on the blood cells and a suppression of erythropoiesis. The mechanism of hemolysis involves depletion of intracellular GSH, resulting in the oxidation of hemoglobin (Saha *et al.*, 1999). Arsenic exposure is also known to influence the activity of several enzymes of heme biosynthesis. Arsenic produces a decrease in ferrochelatase, and decrease in COPRO-OX and increase in hepatic 5-aminolevulinic acid synthetase activity (Woods and Southern, 1989). Subchronic exposure to arsenic has also been reported to inhibit δ-aminolevulinic acid synthetase (ALA-S) and ferrochelatase activities, leading to increased uroporphyrin (URO) and coproporphyrin (Woods and Fowler, 1978) and COPRO urinary excretion (Martinez *et al.*, 1983). In chronically exposed humans, arsenic alters heme metabolism as shown by an inversion of the urinary COPRO/URO ratio (Garcia Vargas *et al.*, 1996). A few recent studies also suggested a significant inhibition of blood δ-aminolevulinic acid dehydratase (ALAD) after subchronic and chronic arsenic exposure (Flora *et al.*, 2002; Flora, 1999; Kannan *et al.*, 2001). Martinez *et al.* (1983) reported that chronic exposure to arsenic alters human heme metabolism. Although anemia is often noted in humans exposed to arsenic, red and white blood cell counts are usually normal in workers exposed to inorganic arsenicals by inhalation (Morton and Caron, 1989). Anemia and leucopenia are common effects of poisoning and have been reported from acute, intermediate, and chronic exposure. These effects may be due to a direct effect of arsenic on the blood cells and a suppression of erythropoiesis. Keeping in view the above there was a proposal that the profile of urinary porphyrins could be used as early biomarkers for arsenic toxicity in humans chronically exposed to arsenic via drinking water.

2. Skin (Dermal)

Dermal changes most frequently reported in arsenic-exposed humans include hyperpigmentation, melanosis, hyperkeratosis, warts, and skin cancer. However, dermal effects appear to be highly dependent on time of exposure (Rossman, 2003). Arsenic-exposed skin cancer occurs mostly in unexposed areas such as trunk, palms, and soles. More than one type of skin cancer is reported and most common are Bowen's disease, squamous cell carcinomas, basal cell carcinomas, and combined forms. It appears that skin cancer lesions related to arsenic exposure act as early warning signals of the subsequent development of cancers of internal organs many years later (Tsuda *et al.*, 1995; Wong *et al.*, 1998). Brittle nails, the surface of which is marked by transverse bands (leukonychia striata arsenicalis transverses), have been associated with arsenic poisoning; the characteristic bands are known as Reynolds-Aldrich-Mees' lines.

3. Hepatic

Arsenic is one of the first chemical agents to which liver disease was attributed in humans (Clarkson, 1991). Early symptoms in patients with arsenic-induced hepatic injury include bleeding esophageal varices, ascites, jaundice, or simply an enlarged tender liver. Another important feature of chronic arsenic toxicity reported in West Bengal, India, is a form of hepatic fibrosis that causes portal hypertension, but does not progress to cirrhosis (Santra *et al.*, 1999, 2000; Rahman *et al.*, 1999). Recent animal studies have shown that hepatic enzyme changes occur following arsenic

exposure and these enzyme changes involved in the antioxidant defense system and membrane damage due to lipid peroxidation precede the pathomorphological lesions of arsenic-induced hepatic fibrosis in mice (Mishra *et al.*, 2008; Santra *et al.*, 2000).

4. Gastrointestinal

Gastrointestinal symptoms are common during acute poisoning. Gastrointestinal effects due to chronic arsenic poisoning are called arsenicosis. Workers exposed to high level of arsenic dust or fumes suffer from nausea, vomiting, and diarrhea (Morton and Caron, 1989). Patients complain of metallic taste and garlic odor. Clinical signs of gastrointestinal irritation due to acute arsenic poisoning include burning lips, painful swallowing, thirst, nausea, and severe abdominal colic (Goebel *et al.*, 1990). The toxic effects of arsenic on the gastrointestinal mucosal vasculature are vasodilatation, transduction of fluid into the bowel lumen, mucosal vesicle formation, and sloughing of tissue fragments. Rupture of the vesicle may cause bleeding, profuse watery stools (''rice-water stools''), and protein losing enteropathy. The most likely mechanism of gastrointestinal toxicity is damage of the epithelial cells, with resulting irritations.

5. Respiratory

Studies from West Bengal draw attention to both restrictive and obstructive lung disease (Mazumder *et al.*, 1998). Respiratory disease is more common in patients with the characteristic skin lesions due to chronic arsenic toxicity (Mazumder *et al.*, 2000). Humans exposed to arsenic dust or fumes inhalation are more likely to be encountered in mining and milling ores, or in industrial processing, such as the smelting industry which often produces irritation of mucous membrane, resulting in laryngitis, bronchitis, rhinitis, and tracheobronchitis, causing stuffy nose, sore throat, dyspnea, chest pain, and chronic cough (ATSDR, 2000). Pulmonary edema may occur, especially in cases of inhalation.

6. Cardiovascular

It has been suggested by several epidemiological studies that chronic inhalation of arsenic trioxide can increase the risk of death in humans from cardiovascular disease (Saha *et al.*, 1999). Both acute and chronic arsenic exposure cause altered myocardial depolarization and cardiac arrhythmias that may lead to heart failure. Arsenic causes direct myocardial injury, cardiac arrhythmias, and cardiomyopathy. Blackfoot disease, causing gangrene of the foot, is unique to a limited area on the southwestern coast of Taiwan, and is due to long-term exposure to high levels of inorganic arsenic in well water (range 0.01–1.82 mg/l) (TPHD, 1993; Tsai *et al.*, 1999). Epidemiological studies also indicate that excess intake of arsenic leads to a variety of vascular diseases such as Blackfoot disease, Reynaud's phenomenon, cardiovascular and cerebrovascular diseases, atherosclerosis, and hypertension (Engel *et al.*, 1994; Lewis *et al.*, 1999; Simeonova and Luster, 2004).

7. Reproductive and Developmental

Reproductive and developmental effects of inorganic arsenic on human and animal species have been reported (Concha *et al.*, 1998). Limited animal studies suggest that arsenic can produce malformation, intrauterine death, and growth retardation (Golub *et al.*, 1998). Arsenic readily crosses the placenta. Sarkar *et al.* (2003) also suggested that spermatogenesis and/or sperm function might be impaired by organic arsenicals. Ahmad *et al.* (2001) observed pregnancy outcome in women chronically exposed to arsenic through drinking water. The authors reported that arsenic contamination is also a threat to healthy and safe pregnancy outcome.

8. Neurological

After initial contradictory reports it is now established that arsenic can cross the blood–brain barrier and produces alternations in whole rat brain biogenic amines levels in animals chronically exposed to arsenite (Tripathi *et al.*, 1997). The neurological effects are many and varied. Usually, peripheral neuropathy, sensory neuropathy (Hafeman *et al.*, 2005), and encephalopathy are the initial complaints associated with acute arsenic poisoning. Acute exposure to arsenic in humans has been shown to result in problems of memory, difficulties in concentration, mental confusion, and anxiety (Hall, 2002; Rodriguez *et al.*, 2003). Other neurological symptoms arising due to arsenic are primarily those of a peripheral sensory neuritis, predominantly numbness, severe paresthesia of the distal portion of the extremities, diminished sense of touch, pain, heat and cold, and symmetrically reduced muscle power (Menkes, 1997).

9. Diabetes Mellitus

Noninsulin-dependent (type 2) diabetes is the prevalent form of diabetes mellitus found in populations chronically exposed to inorganic arsenic from the environment (Rahman *et al.*, 1998; Tseng, 2002). Type 2 diabetes is characterized by insulin resistance of internal organs and peripheral tissues that results in impaired glucose utilization, and, consequently, in abnormally high blood glucose levels between and especially after meals. Insulin resistance and β-cell dysfunction can be induced by chronic arsenic exposure and these defects may be responsible for arsenic-induced diabetes mellitus (Tseng, 2004).

D. Mechanisms of Toxicity

Trivalent inorganic arsenicals, such as arsenite, readily react with sulfhydryl groups, such as GSH and cysteine (Scott *et al.*, 1993; Delnomdedieu *et al.*, 1994). The complex between arsenic and the vicinal sulfhydryl group is particularly strong. Arsenite inhibits pyruvate dehydrogenase (PDH) activity (Hu *et al.*, 1998), perhaps by binding to the

lipoic acid moiety. Inhibition of PDH ultimately leads to decreased production of ATP. Inhibition of PDH may also explain in part the depletion of carbohydrates observed in rats administered arsenite (Reichl *et al.*, 1991). Methylated trivalent arsenicals such as MMA^{III} are potent inhibitors of GSH reductase (Styblo *et al.*, 1997) and thioredoxin reductase (Lin *et al.*, 1999). The inhibition may be due to the interaction of trivalent arsenic with critical thiol groups in these molecules. A mechanism of toxicity of pentavalent inorganic arsenic, such as arsenate, is its reduction to a trivalent form, such as arsenite. The reduction of arsenate to arsenite occurs *in vivo*. Another potential mechanism is the replacement of phosphate with arsenate.

1. Oxidative Stress

Oxidative stress has now been established as one of the major mechanisms involved in arsenic-induced carcinogenesis. A number of recent reports provided direct evidence of an inorganic arsenic-induced free radical formation or production of oxidative stress (Flora, 1999; Liu *et al.*, 2000; Sun *et al.*, 2005). From exposure to the free radical generations, DNA damage such as DNA single strand breaks can occur. It has been suggested in recent studies that arsenic exerts its toxicity through the generation of reactive oxygen species (ROS) such as hydrogen peroxide, superoxide anion, singlet oxygen, and hydroxyl radical that can directly or indirectly damage cellular DNA, lipid, and protein. In addition, sodium arsenite has been shown to enhance heme oxygenase production, an indicator of oxidative stress (Applegate *et al.*, 1991). Reactive oxygen species that damage DNA *in vitro* are generated from iron released from ferritin. The results suggest that some clastogenic effects of arsenic are mediated via free radicals (e.g. peroxynitrite, superoxide, hydrogen peroxide, and possibly free iron). Vega *et al.* (2001) suggested that arsenic exposure could increase the production of ROS, activation of transcription factors (e.g. AP-1, *c-fos*, and NF-κB) and oversecretion of pro-inflammatory and growth promoting cytokines, resulting in increased cell proliferation and finally carcinogenesis. Increased ornithine decarboxylase (ODC) activity is often interpreted as a biomarker for cell proliferation (Kitchin, 2001). Arsenite appears to have an effect on the cell cycle, which may alter cell proliferation. The amplification of the gene which codes for the enzyme dihydrofolate reductase was enhanced by arsenic. Lee *et al.* (1988) suggested that the gene amplification induced by arsenic may have a role in its carcinogenic effects.

E. Diagnosis

1. Clinical Features

Clinical features like skin lesions and neuropathy are crude and imprecise indicators of the severity of poisoning. The early clinical symptoms of arsenic toxicity are headache, dizziness, insomnia, weakness, nightmare, numbness in the extremities, anemia, palpitations, and fatigue. White striae in the fingernails are also a useful clue in the diagnosis of arsenic toxicity; these white striae are also known as ''Mees' lines''. Other symptoms are anemia, leucopenia or pancytopenia, gangrene of the feet (blackfoot disease), hyperpigmentation, hypopigmentation, and hyperkeratosis. Arsenic accumulates in keratin-rich tissues such as skin, hair, and nails due to its high affinity for sulfhydryl groups; the arsenic level in hair and nails may be used as an indicator of past arsenic exposure. Elevated arsenic content in hair and nail segments, normally less than 1 part per million (ppm), may persist for months after urinary arsenic values have returned to baseline (Koons and Peters, 1994). The arsenic content of the fingernails and toenails has also been used as bioindicators of past arsenic exposure, and fingernail arsenic has been reported to be significantly correlated with hair arsenic content (Lin *et al.*, 1998).

Blood arsenic levels are highly variable. Blood arsenic, normally less than 1 μg/dl, may be elevated on acute intoxication. It is probably the most important diagnostic test for detecting arsenic exposure. Arsenic metabolites (inorganic arsenic + MMA + DMA) in urine have also been used as biomarkers of recent arsenic exposure (Yamauchi *et al.*, 1989).

2. Other Biomarkers

Essentially, all organ systems must be evaluated. Thus laboratory tests, should include complete blood count, liver and renal functional tests, and blood, nail and urine arsenic levels. Other biomarkers of arsenic exposure include non-erythrocyte porphyrin enzyme activities and urine transforming growth factor TNF-α, accompanied by induction of heme oxygenase, mitogen-activated protein kinases, the ubiquitin-dependent proteolytic pathway, and protein kinase C in various tissues. These tests are still being investigated in laboratories and their clinical usefulness remains to be proven (Chapell *et al.*, 2001).

VI. TREATMENT

Highly specific treatment is required for poisoning with arsenicals. There is no particular antidote for the treatment of arsine poisoning. Victims may be administered a high flow of oxygen. One of the earlier strategies for the treatment of arsine poisoning involved stopping the ongoing hemolysis which may lead to renal dysfunction (Kimmecki and Carter, 1995). Exchange transfusion is currently the treatment of choice (Pullen-James and Woods, 2006). Chelation therapy generally is not recommended to reduce hemolysis; however, chelating agents are shown to reduce arsenic in arsine-exposed subjects. Since World War II, dimercapol has been the standard treatment for poisoning by arsenicals. In the following paragraphs we discuss the efficacy of chelating agents for treating arsenicals, their drawbacks, and the current advancement in the area.

A. Chelating Agents and Chelation Therapy

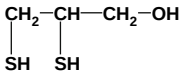
Chelating agents are organic compounds capable of linking together metal ions to form complex ring-like structures called chelates. Chelators act according to a general principle: the chelator forms a complex with the respective (toxic) ion and these complexes reveal a lower toxicity and are more easily eliminated from the body. This mechanism could be represented as:

Metal—*In vivo* site + Chelating agent → *In vivo* site + Metal—Chelating agent complex

Chelation may thus be defined as the incorporation of a metal ion into a heterocyclic ring structure (Flora and Sekhar, 2004).

Some of the chelating agents listed below have been reported to be useful in the treatment of arsenic.

1. 2,3-Dimercaprol (Dimercaprol; British Anti-Lewisite, BAL)



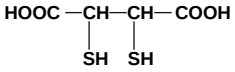
2,3-Dimercaprol (British Anti-Lewisite, BAL) was originally developed to treat the effects of lewisite, namely systemic poisoning and local vesication. The empirical formula of BAL is $C_6H_8OS_2$ and its molecular weight is 124.21. It is an oily, clear, colorless liquid with a pungent, unpleasant smell typical of mercaptans and having a short half-life. Because of its lipophilic nature it is distributed extracellulary and intracellularly. BAL is known to protect against the effects of lewisite and reverse the enzyme inhibition produced by it. Dimercaprol can be used parenterally against systemic toxicity of lewisite and also as an ointment for use against skin burn (Marrs *et al.*, 1996). Skin contamination may be treated with dimercaprol ointment.

a. Drawbacks

BAL is unstable and easily oxidized and therefore difficult to store, therefore it requires ready-to-use preparation. Beside rapid mobilization of arsenic from the body, it causes a significant increase in brain arsenic (Hoover and Aposhian, 1983). Due to its oily nature, administration of BAL requires deep intramuscular injection that is extremely painful and allergic (Flora and Tripathi, 1998). The chelating agent cannot be given intravenously thus denying the possibility of a loading dose. Other side effects include vomiting, headache, lachrymation, rhinorrhea and salivation, profuse sweating, intense pain in the chest and abdomen, and anxiety.

Two water-soluble analogs of dimercaprol have also been been studied as lewisite antidotes. They are meso 2, 3-dimercaptosuccinic acid (DMSA) and 2,3-dimercapto-1-propane sulfonic acid (DMPS). These two drugs circumvent two major disadvantages associated with treatment with BAL, i.e. the need for intramuscular injection and limitation of dose by toxicity.

2. Meso 2,3-Dimercaptosuccinic Acid (DMSA)



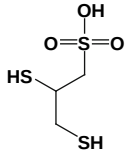
One of the chemical derivatives of dimercaprol (BAL) is DMSA. DMSA is an orally active chelating agent, much less toxic than BAL, and its therapeutic index is about 30 times higher (Angle and Kuntzelman, 1989). The empirical formula of DMSA is $C_4H_6O_4S_2$ and its molecular weight is 182.21. It is a weak acid soluble in water.

The LD_{50} value of sodium salt of DMSA in mice is: i.v. 2.4, i.m. 3.8, i.p. 4.4, and p.o. 8.5 gm/kg. The therapeutic index of DMSA was almost three times greater than that of DMPS because the LD_{50} of DMSA is about 3% greater than that of DMPS (Aposhian *et al.*, 1981). No significant loss of essential metals like zinc, iron, calcium, or magnesium was observed. Flora and Tripathi (1998) also reported a significant depletion of arsenic and a significant recovery in the altered biochemical variables of chronically arsenic-exposed rats. However, a double-blind, randomized controlled trial study conducted on a number of selected patients from arsenic-affected West Bengal (India) regions with oral administration of DMSA suggested that DMSA was not effective in producing any clinical and biochemical benefits or any histopathological improvements of skin lesions (Guha Mazumder *et al.*, 1998).

a. Drawbacks

DMSA distribution is predominantly extracellular, since it is unable to cross hepatic cell membranes. Hence, it is able to chelate arsenic from extracellular sites but not from intracellular sites. Adverse reaction of DMSA includes gastrointestinal discomfort, skin reaction, mild neutropenia, and elevated liver enzymes. Some evidence of embryo toxicity/fetal toxicity due to DMSA administration was also reported (Domingo, 1998).

3. Sodium 2,3-Dimercaptopropane-1-Sulfonate (DMPS)



DMPS was first introduced in the Soviet Union in the 1950s as ''Únithiol''. Its empirical formula is $C_3H_7O_3S_3Na$ and its

molecular weight is 210.3. DMPS, like DMSA, is another analog of BAL, and has been reported to be an effective drug for treating arsenic poisoning. A quantitative comparison has demonstrated that DMPS is 28 times more effective than BAL for arsenic therapy in mice (Hauser and Weger, 1989).

DMSA and DMPS are equally effective in providing significant depletion of body arsenic burden in chronically arsenite-exposed rats. Guha Mazumder *et al.* (1998) presented evidence on the efficacy of treatment of DMPS in a single-blind placebo-controlled trial of patients suffering with chronic arsenic poisoning in West Bengal, India. There was a significant decrease of clinical scores from pretreatment to post-treatment values among both DMPS and placebo groups. There was, however, no change in skin histology, hematology, and liver function test parameters in patients before and after the therapy with DMPS or placebo. No side effects were noticed in patients treated with DMPS.

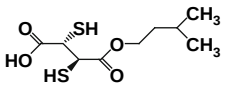
a. Drawbacks

No major adverse effects following DMPS administration in humans or animals have been reported (Hruby and Donner, 1987). However, a dose-dependent decrease in the copper contents was found in the serum, liver, kidneys, and spleen. Szincicz *et al.* (1983) observed that after 10 weeks of DMPS administration there was a decrease in copper concentration in serum and in various organs, an increase in iron contents of liver and spleen, and a decrease in hemoglobin, hematocrit, red blood cells, activity of alkaline phosphatase, and zinc content in the blood. Information regarding the developmental toxicity of DMPS is rather scarce. No abnormalities in the offspring with chronic oral DMPS treatment are reported. Oral administration of DMPS did not adversely affect late gestation, parturition, or lactation in mature mice and fetal and neonatal development does not appear to be adversely affected (Domingo, 1998).

4. Monoesters of DMSA

Recently, some mono- and diesters of DMSA, especially the higher analogs, have been developed and tried against cases of experimental heavy metal poisoning to address the shortcomings of DMSA, particularly depleting intracellular arsenic (Flora *et al.*, 2007a; Kalia and Flora, 2005; Mehta and Flora, 2001; Aposhian *et al.*, 1992). Due to its lipophilic nature it can easily cross the cell membrane and chelate arsenic from intracellular and extracellular sites. This is the best advantage of treatment with DMSA monoesters. It is also assumed that MiADMSA could be able to provide recovery in altered biochemical variables, particularly decreasing oxidative stress in tissues either by removing arsenic from the target organs and/or by directly scavenging ROS via its sulfhydryl group. These monoesters, like monoisoamyl DMSA (MiADMSA), mono n-amyl DMSA, mono n-butyl and mono iso-butyl DMSA, were significantly more efficient than DMSA in decreasing the arsenic content in most of the organs as soon as 1.5 h after administration. Among these monoesters, MiADMSA was the most effective in increasing the survival of mice and depleting tissue arsenic burden (Kreppel *et al.*, 1995; Flora *et al.*, 2004a, b). A few recent published studies clearly point to the fact that the analogs of DMSA were capable of crossing the membranes and were more effective in reducing the toxic metal burden in acute and subchronic arsenic intoxication (Flora *et al.*, 2004a, b, 2003; Flora and Sekhar, 2004; Saxena and Flora, 2004; Saxena *et al.*, 2005). Most of these conclusions are based on experimentally induced metal intoxication and no clinical data are available so far.

5. Monoisoamyl DMSA (MiADMSA)



Monoisoamyl dimercaptosuccinic acid (MiADMSA) is a C_5-branched chain alkyl monoester of DMSA. Kreppel *et al.* (1995) also reported the superior efficacy of MiADMSA and mono n-amyl DMSA in the protecting mice from the lethal effects of arsenic and in reducing body arsenic burden. These studies thus support that MiADMSA could be a potential drug to be used in the treatment of chronic arsenic poisoning. MiADMSA is a new drug and one of the most effective of the vicinal class of metal mobilizing agents (Jones *et al.*, 1992; Xu *et al.*, 1995). Although the compound is more toxic than the parent diacid DMSA (Mehta *et al.*, 2002; Flora and Mehta, 2003), its structural features and recent experimental evidences suggest that it might well be effective in chelating arsenic (Flora and Kumar, 1993; Flora *et al.*, 2002). More pronounced efficacy of MiADMSA could be attributed to its lipophilic characteristic. Lipophilicity and molecular size of this new drug might be important factors for the removal of arsenic from both intra- and extracellular sites possibly leading to better therapeutic efficacy. There could be a possibility of arsenic redistribution to the brain following treatment with this monoester. However, we observed no such effects in a recently conducted study (Flora *et al.*, 2005). It appears plausible that MiADMSA could be decreasing the oxidative stress in tissues either by removing arsenic from the target organs and/or by directly scavenging ROS via its sulfhydryl group (Mishra *et al.*, 2008).

No report is available for the therapeutic efficacy of MiADMSA against lewisite toxicity and other arsenicals. However, we reported the effect of MiADMSA on the reversal of gallium arsenide (GaAs)-induced changes in the hepatic tissue (Flora *et al.*, 2002). MiADMSA was found to be better than DMSA at mobilizing arsenic and in the turnover of the GaAs-sensitive biochemical variables.

Despite a few drawbacks/side effects associated with MiADMSA, the above results suggest that MiADMSA may be the future drug of choice owing to its lipophilic character

and the absence of any metal redistribution. However, significant copper loss requires further studies (Mehta and Flora, 2001; Mehta *et al.*, 2006). Moderate toxicity after repeated administration of MiADMSA may be reversible after the withdrawal of the chelating agent.

a. Drawbacks

It is reported that the toxicity of DMSA with an LD_{50} of 16 mmol/kg is much lower than the toxicity of MiADMSA with an LD_{50} of 3 mmol/kg but less than BAL (1.1 mmol/kg). Flora and Mehta (2003) reported that administration of MiADMSA led to no major alternations in heme synthesis pathway except for a slight rise in the zinc protoporphyrin levels suggesting mild anemia. MiADMSA was seen to be slightly more toxic in terms of copper and zinc loss and some biochemical alterations in the hepatic tissue in females as compared to male rats (Mehta *et al.*, 2006).

6. Role of Antioxidants

Oxidative stress can be partially implicated in arsenic toxicity and a therapeutic strategy to increase the antioxidant capacity of cells may fortify the long-term effective treatment of arsenic poisoning. This may be accomplished by either reducing the possibility of metal interacting with critical biomolecules and inducing oxidative damage, or bolstering the cells' antioxidant defenses through endogenous supplementation of antioxidant molecules (Flora *et al.*, 2007a). Although many investigators have confirmed arsenic-induced oxidative stress, the usefulness of antioxidants in conjunction with chelation therapy has not been extensively investigated yet. N-acetylcysteine (NAC) is a thiol, a mucolytic agent, and a precursor of L-cysteine and reduced glutathione. NAC is a source of sulfhydryl containing antioxidant that has been used to mitigate various conditions of oxidative stress. Combined administration of NAC and succimer post-arsenic exposure led to a significant recovery in biochemical variables indicative of oxidative stress and arsenic depletion from soft organs (Flora, 1999; Kannan and Flora, 2006). Various vitamins have been found to reduce the toxic manifestation of heavy metals. It was observed that vitamin E prevented the arsenite-induced killing of human fibroblasts (Lee and Ho, 1994). The protective mechanism of vitamin E could be attributed to its antioxidant property or its location in the cell membrane and its ability to stabilize the membrane by interacting with unsaturated fatty acid chains. Kannan and Flora (2004) reported that co-administration of vitamin C or vitamin E with DMSA or its monoisoamyl derivative (MiADMSA) produced profound recoveries in subchronically arsenic-exposed rats, although the results suggested that vitamin C was better in providing clinical recoveries and vitamin E was equally efficient in decreasing arsenic burden from the tissues. In an interesting study Wei *et al.* (2005) reported the involvement of oxidative stress in dimethylarsinic acid (DMA)-induced bladder toxicity and proliferation in rat, and inhibitory effects of vitamin C on these alterations.

7. Combination Treatment

As discussed above, metal chelators are given to increase the excretion of arsenic but unfortunately the use of these chelators are compromised by number of drawbacks (Mehta and Flora, 2001). These drawbacks open up the field for a search for new treatment which has no side effects. A number of strategies have been discussed in the recent past (Kalia and Flora, 2005). Among these strategies, combination therapy is a new and better approach to treat cases of metal poisoning (Flora *et al.*, 2007a; Mishra *et al.*, 2008). In a recent study, we investigated whether co-administration of thiol chelators like meso 2,3-dimercaptosuccinic acid (DMSA) or sodium 2,3-dimercaptopropane 1-sulfonate (DMPS) along with newly developed thiol chelators, e.g. monoisoamyl DMSA, is more beneficial than monotherapy with these chelators in counteracting chronic arsenic toxicity (Flora *et al.*, 2005; Bhadauria and Flora, 2007). It was concluded from these studies that concomitant administration of DMSA, a chelator known for its extracellular distribution with lipophilic chelators like MiADMSA, could play a significant and important role in abating a number of toxic effects of arsenic in animals compared to treatment with these chelators alone. We suggested that analogs having a long carbon chain (MiADMSA and MchDMSA) are better chelators than chelators with a shorter carbon chain (MmDMSA) or DMSA. It is assumed that analogs of DMSA eliminate arsenic simultaneously from the cell and provide assistance in bringing GSH homeostasis towards normalcy. Further combinational therapy with DMSA and MiADMSA or MchDMSA proved more beneficial than combined treatment with MmDMSA and DMSA (Mishra *et al.*, 2008).

As little experimental evidence is available there is a need for in-depth investigation in this area. It is thus proposed to investigate the effects of combination therapy particularly in the case of chronic arsenic poisoning, where a strong chelating agent is administered along with another structurally different chelating agent (Kalia and Flora, 2005) to evaluate whether combination treatment is able to promote the elimination of arsenic and restore arsenic-induced biochemical and clinical alterations.

VII. CONCLUDING REMARKS AND FUTURE DIRECTION

Arsenic is used in industry and agricultural production, and also appears in the food chain. Although information about arsenic and its inorganic and organic derivatives is now widely reported, there is very little information about their use as chemical warfare agents. The use of arsenicals remains a potential threat as they are relatively easy to manufacture and may cause significant morbidity and mortality. Knowledge about these arsenicals is very important to plan a response in an emergency. Lewisite is one of the arsenicals which has not been studied in detail. There is very little information available on the detailed

toxic effects of organic arsenicals particularly carcinogenicity, mutagenicity, and teratogenicity. Lewisite, an organic arsenical war gas which is a vesicant, has been reported for its ability to bind with thiol groups leading to the possibility of its undesirable effects on a variety of enzymes. Thus there is a very strong possibility that exposure to lewisite might also lead to carcinogenic effects, but this hypothesis requires experimental and epidemiological evidence. It is not known if lewisite is persistent. However, arsenic is an elemental poison and any residual hydrolysis, combustion, and decontamination product is likely to contain an arsenical compound. Some of the major thrust areas for future research include the possibility of delayed or latent effects arising after organic arsenical (particularly lewisite) exposure. These effects have been studied in detail recently after inorganic arsenic exposure; however, there is very little information available after organic arsenical exposure. Development of antidotes is another area which requires immediate attention. Although one approved antidote, BAL, is available for lewisite, further investigations are required with other derivatives of BAL like DMSA, DMPS, or monoesters of DMSA like MiADMSA. Chelators are generally not of any immediate benefit as far as toxicity of arsine is concerned and once hemolysis has begun. With some new chelating agents, like MiADMSA, at experimental stages the effectiveness and safety of these chelating against arsine poisoning need assurance. The toxicodynamics of arsine is also one area which requires exploration as this information will be of immense help in developing suitable antidotes, particularly for impending hemolysis by removing or displacing arsine.

Inorganic arsenic, particularly arsenic (III), is a well-documented potent carcinogen causing cancer of the bladder, lung, skin, and possibly liver and kidney. Because of failures in the attempt to study the carcinogenic effects of arsenic in animal models, the mechanism of arsenic-induced carcinogenic effects remains unclear. The newly discovered potency of trivalent methylated arsenic metabolites opens up new opportunities for mechanistic studies. No treatment of proven benefit is available to treat chronic exposure. Treatment options advocated are vitamin, mineral supplements, and antioxidant therapy. The benefits of these treatment measures need to be evidence based to receive endorsement and wider application. Further research work is also recommended in the areas of (1) molecular mechanisms of action of clinically important chelators, (2) intracellular and extracellular chelation in relation to mobilization of aged arsenic deposits and the possible redistribution of arsenic to sensitive organs like the brain, (3) effect of metal chelators on biokinetics during continued exposure to arsenicals, (4) combined chelation with lipophilic and hydrophilic chelators, (5) use of antioxidants, micronutrients, or vitamins as complementary agents or antagonists, (6) minimization of the mobilization of essential trace elements during long-term chelation, and (7) fetotoxic and teratogenic effects of chelators.

CHAPTER 10

Psychotomimetic Agent BZ (3-Quinuclidinyl Benzilate)

JOSEF FUSEK, JIRI BAJGAR, JIRI KASSA, KAMIL KUCA, AND DANIEL JUN

I. INTRODUCTION

Experience with the use of chemical warfare agents (CWAs) in WWI has led to an attempt to synthesize new chemicals for military use but without lethal effects (Ketchum and Sidell, 1997). The research was focused on contemporary incapacitants influencing behavior but without substantial effects on important vital functions. Incapacitating agents include the esters of glycolic acid, i.e. atropine-like anticholinergic compounds. BZ (3-quinuclidinyl benzilate QB, QBN, Ro 2-3308) is a prototype of the CNS depressants; and a prototype of CNS stimulants is LSD-25 (D-lysergic acid diethylamide) or cannabinol. LSD-25 was found as the first candidate for this group of CWAs. However, its physical and chemical properties as well as unpredictable behavior after exposure have led to its exclusion from military research. From many tested compounds, anticholinergic drugs were chosen for further research. The anticholinergics are generally ''glycolates'' (substituted glycolic and tropic acid esters) of which the representative and best-known member is atropine. Major symptoms of low-level atropinization include dry mouth, dilatation of pupils, and tachycardia. With toxic doses of atropine, central excitation becomes more prominent, leading to restlessness, irritability, disorientation, and hallucinations or delirium. With still larger doses of atropine, stimulation is followed by depression, coma, and medullary paralysis. A number of anticholinergic compounds influencing psychotic stage and higher nervous functions were tested (Table 10.1).

This group of compounds has both peripheral and central properties. It is known from ancient literature that atropine has psychotomimetic effects (extracts from *Atropa belladona* were used to induce hallucinations in ''wizards''). Central effects increase when the compounds are considered in the following rank: atropine, scopolamine, benactyzine, Ditrane, and, finally, BZ and other esters of glycolic acid (Albanus, 1970). BZ was originally studied for the therapy of gastrointestinal diseases. But even in small doses it produces side effects, such as confusion and hallucinations. Therefore, BZ was withdrawn from commercial studies and turned over to the US Army as a possible candidate for incapacitating agents (Sidell, 1982). BZ is known to neuropharmacologists as the standard drug for testing the central activity of muscarinic cholinergic receptors. At present, BZ is used in the research of cholinergic neurons in the peripheral and central nervous systems (Monica *et al.*, 2008; Yamada *et al.*, 2007), Parkinson's disease, Alzheimer's disease, and other types of dementia (Wyper *et al.*, 1993; Parkasi *et al.*, 2007). In the 1960s, a number of similar compounds including BZ were studied, in the framework of the military, through industrial liaison programs (Pearson, 2006); these compounds, by politico-military goals and requirements, must contain the following criteria:

- high potency for physiological action (acting in μg/kg or less)
- rapid onset (minutes)
- defined duration (optimally minutes–hours) and reversible effect
- stability at storage and delivery
- significant and predictable effect
- capability of rapid dissemination in defined conditions and
- high safety ratio.

II. BACKGROUND

BZ is a white powder with a bitter taste. It has good solubility in water and organic solvents, and is stable at field conditions at a minimum of 1 or 2 days without loss of its incapacitating activity. Its physical and chemical properties are summarized in Table 10.2.

III. TOXICOKINETICS AND MECHANISM OF ACTION

BZ is absorbed by all the usual routes of administration (oral, parenteral, and inhalation). When administered by inhalation, the absorption into the transport system (blood stream) is more pronounced in comparison with oral administration. Experimental studies were performed with

TABLE 10.1. Structural formulae of some anticholinergic psychotomimetics and their antidotes

BZ, 3-quinuclidinyl benzilate			

parenteral administration, and in this case, i.v. administration is without any loss because of direct involvement of BZ in the transport system. In the transport blood, the compound is bound to the plasma proteins (preferably albumin) and it is transported to the sites of toxic effect – central and peripheral nervous systems. At these sites, BZ interferes with cholinergic nerve transmission at muscarinic sites, both in the peripheral autonomic nervous system and in the brain and spinal cord. Because of the wide distribution of these sites, measurable effects upon almost each phase of neural regulation may be observed. BZ readily crosses the blood–brain barrier, is distributed to all areas of the brain and spinal cord, and interacts with cholinergic receptors as a competitor with physiologically active transmitter acetylcholine. At the peripheral system, BZ binds to muscarinic acetylcholine receptors in smooth muscles, like atropine, and it has a very high affinity but without intrinsic activity (Fusek *et al.*, 1971).

At the central nervous system, BZ binds to all subtypes of muscarinic receptors, each of them having different functions in the brain (Lefkowitz, 2004). The particularly long duration of the central action of BZ may be related to its higher affinity

for the nervous tissue, especially strong adsorption on mitochondria, the subcellular organelles concerned principally with the energy supply to the cell; this part of BZ has been found to reduce the oxygen consumption by nerve cells stimulated in various ways (Jovic and Zupanc, 1973).

IV. TOXICITY

The acute toxicity of BZ (expressed as LD_{50}) in different species following different routes of administration is shown in Table 10.4.

TABLE 10.3. Pharmacological activity of the compounds tested on isolated rat jejunum

Compound	i.a.	$pD_2 \pm P_{95}$	$pA_2 \pm P_{95}$
Acetylcholine	$\alpha = 1$	6.79 ± 0.06	
Muscarine	$\alpha = 1$	6.59 ± 0.05	
Atropine	$\beta = 0$		8.92 ± 0.05

Scopolamine	$\beta = 0$		8.83 ± 0.06
Ditrane	$\beta = 0$		8.36 ± 0.07
BZ	$\beta = 0$		8.55 ± 0.09

i.a. = intrinsic activity
α = intrinsic activity of agonist
β = intrinsic activity of antagonist
pD_2 = negative decadic logarithm of agonist ED_{50} ($-\log ED_{50}$ agonist)
pA_2 = negative decadic logarithm of antagonist ED_{50} ($-\log ED_{50}$ antagonist)
P_{95} = 95% confidence limits

It is clear that acute toxicity is relatively low. However, the dose causing incapacitation is much lower. Therefore, the ratio between lethal and incapacitant dose is in the range of the logarithmic scale.

The effective doses (ED) of some psychotomimetic drugs for incapacitation in humans were assessed and are presented in Table 10.5.

The dose required to produce incapacitation is roughly 40 times lower than the lethal dose. For humans the effective dose (ED_{50}) for incapacitation by BZ under field conditions is about 60 mg.min/m^3 with a 75 kg body weight, volume of respiration of 15 l/min, and LD_{50} value about 200 μg/kg, p.o. administration.

A. Symptoms

BZ is active when it is given by the intravenous, intramuscular, inhalation, or oral route of administration. The fragmentary data available indicate that the higher dose caused the greatest effects and longest duration. From 1960 to 1969, field tests had been conducted with 3-quinuclidinyl benzilate by the US Army. Sidell's (1982) description of the effects induced by BZ (4.5–17.1 μg/kg) is as follows.

At low doses, the effects include dry mouth, decreased gastric motility, inhibition of sweating, increase in heart rate, papillary dilatation and loss of accommodation, mild sedation, and mental slowing.

At high doses these effects are severe. There are marked disturbances of function at all levels of the central nervous system: motor coordination, attentiveness, and control of thought and the learning process all decline. Confusion, restlessness, impairment of perception and interpretation, and memory span are observed. The first symptoms occur

TABLE 10.4. Lethal doses of 3-Quinuclidinyl benzilate and other anticholinergic drugs for different species

Animal	Route of administration	LD_{50} (mg/kg)		
		3-Quinuclidinyl benzilate (BZ)	Atropine	Scopolamine

Pig	i.v.	5		

depending on the route of administration; judgment and deficient insight are all features of this syndrome. True hallucinations are present and if the dose is quite high the subject may become stuporous or even comatose for several hours.

After a single injection of BZ (5.0–6.4 μg/kg, i.m.), the following symptoms are observed at various time intervals:

- 10 min: light headedness and giggling.
- 30 min: dry mouth, blurred vision, nausea, chilly sensations, and twitching.
- 1 h: flushed skin, incoordination, fatigue, unsteadiness, sleepiness, and quivering legs.
- 2 h: many of the above, plus poor concentration, restlessness, hallucinations, slurred speech, and muscle fasciculation.
- 3 h: above, plus tremors.
- 4 h: above, plus difficulty in handling the subject, increased pulse to 130.
- 8 h: above, plus delirium and hallucinations.
- 24 h: persistent delirium, hallucinations, restlessness, unsteadiness, increased pulse in some but not all subjects.
- 48 h: persistent impairment of functions.

Mydriasis and disturbed accommodation remain unchanged depending on the dose after 2 or 3 days. BZ has a mean duration of incapacitation of about 70 h. In real situations, wide variations in dosage would occur and thus the results will also be varied over the large time interval.

V. RISK ASSESSMENT

BZ was stockpiled by the US military forces in 1980. However, in 1992, a US delegation to the Conference on Disarmament in Geneva declared that their stocks of BZ were destroyed. It is not known if stocks of BZ are held by any other armed forces. The military use of BZ was limited to

special operations and, at present, BZ agent can be considered as a potential agent dedicated for special military operations. There exist a group of other incapacitants (not anticholinergic hallucinogens) known as nonlethal chemicals with very strong effects, e.g. fentanyl derivatives, as demonstrated in Moscow in 2002. Use of these incapacitants by terrorists and other small groups cannot be excluded either. Today, BZ is considered as one of a number of ''nonlethal'' incapacitating chemical weapons. These compounds are designed and primarily employed to incapacitate personnel or material while minimizing fatalities, permanent injury to personnel, and undesired damage to property and the environment (Pearson, 2006).

VI. TREATMENT

Based on the knowledge of mechanism of action (simply described as a lack of neuromediator acetylcholine), the therapeutic principle of BZ intoxication is to increase the acetylcholine level by inhibitors of cholinesterases. However, their use is limited to their ratio between therapeutic and toxic dose and therefore reversible inhibitors are preferred, although some experiments with interaction of highly toxic nerve agents (VX and sarin) and BZ on healthy volunteers were described (Sidell *et al.*, 1973). Physostigmine was the first antidote proposed against BZ intoxication. Its antidotal effect against intoxication with extract from *Atropa belladona* has been known for more than 150 years. It is known that physostigmine acts as a good antidote against scopolamine intoxication, as it is able to treat all kinds of symptoms, such as electrophysiological, psychiatric, and biochemical changes caused by this anticholinergic drug. Physostigmine was considered as one of the potential antidotes against anticholinergics, including esters of glycolic acid. Its therapeutic and toxic doses are very close, showing side effects and short time duration. There were some attempts to obtain new inhibitors having lower toxicity in comparison with physostigmine. Acridine derivatives were of great interest (Albert, 1966). From these compounds, 1,2,3,4-tetrahydro-9-aminoacridine (tacrine) was found to be very effective (Fusek *et al.*, 1974). It was found to be an antagonist against morphine and curare overdosage. It is an inhibitor of cholinesterases comparable with neostigmine or physostigmine and also having antihistaminic activity. Its effect is prolonged in comparison with physostigmine. During the studies of antidotes against anticholinergic hallucinogens, it was recognized as the most promising antidote at the time (Gershon and Angrist, 1973). The antidotal effect of Tacrine against Ditrane intoxication including improvement of the EEG changes was approved by Itil and Fink (1966) in 74 patients. Atropine, scopolamine, and Ditrane intoxications were successfully treated using physostigmine and Tacrine, but also sarin (Ketchum *et al.*, 1973). However, the toxicity of Tacrine was the reason for its limited use. Moreover, it has other limitations, for example it caused temporary changes in hepatic function tests and therefore was abandoned (Marx, 1987).

The 7-methoxy derivative of Tacrine (7-MEOTA) was synthesized and tested (Fusek *et al.*, 1986). 7-MEOTA inhibited *in vitro* rather more butyrylcholinesterase (BuChE) ($I_{50} = 3.5.10^{-7}$ M) than acetylcholinesterase (AChE) ($I_{50} = 3.5.10^{-6}$ M). The inhibition is a competitive–noncompetitive reversible type. The characteristics of AChE inhibition indicate that 7-MEOTA binds to the active surface of AChE in the gamma-anionic site, like galantamine or coumarine. Inhibition of blood AChE by *O*-ethyl-S-(2-dimethylaminoethyl) methylphosphonothioate (0.042 mg/kg = 1.5 × LD_{50}, i.m.) after premedication with 7-MEOTA (100 mg/kg, i.m.) was substantially smaller than in intoxicated animals pretreated with saline, which highlights its possible use for preventing intoxication by organophosphorus anticholinesterase agents. 7-MEOTA enhanced the contraction response of the guinea pig atria (ED_{50} positive inotropic effect = 1.7×10^{-6} M), reduced the frequency of contractions (by binding the compound to the effectors of the cholinergic system of the heart tissue), increased the contraction response of the isolated rat diaphragm, and antagonized the effect of *d*-tubocurarine. The dose of 3×10^{-6} M of 7-MEOTA entirely suppressed the effect of a dose of 2×10^{-6} M *d*-tubocurarine. 7-MEOTA elicited a contraction response (1×10^{-7} M) and intensified the response of the isolated rat jejunum to the applied concentration of cholinomimetics. The long-term increase of intestinal peristaltic after low concentrations of 7-MEOTA (1×10^{-7} M) bears witness to the inhibitory effect of the compound on tissue cholinesterases. In a dose-dependent manner, 7-MEOTA effectively antagonized symptoms of intoxication elicited by anticholinergics in dogs. A dose of 5 mg/kg, i.m. of 7-MEOTA shortened the time needed for a fall in the score of intensity of symptoms elicited by BZ (0.05 mg/kg, i.m.) from 210 min in untreated intoxication to 54 min, respectively (Fusek *et al.*, 1979).

Our results show that contributing to the effect of 7-MEOTA (besides the direct influence on effectors of the cholinergic system) can also be mediated through the action of the induced cholinesterase inhibition in the central and peripheral nervous systems. The more beneficial properties of 7-MEOTA in comparison with physostigmine suggests the possible therapeutic use of this compound in cases where hitherto physostigmine used to be applied. In contrast to physostigmine, the application of 7-MEOTA will not require repeated doses for maintaining the therapeutic effect at low dosage and has minimum side effects.

7-MEOTA is a potent, centrally active cholinesterase inhibitor. Therefore, this new medicament not only has use as an antidote against BZ intoxication but can be used in general as a drug for the treatment of cholinergic deficit neurological disorders, such as Alzheimer's disease. In isolated rat jejunum, 7-MEOTA increased muscle contractility and in isolated guinea pig ventricular myocytes this

compound was found to prolong transmembrane action potential and decrease the amplitude of the plateau. In isolated rat diaphragm, 7-MEOTA increased muscle contractility after electric stimulation of the phrenic nerve.

7-MEOTA was found to antagonize convulsive action of pentamethylenetetrazole and significantly decreased the number of surviving animals following administration of this drug. Results from behavioral studies indicated that 7-MEOTA antagonized anticholinergic syndrome evoked by scopolamine, Ditrane, and BZ.

TABLE 10.6. Lethal doses of Tacrine, 7-methoxytacrine and physostigmine in laboratory animals

Compound	Animal	Route of administration	LD_{50} (mg/kg)
Tacrine	Mouse	i.m.	28.9 (24.2–35.8)
	Rat	i.m.	33.8 (28.8–40.6)
	Rat	p.o.	103.7 (84.6–135.8)
	Rat	i.p.	20.2 (16.4–24.8)
	Rat	i.v.	12.0 (10.7–13.6)
	Rabbit	i.n.	13.3 (8.0–18.8)
	Dog	i.m.	12.6 (10.1–14.7)
7-Methoxytacrine	Mouse	i.m.	125 (110–143)
	Rat	i.m.	258 (224–313)
	Rat	p.o.	793 (662–950)
	Rat	i.p.	73.3 (61–90)
	Rat	i.v.	22.2 (19.9–25.2)
	Rabbit	i.m.	75.3 (60–89)
	Dog	i.m.	18.9 (15.2–22.1)
Physostigmine	Mouse	i.m.	0.86 (0.7–1.0)
	Rat	i.m.	2.2 (1.9–2.4)
	Dog	i.m.	0.83 (0.68–0.95)

The antidotal effect of 7-MEOTA on the anticholinergic syndrome was potentiated by nootropics, by diazepam, and especially by opioid peptides (Fusek, 1977).

7-MEOTA also antagonized side effects of tricyclic antidepressants and protected AChE against inhibition by some organophosphate anticholinesterase compounds.

Acute toxicity of 7-MEOTA was low, since LD_{50} (i.m.) was 125 mg/kg for mice and 258 mg/kg for rats. The oral LD_{50} in rats was found to be 793 mg/kg. Analogous values for THA at the same order were: 29, 34, and 104 mg/kg (Fusek, 1977). Also, 7-MEOTA was found to be markedly less toxic than THA in dogs and rabbits. A subacute toxicity study of 7-MEOTA (3 months' administration) demonstrated that the compound was well tolerated at doses of 25 mg/kg (i.m.) and 50 mg/kg (p.o.) in rats and 2.5 mg/kg (i.m. and i.v.) in beagle dogs. No pathological changes were observed in biochemical, haematological, and morphological investigations.

VII. ANALYTICAL METHODS

The fluorometric method for 7-MEOTA determination in biological material was developed, and blood concentration profiles of 7-MEOTA in rats and healthy volunteers were estimated (Filip *et al.*, 1991).

Maximal concentrations of 7-MEOTA in human blood were observed approximately 0.5–1 h after i.m. and 4 h after p.o. application of the drug. Half-life was 5 h, and an effective level was maintained for 12 h. Similar results in rats with radiolabeled [H^3]7-MEOTA were obtained. The main part of 7-MEOTA was eliminated by urine, and later by feces 6 h after administration. The majority of the compound was eliminated in unchanged form, and the minority was metabolized. Among the metabolites, 7-MEOTA and its conjugate with glucuronic acid were demonstrated; further metabolites were likely compounds with the OH group in position 1 or 2 (Patocka *et al.*, 1996).

In healthy volunteers, 7-MEOTA was well tolerated in a single dose of 2 mg/kg (p.o.) or 1 mg/kg (i.m.) following daily administration (7 days). The compound did not influence cognitive functions of healthy persons. The blood concentration profiles of volunteers corresponded well with those in rats.

On the basis of the results obtained, it was decided that 7-MEOTA would be studied in more detail including preclinical testing. The first and second phases of clinical testing on healthy volunteers were performed. It was found that 7-MEOTA is well tolerated after peroral or intramuscular administration (dose 2 mg/kg, p.o. and 1 mg/kg, i.m.) (Filip *et al.*, 1991). Clinical testing of this drug was performed on patients with tardive dyskinesias occurring after lengthy administration of neuroleptics with good therapeutic efficacy (Zapletalek *et al.*, 1989). As a result, it was introduced in the form of tablets (7-MEOTA, 100 mg)

and injections (50 mg in 2 ml) to the Czech Army as an antidote against psychotomimetic agents.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

BZ was recognized as an incapacitant agent for military use. It was stockpiled and stored as CWA by the US Army but their stocks were destroyed in 1992. The use of this agent is not excluded. Its mechanism of action is based on the interaction with cholinergic receptors. The symptomatology is characterized by peripheral action (vegetative symptoms) and central symptomatology including hallucinations. The antidotes and effective antidotal therapy are of vital interest and are possible using commonly available physostigmine or 7-MEOTA, respectively. The use of BZ in the research of the cholinergic nervous system cannot be omitted.

CHAPTER 11

Onchidal and Fasciculins

ARTURO ANADÓN, MARIA ROSA MARTÍNEZ-LARRAÑAGA, AND LUIS G. VALERIO, JR.

This research report is not an official US Food and Drug Administration guidance or policy statement. No official support or endorsement by the US Food and Drug Administration is intended or should be inferred.

I. INTRODUCTION

Onchidal and fasciculins are natural toxins, which produce their toxicity in mammalian systems by virtue of primarily acetylcholinesterase (AChE) inhibition. AChE hydrolyzes and inactivates acetylcholine, thereby regulating the concentration of the transmitter at the synapse. Termination of activation is normally dependent on dissociation of acetylcholine from the receptor and its subsequent diffusion and hydrolysis, except in diseases where acetylcholine levels are limiting or under AChE inhibition, conditions that increase the duration of receptor activation (Silver, 1963).

The toxins that inhibit the AChE are called anticholinesterase (anti-ChE) agents. They cause acetylcholine to accumulate in the vicinity of cholinergic nerve terminals, and thus are potentially capable of producing effects equivalent to excessive stimulation of cholinergic receptors throughout the central and peripheral nervous systems (Long, 1963). Nevertheless, several members of this class of compounds are widely used as therapeutics agents; others that cross the blood–brain barrier have been approved or are in clinical trial for the treatment of Alzheimer's disease.

The AChE can be classified in several ways. Mechanistically, it is a serine hydrolase. Its catalytic site contains a catalytic triad – serine, histidine, and an acidic residue – as do the catalytic sites of the serine proteases such as trypsin, several blood clotting factors, and others. However, the acidic group in AChE is a glutamate, whereas in most other cases it is an aspartate residue. The nucleophilic nature of the carboxylate is transferred through the imidazole ring of histidine to the hydroxyl group of serine, allowing it to displace the choline moiety from the substrate, forming an acetyl-enzyme intermediate. A subsequent hydrolysis step frees the acetate group. Understanding of the catalytic properties of the protein has assisted in our understanding of its inhibition by organophosphate and carbamate inhibitors. However, several questions remain to be answered regarding AChE catalysis; for example, the mechanism behind the extremely fast turnover rate of the enzyme (Fair *et al.*, 1994). Despite the fact that the substrate has to navigate a relatively long distance to reach the active site, AChE is one of the fastest enzymes (Nair *et al.*, 1994). One theory to explain this phenomenon has to do with the unusually strong electric field of AChE. It has been argued that this field assists catalysis by attracting the cationic substrate and expelling the anionic acetate product (Ripoll *et al.*, 1993). Site-directed mutagenesis, however, has indicated that reducing the electric field has no effect on catalysis. However, the same approach has indicated an effect on the rate of association of fasciculin, a peptide that can inhibit AChE (Schafferman *et al.*, 1994).

Naturally occurring irreversible inhibitors of AChE are toxins which are often selective inhibitors of protein function, and this property can often be exploited for a variety of purposes (Pita *et al.*, 2003). For instance, physostigmine, also called eserine, is a naturally occurring alkaloid inhibitor of AChE that has been used in understanding the kinetic mechanism of AChE.

II. BACKGROUND

This chapter covers natural agents that prolong the existence of acetylcholine after it is released from cholinergic nerve terminals. Natural toxins are chemical agents of biological origin including chemical agents and proteins, and can be produced by all types of organisms; such is the case of onchidal and fasciculins. Although a chemical and a protein, respectively, onchidal and fasciculins share the same toxic effect of inhibiting AChE, which is concentrated in synaptic regions and is responsible for the rapid catalysis of the hydrolysis of acetylcholine. As such, the natural toxins onchidal and fasciculins can produce disorders of neuromuscular transmission clinically categorized as either pre- or post-synaptic; some toxins simultaneously affect both sites. Chemical agents associated with neuromuscular transmission syndromes include the fasciculins, crotoxin, taipoxin, tubocurarine, organophosphorus compounds, and others (Anadón and Martínez-Larrañaga, 1985).

These aforementioned natural anti-ChE agents can be developed for a different utility including the extensive application as toxic agents (i.e. potential chemical warfare).

One of the first interesting structures with cholinergic properties isolated from a marine source is the chemical onchidal. This compound was first isolated from the mollusc *Onchidella binneyi* and has an acetate ester similar to acetylcholine. Upon isolation, onchidal was discovered to be an active site-directed irreversible inhibitor of AChE (Abramson *et al.*, 1989).

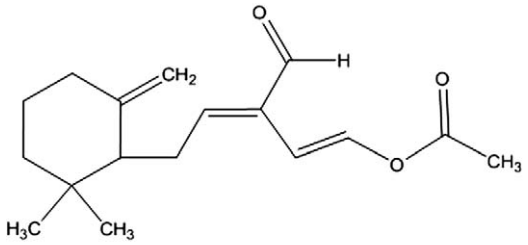
Neurotoxins from snake venoms have proved to be valuable tools for the understanding of synaptic transmission mechanisms. Likewise, the powerful inhibitory action of fasciculins against mammalian AChE makes them potentially useful tools for pharmacological and neurochemical research. Studies of their biochemical and electrophysiological effects on the central nervous system and biochemical characterization are now being carried out.

Natural toxins can be extremely potent and many of them are effective at far lower dosages compared to conventional chemical agents. Natural toxins, as compounds of biological origin, are often classed as biological agents, but they are not infectious and are more similar to chemicals with respect to their military potential for tactical use; therefore, they should be considered to be chemical agents. The Chemical Weapons Convention (2003) (available at: www.fas.harvard.edu/~hsp/cwc/cwcbyart.html) also includes natural toxins as chemical agents, and, specifically, includes the onchidal and fasciculins toxins in its control regime along with other highly toxic chemicals.

A. Onchidal

Onchidal is a toxic component of a certain poisonous marine opisthobranch mollusc. Like other opisthobranchs, the Onchidiacea family of molluscs does not have the protection of a hard external shell as do most molluscs. They rely instead on the production of a defensive secretion. When the animal is disturbed it secretes a viscous fluid from specialized glands. In two species of Onchidella (*Onchidella floridanun* and *Onchidella borealis*), this defensive secretion has been shown to act as a deterrent to potential predators, including fish and crabs. Chemically, it is a simple lipophilic acetate ester (see Figure 11.1).

Onchidal has been identified as the major lipid-soluble component of the defensive secretion of *Onchodella binneyi* and it has been proposed as the compound responsible for the chemical protection of *Onchidella*. *Onchodella binneyi* is an opisthobranch mollusc which inhabits the rocky intertidal zone near the area of Baja California, Mexico. The defensive secretion was obtained in the field by squeezing the mollusc and collecting the mucus discharge in capillary tubes. Large quantities of this material could be obtained after extraction of intact animals with acetone (Ireland and Faulkner, 1978). However, the distribution of onchidal in different species of *Onchidella* was not reported and, apart from inhibiting the growth of *Staphylococcus aureus* (MIC value was between 0.21 and 0.63 μg/ml), implying that onchidal is a potent inhibitor of Gram-positive



Onchidal

FIGURE 11.1. Chemical structure of onchidal.

microorganisms, no biological activity of onchidal was described. Additional studies demonstrated that onchidal is contained in several different species of *Onchidella* and that, once purified, is toxic to fish (Abramson *et al.*, 1989). Onchidal can be found in four of the eight known species of *Onchidella* collected from different countries (Table 11.1). In addition, the Abramson study found onchidal to be toxic to goldfish. Although goldfish are not potential predators of *Onchidella*, these results demonstrate that onchidal has a distribution and a biological activity consistent with its proposed role in the chemical defense of *Onchidella*.

B. Fasciculins

Mamba snake venom (*Dendroaspis angusticeps*, *polylepis*, *viridis*, *jamesoni*) contains a mixture of neurotoxic compounds including post-synaptic cholinoreceptor α-neurotoxins, dendrotoxins, fasciculins, and muscarinic toxins (Hawgood and Bon, 1991). Effects at the neuromuscular junction include AChE inhibition by fasciculins, and increased presynaptic release of acetylcholine by dendrotoxins (polypeptides which facilitate acetylcholine release in response to nerve stimulation); together with the high acetylcholine content of mamba toxin (6–24 mg/g), these effects are synergistic and enhance neurotoxicity and lethality. Moreover, the venom may contain other components having a synergistic action with dendrotoxin.

Toxins that facilitate neuromuscular transmission are a characteristic component of mamba venom. The four known fasciculins bind to a peripheral regulatory anionic site of AChE in a noncompetitive and irreversible manner

TABLE 11.1. Concentration of onchidal in different species of *Onchidella* (Abramson *et al.*, 1989)

Organism	Collection site	Onchidal concentration (μg/animal)
O. binneyi	Baja California, Mexico	230
O. borealis	Central California, USA	33
O. nigricans	New Zealand	18
O. patelloides	Australia	42

(Hawgood and Bon, 1991). The dendrotoxins comprise the second group of facilitatory neurotoxins and are present in most mamba venoms (with the exception of *Dendroaspis jamesoni*); they inhibit voltage-dependent K^+ channels in motor nerve terminals and facilitate acetylcholine release at the neuromuscular junction. Post-synaptic toxins present in mamba venom bind to and block nicotinic acetylcholine receptors. The muscarinic toxins present in mamba venom are small (7 kDa) proteins that selectively bind to muscarinic cholinergic receptors and may constitute up to 1% of the venom protein (Adem and Karlsson, 1985; Jerusalinsky and Harvey, 1994). About 12 muscarinic toxins have been isolated. M1 toxin binds noncompetitively and with high affinity to the M_1 muscarinic receptor sybtype. MTx1 and MTx2 show high affinity for both muscarinic M_1 and M_3 receptors; little is known about the receptor selectivity of MTx3 and MTx4. Dpα and Dpβ are also muscarinic agonists displaying similar affinity for both the M_1 and M_2 receptor subtypes. The last two agonists, DpMTx and DvMTX, are selective muscarinic agonists present in the venom of some mamba species; these agonists also show affinity for the M_1 muscarinic receptor subtype.

The fasciculins are a family of closely related ~6,750 Da peptides isolated from the venom of mambas (genus *Dendroaspis*), and are named after the long-lasting muscle fasciculations they produce in mice (Rodriguez-Ithurralde *et al.*, 1983). They are potent and selective inhibitors of AChE. Fasciculins (Fas) are 61 residue long polypeptides. They share a three-looped structural motif with other toxins, such as α-neurotoxins, cytotoxins, and muscarinic toxins, directed to diverse specific tagets. Four fasciculins are known (Table 11.2) which differ only by one to three residues and show selective and potent anti-AChE activity: Fas1 and Fas2 from the venom of *Dendroaspis angusticeps* (eastern green mamba) contains 61 amino acid residues including eight half-cystines (Rodriguez-Ithurralde *et al.*, 1983), ToxC from the venom of *D. polylepis polylepis* (black mamba) (Joubert and Taljaard, 1978), and Fas3, which was isolated from a particular batch of *D. viridis* (western green mamba) venom and found to have the same primary structure as ToxC (Marchot *et al.*, 1993). No fasciculin has been found in other *D. viridis* venoms (Marchot *et al.*, 1993), or in *D. jamesonii* (Jameson's mamba).

TABLE 11.2. Types of fasciculin identified

Fasciculins characterized	**From the mamba snake venoms (Elapidae family) (*Dendroaspis* genus)**
Fasciculin 1	*Dendroaspis angusticeps* (green mamba)
Fasciculin 2 (formally F_7 toxin)	*Dendroaspis angusticeps* (green mamba)
Fasciculin 3 (formally toxin C)	*Dendroaspis polylepis* (black mamba)
Fasciculin 4	*Dendroaspis viridis* (western green mamba)

Angusticeps-type toxins constitute a group of toxins typical for mamba venoms. They consist of 59–61 amino acid residues and four disulfides, and show sequence homology with short-chain post-synaptic toxins and cardiotoxins, but they are immunochemically distinct from these toxins. Eight toxins of this type have been sequenced and structurally classified into four subgroups (Joubert and Taljaard, 1978). Pharmacological studies on these *angusticeps*-type toxins have revealed that only toxins F_7 and C, which belong to subgroup I, exhibit a potent inhibition of cholinesterase of various tissues, except for that of chick skeletal muscle. Both F_7 and C stimulate mouse and toad skeletal muscles by their anticholinesterase activity, as well as possibly by facilitating acetylcholine release from nerve terminals (Lee *et al.*, 1985). Fasciculins account for 3–6% of the venom protein and the relative proportion between fasciculin 1 and 2 is about 1/3 (Cerveñanský *et al.*, 1994).

The structural similarity between onchidal (an acetate ester) and acetylcholine suggested that the toxicity of onchidal could result from inhibition of either nicotinic acetylcholine receptors or AChE. Although onchidal (1.0 mM) did not prevent the binding of ^{125}I-α-bungarotoxin to nicotine acetylcholine receptors, it inhibited AChE in a progressive, apparently irreversible, manner. The apparent affinity of onchidal for the initial reversible binding to AChE (K_d) was approximately 300 µM, and the apparent rate constant for the subsequent irreversible inhibition of enzyme activity (K_{inact}) was approximately 0.1 min^{-1}.

The fasciculins are a family of closely related peptides that are isolated from the venom of mambas and exert their toxic action by inhibiting AChE. The crystal structure of fasciculin 2 from green mamba (*Dendroaspis angusticeps*) snake venom was first resolved in 1992 (Le Du *et al.*, 1992). The three-dimensional (3D) structure of fasciculin 1 obtained from the US National Library of Medicine, National Center for Biotechnology Information, MMDB database is illustrated in Figure 11.2.

Fasciculins belong to the structural family of three-fingered toxins from Elapidae snake venoms, which include the α-neurotoxins that block the nicotinic acetylcholine receptor and the cardiotoxins that interact with cell membranes. The features unique to the known primary and tertiary structures of the fasciculin molecule were analyzed by Harald and associates (1995). Loop I contains an arginine at position 11, which is found only in the fasciculins and could form a pivotal anchoring point to AChE. Loop II contains five cationic residues near its tip, which are partly charge compensated by anionic side chains in loop III. By contrast, the other three fingered toxins show full charge compensation within loop II. The interaction of fasciculin with the recognition site on acetylcholinesterase was investigated by estimating a precollision orientation followed by determination of the buried surface area of the most probable complexes formed, the electrostatic field

[Image obtained from the public domain at the US National Library of Medicine, National Center for Biotechnology Information, Molecular Modeling Database 3D Structure Database (MMDB)].

contours, and the detailed topography of the interaction surface. This approach has led to testable models for the orientation and site of bound fasciculin.

III. MECHANISM OF ACTION AND BIOLOGICAL EFFECTS

A. Onchidal

Onchidal is an irreversible inhibitor of enzyme AChE with a novel mechanism of action. It has been suggested, however, that its toxicity could be a consequence of the inhibition of either nicotinic acetylcholine receptor or AChE enzyme.

Incubation of AChE with onchidal resulted in the production of acetate, demonstrating that onchidal was a substrate for AChE, and approximately 3250 mol of onchidal was hydrolyzed/mol of enzyme irreversibly inhibited. Organophosphate and carbamate inhibitors of AChE have partition ratios (mol of toxin hydrolyzed/mol of enzyme irreversibly inhibited) that approach unity. Therefore, the relatively high partition ratio for onchidal suggests that the mechanism of inhibition utilized by onchidal may be distinctly different from other irreversible inhibitors (Walsh, 1984). The rate of hydrolysis of onchidal (K_{cat}) was 325 min^{-1}; this value is relatively slow suggesting that onchidal is not a very good substrate. The ability of AChE to hydrolyze onchidal raised the question of whether inhibition of enzyme activity resulted from onchidal itself or from a product of the enzymatic hydrolysis of onchidal. Enzyme kinetics revealed that onchidal was unable to completely inhibit higher concentrations of AChE. From the experiments performed by Abramson *et al.* (1989), onchidal was in molar excess and was completely hydrolyzed. Thus, irreversible inhibition of enzyme activity resulted either from onchidal itself or from a reactive intermediate produced during hydrolysis of onchidal (Walsh, 1984).

In another investigation, irreversible inhibition of enzyme activity was prevented by coincubation with reversible agents that either sterically block (edrophonium and decamethonium) or allosterically modify (propidium) the acetylcholine site (Barnett and Rosenberry, 1977). Enzyme activity was not regenerated by incubation with oxime reactivators; therefore, the mechanism of irreversible inhibition does not appear to involve acylation of the active site serine.

Because onchidal is an acetate ester similar to acetylcholine and because cholinergic neurotransmission is often the site of action of natural products involved in chemical defense, Abramson *et al.* (1989) investigated the ability of onchidal to inhibit AChE and the nicotinic acetylcholine receptor. Although onchidal did not prevent the binding of ^{125}I-α-bungarotoxin to nicotinic acetylcholine receptors, it was shown to be an active site-directed irreversible inhibitor of AChE. The structure and pharmacology of onchidal suggest that inhibition of AChE results from a novel covalent reaction between onchidal and an amino acid within the acetylcholine binding site. The onchidal could potentially be exploited in the design of a new class of natural anti-ChE agents and in the identification of amino acids that contribute to the binding and hydrolysis of acetylcholine.

B. Fasciculins

Various toxins in snake venoms exhibit a high degree of specificity in the cholinergic nervous system. The α-neurotoxins from the Elapidae family interact with the agonist binding site on the nicotinic receptor. α-Bungarotoxin is selective for the muscle receptor and interacts with only certain neuronal receptors, such as those containing α7 through α9 subunits. Neuronal bungarotoxin shows a wider range of inhibition of neuronal receptors. A second group of toxins, called the *fasciculins*, inhibits AChE. A third group of toxins, termed the muscarinic toxins (MT_1 through MT_4), are partial agonists and antagonists for the muscarinic receptor. Venoms from the Viperaridae family of snakes and the fish-hunting cone snails also have relatively selective toxins for nicotinic receptors.

Other reversible inhibitors, such as propidium and the peptide toxin fasciculin, bind to the peripheral anionic site on AChE. This site resides at the lip of the gorge and is defined by tryptophan 286 and tyrosines 72 and 124 (Taylor, 2001).

A large number of organic compounds reversibly or irreversibly inhibit AChE (Long, 1963), which bind either to the esteratic or the anionic subsite of AChE catalytic site or to the peripheral site of the enzyme. Most of them are synthetic substances, sometimes bearing insecticidal properties. Few natural inhibitors of AChE are known and, to date, fasciculins are the only known proteinic AChE

inhibitors and they have been shown to display a powerful inhibitory activity toward mammalian AChE. Iodination of fasciculin 3 provided a fully active specific probe of fasciculin binding sites on rat brain AChE (Marchot *et al.*, 1993). These authors demonstrate that fasciculins bind on a peripheral site of AChE, distinct from the catalytic site, and, at least partly, common with the sites on which some cationic inhibitors and the substrate in excess bind, since phosphorylation of the catalytic serine (esteratic subsite) by [1,3-^{3}H]diisopropyl fluorophosphate can still occur on the fasciculin 3. In the AChE complex, the structural modification induced by fasciculins may affect the anionic subsite of the AChE catalytic site.

Cholinesterases have a very different sensitivity towards fasciculins. AChEs from rat brain, human erythrocytes, and electroplax of electric eel (*Electrophorus electricus*) are inhibited by fasciculins with a K_i of about 10^{-11} M and pseudocholinesterases as human serum cholinesterase are inhibited by fasciculins with a K_i of about 0.5 μM. A second group of enzymes is partially (10–30%) inhibited by low concentrations (<0.5 nM) of fasciculin. Increasing the concentration of fasciculins to a toxic level of about 1 nM inactivates the enzymes to 90–110% of their initial activity. AChEs from guinea pig ileum, ventricle, and uterus behave similarly. A third group consists of enzymes insensitive to fasciculin; AChEs from chick biventer cervicis muscle and brain and from insects, heads of *Musca domestica* (common house fly), and cobra (*Naja naja*) venom. The biochemical mechanism of fasciculins involves displacement of propidium from its binding site on AChE. Since propidium is a probe from a peripheral anionic site, it is concluded that fasciculins also bind to the same site. The different sensitivity of cholinesterase to fasciculin should depend on the nature of their peripheral sites. Fasciculins are basic proteins of 61 amino acid residues and four disulfides, highly homologous to short α-neurotoxins and cardiotoxins. Indeed, a large number of AChE inhibitors are cations, e.g. neostigmine, physostigmine, and propidium.

The binding between fasciculin and AChE is strong, as indicated by a K_i of about 10^{-11} M. This should result from interaction of several amino acid residues in the toxin with the enzyme. A modification of one of these residues should not abolish but significantly decrease the activity. But the decrease in activity can also depend on structural perturbations caused by the modification. Chemical modification and structural data suggest that Lys 32 and 51 have a functional role (Cerveñanský *et al.*, 1994). This author acetylated the amino groups of fasciculin 2 with acetic anhydride. The monoacetyl derivatives of the ε-amino acids (Lys 25, 32, 51, and 58) retained between 28 and 43% of the initial activity and that of the α-amino group 72%. Acetylation of Lys 25 that has the most reactive amino group decreased the activity by 65% apparently without producing structural perturbation since the circular dichroism spectrum was not affected. The three-dimensional structure shows a cationic cluster formed by Lys 32, 51, Arg 24 and 28. A comparison of 175 sequences of homologous toxins shows that Lys 32 is unique for fasciculin. Acetylation of lysine residues in the cluster had a large effect and reduced the activity by 72% (Lys 32) and 57% (Lys 51).

Fasciculins inhibit AChE from mammals, electric fish, and some snake venoms with *K*i values in the pico- to nanomolar range; in contrast, avian, insect, and some other snake venom AChEs are relatively resistant, and high micromolar concentrations are required to inhibit mammalian butyrylcholinesterases (BuChE) (Marchot *et al.*, 1993). Dissociation constants of Fas1 and Fas3 are two-fold and 60-fold lower, respectively, than that of Fas2 for synaptosomal rat brain.

An examination of fasciculin association with several mutant forms of recombinant DNA-derivated AChE from mouse shows that it interacts with a cluster of residues near the rim of the gorge on the enzymes; the aromatic residues, Trp 286, Tyr 72, and Tyr 124, have the most marked influence on fasciculin binding, whereas Asp 74, a charged residue in the vicinity of the binding site that affects the binding of low molecular weight inhibitors, has little influence on fasciculin binding. The three aromatic residues are unique to the susceptible AChE and, along with Asp 74, constitute part of the peripheral anionic site. Fasciculin falls in the family of three-loop toxins that include the receptor blocking α-toxins and cardiotoxins. A binding site has evolved on fasciculin to be highly specific for the peripheral site on AChE. Acetylthiocholine affects rates of fasciculin binding at concentrations causing substrate inhibition. In the case of the mutant cholinesterase where rates of fasciculin dissociation are more rapid, steady state kinetic parameters also show ACh–fasciculin competition to be consistent with occupation at a peripheral or substrate inhibition site rather than the active center (Radic *et al.*, 1994).

Fasciculin inhibition of AChE is prevented by chemical modification of the enzyme at a peripheral site (Durán *et al.*, 1994). The specific interaction of fasciculin 2 with peripheral sites present in *Electrophorus electricus* AChE (K_i, 0.04 nM fasciculin) was investigated by chemical modification with *N*,*N*-dimethyl-2-phenylaziridium (DPA) in the presence of active or peripheral anionic site protective agents. An enzyme was obtained that compared to the native AChE and was 10^6 times less sensitive to fasciculin 2. This enzyme was fully inhibited by edrophonium and tacrine, and was 25–170 times less sensitive to several peripheral site ligands. It seems fasciculin 2 binding to an AChE peripheral site partially overlaps the site of other peripheral site ligands including acetylcholine.

IV. EXPERIMENTAL AND HUMAN TOXICITY

Administration of fasciculin 1 and fasciculin 2 to mice at doses of 1–3 mg/kg and 0.05–2.0 mg/kg, respectively, after

i.p. injection caused severe, generalized, and long-lasting fasciculations (5–7 h) followed by gradual recovery to normal behavior. *In vitro* preincubation with fasciculins at concentrations of 0.01 μg/ml inhibited brain and muscle AChE up to 80%. Histochemical assay for AChE showed an almost complete disappearance of the black–brown precipitate at the neuromuscular endplate after *in vitro* incubation with fasciculins. Fasciculins represent a new type of AChE inhibitors exerting muscle fasciculations through a powerful inhibition of enzyme activity at the neuromuscular endplate, interfering with the normal hydrolysis of ACh molecules. Fasciculins have also been demonstrated to be powerful inhibitors of brain AChE (Rodriguez-Ithurralde *et al.*, 1983).

The cause of death due to toxin F_7, an *angusticeps*-type toxin, isolated from the venom of *Dendroaspis angusticeps* was studied in anesthetized mice (Lee *et al.*, 1986). The carotid arterial blood pressure, ECG, and the respiratory movements were recorded. Within a few minutes after i.v. injection of toxin F_7 (1 mg/kg), both the rate and amplitude of the respiratory movements decreased and respiratory arrest took place within 15 min in most cases. Before respiratory arrest, marked bradycardia with various types of arrhythmia and oscillation of blood pressure were observed. Artificial ventilation could abolish these cardiovascular changes and maintain the blood pressure for a long period. Toxin F_7 caused a transient and slight increase of arterial blood pressure which could be prevented by hexamethonium. Intracisternal application of toxin F_7 (1 mg/kg) caused a long-lasting hypertension and bradycardia and the respiratory arrest time was significantly longer than after i.v. injection. A large dose (50 mg/kg, i.p.) of atropine, but not smaller doses (5–10 mg/kg), protected mice against respiratory failure induced by toxin F_7.

In rats, the phrenic nerve discharge was prolonged during respiratory depression. Since the toxin F_7 has a potent anti-ChE activity, it is concluded that the respiratory failure induced by toxin F_7 is peripheral in origin, chiefly, if not entirely, due to its anticholinesterase activity.

Strydom (1976) performed the purification of *Dendroaspis polylepis polylepis* (black mamba) venom, and found 12 low molecular weight proteins, of which 11 have subcutaneous LD_{50} values of less than 40 μg/g mouse.

Clinically, mamba bites may not provoke a major local reaction. If neurotoxins are injected by the bite, clinical symptoms appear within minutes to hours. Clinical signs of impairment of neuromuscular transmission (ptosis, ophthalmoplegia, bulbar symptoms, or generalized weakness) dictate administration of antivenom (Ludolfph, 2000). For Elapidae (coral snakes) venom is known that is a potential neurotoxin and may cause paresthesias, weakness, cranial nerve dysfunction, confusion, fasciculations, and lethargy. Often mild local findings, diplopia, ptosis, and dysarthria are common early symptoms. Patients die because of respiratory paralysis. In these cases, early and aggressive airway management is vital. Symptoms may be delayed by 8 to 12 h (Cameron, 2006).

V. RISK ASSESSMENT

Toxicity databases and computer-assisted computational predictive toxicology modeling are now becoming of increasing importance to risk assessors when risk assessment of a chemical using experimental animal toxicological studies is unclear because the data are equivocal or even absent (Benz, 2007). Furthermore, the European Community has passed a law called REACH (Registration, Evaluation, Authorization, and restriction of Chemicals), which entered into force on June 1, 2007, to identify and more effectively avoid the risks of the toxic properties of chemicals to humans and the environment (Lahl and Gundert-Remy, 2008). Under the REACH regulation, manufacturers or importers to the European Community with more than 1 ton of a chemical substance per year are required to assess the chemical's potential toxicological or environmental adverse effects, and to register this information in a central database (Saiakhov and Klopman, 2008). The REACH regulation has impact on the widespread use of computational predictive modeling because it rules that no animal test should be used if it can be replaced with other techniques such as reliable computer-based predictions (Lahl and Gundert-Remy, 2008; Saiakhov and Klopman, 2008). Therefore, the use of computer-assisted computational predictive toxicology software has arrived at a point of considerable attention worldwide because it may not only reduce, but eliminate the need for animal testing under certain circumstances. Since the acute and chronic toxic potential of onchidal in experimental animal studies is rather limited, strategies using *in silico* assessment of its toxic potential could be envisioned. Computational-based strategies with pharmaceuticals and natural product toxins have already been developed for use in safety evaluation and risk assessment practices at US government agencies (Benz, 2007; Valerio *et al.*, 2007; Arvidson *et al.*, 2008; Matthews *et al.*, 2008; Demchuk *et al.*, 2008; Bailey *et al.*, 2005; Contrera *et al.*, 2005). These strategies can be considered for an *in silico* risk assessment of onchidal. One approach is to combine different predictive models for the same toxicological endpoint to determine if a consensus prediction regarding the effect is possible (Matthews *et al.*, 2008). Another approach is to combine computational software that employs human rule-based approaches with software that utilize statistical algorithm-based predictions using QSAR models for the toxic potential of the compound of interest (Arvidson *et al.*, 2008). A variety of computational toxicology predictive software and data mining databases are available at no cost, commercially, or through non-profit organizations (Richard *et al.*, 2008; Marchant *et al.*, 2008; Yang *et al.*, 2008; Saiakhov and Klopman, 2008; Shi *et al.*, 2008). The information obtained from a predictive and data mining *in silico* assessment can be used judiciously as

a decision support tool in risk assessment and management regarding the safety of an organic chemical (Arvidson *et al.*, 2008; Matthews *et al.*, 2008).

In order to assess the potential toxicological effects of onchidal from a predictive standpoint, the author subjected the molecular structure of onchidal to an *in silico* computational analysis using a human rule-based software known as Derek for Windows (Deductive Estimation of Risk from Existing Knowledge; DfW), and a high-throughput *in silico* quantitative structure activity relationship (QSAR) screening software called MDL-QSAR that uses a statistical-based algorithm called discriminant analysis with validated models for genetic toxicity and rodent carcinogenicity (Contrera *et al.*, 2008). Details regarding the approaches of these software programs and the *in silico* screening procedures and methods have been well described previously (Marchant *et al.*, 2008; Matthews *et al.*, 2008; Contrera *et al.*, 2003, 2005, 2008). By employing these two different software programs with the molecular structure of onchidal, our *in silico* analysis produced predictive information pertinent to when conditions of potential acute and chronic human exposure are encountered (Table 11.3).

The results summarized in Table 11.3 show that the software DfW identified the α,β-unsaturated aldehyde moiety on onchidal as a structural alert and predicted this reactive center of the molecule to possess bacterial (*Salmonella typhimurium*) mutagenic potential at the reasoning level the software defines as ''plausible''. Plausible is an uncertainty term in the software's reasoning tree and is defined as ''The weight of evidence supports the proposition'' (Marchant *et al.*, 2008). The prediction of mutagenicity for the α,β-unsaturated aldehyde moiety on onchidal is consistent with a large body of scientific literature demonstrating the experimental mutagenicity of small organic molecules that have α,β-unsaturated aldehydic groups (Petersen and Doorn, 2004; Eckl, 2003; Burcham, 1998). In addition to the α,β-unsaturated aldehyde, DfW also identified the enol ether portion of onchidal's structure as a basis for a ''plausible'' prediction for dermal sensitization according to the rules of the software's computational-based reasoning. Both the mutagenicity and sensitization predictions arise as a consequence of the presence of alerts (alerts #302 for mutagenicity, #425 and #479 for dermal contact sensitization) in the onchidal query. In essence, these alerts describe the relationship between the chemical functionality and the occurrence of mutagenicity and dermal contact dermatitis. The software provides supporting evidence for the alert as well as a selected compound known to exhibit the toxic endpoint. An illustration of the DfW prediction for onchidal is shown in Figure 11.3. Given the potential for the chemical warfare application of onchidal, the information obtained from the DfW *in silico* predictive toxicological assessment seems to be useful if such an application of acute widespread human exposure would be encountered. Therefore, onchidal could be considered as a potential sensitizer for both Type I hypersensitivity and Type IV allergic contact dermatitis. Since many sensitizers are also dermal contact irritants, then another potential human health hazard that may be deduced for onchidal is irritant contact dermatitis. Clearly, under long-term exposure conditions the potential for mutagenic DNA damaging effects would be of concern. However, adverse effects from onchidal as a result of its ACE inhibition would likely supersede the period of time to the ensuing tissue injury produced as a result of DNA damaging effects.

MDL-QSAR *in silico* predictive screening for the mutagenic and carcinogenic potential of onchidal is presented in Table 11.3. The software classified onchidal to be of low mutagenic potential in bacteria, but classified the compound as high for potential to be a rodent carcinogen. MDL-QSAR utilizes a statistical algorithm-based approached called discriminant analysis that classifies a compound by determining the probability that the compound will fall into a membership class of either high or low for the toxic endpoint being predicted. In this case, it is predicted that onchidal be of low bacterial mutagenic potential in *Salmonella typhimurium* and of high rodent (rats and mice, male and female) carcinogenic potential with a high degree of confidence (probability for membership in class >85%). An illustration of MDL-QSAR's prediction for onchidal is given in Figure 11.4. Although the prediction of mutagenicity conflicts with DfW, the information is still useful from a risk assessment standpoint because a risk assessor will likely have additional information such as an estimate of exposure and route of exposure conditions as well as potential experimental studies that may ''weigh in'' during the overall analysis of human health risk.

TABLE 11.3. Summary of *in silico* predictive toxicological evaluations of onchidal by Derek for Windows and MDL-QSAR

Computational toxicology software	Prediction for onchidal
Derek for Windows	Mutagenicity – plausible Alert 302: α,β-unsaturated aldehyde Skin sensitization – plausible Alert 425: Enol ether Alert 479: α,β-unsaturated aldehyde
MDL-QSAR	Classified as low potential for rodent mutation *in vivo* Classified as high potential for rodent carcinogenicity High probability 0.8677 Low probability 0.1322

The computational toxicology software programs and models were obtained by FDA/CDER/ICSAS through cooperative research and development agreements with MDL Information Systems and Lhasa Ltd (Benz, 2007)

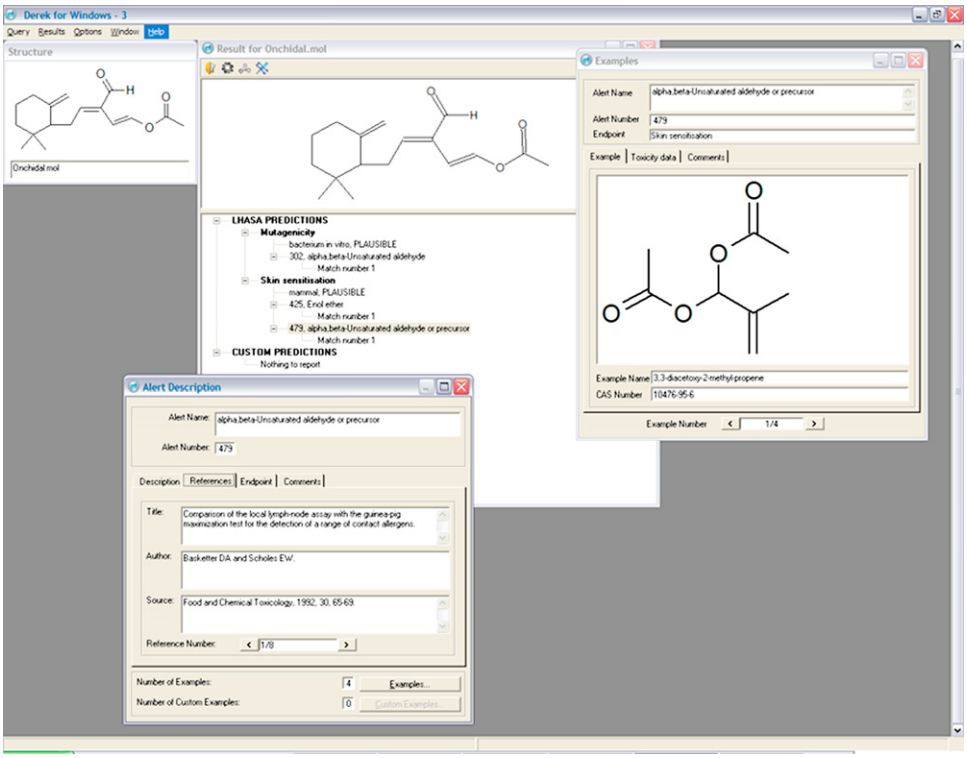


FIGURE 11.3. The Derek for Windows version 10.0.2 (DfW) prediction for onchidal under default processing contraints.

Overall, these computational toxicology models and many others developed at the US Food and Drug Administration, Center for Drug Evaluation and Research, Informatics and Computational Safety Analysis Staff (ICSAS) can predict with considerable precision the toxicological and adverse human effects of many classes of organic substances (Benz, 2007). Further information about ICSAS, including program activities, can be found at the FDA ICSAS internet website (http://www.fda.gov/cder/Offices/OPS_IO/default.htm).

VI. TREATMENT

Antidotal therapy of the toxic effects of cholinesterase inhibitors such as onchidal and fasciculins used as potential chemical warfare agents is directed to blocking the effects of excessive acetylcholine stimulation and reactivating the inhibited enzyme. Atropine in sufficient dosage effectively antagonizes the actions at muscarinic receptor sites (Taylor, 2001). Atropine is used in adults at doses of 1–2 mg i.v. and in pediatrics at a dose of 0.05 mg/kg i.v.; doubling this dose every 5 min (DeLisle, 2006). Larger doses are required to get appreciable concentrations of atropine into the CNS. Atropine is virtually without effect against the peripheral neuromuscular compromise. The last-mentioned action of the anti-ChE agents as well as all other peripheral effects can be probably reversed by reactivators of cholinesterase such as pralidoxime (2-PAM) in the treatment of onchidal and fasciculins poisonings. Usual dosages are as follows: in adults 1–2 g i.v. over 15–30 min, may repeat in 1 h if necessary or start a drip at 500 mg/h; in pediatrics, 25 mg/kg i.v. over 15–30 min, follow with continuous infusion of 10–20 mg/kg i.v. (DeLisle, 2006). On the other hand, the antivenom is indicated for all confirmed eastern coral snake bites (western, no antivenom) (Cameron, 2006).

VII. CONCLUDING REMARKS AND FUTURE DIRECTION

The natural toxins onchidal and fasciculins behave as anti-ChE agents. Onchidal is an active site-directed irreversible inhibitor of AChE, and fasciculins are proteinic AChE inhibitors which bind to a peripheral regulatory anionic site of AChE in a noncompetitive and irreversible manner.

There is limited information about the toxicity, toxicokinetics, and toxicological properties of onchidal and additional data are needed to make a health effects-based risk assessment of the natural compound. Although fasciculins are much better known, data on toxicological properties and toxicokinetics will be of interest and useful for risk assessments despite it being generally accepted that the toxicity of this proteinic toxin occurs at very low doses.

Onchidal and fasciculins are interesting natural compounds and it is difficult to predict their toxicity. In the case of onchidal, *in silico* computational predictive modeling for toxic endpoints of interest may prove useful for risk assessment decision support. Likewise, it is a challenge to predict the military potential and human impact of these natural toxins since their affinity for enzyme inhibition depends upon the amount and duration of the human exposure.

CHAPTER 12

Riot Control Agents

COREY J. HILMAS, MELISSA J. POOLE, ALEXANDRE M. KATOS, AND PATRICK T. WILLIAMS

I. INTRODUCTION

Nonlethal agents are a broad class of compounds intended to produce transient incapacitation of an individual or individuals. Both incapacitating agents and riot control agents (RCA) are separate classes of nonlethal agents. Although the two classes share the characteristic to incapacitate, a distinction must be drawn between these two types of agents. RCAs differ from incapacitating agents in several respects. RCAs possess a relatively short onset and limited duration of action. RCAs induce short-term toxic effects that subside within minutes following termination of the exposure. Additionally, modern RCAs have a very high safety ratio compared to incapacitating agents and first generation RCAs. Many incapacitating agents were developed during the Cold War which produced either limited lethality and/or prolonged morbidity. Consequently, incapacitating agents have been banned by international treaties recognized by the USA, including the Chemical Weapons Convention (CWC). Specifically, the CWC has placed a ban on the development, production, and possession of any chemical weapon intended to cause death or ''temporary incapacitation''. The USA considers these broad incapacitating agents as chemical warfare agents (CWAs). However, the USA does not recognize RCAs as CWAs, and therefore, US policy considers them to be legal for use by civilian police or the military. The CWC does prohibit their use in times of war. Thus, the USA has opted not to utilize RCAs in Iraq during the early 21st century against organized and armed insurgents.

While the field of nonlethal agents is diverse and interesting, we will limit our discussion to only those agents considered to be RCAs. The goal of RCAs is to temporarily incapacitate through irritating the skin and mucosal membranes of the eyes, airways, and digestive tract. As a result of their short-term toxicity, they are effective agents used by military and law enforcement personnel to disperse crowds, clear buildings, and quell riots. While RCAs are often thought of as ''tear gas'' or pulmonary irritants, they encompass more than this terminology would suggest. They are neither gases nor exclusively pulmonary irritants. Historically, RCAs were categorized as lacrimators, sternutators, and vomiting agents based upon their predominant toxicity on the eyes, lungs, or digestive tract. This nomenclature is outdated since modern RCAs affect a wide variety of organ systems. This fact will be clearly evident in the subsequent discussion concerning their mechanism of action and toxicity. Today, RCAs comprise a diverse array of chemical compounds with similar toxic effects since their introduction on the battlefield in the early part of the last century.

II. HISTORY

The Chinese were perhaps the first to employ pulmonary irritants with their stink bombs (Smart, 1996). The smoke emanating from them was a primitive sternutator designed to harass the enemy. RCAs were used during the 5th century BC Peloponnesian War when the Spartans used smoke from burning coal, sulfur, and pitch to temporarily incapacitate and confuse occupants of Athenian strongholds (Thoman, 2002). During antiquity, the Romans used irritant clouds to drive out their Spanish adversaries from hidden dwellings (Robinson, 1971). Almost all of these examples involved the use of incapacitating agents as an offensive tactical weapon as opposed to controlling crowds for defensive purposes.

World War I (WWI) marked the birth of RCAs as well as the modern age of CWAs (Figure 12.1). Both German and French forces used a wide variety of irritating agents, such as acrolein (papite), chloropicrin (PS), and diphenylaminearsine (DM; Adamsite); however, bromoacetone (BA) was the most widely used lacrimator agent at that time. At the end of WWI, the US military investigated the use of chloroacetophenone (CN) as a chemical irritant. First developed by Graebe in 1869 and formulated as Chemical Mace®, CN was the most widely used RCA up until World War II (Olajos and Stopford, 2004).

Two chemists, Carson and Stoughton (1928), synthesized 2-chlorobenzylidene malononitrile (CS); however, it was not adopted by the military as an official RCA until 1959. As a more chemically stable compound and having a greater potency with less toxicity than CN, it gradually replaced CN as the preferred RCA. CS was widely used during the Vietnam War to flush the Viet Cong out of the

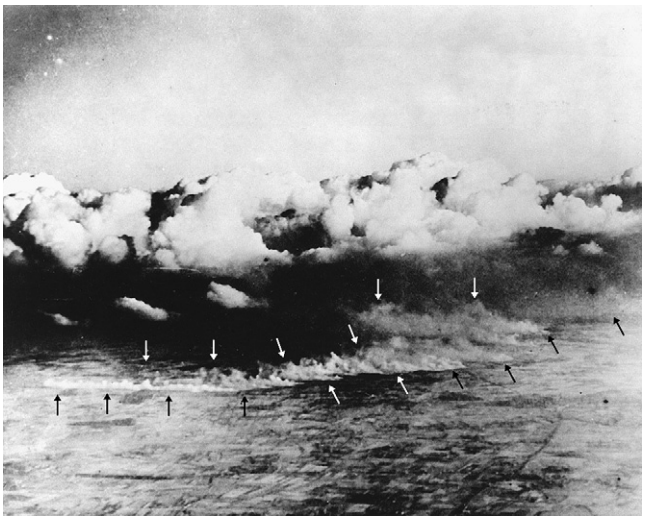

FIGURE 12.1. The birth of chemical warfare agents in World War I. The photograph depicts the initial chlorine gas attack by Germany at Ypres, Belgium, on April 22, 1915. The German Army released chlorine gas from cylinders to form a poisonous cloud (indicated by black and white arrows) directed toward the French lines by the prevailing winds. Photograph: courtesy of the US Army, Chemical Warfare Service, Edgewood, MD.

FIGURE 12.2. *Top*: US Army Engineers unpack and test a Mitey-Mite blower in the jungles of Vietnam. The Mighty-Mite aerosolized and dispersed smoke, CS powder, or other RCA as a means of tunnel denial. Photograph: courtesy of the US Army Engineer School, Fort Belvoir, VA. *Bottom*: American soldiers (''tunnel rats'') wearing M28 protective masks just prior to entry into underground tunnels previously saturated with CS. Photograph: courtesy of the US Army Research Development and Engineering Command, Historical Research and Response Team, Aberdeen Proving Ground, MD.

labyrinth of underground tunnels and bunkers throughout Southeast Asia (Figure 12.2). In the years following the Vietnam War, other militaries adopted CS. Saddam Hussein's forces used it against Iran during the Iran–Iraq War of the 1980s. Today, CS is commonly used by law enforcement agencies and militaries for riot control training, respirator training in boot camps, temporary incapacitation of an assailant, and civil disturbances. A famous case of RCA use by the US Federal government involved CS dissemination on the Branch Davidian cult members in 1993. Because of its high flammability rating, CS was believed to be a large contributor to the inferno that burned down the Waco, Texas, compound and its inhabitants. Even before fire broke out and destroyed the compound, it is believed that CS concentrations ranged from five to 60 times the amount required to deter individuals (Bryce, 2000).

During the 1980s and 1990s, the use of CS gas was rapidly on the decline and slowly being replaced by oleoresin capsicum (OC) spray. OC, an extracted resin from *Capsicum* pepper plants, was first developed in the 1970s as an alternative to CN and CS agents. Commercially available OC sprays used by the public are approximately 1% capsaicin, while formulations used by law enforcement agencies can contain up to 15% capsaicin. Most recently, a synthetic form of capsaicin called nonivamide, marketed as Captor, gained popularity as a defensive aerosol in the early 1990s (Olajos and Stopford, 2000).

Under the CWC of 1997, RCAs were banned from use as a method of warfare because in high concentrations RCAs are toxic chemicals with the potential to incapacitate individuals for prolonged periods, produce long-term sequelæ, and cause death. The CWC allows RCAs to be used in domestic riot control, as well as enforcement of domestic law and ''extraterritorial law enforcement activities undertaken by military forces'' (Rosenberg, 2003). These boundaries and definitions, while vague, were clarified in 2003 by President George W. Bush (Wade and Schmitt, 2003). Bush authorized the use of tear gas against Iraqi troops for defensive purposes as allowed in Executive Order 11850 of 1975. Many experts believed this would violate the CWC (which was not signed by Iraq) and give Saddam Hussein the power to use chemical agents against the US under the authority of the Geneva Protocol (Wade and Schmitt, 2003). In the end, RCAs were never used during that conflict.

III. BACKGROUND

A. The Agents and Their Physicochemical Properties

Unlike the majority of chemical agents which are liquid at room temperature, modern RCAs are crystalline solids with low vapor pressure (see Table 12.1). RCAs are typically administered as fine particles, aerosol sprays, or in solutions; therefore, they are not true gases. The inhalation toxicity of RCAs, as well as CWAs, is often indicated by the expression Ct. This term is defined as the product of concentration (C) in $mg \cdot m^{-3}$ multiplied by exposure time (t) in minutes ($mg \cdot min\ m^{-3}$). LCt_{50} and ICt_{50} are conventional terms used to describe airborne dosages that are lethal (L) or incapacitating (I) to 50% of the exposed population. The intolerable concentration (mg/m^3), ICt_{50} and minimal lethal concentration (mg/m^3) are provided in Table 12.1 for the most common RCAs. The ocular irritancy threshold (minimal irritant or minimal effective dose), estimated human LCt_{50}, and safety ratio are provided in Table 12.2 for these same RCAs. The modern RCAs are characterized by a high LCt_{50}, low effective Ct_{50}, low ICt_{50}, low minimal irritating concentration and large safety index ratio (LCt_{50}/irritancy threshold). As a rule of thumb, clinical signs and symptoms from RCA exposure generally subside within 30 min but may persist depending on dose and duration of exposure (Blain, 2003). Ortho-chloroacetophenone (CN) and chlorobenzylidene malononitrile (CS) are the classic representative agents of this class of compounds. The toxicity of CN and CS will be discussed in depth due to the vast volume of literature available for these compounds.

1. Chloroacetophenone (CN)

CN is a crystalline solid with a strong, pungent odor (see Figure 12.3). It is dispersed as a smoke, powder, or liquid formulation from grenades or other devices. It is perhaps better known under the trade name Chemical Mace® and was once used widely for self-protection. It was also the standard tear gas used by the military (Figure 12.4) and police personnel. It has been replaced in favor of the less toxic CS for riot control and capsaicin pepper spray for self-defense.

CN exhibits the greatest toxicity among RCAs in use today. Consequently, it has been replaced by compounds with higher safety ratios. CN is three- to ten-fold more toxic than CS in rats, rabbits, guinea pigs, and mice (Ballantyne and Swanston, 1978). Pathological findings in the lungs tend to be more severe and CN causes far greater edema. CN typically causes an acute, patchy, inflammatory cell infiltration of the trachea, bronchi, and bronchioles, in addition to early bronchopneumonia. CN not only demonstrates greater irritation to the skin than CS, it is also a more potent skin sensitizer (Chung and Giles, 1972). Patients frequently exposed to CN are at a high risk of developing allergic dermatitis (Penneys, 1971).

2. Ortho-chlorobenzylidene Malononitrile (CS)

The term CS was adopted after the two chemists, Carson and Stoughton, who synthesized the compound. CS is a white, crystalline powder with a pepper-like odor and low vapor pressure (see Figure 12.5). It is rapidly hydrolyzed following contact with water but minimally soluble in ethyl alcohol. CS is the most widely used RCA today, although many countries are switching to even less toxic compounds. CS is used by the US Armed Forces for gas discipline training exercises to help new recruits learn the importance of donning their protective masks quickly (Figure 12.6). It was also used by the USA during the Vietnam War for tunnel denial and crowd control (Figure 12.7) and by police forces for dispersing violent protests and incapacitating assailants.

3. Dibenz(*b,f*)-1:4-Oxazepine (CR)

Dibenz(*b,f*)-1:4-oxazepine (CR) (see Figure 12.8) is a potent sensory irritant with less toxicity than CS or CN (Ballantyne, 1977b). CR causes an immediate and effective irritation of the eyes, nose, and skin without persistent effects in these target organs. The irritation associated with CR is more transient compared to other RCAs. It is five to ten times greater in potency than CS; therefore, a smaller concentration is needed to cause irritation (low minimal irritant concentration or dose) and incapacitation (low ICt_{50}) (see Tables 12.1 and 12.2). CR has a favorable safety ratio; it is safer than other RCAs based on its higher LCt_{50} (Table 12.1) and greater LCt_{50}/irritancy threshold (safety ratio). In humans, the effects caused by CR are identical to CS. The LCt_{50} for humans is estimated at $>$100,000 $mg.min/m^3$. Despite its reduced toxicity in man, CR is not entirely without risk. CR is fairly stable, resists weathering, and persists in the environment (Sidell, 1997); therefore, enhanced toxicity may occur with prolonged exposure.

4. Diphenylaminechlorarsine (DM)

Diphenylaminechlorarsine (DM) (see Figure 12.9) or Adamsite are pro-emetic agents used in WWI. DM has greater toxicity than other RCAs and has been abandoned in favor of compounds with less toxicity and greater safety ratios. While toxicity is typically delayed with DM exposure, toxic signs and symptoms can occur within minutes after exposure. Systemic toxicity may also be more pronounced and prolonged. Symptoms often subside hours after exposure. Because DM is an antiquated RCA, this compound is irrelevant today and will not be discussed further.

5. Oleoresin Capsicum (OC)

Oleoresin capsicum (OC) is an oily resin derivative from capsicums and composed of several related compounds. Capsicums are solanaceous (nightshade species) plants from the genus *Capsicum*. More than 20 species fall within the genus. Capsaicinoids are considered the active ingredients of OC. These active compounds are endocrine products of glands found in the plant placenta and are a mixture of two unsaturated and three saturated homologs

TABLE 12.1. Physical characteristics and toxicity data for the common RCAs

		Physical characteristics			Toxicity data			
Agent	**Discovered in**	**Solubility**	**Vapor pressure (mm Hg @ 20°C)**	**Vapor density**	**Onset**	**Intolerable concentration (mg/m^3)**	**ICt_{50} ($mg \cdot min/m^3$)**	**Minimal lethal concentration[g] (mg/m^3)**
CS	1928 (Carson and Stoughton)[a]	Insoluble in water Soluble in organic solvents	0.00034	6.5	Immediate	5	3–10	2,500
CN	1871 (Graebe)[b]	Poorly soluble in water	0.0054	5.3	Immediate	35	20–40	850–2,250
DM	1915 (Wieland)[c] and 1918 (R Adams)[d]	Insoluble in water Poorly soluble in organic solvents except acetone	2×10^{-13}	9.6	Delayed with long recovery period	5	22–150	1,100–4,400

(see Figure 12.10). Capsaicinoids are isolated through a volatile solvent extraction of the dried, ripened fruit of chili peppers. The capsaicinoids are distilled, dried, and compounded together. The final oleoresin contains several branched-chain alkyl vanillylamides, in addition to capsaicin, the major component in OC. The predominant capsaicinoid components of OC are capsaicin (70%), dihydrocapsaicin (20%), norhydrocapsaicin (7%), homocapsaicin (1%), and homodihydrocapsaicin (1%) (Salem *et al.*, 2006; see Figure 12.10).

Capsaicinoids cause dermatitis as well as nasal, ocular, pulmonary, and gastrointestinal effects in humans. OC gained popularity in the 1990s as a defensive weapon for civilians and law enforcement agencies because they produce an immediate, temporary immobilization and incapacitation when sprayed directly into the face or eyes. It is important to note that hand-held pepper spray formulations can contain OC by themselves or a mixture of OC and CS.

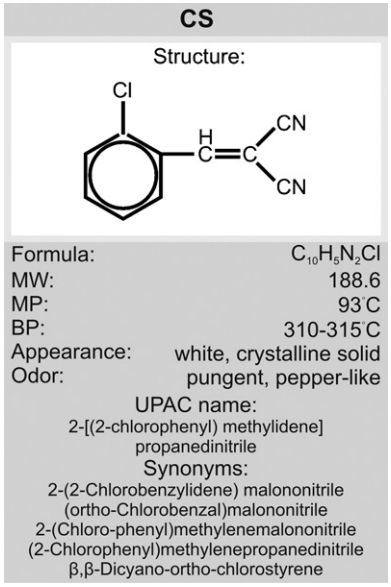

FIGURE 12.5. Chemical structure and physicochemical properties of ortho-chlorobenzylidene malononitrile (CS).

6. Pelargonic Acid Vanillylamide (PAVA)

Other capsaicinoids are available. Pelargonic acid vanillylamide (PAVA or nonivamide), shown in Figure 12.10, is a ''synthetic'' form of capsaicin. Nonivamide was first synthesized by Nelson (1919). Nonivamide was originally found to be a minor component in *Capsicum annum* peppers (Constant and Cordell, 1996); however, the majority of PAVA is derived from synthesis rather than extraction from natural plant sources. As a result, the composition and concentration of PAVA can remain consistent (Haber *et al.*, 2007).

FIGURE 12.7. US Army soldiers using CS tear gas in South Vietnam. Photograph: courtesy of the US Army Research Development and Engineering Command, Historical Research and Response Team, Aberdeen Proving Ground, MD.

In order for PAVA to work, it must be directed at the subject's eyes. The pain to the eyes is reported to be higher than that caused by CS tear gas (Smith *et al.*, 2004; ACPO, 2006). The effects are immediate but will subside 15–20 min after exposure to fresh air. PAVA does display disadvantages. While PAVA has a high rate of effectiveness, it has proven to be ineffective against those under the influence of alcohol (ACPO, 2006). Additionally, the Smith *et al.* (2004) study mentions a number of cases where PAVA was used without effect. The effect of PAVA was also reported to be almost instantaneous, with the undesirable effect that recovery was also immediate. PAVA is commercially available in two forms, Captor I and Captor II. Captor I contains 0.3% PAVA with a solvent of equal parts ethanol and water. Captor II contains 0.3% PAVA with propylene glycol, water, and ethanol (COT, 2007).

IV. MECHANISM OF ACTION

A. CS, CN, and CR

The mechanisms of action through which RCAs act are not completely understood. One explanation for the toxic effects of RCAs is the production of hydrochloric acid through reduction of chloride ions on mucosal membranes (Worthington and Nee, 1999). This may help explain the marked, focal irritation and burns on skin resulting from exposure to CS (Anderson *et al.*, 1996). In addition, CS and CN are SN_2 alkylating agents (Cucinell *et al.*, 1971; Ballantyne and Swanston, 1978); in contrast, the vesicant mustard is an SN_1 alkylating agent. The SN_2 moniker describes direct reaction of the agent with nucleophilic compounds in a bimolecular fashion. In particular, they react with intracellular thiol or SH-containing enzymes, thereby inactivating them (Ballantyne, 1977a). Mackworth (1948) first showed that CN and other first generation lacrimators used during WWI (bromoacetophenone, ethyl iodoacetate, chloropicrin, bromobenzyl cyanide) strongly inhibited thiol-containing succinic dehydrogenase and pyruvic oxidase, major players of crucial metabolic pathways. Some suggest that lactic dehydrogenase is completely insensitive to lacrimators (Mackworth, 1948), but only lacrimators from the iodoacetate family were ever studied by this group. Another group reported that lactic dehydrogenase is in fact strongly inhibited by CS (Cucinell *et al.*, 1971). Chloropicrin also interferes with oxygen transport to the tissues by reacting with SH groups on hemoglobin.

In addition, CS reacts with the disulfhydryl form of lipoic acid, a coenzyme in the pyruvate decarboxylase system (Olajos and Salem, 2001). Alteration in dihydrolipoic acid biochemistry can lead to decreased acetyl CoA levels, resulting in cellular injury. Therefore, tissue injury seems to be related to inactivation of these metabolic enzyme systems. The damage is transient because the enzymes can be rapidly reactivated if exposure is terminated (Beswick, 1983).

Based on these studies, it has been suggested that alkylation of nucleophilic sites, including SH-containing enzymes, is the underlying biochemical lesion responsible

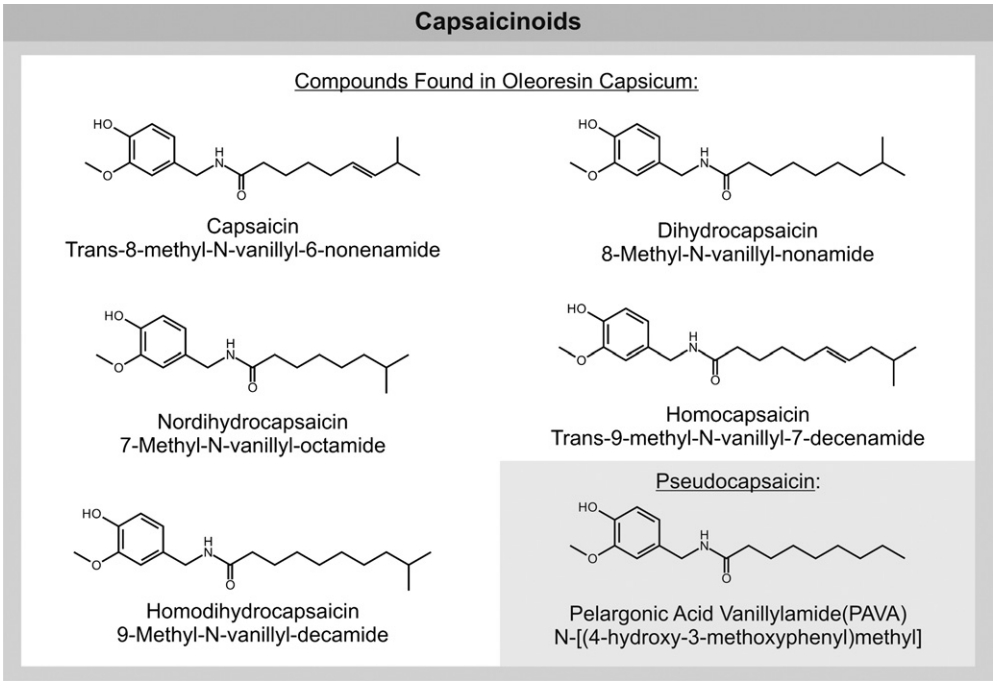

FIGURE 12.10. Chemical structures of the most common capsaicinoids found in oleoresin capsicum.

for lacrimator-induced toxicity. However, pain from RCA exposure can occur without tissue injury. It has been suggested that the irritant and painful effect of CS may be bradykin mediated (McNamara *et al.*, 1969; Cucinell *et al.*, 1971; Olajos and Salem, 2001). CS causes bradykinin release *in vivo* in humans (Cucinell *et al.*, 1971) and *in vitro* (Blain, 2003). Elimination of bradykininogen *in vivo* abolishes the systemic response to CS (USAMRICD, 2000; Salem *et al.*, 2006).

The metabolism of CS to cyanide (see section V) was once thought to be responsible for agent-induced lethality in animals (Cucinell *et al.*, 1971; Jones and Israel, 1970). Despite reports on alleged fatality cases, mortality in humans following CS administration has not been authenticated (Ballantyne, 1977a; Hill *et al.*, 2000; Olajos and Salem, 2001). CS has been demonstrated to cause death in dogs (Cucinell *et al.*, 1971). CS is hydrolyzed to malononitrile and 2-chlorobenzaldehyde (Brewster *et al.*, 1987). Further metabolism of malononitrile yields two potential cyanides, which could interact with sulfur thiols to yield thiocyanate. Cyanide typically causes death immediately, but animals administered CS by inhalation far above the lethal C*t* do not die immediately; death occurs 12 to 24 h after exposure. In fact, death seems to be due to airway and lung damage (Ballantyne and Swanston, 1978; Ballantyne and Callaway, 1972). Studies to ascertain cyanide production after CS exposure in humans showed negligible levels of plasma thiocyanate (Swentzel *et al.*, 1970; Leadbeater, 1973). Another study revealed low levels of cyanide production in mice administered carbon 14-labeled CS (Brewster *et al.*, 1987). In short, cyanide is not liberated in sufficient quantity from CS metabolism to become toxic enough to cause death.

While cyanide inhibition of cytochrome *c* oxidase may not account for the full spectrum of toxicity in CS exposure, cyanide toxicity may include an array of biochemical interactions (Way, 1984). These include lipid peroxidation (Johnson *et al.*, 1987), cyanide release of endogenous opioids to cause respiratory paralysis (Leung *et al.*, 1986), disruption of neuronal calcium homeostasis (Johnson *et al.*, 1986), and phospholipids hydrolysis (Sakaida and Farber, 1990). The mechanism of action for CN follows very closely that of CS as they are both alkylating agents. The effect of both agents on SH-dependent enzyme systems has been studied (Lovre and Cucinell, 1970; Cucinell *et al.*, 1971). Less is known regarding the mechanism of action for CR intoxication.

B. Capsaicinoids

Capsaicinoids interact with a population of neuropeptide-containing afferent neurons and activate a ''vanilloid'' receptor (Szallasi and Blumberg, 1990, 1992; Szallasi *et al.*, 1991). There seems to be a requirement by the receptor for a vanilloid ring and an acyl chain moiety for activity (Szallasi and Blumberg, 1999; Caterina and Julius, 2001). Vanilloid receptors are part of a superfamily of transient receptor potential (TRP) cation channels (Montell *et al.*, 2002). Binding of a vanilloid-containing ligand to the receptor causes channel opening, influx of Ca^{2+} and Na^{+}, depolarization of the neuron, and release of neuropeptides (Lundblad and Lundberg, 1984; Martling, 1987). In addition to transitory excitation of primary afferents, activation of these receptors leads to a prolonged refractory period, indicative of an apparent nonconducting, desensitized state of the receptor. In this refractory period, primary afferents become unresponsive to further application of capsaicinoids. Furthermore, it has been suggested that influx of Ca^{2+} and Na^{+} may lead to rapid cellular damage and eventual cell death (Jancso *et al.*, 1984), possibly by Ca^{2+}-dependent protease activity. Administration of capsaicin in neonatal rats causes destruction of the dorsal root ganglion neurons (Jancso *et al.*, 1977).

The biological actions of capsaicin are primarily due to release of the neuropeptide substance P, calcitonin gene-related peptide (CGRP), and neurokinin A from sensory neurons. These transmitters from primary sensory neurons communicate with other cell types. They produce alterations in the airway mucosa and neurogenic inflammation of the respiratory epithelium, airway blood vessels, glands, and smooth muscle. Alterations in multiple effector organs lead to bronchoconstriction, increased vascular permeability, edema of the tracheobronchial mucosa, elevated mucosal secretion, and neutrophil chemotaxis (Lundberg and Saria, 1982; Lundberg *et al.*, 1983, 1984; Blanc *et al.*, 1991; Tominack and Spyker, 1987). Capsaicin-induced effects of bronchoconstriction, vasodilation, and plasma protein extravasation are mediated by substance P. In addition, substance P can cause bronchoconstriction through stimulation of c-fibers in pulmonary and bronchial circulation.

V. TOXICOKINETICS

The uptake, distribution, and metabolism of CS, CR, and capsaicins (but not CN) have been well characterized.

A. Uptake, Distribution, and Metabolism of CS

CS is rapidly absorbed and distributed throughout the body after inhalation exposure. Pharmacokinetic studies show that CS is removed from circulation quickly with first-order kinetics, following inhalation exposure. CS half-life is just under 30 s (Olajos, 2004). Short half-lives in the circulatory system are also demonstrated for the major CS metabolites (2-chlorobenzyl malononitrile and 2-chlorobenzaldehyde) (Leadbeater, 1973). Currently, it is thought that significant amounts of CS, near the tolerable concentration around 10 mg/m^3, would not be absorbed following CS inhalation. The absorption of CS from the digestive tract in cases of exposure by ingestion is unknown at this time. Systemic toxicity

has been noted after ingestion of CS pellets (Solomon *et al.*, 2003).

In mammalian species, CS rapidly hydrolyzes to form 2-chlorobenzaldehyde and malononitrile (Leadbeater, 1973; Paradowski, 1979; Rietveld *et al.*, 1986). The malononitrile intermediate is further metabolized from two cyanide moieties, which are converted to thiocyanate (Cucinell *et al.*, 1971). The aldehyde intermediate undergoes oxidation to 2-chlorobenzoic acid or reduction to 2-chlorobenzyl alcohol. These metabolites are conjugated and excreted in the urine.

B. Uptake, Distribution, and Metabolism of CR

Absorption of CR after aerosol inhalation is rapid with a plasma half-life of 5 min; this is consistent with half-life estimates following intravenous administration (Upshall, 1977) and gastrointestinal uptake (French *et al.*, 1983). Corneal tissue has been demonstrated to take up CR and metabolize it to the lactam derivative (Balfour, 1978; King and Holmes, 1997).

A number of studies have investigated the bioconversion, fate, and elimination of CR in various animal species (French *et al.*, 1983; Furnival *et al.*, 1983; Balfour, 1978; Harrison *et al.*, 1978). Human metabolic studies on CR have not been performed due to the high degree of sensitivity of human tissues to CR. The maximum tolerated dosage is far too low to allow for detection in metabolic studies (Olajos, 2004). The lactam derivative dibenz[*b*,*f*]1:4-oxazepin-11-(10H)-one is a primary metabolic product of metabolism and a direct precursor of the urinary hydroxylated metabolites. In rats, the lactam, a dihydro-CR metabolite, an amino alcohol of CR, and an arene oxide are metabolites in CR degradation. In the rat, the major mechanism for elimination is sulfate conjugation and biliary excretion to a limited extent. Phase I metabolism by microsomal mixed function oxidases involves reduction of CR to the amino alcohol, oxidation to form the lactam ring, and hydroxylation to form the hydroxylactams. Phase II conjugation reactions sulfate the hydroxylactam intermediates for renal elimination. Amino alcohol intermediates are conjugated with glucuronide for biliary secretion.

C. Uptake, Distribution, and Metabolism of CN

The uptake, distribution, and fate of CN have been poorly characterized despite numerous investigations reporting its toxicity. Inhalation of lethal CN, which does not metabolize to liberate cyanide, also causes death secondary to effects on the pulmonary system (pulmonary congestion, edema, bronchopneumonia, cellular degeneration in the bronchiole epithelium, and alveolar thickening) in mice, rats, guinea pigs, and dogs (Olajos and Salem, 2001). CN presumably reacts irreversibly with the free sulfhydryl groups of proteins and enzymes. It is thought that CN metabolically converts to an alkylating agent with this affinity for SH groups and nucleophilic sites in tissues (Mackworth, 1948; Olajos, 2004).

D. Uptake, Distribution, and Metabolism of Capsaicins

Capsaicin and capsaicinoids undergo Phase I metabolic bioconversion to catechol metabolites via hydroxylation of the vanillyl ring moiety (Lee and Kumar, 1980; Miller *et al.*, 1983). Metabolism involves oxidative, in addition to nonoxidative, mechanisms. An example of oxidative conversion involves the liver mixed-function oxidase system to convert capsaicin to an electrophilic epoxide, a reactive metabolite (Olajos, 2004). Surh and Lee (1995) have also demonstrated the formation of a phenoxy radical and quinine product; the quinine pathway leads to formation of a highly reactive methyl radical (Reilly *et al.*, 2003). The alkyl side chain of capsaicin also undergoes rapid oxidative deamination (Wehmeyer *et al.*, 1990) or hydroxylation (Surh *et al.*, 1995; Reilly *et al.*, 2003) to hydroxycapsaicin as a detoxification pathway. An example of nonoxidative metabolism of capsaicin is hydrolysis of the acid–amide bond to yield vanillylamide and fatty acyl groups (Kawada *et al.*, 1984; Oi *et al.*, 1992).

VI. TOXICITY

RCAs produce a wide variety of physiological effects in man. Figure 12.11 illustrates these generalized toxic signs and symptoms of exposure. The clinical effects in the figure are representative of those encountered after CN or CS exposure. CR causes qualitatively similar effects to those caused by CS, except it has greater potency. The predominant anatomical regions affected include eye, lung, and skin. RCAs also cause nasal, oral, neuronal, and gastrointestinal effects.

A. Ophthalmological Effects

1. CN and CS

The eyes are a major target for the short-lived toxic effects of RCAs. Eye findings from RCA toxicity can range in severity from conjunctival erythema to ocular necrosis. Lacrimation, conjunctival erythema/edema, blepharitis, and erythema are the most typical findings after exposure to all RCAs. Toxic signs may further include periorbital edema (Vaca *et al.*, 1996; Yih 1995), blepharospasm or spasms during eyelid closure (Grant, 1986; Blain, 2003), apraxia of eyelid opening, ophthalmodynia, corneal injury, and ocular necrosis (Grant, 1986). Figure 12.12 illustrates and summarizes the common toxic ophthalmological signs and symptoms associated with RCA aerosol exposure. It is important to note that eye findings tend to be more severe in

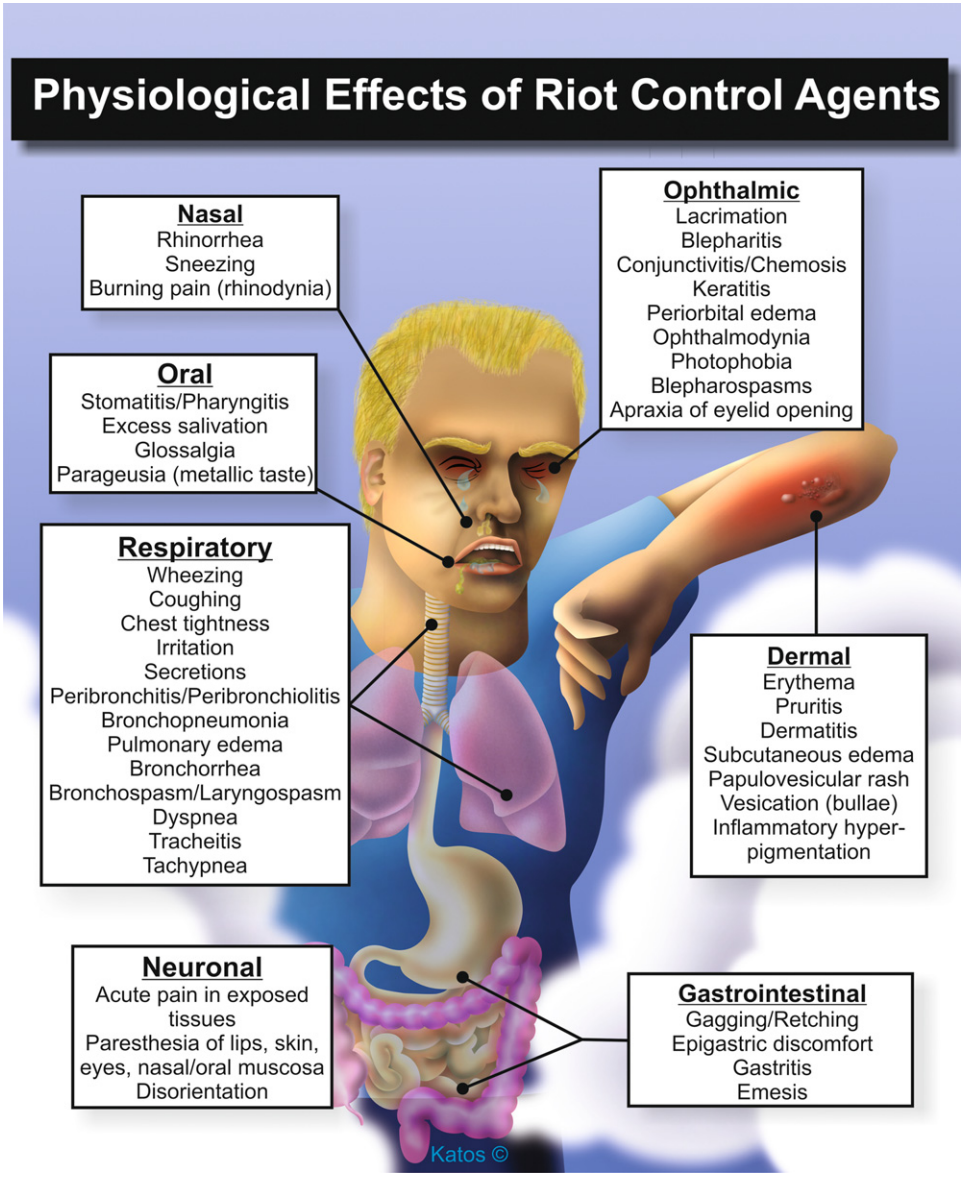

FIGURE 12.11. Physiological effects of riot control agents. Illustrated, copyright protected, and printed with permission by Alexandre M. Katos.

RCA exposure victims if they are wearing contact lenses (Solomon *et al.*, 2003).

Erythema and edema may last up to 48 h and vascularizing keratitis is not uncommon (Ballantyne *et al.*, 1974), but symptoms generally subside after 30 min (Beswick, 1983) depending on the concentration and duration of exposure (Blain, 2003). Recovery is typically complete within 15 to 30 min after exposure, but a few signs such as erythema of the lid margins and photophobia may persist slightly longer. The conjunctivae may appear injected or even progress to fulminant conjunctivitis and blurred vision following some RCAs including CS (Euripidou *et al.*, 2004). Toxic signs in the conjunctivae from CN Mace exposure can include conjunctivitis, sloughing, limbal ischemia, and symblepharon formation (adhesion of the eyelids to the eyeball) (Scott, 1995). Permanent eye injury is unlikely except after exposure to high concentrations of CN Mace (Grant, 1986). While permanent eye damage is uncommon, raised intraocular pressure from edema may precipitate acute angle closure glaucoma if left untreated. Long-term sequelæ may include cataracts, vitreous hemorrhage, and traumatic optic neuropathy (Gray and Murray, 1995).

In studies involving human exposure (Rengstorff and Mershon, 1969a, b), CS (0.1% or 0.25% in water; 1.0% in triocyl phosphate) sprayed or administered as ophthalmic drops onto the eyes, caused apraxia of eyelid opening with blepharospasm upon eyelid closure for 10 to 135 s. It also caused a transient conjunctivitis but no corneal damage upon further inspection with a slit lamp. Rabbit eyes contaminated with CS as a solution (0.5–10% in polyethylene glycol), as a solid, or thermally dispersed as a smoke (15 min at 6,000 mg/m^3) showed a greater toxicity with solution. CS in solution caused profuse lacrimation, conjunctivitis, iritis, chemosis, keratitis, and corneal vascularization at concentrations at or above 1%.

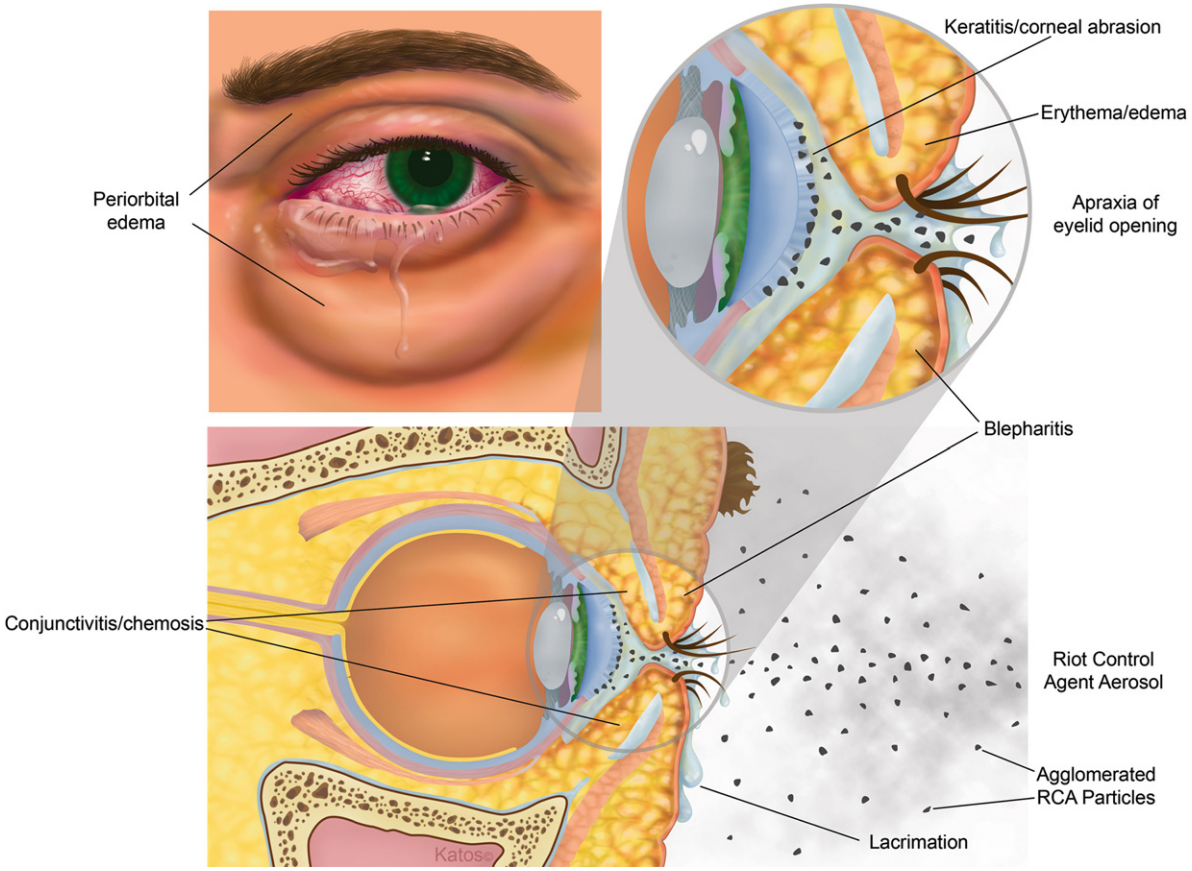

FIGURE 12.12. Exposure of the eye to CS aerosol. *Top left panel*: external view of left eye immediately after exposure to CS aerosol, showing scleral injection, periorbital edema, and lacrimation. *Bottom panel*: Penetration of CS aerosol into the eye, sagittal view. Following exposure to CS, the eye responds with inflammation, edema (chemosis), lacrimation, erythema, eye pain, and eyelid closure. *Top right panel*: Close-up of the eye and eyelids, sagittal view. Inflammation of the eyelids (blepharitis), conjunctivae (conjunctivitis), and cornea (keratitis) are apparent. The eye, in turn, responds with spasms of eyelid closure (blepharospasms) followed by an inability to open the eyelids (apraxia of eyelid opening). Agglomerated CS particles can penetrate the eye upon initial contact and cause corneal abrasions. Illustrated, copyright protected, and printed with permission by Alexandre M. Katos.

The lesions tended to be more severe and have a greater duration at higher doses. Histologically, the cornea appeared with patchy denudation of the epithelium and infiltration of neutrophils to the site of injury (Ballantyne *et al.*, 1974). In general, more severe eye exposures have resulted from CN compared to CS agent.

CN causes a similar constellation of ocular signs and symptoms as CS, but CN toxicity is likely to be more severe in the eyes and skin. CN sprayed into the eyes from a distance causes lacrimation, edema of the corneal epithelium and conjunctivae, and reversible epithelial defects of the cornea (Leopold and Lieberman, 1971). At close range, CN can cause long lasting and permanent damage to the eye. Because RCAs are solids, it is possible for a particle to clump or agglomerate, causing penetration into corneal or conjunctival tissues (see Figure 12.12). Agglomerated CN particles can penetrate eye tissue as a result of tear gas cartridge discharge (Levine and Stahl, 1968). In addition to large powder CN agglomerates, traumatic effects from the propellant charge, wadding, or foreign pieces from the cartridge should also be suspected when evaluating eye damage from CN.

While RCAs produce short-lived effects, rabbits exposed to 10% CN solution caused iritis and conjunctivitis >7 days and corneal opacity (Grant, 1986) lasting longer than 2 months (Gaskins *et al.*, 1972). In comparison, CS at the same concentration produced moderate conjunctivitis without iritis or corneal opacity, and eyes returned to normal by the end of one week. Another difference between the two agents is that CN produces a more severe reaction than CS when applied to the eye in powder form or as a spray at close range (McNamara *et al.*, 1968).

In addition to opacification, additional corneal effects from particulate CN exposure include possible penetration of the corneal stroma, severe scarring and ulceration, and deficits in the corneal reflex (Blain, 2003; Scott, 1995). Penetration of the corneal stroma may lead to stromal edema and later vascularization, resulting in further ocular complications. These may include pseudopterygium, infective keratitis, symblepharon, trophic keratopathy, cataracts,

hyphema, posterior synechia, secondary glaucoma, vitreous hemorrhage, and traumatic optic neuropathy (Hoffman, 1967). Furthermore, a 4% CN formulation produced permanent corneal injury while a 10% CS product did not (Gaskins *et al.*, 1972). In animal studies, high concentrations of CN produce ocular necrosis (Grant, 1986).

The eyes are also affected from CS agent without direct contact of the agent with the eye. In one report, seven patients were exposed to oral ingestion of a juice drink contaminated by CS pellets (Solomon *et al.*, 2003). In addition to mild headache and gastrointestinal irritation, patients complained of ocular irritation and lacrimation. The majority of symptoms resolved within 24 h of exposure.

2. CR

Higginbottom and Suschitzky (1962), the chemists who discovered CR, first noted the intense lacrimal response to this compound. A splash of CR (0.01 to 0.1% range solution) causes immediate ophthalmodynia, lacrimation, and blepharospasm, similar to CS and CN (Sidell, 1997). These effects can last 15 to 30 min before subsiding. Blepharitis (edema of the eyelids), periorbital edema, and injected conjunctivae can last for up to 6 h. In rabbits and monkeys, CR (0.1% solution) causes mild, transient erythema, chemosis, and keratitis in the eye. Moderate conjunctivitis has been demonstrated with higher CR concentrations (5% solution) applied directly to the rabbit eye (Rengstorff *et al.*, 1975). Ballantyne *et al.* (1975) showed that increasing CR concentrations as a solution caused dose-dependent corneal thickening but minor eye effects (mild conjunctivitis and lacrimation) as an aerosol. In animal studies, the effects of CR on the eye are very transient as they are cleared in 1 h, and it produces far less toxicity to the eye than CN (Salem *et al.*, 2006).

3. Capsaicin

Capsaicin causes conjunctivitis, periorbital edema/erythema, ophthalmodynia, blepharospasm, blepharitis, corneal abrasions, and lacrimation. In a retrospective study of 81 patients who presented to the emergency department following aerosol exposure from law enforcement use of OC, 56% of individuals developed ophthalmodynia, 44% conjunctivitis, 40% conjunctival erythema, 13% lacrimation, and 9% corneal abrasions (Watson *et al.*, 1996). Another study involved exposure of 47 human volunteers to OC for evaluating effects on the cornea and conjunctivae (Zollman *et al.*, 2000). All subjects reported significant eye pain, blurred vision, and lacrimation 10 min after exposure to OC pepper spray, but symptoms improved by 1 h later. Corneal abrasions were not apparent, but 21% of subjects showed evidence of punctate epithelial erosions and reduced corneal sensitivity. Corneal abnormalities were absent 1 week after exposure. Another human study identified 23% of subjects (7 of 30) with corneal abrasions following aerosol exposure to OC spray (Watson *et al.*, 1996). In mice, a single subcutaneous injection of 12.5, 25, or 50 mg/kg capsaicin causes corneal changes characterized by neuronal axon degeneration in the corneal epithelium (Fujita *et al.*, 1984).

B. Nasal/Pharyngeal Toxicity

RCAs produce oral and nasal symptoms immediately after exposure. Inhalation exposure to CN and CS causes rhinorrhea, sneezing, and burning pain within seconds (Beswick, 1983); a similar burning sensation with increased salivation occurs after oral contact with aerosolized powder or solution. The salivation, pharyngitis, and glossalgia occur within minutes after exposure (Thorburn, 1982; Beswick, 1983). A CR solution (0.01 to 0.1% range) splashed in the mouth causes salivation and burning of the tongue (Ballantyne and Swanston, 1974) and palate for several minutes. Splashes of the solution can cause nasal irritation and rhinorrhea (Sidell, 1997). Fumes from burned *Capsicum* plants or capsaicin-containing pepper sprays are highly irritating to the nasal mucosa and cause immediate rhinorrhea (Morton, 1971; Collier and Fuller, 1984; Geppetti *et al.*, 1988).

C. Cardiovascular Toxicity

While the evidence is not overwhelmingly impressive, RCAs have apparent effects on the cardiovascular system. Tachycardia and mild hypertension have been noted after exposure (Beswick, 1983). This response may result from anxiety or a response to the pain as opposed to any toxicological effect. The initial response to aerosolized CS is hypertension and irregular respiration, suggestive of the Sherrington pseudoaffective response. Bypassing the pain receptors of the nose and upper airway by endotracheal administration of CS leads to a decrease in blood pressure and bradypnea, effects also seen after intravenous injection. This suggests the initial pressor effect and irregular respiration are generalized responses to noxious stimuli rather than pharmacological effects of CS. Splash contamination of the face or whole-body drenching with dilute CR solution (0.0010 and 0.0025%) causes an immediate increase in blood pressure and bradycardia (Ballantyne *et al.*, 1973, 1976). Intravenous administration of CR in cats causes a transient but dose-dependent tachycardia. These pressor effects are postulated to be secondary to CR effects on sympathetic tone to the cardiovascular system (Lundy and McKay, 1975) or the result of stress and discomfort from the irritation (Ballantyne, 1977a, b).

RCAs have been shown to have a direct effect on the heart. One report linked exposure of high CS concentrations to the development of congestive heart failure (Hu *et al.*, 1989). Furthermore, underlying cardiac disease has been shown to exacerbate toxicity from CS (Worthington and Nee, 1999).

D. Respiratory Toxicity

CS and CN are disseminated as an aerosol powder or solution. Therefore, the most common route of CN or CS absorption is by inhalation. Inhalation of RCAs causes burning and irritation of the airways leading to cough, chest tightness, dyspnea (Beswick, 1983, Hu *et al.*, 1989; Blain, 2003), shortness of breath (Euripidou, 2004), bronchospasm (Hu and Christiani, 1992), and bronchorrhea (Folb and Talmud, 1989). Estimates of the minimal irritant exposure and ICt_{50} are 0.004 and 5 mg·min/m^3, respectively, for CS (Olajos and Salem, 2001). Similar estimates have been made for CN (0.3–1 and 20–50 mg·min/m^3; Olajos and Salem, 2001). Other estimates report that 31 mg/m^3 CN vapor is intolerable to humans after 3 min (Punte *et al.*, 1962).

Laryngospasm can occur either immediately or delayed for 1 to 2 days after CN or CS exposure. Delayed onset laryngotracheobronchitis 1–2 days post-exposure, characterized by wheezing, dyspnea, tachypnea, hoarseness, fever, and purulent sputum, was reported in three of eight patients exposed to high concentrations of CN (Thorburn, 1982). Long-term bronchodilator therapy was required in one patient with pre-existing pulmonary disease. Reactive airways are associated with high-level exposure to CS and CR (Blain, 2003). Paroxysmal cough, shortness of breath, and chest tightness, characteristic of reactive airway disease, have been demonstrated to last up to several weeks. Pulmonary effects typically resolve by 12 weeks post-exposure.

Pulmonary edema may occur up to 24 h post-exposure (Stein and Kirwan, 1964; Gonmori *et al.*, 1987). Gonmori *et al.* (1987) reported a fatality from chloropicrin spray intoxication. The patient, an 18-year-old female, developed pulmonary edema 3 h after exposure. Furthermore, a 43-year-old man developed pulmonary edema complicated by pneumonia, heart failure, and hepatocellular damage after CS intoxication (Krapf and Thalmann, 1981). Delayed onset bronchopneumonia may occur from prolonged exposure to some RCAs in enclosed spaces (Beswick, 1983).

There is no evidence that CS causes permanent lung damage after one or several exposures to field concentrations (Blain, 2003). Inhalation of an irritant might be expected to exacerbate underlying pulmonary disease such as asthma, emphysema, or bronchitis. Histories of asthma and chronic obstructive pulmonary disease may exacerbate effects from CS (Worthington and Nee, 1999) or CN (Thorburn, 1982). CS may exacerbate chronic bronchitis or precipitate an attack in known asthmatics (Anonymous, 1971).

1. CN and CS Toxicity in Animals

In animal studies, the cause of death from CN inhalation is the result of toxicity in the pulmonary system. Post-mortem examination from acute toxicity lethality studies in animals exposed to CN aerosols reveal pulmonary congestion, edema, emphysema, tracheitis, bronchitis, and bronchopneumonia in dogs and pulmonary congestion, edema, and bronchopneumonia in mice, rats, and guinea pigs (Olajos and Salem, 2001). Sublethal CN aerosol exposure (62.6 mg/m^3, 0.1 LC_{50}) for 60 min causes cellular degeneration in the bronchiole epithelium and alveolar septal wall thickening due to infiltration of mononucleocytes (Kumar *et al.*, 1995).

Exposure to aerosol CS (unreported concentration) in male Wistar rats for 20 min can cause decreased minute ventilation and induce histological lesions of the trachea (cytoplasmic vacuoles in epithelial cells) and lung (emphysema) (Debarre *et al.*, 1999). Lower respiratory tract injury, including fibrosing peribronchitis and peribronchiolitis, can be produced by chloropicrin (Buckley *et al.*, 1984).

2. CR

CR does not produce any significant respiratory toxicity (Sidell, 1997). CR causes tachypnea and labored breathing in multiple animal species. In humans, aerosol exposure to CR causes respiratory irritation, choking, and dyspnea. One human study involving aerosol exposure to CR (0.25 mg/m^3) in volunteers for 60 min noted decreased expiratory flow rate minutes after exposure. CR was thought to stimulate irritant receptors in the conducting portion of the pulmonary system, causing bronchoconstriction (Ashton *et al.*, 1978). Additionally, CR increased blood volume in the lungs by driving sympathetic tone. Two animal studies evaluated the effect of CR aerosol exposure on the physical and ultrastructural changes in rat lungs (Pattle *et al.*, 1974; Colgrave *et al.*, 1983). Even high CR aerosol doses did not produce significant pulmonary damage. Gross examination of the lungs was normal in both studies. Microscopic examination showed mild congestion, lobar hyperinflation characteristic of emphysema and hemorrhage. Further pulmonary damage was evident on electron microscopy. CR exposed lungs showed capillary damage of the endothelium and a thickened, swollen epithelial layer (Colgrave *et al.*, 1983).

3. Capsaicin

In children, capsaicin spray was demonstrated to cause a severe bronchospasm and pulmonary edema (Winograd, 1977; Billmire *et al.*, 1996). In the Billmire study, a 4-week-old infant was exposed to 5% pepper spray after discharge from a self-defense device. The infant suffered respiratory failure and hypoxemia, requiring immediate extracorporeal membrane oxygenation. Inhaled capsaicin causes an immediate increase in airway resistance (Fuller, 1991). This dose-dependent bronchoconstriction after capsaicin inhalation in humans is the same as that demonstrated in asthmatics and smokers (Fuller *et al.*, 1985). The capsaicin-induced bronchoconstriction and release of substance P is due to stimulation of nonmyelinated afferent C-fibers.

E. Neurologic Toxicity

RCAs are irritants to the peripheral nervous system (Anonymous, 1999). CN and CS interact with receptors on sensory nerves in the eyes, other mucous membranes, and skin, resulting in discomfort and burning pain. Their neurologic toxicity can range from paresthesias of the lips to burning pain of the eyes (ophthalmodynia), tongue (glossalgia), nose (rhinodynia), throat (pharyngodynia), and skin (dermatalgia). The reaction of CN with sulfhydryl (SH)-containing proteins and enzymes is the cause of denaturation associated with sensory nerve activity (Chung and Giles, 1972). As RCAs affect the senses, the feeling can become disorienting after exposure, which may explain why some experience temporary loss of balance and orientation after exposure (Thorburn, 1982).

Agitation and panic may develop in those not previously exposed to CN (Beswick, 1983; Stein and Kirwan, 1964). Syncope has also been reported (Athanaselis *et al.*, 1990; Thorburn, 1982), but this is likely attributed to panic. Headaches have been reported in 48% of symptomatic persons exposed to chloropicrin (Goldman *et al.*, 1987). When CN was released into 44 prisoner cells, eight inmates experienced malaise and lethargy and among those hospitalized, one experienced syncope and a severe systemic illness (Thorburn, 1982).

A clinical case report of hand injuries caused by accidental discharges from tear gas pens (Adams *et al.*, 1966) revealed specific neuronal toxicological findings. In each case, CN penetrated into the skin to cause a wound. Neurological examination indicated hyperesthesia of select digits in all cases. Biopsies of digital neurons taken for pathology showed thickened epineurium and tendon sheaths. Some of the patients complained of paresthesias months after exposure. The study suggests a possible link between direct chemical injury and nerve damage. The same investigators exposed the sciatic nerves of rabbits to agent by discharge of a CN pen or by dusting the exposed nerve with 0.2 g CN powder. These animal studies suggested CN can cause inflammation and necrosis in skeletal muscle, loss of axon cylinders, and replacement of neural elements with granulation tissue and fibroblasts (Adams *et al.*, 1966). Animals exposed to CR exhibit fasciculations, tremors, convulsions, and ataxia; intraperitoneal administration of CR can also cause muscle weakness (Salem *et al.*, 2006).

Capsaicin activates receptors in trigeminal (cranial nerve V) and intestinal neurons. These include pain receptors located in the mouth, nose, stomach, and mucous membranes. Trigeminal neurons utilize substance P as their primary pain neurotransmitter. Capsaicin first induces the release of substance P from the neuron and then blocks the synthesis and transport of substance P to the effector side (Bernstein *et al.*, 1981; Tominack and Spyker, 1987). Substance P depolarizes neurons to produce dilation of blood vessels, stimulation of smooth muscle, and activation of sensory nerve endings (Helme *et al.*, 1987; Tominack and Spyker, 1987). Jancso characterized the effects of capsaicin as an initial intense excitation of sensory neurons followed by a lengthy period of insensitivity to physicochemical stimuli (Jancso *et al.*, 1968, 1987; Buck and Burks, 1986). Substance P is associated with sensory (pain) or skin inflammation afferents. It is also a peripheral mediator of neurogenic inflammation and smooth muscle contraction (Lembeck and Holzer, 1979; Pernow, 1983). It contributes to contraction of the esophagus, trachea, respiratory tract, and levator palpebrae muscles (blepharospasm and apraxia of eyelid opening). Capsaicin directly applied to the eye causes a neurogenic inflammation, involving vasodilatation and extravasation of fluid, and unresponsiveness to chemical stimuli. Capsaicin renders the skin of humans and animals insensitive to various types of painful chemical stimuli (Bernstein *et al.*, 1981). In humans, OC exposure eventually causes loss of the corneal blink reflex (Olajos and Salem, 2001), which is mediated by sensory input from cranial nerve V and motor output via cranial nerve VII.

F. Gastrointestinal Toxicity

Many reviews state that gastrointestinal effects do not occur upon inhalational exposure to RCAs with the exception of DM; however, nausea, vomiting, and alterations in taste are commonplace in clinical case reports of exposure to CS (Solomon *et al.*, 2003; Athanaselis, 1990) and CN (Thorburn, 1982; Blain, 2003). The involvement of retching and emesis tends to occur if the individual is sensitive, the concentration is sufficiently high, the exposure prolonged, the range is close, or the event occurs in a confined space. Vomiting was reported in 25% of patients with severe reactions to CN in a confined area (Thorburn, 1982). Emesis did not resolve until the following week in one patient. Inhalation of RCAs often leads to parageusias or altered taste of the tongue. In particular, a metallic or burning sensation is often reported (Folb and Talmud, 1989).

Ingestion of CS can also produce episodes of nausea, vomiting, crampy abdominal pain (Blain, 2003), and diarrhea (Blain, 2003; Solomon, 2003). Seven patients in the Solomon study drank juice contaminated with CS pellets and primarily developed gastrointestinal symptoms. Two of the seven patients reported emesis and diarrhea; all patients reported abdominal pain, epigastric discomfort, and burning gastroesophageal reflux. Symptoms resolved 24 h later. Surprisingly, they did not develop parageusia or burning of the tongue after CS ingestion which is often the case after inhalational CS exposure. Another study designed for patients to taste an admixture of sugar and CS (5–10 pellets, 500 mg each and dissolved in 10 liters of water) indicated that patients experienced a 30 s delay in onset of altered taste (Kemp and Willder, 1972); this was most likely due to a masking effect from the sugar. In animal studies, rabbits and rats develop gastroenteritis upon CN or CS exposure by ingestion (Gaskins *et al.*, 1972).

Biting and ingesting *Capsicum* plants can cause nausea and vomiting (Morton, 1971; Tominack and Spyker, 1987; Snyman *et al.*, 2001). Nausea has also been reported in individuals exposed to pepperball tactical powder containing capsaicin (Hay *et al.*, 2006). Capsaicin causes effects on gastric mucosa including mild erythema, edema, epithelial cell damage (Desai *et al.*, 1976), and gastric hemorrhage (Viranuvatti *et al.*, 1972; Desai *et al.*, 1977; Kumar *et al.*, 1984).

G. Dermatological Toxicity

CN and CS are primary irritants of the integumentary system able to cause first and second degree burns (Stein and Kirwan, 1964; Weigand, 1969; Hu *et al.*, 1989). Low concentrations of either agent cause erythema, pruritis, subcutaneous edema, paresthesias, and/or burning sensations in exposed areas of the skin within minutes. Erythema is often the first sign of contact dermatitis, occurring minutes after exposure and subsiding about an hour after exposure. These agents follow a time course of skin damage similar to mustard agent. Further, if the skin is wet or abraded, the toxic effects on the skin are more prominent (Holland and White, 1972; Thorburn, 1982; Sidell, 1997). Exposure to higher doses leads to worsening erythema, edema, vesication with bullae (observed hours later), and fever. The extent of toxic effects also depends on thickness of the stratum corneum and time of exposure. Furthermore, contact with water up to 48 h after exposure can exacerbate the painful symptoms (Pinkus, 1978; Blain, 2003). High humidity, diaphoretic subjects, and warm temperatures can all exacerbate the contact dermatitis from RCAs (Hellreich *et al.*, 1969). Areas of occlusive dress over the skin may also result in worse reactions.

Higher concentrations of CS or longer exposures will result in more than erythema, pruritis, and burning pain. Papulovesicular rashes are not uncommon with high concentrations of RCAs. Typically, edema and vesiculation (bullae dermatitis) follow 24 h after CS or CN exposure (Sidell, 1997). Common sites of bullae are areas under the cuff of a shirt or glove and just under the collar. One study examined the effect of high CS concentrations (300 mg/m^3), tested on the arms of volunteer study patients, at times ranging between 15 and 60 min exposure (Hellreich *et al.*, 1967). All participants experienced burning pain approximately 5 min after exposure onset. A C*t* range of 4,440 and 9,480 $mg.min/m^3$ caused an immediate patchy erythema, which subsided after 30 min. A C*t* range of 14,040 and 17,700 $mg.min/m^3$ led to greater dermal toxicity and required several hours to subside. Bullous dermatitis occurred in 50% of subjects as a delayed reaction. These bullous lesions resolved in 2 weeks, but an inflammatory hyperpigmentation of the skin remained by 6 weeks post-exposure. Differences in individual sensitivities are due to skin pigmentation, complexion, and susceptibility to sunburns (Hellreich *et al.*, 1969).

Exposure to other RCAs causes similar dermal effects. CN is a more potent irritant than CS. In a human study involving dermal application, CN (0.5 mg) powder caused irritation and erythema when on the skin for 60 min (Holland and White, 1972). It took 20 mg CS to cause similar effects for the same duration of exposure. Exposure to 5% capsaicin pepper spray causes immediate and severe erythema and edema in the skin (Herman *et al.*, 1998). Similarly, pepper ball pellets fired at individuals will cause erythema, pain, and edema at the site of impact. The initial point of contact may become infected, scar, or heal with hyperpigmentation (Hay *et al.*, 2006).

Dermal exposure to CN or CS may lead to an allergic contact dermatitis (Madden, 1951; Penneys, 1971), a delayed hypersensitivity reaction developed from a previous exposure to RCAs. CS and CN are both skin sensitizers, but CN is more potent (Chung and Giles, 1972). Initial exposure to either may not cause significant toxic signs or symptoms. Exposure to small amounts of the same agent years later, however, may produce a severe allergic erythematous, patchy rash with edema, bullae, purpura, and necrosis. Sensitization is likely to occur after dermal exposure to high concentrations of RCAs (Penneys *et al.*, 1969; Holland and White, 1972; Leenutaphong and Goerz, 1989). Hypersensitivity reactions can persist for up to 4 weeks (Leenutaphong and Goerz, 1989). This phenomenon has been demonstrated so far by CN (Ingram, 1942; Kissin and Mazer, 1944; Steffen, 1968; Frazier, 1976) and CS (Ro and Lee, 1991) but not CR.

Dermal exposure to CR causes a burning sensation and erythema several minutes later. Burning pain goes away after 15 to 30 min, but the erythema lasts up to 2 h (Holland, 1974). CR does not induce inflammatory cell migration to the site of injury, bullous dermatitis, or contact sensitization (Ballantyne, 1977a). Repeated application of CR to the skin (applied 5 days/week for 12 weeks) has little effect (Marrs *et al.*, 1982). Similar to the eye and lungs, CR does not demonstrate significant toxicity to the skin.

CS, CN, or CR can pose a toxic danger hours after dissemination as they are persistent in the environment. During the riots of the late 1960s, CS was frequently used to control crowds. Inadvertently, firefighters in those metropolitan areas sometimes were exposed as they entered buildings where CS had been disseminated. The force of water from firehose and movement within the buildings reaerosolized enough agent toxic enough to cause erythema and edema around their eyes and other areas of exposed skin (Rengstorff and Mershon, 1969a).

While capsaicinoids may have a vesicant effect, depending on length of exposure, in most cases it produces a burning sensation and mild erythema. Capsaicins cause erythema and burning pain without vesiculation when applied topically to human skin (Smith *et al.*, 1970; Burnett, 1989; Watson *et al.*, 1996; Herman *et al.*, 1998). Skin blistering and rash may occur after chronic or prolonged capsaicin exposures (Morton, 1971).

H. Other Toxicity

One report noted renal tubular nephritis in a worker killed after an explosion inside a plant manufacturing CS agent (Cookson and Nottingham, 1969). Hepatocellular injury has been linked to serious CS inhalation (Krapf and Thalmann, 1981). To date, animal studies have not documented any relationship between RCA exposure and teratogenicity (Himsworth *et al.*, 1971; Upshall, 1973; Folb and Talmud, 1989). CS did not demonstrate mutagenic potential with the Ames assay (Rietveld *et al.*, 1983). Similarly, CR did not have carcinogenic effects in mice or hamsters (Blain, 2003); CS lacks mutagenicity in several test systems (Daniken *et al.*, 1981; Wild *et al.*, 1983).

I. Lethality

Human deaths have been reported from RCA exposure (Thorburn, 1982; Ferslew *et al.*, 1986; Danto, 1987). Death is usually the result of excessive concentrations used, confined spaces, and prolonged exposures. Death occurs hours after initial exposure, and post-mortem findings are consistent with severe airway damage seen in animals. Deichmann and Gerarde (1969) reported a fatality following exposure to high CN vapor concentrations (5.4 gm in a 34 m^3 room) for less than 20 min, which equates to approximately 160 mg/m^3. Estimates of the human LCt_{50} range between 25,000 and 150,000 $mg \cdot min/m^3$ for CS and between 8,500 and 22,500 $mg \cdot min/m^3$ for CN (Olajos and Salem, 2001). High doses of CR aerosol do not produce lethality in animals; CR aerosols of 68,000 $mg \cdot min/m^3$ are not lethal in mice, guinea pigs, or rabbits. The large safety ratio for CR is clearly evident as compared to the other agents.

While OC is widely regarded as a safe substance with low toxicity (Clede, 1993), more research should be conducted in light of recent deaths involving pepper spray use by law enforcement agencies. One case involving an inmate who died in custody implicated pepper spray as a direct contributor to death (Steffe *et al.*, 1995). Billmire *et al.* (1996) reported the life-threatening effects in a 4-week-old infant exposed to OC spray as a result of an accidental discharge.

VII. RISK ASSESSMENT

The ideal process in RCA risk assessment is to characterize the effectiveness and risk from exposures to situations where RCAs may be used (NAS, 1983, 1984; NAS/NRC, 1994; TERA, 2001; Patterson *et al.*, 2004). In order to do that, one must identify all pertinent effects of the RCA in question, develop a dose–response assessment, consider an exposure assessment, and finally characterize the risk. When used as intended, RCAs are thought to be safe and of sufficient low toxicity. They are designed with the purpose of disabling a targeted individual through sensory irritation of the eyes, respiratory tract, and skin. As discussed previously, they are not without additional, unwanted effects especially in circumstances where high concentrations are used or exposure is prolonged. The previous sections have provided sufficient discussion regarding the potential toxicity to humans as a result of exposure to RCAs, including case reports.

A. Identification of Intended and Unintended Effects

By providing a minimal force alternative for controlling and managing individual(s), RCAs are a desired public health and safety tool for military, domestic law enforcement, and civilian use. As with any chemical intended to benefit the public, it is important first to identify the compounds, their potential adverse impact (unintended effects), and their beneficial impact (intended effects). There are a number of chemicals designed and used as RCAs. In general, they are compounds with low vapor pressures and dispersed as fine particles or in solution from a variety of devices. These dispersal methods can include the gamut from aerial spray (Figure 12.6) to large spray tanks (see Figures 12.2 and 12.4) and small, hand-held devices for self-protection. The modern RCAs used today include CN, CS, CR, OC, and PAVA. Their major adverse effects are summarized in Table 12.2. The intended effect for all RCAs is a change in behavioral response of the target. A better measure of this intended effect would be the actual physiological effects produced by RCAs on the eyes, skin, and respiratory tract (Patterson *et al.*, 2004). These are the target organs designed for harassment by RCAs (see Figure 12.11 for review).

Each physiological effect can be evaluated and categorized on a broad spectral continuum from mild to severe. At lower aerosol dosages, the effects from RCAs will be reversible with no serious injury. For instance, typical mild ophthalmic effects include lacrimation (tearing) and transient burning pain (ophthalmodynia). When used at higher levels, in confined spaces and/or for prolonged duration, there is a greater potential for the toxicity to escalate. Moderate effects would include conjunctivitis, keratitis, blepharitis, chemosis, and periorbital edema. Severe effects result from significantly prolonged duration or high concentrations leading to irreversible damage in the tissues (i.e. loss of vision). These include corneal abrasions, scarring, or opacification. Very serious effects on the eye include symblepharon, pseudopterygium, cataracts, hyphema, posterior synechia, secondary glaucoma, vitreous hemorrhage, and traumatic optic neuropathy. The same analysis can be applied to effects on the skin, respiratory tracts, and additional organ systems affected for each agent.

B. Dose Response

Dose–response assessment involves evaluating the dose required to produce a particular effect of interest. Ideally,

quantitative data on specific doses and their corresponding responses are desired. In reality, threshold data for a particular target organ or effect in a target organ are often available as a substitute. The ophthalmic threshold levels and toxicity estimate for human responses to CN, CS, and CR are shown in Table 12.2. If empirical dose–response data are available, a dose–response evaluation for a given RCA might include plotting the percent of individuals responding as a function of dose for each toxicological sign or symptom and target organ of interest. Dose–response curves can then be used in modeling studies to estimate the probabilities of intended and unintended effects for a particular risk assessment scenario (Patterson *et al.*, 2004).

C. Exposure Assessment

The crux of exposure assessment is creating a scenario for human exposure to a given RCA and identifying the exposure factors. This would involve describing the intended target(s), environmental conditions (windy, rainy weather, etc.), crowd size and characteristics, delivery device (tear gas canisters or grenades, powder or aerosol), hazards associated with the delivery system like blunt trauma, as well as the nature of the agent selected (physicochemical properties, solvents, concentration/dose), and duration of exposure. An exposure assessment might include estimation of the amount of systemic exposure through RCA inhalation, absorption through the skin from dermal contact, or intestinal uptake after ingestion. Availability of quality data for each of the aforementioned exposure factors will estimate exposure with high confidence and minimal uncertainty level. Unavailability of data is a major limitation if models are used to estimate exposure.

D. Characterization of the Risk and Risk Management

Estimating or developing probabilities of toxic effects within a population is at the heart of risk characterization. It integrates dose–response and exposure assessments. It is designed to provide the probability of occurrence for effects induced by a given RCA given a particular exposure scenario. For example, a decision-maker will use risk characterization to estimate the probability of a group of effects occurring as a result of clearing a confined space with CS. The probability can be derived as a function of the number of tear gas grenades employed. Unfortunately, there is a dearth of specific Federal risk assessment and risk management guidance or mandates on RCAs. Therefore, the potential for risk management or mitigation of concerns is not optimized for the health and benefit of the public good (Hauschild, 2004). This is partly due to the fact that the process for assessing risk of toxic chemicals has yet to be standardized among Federal programs (Burke *et al.*, 1993; Rhomberg, 1997). Computer modeling to aid risk assessment without empirical data to feed the model can be an academic exercise. The two in combination can be a powerful predictor for risk assessment of any toxic chemical.

VIII. TREATMENT

Exposure to RCAs leads to a generalized stress reaction, causing leukocytosis (Thorburn, 1982; Park and Giammona, 1972), hypokalemia, elevated total protein, increased globulin, and high bicarbonate levels (Beswick *et al.*, 1972). Treatment for RCA toxicity is not often required since the course of intoxication is self-limiting for the most part. Serum toxicological testing is not available to detect RCAs (Sidell, 1997). Clinical signs and symptoms from RCA exposure subside in less than an hour. Initial care involves removing the victim from a potentially crowded area of dispersal immediately to minimize exposure time. It is important to note that these victims may require additional assistance during evacuation because of their reduced vision and disorientation. In circumstances where the concentration of agent is substantially elevated or the area of release is confined, increased complications and risks of morbidity may arise in the eyes, skin, airways, and lungs.

A. Eyes

If the eyes are involved to any degree, a protective mechanism to close the eyelids will be initiated as a result of conjunctivitis, iritis, or keratitis. Photophobia, blepharospasm, and apraxia of eyelid opening prevent the clinician from evaluating the damage. However, a local anesthetic applied to the eye will help with eye pain and allow for further evaluation of the eye by slit lamp. Contact lenses should be immediately removed and the eyes flushed of any dusting or agglomerated solid particles (see Figure 12.12). Eyes should be irrigated with copious volumes of water or saline for at least 15 min to adequately flush the irritant. Diphoterine has also been used to decontaminate eyes and skin after CS tear gas exposure (Viala *et al.*, 2005). If symptoms or signs of eye toxicity persist, consultation with an ophthalmologist is critical. Elderly patients should be monitored for evidence of possible acute glaucoma (Yih, 1995).

B. Skin

Early signs of skin toxicity at the time of clinical presentation will often be contact or allergic dermatitis since blisters form hours later. Removal of clothing should be the first step in decontamination. Placement of contaminated clothes in sealed plastic bags by first responders will prevent secondary contamination as a result of reaerosolized agent (Horton *et al.*, 2005). Early studies of CS indicated that mixing CS with sodium hypochlorite (or household bleach) produced a greater reaction than CS alone in patch testing

(Punte *et al.*, 1963). Despite its usefulness as a decontaminant for many chemical agents, hypochlorite should never be used to decontaminate RCAs on skin. Use of water for decontamination of skin may result in an initial worsening of the burning sensation (described previously). A solution of 6% sodium bicarbonate, 3% sodium carbonate, and 1% benzalkonium chloride has been shown to provide immediate relief from CS dermatitis as the alkaline solution hydrolyzes the agent (Weigand, 1969; Sidell, 1997). Consultation with a burn unit should be considered when large areas of skin are involved or when children are affected. Medical treatment for dermatitis may include topical steroids such as triamcinolone acetonide (Hellreich, 1967; Sidell, 1997), oral antihistamines for pruritis, and topical antibiotics such as silver sulfadiazine (Hellreich, 1967; Roberts, 1988). Systemic antibiotics can be given for secondary infection. Oozing lesions from bullae dermatitis should be treated with wet dressings, changed daily. Deroofing closed vesicles is controversial (Carvajal and Stewart, 1987; Roberts, 1988). Tetanus prophylaxis should be considered.

C. Respiratory

Removing an exposed patient from the source of intoxication to fresh air will provide immediate improvement. Patients should be evaluated for hypoxia with pulse oximetry and arterial blood gases. Pulmonary function tests may be helpful in patients with prolonged pulmonary complaints and followed until symptoms resolve. Chest radiography might be useful if concentration was sufficiently high, exposure was prolonged, or dispersal occurred in a confined space. Pulmonary edema may be delayed for 12 to 24 h after exposure, suggesting a need for follow-up radiographs (Stein and Kirwan, 1964; Solomon, 2003). Laryngospasm is a serious complication that may require tracheal intubation to secure a patent airway. Bronchospasm may be treated with inhaled beta-2 agonists, steroids (methylprednisolone), and aminophilline (Ballantyne and Swanston, 1978; Folb and Talmud, 1989). Arterial blood gas (Vaca *et al.*, 1996) and pulse oximetry should be continued if patients are symptomatic hours after exposure.

IX. CONCLUDING REMARKS AND FUTURE DIRECTION

The goal of RCAs is to harass or produce temporary incapacitation. Use of irritants to harass enemies dates back several thousand years. Today, law enforcement agencies and military personnel use RCAs for quelling protestors, controlling crowds, subduing combatants, clearing buildings, training in chemical warfare, and area denial. Individuals use hand-held devices for self-protection against an assailant. RCAs are dispersed as aerosols or sprays, causing irritation of mucous membranes of the eyes, respiratory tract, and skin. Symptoms and signs of toxicity typically subside by 30–60 min.

Several lines of evidence suggest that RCAs are safe if used as they were originally intended. Even though RCAs are considered safe, nonlethal, temporary incapacitating agents, they are not without risk. Some of the adverse clinical effects from RCA exposure reported in the literature have involved indiscriminate use (excessive concentrations), prolonged exposure, and dissemination of compound in a confined space. In short, these nonlethal agents can pose a serious health hazard in their intended targets. Some RCAs have such a poor safety profile that they have been abandoned long ago (DM and CA). CN and CS have a large body of literature from which to compare and contrast their safety, toxicity, and potency. As the data clearly suggest, CS is a safer compound to use compared to CN. The latest newcomers to the RCA scene are the inflammatory capsaicinoids. OC and PAVA are highly effective irritants that cause similar symptoms to CN and CS. Capsaicinoids gained considerable attention in the 1990s from police departments and the public at large for safe, effective chemical incapacitation of individuals. These compounds are primarily used as defensive sprays by law enforcement to subdue a combative suspect or by individuals for self-protection. While OC, PAVA, and related capsaicinoids produce a similar constellation of toxic signs and symptoms, they are not currently used to control crowds at the level of a riot. If OC-containing pepper spray is preferred for riot control, more research will be required to determine whether it is indeed safe for humans. Finally, risk assessment is a process which can identify gaps in the literature and therefore serves to highlight research needs.

CHAPTER 13

Fluoroacetate

NIKOLAY GONCHAROV, LIDIA GLASHKINA, ELENA SAVELIEVA, VALERIY ZINCHENKO, SERGEY KUZNETSOV, MAXIM VINOKUROV, IGOR MINDUKSHEV, PETER AVDONIN, RICHARD JENKINS, AND ANDREY RADILOV

I. INTRODUCTION

Fluoroorganic compounds attracted the attention of researchers nearly 70 years ago when among a large class of biologically inert chemicals a group of very toxic compounds was revealed, having the general formula CH_2FCOOR and the common name ''fluoroacetate'' (FA). The toxicological effects of FA do not become apparent immediately even after exposure to lethal doses, but after a latent period of half an hour to several hours for animals and humans. The level of FA in some Australian plants can reach up to 5 g/kg dry weight (Hall, 1972) and can cause death of domestic animals, sometimes with appreciable economic damage (McCosker, 1989; Minnaar *et al.*, 2000a). FA can be found in fog and rain drops in some industrial regions (Rompp *et al.*, 2001). The best known representative of FA is its sodium salt (SFA, compound 1080). This substance is used in several countries for controlling populations of some vertebrates. There are also series of fluorocompounds whose metabolism is connected with the formation of FA, these are: antineoplastic drugs (5-fluorouracil and isomers of fluoronitrosourea); N-(2-fluoroethyl) derivatives of the narcotic analgetics normeperidin and normethazocin; pesticides, 1,3-difluoro-propanol and fluoroacetamide (FAA, compound 1081); and 1-(di)halo-2-fluoroethans and fluoroethanol (Reifenrath *et al.*, 1980; Tisdale and Brennan, 1985; Feldwick *et al.*, 1998). The urgency of the problems associated with FA toxicity; and therapy for acute intoxication has greatly increased in connection with a new threat – international terrorism (Holstege *et al.*, 2007). Physicochemical features of FA, the lack of taste and odor, delayed manifestation of toxicity, and similarity of clinical signs of intoxication to some natural indispositions are all characteristics that necessitate comprehensive studies of mechanisms of action of FA and a search for effective therapeutic means for treatment of acute intoxication.

II. BACKGROUND

FA was initially synthesized in 1896 and only decades after that was found in *Dichapetalum*, *Gastrolobium*, *Oxylobium*, *Acacia* and *Palicourea* plants growing in Australia, South Africa, and South America (Oerlichs and McEwan, 1961; De Oliveira, 1963; McEwan, 1964; Aplin, 1971; Vickery *et al.*, 1973). Chemically pure FA is a very stable compound, and the energy of dissociation of the fluorocarbon bond in the molecule is regarded as one of the highest among the natural compounds (Ichiyama *et al.*, 2004). However, FA is broken down in biological preparations from plants (Minnaar *et al.*, 2000a). After inhalation or ingestion, FA is easily absorbed by tissues and its high toxicity is independent of its route of entry into organisms (Chenoweth, 1949). The mechanism of toxic action of FA is widely known as ''lethal synthesis'' (Peters, 1952; Peters and Wakelin, 1953), the essence of which is conversion of nontoxic FA to toxic fluorocitrate (FC) within the cells of an organism. The main reasons for death are considered to be disbalance of intracellular ions, osmotic disbalance, and deficit of ATP as a consequence of aconitase blockade (Buffa *et al.*, 1973). The latent period from the moment of poisoning with FA to manifestation of clinical signs is 0.5–3 h (in warm-blooded animals). This period reflects penetration of FA into blood and cells and conversion of FA to FC, with the consequent uncoupling of intracellular metabolism. Death usually occurs within 24–48 h, but can be later. At autopsy there are no specific signs of intoxication (Peters *et al.*, 1981). For warm-blooded animals unadapted to FA the lethal dose is less than 2 mg/kg (Atzert, 1971). But there is a considerable species-specific difference in clinical signs of intoxication and differences in sensitivity to the poison (Chenoweth, 1949). The mean lethal dose varies within the range from 0.05 mg/kg for dogs to 150 mg/kg for possums. The most common criterion for tolerance, or sensitivity, of animals to FA is intensity of metabolism. Thus, in the lizard *Tiliqua rugosa* the level of metabolism of FA is ten times lower in comparison with that of rat (*Rattus norvegicus*), and the lethal dose for lizard is 100 times higher than that of rat (Twigg *et al.*, 1986). Low intensity of metabolism means low conversion of FA to FC, which makes more effective excretion and detoxication possible. In the absence of specific clinical, physiological, and morphological signs of intoxication, determination of FA in tissues together with

citrate and fluoride ions can be a diagnostic confirmation of FA intoxication (Harrison *et al.*, 1952; Schultz *et al.*, 1982; Koryagina *et al.*, 2006).

III. TOXICOKINETICS

A. Detoxification

The main pathway of detoxification of FA is its defluorination via a glutathione-dependent mechanism involving nucleophilic attack on the β-carbon atom and formation of fluoride and S-carboximethylglutathion, with subsequent cleavage of the latter into amino acids and S-(carboxymethyl) excreted in the urine as a conjugate complex (Mead *et al.*, 1979, 1985; Tecle and Casida, 1989). The highest defluorinating activity was found in liver, followed by kidney, lung, heart, and testicles in a descending line. No defluorinating activity was found in brain. The activity of enzymes responsible for defluorination depends on glutathione (GHS) concentration with a maximum above 5 mmol/l, the apparent K_m being 7 mmol/l at saturating concentrations of GHS (Soiefer and Kostyniak, 1983). Defluorination is mainly carried out by anionic proteins having glutathione transferase activity, though the anionic fraction contains nearly 10% of proteins without this activity but is also capable of defluorination of FA. Moreover, cationic enzymes were shown to be responsible for about 20% of cytosolic defluorination of FA (Wang *et al.*, 1986). The GHS-dependent enzyme defluorinating FA is not identical to GHS-dependent S-transferases; it is an FA-specific defluorinase having an acidic isoelectric point (pH = 6.4) and a molecular weight of 41 kD (27 kD for the main subunit) (Soiefer and Kostyniak, 1984). Activity of defluorinase isoenzymes varies markedly and has been the subject of recent research (Tu *et al.*, 2006).

B. Analytical Procedure

Analysis of biological samples of FA is problematic because of the high polarity of the fluorine–carbon bond in the molecule. Liquid chromatography (LC) has been applied for analysis of FA in different media (Livanos and Milham, 1984; Allender, 1990), and analysis of FA in plants and gastric contents by HPLC with UV detection has also been described (Ray *et al.*, 1981; Minnaar *et al.*, 2000b). Being a nonvolatile substance, FA was commonly analyzed by gas chromatography (GC), as a methyl derivative (Stevens *et al.*, 1976), ethyl or *n*-propyl derivatives (Peterson, 1975) and as pentafluorobenzyl esters (Okuno *et al.*, 1982; Vartiainen and Kauranen, 1984). Derivatization with 2,4-dichloroaniline in the presence of N,N-dicyclohexylcarbodiimide was used for GC analysis of SFA in water (Ozawa and Tsukioka, 1987) and blood serum (Demarchi *et al.*, 2001). A modified procedure by Eason *et al.* (1994) achieved low detection limits for FA at the level of 0.01 μg/g in plasma and urine and 0.002 μg/g in tissue and feces of sheep and goats. However, this procedure is labor and time consuming, and the GC-electron capture detection procedure applied is considered to be unreliable at this level of sensitivity.

The main problem for GC analysis of FA in biological samples is coelution of the matrix components. This can be overcome by sampling the analyte from an equilibrium vapor phase. Static head-space analysis of SFA as ethyl fluoroacetate, with a linear range for SFA in water of 5–200 μg/ml and a detection limit of 0.5 μg/ml has been reported (Mori *et al*, 1996). Solid-phase microextraction (SPME) from an equilibrium vapor phase has all the advantages of head-space analysis, while being a much more sensitive technique. We reported on a novel procedure for determination of FA in water and biological samples, involving ethylation of FA with ethanol in the presence of sulfuric acid, SPME of the ethyl fluoroacetate formed with subsequent analysis by GC-MS (Koryagina *et al.*, 2006). To overcome the problem of the presence of the components coeluting with FA derivatives we made use of GC-MS in the SIM (selective ion monitoring) mode. To avoid a partial overlapping of the internal standard's peak with the sample matrices' components, quantification was performed with the use of two internal standards, carbon tetrachloride and toluene. GC-MS was performed on a Shimadzu QP5000 GC-MS system, using a Supelco SPB-5 capillary column. A stable PDMS-Carboxen-Stable-Flex microfiber (75 μm) was used. The GC-FID, combined with SPME under the optimal conditions, achieved reliable determination of FA in water in the concentration range 0.001–10 μg/ml. The calibration plot for the determination of SFA in biological samples was linear in the SFA concentration range 0.01–5.0 μg/ml for both internal standards, and a linear relationship in blood plasma was observed in the range 0.01–5.0 μg/ml ($r = 0.95$). With toluene as internal standard, the linear regression equation was $Y = 0.014\,X$ [Y was a ratio S(EthylFA)/S(toluene); X was the concentration of SFA, μg/ml]. The RSD (relative standard deviation) for fluoroacetate quantification at 0.1 μg/ml was 12% ($n = 5$). With carbon tetrachloride as internal standard, a linear relationship in plasma was observed in the range 0.01–5.0 μg/ml ($r = 0.98$). The linear regression equation was $Y = 0.1656\,X$ [Y was the ratio S(EthylFA)/S(CCl4); X was the concentration of FA, μg/ml]. The RSD for FA quantification at 0.1 μg/ml was 6% ($n = 5$), and the detection limit was 0.01 μg/ml ($S/N = 3$). The calibration characteristics of rat organ homogenates were identical to those of plasma.

C. Tissue Distribution and Elimination

The data on toxicokinetics of FA are rather contradictory, apparently depending on analytical procedures and dose of the poison; also, there is evidence for animal species specificity. The first data on toxicokinetics of FA demonstrated its rather uniform distribution between organs, with some

predominance in heart, brain, and kidneys (Hagan *et al.*, 1950; Gal *et al.*, 1961). The half-life was calculated to be not less than 2 days, and this could cause secondary toxicity arising from ingestion of meat from the poisoned animals (Aulerich *et al.*, 1987). For the purposes of risk assessment for humans in case of secondary poisoning with meat, sheep and goats were given FA (0.1 mg/kg) and their tissues were analyzed for FA content. The half-life of FA was shown to be 10.8 h for sheep and 5.4 h for goats; maximal concentration of FA 2.5 h after the poisoning was revealed in blood plasma (0.098 μg/ml), followed by kidneys (0.057 μg/g), skeletal muscles (0.042 μg/g), and liver (0.021 μg/g). Only traces of FA were found in all the tissues examined 96 h after the poisoning (Eason *et al.*, 1994). At 1 and 12 h after introduction of SFA (0.2 μg/kg) to rats a similar ratio of FA was found in rat plasma (0.26 and 0.076 μg/ml, correspondingly) (Eason and Turck, 2002), the half-life period being 2.9 h. On the other hand, for rabbits under subacute intoxication with FA the half-life was found to be 1.1 h, and the level of FA in rabbit muscles, kidneys, and liver was much higher than in blood plasma (Gooneratne *et al.*, 1995).

In our laboratory, the use of the above-mentioned SPME method in combination with GC-MS produced the following results (Figure 13.1): maximal concentrations were found in rats 1 h after the poisoning, 2.2 μg/ml in blood plasma and 1.89 μg/g in brain; there was 3–4 times less FA in rat kidneys, liver, and heart (from 0.64 to 0.50 μg/g). After a further 2 h the distribution between the tissues was more equal, resulting from a prominent decrease of FA in plasma and brain and a small decrease or even elevation of FA in other organs. A further decrease of FA was found in all the tissues, except for heart, 24 h after the poisoning. After 72 h, no FA was detected in plasma; we did not measure FA in rat organs at this point. The half-life was calculated to be 3.6 h.

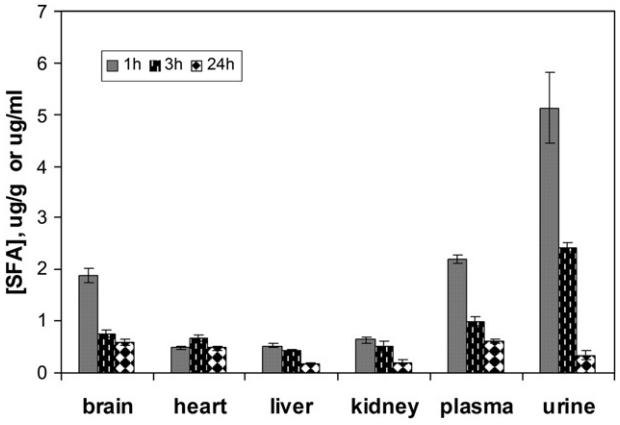

FIGURE 13.1. Data on determination of FA (recounted as SFA) in rat organ homogenates and body fluids, at times following poisoning with SFA at a peroral dose of 2 mg/kg ($1/2LD_{50}$). Standard deviations (shown) were based on 4–6 replicate analyses.

IV. MECHANISM OF ACTION

A. Molecular Mechanism of Aconitase Inhibition

The mechanism of the inhibitory effect of FA on aconitase [citrate (isocitrate) hydro-lyase, EC 4.2.1.3] is one of the most interesting in biochemistry. Upon entering an organism, nontoxic FA undergoes a series of metabolic conversions the result of which is synthesis of highly toxic fluorocitrate (FC); this process was termed ''lethal synthesis'' (Peters, 1952). FC is formed by the enzymatic condensation of fluoroacetyl-CoA with oxaloacetate, catalyzed by citrate (*si*)-synthase (EC 4.1.3.7) (Eanes and Kun, 1974; Kirsten *et al.*, 1978). FC was initially considered to be a competitive aconitase inhibitor, but in the early 1990s it was suggested that FC acts as a ''suicide substrate'', because it has a high affinity for aconitase at any concentration of the competitive citrate (Clarke, 1991). Aconitase effects conversion of citrate to isocitrate through an intermediate, *cis*-aconitate, which binds with aconitase in two different ways, swung 180° to the C^{α}—C^{β} bond (Gawron and Mahajan, 1966). Aconitase includes a [4Fe-4S] cluster and the catalytic conversion involves substrate coordination to a specific iron atom in this cluster, Fe_a (Lauble *et al.*, 1992). The single inhibitory isomer was shown to be (–)-*erythro*-2-fluorocitrate (2R, 3R) (Carrell *et al.*, 1970), from which aconitase removes fluoride ion with a stoichiometry of 1 F^- per enzyme molecule (Kent *et al.*, 1985; Tecle and Casida, 1989). The defluorination results in generation of an actual aconitase inhibitor, 4-hydroxy-*trans*-aconitate (HTA), which binds very tightly – though not covalently – with aconitase (Kent *et al.*, 1985; Lauble *et al.*, 1996). The natural aconitase substrate isocitrate should be at a 10^6-fold excess in order to slowly displace HTA from its complex with aconitase. The HTA–aconitase complex involves four hydrogen bonds, which hold together HTA, a water molecule, Asp165, and His167 (Lauble *et al.*, 1994, 1996). In contrast, isocitrate has only one such bond.

B. Physiological and Biochemical Effects of FA

1. Effects of FA and FC on Mitochondria and Other Intracellular Organelles

Functional disturbances of mitochondria (MCh) precede the appearance of structural anomalies (Buffa and Pasquali-Ronchetti, 1977) and consist of their decreased capacity to oxidize the substrates introduced. Within the mitochondrial matrix, FA induces changes which develop in several minutes resulting in its swelling and loss of electronic density. These changes are explained by accumulation of citrate, rise of osmotic pressure, and decrease of energy production (Corsi and Granata, 1967; Buffa and Pasquali-Ronchetti, 1977). Change in the level of ATP is not caused by uncoupling of respiration and phosphorylation (Fairhurst *et al.*, 1958; Corsi and Granata, 1967). Mitochondrial

volume changes are accompanied by their conformational reorganizations: these are displacement of granules and disintegration of cristae, and extension and rupture of their membranes. Axonal cylinders stretch in 3–4 h after small doses of the poison and in 1–2 h after lethal doses. The cylinders are filled with MCh (most of which are being swelled and degenerated), multilamellar lisosome-like bodies, vesicules, and neurofibrils. In the Golgi complex, a condensation of cisternae takes place (McDowell, 1972). Concurrently, a disruption of endoplasmic reticulum, swelling of nucleus, and reduction of aggregated chromatin can be seen.

Having studied *in vitro* effects of FC on rat liver MCh we revealed that maximal inhibition of respiration was registered when MCh were uncoupled (Figure 13.2). The level of alkalinization of the medium at addition of ADP was much lower in the presence of FC, thus evidencing an inhibition of ATP synthesis. The amplitude of alkalinization was also decreased, which could be caused by incomplete ATP synthesis, an additional transmembrane redistribution of protons, and/or change of the binding constant of ADP. FC induced a leak of Ca^{2+} from MCh, which was consistent with the observed inhibition of oxygen consumption in respiratory state 1. Addition of the substrates caused re-entry of Ca^{2+} into MCh. In the presence of FC, the MCh only partially took up the Ca^{2+} ions added to the medium, followed by their spontaneous efflux through an electroneutral $2H^+/Ca^{2+}$ exchanger with $K_{1/2} = 10$ µmol/l (Teplova *et al.*, 1992).

The effects observed under exposure of MCh to SFA developed at much higher concentrations (from 4 mmol/l), as compared to FC, and greatly depended on respiratory substrates. With pyruvate as substrate, the time period of oxidative phosphorylation (OP) and the level of NADH oxidation increased linearly at increasing SFA concentration in the medium (Zinchenko *et al.*, 2007). However, with

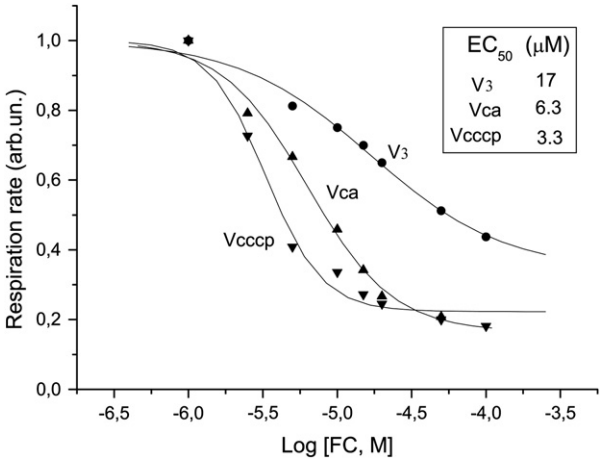

FIGURE 13.2. Effects of FC on respiration of rat liver MCh. Dependence of respiration rate activated by ADP (V_3), calcium transport (V_{Ca}), and protonophore CCCP (Vcccp) upon concentration of FC. Substrates: pyruvate *plus* malate.

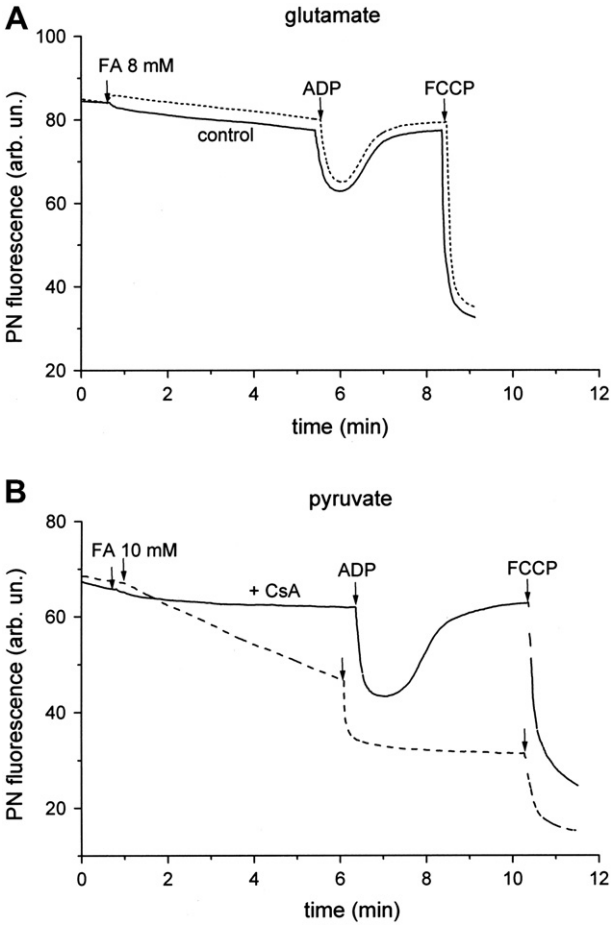

FIGURE 13.3. Effects of FA on redox state of pyridine nucleotides (PN) of rat liver MCh. (A) Glutamate as respiratory substrate. (B) Prevention of PN oxidation and/or leakage by cyclosporin A (CsA) when pyruvate used as respiratory substrate. Additions: (A) SFA 8 mmol/l (dots) or sodium acetate 8 mmol/l (control line), ADP 120 µmol/l, FCCP 1 µmol/l; (B) SFA 10 mmol/l (dots) or SFA 10 mmol/l plus CsA 1 µmol/l (line).

utilization of succinate and especially glutamate, SFA had no effect on OP in concentrations as high as 8 mmol/l (Figure 13.3A) and even 16 mmol/l (not shown here). Moreover, the effect of SFA with pyruvate as respiratory substrate can be prevented by incubation of MCh with cyclosporine A, a known inhibitor of the mitochondrial transition pore (Figure 13.3B). This means that under exposure to FA development of mitoptosis and apoptosis is possible, but opening of the pore is reversible in nature and preventing oxidation or leak of NADH from MCh can turn them back to normal functional state.

2. Effects of Fluoroacetate on Isolated Cells

The effects of FA on the physiological and biochemical status of cells and tissues are tightly dependent upon the level of their oxidative metabolism. Thus, FA does not inhibit phagocytosis because of the low level of TCA cycle

activity within macrophages (Cifarelli *et al.*, 1979). We investigated a series of cell types, transformed lines and those obtained from animals, under exposure to FA or FC. The level of NAD(P)H in Ehrlich ascite tumor (EAT) cells slowly decreased and the level of Ca^{2+} increased when the cells were incubated with SFA (Zinchenko *et al.*, 2007). SFA could induce depletion of intracellular calcium stores and activation of influx of extracellular Ca^{2+} ions through the store-operated calcium (SOC) channels. Discovery of other calcium channels such as TRPV5 and TRPV6 (Hoenderop *et al.*, 2003; van de Graaf *et al.*, 2006), which remain inactivated when $[Ca^{2+}]_i$ is increased and become activated when $[Ca^{2+}]_i$ is decreased, stimulated the investigation of the level of calcium ions in endoplasmic reticulum (ER) with chlortetracycline (CTC). Under exposure to ATP, FC does not affect the velocity of calcium efflux from ER, so the signal transmission from P2Y receptor via G-protein is not inhibited in EAT cells (Zinchenko *et al.*, 2007). However, FC induced a growth in both amplitude of Ca^{2+} leakage and velocity of its influx into ER. A rather long period (8–10 min) of Ca^{2+} influx into ER was observed, which indicated efflux of intracellular Ca^{2+} from cells by plasma membrane Ca-ATPase immediately after mobilization and leaving ER. This greatly reduces $[Ca^{2+}]_i$ for transport back to ER. It was demonstrated earlier (Zinchenko *et al.*, 2001) that the velocity of return transport of Ca^{2+} into ER depends upon activity of plasma membrane SOC channels. Therefore, we suggest that FA (or FC) can induce entry of calcium ions into cells through SOC channels.

The toxic effects of FC on endothelial cells have been shown to be similar to its effects on other energy-dependent tissues: a reduction of ATP level and oxygen consumption but accumulation of lactate and considerable decrease of protein synthesis (Rist *et al.*, 1996). We have demonstrated a gradual decrease of the mitochondrial membrane potential and elevation of $[Ca^{2+}]_i$ under exposure to SFA (unpublished data). Conversely, in cardiomyocytes SFA induced a slow enhancement of the mitochondrial membrane potential together with a rise of basal $[Ca^{2+}]_i$; propagation of calcium waves along the surface of sarcoplasmic reticulum, or visible elevation and velocity of spreading of the pre-existing waves, was also observed (Zinchenko *et al.*, 2007). Probably the increased level of $[Ca^{2+}]_i$ is the reason for its transport into MCh with a subsequent inhibition of the proton ATPase and rise of the membrane potential. Mechanistically, this phenomenon could be explained by the existence of a Ca^{2+}-dependent protein inhibiting H^+-ATPase (Hubbard and McHugh, 1996).

We have also studied the kinetic parameters of platelet aggregation in experiments with rats *in vitro* and *ex vivo* (Mindukshev *et al.*, 2006). Aggregation of platelets was induced with ADP over the concentration range 10–100 nmol/l. The median effective concentrations (EC_{50}) of ADP for the cells exposed to SFA, 10 and 5 mmol/l, were calculated to be 25 nmol/l and 35 nmol/l, correspondingly, and these platelets can be characterized as hypersensitive to ADP. Studying the kinetic parameters of platelet aggregation under intoxication of rats with SFA, we encountered a problem of spontaneous aggregation of the platelet-rich plasma, which was in agreement with the data on primary transition of the platelets to the hypersensitive state. However, the cells that avoided aggregation demonstrated an extremely high level of desensitization. In some experiments, ADP could not induce platelet aggregation at very high (nonphysiological) concentrations near 10 μmol/l.

Under intoxication with SFA a significantly reduced thymus, as well as a prominent quantity reduction of freshly obtained thymocytes and elevation of apoptosis, were revealed (Figure 13.4). SFA also caused an acceleration of apoptosis of control and dexamethazone-treated human lymphocytes *in vitro*, although spontaneous apoptosis of

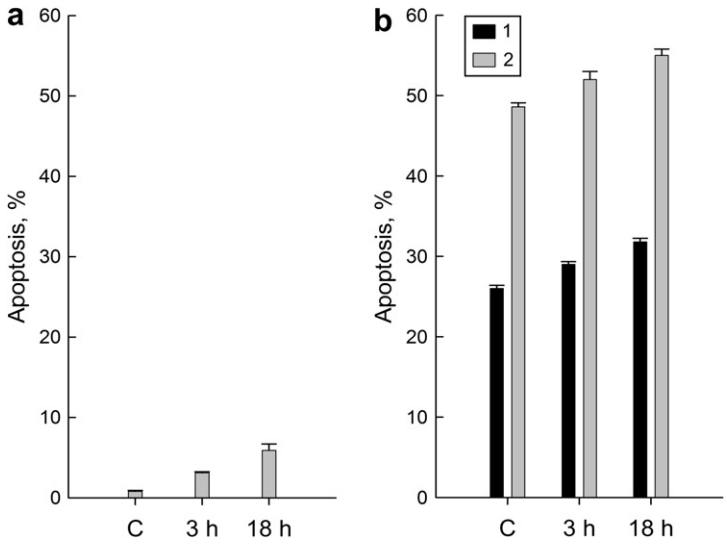

FIGURE 13.4. Effect of SFA on development of apoptosis of rat thymocytes 3 and 18 h after administration of SFA at $1/2LD_{50}$. Registration of apoptosis with Hoechst-33258. (A) Apoptosis in freshly isolated thymocytes; (B) Apoptosis in thymocytes cultivating for 20 h after isolation in the absence (1, black) and presence (2, gray) of dexamethasone.

human neutrophils was inhibited (not shown here). Moreover, SFA practically had no effect on reactive oxygen species (ROS) production by peritoneal macrophages of mice. One can suggest that the inhibitory effect of FA on neutrophil apoptosis is realized through ROS, whereas the enhanced apoptosis and depression of the cells responsible for adaptive immunity is a nonspecific reaction under SFA intoxication, reflecting a general decline and redistribution of energy resources of the organism.

3. Biochemical Parameters Under Intoxication with Fluoroacetate

Among the biochemical effects caused by FA are: accumulation of citrate and disturbance of its transport from MCh; elevation of lactate and disturbances in carbohydrate metabolism; decrease of free fatty acids (FFA) concentration; elevation of adenosine and ammonia; disbalance of bivalent cations and acid–base equilibrium; changes in GABA balance in brain; and rise in phosphates and various enzymes in blood plasma (Buffa and Peters, 1950; Engel *et al.*, 1954; Elliott and Phillips, 1954; Maytnert and Kaji, 1962; Williamson, 1967; Stewart *et al.*, 1970; Bgin *et al.*, 1972; Eanes *et al.*, 1972; Buffa *et al.*, 1973; Liang, 1977; Kirsten *et al.*, 1978; Taitelman *et al.*, 1983a; Bobyleva-Guarriero *et al.*, 1984; Bosakowski and Levin, 1986; Szerb and Redondo, 1993). However, among such a variety of biochemical changes citrate seems to be the only parameter whose qualitative (but not quantitative) trends are not a matter of controversy. In rat hearts under acute intoxication with FA, concentration of citrate can exceed control values 8–15 times (Bosakowski and Levin, 1986). Elevation of citrate concentration is in direct proportion to respiratory activity of a tissue: metabolically active tissues – such as heart, kidneys, and spleen – maximally accumulate citrate, though in liver, which is also characterized by high respiratory level and metabolic activity, a small accumulation of citrate has been observed (Cole *et al.*, 1955; Twigg *et al.*, 1986). In our experiments with rats poisoned with SFA at a dose of $1/2LD_{50}$, concentration of citrate in blood plasma and organs increased within 1 h (Figure 13.5). The most prominent elevation of citrate was revealed 6 h after the poisoning in heart (5×), kidneys (3×), and brain (2.5×). There was doubling of the level of citrate in blood plasma after 1 h, though it was the only biochemical parameter of plasma that remained elevated for 3 days.

Transfer of citrate through the inner membrane of MCh is provided by a tricarboxylate transporter (m.w. 32.5 kD), which also catalyzes transport of *treo*-D_s-isocitrate, *cis*-aconitate and other tricarboxylates (LaNoue and Schoolwerth, 1979; Kaplan *et al.*, 1990). This is electroneutral exchange for either another tricarboxylate or dicarboxylate (e.g. malate or succinate), or for phosphoenolpyruvate. Formation of glutathione-citryl thioester is irreversibly inhibited by (–)erythrofluorocitrate ($IC_{50} = 25$ pmol FC/mg protein), which makes a stable adduct with the synthase (Kun *et al.*, 1977). However, the block of citrate transport

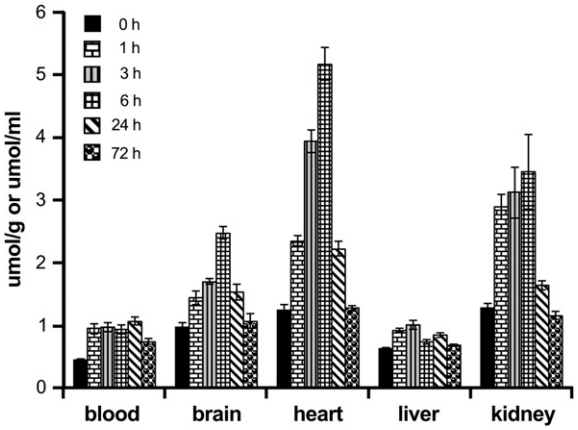

FIGURE 13.5. Concentration of citrate in blood and organs of rats under intoxication with SFA at $1/2LD_{50}$.

is not absolute and universal for all the organs and tissues. There are data on citrate transfer from MCh to cytosol with its subsequent utilization by cytoplasmic aconitase (c-aconitase), which is virtually not affected under FA intoxication, and then by cytoplasmic NADP-dependent isocitrate dehydrogenase (cICDH) (Max and Purvis, 1965). Around 32% of citrate produced in MCh can be transported to cytosol (Buffa *et al.*, 1972). These processes should be regarded as being adaptive and positive, they lead to reduced oxygen consumption because the NADPH generated does not require further oxidation in the respiratory chain and can be utilized in other metabolic pathways.

Among the negative consequences of citrate accumulation is a change of electrolyte composition and acid–base disbalance in the organism. Moreover, elevation of citrate level in cells leads to disturbance of glucose metabolism due to inhibition of the key glycolytic enzyme phosphofructokinase (Bowman, 1964; Peters, 1972). Hyperglycemia during intoxication with FA can be very prominent, in spite of inactivation of gluconeogenesis (Godoy *et al.*, 1968; Bobyleva-Guarriero *et al.*, 1983, 1984). Nevertheless, we could not find significant changes in rat blood glucose level throughout the periods of intoxication with FAA or SFA at a dose of $1/2LD_{50}$; at the same time there was a significant increase of glucose level in liver, heart, and brain (unpublished data). This may signify a utilization of glucose by other tissues and first of all by skeletal muscles, as a result of which the local increase of glucose in organs is not reflected by the level of glucose in blood. Thus, glucose cannot serve as a reliable criterion of intoxication.

Some researchers considered the elevated glucose level to be a result of decreased insulin secretion by pancreatic β-cells due to their damage by FA (Cole *et al.*, 1955; Karam and Grodsky, 1962). Along with hyperglycemia there was hyperketonemia, observed characteristically for the diabetic state, caused by inhibition of TCA cycle and depletion of oxaloacetate (Williamson, 1967; Buffa *et al.*, 1973; Taitelman *et al.*, 1983a). Also consistent with diabetes is

inhibition of hormone-induced lipolysis in adipose tissue (Taylor *et al.*, 1977). Moreover, FA increased glucose conversion to fatty acids, and such coincidence of antilipolytic and lipogenetic effects of FA provides a basis for suggesting a relation in effects of FA and insulin. However, injection of insulin does not alleviate FA intoxication in general and ''FA diabetes'' in particular (Reichelt, 1979). During FA intoxication, the initial hyperglycemia can even be reversed into hypoglycemia (Boquist *et al.*, 1988), so this effect of FA was considered to be an insulin-like phenomenon (Zieve *et al.*, 1983). The principal distinction, however, should be depletion of glycogen stores in different tissues under intoxication with FA (Godoy *et al.*, 1968; Boquist *et al.*, 1988). After poisoning with FA, glycogen levels in animal tissues may decrease by 75% in 1 h and by 90% in 2 h (Buffa *et al.*, 1973; Zhou *et al.*, 1984). According to our data, during SFA intoxication ($1/2LD_{50}$) glycogen levels are maximally decreased after 6 h in both liver (by 55%) and brain (by 40%), and the dynamics of the glycogen levels was similar in these organs. Such a decrease could result from the indirect action of adrenalin or sympathetic regulation (Buffa *et al.*, 1973). In addition, inhibition of *de novo* glycogen synthesis has been reported (Zhou *et al.*, 1984).

Nevertheless, disturbances in hormonal regulation during the FA intoxication can also take place: reduction of calcium concentration in blood plasma could be caused by a poor reabsorption of calcium ions in kidneys due to a decrease of parathyroid hormone level; an excess of Ca^{2+} excretion up to 0.173 mg/min (the control rate being 0.06 mg/ml) has been registered (Perez and Prindt, 1977). Decrease of calcium level could be the reason for the so-called ''hypocalcemic tetanus'' (Roy *et al.*, 1980), manifesting itself as typical convulsions, disturbances of blood clotting, and hypotension leading to vascular attacks. The level of decrease of calcium correlates with extension of the Q-T interval on ECG, which is a consequence of broad spectrum of cardiac arrhythmia (Buffa and Peters, 1950; Arena, 1970).

ATP level is usually reduced, though ADP and AMP levels can be elevated in the first hours of the FA intoxication, with subsequent decrease (Bowman, 1964; Stewart *et al.*, 1970). There are other reports of a constant level of ATP in some organs and tissues. For example, FA did not affect ATP and GTP, as well as cyclic nucleotides and levels in hepatocytes *in vitro* (Dohi and Murad, 1981). When dogs were intoxicated with sublethal doses of FA there was no observable decrease in oxygen consumption and ATP level; this was explained by utilization of glutamate and aspartate which can enter the TCA cycle distally of aconitase (Liang, 1977). The inversion of reactions at glutamate dehydrogenase (GDH) is a simple and effective compensative mechanism during blockade of the TCA cycle in kidney cells: instead of glutamine synthesis, glutamate is deaminated to form 2-oxoglutarate to support the flow of reducing equivalents in the TCA cycle and ATP synthesis, while the ammonia produced neutralizes local tissue acidosis (Yu *et al.*, 1976). Such utilization of glutamate may account for the significant reduction of glutamate level in rat organs, beginning at the first hour after intoxication with FA. The data obtained according to the GC method of Matsumura *et al.* (1996) have shown a decrease of glutamate, aspartate, and some other amino acids in rat brain (Figure 13.6), as well as a decrease of glutamate and nearly complete absence of glutamine in blood plasma of rats and rabbits (not shown here) 3 h after poisoning with SFA. The levels of amino acids in blood plasma of animals indicate the extent of protein breakdown in muscles, on the one hand, and the level of their utilization by other organs and tissues, on the other hand. Under intoxication with FA, glutamate and its precursor glutamine are probably the main nutrients. Elevation of amino acid levels in blood plasma of rats within 3 h after poisoning signifies an elevation of protein breakdown. Furthermore, this indicates that other amino acids – because of their transport, catabolism, etc. – are not nutrients of primary importance under energetic deficit conditions.

Elevation of lactate level in the blood of animals poisoned with FA has been reported (Engel *et al.*, 1954; Taitelman *et al.*, 1983a). In agreement with these workers, we observed a prominent rise in lactate levels in blood just after convulsions (unpublished data). In rat heart and brain, lactate levels decreased under intoxication with SFA or FAA, irrespective of convulsions. During SFA intoxication the decrease in lactate level (and increase of glucose level) in rat heart takes place earlier and to a greater extent than for FAA intoxication: 38% decrease in 3 h for lactate, as compared with 25% in 6 h in the case of FAA; 100% increase in 3 h for glucose, as compared with 67% in 6 h in the case of FAA. Also, the maximal increase of citrate was registered at 24 h after poisoning with FAA, but at 6 h after poisoning with SFA. These and other biochemical data are

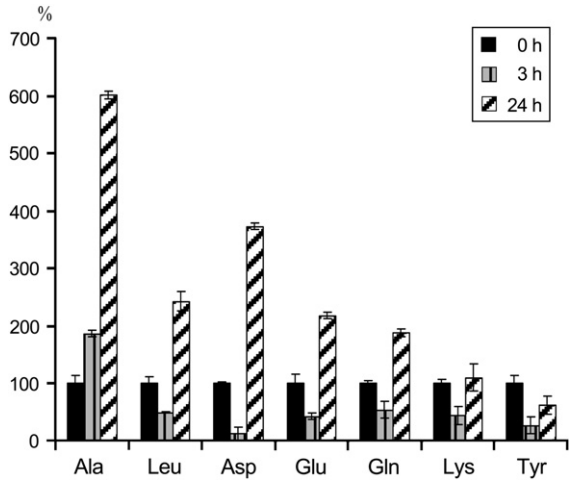

FIGURE 13.6. Changes of some amino acids in rat brain 3 and 24 h after administration of SFA at $1/2LD_{50}$.

consistent with clinical pictures of intoxication with equipotential doses of SFA and FAA: intoxication with SFA is generally more violent and takes a shorter period of time.

4. Effects of FA on the Cells of the Nervous System: Interaction of Glia and Neurons

Acetate is metabolized in astrocytes nearly 18 times faster than in cortical synaptosomes, though activity of acetyl-CoA synthase in synaptosomes is almost double that in astrocytes (5.0 and 2.9 nmol/min per mg of protein, respectively). The principal difference in the acetate metabolism rates is explained by differences in the kinetics of its transport, which is mediated by a monocarboxylate carrier (Hosoi *et al.*, 2004); acetate uptake by astrocytes, unlike synaptosomes, rapidly increases and follows saturation kinetics (V_{max} = 498 nmol/mg protein/min, K_M = 9.3 mmol/l) (Waniewski and Martin, 1998). Having penetrated into astrocytes at one site, FA can diffuse into other cells through gap junctions (Ransom, 1995). Citrate accumulating in astrocytes is readily released from cells and effectively penetrates other astrocytes (Westergaard *et al.*, 1994). The TCA cycle in nerve tissues is blocked by FA but not completely, only by 35–55% (Patel and Koenig, 1968). This leads to decreased consumption of glucose and increased consumption of glutamine (if the latter is available); no reduction of ATP was observed (Hassel *et al.*, 1994). The natural metabolic pathway is switched over to utilization of glutamine, glutamate, and 2-oxoglutarate in the TCA cycle. GDH of astroglia plays a big role in this switching over, promoting the ATP-independent utilization of glutamate (Plaitakis and Zaganas, 2001). The absence of an aspartate/glutamate mitochondrial exchanger (the key component of the malate/aspartate cycle) in astrocytes also plays in support of this (Xu *et al.*, 2007). There is little GDH in neurons as compared to astrocytes, with activity of GDH depending not only upon proximity to glutamatergic fibers and terminals, but also upon activity of neighboring neurons regardless of their functional specialization; a deficiency of GDH activity in astroglia may be a cause of cytotoxic effects of glutamate and aspartate (Aoki *et al.*, 1987).

The taking of glutamate by astrocytes is an electrogenic process in which one molecule of glutamate is cotransported with three sodium ions (or $2Na^+$ and $1H^+$), being exchanged for $1K^+$ and $1OH^-$ or $1HCO_3^-$ (Bouvier *et al.*, 1992). To re-establish the ionic balance, Na^+/K^+-ATPase would work with ATP provided by phosphoglycerate kinase bound to plasma membrane. This stimulates glycolysis and lactate production in astrocytes. Lactate is released from astrocytes and then taken by neurons to be further oxidized. Pyruvate, which is also produced in astrocytes, can be utilized in the TCA cycle to form 2-oxoglutarate or transaminated to form alanine; the latter can also enter neurons (Tsacopoulos and Magistretti, 1996; Tsacopoulos, 2002). However, the rate of alanine metabolism through alanine transaminase (ALT) in synaptosomes is much less than the rate of its uptake; moreover, neuronal ALT and AST work mainly to synthesize alanine and aspartate (Erecinska and Silver, 1990), hence a stable elevation of alanine level, in contrast to that of other amino acids, in brain of rats poisoned with SFA (Figure 13.6). The role of alanine as a source of glutamate is increased during the restoration period after ischemia/hypoxia, when alanine concentration is elevated and glutamate concentration is reduced.

Inhibition of glutamate uptake by astroglial cells can be one of the causes of convulsions observed under intoxication with FA (Szerb and Issekutz, 1987). The toxic effect is governed mainly by citrate, which chelates calcium ions (Fonnum *et al.*, 1997). Intrathecal injection of FC in mice caused convulsions in about 15 s, while in about 37 min by intracerebroventricular injection (Hornfeldt and Larson, 1990). Moreover, intrathecal injection of sodium citrate caused the same effect. This means that the main target of FC and citrate, and the area for generation of convulsions, should be the spinal cord. Convulsions could also be generated by other compounds having the common property of chelating calcium ions; these are EDTA, EGTA, glutamate, and lactate (Hornfeldt and Larson, 1990). Thus, along with elevation of citrate level, activation of anaerobic oxidation of glucose in neurons followed by accumulation of lactate in cerebrospinal fluid could also lead to coma and convulsions (Stewart *et al.*, 1970). Chelation of zinc and other divalent cations by citrate enhances the signaling activity of NMDA receptors (Westergaard *et al.*, 1995). In addition, disturbances of GABA metabolism were revealed as a result of the TCA cycle blockade: after injection of FA, there was initially an elevated level of GABA registered in different regions of the brain, followed by its reduction concurring with the beginning of clonicotonic convulsions (Maytnert and Kaji, 1962; Stewart *et al.*, 1970).

The convulsive state is aggravated by increasing the concentration of ammonia ions (Raable, 1981), an excess of which can lead to redistribution of K^+ and Cl^- ions, disturbances of neuronal depolarization and hyperpolarization, and impairment of post-synaptic inhibition. The neuron dysfunctions observed result in encephalopathy, ataxia, convulsions, and coma (Iles and Jack, 1980; Raable and Lin, 1983, 1984; Xiong and Stringer, 1999). On the other hand, FC affecting astroglia cause a drop in membrane potential and depolarization, and decrease of $[K^+]_i$ (Largo *et al.*, 1997); this should lead to compensatory transport of bicarbonate ions into astrocytes and acidification of the extracellular medium. Together with the natural carbonate acidification of the medium close to chemoceptors of the retrotrapezoid nucleus, this activates the diaphragmal nerve and increases the expired minute ventilation (Erlichman *et al.*, 1998; Holleran *et al.*, 2001): maximum ventilation is attained at 4% CO_2 against 8–10% in control hypercapnic trials. Control of extracellular pH in nervous tissue is coupled with functioning of the Na^+/HCO_3^- cotransporter, existing in plasma membrane of astrocytes but lacking in that of neurons (Deitmer, 1992; Romero and Boron, 1999). This transport has an electrogenic character, because two or

even three bicarbonate ions are transferred per one sodium ion. Again, however, a continuous supply of glutamine to the glutamatergic nerve terminals is the necessary condition of respiratory rhythm generation; blockade of the TCA cycle in astroglial cells with FA can impair the respiratory activity (Hulsmann *et al.*, 2000).

5. Physiology of Blood Vessels Under Intoxication with FA

FA does not affect circulation in resting organs, but a significant increase of blood flow can be seen in working respiratory muscles (Johnson and Reid, 1988). Conversely, a reduction of blood was registered in hepatic artery, and contractive activity of isolated portal veins was suppressed after introduction of FA into the medium (Liang, 1977). These data, along with data on the effects of FA on endothelial cells *in vitro*, suggested that endothelium of blood vessels could be one of the primary targets for FA. If so, the endothelium-dependent relaxation of blood vessels would be affected. To test the hypothesis, we administered SFA to rats subcutaneously at a dose of 2–3 mg/kg (LD_{50}–LD_{84}), and investigated endothelium-dependent relaxation of rat aorta 3 and 24 h after the poisoning. Norepinephrine in saturating concentrations induced a rapid constriction of aorta followed by a smooth transition to plateau; in contrast, vasoconstricting hormones angiotensin II, vasopressin and 5-hydroxytryptamine induced a bell-shaped vasoconstricting response of aorta. To assess the functional state of endothelium, carbocholine was introduced at 10^{-5}mol/l. Acting on muscarinic receptors of endothelial cells, it induced generation of nitric oxide and release of endothelium-derived hyperpolarizing factor (McCulloch *et al.*, 1997). All the agonists applied had similar effects on contraction of aortas obtained from control and poisoned animals (not shown here). The experiment clearly demonstrated that FA has no influence upon the contractile properties of isolated rat aorta at 3 and 24 h after poisoning. This endothelial function is not affected, at least directly, under intoxication with FA.

6. Body Temperature of Rats and Rabbits Under Intoxication with FA

One of the main pathophysiological features of intoxication with FA is decrease of the body core temperature of endotherms, which indicates a disturbance of heat production and/or regulation (Brockmann *et al.*, 1955; Taitelman *et al.*, 1983b; Misustova *et al.*, 1980). It is interesting to note that the effects of FC are comparable with those of selective inhibitors of p38 MAP-kinases (activation of which precedes production of pyrogens) and antagonists of cytokines TNF, IL-1, and IL-6 (Milligan *et al.*, 2001, 2003). In our experiments, following administration of lethal doses of SFA to male rats, a marked decrease of rectal temperature was registered beginning from 1 h after the poisoning and gaining minimal levels in 6 or 24 h depending on doses. Then a gradual increase in temperature took place in surviving rats, returning to normal in 2–7 days. For example, under intoxication with SFA at a dose LD_{50}, a minimal rectal temperature of the surviving male rats (31.5°C as compared to 38.5°C in control animals) was registered in 6 h, and 7 days after the poisoning the temperature was 1°C below the control level. Under intoxication with FAA at equipotential doses, a minimal rectal temperature of the surviving male rats (32.6°C as compared to 38.9°C in control animals) was registered in 2 days, and even 7 days after the poisoning the temperature was 3°C below control level. But we observed fewer changes of the rectal temperature in rabbits after s.c. administration of SFA at a dose LD_{50}: maximal decrease was only 1°C (38°C as compared to 39.1°C) in 6 h. According to our observations, decrease of the temperature below 38°C in 3 h can serve as a reliable sign forecasting the lethal outcome of the poisoned rabbits.

7. Electrophysiological Studies of FA Intoxication

Clinical analysis of ECG of rats poisoned with SFA or FAA (Kuznetsov *et al.*, 2007) revealed a similar dynamic of the temporal parameters of ECG, with slowing down and delay of the repolarization processes being the most important (Table 13.1). A drop in amplitudes of the atrial and ventricular ECG complexes can be observed within an hour after poisoning, followed by decrease of the systolic index in 24 h thus indicating an impairment of the contractile capacity of myocardium. Registration of ECG of rats which died in 2 days of intoxication with SFA revealed a sharp drop of heart rate (down to 120–180 per min) 24 h after poisoning, together with complete absence of the P wave which reflects atrial depolarization (Figure 13.7A). Simultaneous reduction of both amplitude and duration of the T wave can be seen. An upward shift of the ST segment, though not accompanied by growth of the T wave amplitude, was registered in 70% of rats (Figure 13.7B). The cumulative evidence of the shape and amplitude changes of the ECG waves indicates a development of acute myocardial ischemia, though a transient one and maximally expressed 24 h after poisoning. Reduction of the S wave amplitude could be caused by disturbances of excitation processes in basal ventricular regions and in some areas of the right vetricle. Taking into account an increase in duration and shape distortions of the ventricular complex, one cannot exclude an incomplete right bundle-branch block. A significant extension of the T wave during the course of examination is indicative of deceleration of the fast repolarization of myocardium, though the process of slow repolarization (the QT interval in ECG, corresponding to the systole of ventricles) is accelerated within 3–24 h after poisoning.

Respiratory rhythm was gradually increased in rats under intoxication with SFA, and there were additional respiratory components in 50% of animals 24 h after administration of the poison (Figure 13.8) that may indicate disturbances of innervation of respiratory muscles. Spectral analysis of the

respiratory curve demonstrated that there was an enhanced synchronization of the respiratory rhythm observed within 3 h after poisoning. Simultaneously, the amplitude of respiration increased followed by a gradual decrease to the third day. Over the same period, a certain reduction of lability of respiratory rhythm was noted, accompanied by the appearance of two distinct peaks corresponding with frequencies of 90 and 120 cycles of respiration per minute. By the seventh day, the respiratory spectrogram was similar to the initial one, though the frequency of respiration was not completely restored. Comparison of spectrograms of respiration and ECG demonstrates disturbances of control mechanisms underlying generation of the second-order waves (respiratory arrhythmia visible at the spectrogram as a peak in the high-frequency region 0.8–2.5 Hz). One day after administration of SFA, there was a marked frequency

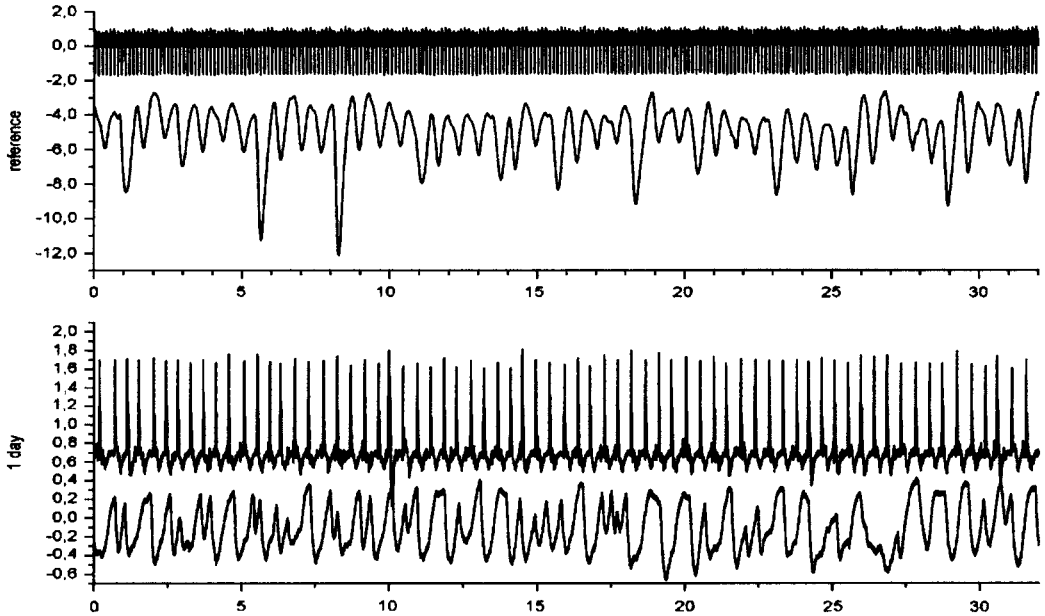

FIGURE 13.8. Records of ECG (upper) and respiratory rhythm (lower) from a narcotized rat before and 24 h after introduction of SFA.

maximum at the respiratory spectrum, in contrast to that of the ECG spectrogram.

Analysis of the heart rate variability (HRV) demonstrates that 1 h after poisoning an enhancement of parasympathetic influence took place, and this was accompanied by insignificant and paradoxical enhancement of heart and respiratory rates (Table 13.2). Then against a background of enhancement of humoral (metabolic) and sympathetic influences and simultaneous decline of parasympathetic influence, a stable decrease of heart and respiratory rates took place indicating a prominent divergence between vagosympathetic balance and resulting physiological parameters. Previously it was shown in experiments with dogs that systemic, pulmonary, and coronary hemodynamic parameters during the first hours after introduction of FA were not mediated by the autonomic nervous system and adrenergic neuromediators (Liang, 1977). This is in partial agreement with our results obtained with rats, though this cannot be extrapolated to all the periods of intoxication and all animal species.

V. TOXICITY AND RISK ASSESSMENT

A characteristic feature of the clinical picture of intoxication with FA is a latent period of 0.5 to 6 h (Egekeze and Oehme, 1979). The duration of the latent period depends on animal species' metabolism and dose administered (Chenoweth, 1949; Goncharov *et al.*, 2006). A broad variability of clinical manifestations of FA effects in different animal species is one of its characteristic features. There is a correlation between food specificity and toxic effect of FA; the cardiovascular system is mainly affected in herbivores, while the CNS is mainly affected in carnivores. According to this, four groups were recognized in terms of clinical signs of intoxication (Chenoweth and Gilman, 1946). The first comprised herbivores (rabbits, goats, sheep, cattle, and horses), in which FA induced ventricular fibrillation without notable CNS disorders (Marais, 1944; Chenoweth, 1949; Egekeze and Oehme, 1979). The second group comprised dogs and guinea pigs, in which the CNS was primarily affected. In dogs, a species highly sensitive to FA, symptoms of secondary intoxication appear after a latent period of 1 to 10 h (Chenoweth and Gilman, 1946; Egyed and Shupe, 1971). For animals of the third group the clinical pattern of intoxication is similar to that of the second group of animals, but slightly less pronounced. This group comprised rats and hamsters relatively tolerant to FA. After a latent period lasting 1–2 h, tremor and elevated excitability were common symptoms. Death usually occurred within 4–6 h as a result of respiratory depression, after exposure to high FA doses (Chenoweth and Gilman, 1946; Pattison, 1959). The surviving animals demonstrated depression, weakness, ataxia, and strongly pronounced bradycardia down to 30 heartbeats per minute. At sublethal doses of FA, a full recovery can occur in 72 h after poisoning (Chenoweth and Gilman, 1946; Pattison, 1959). A mixed response to FA exposure was described in animals of the fourth group – cats, pigs, and rhesus monkeys; it included disturbances of both CNS and cardiovascular system. On acute poisoning, adynamia, salivation, vomiting, frequent defecation, pupil dilatation, nystagmus, accelerated respiration, enhanced excitability, tremor, and clonicotonic convulsions were observed in these animals (Chenoweth and Gilman, 1946; Gammie, 1980).

This classification has been revised recently (Sherley 2004). The division of animals into cardiac and neurological symptomatic groups is considered to be unnatural as it ignores common neurological signs manifested in all the groups: among these are tremor, ataxia, hypersensitivity, myotonic convulsions, weakness, and partial paralysis. The cardiac response in a pure form was not a common event and was described just for a limited number of animals, though CNS involvement is obviously widespread.

As for humans, exposure to stock solution during formulation and dermal or respiratory exposure during application of baits, as well as accidental or intentional acute intoxications, are the main human health concerns. Formulators and pest control workers are the largest occupational risk group (Norris, 2001). The clinical picture of acute intoxication of humans is similar to that of rhesus monkeys, and among the symptoms are nausea, vomiting, abdominal pains, salivation, irrational fear, weakness, tachypnoe, cyanosis, and sometimes sweating and increased temperature (Brockmann *et al.*, 1955; Pattison, 1959; Arena, 1970; Taitelman *et al.*, 1983b). Psychomotor agitation and sometimes a loss of spatiotemporal feeling can occur. In addition, tremor, nystagmus, involuntary dejection and urination, muscle spasms, hypertonus of the extremities, and even alalia, have been reported (Gajdusek and Lutheer, 1950; Harrison *et al.*, 1952; Robinson *et al.*, 2002). The most characteristic signs of intoxication involve generalized recurrent convulsions alternating with deep depression. Sudden loss of consciousness and coma may occur. These symptoms were associated with metabolic acidosis and hypotension (Pattison, 1959; Chi *et al.*, 1996, 1999), as well as cardiac rhythm disturbances, such as tachycardia, bradycardia, asystolia, and sustained ventricular fibrillations (Gajdusek and Lutheer, 1950; Reigart *et al.*, 1975; Trabes *et al.*, 1983). Death usually occurs in 3 h to 5 days of heart block, arrhythmia, or respiratory failure (Reigart *et al.*, 1975; Montoya and Lopez, 1983). Important diagnostic symptoms registered with ECG are arrhythmia, the QT and ST intervals, and the T wave (Pattison, 1959; Taitelman *et al.*, 1983b; Chi *et al.*, 1996). Kidneys are among the most sensitive organs: acute renal failure associated with uremia and increased level of creatinine in serum can be observed under acute FA poisoning (Chung, 1984; Chi *et al.*, 1996). Pathomorphological abnormalities of humans poisoned with FA are also nonspecific and similar to those of animals. In the case of lethal outcome, petechial hemorrhages and excess blood filling of internal organs (Hayes, 1982), edema

of lungs and brain, and sometimes mediastenal emphysema and acute inflammatory reaction with coagulating necrosis in esophagus were registered in humans (Brockmann *et al.*, 1955). The morphological basis of cardiotoxic effects is acute myocardial dystrophy, a characteristic of which is diffuse lesions of cardiac muscle (Pattison, 1959; Taitelman *et al.*, 1983b). Acute renal failure develops due to the influence of FA on subcellular structures of kidneys. Metabolic acidosis aggravates the clinical course of renal failure. Diffuse degeneration of renal tubules was observed (Hayes, 1982). For cases that lack clinical and morphological specificity, biochemical data and primarily citrate and fluoride levels can be used for diagnostic purposes (Pattison, 1959; Schultz *et al.*, 1982). Thus under acute intoxication with FAA, citrate (108 μg/g in heart and 23.9 μg/g in kidney) and fluoride (6.3 mg/g dry weight of heart and kidney) were found in human corpse; the dose of FAA was estimated to be near 23 mg/kg (Hayes, 1975). In addition, the indubitable diagnostic confirmation of the intoxication should be based on determination of the poison in tissues. Under acute SFA poisoning with lethal outcome, FA was found in urine (368 μg/ml), liver (58 μg/g), and brain (76 μg/g) (Harrison *et al.*, 1952).

Among the after-effects that develop after acute intoxication with FA are various neurological disturbances: impaired muscular tonus and reflex activity, and transient spasmodic and meningeal syndromes. Long after an acute poisoning (from 1.5 to 9 years) a tendency for epileptoid seizures, ataxia, extremity muscular hypertension, spastic tetraplegia, blindness of cortical origin, diffuse brain atrophy, and psychic disorders were observed (Pridmore, 1978; Trabes *et al.*, 1983). A case of chronic intoxication with FA of a farm worker has been described (Parkin *et al.*, 1977): the clinical signs were renal insufficiency and less pronounced injuries of other organs.

VI. TREATMENT

Decades of studies on the toxicology of FA have led scientists to the conclusion that treatment of intoxications can be successful only if timely general and symptomatic therapy is applied, but not specific antidotes (Dorman, 1990; Norris, 2001). Much experimental work over an extensive period has been undertaken in an effort to find effective donors of acetate groups, because of their ability to inhibit conversion of FA to FC. Ethanol, monoacetin (glycerol monoacetate), acetamide, and cortisone acetate were tested for their potency to serve as antidotes (Hutchens *et al.*, 1949; Chenoweth, 1949; Cole *et al.*, 1955; Giller, 1956; Egyed, 1971; Egyed and Shlosberg, 1977). Therapeutic effect was revealed for simultaneous introduction of ethanol and acetate (Hutchens *et al.*, 1949; Tourtelotte and Coon, 1949). Negative effects of monoacetin and acetamide were enhancement of hyperglycemia and metabolic acidosis, damage to capillaries and hemolysis of red blood cells, and increase of citrate concentration in different organs (Engel *et al.*, 1954; Egyed and Shlosberg, 1973). Administration of cortisone acetate inhibited the FC synthesis and prevented development of ketosis, though increased hyperglycemia (Cole *et al.*, 1955).

Several antidotes were tested for their capacity to activate transport of the TCA cycle intermediates through mitochondrial membranes. For this purpose fluoromalate was proposed, though any positive result was negligible (Peters *et al.*, 1972). Malate was also tested, but proved to be effective only in *in vitro* experiments (Buffa *et al.*, 1972). Also *in vitro*, glutathione and a series of SH-containing compounds (cysteamine and *N*-acetylcysteine) were tested (Mead *et al.*, 1985). However, they were incapable of replacing glutathione in enzymatic defluorination of FA and have not found practical application. TCA cycle intermediates (succinate, malate, citrate, and glutamate) were tested, but did not exhibit protective effect (Hutchens *et al.*, 1949). A positive result was observed in experiments with mice, which were administered calcium gluconate and succinate (Omara and Sisodia, 1990). This therapy was hardly more effective than ethanol. Some 16 years later another research group tested the therapy with cats, which are known to be much more sensitive to FA. Again, differences in survival between treated and nontreated animals were not significant ($p > 0.05$) (Collicchio-Zuanaze *et al.*, 2006). Administration of calcium chloride to cats under acute intoxication with FA made it possible to postpone their death by up to 166 min combination of calcium chloride with monoacetin gave a similar effect (Taitelman *et al.*, 1983a). Nevertheless, calcium chloride caused reduction of the QT interval and favored survival of humans in case of their intoxication with FAA (Taitelman *et al.*, 1983b).

Our strategy for development of therapeutic means of treating acute FA intoxication was based on a deep analysis of the biochemical literature, together with our own experimental data. Thus, a high sensitivity of aconitase to inhibition by superoxide anion and nitric oxide (Gardner *et al.*, 1994; Andersson *et al.*, 1998; Castro *et al.*, 1998) means that ROS and NO could be competitive antagonists of FC to avert its effect on aconitase. Also, as considered earlier, during FA intoxication glutamate could be utilized in the TCA cycle through GDH or transaminases (Yu *et al.*, 1976; Liang, 1977; Hassel *et al.*, 1994). Moreover, the effects of FC could be prevented by prior introduction of isocitrate (bypass of inhibited aconitase) and fructose-1,6-bisphosphate (energy substrate for neurons) (Lian and Stringer, 2004).

We have demonstrated that FA can adversely affect mitochondrial functions only if pyruvate was available as respiratory substrate, and that changes of redox-state of pyridine nucleotides (PN) or their leakage from MCh could be critical factors that impair mitochondrial respiration and lead to cell death (Zinchenko *et al.*, 2007). Opening of the mitochondrial pore is a reversible phenomenon: prevention of oxidation and/or leakage of NADPH from MCh can

restore the normal functional state of MCh. For example, when succinate or glutamate was used as a respiratory substrate, mitochondrial functions were not affected by FA (Figure 13.3A).

As for other alternative substrates, we suggest that the accumulating intracellular citrate could be one of them. As discussed earlier, blockade of citrate transport from MCh under FA intoxication is not an obligatory event, and citrate can enter cytosol to be further utilized by cICDH (Max and Purvis, 1965; Buffa *et al.*, 1972). The cICDH activity is almost equally distributed between cytosol and MCh of astroglia and microglia, whereas cICDH accounts for about 75% of activity in neurons and oligodendrocytes (Minich *et al.*, 2003). We have not found data on the ratio of mitochondrial and cytoplasmic aconitases in cells of the nervous system, but it is interesting to note that a similar ratio of m- and cICDH exists in hepatocytes (Rakhmanova and Popova, 2006), and that c-aconitase accounts for 65% of the aconitase in these cells (Konstantinova and Russanov, 1996). In rat heart a similar ratio of m- and c-aconitases has been revealed: 35 and 65%, correspondingly (Medvedeva *et al.*, 2002). Based on these data, one may suggest that an effective pathway for citrate utilization and NADPH synthesis exists in these (and other) cells in case of inhibition of m-aconitase. This alternative pathway could play a positive physiological role because NADPH might be used for anabolic reactions and heat generation, glutathione reduction and NO synthesis, and regulation of blood vessel tone by means of ROS generation (Winkler *et al.*, 1986; Bobyleva *et al.*, 1993; Lee and Yu, 2002; Gupte and Wolin, 2006). As was pointed out earlier, studies focused on the pentose cycle as the main source of NADPH need to be re-evaluated taking into consideration the metabolic activity and substrate specificity of a tissue (Winkler *et al.*, 1986). cICDH along with malic enzyme and transhydrogenase participates in NADPH regeneration to further reduce glutathione in brain mitochondria (Vogel *et al.*, 1999), but cICDH can provide a seven-fold greater generation of NADPH as compared to malic enzyme (Winkler *et al.*, 1986). The level of cytoplasmic NADPH can influence potassium channels and calcium balance (Wolin *et al.*, 2005; Gupte and Wolin, 2006). In our *in vitro* studies, FA induced a slow elevation of $[Ca^{2+}]_i$ in different cells (Zinchenko *et al.*, 2007). This could indicate an activation of the SOC channels; the process is not affected by FA and does need ATP to be implemented, at least in glial cells (Lian and Stringer, 2004). We suppose this mechanism to be common for many types of cells, and this could explain a primary hypersensitivity of platelets exposed to FA (Mindukshev *et al.*, 2006). In cardiomyocytes, elevated $[Ca^{2+}]_i$ can stimulate their functional activity observed in our experiments *in vitro* and also supported *in vivo* by a primary increase of systolic index (Table 13.1). As for modulating effects of Ca^{2+} on bioenergetics of MCh, it is pertinent to recall ''classic'' activation of the TCA cycle dehydrogenases followed by increase of mitochondrial potential and NADH generation: 2-oxoglutarate dehydrogenase (OGDH) and mICDH can be activated by calcium ions through allosteric mechanisms and pyruvate dehydrogenase is activated due to dephosphorylation by the Ca^{2+}-dependent phosphatase (McCormack *et al.*, 1990; Hansford, 1994). The exact role of these dehydrogenases in the bioenergetic status of MCh affected by FA needs to be clarified, though one can suppose that OGDH could derive a special benefit from such an activation if it is provided with exogenic or endogenic 2-oxoglutarate.

TABLE 13.3. Assessment of therapeutic effectiveness of METIS preparations under acute intoxication of rats with SFA

Therapy	Index of therapeutic efficiency: Ratio LD_{50} treated/LD_{50} nontreated
Ethanol, $n = 42$	**1.6**
METIS-1, $n = 48$	**2.5**
METIS-2, $n = 92$	**3.3**
METIS-4, $n = 39$	**4.3**

n – number of animals used in experiment to calculate the index

According to the above discussion, we have defined several directions for biochemical correction under acute intoxication with FA and suggested suitable preparations for therapeutic complexes: (1) competitive inhibition of FA and CoA interaction; (2) competitive inhibition of FC and aconitase interaction; (3) replenishment of the TCA cycle distally of aconitase; (4) utilization of accumulating citrate. In a previous publication we presented the first data on effectiveness of a therapeutic complex named METIS (Goncharov *et al.*, 2006). Further experiments proved the validitity of the therapeutic approach, and we have now appreciably enhanced the efficacy of the complex (Table 13.3). In addition to these data on the index of therapeutic effect, a spectrum of physiological and biochemical data was obtained. Animals treated with METIS complex had little changes of body weight, temperature, and oxygen consumption. Dynamics of citrate in brain, kidneys, and blood was also improved, and kinetic parameters of platelet aggregation were corrected. Comparative analysis of the FA level in tissue homogenates, blood plasma, and urea of rats revealed that the METIS complexes reduced the level of FA in brain almost two-fold, thus indicating inhibition of FA utilization first of all in the cells of the nervous system.

VII. CONCLUDING REMARKS AND FUTURE DIRECTION

The extreme toxicity of FA is determined by its similarity to acetate, which has a central role in cell metabolism. FA enzymatically condenses with CoA-SH to produce

fluoroacetyl-CoA, which replaces acetyl-CoA entering the TCA cycle and produces FC. The latter reacts with aconitase and blocks the TCA cycle. Energy production is reduced, as well as concentration of metabolites generated distally to aconitase. 2-Oxoglutarate is the most important of them, being a precursor of glutamate, which is a neuromediator in the CNS and participates in neutralizing ammonia either directly through glutamine synthase or indirectly through the urea cycle. Accumulation of citrate is one of the causes of metabolic acidosis. Chelating of Ca^{2+} is apparently one of the central events in pathogenesis of intoxication.

The first papers on toxicology of FA were published in the 1940s. The long history of investigations was fruitful, with several important discoveries: biochemical mechanism of ''lethal synthesis''; structure of aconitase; functional relations of glia and neurons; and switching of metabolic pathways. However, the main problem of toxicology (for any poison) was not solved – development of an effective therapy. Analysis of the scientific literature has demonstrated that reciprocal relations of signaling and metabolic pathways under intoxication with FA are unclear. Inhibition of m-aconitase causes blockade of TCA cycle, reduction of pyridine nucleotides, accumulation of citrate, disturbances of intracellular signaling, deenergization, and cell death. However, the dynamics and significance of these events are different depending of the type of cells and tissues, which is why it is very difficult to predict the primary reaction of different cells and more so the whole organism.

Biochemical pathways underlie the basis of physiological rhythms; they should have a certain space–time structure and presuppose coordinated interactions of different cells. Thus, one of the causes of disturbances of normal respiration under FA intoxication could be disturbances in rhythmic activity of respiratory neurons; but suppression of these neurons is a consequence of the inhibiting effect of FA on astrocytes, not neurons (Hulsmann *et al.*, 2000). We described development of cardiac and respiratory tachyarrhythmias reflecting reproduction of decasecond rhythms characteristic for immature or abnormal excitatory structures (Kuznetsov *et al.*, 2007). Previously, it was suggested that such endogenic rhythmic activity could be determined by the level of the pentose cycle activity (Kuznetsov, 1999, 2002). This cycle indeed plays an important role in neurons, protecting them from oxidative or traumatic stress (Ben-Yoseph *et al.*, 1994; García-Nogales *et al.*, 2003; Bartnik *et al.*, 2005). However, it should be noted that although the activity of NADPH-generating enzymes of the pentose cycle in astrocytes (glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase) is 2–3 times higher than in brain as a whole, the activity of cICDH is also very high in these cells (Rust *et al.*, 1991). This metabolic pathway is interesting primarily because under FA intoxication citrate is accumulated, and the pathway may be regarded as a form of biochemical adaptation that facilitates utilization of the central metabolite. Modern data suggest that spatial and temporal division of m- and c-aconitases not only provides regulation of iron balance in cells, but actually provides regulation of balance between catabolic and anabolic processes (Tong and Rouault, 2007).

Providing the cells have utilized citrate entering cytosol, another problem should be utilization of generating NADPH. One possible and very important mechanism of PN oxidation is heat generation through shiver and nonshivering thermogenesis. Rise in activity of NADPH-generating enzymes and pathways, including c-aconitase and cICDH, is accompanied by enhanced thermogenesis (Bobyleva *et al.*, 1993). It was shown that NADPH could be used together with or even instead of NADH as a reducing cofactor for cytoplasmic glycerophosphate dehydrogenase (Bobyleva *et al.*, 1993; Fahien *et al.*, 1999). But if the role of this pathway for transferring electrons from cytoplasma to MCh in skeletal muscles is rather clear, then the level of activity and functional state of glycerophosphate shuttle in brain cells are contradictory and serve as a subject for discussion. Activity of glycerophosphate shuttle in brain is explained by the need for glycerol-3-phosphate as a substrate for phospholipid synthesis in oligodendroglia (Adler and Klucznik, 1982; Nguyen *et al.*, 2003). In neurons and astrocytes, the activity of glycerophosphate dehydrogenases is much lower than in oligodendrocytes (Rust *et al.*, 1991; Nguyen *et al.*, 2003). There are data, however, that indicate an important role of this shuttle in astrocytes, taking into consideration (1) the absence of malate–aspartate shuttle in these cells (Waagepetersen *et al.*, 2001; McKenna *et al.*, 2006), and (2) the elevated level of mRNA of cICDH in astrocytes after convulsions, under exposure to morphine, indometacine, and some other preparations (Link *et al.*, 2000). In conclusion, we suggest that future progress in toxicological studies of FA and development of effective therapy will depend on comprehensive consideration of these and other modern data, together with reevaluation of old and forgotten data.

CHAPTER 14

Strychnine

JIRI PATOCKA

I. INTRODUCTION

Strychnine is a poisonous alkaloid of indole type found in the genus *Strychnos*. It is a basic compound which forms colorless or white rhombic crystals. The compound has a bitter taste and melts at around 290°C. Strychnine was the first alkaloid to be identified in plants of the genus *Strychnos*, Family Loganiaceae. *Strychnos*, created by Linnaeus in 1753, is a genus of trees and climbing shrubs of the gentian order. The genus contains 196 various species and is distributed throughout the warm regions of Asia (58 species), America (64 species), and Africa (75 species). Plants of the genus *Strychnos* have opposite leaves and bear cymes of white or yellowish flowers that have a four-lobed or five-lobed calyx, a four-parted or five-parted corolla, five stamens, a solitary pistil and bear fruit in the form of a berry. The seeds and bark of many plants in this genus contain the powerful poison strychnine. Strychnine is obtained commercially from the seeds of the Saint-Ignatius' bean (*Strychnos ignatii*) and from the nux-vomica tree (*Strychnos nux-vomica*) (Volfova and Patocka, 2003). Strychnine was first discovered by French chemists Joseph-Bienaime Caenoiu and Pierre-Joseph Pelletier in 1818 in the Saint-Ignatius' bean. In some *Strychnos* plants a 9,10-dimethoxy derivative of strychnine, alkaloid brucine, is also present (Li *et al.*, 2006). Brucine is not as poisonous as strychnine.

II. BACKGROUND

A. Chemistry and Physicochemical Properties

Strychnine has a molecular formula of $C_{21}H_{22}N_2O_2$ and its structural formula is shown in Figure 14.1. CAS No: 57-24-9 (base), 60-41-3 (sulfate). It occurs as white crystals or powder, odorless, with a melting point of 286°C, boiling point 270°C at 5 mm Hg, density 1.36 g/cm^3, vapor density 11.0 (air = 1) and vapor pressure 0 torr at 20°C (Mackison *et al.*, 1981). Strychnine is a stable compound and incompatible only with strong oxidizing agents.

Water solubility of strychnine is negligible, only 160 mg/l at 25°C; the pH of saturated solution is 9.5. The octanol/water partition coefficient (logK_{ow}) is 1.93 (Hansch *et al.*, 1995). Strychnine is very slightly soluble in ether, slightly soluble in benzene, ethanol (6.7 g/cm^3), and acetone, and soluble in chloroform and pyridine (Budavari, 1996).

B. History

The toxic and medicinal effects of strychnine have been well known from the times of ancient China and India. The inhabitants of these countries had ancestral knowledge of the species nux vomica and Saint-Ignatius' bean. The species *Strychnos nux-vomica* is a tree native to Indonesia which attains a height of 12 m. The tree has a crooked, short, thick trunk and the wood is close grained and very durable. The fruit is an orange color about the size of a large apple with a hard rind and contains five seeds, which are covered with a soft wool-like substance. The ripe seeds look like flattened disks, which are very hard. These seeds are the chief commercial source of strychnine and were first imported to and marketed in Europe as a poison to kill rodents and small predators. *Strychnos ignatii* is a woody climbing shrub of the Philippines. The fruit of the plant contains as many as 25 seeds embedded in the pulp. The seeds contain more strychnine than other commercial alkaloids. The properties of nux-vomica and Saint-Ignatius seeds are substantially those of the alkaloid strychnine.

Strychnine was discovered and identified as the main toxic principle of *Strychnos* in 1818, although *nux vomica*, the unpurified plant extract in which it is the active component, had been known and used for both medicinal and criminal purposes for some time. Historic records indicate that the strychnine alkaloid had been used to kill dogs, cats, and birds in Europe as far back as 1640. The structure of strychnine was first determined in 1946 by Sir Robert Robinson and in 1954 this alkaloid was synthesized in a laboratory by Robert W. Woodward. This is one of the most famous syntheses in the history of organic chemistry. Both chemists won the Nobel prize (Robinson in 1947 and Woodward in 1965).

C. Therapeutic Purpose

Strychnine does have a history of use for therapeutic purposes, although in most cases this was entirely misguided, and not a little dangerous. It has a very bitter taste and so

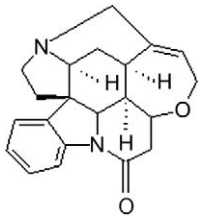

FIGURE 14.1. Chemical structure of strychnine.

stimulates salivary and gastric secretion. This increases appetite, and was used to counteract the loss of appetite associated with illness, giving the impression that strychnine had restorative properties. In fact, any constitutional improvement resulting from the increased appetite would probably be outweighed by the harmful effects of strychnine, and the underlying illness would be more or less unaffected. This is the same mechanism that gives tonic water its apparent ''tonic activity'', although in that case the bitter agent is quinine, which is much less dangerous.

Strychnine has an undeserved reputation as a useful therapeutic agent. There is no current justification for its presence in any medication. However, preliminary experimental reports suggest that judicious treatment with strychnine may modify the neurological deterioration in some infants with nonketonic hyperglycinemia, a rare metabolic disorder characterized by abnormally high concentrations of glycine in the brain and cerebrospinal fluid. Strychnine was used as a tonic stimulant for atonic constipation and as a stomachic and bitter. It produces no selective gastrointestinal effects and has no place in the therapy of any gastrointestinal disorder. At present, strychnine has no demonstrated therapeutic value in human medicine, despite a long history of unwarranted popularity. It was first employed in medicine in 1540, but did not gain wide usage until 200 years later (Gilman *et al.*, 1985).

Although strychnine was earlier used extensively in animals, it no longer has a rational place in the therapeutic armamentarium of the veterinarian. Its only interest is from a veterinary toxicology standpoint because animals are sometimes poisoned inadvertently or intentionally (Booth and McDonald, 1982).

III. PHARMACOKINETICS AND TOXICOKINETICS

A. Absorption, Distribution, Metabolism and Excretion

Strychnine is rapidly absorbed from the gastrointestinal tract, mucous membranes, and parenteral sites of injection (Thienes and Haley, 1972) and also from the oral cavity (LaDu *et al.*, 1971). A nonfatal case of strychnine poisoning through dermal exposure is also described (Greene and Meatherall, 2001). Strychnine is transported by plasma and erythrocytes, but protein binding is slight and distribution to the tissues rapidly occurs. Within a few minutes of ingestion, strychnine can be detected in the urine, and excretion by that route accounts for about 15% of sublethal (4 mg) dose over 6 h. Little difference was noted between oral and intramuscular administration of strychnine with a 4 mg dose. Blood levels in human poisoning were less than 0.5 μg/ml from 1 to 48 h following ingestion a sublethal dose (700 mg), 2.7 μg/ml in a patient who survived the acute episode, and 40 μg/ml in a patient who died following a massive ingestion (Haddad and Winchester, 1983). In persons killed by strychnine, the highest concentrations are found in the blood, liver, and kidney (Hayes and Laws, 1991).

The half-life of absorption is about 15 min and the half-life of metabolism is about 10 h. The apparent volume of distribution in one patient was 13 l/kg (Ellenhoorn *et al.*, 1997).

Strychnine is rapidly metabolized by the liver microsomal enzyme system requiring NADPH and O_2. Five metabolites formed *in vitro* by rabbit liver were isolated and identified as 2-hydroxystrychnine, 11,12-dehydrostrychnine, strychnine-21, 22-epoxide, 21,22-dihydroxy-22-hydrostrychnine, and strychnine-N-oxide which was the major metabolite and accounted for approximately 15% of the metabolized strychnine. All other metabolites accounted for less than 1% (Mishima *et al.*, 1985). Similar metabolites were identified in rat urine where the major metabolite was strychnine-21,22-epoxide (Oguri *et al.*, 1989). The metabolic fate of strychnine in humans is unknown.

B. Toxicokinetics

Strychnine competes with the inhibitory neurotransmitter glycine producing an excitatory state characterized clinically by hyperreflexia, severe muscle spasms, and convulsions. However, the toxicokinetics after overdose have not been well described. In most severe cases of strychnine poisoning, the patient dies before reaching the hospital (Shadnia *et al.*, 2004).

Palatnick *et al.* (1997) described a case of a 34-year-old male presented to the emergency department 20 min after ingesting 125 ml of 2% strychnine sulfate (2.25 g). He was alert and oriented and experiencing muscle spasms. His condition deteriorated prompting sedation, muscle paralysis, and tracheal intubation. He was given activated charcoal 100 g per nasogastric tube. He was admitted to intensive care where he was managed with diazepam, pentobarbital, and pancuronium. Despite mild rhabdomyolysis, he recovered and was extubated on day three. Although receiving prophylactic heparin therapy, a massive fatal pulmonary embolus ensued. Eighteen blood specimens for strychnine analysis were obtained from 20 min to 51 h after ingestion. Serum concentrations were determined with gas chromatography–mass spectroscopy. Disappearance followed a first-order process with a $t_{1/2}$ of 16 h. Results confirmed the findings of an earlier case report of

19 strychnine levels obtained between 4 and 19 h which described first-order kinetics with a $t_{1/2}$ of 10–16 h (Palatnick *et al.*, 1997).

In a case report of Wood *et al.* (2002) a 42-year-old man ingested an unknown quantity of strychnine powder. Eight serum samples were taken over the first 5 days and analyzed subsequently for strychnine concentrations. The initial concentration at 1.5 h after ingestion was 4.73 mg/l, falling to 0.38 mg/l at 74 h post-ingestion. Serum concentrations followed a monoexponential elimination curve with a calculated elimination half-life of 12 h. The initial serum concentration of 4.73 mg/l is the highest reported concentration in a patient who has survived.

IV. MECHANISM OF ACTION

Strychnine acts as a blocker or antagonist at the inhibitory or strychnine-sensitive glycine receptor, a ligand-gated chloride channel in the spinal cord and the brain (Song *et al.*, 2006). The glycine receptor is the receptor for the amino acid neurotransmitter glycine (Rajendra *et al.*, 1997). It is one of the most widely distributed inhibitory receptors in the central nervous system. Strychnine-sensitive glycine receptor is a member of a family of ligand-gated ion channels. This ionotropic receptor can be activated by a range of simple amino acids, except glycine, β-alanine and taurine, and can be selectively blocked by the high-affinity competitive antagonist strychnine. The receptor is arranged as five subunits surrounding a central pore, with each subunit composed of four α helical transmembrane segments. There are presently four known isoforms of the α subunit (α_{1-4}) of GlyR that are essential to bind ligands and a single β subunit. The adult form of the glycine receptor is the heteromeric $\alpha_1\beta$ receptor, which is believed to have a stoichiometry of three α_1 subunits and two β subunits or four α_1 subunits and one β subunit (Kuhse *et al.*, 1993, 1995). The strychnine-binding subunit of the glycine receptor shows certain homology with nicotinic acetylcholine receptors (Grenningloh *et al.*, 1987). The glycine receptor is highly enriched in microdomains of the post-synaptic neuronal surface apposed to glycinergic afferent endings. There is substantial evidence suggesting that the selective clustering of glycine receptors at these sites is mediated by the cytoplasmic protein gephyrin (Meier *et al.*, 2000).

V. TOXICITY

Strychnine has been placed in Toxicity Category I, indicating a high degree of acute toxicity, for oral and ocular effects. Inhalation toxicity is also presumed to be high. Acute toxicity of strychnine to birds is very high. Mammalian studies indicate that strychnine is very highly toxic to small mammals on both an acute oral basis and a dietary basis. The extent of poisoning caused by strychnine depends on the amount and route of strychnine exposure, time of exposure, and in humans the person's condition of health. The signs of toxicity, including death, usually occur within 1 h.

A. Animal Toxicity

Reported toxic doses of strychnine by different routes of adinistration in some animals and humans are summarized in Table 14.1.

Strychnine toxicity in rats is dependent on sex. It is more toxic to females than to males when administered s.c.or i.p. and differences are due to higher rates of metabolism by male rat liver microsomes (Parke, 1968). Dogs and cats are more susceptible among the domestic animals, pigs are believed to be as susceptible as dogs, and horses are able to tolerate relatively larger amounts of strychnine (Humphreys, 1988). Birds affected by strychnine poisoning exhibit feathers fluffed or held tightly against the body, ataxia, wing droop, salivation, tremors, muscle tenseness, and convulsions. Death occurs as a result of respiratory arrest.

The clinical signs of strychnine poisoning relate to its effects on the central nervous system. The first clinical signs of poisoning include nervousness, restlessness, twitching of the muscles, and stiffness of the neck. As the poisoning progresses, the muscular twitching becomes more pronounced and convulsions suddenly appear in all the skeletal muscles. The limbs are extended and the neck is curved to opisthotonus. The pupils are widely dilated. As death approaches, the convulsions follow one another with increased rapidity, severity, and duration. Death results from asphyxia due to prolonged paralysis of the respiratory muscles (Humphreys, 1988). Following the ingestion (swallowing) of strychnine, symptoms of poisoning usually appear within 15 to 60 min.

B. Human Toxicity

People exposed to low or moderate doses of strychnine by any route will have the following signs or symptoms: agitation, aprehension or fear, ability to be easily startled, restlessness, painful muscle spasms possibly leading to fever and to kidney and liver injury, uncontrollable arching of the neck and back, rigid arms and legs, jaw tightness, muscle pain and soreness, difficult breathing, dark urine, and initial consciousness and awareness of symptoms. The reported medium lethal doses of strychnine in humans range from 5 to 120 mg/kg.

There are some cases of human poisoning. A 46-year-old man presented 2 h after ingestion of about 250 mg strychnine eperienced severe violent, generalized convulsions, triggered by external stimuli. During the convulsion-free periods, there were no abnormal signs in the physical examination (Scheffold *et al.*, 2004). A 28-year-old man was admitted 2 h after ingestion of 1 to 1.5 g of strychnine. He was severely agitated and in mild respiratory distress; his blood pressure was 90/60 mm Hg, pulse 110/min, and

TABLE 14.1. Toxicity values (LD_{50}) of strychnine in humans and animals

Organism	Route	LD_{50} (mg/kg)	Source

RTECS – Registry of Toxic Effects of Chemical Substances

peripheral pulses weak. He had generalized hyperactive reflexes and had several generalized tonic–clonic convulsions in the emergency department. Treatment consisted of gastric lavage with water, oral administration of activated charcoal and sorbitol solution, continuous intravenous administration of midazolam, and then sodium thiopental, furosemide, sodium bicarbonate and hemodialysis for acute renal failure. His clinical course included respiratory distress, agitation, generalized tonic–clonic convulsions, hyperactivity, oliguria, and acute tubular necrosis prior to recovery in 23 days. This patient ingested what would normally be a fatal amount of strychnine. He had signs and symptoms of severe toxicity but recovered, suggesting that with aggressive supportive care patients may have favorable outcomes (Shadnia *et al.*, 2004). In another case report described by Wood *et al.* (2002), a 42-year-old man presented shortly after ingestion of an unknown substance had in fact taken a lethal quantity of strychnine powder. After a respiratory arrest, with intensive supportive management requiring admission to an intensive care unit, he survived.

People exposed to high doses of strychnine may have the following signs and symptoms within the first 15 to 30 min of exposure: respiratory failure (inability to breathe), possibly leading to death or brain death; no postmortem lesions are observed with the exception of small pinpoint hemorrhages in the lungs resulting from death due to asphyxia; and rigor mortis occurs shortly after death and persists for days.

Toxicity of strychnine in humans, expressed as LDLo (lethal dose low), is approximately 30 mg/kg. It is evident that strychnine is less toxic in humans than in most other animals. If the person survives the toxic effects of strychnine poisoning, long-term health effects are unlikely. However, long-term effects may result from damage caused by the poisoning, for example brain damage from low oxygen or kidney failure. People severely affected by strychnine poisoning are not likely to survive.

1. Clinical Symptomatology

The symptomatology of human intoxication beginning 15 to 30 min after ingestion of strychnine, usually without any warning, may cause the subject to fall into violent convulsions. Convulsions lead to severe lactic acidosis which secondarily result in visceral (lung, heart, kidney,

liver, and brain) collapse and death (Gordon and Richards, 1979). Prodromal symptoms are described such as apprehension, restlessness, heightened acuity of hearing, vision and feeling, hyperreflexia, abrupt movement, and muscular stiffness of face and legs. Generalized convulsions last from 30 s to 2 min. Ten to 20 minutes after exposure, the body's muscles begin to spasm, starting with the head and neck. At first, convulsions are clonic, but a tetanic phase quickly intervenes. The body typically arches in hyperextension, the legs are adducted and extended, the arms are flexed over the chest, and the fists are tightly clenched. The jaw is rigidly clamped, the face has a fixed grin and the eyes protrude in a fixed stare (Philippe *et al.*, 2004).

The convulsions progress, increasing in intensity and frequency until the backbone arches continually. Death comes from asphyxiation caused by paralysis of the neural pathways that control breathing, or by exhaustion from the convulsions. The subject usually dies within 2–3 h after exposure. At the point of death, the body ''freezes'' immediately, even in the middle of a convulsion, resulting in instantaneous rigor mortis.

C. Diagnosis

A tentative diagnosis can be made based on clinical signs and history. However, a positive diagnosis can only be made by identifying strychnine in the stomach contents, viscera, or blood. The drug can be identified by chemical tests and microscopic identification of typical strychnine crystals.

VI. RISK ASSESSMENT

A. Human Health Hazard

The human health assessment for strychnine is based on the acute toxicity. Strychnine has been placed in Toxicity Category I, indicating the greatest degree of acute toxicity, for oral and ocular effects. It has been reported that the probable lethal oral dose is 1.5 to 2 mg/kg (Gosselin *et al.*, 1984). Inhalation toxicity is also presumed to be high. An oral dose of 1.5 to 2 mg/kg is equivalent to 70 to 93 mg/m^3 exposure for 30 min for a 70 kg human being.

Strychnine was first registered as a pesticide in the USA in 1947; however, this natural toxin had been used in many countries to control vertebrate animals for many years prior to 1947. Currently, strychnine is registered for use only below ground as a bait application to control pocket gophers. The end-use products are formulated as a grain-based bait or a paste. Baiting can be done manually, or with the use of application equipment.

The European Union (EU) withdrawal of strychnine marks its end as a method of mole control. The EU Directive 91/414/EEC is midway through an ambitious program to review all pesticides used within Member States. This requires manufacturers to provide health and safety data to support the continued registration of their products. Strychnine was to be reviewed in the fourth part of this program but manufacturers have failed to provide such data. Despite last ditch appeals by users, from September 1, 2006 it was no longer legal to use.

B. Safety Data

The strychnine oral reference dose (RfD) of 0.0003 mg/kg/day or 0.02 mg/day for a 70 kg person is derived from the Seidl and Zbinden (1982) short-term to subchronic study by applying an uncertainty factor of 10,000. This factor accounts for extrapolation from a less than chronic to a chronic exposure study, extrapolation from animals to humans, and differences in sensitivity among the human population. An additional factor of 10 is used because an LOAEL/FEL (2.5 mg/kg/day) was utilized in the estimation of the RfD instead of an NOAEL. The immediately dangerous to life and health (IDLH) dose for strychnine by NIOSH REL is 0.15 mg/m^3 and the current OSHA PEL is 0.15 mg/m^3.

The work of Seidl and Zbinden (1982) is the only oral short-term or subchronic study reported, in which rats received daily doses of 0–10 mg/kg of strychnine by gavage for 28 days. Data recorded for the surviving animals included blood cell counts, electrocardiograms, eye examinations, urine chemistry, weight gain, tissue histology, organ weights, behavioral tests, and food and water consumption. Mortality was observed in five out of 12 male rats receiving 10 mg/kg, one in 12 in each of the 5 mg and 2.5 mg/kg groups. All deaths occurred 0.5–6 h after oral doses.

Additional studies (Gitzelmann *et al.*, 1978) reported that a 6-month-old human patient received strychnine doses of 0.3–1.1 mg/kg/day over an 18-month period without any adverse effects. However, the patient may have had a higher strychnine tolerance as a result of nonketotic hyperglycinemia.

The risk phrases of strychnine are R26, R27, and R28.

VII. TREATMENT

There is no specific antidote for strychnine but recovery from strychnine exposure is possible with early hospital treatment. Treatment consists of removing the drug from the body (decontamination) and getting supportive medical care in a hospital setting. Supportive care includes intravenous fluids, medications for convulsions and spasms, and cooling measures for high temperature.

Treatment of strychnine poisoning involves an oral administration of an activated charcoal which absorbs any unabsorbed poison within the digestive tract. Unabsorbed strychnine can be removed from the stomach by gastric lavage with tannic acid (strong tea) or potassium permanganate solutions to oxidize strychnine. Seizures are controlled by anticonvulsants, such as phenobarbital or diazepam, along

with muscle relaxants such as dantrolene to combat muscle rigidity. Because diazepam, as the anticonvulsant of choice, is not effective in all cases, a combination with midazolam, fentanyl, or pancuronium is recommended in controlling the convulsions (Scheffold *et al.*, 2004). The fatal outcome of strychnine poisoning demands an aggressive management with early intubation, control of muscle tremors, and prevention of rhabdomyolysis and renal failure. If the patient survives past 24 h, recovery is probable.

Small doses of strychnine were once used in medications as a stimulant, a laxative, and as a treatment for other stomach ailments. Strychnine has stimulant effects at low doses but because of its high toxicity and tendency to cause convulsions the use of strychnine in medicine was eventually abandoned once safer alternatives became available.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

Strychnine is a highly poisonous natural substance that is used in some countries for the control of wild animals. Today, strychnine is used primarily as a pesticide, particularly to kill rats. Its use is restricted by law. Because strychnine is highly toxic and can be rapidly absorbed through the mucous membranes of the mouth, stomach, and small intestines, theoretically it may be used as a military toxicant or terroristic agent. There are three main ways that strychnine can enter the body: inhalation, ingestion, and through broken skin.

Goal-directed misuse of strychnine against humans is unlikely; its misuse against domestic animals, however, is realistic and more likely.

Uncommonly, strychnine is found mixed with ''street'' drugs such as LSD, heroin, and cocaine. It is very likely that seizures observed occasionally after cocaine application may be caused by admixed strychnine (Haddad and Winchester, 1983; Wijesekera *et al.*, 1988). As a result of analysis of heroin samples seized in the Florence area between 1975 and the first half of 1981 no dangerous substances were found and strychnine, if present, was found only in very low concentrations (Mari *et al.*, 1982).

CHAPTER 15

Superwarfarins

MICHAEL J. MURPHY AND ANDRES M. LUGO

I. INTRODUCTION

Chemical warfare agents may be manufactured from a wide range of commercially manufactured household industrial products such as bleach, antifreeze, fertilizers containing anhydrous ammonia, pesticides, or anticoagulant rodenticides particularly superwarfarins, to name a few (WHO, 2008). Some chemical warfare agents, e.g. nerve agents, are capable of harming or killing a large number of people when dispersed in air. On the other hand, superwarfarins may be used to harm or terrorize people through the ingestion of contaminated food or water.

Superwarfarins are the ''second-generation anticoagulant rodenticides''. They are referred to as ''superwarfarins'' in the modern medical literature (Pavlu *et al.*, 2005; Sharma and Bentley, 2005; Dolin *et al.*, 2006, POISINDEX, 2007). Superwarfarins are a group of commercially available long-acting anticoagulant rodenticides that are structurally similar to warfarin but are many times more potent and many have the capacity to cause severe bleeding problems that may last for 2 to 8 months in humans (Ellenhorn *et al.*, 1997; Goldfrank *et al.*, 2002).

This group of long-acting anticoagulants may be used as chemical warfare agents because of their high potency and duration of action. The capability of terrorists to use these commercially available poisons is dependent upon the availability of large amounts of high concentration product whether bought or stolen, the target population and its vulnerability, and a method of effective delivery and dissemination (EPA, 2005; WHO, 2008). Although these anticoagulants may be absorbed through the skin and lungs, the main route of exposure is ingestion of food or water containing the product (Jones *et al.*, 1984; Katona and Wason, 1989; Swigar *et al.*, 1990; Wallace *et al.*, 1990; Exner *et al.*, 1992; Rauch *et al.*, 1994; Gallo, 1998; Corke, 1997). The United Nations report from 1969 defines chemical warfare agents as ''chemical substances, whether gaseous, liquid or solid, which might be employed because of their direct toxic effects on man, animals and plants …''. Superwarfarin poisoning may result in a number of casualties if these substances are ingested (Baker *et al.*, 2002; EPA, 2005; Palmer *et al.*, 1999; POISINDEX, 2007; HSDB, 2008).

Superwarfarin rodenticides are used to kill urban and agricultural rodent pests. They are readily available to the general public and pest controllers, are easy to obtain and conceal, so may pose a risk of being used as chemical warfare agents (EPA, 2003, 2005; WHO, 2003, 2008).

These rodenticides are available as meal bait packs, pellets, mini pellets, blocks, mini blocks, wax blocks, liquid bait formulations, tracking powder, and concentrate formulations (POISINDEX, 2007; WHO, 2008; Wilton, 1991).

II. BACKGROUND

Anticoagulants were discovered in the early 20th century after livestock had eaten moldy sweet clover contaminated with bis-hydroxycoumarin and died of hemorrhagic disease. Newer long-acting warfarin derivatives such as brodifacoum, bromadiolone, diphenadione, chlorophacinone, and a few more can produce profound and prolonged anticoagulation and bleeding after a latency period that is generally 24 to 72 h (Chong *et al.*, 1986; Greeff *et al.*, 1987; Swigar *et al.*, 1990; Wallace *et al.*, 1990; Routh *et al.*, 1991; Wilton, 1991; Exner *et al.*, 1992; Rauch *et al.*, 1994; Hui *et al.*, 1996; Tecimer and Yam, 1997; Gallo, 1998; Chua and Friedenberg, 1998; Gill and Redfern, 1980; FDA, 1985; Smolinske *et al.*, 1989; IPCS, 1995a–e; EPA, 2003, 2005).

In the 1940s, a small British pharmaceutical company suggested that dicoumarol might have rodenticidal properties. Trials carried out by Armour and Barnett (1950) confirmed the idea and started the era of anticoagulant rodenticides. Warfarin was the first anticoagulant rodenticide introduced into the market shortly after World War II and became widely used in many countries. Other anticoagulant compounds with potency similar to that of warfarin were also synthesized. These early anticoagulant rodenticides have often been called ''first-generation anticoagulant rodenticides''. These first-generation compounds generally have moderate toxicity, with acute LD_{50} values ranging from 10 to 50 mg/kg body weight (Table 15.2).

The first-generation compounds often needed continuous bait exposure for rodent control. Many rodent species developed a resistance to warfarin (Jackson *et al.*, 1975)

TABLE 15.1. Common commercial products containing superwarfarins

Name	Molecular formula	Commercial names
Brodifacoum CAS: 56073-10-0	C_{31}-H_{23}-Br-O_3	D-Con Mouse-Prufe I & II®, Havoc®, Klerat®, Ratak Plus®, Talon G®, Void® Finale, Folgorat, Matikus, Mouser, Rodend, Volak, Volid
Difenacoum CAS: 56073-07-5	C_{31}-H_{24}-O_3	Compo®, Diphenacoum®, Frunax DS®, Matrak®, Neosorexa®, Rastop®, Ratak®, Ratrick®, Silo®
Bromadiolone CAS: 28772-56-7	C_{30}-H_{23}-Br-O_4	Apobas®; Bromard®; Bromone®, Bromatrol®; Bromorat®; Contrac®; Deadline®; Hurex®; Lanirat®; Maki®; Morfaron®; Musal®; Maki®, Ramortal®; Ratimon®; Rodine-c®; Slaymore®; Super-caid®; Toidon®
Diphacinone CAS: 82-66-6	C_{23}-H_{16}-O_3	Diphacine®, Ditrac®, Gold Crest®, Kill-Ko®, P.C.Q.®, Promar®, Ramik®, Rat Killer®, Rodent Cake®, and Tomcat®
Chlorophacinone CAS: 3691-35-8	C_{23}-H_{15}-Cl-O_3	Caid®, Liphadione®, Microsul®, Ramucide®, Ratomet®, Raviac®, Rozol®, Topidox®
Difethialone[a] CAS: 104653-34-1	C_{31}-H_{23}-Br-O_2-S	None to report
Pindone[a] CAS: 83-26-1	C_{14}-H_{14}-O_3	Pestanal®, Pindone®, Pival®, Pivalyn®, Pivalyl Valone®, Tri-ban®
Coumatetralyl[a] CAS: 5836-29-3	C_{19}-H_{16}-O_3	Racumin®
Coumafuryl[a] CAS: 117-52-2	C_{17}-H_{14}-O_5	Fumarin®, Tomarin®
Valone CAS: 83-28-3	C_{14}-H_{14}-O_3	None to report
Flocoumafen[a] CAS: 90035-08-8	C_{33}-H_{25}-F_3-O_4	None to report

Available forms include: meal bait packs, pellets, mini pellets, blocks, mini blocks, wax blocks, liquid bait formulations, and tracking powder
[a]No longer produced or used in the USA

presumably due to continued exposure and widespread use. Consequently, new chemical structures were synthesized and used as anticoagulant rodenticides. These newer compounds are generally more toxic than warfarin with acute LD_{50}s of 0.2–3.9 mg/kg body weight. For example, a bait concentration of only 50 ppm of brodifacoum is adequate to give control in a single feeding for most rodents and noncommensal species (Matolesy *et al.*, 1988). These newer compounds were called ''second-generation anticoagulant rodenticides'' and are often now referred to as ''superwarfarins'' in the contemporary medical literature (Chong *et al.*,1986; Greeff *et al.*, 1987; Swigar *et al.*, 1990; Wallace *et al.*, 1990; Routh *et al.*, 1991; Wilton, 1991; Exner, 1992; Rauch *et al.*, 1994; Hui *et al.*, 1996; Tecimer and Yam, 1997; Gallo, 1998; Chua and Friedenberg, 1998; Pavlu *et al.*, 2005; Sharma and Bentley, 2005; Dolin *et al.*, 2006).

During the past 30 years there have been more than 600 articles published in the medical literature relating to the clinical assessment, laboratory testing, and treatment of patients exposed to superwarfarins. A great number of these articles are related to children under 6 years old, who accidentally ingested small amounts of these products and, in most cases, did not experience adverse effects (AAP, 2003, Brands *et al.*, 1995, Ingels *et al.*, 2002; Osterhoudt and Henretig, 2003). Also, there are a few cases describing severe bleeding or bleeding-related complications from patients who intentionally ingested large amounts, as well as a few fatal ingestion cases (AAPCC, 2006; Casner, 1998; Walker and Beach, 2002; Wallace *et al.*, 1990). Most of the

TABLE 15.2. The oral LD_{50} values (mg/kg body wt) of some anticoagulant rodenticides

Animals	Bromadiolone	Brodifacoum	Difenacoum
Rat (acute)	0.65	0.27	1.8
Rat (chronic)	(0.06–0.14) × 5	(0.05–0.08)	0.15 × 5
Mouse	0.99	0.4	0.8
Rabbit	1.0	0.2	2.0
Pig	3.0	10.0	80.0
Dog	10.0	3.5	50.0
Cat	25.0	25.0	100.0
Chicken	5.0	10.0–20.0	50.0
Guinea pig	2.8	–	–
Opossum	–	0.17	–
Sheep	–	10.0	100.0

health hazards are associated with accidental ingestion of superwarfarins, and the risk for dermal and inhalation exposure is minimal (Bruno *et al.*, 2000, POISINDEX, 2007). One-third of these publications are related to domestic animals and a few to nontarget wild animals (Newton *et al.*, 1990; Stone *et al.*, 1999), with a small number of reported deaths. All animal exposures are due to accidental direct and indirect ingestion of these rodenticides. The great majority of animal exposures include dogs, which may need gastric decontamination, and in some cases referral to a veterinarian for further clinical evaluation and treatment (Borst and Counotte, 2002; DuVall *et al.*, 1989; Hornfeldt and Phearman, 1996; McConnico *et al.*, 1997; Robben *et al.*, 1997). In most cases gastric decontamination will be recommended and treatment with vitamin K_1 may be needed. There are few data of the incidence or mortality rates from animal exposures to rodenticides.

Warfarin and dicoumarol found application as both oral anticoagulants and as rodenticides. Sweet clover requires the action of molds to form dicoumarol; giant fennel does not. Giant fennel (*Ferula communis*) grows in Mediterranean countries. It has a naturally occurring anticoagulant effect. An association between the plant and anticoagulation was first reported in the 1950s (Costa, 1950a, b; Carta, 1951). It was further investigated in Italy (Mazzetti and Cappelletti, 1957; Corticelli and Deiana, 1957; Corticelli *et al.*, 1957; Cannava, 1958) then in Israel (Shlosberg and Egyed, 1983). The anticoagulant activity of the plant in Morocco has recently been reviewed (Lamnaouer, 1999).

Warfarin and its congeners are still used as therapeutic agents. Oral anticoagulants available therapeutically in Europe include warfarin, phenprocoumaron, and nicoumalone – also called acenocoumarol (Shetty *et al.*, 1993). Oral anticoagulants are used therapeutically to reduce thromboembolic events. Warfarin examples include a reduction in catheter-related thrombosis (Guidry *et al.*, 1991; Magagnoli *et al.*, 2006), early venous thrombosis after operations (Calnan and Allenby, 1975; Pan *et al.*, 2005), including hip surgery, atrial fibrillation (Middlekauff *et al.*, 1995; Reiffel, 2000), and myocardial infarction (Asperger and Jursic, 1970). A number of adverse events have been recognized, and most are related to drug interactions (Dayton and Perel, 1971).

An association between vitamin K and coagulopathies was made in the mid-1930s (Dam, 1935; Fieser *et al.*, 1939). Soon, thereafter Prof. Link reported the discovery of dicoumarol in the moldy hay (Last, 2002). Naturally occurring coumarin in the sweet-clover hay is converted by fungi to dicoumarol. Dicoumarol was found to be the causative agent of the disease, so the elements needed for the disease were coumarin-containing plant material plus mold growth. Subsequently, a range of molecules were synthesized. One named warfarin became the most popular (Duxbury and Poller, 2001). Warfarin takes its name, in part, from the Wisconsin Alumni Research Foundation.

A. American Association of Poison Control Centers Data on Superwarfarins

Every year there are tens of thousands of accidental ingestions of long-acting anticoagulant rodenticides reported worldwide in the medical literature. These include the annual report from the American Association of Poison Control Centers (AAPCC). During the past 23 years the AAPCC reported 209,047 exposures to long-acting anticoagulant rodenticides (LAAR), which included 24 deaths due to LAAR ingestion. All fatalities were in adults who intentionally committed suicide.

III. CLASSIFICATION OF SUPERWARFARINS

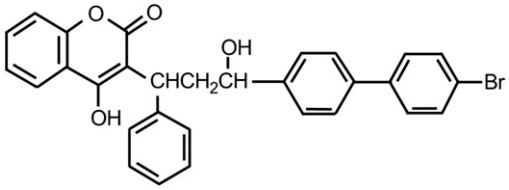
Anticoagulant rodenticides are also categorized by chemical structure. The chemical structure of the currently marketed products fits in one of two chemical classes: 4-hydroxycoumarins and indanediones.

A. 4-Hydroxycoumarins

This group of compounds have a 4-hydroxycoumarin ring with different side-chain substituents at the 3-position. Commonly used superwarfarin anticoagulant rodenticides in this group are bromadiolone, brodifacoum, coumatetralyl, coumafuryl, and difenacoum. Brodifacoum, difenacoum and bromadiolone are three of the most commonly used rodenticides around the world. Brodifacoum is the most frequently used rodenticide in the USA. These rodenticides share most of their physical and chemical characteristics, as well as their toxicokinetics, toxicodynamics, and mechanism of toxicity, and the medical toxicological management is the same for all superwarfarins.

1. Bromadiolone

Chemical formula: $C_{30}H_{23}BrO_4$

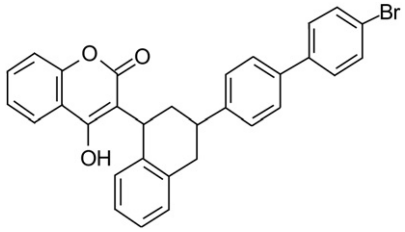


Bromadiolone [3-(3-(4′-bromobiphenyl-4-yl)-3-hydroxy-1-phenyl propyl)-4-hydroxycoumarin] was synthesized and marketed by the French company Lipha SA during the mid-1970s. It is used widely for control of commensal and field rodents in many countries. Technical grade bromadiolone is 97% pure. It is a yellowish powder and stable up to 200°C (Chalermchaikit *et al.*, 1993). It is very soluble in dimethylformamide (730 g/l), but less soluble in ethyl acetate

(25 g/l), and ethanol (8.2 g/l), and sparingly soluble in water (0.019 g/l). Bromadiolone is considered more palatable to rodents than most other anticoagulants. Its concentration in baits is usually 50 ppm (Chalermchaikit *et al.*, 1993). Although bromadiolone is considered a ''second-generation anticoagulant rodenticide'', some resistance problems have been reported with *Rattus norvegicus* and *Mus musculus* in the UK and Denmark (IPCS, 1995d; Lund, 1984; Rowe *et al.*, 1981).

2. Brodifacoum

Chemical formula: $C_{31}H_{23}BrO_3$



Brodifacoum [3-(3-(4′-bromobiphenyl-4-yl)-1,2,3,4-tetrahydro naphth-1-yl)-4-hydroxycoumarin] is one of the newer and more potent second-generation anticoagulant rodenticides. It was first introduced in 1977 by Sorex Ltd of London, and then developed by the Imperial Chemicals Incorporated (ICI) Plant Protection Division (Chalermchaikit *et al.*, 1993).

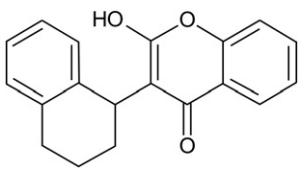
Pure brodifacoum is an off-white to fawn colored powder with a solubility of 6–20 g/l in acetone, 3 g/l in chloroform, 0.6–6 g/l in benzene, and less than 10 mg/l water. It is very stable in the environment with no loss after 30 days' exposure to direct sunlight (Chalermchaikit *et al.*, 1993).

Brodifacoum has been marketed in several countries for the control of a wide range of rodent pest species. It is available as a 0.005% pellet for rat and mouse control, a smaller 0.001% pellet for field rodent control, and as 29 g wax blocks for sewer rat control. It is the only anticoagulant rodenticide found to produce 100% mortality in most rodent species after only a 24 h dose (Chalermchaikit *et al.*, 1993). Brodifacoum was effective against warfarin-resistant rats and mice in 1984, but the possibility of resistance has been raised (Lund, 1984).

There is variation in the susceptibility of species to brodifacoum. Dogs are susceptible and are commonly exposed to potentially toxic quantities of brodifacoum (Chalermchaikit *et al.*, 1993).

3. Coumatetralyl

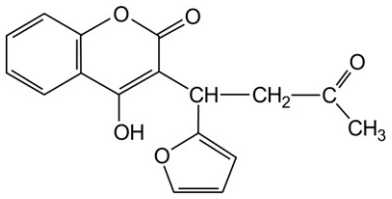
Chemical formula: $C_{19}H_{16}O_3$



Coumatetralyl [3-(alpha-tetralyl)-4-hydroxycoumarin] was introduced by Bayer AG with the trademark name of Racumin. It has been used for commensal rodent control in many countries. It is formulated as a dry bait (0.0375%), a liquid bait of its sodium salt, and a 0.75% tracking dust (Chalermchaikit *et al.*, 1993). Pure coumatetralyl is a colorless powder which is stable at temperatures below 150°C. Its solubility is 20–50 g/l in propan-2-ol, 50–100 g/l in methylene dichloride, and 4 mg/l in water. The acute and chronic LD_{50}s to *R. norvegicus* are 16.5 and 0.3 mg/kg for five consecutive doses, respectively. Chickens are somewhat resistant to coumatetralyl, with a chronic LD_{50} of 50 mg/kg for eight consecutive doses. Signs did not appear in fish until the concentration of coumatetralyl reached 1,000 mg/l in water (Chalermchaikit *et al.*, 1993). In spite of its low toxicity, it is reported to be a little more effective than warfarin against *R. norvegicus*, apparently due to a higher palatability. Coumatetralyl was introduced after the detection of warfarin-resistant rat populations and showed considerable success for a number of years, but resistant pests have been reported in the UK and Denmark (Rowe and Redfern, 1968; Lund, 1984).

4. Coumafuryl

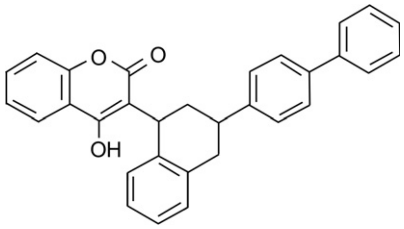
Chemical formula: $C_{17}H_{14}O_5$



Coumafuryl [3-(alpha-acetonylfurfuryl)-4-hydroxycoumarin] is a German anticoagulant, introduced in 1952, and is used at 0.025–0.05% in baits. Its toxicity is considered equal to warfarin for *R. norvegicus* but slightly less efficient against *M. musculus*. The chronic LD_{50} in *R. norvegicus* is 1.4 mg/kg for five repeated doses. Cats and dogs seem to be almost as susceptible as rats, with dogs being killed by 2 mg/kg for five repeated doses and cats by 10 mg/kg for four repeated doses (Chalermchaikit *et al.*, 1993).

5. Difenacoum

Chemical formula: $C_{31}H_{24}O_3$

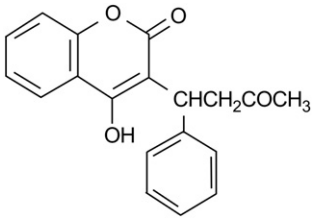


Difenacoum [3-(3-p-diphenyl-1,2,3,4-hydronaphth-1-yl)-4-hydroxycoumarin] was synthesized in the UK and marketed in 1975 by Sorex Ltd under the trademark

''Neosorexa'', and by ICI Plant Protection Division under the trademark ''Ratak'' as a 0.005% pelleted bait, and as a wax block. Pure difenacoum is an off-white powder with a solubility of greater than 50 g/l in acetone, 600 mg/l in benzene, and less than 10 mg/l in water. It is more toxic than warfarin, but less palatable (IPCS, 1995c). Difenacoum is still effective against many populations of warfarin-resistant rats (Desideri *et al.*, 1979), but resistance may be developing in the UK (Greaves *et al.*, 1982).

6. Warfarin

Chemical formula: $C_{19}H_{16}O_4$



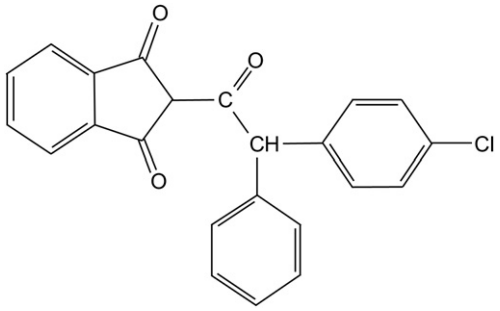
Warfarin [3-(a-acetonylbenzyl)-4-hydroxycoumarin] was the first anticoagulant rodenticide introduced shortly after World War II after development by the Wisconsin Alumni Research Foundation. Warfarin is still used widely, especially for the control of *R. norvegicus* in areas where resistance has not developed. In its racemic form, warfarin is colorless and crystalline, insoluble in water, but readily soluble in acetone, dioxane, and moderately soluble in alcohols. Warfarin is formulated as dry bait (0.005–0.05%) as well as a liquid bait, based on the sodium salt, and a tracking dust (0.5–1.0%). It is generally applied as the S-isomer, which has a toxicity ten times greater than the R-isomer. The acute and chronic LD_{50}s for *R. norvegicus* are around 10–12 and 0.75 mg/kg for five repeated doses, respectively (Colvin and Wang, 1974). Warfarin is sometimes combined with an antibacterial agent, sulfaquinoxaline, in order to reduce the bacterial production of vitamin K in the rat intestine, but the effectiveness of this combination has not been proven. Warfarin is considered one of the safest anticoagulants, as far as domestic and other nontarget animals are concerned. Serious resistance problems have been reported in Europe. It has recently been evaluated against sewer rats in London (Channon *et al.*, 2000).

B. Indanediones

This group of compounds has a 1,3 indanedione structure with different side-chain substituents at the 2-position. The most common superwarfarins in this group are chlorophacinone and diphacinone.

1. Chlorophacinone

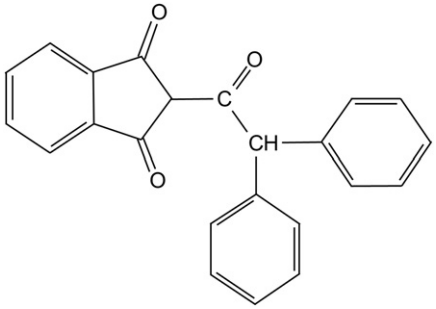
Molecular formula: $C_{23}H_{15}ClO_3$



Chlorophacinone [2-(alpha-4-chlorophenyl-a-phenylacetyl)-1,3-indandione] was first introduced during the mid-1960s by Lipha SA of France, at concentrations of 0.05% in baits and 0.2% in tracking dust. Pure chlorophacinone is a yellow crystalline solid which is very soluble in acetone, ethanol, ethyl acetate, but is sparingly soluble in water. It is quite stable and resistant to weathering. Chlorophacinone does not induce bait-shyness and is compatible with cereals, fruits, roots, and other potential bait substances. Its acute LD_{50} in *R. norvegicus* is about 20.5 mg/kg which is less toxic than warfarin, but it has a stronger initial effect on rats and mice. For control of house mice populations, a prolonged feeding period is needed. Chlorophacinone may not be effective against warfarin-resistant rodents (Chalermchaikit *et al.*, 1993).

2. Diphacinone

Molecular formula: $C_{23}H_{16}O_3$



Diphacinone (2-diphenylacetyl-1,3-indandione) is an old anticoagulant rodenticide, introduced by Vesicol Chemical Corp. and the Upjohn Co. It has been produced and used primarily in the USA as a 0.005% dry or liquid bait. Pure diphacinone is a yellow powder which is very soluble in chloroform (204 g/kg), toluene (73 g/kg), xylene (50 g/kg), and acetone (29 g/kg), but sparingly soluble in water (0.30 g/l). It will decompose in water due to sunlight. The acute LD_{50}s in *R. norvegicus* are 22.7 mg/kg in females and 43.3 mg/kg in males. It is more toxic than warfarin to rats, mice, and dogs, but its palatability is somewhat lower. Diphacinone may not be effective against some warfarin-resistant rodents (Chalermchaikit *et al.*, 1993). The anticoagulant rodenticides are marketed to have efficacy against a number of target pest species.

IV. TOXICOKINETICS

A. Absorption, Metabolism, and Excretion in Laboratory Animals and Humans

Superwarfarins are primarily well absorbed from the gastrointestinal tract. Almost 90% is absorbed with peak plasma concentrations often occurring within 12 h of ingestion. Binding to plasma proteins may prolong distribution and half-life. Toxicity after dermal or respiratory exposure is rare (Berry *et al.*, 2000; Boermans *et al.*, 1991) but not unreported (Spiller *et al.*, 2003).

The metabolism and elimination of the trans-isomer was more rapid than those of the cis-isomer. The elimination from the liver is biphasic with an initial rapid phase of 3 days and a slower phase with a half-life of 120 to 130 days. The liver is the major organ for the accumulation and storage, which has been found mainly as the unchanged parent compounds. The major route of elimination in different species after oral administration is via the feces. The urine is a very minor route of elimination (Watt *et al.*, 2005).

V. MECHANISM OF ACTION

The mechanism of action of all anticoagulant rodenticides is similar to that of warfarin, specifically inhibition of vitamin K_1 epoxide reductase (Park *et al.*, 1979; Leck and Park, 1981; Breckenridge *et al.*, 1985). In the coagulation cascade, the clotting factors II, VII, IX, and X must bind calcium ions to be active in clot formation. The Ca^{2+}-binding ability requires converting glutamyl residues on these clotting factors to carboxyl glutamyl residues by the process of carboxylation. This carboxylation uses vitamin K_1 hydroquinone as a cofactor. This vitamin K-dependent carboxylase reaction converts vitamin K_1 hydroquinone to its epoxide form, vitamin K_1 2,3-epoxide. In the normal cycle, vitamin K_1 2,3-epoxide is reduced to the original vitamin K_1 (phylloquinone) by epoxide reductase, and thus ''recycled''. The anticoagulant rodenticides produce their effect by interfering with vitamin K_1 epoxide reductase, resulting in the depletion of vitamin K_1 and subsequently impairing the synthesis of normal clotting factors II, VII, IX, and X (Craciun, 1997, 1998). Clinical coagulopathy soon follows the depletion of vitamin K_1 in the liver. These clotting factors in the dog have plasma half-lives of 41, 6.2, 13.9, and 16.5 h, respectively. The coagulation system continues to function well until about 3 to 5 days after ingestion when the natural decay of clotting factors occurs. It has been suggested that they bind more strongly to the liver than warfarin resulting in more persistent effects (Babcock *et al.*, 1993; Barnett *et al.*, 1992; James *et al.*, 1998; Jackson and Suttie, 1977; Suttie, 1986; Murphy and Gerken, 1989). The interrelationship of vitamin K, prothrombin, and gamma-carboxyglutamic acid is reviewed in Stenflo (1978). The interaction of warfarin and vitamin K is reviewed in Suttie (1990).

VI. TOXICITY

A. Clinical Effects: Signs and Symptoms

Clinical signs and symptoms of acute intoxication by superwarfarins range from a mild tendency to bleed in less severe poisoning cases to severe coagulopathy. Mild bleeding tendencies are often recognized clinically as nose or gum bleeding, hemoptysis, ecchymosis, bloody or melenotic stools, hematuria, abdominal or flank pain, enhanced bruising, or ventral hematomas. Severe bleeding may lead to shock and death. Internal and external bleeding are the most frequent clinical signs followed by tachycardia and hypotension, then multiple organ failure due to substantial blood loss. The onset of the signs of poisoning may not be evident until a few days after absorption (Baker *et al.*, 2002; Casner, 1998; Chua and Friedenberg, 1998; Corke, 1997; Nighoghossian *et al.*, 1990; Ross *et al.*, 1992; Swigar *et al.*, 1990; Tsutaoka *et al.*, 2003; Vogel *et al.*, 1988; Weitzel *et al.*, 1990; Wilton, 1991).

1. Animal Toxicology

Clinical signs are usually delayed until 24–36 h post-ingestion. The most common signs include vomiting, diarrhea, dyspnea, weakness, depression, anorexia, hematuria, and melena. Other signs such as pale mucous membranes, bleeding from nose and gums, and generalized bruising may be noticeable. Internal bleeding also causes generalized pain, fever, and lameness from bleeding into a joint, bleeding into the thorax or abdomen, brain, pericardium, or sudden death (Berny *et al.*, 1995; Braithwaite, 1982; Munday and Thompson, 2003).

2. Pediatric Exposures

The great majority of human exposures are children under the age of 6 due to accidental or unintentional ingestion. They usually do not require any medical intervention or routine follow-up laboratory studies and can be adequately managed by Poison Control Centers with home observation and parent education (Ingels *et al.*, 2002; Kanabar and Volans, 2002; Mullins *et al.*, 2000; Shepherd *et al.*, 2002). Children with acute unintentional superwarfarin ingestions may often be managed without gastric decontamination or prophylactic vitamin K. Laboratory testing for coagulopathy should be reserved for cases involving clinically evident bleeding abnormalities (Ingels *et al.*, 2002).

A small number of reported cases of children have presented with mild to moderate hematological effects, requiring minimal to nonmedical intervention (Babcock *et al.*, 1993, Golej *et al.*, 2001; Osterhoudt and Henretig, 2003; Smolinske *et al.*, 1989; Travis *et al.*, 1993; Watts *et al.*, 1990).

Intentional suicidal ingestion of large amounts of product conveys a greater risk for severe toxicity and increased mortality and should be referred to a healthcare facility for examination and treatment if needed (Ingels *et al.*, 2002).

3. Adult Exposures

The great majority of adult exposures to rodenticides are due to deliberate acute and chronic surreptitious ingestion. Bleeding disorders may persist for 6 weeks to many months. Serious poisoning had been reported in adults with massive overdoses. These long-acting anticoagulants have produced rapid and persistent bleeding due to hypoprothrombinemia (Barnett *et al.*, 1992; Berry *et al.*, 2000; Chong *et al.*, 1986; Exner *et al.*, 1992; Gallo, 1998; Hoffman *et al.*, 1988; Katona and Wason, 1989; Mack, 1994; McCarthy *et al.*, 1997; Morgan *et al.*, 1996; Routh *et al.*, 1991; Wallace *et al.*, 1990). There is a risk of spontaneous abortion with long-acting anticoagulants (Lipton and Klass, 1984; Nelson *et al.*, 2006; Zurawski and Kelly, 1997).

The severity of the intoxication depends on the amount of rodenticide ingested, preexisting co-morbidity, and co-ingestion of other toxic substances (Palmer *et al.*, 1999; Stanziale *et al.*, 1997; Tecimer and Yam, 1997; Seidelmann *et al.*, 1995; Walker and Beach, 2002). Fatalities are usually due to intentional suicidal ingestion of large amounts. Bleeding disorders and organ failure have been described in adults due to deliberate acute and chronic surreptitious ingestion. Twenty four deaths have been reported by the American Association of Poison Control Centers in the past 20 years (see Table 15.3; AAPCC-TESS annual reports from 1983–2006).

4. Household Pets and Farm Animal Exposures

Household pets and farm animals may be accidentally exposed to rodenticides. The possible effects on nontarget organisms can be considered in two categories, specifically direct poisoning and secondary poisoning. Secondary poisoning is generally considered to be after consumption of anticoagulant rodenticide poisoned rodents. The most common type of exposure is direct exposure of eating a cereal-based bait containing the rodenticide. The most commonly affected household pets are dogs, followed by cats, hamsters, rabbits, and pet birds (Boermans *et al.*, 1991; Hornfeldt and Phearman, 1996; McConnico *et al.*, 1997; Munday and Thompson, 2003; Park and Leck, 1982; Peterson and Streeter 1996; Radi and Thompson, 2004; Redfern and Gill, 1980; Robben *et al.*, 1997, 1998; Woody *et al.*, 1992).

Cats may be more resistant to the toxic effects of brodifacoum and difenacoum than dogs. Cases of abortion and hemorrhage in sheep and goats after misuse of brodifacoum have been reported (Jones, 1996; Watt, 2005).

5. Nontarget Wildlife Exposures

Nontarget wildlife may be exposed to rodenticides. The possible effects on nontarget organisms can also be considered in two categories, specifically direct poisoning and secondary poisoning. The potential for secondary poisoning is more likely in carnivorous wildlife (Borst and Counette, 2002; DuVall *et al.*, 1989; Eason *et al.*, 2002; Greaves *et al.*, 1982; James *et al.*, 1998; Mahmoud and Redfern, 1981; Mathur and Prakash, 1980; Newton *et al.*, 1990; Stone *et al.*, 1994). The most commonly affected species are birds such as great horned owls, barn owls, eastern screech-owls, golden eagles, red-tailed hawks, Cooper's hawks, and crows. Bird species varied in their susceptibility. Other wild animals may be exposed such as polecats, wild cats, foxes, etc. Brodifacoum was highly toxic for fish when tested as a technical material.

6. Laboratory/Monitoring and General Recommendations

Superwarfarins lower the blood concentrations of the vitamin K-dependent clotting factors II, VII, IX and X; this results in prolongation of prothrombin time (PT) and partial thromboplastin time (PTT). PT and PTT should be repeated at least twice daily until a normal PT and PTT are established. Also, the blood clotting time and the bleeding time should be measured. Blood is often demonstrable in the excreta. Secondary hypochromic or microcytic anemia may be marked (Goldfrank *et al.*, 2002; Nelson *et al.*, 2006).

A PT 24 to 48 h after exposure in asymptomatic children with accidental ingestions of large or unknown amounts should be obtained. In adults with deliberate ingestions and children with clinical evidence of bleeding, an initial PT and PTT should be obtained and then repeated at 24 and 48 h post-ingestion (Manoguerra and Cobaugh, 2005).

7. Analytical Methods

A number of analytical methods have been reported for detecting anticoagulant rodenticides in various matrices. Early fluorimetric methods were used to detect warfarin in serum (Corn and Berberich, 1967; Fasco *et al.*, 1977; Hanna *et al.*, 1978; Keiser and Martin, 1974; Lee *et al.*, 1981; Lewis *et al.*, 1970; O'Reilly *et al.*, 1962; Vesell and Shively, 1974; Welling *et al.*, 1970) and GLC for warfarin (Mildha *et al.*, 1974).

Warfarin-specific methods were generally not adequate for the anticoagulant rodenticides, so a number of other methods were developed. These include thin-layer chromatography (TLC), high-pressure liquid chromatography (HPLC), mass spectroscopy (MS), and antibody-mediated tests. Coumarin anticoagulant rodenticides were initially detected using TLC (Lau-Cam and Chu-Fong, 1972; Mallet *et al.*, 1973). A high-performance TLC method with an estimated detection limit of 200 ppb and 87% recovery from liver has recently been reported (Berny *et al.*, 1995).

Early HPLC methods focused on an individual chemical. For example, methods to detect chlorophacinone in formulations (Vigh *et al.*, 1981; Grant and Pike, 1979), brodifacoum in serum (Murphy and Gerken, 1989), brodifacoum (Koubek *et al.*, 1979; Hoogenboom and Rammell, 1983; Keiboom and Rammel, 1981; Ray *et al.*, 1989), bromadiolone (Subbiah *et al.*, 2005; Hunter, 1983), chlorophacionone (Hunter, 1985), difethiolone (Goldade *et al.*,

TABLE 15.3. Number of exposures to long-acting anticoagulant rodenticides and deaths reported by the American Association of Poison Control Centers – Toxic Exposure Surveillance System (AAPCC-TESS) Annual Reports: 24-year data

Year	No. of participating centers	Population served (millions)	No. of human exposures reported (all substances)	No. of exposures/ thousand population	No. of exposures to long-acting anticoagulant rodenticides (LAAR)	No. of deaths due to anticoagulants (alone and combined with other substances)	Reason: intentional suicidal (IS)	% of deaths from exposure to (LAAR)
1983	16	43.1	251,012	5.8	1,724	0	No deaths	0.00%

Source: Extracted from reviewing the AAPCC-TESS annual reports from 1983 to 2006. http://www.aapcc.org/annual.htm

1998), and difenacoum (Mundy and Machin, 1977) in tissue have been reported.

Then a method was developed to look for all the anticoagulant rodenticides on the market at the time. It succeeded in extracting and detecting eight anticoagulant rodenticides in serum and liver using fluorescence and UV detection. Samples were extracted with acetonitrile then cleaned up on solid phase columns. Four hydroxycoumarins were detected by fluorescence with excitation at 318 and emission at 390 nm. The indandiones were detected at 285 nm. An extraction recovery of 75% from serum and 69% from liver was reported. Hydroxycoumarins may be detected down to about 1 ng/ml of serum and 1 ng/g of liver, and indandiones down to 10 ng/ml of serum and 10 ng/g of liver (Chalermchaikit *et al.*, 1993; Felice *et al.*, 1991; Felice and Murphy, 1989). Another HPLC method for detecting brodifacoum in serum and liver using difenacoum as the internal standard has been reported (O'Bryan and Constable, 1991). There is also a method for the simultaneous detection of five superwarfarin rodenticides in human serum (Kuijpers *et al.*, 1995).

Other serum methods have been reported, for example, detection limits of 3 to 12 ng/ml for fluorescence and 20 to 75 ng/ml for UV detection (Kuijpers *et al.*, 1995; McCarthy, 1997; Mura *et al.*, 1992; Feng *et al.*, 1999).

Tissue methods include a solid phase cartridge extraction from liver with recoveries ranging from 52% for difenacoum to 78% for warfarin. The limit of detection is 10 ppb for warfarin and difenacoum and 110 ppb for chlorophacinone (Fauconnet *et al.*, 1997; Jones, 1996; Addison, 1982).

HPLC methods have also been published to distinguish cis- and trans-isomers of difenacoum with detection limits of 5 ng/ml (Kelly *et al.*, 1993). An early interesting approach was use of a post-column pH shift to enhance fluorescence detection (Hunter, 1985, 1983). Several earlier HPLC methods have also been reported (Hunter 1983; Mundy and Machin, 1982; AOAC, 1976a, b): diphacinone (Bullard *et al.*, 1975, 1976), fluorescence for bromadiolone (Deepa and Mishra, 2005), brodifacoum (Fu *et al.*, 2006), brodifacoum in tissues (Hoogenboom and Rammell, 1983), difenacoum (Hadler and Shadbolt, 1975), determinaiton of Rozol in parafinized formualtions (Kawano and Chang, 1980), and bromadiolone in tissues (Nahas, 1986).

A recent method uses DAD detection (Yang *et al.*, 2001). An interesting new method uses HPLC to detect anticoagulant rodenticides in soft drinks (Dimuccio *et al.*, 1991). An ion pair liquid chromatography method has been reported to detect chlorophacionone and diphacinone in oats (Primus *et al.*, 1998).

Contemporary confirmatory methods use mass spectroscopy. Most recently, liquid chromatography-electrospray ionization-mass spectroscopy (LC-EIS-MS) has been reported for the analysis of ten anticoagulant rodenticides with a limit of quantitation of about 5 µg/l (Grobosch *et al.*, 2006). Other recent methods use LC-MS-MS for unknown drugs including warfarin (Marquet *et al.*, 2003) and LC-ESI-MS and HPLC UV to detect anticoagulant rodenticides as low as 20 ng on column (Mesmer and Flurer, 2000). One of the earlier MS methods used a direct probe technique to detect indandione residues in food animals (Braselton *et al.*, 1992).

A cell culture/ELISA assay has recently been developed to detect anticoagulant rodenticides in treated grain (Lawley *et al.*, 2006). A prior immunoassay was developed to detect diphacinone and chlorophacionone (Mount *et al.*, 1988). Enantiomers of warfarin, coumachlor, and coumafuryl can be separated chromatographically (Armstrong *et al.*, 1993).

Serum concentration of dogs with anticoagulant rodenticide poisoning ranged from less than 10 ng/l to 851 ng/l for brodifacoum, difethialone, and difenacoum (Robben *et al.*, 1998).

Animal samples are routinely analyzed in veterinary diagnostic laboratories. For example, the Texas Veterinary Medical Diagnostic Laboratory, in College Station, Texas (http://tvmdlweb.tamu.edu), performs such analyses. Other laboratories performing anticoagulant rodenticide analyses on animal samples can be obtained from www.aavld.org Human samples are generally analyzed at either the National Medical Services Laboratory in Willow Grove, PA (800-522-6671) or the Medtox Scientific Laboratories in St Paul, MN (800-832-3244).

VII. GENERAL TREATMENT RECOMMENDATIONS

A. Referral to Healthcare Facility

In case of suspected terrorist act, misuse, intentional criminal, or any deliberate intentional suicidal ingestion, or when the amount ingested is either a large amount, or cannot be determined, the patient should be referred to a healthcare facility for clinical and laboratory assessment, and treatment if necessary (POISINDEX, 2007; Manoguerra and Cobaugh, 2005).

B. Home Observation Criteria

Accidental ingestion of a small piece or less than a few pellets can be adequately managed at home by Poison Control Centers, or by a healthcare professional with home observation and parent education. Usually, these types of exposures do not require any medical intervention or routine follow-up laboratory studies. Gastric decontamination has no effect on the clinical outcome after ''taste'' amounts are ingested by children (Kanabar and Volans, 2002; Mullins *et al.*, 2000; Shepherd *et al.*, 2002).

If the amount ingested by a child is a ''moderate amount'' (more than a handful, or a mouthful), or is questionably ''high'', then it is recommended that the parent contact their physician or call a local Poison Control Center

for instructions on how to induce emesis with syrup of ipecac (AAP, 2003; Tenenbein *et al.*, 1987).

There is no risk of poisoning for animals ingesting taste amounts, but if the amount ingested is unknown, or cannot be estimated, then a local Poison Control Center or veterinarian should be contacted for instructions on how to induce emesis and obtain a 24 to 48 h blood test (PT) to determine the need for treatment with vitamin K_1 (Munday and Thompson, 2003; Murphy and Gerken, 1989; Woody *et al.*, 2003).

C. Treatment at a Healthcare Facility

A PT should be obtained 48 h after exposure in asymptomatic children with accidental ingestion of a suspected large amount of rodenticide (Babcock *et al.*, 1993; Berry *et al.*, 2000). Adults with intentional ingestion and children with clinical evidence of bleeding, should obtain an initial PT and PTT, repeated at 24 and 48 h post-ingestion (Goldfrank *et al.*, 2002; Greeff *et al.*, 1987; Hoffman *et al.*, 1988). If any significant prolongation or evidence of bleeding is observed, PT should be repeated every 6 to 12 h. Determination of factors II, VII, IX, and X may be abnormal in patients with a normal PT and PTT and may provide earlier evidence of significant ingestion (Brands *et al.*, 1995; Corke, 1997; Pavlu *et al.*, 2005; Spahr *et al.*, 2007). Hemoglobin and hematocrit should be monitored in patients with clinical evidence of bleeding or significant coagulopathy. Determination of ABO blood type may be necessary in cases of toxic ingestions and bleeding. Patients may require red blood cell transfusions, or the administration of fresh frozen plasma (Bruno *et al.*, 2000; Ellenhorn *et al.*, 1997; Laposata *et al.*, 2007; Olmos and Lopez, 2007).

1. Emesis

Currently, there is a controversy regarding the use of syrup of ipecac; the American Academy of Pediatrics reversed its policy position about using syrup of ipecac to help with poisoning emergencies in children (AAP, 2003). Simultaneously, the American Association of Poison Control Centers (AAPCC) is still indicating that syrup of ipecac does have a place in therapy, and ''concluded that individual practitioners and poison control centers are best able to determine the particular patient population, geographic and other variables that might influence the decision to recommend having ipecac on hand'' (Manoguerra and Cobaugh, 2005). We recommend that the first action for a caregiver of a child who may have ingested one of these rodenticides is to consult with their local Poison Control Center (AAP, 2003).

Emesis with syrup of ipecac has been recommended for children with a history of accidental ingestion of small amounts, more than a ''grain or two'', if it can be administered within 1 h from the time of ingestion (Katona and Wason, 1989).

TABLE 15.4. Dosing of ipecac

Adult[a]	15–30 ml
Adolescent[a]	15–30 ml
Child 1–12 years old	15 ml
Child 6–12 months	Dose: 5–10 ml (Position child in left lateral decubitus position to reduce risk of aspiration)
Child under 6 months of age	NOT recommended for pre-hospital use

Katona and Wason (1989)

Emesis is contraindicated in patients with a prolonged PT or a bleeding disorder due to the risk of bleeding following ipecac-induced increased intracranial pressure (POISINDEX, 2007). Taste amounts, or a few pellets, or a bite on one block bait, do not require emesis. More than two mouthfuls or one block bait, or an unknown amount ingested, then emesis is most effective if initiated within 30 min to 1 h from the time of ingestion. The decision to induce or not to induce emesis is often controversial, and must be carefully considered. It could be most appropriate in the prehospital setting and is not recommended once the patient is in the emergency room (Krenzelok *et al.*, 1997; Chyka and Seger, 1997).

Contraindications: Patients with a bleeding disorder, particularly those under treatment with anticoagulants, or with history of chronic long-acting anticoagulant ingestion, are at risk from gastrointestinal and central nervous system bleeding from ipecac-induced emesis. The administration of activated charcoal is preferred when large amounts or chronic ingestion have occurred. Also, it is contraindicated if there is a risk for choking or aspiration, central nervous system excitation or depression, coma, seizures, signs of oral, pharyngeal, or esophageal irritation (Chyka and Seger, 1997; Golej *et al.*, 2001; Goldfrank *et al.*, 2002).

Before or after ipecac is administered, patients should be encouraged to drink water. Adults are given approximately 8 ounces (240 ml), and children 4 to 8 ounces (120 to 240 ml) (POISINDEX, 2007; Goldfrank *et al.*, 2002).

2. Activated Charcoal

For patients with a potentially toxic ingestion who are awake and able to protect their airway, activated charcoal diluted in water may be administered before going to the

TABLE 15.5. Dosing of activated charcoal

Charcoal dose Recommended to dilute 240 ml of water per 30 g charcoal (FDA, 1985)	
Adults and adolescents	50 to100 g
Children aged 1 to 12 years	25 to 50 g
Infants up to 1 year old	1 g/kg of body weight

Chyka and Seger (1997)

hospital. It is more effective when administered within 1 h post-ingestion. It is recommended to dilute 240 ml of water per 30 g charcoal (Chyka and Seger, 1997).

In patients who are at risk from the abrupt onset of seizures or mental status depression, activated charcoal should be administered by medical or paramedical personnel capable of airway management to prevent aspiration in the event of spontaneous emesis (POISINDEX, 2007; Ellenhorn *et al.*, 2002).

Use of a cathartic with activated charcoal is not routinely recommended as there is no evidence that cathartics reduce drug absorption and because cathartics can cause adverse effects such as nausea, vomiting, abdominal cramps, electrolyte imbalances, and occasionally hypotension. Complications include emesis and aspiration (Chyka and Seger, 1997; Golej *et al.*, 2001).

3. Gastric Lavage

Gastric lavage is recommended within 1 to 2 h post-ingestion. In chronic ingestions, it is not recommended as it may induce bleeding in adults with significant coagulopathy and is not necessary in children after accidental ingestion (Brands *et al.*, 1995; Ellenhorn *et al.*, 2002).

4. Laboratory Monitoring

A PT and PTT should be obtained 24 and 48 h post-ingestion in asymptomatic children with nonintentional ingestion of a ''large amount''. Adults with intentional ingestions and children with clinical confirmation of bleeding should obtain an initial PT and PTT, repeated at 24 and 48 h post-ingestion, followed by blood type verification (Barnett *et al.*, 1992; Ellenhorn *et al.*, 1997; Robben *et al.*, 1998). If any significant prolongation or evidence of bleeding is observed, PT should be repeated every 6 to 12 h. Determination of factors II, VII, IX, and X may be abnormal in patients with a normal PT and PTT, which may provide earlier proof of significant ingestion. Serial hemoglobin and hematocrit in patients should be followed with clinical evidence of bleeding or significant coagulopathy (Babcock *et al.*, 1993; Robben *et al.*, 1998). Hematocrit should be monitored closely at least every 4 h until the patient is stable (Brands *et al.*, 1995).

Hematest should be performed in stools and vomit for occult blood, and prothrombin time (PT) and partial time of thromboplastin (PTT) monitored routinely. A PT and PTT obtained within 48 h post-ingestion may not be predictive of subsequent coagulopathy (Greeff *et al.*, 1987). A 24 h and 48 h PT and PTT are therefore recommended every 6 to 12 h to assess efficacy of therapy. If prolongation is observed, then PT or INR should be repeated (Hoffman *et al.*, 1988; Smolinske *et al.*, 1989).

Antidote: Vitamin K_1 (Phytonadione: AquaMephyton®, Mephyton®) is the specific antidote and should be administered to any patient with a prolonged PT (Braithwaite, 1982; Bruno *et al.*, 2000; Tsutaoka *et al.*, 2003).

Blood and fresh or frozen plasma are recommended if the anticoagulation is severe.

Administration of vitamin K_1 is recommended if anticoagulation is excessive. A small intravenous dose of 1 to 5 mg, titrated to return PT to the therapeutic range, has been recommended. In anemic patients, the hematocrit should be monitored about every 4 h until it is stable. Stools and vomit may also be tested using Hematest (Jackson and Suttie, 1997; Hornfeldt and Phearman, 1996).

Oral vitamin K_1 may be administered in small ingestions and after the patient has been stabilized. Recommended doses are 15 to 25 mg p.o. in adults, 5 to 10 mg in children (Greeff *et al.*, 1987), and 2.5 to 5 mg/kg body weight in animals. A large daily maintenance dose of vitamin K_1 may be required for prolonged therapy in severe overdose, particularly in patients in whom vitamin K_1 absorption is variable (Lipton and Klass, 1984; Hoffman *et al.*, 1988; Ross *et al.*, 1992).

Intravenous phytonadione may be instituted in severe cases where rapid correction is needed. The adult dose is a minimum of 10 mg diluted in saline or glucose, injected i.v. at a rate not exceeding 5% of the total dose per minute. Doses should be repeated each at 6 to 8 h. Initial i.v. doses of 25, 100, 150, 160, and 400 mg have been required in patients actively bleeding (Hoffman *et al.*, 1988; Vogel *et al.*, 1988). Anaphylaxis may occur if vitamin K_1 is injected too rapidly.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

Today there is a greater risk than ever before that extremist or terrorist groups may use industrial or household chemical substances to harm, kill, or terrorize our society because these substances are very easy to obtain and conceal. Also, numerous highly toxic chemicals can be stolen and released or detonated from storage tanks or from transportation and manufacturing facilities. These commercial and industrial chemicals stored in large quantities are considered ''Agents of Opportunity'' because they are readily commercially available. A large number of industrial and household chemicals have the potential to be used as chemical warfare or terrorist agents. These include the superwarfarins. However, the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) classifies these rodenticides in the ''Low Toxicity Group''. Nevertheless, they may be used to harm and terrorize people through the ingestion of contaminated food or water. Superwarfarins are available to consumers as meal bait packs, pellets, mini pellets, blocks, mini blocks, wax blocks, liquid bait formulations, as well as in tracking powder, in diluted to concentrated formulations. The ingestion of small amounts may not cause any bleeding problems. Ingestion of greater amounts provides increased risk of severe bleeding in 36 to 48 h. The coagulopathy may last several weeks to months despite vitamin K_1 treatment.

Inhibition of synthesis of vitamin K_1-dependent clotting factors may also occur following repeated ingestion of small amounts making these agents insidious.

The use of chemical weapons by terrorists still remains a big threat. Until recently, United Nations resolutions required a complete disclosure of chemical warfare agents and their destruction. More action is needed to prevent radical groups from accessing or accumulating these agents. Participation of the entire community, particularly the civilian population, is needed. Participation may increase due to educational programs that boost awareness, improved surveillance, and reporting to the authorities of any suspicious activity, or purchase/stockpile of large quantities of these commercial products.

What to do? Be wary if people from a community that attended the same event, meal, party, or restaurant present with similar signs of bleeding disorders. Ingestion of superwarfarins may go unnoticed when these are mixed with food, and signs or symptoms are delayed 36 to 48 h. Consequently, the victims may not associate the ingestion with the coagulopathy.

Identification of superwarfarins is easy today. Analytical methods for the detection of these products in serum and tissues are readily available. Routine laboratory tests for coagulopathy may help support the need for such analytical chemistry testing. Stockpiles of vitamin K_1 may be useful to consider, particularly in places where large stocks of superwarfarin rodenticides are used such as livestock areas.

Although viral infections are manifest with different signs and symptoms there is a possibility that members from a community who are victims of superwarfarins may begin to panic thinking that they were victims of a ''virus'', such as Ebola, but the signs and symptoms are different. Consequently, good differential diagnostic and laboratory work-up algorithms are needed for both humans and animals. Teams of subject matter experts for both humans and animals may be useful in this regard.

Superwarfarin intoxication may have no signs or symptoms other than the appearance of bleeding in the stools, urine, mucous membranes, thoracic or abdominal cavity. Ebola virus causes sudden hemorrhagic fever, weakness, muscle pain, headache, and sore throat, followed by vomiting, diarrhea, rash, limited kidney and liver functions, and both internal and external bleeding.

Community education programs should be developed to inform residents about superwarfarin rodenticides and other household commercial chemicals with the potential to be used as chemical warfare or terror agents. Fact sheets may be one method of informing the public. Identifying those at risk and when they should be informed may be a useful part of this education campaign – this may also improve security in industrial plants, and limit any access from outsiders in all industrial and storage facilities where flammable or highly toxic chemicals are stored, particularly livestock facilities.

Finally, surveillance of food sources, particularly those derived from livestock, should be assessed to determine whether these agents are available to consumers in low concentrations which may lead to long-term accumulation and eventual coagulopathies.

CHAPTER 16

Thallium

LARRY J. THOMPSON

I. INTRODUCTION

Thallium (Tl) is a soft, bluish-white metal that occurs naturally in the earth's crust. It was discovered by Sir William Crookes in 1861 while making spectroscopic determinations of tellurium in residue material from a sulfuric acid plant. The name comes from the Greek word ''thallos'' which means a green shoot or twig, a reference to the green spectral emission lines originally used to identify the element. It is a heavy metal (density 11.83 g/cm^3, atomic number 81) whose use is mainly in the electronics industry (e.g. infrared detectors, semiconductor materials) with smaller quantities used in glass manufacturing and pharmaceutical industries, including the radioactive isotope Tl-201. Thallium can be released into the environment by cement manufacture, the burning of certain coal deposits and the production of nonferrous metals (Kazantzis, 2000; Peter and Viraraghavan, 2005). Thallium is a highly toxic element and salts of Tl are colorless, odorless, and tasteless. Thallium has no known biological function and has been the least studied of the toxic metals such as lead, mercury, and cadmium. Thallium salts were introduced as pesticides in Germany in 1920. The sulfate salt is most common and has been widely used as a rodenticide and ant killer. Tl has been associated with intentional and accidental poisonings since that time, although problems decreased greatly after its use was banned in major parts of the world (Saddique and Peterson, 1983).

II. BACKGROUND

Thallium has two important oxidation states, Tl (+1) and Tl (+3). The trivalent form more closely resembles aluminum and the monovalent form more resembles alkali metals such as potassium. The toxic nature of the monovalent Tl is due to its similarity to potassium in ionic radius and electrical charge. Thallium sulfate use as a pesticide was restricted in 1965 in the USA and the World Health Organization (WHO) recommended in 1973 against its use as a rodenticide due to its toxicity (WHO, 1973). From 1912 to 1930, thallium compounds were used extensively for medicinal purposes; for example in the treatment of ringworm (because of the depilatory effects), dysentery, and tuberculosis. The narrow margin between toxicity and therapeutic benefit, however, eventually eliminated the practical use of these compounds. Due to their highly toxic nature, delayed symptoms, and lack of taste or odor, Tl salts have been used for suicide attempts and in the intentional poisoning of individuals or small groups of people. Although the reported symptoms of Tl poisoning are diverse, the classic syndrome involves gastroenteritis, polyneuropathy, and alopecia. Fictional accounts of Tl as the agent of an intentional poisoning include Agatha Christie's book *The Pale Horse*. More recent accounts or suspicions of Tl use include medical case reports as well as lay press reports. Chronic Tl exposure has been reported in the industrial setting and exposure limits have been established (Peter and Viraraghavan, 2005). The radioactive isotope Tl-201 is a gamma emitter and is used in cardiac imaging, similar to technetium-99, and has a half-life of approximately 3 days. Although Tl-201 is the most common isotope in use, Tl-204 decays by beta particle emission and has a half-life of 3.8 years.

III. TOXICOKINETICS

Thallium is rapidly absorbed from the gastrointestinal tract and is well absorbed through the skin. There is little information concerning absorption from the respiratory tract. Once absorbed, Tl is rapidly distributed throughout the body to all organs, with the highest concentrations occurring in the kidney following an acute exposure. Both monovalent and trivalent Tl appear to distribute in similar manners, and it is not known if metabolic processes can change the valence state. Thallium can pass the placental barrier as well as the blood–brain barrier (Sullivan, 1992).

Elimination of Tl is mainly through the gastrointestinal tract but elimination also occurs through the kidneys, saliva, hair, skin, sweat, and breast milk. Relative amounts excreted by each route vary by species. Thallium is likely excreted through intestinal and gastric secretions associated with potassium loss or excretion. Likewise, reabsorption of Tl also occurs, mainly from the colon. The estimated biological half-life of Tl is 10 days but values up to 1 month have been reported (WHO, 1996).

IV. MECHANISM OF ACTION

Although the precise mechanism of action of Tl is unknown, its similarity to potassium has been shown to play a significant role. Thallium has an atomic radius similar to potassium and has shown a 10-fold affinity over potassium in Na^+/K^+-ATPase, resulting in lower activity of the enzyme. Tl will inhibit the influx and efflux of potassium in mitochondria, without affecting the movement of sodium. In addition to disturbing mitochondrial function, Tl has been shown to increase the levels of hydrogen peroxide and increase lipid peroxidation and oxidative stress (Hanzel and Verstraeten, 2005). Thallium can also inactivate sulfhydryl groups including those affecting the permeability of the outer mitochondrial membrane. Thallium can act as a Lewis acid, having an affinity for organosulfur compounds, which may account for its action to cause hair loss. The binding of cysteine by Tl may inhibit keratinization of hair by preventing the crosslinking of proteins (Mulkey and Oehme, 1993).

V. TOXICITY

Available human literature on Tl is mainly case reports from the results of acute poisonings, accidental ingestions, or suicide attempts. Although the acute classic syndrome of Tl poisoning involves gastroenteritis, polyneuropathy, and alopecia, not all these effects are observed in every case. The onset and sequence of symptoms will vary with the dose and duration of exposure. The lowest known toxic dose in the human is 0.31 g, which was reported to cause symptoms but did not cause death (Cavanagh *et al.*, 1974). Oral doses of 6–40 mg/kg body wt have been lethal within 10–12 days. Other oral human toxic doses are given as 10–15 mg/kg body wt (WHO, 1996; Moore *et al.*, 1993). Children have been poisoned with Tl at 4–8 mg/kg body wt.

Several hours following an acute exposure, initial symptoms may include gastroenteritis including nausea, vomiting, and diarrhea. With a relatively small dose, these symptoms may be relatively mild and diffuse, with little progression for 2–5 days. Gastrointestinal bleeding or constipation may then develop along with central and peripheral nervous system effects. These include paraesthesia with reports of the feeling of ''burning feet''. Additional neurological symptoms can include lethargy, delirium, seizures, and coma (Tsai *et al.*, 2006). An initial presentation simulating Guillain-Barré syndrome has been reported (Misra *et al.*, 2003). Nonspecific kidney and liver damage can develop. In severe exposures, circulatory symptoms may include hypertension, tachycardia, and cardiac failure. Initial dermatological involvement may include anhydrosis (which can cause fever) and this can be followed some time later by diaphoresis. In the second week following exposure additional dermatologic symptoms appear including an increased darkening of the hair papillae followed in several days by a developing alopecia. By 3 weeks following exposure there may be almost complete alopecia. At this time in the syndrome there may be ataxia and tremors with a painful neuritis in the lower extremities which may be severe. Following a lethal dose, death commonly occurs within 10–12 days caused by renal or cardiac failure. Recovery from Tl poisoning can require several months and residual neurological problems may remain including weakness, memory impairment, and psychological disturbances (Pau, 2000; Tsai *et al.*, 2006).

VI. RISK ASSESSMENT

Although reported as an agent of intentional poisoning for an individual or small group of people, the broad use of Tl as an agent in chemical warfare or terrorism has not been reported (Salem *et al.*, 2008). The most commonly available radioisotope of Tl-201 is a gamma emitter with a short half-life, making it a poor candidate for a radiological dispersion device (Burnham and Franco, 2005; Chin, 2007). Although the Tl-204 isotope is a beta emitter with a half-life of 3.8 years, its commercial use is limited. The chelating agent used for treatment of Tl exposure (Prussian blue) is also used in the treatment of radiocesium exposure, and thus is included in many antidote stockpiles (Ansari, 2004).

VII. TREATMENT

Diagnosis of Tl poisoning is based upon exposure history if available, compatible clinical time course and symptoms, along with the finding of above-background levels of Tl in urine, serum, or other clinical specimens. Appropriate methodology for urine or blood Tl includes atomic absorption spectroscopy (flame or flameless) and evolving methodology such as inductively coupled plasma emission spectroscopy (ICP). Use of colorimetric analyses of these specimens can lead to false positives (CDC, 1987). Normal or background concentration of Tl in urine is given as <0.5 μg/l up to a level of <10 μg/l, depending upon the laboratory reference, with concentrations elevating several hundred- to several thousand-fold following an acute exposure. Treatment should be initiated when 24-h urinary Tl excretion exceeds 0.5 mg. Additionally, a toxic level of Tl in the urine of >300 μg/l has been suggested (Sullivan, 1992). Blood Tl levels in exposure situations are less well characterized and values above 5 μg/l are considered to be evidence of excess Tl exposure (CDC, 1987). Prussian blue [ferric-hexacyanoferrate (II)] is the treatment of choice for Tl exposure in that it acts by binding Tl in the gastrointestinal tract, making it unavailable for reabsorption. This will increase the fecal excretion of Tl and decrease the half-life. Prussian blue is also used in the treatment of radiocesium and acts by the same mechanism [Yang *et al.*, 2008]. Suggested dosage regime is 3 g given orally three times a day for adults and adolescents. Children between

the ages of 2 and 12 years can be given 1 g orally three times a day. The clinician should insure proper gut functioning because constipation is a common finding in Tl intoxication. Fluid diuresis and other symptomatic and supportive care should also be provided.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

Thallium remains a toxic metal of concern for both accidental and intentional exposure. Its historical use as an intentional poison against individuals or small groups is based on its delayed onset of symptoms and the nature of its salts being tasteless and odorless. Although the incidence of intoxication with Tl has been decreasing with its decreasing availability, clinicians should remain familiar with clinical features, diagnostic considerations, and treatment regimens. History has shown Tl not to be an agent of choice for chemical warfare or terrorism, and the use of radiological Tl for these purposes is also unlikely. However, preparations for such an unlikely event are relatively straightforward with major considerations being the stockpiling of Prussian blue, also needed for radiocesium treatment, and the retention of analytical capabilities for Tl in biological and other samples. Future directions for Tl should include the further characterization of environmental contamination with Tl, the characterization of its chronic effects in humans and basic research to better explain its mechanism of action at the cellular and molecular level.

CHAPTER 17

Polycyclic Aromatic Hydrocarbons: Exposure from Emission Products and from Terrorist Attacks on US Targets – Implications for Developmental Central Nervous System Toxicity

DARRYL B. HOOD, ARAMANDLA RAMESH, AND MICHAEL ASCHNER

I. INTRODUCTION

The goal of this chapter is to stimulate research activity to develop both novel intervention strategies and therapeutic approaches to mitigate the neurotoxicity associated with prenatal exposure to polycyclic aromatic hydrocarbons (PAHs). The focus of this chapter is PAH exposure of vulnerable populations as a result of terrorist attacks on US targets. We will attempt to define the signature of prenatal PAH exposure-induced neurotoxicity within the context of human epidemiological data and translate this to appropriate animals models.

A critical review of the post-September 11, 2001 literature has resulted in a specific focus on studies that have revealed critical neural signaling/activity pathways and the identification of primary targets of PAH toxicity, as well as toxicity modifiers. It is hoped that as a result of this review, the interdisciplinary conduct of simultaneous temporal measurements of relevant markers and integrative analysis of critical signaling processes during development will increase two-fold; such that a better understanding of the mechanism of PAH exposure-induced neurotoxicity results.

II. BACKGROUND

A. Particulate PAH Release in the World Trade Center Disaster

The attack on the World Trade Center (WTC) on September 11, 2001 caused the largest acute environmental disaster in the history of New York City (Lioy *et al.*, 2002). As a result of this terrorist attack, combustion of more than 90,000 liters of jet fuel at temperatures above 1,000°C released a very dense and toxic atmospheric plume which contained thousands of tons of particulate matter (PM) composed, in part, of polycyclic aromatic hydrocarbons (PAHs). The plume dispersed over lower Manhattan, Brooklyn, and for miles beyond. The toxic materials contained in this plume entered nearby offices, schools, and residential buildings (Clark *et al.*, 2003; Lioy *et al.*, 2002; McGee *et al.*, 2003).

The populations that were faced with the greatest risk of exposure to this toxic plume included firefighters, police, paramedics, other first responders (Prezant *et al.*, 2002; Centers for Disease Control and Prevention [CDC], 2002), construction workers and volunteers who worked initially in rescue and recovery and then for many months cleared rubble at Ground Zero. Other vulnerable populations and individuals at a potentially elevated risk included women who were pregnant on September 11 and succeeding weeks in lower Manhattan and adjacent areas of Brooklyn and workers who cleaned WTC dust from nearby buildings as well as community residents including the 3,000 children who resided within 1 km of the towers and the 5,500 who attended school there. A consequence of the intense fire and the subsequent complete collapse of the two main towers was the development of a large plume of dust and smoke that released both particles and gases into the atmosphere.

An assessment of the potential exposure to dust and smoke among the residential and commuter populations was conducted and samples were taken from three undisturbed protected locations to the east of the WTC site (on Cortlandt, Cherry, and Market Streets). Analysis of samples provided for the determination of (a) chemical and physical characteristics of the material present in the dust and smoke

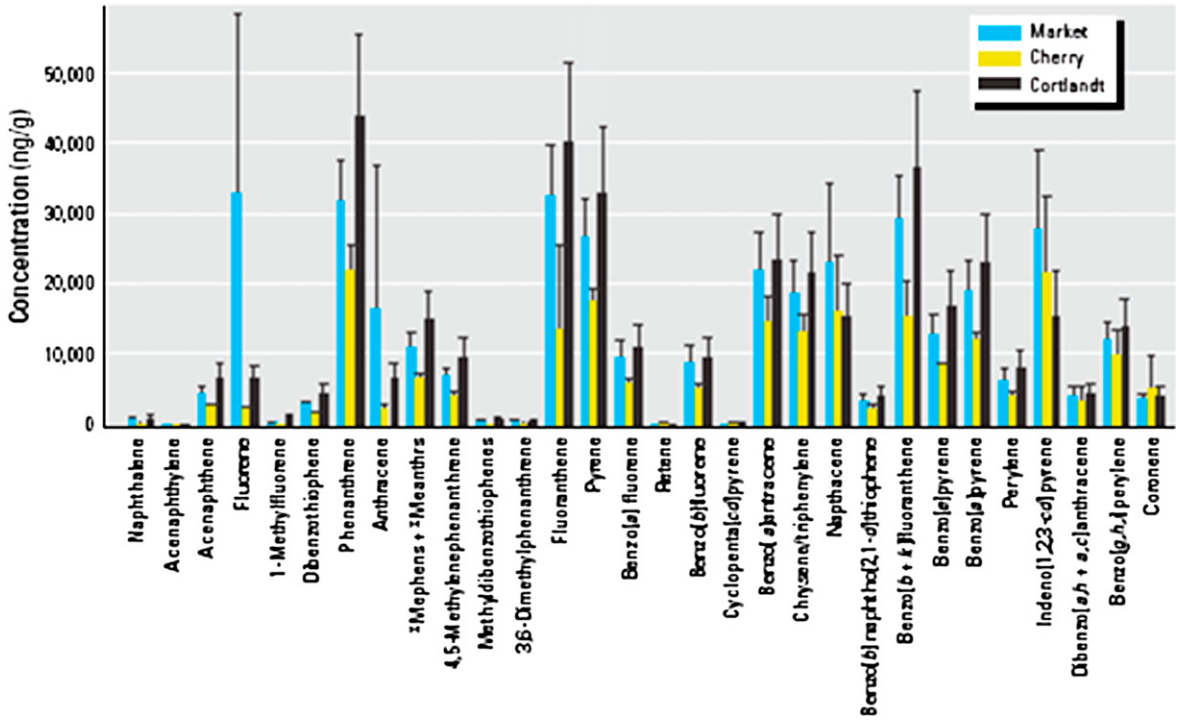

FIGURE 17.1. Airborne $PM_{2.5}$ mass concentrations at NYU Downtown Hospital (five blocks east of Ground Zero) and other sites in Manhattan, September through mid-October 2001. PS, public school. Data from Thurston *et al.* (2003) and adapted from Lioy *et al.* (2002). Adapted with permission from *Environ. Health Perspect.*

that settled from the initial plume, and (b) information on contaminants that could potentially affect acute or long-term human health by inhalation or ingestion. The highest concentrations of the 40 specific PAHs reported in Figure 17.1 were found in the Cortlandt Street sample. This is logical because this site was deemed to be the site closest to the fire after the collapse; however, a larger variety of other PAHs at concentrations >10 μg/g were found in the Market Street samples. The intense and uncontrolled fire(s) would be expected to burn at different temperatures, and the homogeneity of the material that burned would lead to a variety of unburned or partially burned hydrocarbons. These PAHs were found to be derived from burning plastics, metals, woods, synthetic products, and other materials, using morphologic analyses. It was anticipated and subsequently verified that the actual compounds and materials, that were present in the plume might be similar to those found in building fires. The morphologic analyses of the large mass of material present in the toxic plume found that the total concentrations of the above-mentioned 40 typical PAHs with higher molecular weights were in excess of 200–300 μg/g. The distribution of the 40 PAH compound levels ranged from hundreds of nanograms per gram to >40 μg/g. The concentration of benzo(a)pyrene ranged from 12 to 24 μg/g, and the highest values were detected at the Cortlandt Street site.

Data collected to date clearly document that PAHs were present in the samples at levels of 5 μg/g to hundreds of micrograms per gram as a result of the incomplete combustion of jet fuel and building materials that were produced by the intense fire. Concentrations of the individual compounds, e.g. benzo(a)pyrene, [B(a)P] were >20 μg/g, and the total mass of PAHs present was in excess of 0.1% of the mass. When placed in the context of the vast amounts of other materials present in the air during the first day after the collapse and fires, these levels were high and could lead to significant short-term inhalation exposure. Based on the PAH results from air samples collected after September 25, 2001 the types of PAHs released into the atmosphere at that time were similar to the PAHs detected in the settled dust and smoke samples collected during the first week after the collapse and fires (ATSDR, 1995, 2002).

B. Exposure of Pregnant Women to PAHs as a Result of the WTC Terrorist Attack

Pregnant women who were either working in the WTC or residing in the communities of lower Manhattan on September 11, 2001 were successfully recruited to a Mount Sinai cohort population for the purpose of assessing pregnancy outcomes and impacts on their infants (Berkowitz *et al.*, 2003). Of the 187 recruited pregnant women, 12 were inside the WTC towers at the time of attack and an additional 122 (65%) were within ten blocks. A comparison group ($n = 2{,}367$) consisted of all private patients not known to have been near the WTC who delivered at Mount Sinai Hospital during the same time period.

TABLE 17.1. Unadjusted birth outcomes by place of residence and employment (within 2 miles of the WTC)

Birth outcomes	Group 1: resided	Group 2: worked	Group 3: neither resided nor worked	*p*-Value
Length of gestation (days)	277.7 [*n*=80]	275.5 [*n*=51]	279.0 [*n*=169]	0.026
Birth weight (g)	3339.6 [*n*=80]	3442.7 [*n*=51]	3511.8 [*n*=169]	0.019
Birth length (cm)	50.06 [*n*=80]	51.44 [*n*=48]	51.15 [*n*=165]	0.008
Head circumference (cm)	34.10 [*n*=80]	34.18 [*n*=49]	34.51 [*n*=164]	0.097
Ponderal index	2.75 [*n*=80]	2.54 [*n*=48]	2.65 [*n*=165]	0.286
Percent SGA (<10th percentile)	8.75 [*n*=80]	5.88 [*n*=51]	5.33 [*n*=169]	0.581
Percent SGA (<20th percentile)	23.8 [*n*=80]	15.7 [*n*=51]	18.3 [*n*=169]	0.465

C. Birth Outcomes of Pregnant Women in or Near the WTC During Terrorist Attack

Term infants born to women who were pregnant on September 11, 2001 and who were living within a 2-mile radius of the WTC during the month after the event showed significant decrements in term birth weight (−149 g) and birth length (−0.82 cm), compared with infants born to the other pregnant women studied, after controlling for socio-demographic and biomedical risk factors. The decrements remained significant with adjustment for gestational duration (−122 g and −0.74 cm, respectively). Women in the first trimester of pregnancy at the time of the WTC attack delivered infants with significantly shorter gestation (−3.6 days) and a smaller head circumference (−0.48 cm), compared with women at later stages of pregnancy, regardless of the distance of their residence or work sites from the WTC. The observed adverse effects suggest an impact of pollutants and/or stress related to the WTC disaster and have implications for the health and development of exposed children (Lederman *et al.*, 2004).

D. Conclusion from WTC Prospective Epidemiology Cohort Studies

An increase in incidence in small for gestational age (SGA) was the major adverse health effect seen in infants born to women who were inside the towers or within approximately ten blocks of the WTC on September 11 (Berkowitz *et al.*, 2003). The incidence of SGA infants was two-fold greater among the WTC mothers than in a demographically similar comparison population not known to have been in lower Manhattan on September 11, 2001 ($p < 0.01$). SGA is an index of intrauterine growth restriction (IUGR). Biologically plausible causes of IUGR in these babies include exposures to fine PM and PAHs. Previous studies have found associations between particulate air pollution and IUGR (Bobak *et al.*, 2001; Dejmek *et al.*, 1999). Other investigations have linked air pollution to preterm births (Ritz *et al.*, 2000). Additionally, high levels of PAH-DNA adducts in umbilical cord leukocytes have been associated with reduced birth size (Perera *et al.*, 1998). Prenatal exposure to cigarette smoke, which contains PAHs among other toxins, is a well-established risk factor for IUGR. Maternal stress is another possible cause of the observed increase in SGA, but the authors in the prospective cohort studies did not detect any correlation between reported levels of stress and SGA incidence. An important question that arose as a result of the studies discussed above was: Will the increased frequency of SGA observed in babies born to women who were within or near the WTC on September 11 result in long-term adverse effects on growth and cognitive development?

E. The Human Health Relevance of Prenatal Exposure to PAHs

Exposure to benzo(a)pyrene, the prototypical PAH, occurred through the inhalation of particulates in the ambient air that was produced as a result of the terrorist attack on the WTC as described above. Subsequent evidence from human epidemiological studies has shown that unintended prenatal exposure of the fetus to PAHs adversely affects fetal development resulting in low birth weight and reduced head circumference that can manifest as neurobehavioral deficits in the early years of childhood. Neurobehavioral deficits in offspring from PAH-exposed mothers have been quantified as low scores on selective types of cognitive and neuromotor functioning (Hack *et al.*, 1991; Perrera *et al.*, 2003; Landrigan *et al.*, 2004). Recently published studies on PAH-exposed populations provide further evidence that exposure to environmentally relevant levels of PAH adversely affects childhood development as assessed by the mental development index on the Bailey Scales of Infant Development (BSID-II) (Perera *et al.*, 2006).

While the brain levels of PAH in the children who scored low on the mental development index component of the BSID-II cannot be known, studies such as the aforementioned are valuable from a translational standpoint as they can assist in the design of molecular neurotoxicity studies. Mechanistic studies that utilize transgenic mouse models will facilitate the understanding of the molecular signaling events that give rise to the observed neurotoxic effects resulting from exposure to PAHs during development. The

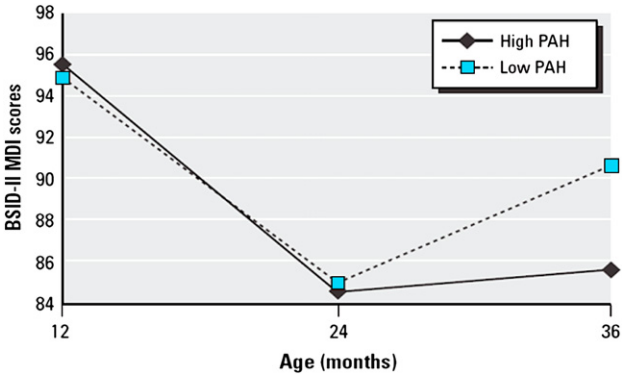

FIGURE 17.2. Estimated effects of prenatal PAH exposure on cognitive development in children 12 months through 36 months of age by GEE. The model was adjusted for the child's exact age at test administration, child's sex, ethnicity, gestational age at birth, quality of the (caretaking) home environment, and prenatal exposure to ETS and CPF. Adapted with permission from *Environ. Health Perspect.* and Perera *et al.* (2006).

gaps with respect to several reports in the literature illustrate the need for such basic mechanistic studies.

III. PAH-INDUCED PHYSIOLOGICAL AND BEHAVIORAL TOXIC MANIFESTATIONS IN ANIMAL MODELS: EARLY PAH STUDIES WHICH IMPLICATED THE CNS AS A TARGET

In the 1970s it was shown that pregnant mice treated with PAHs produced offspring with a high incidence of brain tumors (Rice *et al.*, 1978). Acute B(a)P exposures in laboratory animals were shown to cause malignant brain tumors (Markovits *et al.*, 1976). Additionally, malignant transformations of fetal mouse brain cells were observed subsequent to *in vitro* B(a)P exposure (Markovits *et al.*, 1976). High levels of several PAHs including B(a)P were found in soil, sludge, and water samples along with other solvents and metals that were used for processing motor oil and chemical wastes during the mid-1970s and early 1980s (Kilburn and Warshaw, 1995). Later in the 1980s, microinjections of diesel exhaust fraction (rich in PAHs) into the rat hippocampus and striatum were shown to cause neuronal lesions in a study by Andersson *et al.* (1998). Plant workers in Poland employed to process coke were reported to develop neurotic syndromes with vegetative dysregulation, and loss of short-term memory; their prevalence depended on the level of exposure to B(a)P (Majachrzak *et al.*, 1990). Children born in years of maximal air pollution in the Czech Republic were shown to have learning disorders that were attributed to elevated levels of PAHs in the atmosphere from the mining and combustion of coal (Otto *et al.*, 1997). In the USA, neurological symptoms were reported from a community that was chronically exposed to B(a)P, benz(a)anthracene, chrysene, naphthalene, fluorine, and pyrene dumped at a site in Texas from the 1960s until the 1970s (Dayal *et al.*, 1995). Similarly, residents in close proximity to a combustion Superfund site in Louisiana were reported to have displayed neurophysiological and neuropsychological impairments. Paternal occupational exposure to PAHs was shown to be associated with an increased risk of neuroectodermal tumors in children from Italy, France, and Spain (Cordier *et al.*, 1997a, b). Similarly, an association between paternal exposure to creosote (rich in PAHs) and diagnosed cases of neuroblastoma in children was seen (Kerr *et al.*, 2000). As can be seen from the early work, *in utero* exposure to this toxic chemical produces functional alterations in nervous system functioning resulting in various forms of developmental disorders or behavioral impairments in higher mammals (Srám, 1999).

In the late 1990s a mounting body of literature suggested that a likely long-term effect of prenatal exposure to PAHs was to interfere with the development and function of normal CNS development. Although the mechanism of PAH-induced impairment of CNS function was not well understood at the time, it was clear that additional research on PAH-induced neurobehavioral alterations and the underlying cellular and molecular mechanisms was warranted. At the time, we commenced studies [at environmentally relevant B(a)P concentrations] to assess the developmental neurotoxicological effects subsequent to exposure to B(a)P aerosol (Hood *et al.*, 2000; Ramesh *et al.*, 2001a, b, 2002; Wormley *et al.*, 2004; Wu *et al.*, 2003). Additionally, PAHs have been implicated as causative agents of lung, breast, esophageal, pancreatic, gastric, colorectal, bladder, skin, prostate, and cervical cancers in humans and animal models. Other than carcinogenicity, PAHs have also been reported to cause hemato-, cardio-, renal, neuro-, immuno-, reproductive, and developmental toxicities in humans and laboratory animals. Details of the toxicities and cancers caused by PAHs are beyond the scope of this chapter. Interested readers may refer to the reviews of ATSDR (1995), WHO (1999), Pickering (1999), and Ramesh *et al.* (2004).

A. Development of a Susceptibility Exposure Paradigm to Access the Effects of Prenatal Exposure to PAHs on CNS Development

Over the years, work from our laboratory focused on the refinement of a susceptibility exposure paradigm to better assess the effects of prenatal exposure to environmental toxicants on certain aspects of CNS development (Hood *et al.*, 2000; Ramesh *et al.*, 2001a, b; Wormley *et al.*, 2004). Because CNS events have ''windows of susceptibility'' during development, it was reasoned that there should be a time frame when the lowest dose and shortest duration of exposure to an environmental contaminant would be

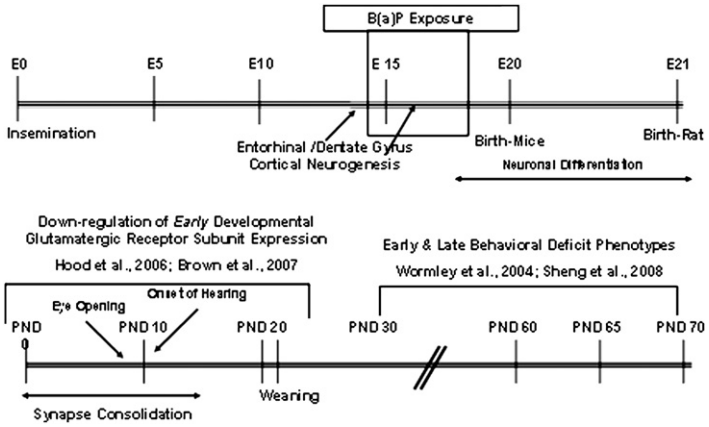

FIGURE 17.3. A Modified Barker Hypothesis: the susceptibility exposure paradigm used as a model to assess the effects of prenatal exposure to polycyclic aromatic hydrocarbons. Adapted with permission from *Neurotoxicology* and Brown *et al.* (2007).

expected to have a significant negative impact on brain development.

The susceptibility exposure paradigm was developed based on the peak periods of neuroepithelial cell proliferation (neurogenesis) for specific brain structures. Gestation days 14–17 represent the peak period of neurogenesis for the cerebral cortex in the mouse. Subsequent to this peak period of neurogenesis, each neuronal cell continues to mature through a process of migration, settling to a specific location and extending projections to a designated target site. In many cases such as for the external germinal layer, this process of migration continues well after birth and in the human can continue for 7 months to 2 years after birth. Specifically, cortical synapses at birth are still immature and in the human the morphological characteristics of maturity are reached between 6 and 24 months after birth. The use of our susceptibility exposure paradigm has allowed us to ask relevant questions pertaining to nervous system dysfunction during development that arise as a result of modulation of the process of neurogenesis.

B. Benzo(a)pyrene Aerosol CNS Disposition Studies as a Model of Prenatal Environmental Contaminant Exposure

We routinely use nose-only inhalation exposure of B(a)P aerosol to evaluate the consequence of prenatal exposure to this toxicant on physiological and behavioral endpoints. The properties of this B(a)P aerosol are shown in Figure 17.4. The aerosol typically exhibits a trimodal distribution with a 93% cumulative mass less than 5.85 μm, 89% cumulative mass less than 10 μm, 55.3% cumulative mass less than 2.5 μm, and 38% less than 1 μm. Fifty-five percent of the aerosol generally has a cumulative mass less than $PM_{2.5}$ and the mass median aerodynamic diameter (MMAD) + geometric standard deviation for this mode is consistently 1.7 ± 0.085 μm. For several years we employed a rat model exposing timed pregnant dams to inhalation concentrations of 25, 75, and 100 $\mu g/m^3$.

C. Benzo(a)pyrene Metabolite CNS Disposition in Offsprings

Bioavailability and B(a)P disposition studies conducted in timed pregnant rat dams have demonstrated a progressive increase in plasma and cortex metabolite concentrations in offspring pups as a function of B(a)P aerosol exposure concentration. Additionally, differences in metabolite disposition from plasma to cortex within individual exposure concentration cohorts were noted. No detectable levels of B(a)P metabolites are ever in the control (carbon-black exposed; Hood *et al.*, 2000) rats as reported in Wu *et al.*

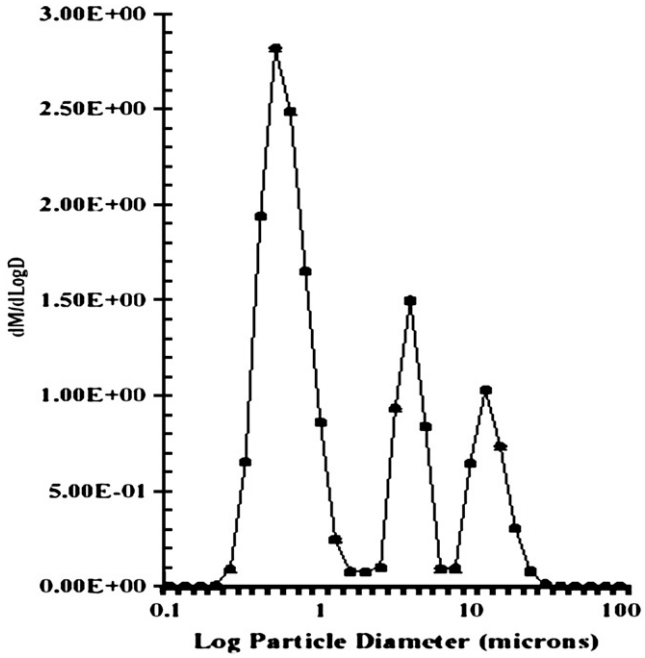

FIGURE 17.4. Differential particle size distribution of B(a)P: carbon black aerosol (100 $\mu g/m^3$). Subsequent to exposure, substrate post-weights were recorded and entered into the Win-CIDRS (Windows–Cascade Impactor Data Reduction Program) to generate the particle size distribution for the particulate aerosol. From Hood *et al.* (2000).

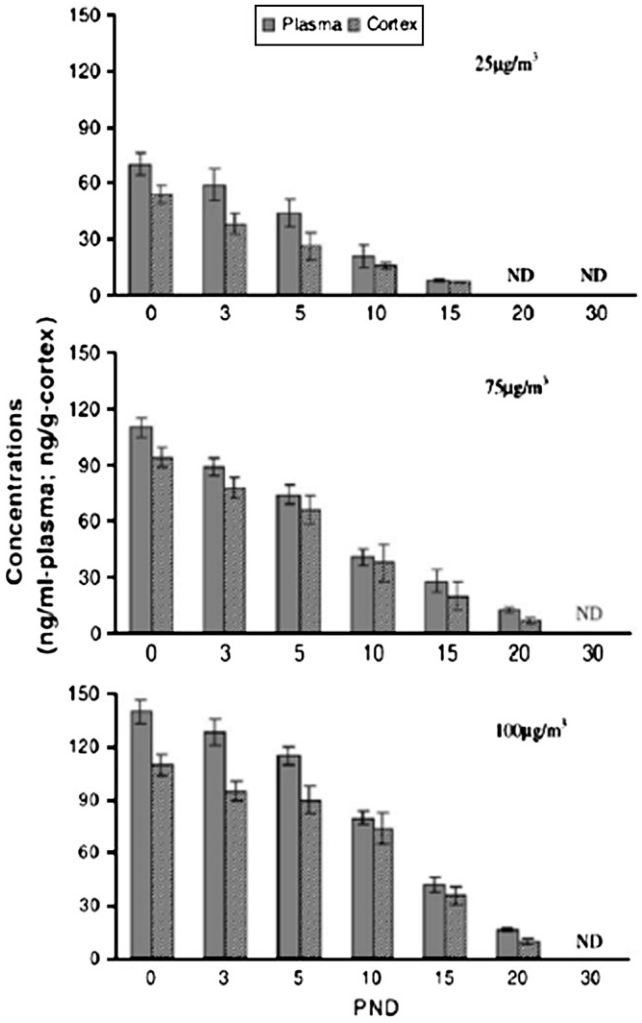

FIGURE 17.5. The time course of mean plasma and cerebrocortical total B(a)P metabolite concentrations in offspring pups. Adapted from Hood *et al.* (2000).

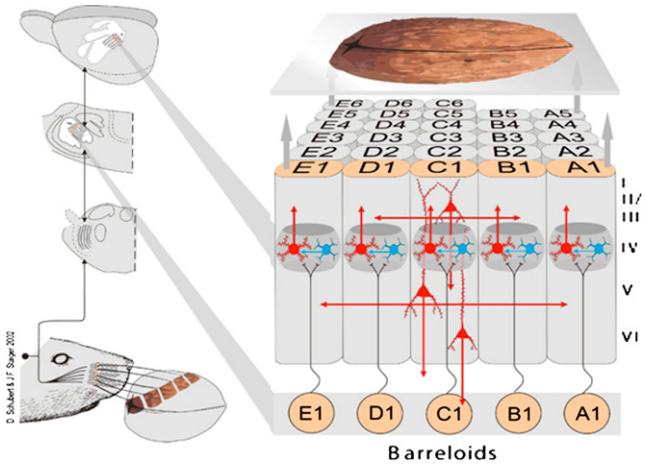

FIGURE 17.6. Main elements in the neural pathway from the axons innervating the whisker follicles on a rat's face (lower left) to the primary somatic sensory cortex (upper right). The diagram shows the rat palpating a walnut with its whiskers and perceiving the walnut through activity transmitted in the sensory pathway to cortex. The pathway contains a first synapse in the brainstem trigeminal nuclei (''Trig''), a second synapse in the contralateral thalamus (''Thal'') and a third relay from thalamus to barrel cortex [called barrels (Cortex)]. There is a separate channel for each whisker on the rat's face up to and including primary sensory cortex as illustrated on the right, each labeled by a row (A, dorsal to E, ventral) and a number starting from posterior and counting anteriorly. The roman numerals to the right of barrel cortex identify the six cortical layers. The results in the present paper were generated by analyzing neurons in the barrel cortex using single cell electrophysiology and biochemical techniques (adapted from Woolsey and Van der Loos, 1970).

(2003). Importantly, total metabolite distribution at an exposure concentration of 100 μg/m^3 was reported and the B(a)P 4,5; 7,8; 9,10-dihydrodiols, B(a)P 3,6-dione, 3- and 9-hydroxy B(a)P metabolites were detected and the B(a)P 7,8; 9,10-diols, and 3-hydroxy B(a)p were found to be predominant in cerebrocortical extracts.

D. Identification of Prenatal PAH Exposure-Induced Deficits in Offspring Cortical Neuronal Activity and Behavior

Recent B(a)P studies have established reductions in learning and memory correlates both in rodent and humans (Grova *et al.*, 2007; Wormley *et al.*, 2004; Widholm *et al.*, 2003; Gilbert *et al.*, 2000; Hack *et al.*, 1991; Perrera *et al.*, 2003, 2006; Landrigan *et al.*, 2004). We decided to use the rat cortex as a model of primary somatosensory (S1) cortex (Figure 17.6). Because of the unique organization of the rodent whisker to cortex pathway, and the already demonstrated effects of other toxins, such as alcohol, lead, and TCDD on this cortex as the system was ideal for deciphering the effects of B(a)P on a well-characterized model (Rema *et al.*, 1998; Rema and Ebner, 1999; Wilson *et al.*, 2000; Benusková *et al.*, 2001; Hood *et al.*, 2006). Whiskers are arranged in vertical and horizontal arrays on both sides of the face. Each whisker projects to a cellular aggregate called a barrel in layer IV of the S1 cortex (Woolsey and Van der Loos, 1970). The arrangement of this whisker-to-barrel circuit makes the S1 cortex in offspring animals that received a prenatal insult an *ideal* system to quantify alterations in stimulus–response relationships which manifest as a result of *in utero* exposure. The results from McCallister *et al.* (2008) shown in Figure 17.7 are consistent with earlier studies (Hood *et al.*, 2006) of the neurotoxic effects in offspring cortex subsequent to prenatal TCDD exposure. B(a)P-exposed offspring also exhibit diminished, stimulus-evoked activity in the barrel field cortex. In this work, responsive neurons were identified in most penetrations by advancing the electrode at 20 μm intervals, monitoring spontaneous activity and then manually stimulating the whiskers to test for evoked responses from neurons near the electrode. When post-stimulus time histogram (PSTH) time bins are subdivided into 10 ms time domains, the data

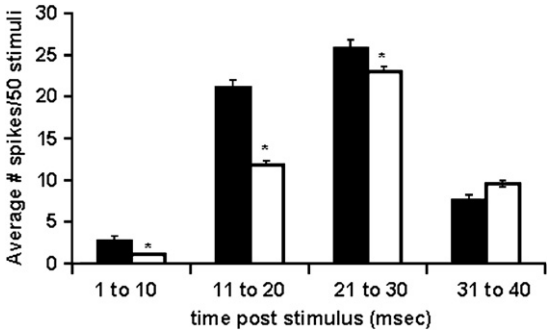

FIGURE 17.7. Bar graph of the mean ± SE stimulus evoked activity from control and PAH-exposed (300 µg/kg BW) offspring. White bars represent vehicle control offspring and black bars represent B(a)P-exposed offspring. Data are derived from a suprathreshold intensity (50 V stimulus applied to piezoelectric element) with whiskers deflected approximately 600 µm from the face. Response magnitudes (+SEM) were assessed for statistical differences within each group (* $p < 0.05$, ANOVA). This epoch analysis shows that prenatal B(a)P exposure significantly impacts the shorter latency components (from McCallister *et al.*, 2008).

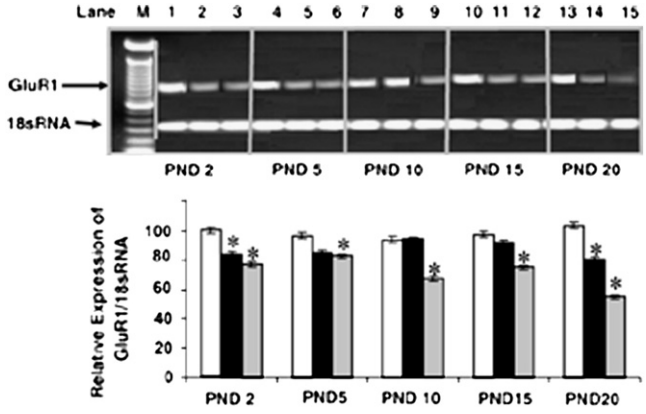

FIGURE 17.8. Offspring pre-weaning hippocampal developmental expression profile of GluR1 mRNA on PND 2, 5, 10, 15, and 20 following gestational exposure to B(a)P on GD14–17. Upper panel shows the electrophoretic agarose gel results from semi-quantitative RT-PCR. The upper band is the GluR1 (791 bp) subunit and the lower band is the internal control, 18sRNA (324 bp). Lower panel displays a histogram of the densitometric quantitation of the relative expression of target to internal 18sRNA control. M represents the DNA marker. Lanes 1–3: offspring GluR1 mRNA levels for PND 2; (lane 1) white bar – control, (lane 2) black bar – 50 mg/kg B(a)P, and (lane 3) gray bar – 150 mg/kg B(a)P. Lanes 4–6: offspring GluR1 mRNA levels for PND 5; (lane 4) white bar – control, (lane 5) black bar – 50 mg/kg B(a)P, and (lane 6) gray bar – 150 mg/kg B(a)P. Lanes 7–9: offspring GluR1 mRNA levels for PND 10; (lane 7) white bar – control, (lane 8) black bar – 50 mg/kg B(a)P, and (lane 9) gray bar – 150 mg/kg B(a)P. Lanes 10–12: offspring GluR1 mRNA levels for PND 15; (lane 10) white bar – control, (lane 11) black bar – 50 mg/kg B(a)P, and (lane 12) gray bar – 150 mg/kg B(a)P. Lanes 13–15: offspring GluR1 mRNA levels for PND 20; (lane 13) white bar – control, (lane 14) black bar – 50 mg/kg B(a)P, and (lane 15) gray bar – 150 mg/kg B(a)P. * $p < 0.05$ relative to control on the respective PND.

are very similar to what was observed in TCDD-exposed offspring. Prenatal B(a)P exposure clearly induces suppression of evoked cortical neuronal activity and is greatest in the early latency components of the response after stimulation of the best whisker (Figure 17.7). The overall reduction in B(a)P-induced suppression is clearly apparent in the average responses. Further, the most robust suppression after prenatal B(a)P is found at the two shortest post-stimulus epochs of 1–10 ms and 11–20 ms. The short latency response (3–10 ms) of cortical neurons is thought to reflect activity generated at the thalamocortical synapses that depend heavily on alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type glutamate receptors (Armstrong-James *et al.*, 1993). This is the component of the cortical response that seems to be most strongly diminished in B(a)P-exposed offspring. The longer latency responses (11–40 ms) have been shown to be strongly dependent on N-methyl-D-aspartate (NMDA) receptor activation (Armstrong-James et al., 1993). Therefore, the data from our laboratory suggest that prenatal B(a)P-exposure reduces evoked cortical neuronal activity and indicates that these reductions are due to environmental contaminant-AhR agonist effects on the normal development of both AMPA and NMDA subunits.

Interestingly and consistent with previously reported results for prenatal TCDD exposure (another environmental contaminant found to be released as a result of the terrorist attack on the WTC) the effects on the aforementioned AMPA-mediated single cell responses were validated by RT-PCR. Glutamate receptor, AMPA-type subunit (GluR1) temporal developmental mRNA expression was determined in control and B(a)P-exposed offspring. The results shown in Figure 17.8 were normalized to 18sRNA expression. The results presented in this pre-weaning developmental expression profile figure from Brown *et al.* (2007) reveal a significant 50% down-regulation in GluR1 developmental expression in the 150 mg/kg body wt B(a)P-exposed offspring by PND 20 as compared to offspring controls.

In order to ascertain a behavioral phenotype for PAH-exposed offspring, an operant behavioral paradigm was used. The results from Wormley et al. (2004) are shown in Figure 17.9. On PND 100, offspring male and female littermates were prepared for initiation of learning behavior analysis (Weiss and Laties, 1964). Initially, animals were trained to press a lever in the operant chamber. This initial session is referred to as magazine training. In this session, animals are trained to retrieve pellets from the delivery trough that are dispensed every 120 s (variable time, VT 120) on average independently of the animal's behavior. Random lever pressing also initiates delivery of a food pellet. If ten lever presses occurred during a 20-min magazine training period, the schedule was automatically switched to a fixed-ratio of 1 (FR1; specifying that one lever press would produce one food pellet). If no responses occurred, the VT 120 s schedule automatically shifted to an

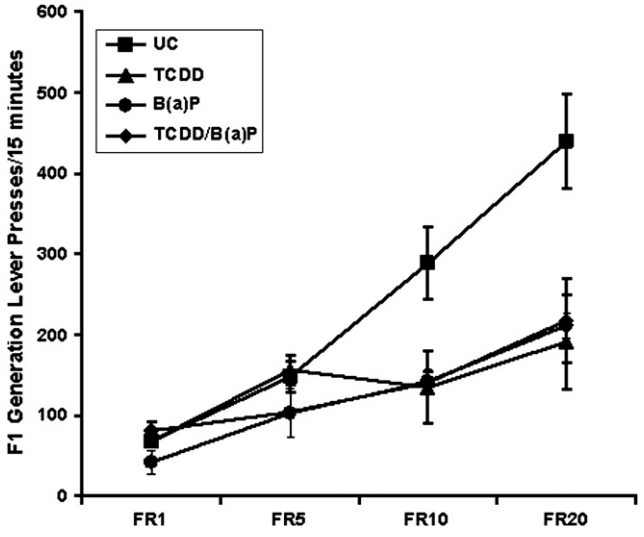

FIGURE 17.9. Gestational exposure to environmental contaminants (including PAH aerosol) produced as a result of the terrorist attack on the WTC; results in significant deficits in learning behavior in offspring animals. Control ($n = 8$) and B(a)P-exposed ($n = 8$) F1 generation animals were magazine trained where they learn to press a lever n number of times (FR) in order to receive a food reinforcement. Automated overnight shaping of this learning behavior proceeded at FR(n) until the animal met the criteria for inclusion in the study. Acquisition of data at an FR(n) for 15 min each day for 5 days was followed by data averaging and statistical analysis (* $p < 0.05$).

FR1 after 30 min. This FR1 component then proceeded for an additional 100 responses or 60 min, whichever occurred first. Further training proceeded overnight in a 12-h session and is referred to as automated overnight shaping. During this overnight, automated session the FR1 schedule was in effect. All animals responded well by the end of the overnight session as revealed by analysis of the cumulative record for each animal per overnight session. At the end of each testing session, the animals were returned to their cages. Analysis of fixed-ratio performance learning behavior was initiated on the following day by analyzing behavior for 15 min/day for 5 days (equals 5 session block; $n = 5$ F1 generation animals/group). The analysis was conducted for an FR1, FR5, FR10, and FR20 (Weiss and Laties, 2000). Data for five session blocks/FR were analyzed and the mean ± SEM was plotted for each FR versus lever presses/15-min acquisition session. These findings emphasize that as the complexity of the task increased from FR1 to FR5 to FR10 to FR20, the exposed offspring animals reveal significant deficits in lever pressing learning behavior which does not occur in the controls (Figure 17.9). The B(a)P exposed offspring animals simply were not able to learn the lever pressing task beyond a complexity of FR5. These results demonstrate that there is clearly a reduced capacity for behavioral learning in offspring progeny subsequent to prenatal PAH exposure. The results from these *in vivo* experiments correlate well with behavioral studies in animals and humans, which have reported deficits in learning and memory tasks produced by prenatal exposure to polychlorinated biphenyl compounds (Schantz *et al.*, 2003).

The translational relevance of our work utilizing this susceptibility exposure paradigm to assess the effects of PAH exposure during gestation is based on the fact that the earliest synapses develop during the early postnatal (PND13-15) in the mouse model. Unintended prenatal exposure of the fetus to environmental contaminants has been shown to result in alterations in neurodevelopment such as reduced head circumference and neurobehavioral deficits such as poorer outcome on selective aspects of cognitive and neuromotor functioning in both rodent and human offspring. Previous studies from our group utilized this susceptibility exposure paradigm to uncover deficits in behavioral learning in parallel with reduced expression of glutamate receptor subunits (Wormley *et al.*, 2004). As mentioned above, findings presented in a recent report from the Perera group have demonstrated for the first time that prenatal exposure to polycyclic aromatic hydrocarbons during development results in a significant reduction in mental development index at 36 months in children born to mothers in the urban cohort that was studied (Figure 17.2 above; Perera *et al.*, 2006). The phenotype of the 3-year old children born to these women who were prenatally exposed to PAHs resembled the observed phenotype of rodents from our studies where the effect of B(a)P-induced dysregulation of developmental signaling processes was to degrade neuronal function to result in significant deficits in neuronal activity, plasticity, and behavioral learning (Wormley *et al.*, 2004; Brown *et al.*, 2007).

Overall, the results from these electrophysiology and molecular studies quantify deficits in early postnatal glutamatergic receptor subunit neuronal activity, developmental expression, and behavioral learning suggesting dysregulation of temporal developmental expression of glutamate receptor subunit expression as a result of prenatal B(a)P exposure when synapses are developing for the first time.

IV. UNDERLYING MECHANISMS OF PAH NEUROTOXICITY

Polycyclic aromatic hydrocarbons exert their toxicity in the central nervous system through various mechanisms. The following is a brief overview of the pathways involved.

A. Biotransformation

The relatively high affinity of these chemicals for lipid-rich tissues (Lipniak and Brandys, 1993) leads to disposition of B(a)P in rodent brain regions (Das *et al.*, 1985). The intraregional distribution of cytochrome P450 in brain tissues contributes to quantitative differences in PAH metabolite levels (Saunders *et al.*, 2002; Brown *et al.*, 2007). Several

cytochrome P450 enzymes, such as CYP1A1, CYP1A2, CYP1B1, CYP2B, CYP2C, and CYP3A, are involved in the metabolism of PAH compounds in both animal models and humans (Shimada *et al.*, 1989; Guengerich and Shimada, 1991). Using C57BL/6J mice, Shimada *et al.* (2003) studied the induction of PAHs in brain tissue. The CYP1A1 was constitutively expressed in brain tissue at very low levels, but highly induced by B(a)P. On the other hand, CYP1B1 was significantly expressed in brain tissues. This isoform was the most highly inducible one in brain tissues. Recent studies by Kommaddi *et al.* (2007) have demonstrated the existence of a unique P4501A1 variant in human brain that failed to bioactivate PAHs. The existence of such variants provides clues why some people are vulnerable to toxicity while others are not. To what extent these novel site-specific biotransformation pathways prevail over the established epoxide and quinone pathways in causing/altering the PAH toxicity is a potential area for exploration. Besides metabolites produced in the brain by the cytochrome P450 (Ravindranath and Boyd, 1995), metabolites sequestered in the plasma lipoproteins and transported to the brain through vascular circulation (Polyakov *et al.*, 1996) also contribute to the brain PAH metabolite pool.

Though the disposition of B(a)P in rodent brain regions has long been established, studies linking neurotoxicity to the spatial and temporal distribution of PAHs and their metabolites are limited (Saunders *et al.*, 2002; Wu *et al.*, 2003; Brown *et al.*, 2007). In studies conducted by our research group, when B(a)P was administered to rats either through oral (Saunders *et al.*, 2002, 2006) or inhalation (Wu *et al.*, 2003; Brown *et al.*, 2007) routes, a concordance between temporal and spatial distribution of B(a)P metabolites and behavioral activity was noticed. Adult F-344 rats were exposed to 0**,** 25, 50, 100, and 200 mg/kg of B(a)P through oral gavage, and their motor activity was monitored at 0, 2, 4, 6, 12, 24, 48, 72, and 96 h time points. The accumulation of both B(a)P parent compound and metabolites in the striatum and hippocampus 2 h post-oral treatment of B(a)P corresponded with the onset of behavioral effects and their peak concentrations at 6 h also coincided with the behavioral deficits (Figure 17.10). These observations document that metabolism plays an important role in modulating B(a)P-induced neurotoxic effects in rats.

In addition to the behavioral changes produced by oral exposure to B(a)P in adult rats (Saunders *et al.*, 2002), we also documented behavioral deficits produced as a result of gestational exposure to B(a)P. Timed pregnant Long-Evans rats were exposed in an oral subacute exposure regimen to 0, 25, and 150 µg/kg body wt B(a)P on gestation days 14–17. On PND 2, 5, 10, 15, and 20, offspring pups were randomly selected and analyzed for B(a)P disposition and glutamate receptor subunit developmental expression. A dose-dependent increase and post-exposure time-dependent increase in B(a)P metabolite concentrations and a significant interaction effect of dose and time ($p < 0.005$) were also observed in plasma and

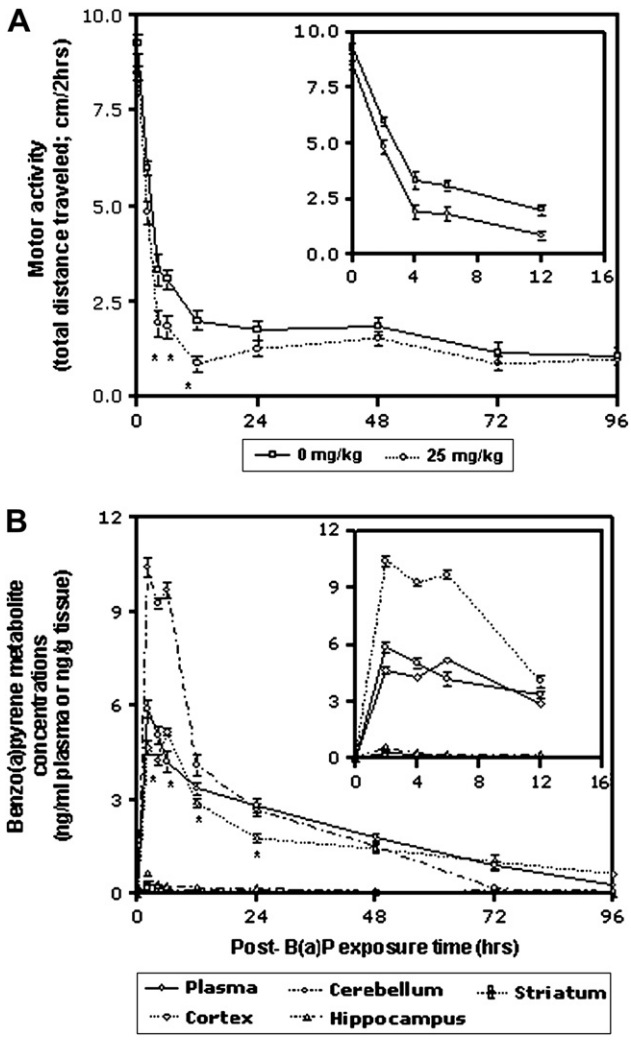

FIGURE 17.10. Relationship between motor activity (A) and disposition (B) of benzo(a)pyrene [B(a)P] metabolites in plasma, cortex, cerebellum, hippocampus, and striatum of male F-344 rats orally dosed with 25 mg/kg body weight (Saunders *et al.*, 2006). Values represent mean + SE for six rats/treatment group at each time point. * $p < 0.05$ between control and B(a)P treatment group in the case of motor activity (A), and between the time points showing peak metabolite concentrations and other time points post-B(a)P exposure (B). Data in the inset depict motor activity (A) and disposition (B) of B(a)P from 0 to 16 h time points.

cerebrocortical extracts (Figure 17.5) in offspring pups. Gestational B(a)P-exposure has also been found to reduce both hippocampal plasticity (Wormley *et al.*, 2004) and cortical neuronal activity (McCallister *et al.*, 2008; Figure 17.7). Glutamatergic receptor subunit expression ratios have also been shown to be inversely proportional to time and have paralleled with metabolite levels (Brown *et al.*, 2007).

Our studies have also revealed that the total B(a)P metabolite load in brain regions as well as the qualitative distribution of metabolites in the aforementioned brain

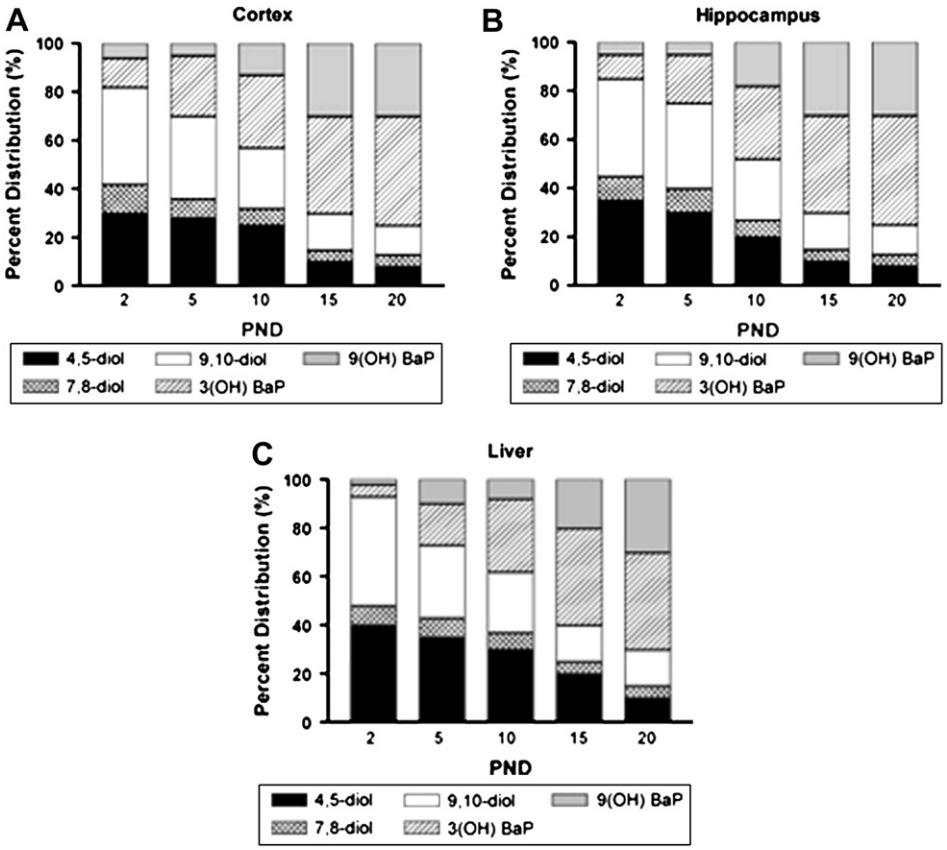

FIGURE 17.11. Percentage distribution of B(a)P metabolites in offspring pups. (A) Cerebral cortex, (B) hippocampus, and (C) liver (from Brown *et al.*, 2007). Timed pregnant dams were dosed with 25 μg B(a)P/kg BW. Offspring pups were sacrificed on PND 2, 5, 10, 15, and 20 and metabolite concentrations were determined and authenticated using standards obtained from the National Cancer Institute.

regions are important determining factors of toxicity. The concentrations of B(a)P diol metabolites (4, 5; 7, 8, and 9, 10 diols) were high up to PND 10, whereas the hydroxy metabolites (3 and 9-OH) constituted higher percentages at PND 15 and 20 (Figure 7.11). The formation of diols during this early period of development is interesting in that the diols can be converted further into dihydrodiol epoxides. From a toxicity standpoint, the dihydrodiol epoxides are important as they are very reactive to nucleophilic attack by nucleophilic sites in cellular macromolecules. The predominance of hydroxy metabolites at PND 15 and 20 indicates that the mechanism of detoxification may be more prominent at later stages of development. The total metabolite concentrations and the specific type in plasma and brain support the contention that B(a)P metabolism plays an important role in modulating neurobiological effects during early developmental expression of key synaptic proteins (McCallister *et al.*, 2008).

B. Oxidative Stress

During PAH metabolism, the uncoupling of electron transfer and oxygen reduction from monooxygenation by CYP1A1 and CYP1A2 results in the release of O_2-, H_2O_2, and OH- (Dutton *et al.*, 1989). These reactive oxygen species (ROS) or oxyradicals react with DNA, proteins, and membrane lipids in the intracellular milieu (Nebert *et al.*, 2000; Zangar *et al.*, 2004). In addition to the CYP family of enzymes, dihydrodiol dehydrogenase (Bolton *et al.*, 2000) and peroxidases (Mulder *et al.*, 2003) were reported to be involved in metabolic conversion of B(a)P to reactive and redox active *o*-quinones, resulting in the formation of ROS such as superoxide anion, H_2O_2, and hydroxyl radicals. Several laboratories have hypothesized that many cellular effects of B(a)P may be attributed to its metabolism to BaP quinones and their subsequent ability to generate intracellular ROS and lipid peroxidation (Lemiere *et al.*, 2005; Casetta *et al.*, 2005). The increase in lipid peroxidation and subsequent decrease in antioxidant defense systems may contribute to an increased susceptibility to oxidative stress (Badary *et al.*, 2003).

Since ROS are generated during metabolism, Saunders *et al.* (2006) conducted studies on antioxidant enzymes during peak periods of B(a)P-induced neurobehavioral activity to see whether neurobehavioral toxicity is driven by oxidative stress as a result of B(a)P metabolism. A correlation between time-dependent changes in motor activity and oxidative stress has been noted by these authors. For example, B(a)P caused inhibition in activity of SOD and glutathione peroxidase and an increase in catalase and lipid peroxidation at 6 and 96 h post B(a)P treatment [time periods where motor activity peaked and diminished post-B(a)P exposure], respectively. These findings reiterate that B(a)P-induced acute neurobehavioral toxicity may occur through oxidative stress due to inhibition of brain antioxidant scavenger systems.

C. Cholinesterase Inhibition

Inhibition of acetylcholinesterase (AChE) is one of the mechanisms of neurotoxicity caused by many commonly used chemicals. Acetylcholine is responsible for neurotransmission at all neuromuscular junctions as well as many synapses within the central nervous system (IPCS, 2001). Published reports demonstrate potent acetylcholinesterase inhibition *in vitro* following exposure to B(a)P (Jett *et al.*, 1999; Tzekova *et al.*, 2004). To study the PAHs increased chlorpyrifos inhibition of cholinesterase, Jett *et al.* (1999) added specific concentrations (2 to 28 μM) of pyrene, B(a)P, fluoranthene, and anthracene to an incubation mixture containing chlorpyrifos (1 to 180 nM concentrations) and purified cholinesterase. They then measured cholinesterase inhibition in the presence or absence of different concentrations of the four PAHs, noting the concentrations that caused cholinesterase to be inhibited by 50%, as well as the maximal activity of the enzyme. The data suggested that the combined effects of the PAHs were additive, but not synergistic with the effects of low concentrations of chlorpyrifos. Although all four PAHs inhibited cholinesterase activity by themselves, their potencies differed, with B(a)P having the greatest relative effect on cholinesterase in combination with chlorpyrifos, and fluoranthene having the least.

D. Tyrosine Hydroxylase Inhibition

Andersson *et al.* (1998) show marked inhibition of tyrosine hydroxylase (TH), the rate-limiting enzyme in dopamine biosynthesis in the striatum and hippocampus after intracranial injections of PAH mixtures. Inhibition of TH can lead to reductions in striatal dopamine (Stephanou *et al.*, 1998; Andersson *et al.*, 1998), which may also contribute to the suppression in motor activity (Saunders *et al.*, 2006).

These results provide additional evidence that enzyme repression is an important mechanism in B(a)P-induced neurotoxicity and likely results from oxidative stress in the nervous system. Inhibition of Na^+/K^+-ATPase, an important enzyme in muscle contraction and nerve excitability, in addition to decreased motor conduction velocities may explain the suppression of motor activity observed in B(a)P intoxicated rats (Kim *et al.*, 2000; Saunders *et al.*, 2001). Furthermore, there is also strong experimental evidence showing that oxidative stress and lipid peroxidative products can cause decreases in dopamine and inhibit Na^+/K^+-ATPase activity as well (Madrigal *et al.*, 2003).

E. Monitoring and Treatment of Individuals Exposed to PAHs (First Responders, Pregnant Women)

Adverse health symptoms resulting from acute exposure to PAHs were rarely reported in humans. So far, no therapeutic agents have been developed to counteract PAH toxicity. Law enforcement personnel and deployed defense personnel injured in explosions and suspected to be exposed to PAHs can be treated in the same way as civilians and firefighters are treated after smoke inhalation. These cohorts must be followed for several years for behavioral perturbations, reproductive failure, and cancerous signs as PAHs have been reported to cause toxicity to several organ systems (Ramesh *et al.*, 2004). The serum immunoglobulin levels of exposed service personnel must be regularly monitored because immunosuppression is the first adverse effect in people occupationally exposed to PAHs (Szczeklik *et al.*, 1994). Also chromosomal damage including chromosomal aberrations (sister chromatid exchanges) in peripheral blood lymphocytes of these individuals (Cheng *et al.*, 2007) should be evaluated for several years as latency periods between occupational PAH exposure and development of cancer can last several years. Police, army and emergency management teams involved in rescue and cleanup operations (first responders) must be advised to carry portable personal monitors to keep an eye on their exposure to PAHs, similar to those used by policemen and bus drivers in epidemiology studies involving PAHs (Farmer *et al.*, 2003).

V. CONCLUDING REMARKS AND FUTURE DIRECTION

Incendiary and explosive devices are used in most terrorist attacks. As a result of combustion of fuel and hazardous materials, PAHs are released in high volumes. Exposure of civilians or deployed personnel to fumes containing PAHs constitutes an acute exposure scenario. Additionally, defense forces involved in extinguishing oil well fires, and cleanup tasks are exposed to low levels of PAHs over a more protracted time period. In addition, over 1.3 million civilian and military personnel are occupationally exposed to hydrocarbon fuels, particularly gasoline, jet fuel, diesel fuel, or kerosene on a near daily basis. Studies have reported acute or persisting neurotoxic effects from acute, subchronic, or chronic exposure of humans or animals to hydrocarbon fuels (Ritchie *et al.*, 2001), specifically burning of jet fuels, which release PAHs in considerable proportions.

The toxicity to the nervous system depends on the delivered dose and exposure duration. In the case of pregnant women, pharmacokinetic processes (absorption, distribution, metabolism, and excretion) govern PAH disposition within the mother and the nervous system of children. Moreover, unique physiological features, such as the presence of a placental barrier and the gradual development of the blood–brain barrier influence PAH disposition and thus modulate developmental neurotoxicity. Because CNS effects are dependent upon ‘‘windows of susceptibility’’ when the lowest dose and shortest duration of exposure to environmental PAHs will have the greatest negative impact on brain development, a susceptibility exposure paradigm has proven to be the most reliable model in which to study developmental insult. The intent of this chapter was to review

the relevant available literature regarding characterizing the neurotoxic effects of prenatal exposure to PAHs (a toxicant that was released as a result of the terrorist attack on the WTC) in various models. Characterizing the prenatal neurotoxic effects of PAH exposure will lead to a better understanding of the results of PAH exposures. It remains a significant challenge to continue to develop and refine appropriate investigational models that are capable of reliably assessing the consequences and underlying mechanisms by which environmental toxicants alter CNS function and behavior.

Exposures of newborns to PAHs depend on pharmacokinetic processes operating in the mother, and transfer through breast milk. Since it is difficult to characterize these pathways in humans, physiologically based pharmacokinetic (PBPK) and pharmacodynamic (PD) models need to be developed using appropriate animal models, and incorporating key parameters such as dose, exposure duration, and developmental stage (Dorman *et al.*, 2001). Thus, development of PBPK and PBPD models for PAHs is an immediate need that will help in not only characterizing the dose–response relationship, but also extrapolation of results from animal studies to humans.

Exposure to a single PAH compound seldom occurs in situations of relevance to local law enforcement agencies or defense forces. Often, people are exposed to PAHs in combination with other toxicants such as aliphatic hydrocarbons and/or metals (NRC, 2005). Information on toxicity of chemical mixtures, of which PAHs are a constituent, is lacking. Until such studies are undertaken in animal models, it is difficult to establish whether PAHs have an additive or a synergistic effect in determining neurotoxicity.

Studies are also warranted on developing biomarkers that complement a battery of neurotoxicity tests in field situations. One of the enzymes that can be used as an environmental biomarker is lactate dehydrogenase (LDH; an indicator of cell injury). It is a key enzyme in the anaerobic pathway of energy production. LDH is important for neuromuscular physiology in conditions of chemical stress when high levels of energy may be needed within a short period of time (often faced by troops deployed for a special operation). One such example of civilian and service personnel exposure is the first Persian Gulf War when departing Iraqi troops set fire to more than 600 oil wells in Kuwait. As the oil burned, the magnitude of hydrocarbons released through smoke plumes contributed to adverse health effects (Hobbs and Radke, 1992). In smoke inhalation studies involving rats, LDH activity was found to increase more than once and did not return to control values 4 weeks after exposure (cited in NRC, 1999). These findings suggest that LDH levels serve as a robust biomarker, worthy of consideration.

Since PAHs disrupt the antioxidant defense system thereby inducing oxidative stress, markers of oxidative stress such as glutathione levels, catalase, and superoxide dismutase activities could be measured in plasma along with the total blood burden of PAHs for personnel exposed to PAHs (Singh *et al.*, 2007). To determine if there is any correlation between blood PAH levels and oxidative damage, measuring the concentrations of 8-oxodG adducts in blood cells serves as a useful metric (Singh *et al.*, 2008). Recent studies also discuss the quantification of a group of compounds called F(2)-isoprostanes (which are prostaglandin F_2-like compounds derived from the nonenzymatic oxidation of arachidonic acid) as the most reliable biomarkers of oxidative stress (Milne *et al.*, 2007). A subclass of these compounds called neuroprostanes (F_4-neuroprostanes) are markers of brain lipid peroxidation and are potential therapeutic targets of neurodegenerative diseases (Montine *et al.*, 2004).

The research described in this chapter represents the first step leading to the development of novel methodology to systematically discover and develop therapeutic glutamate receptor/aryl hydrocarbon receptor antagonists that will prevent neurotoxicity associated with PAH exposure in first responders and/or pregnant women. A fundamental premise of future research takes into account the need for simultaneous temporal measurements and integrative physiological analysis of critical signaling processes to better understand the mechanisms of PAH-induced neurotoxicity. Future experiments should also define the signatures of PAH exposure-induced neurotoxicity and novel therapeutics/protectants in animal models.

CHAPTER 18

PCBs, Dioxins, and Furans: Human Exposure and Health Effects

BOMMANNA G. LOGANATHAN AND SHIGEKI MASUNAGA

I. INTRODUCTION

Polychlorinated biphenyls (PCBs), polychlorinated dibenzo-p-dioxins (PCDDs), and polychlorinated dibenzofurans (PCDFs) are members of the group of halogenated aromatic hydrocarbons (HAHs). This group of chemicals has been identified by the national and international agencies as priority environmental pollutants posing significant effects on aquatic and terrestrial animals including humans (Loganathan and Kannan, 1994; Jacobson, 1994; Van den Berg *et al.*, 1998; Kodavanti *et al.*, 2008). PCBs were produced in large quantities (millions of pounds) for a variety of industrial uses during the 1940s to the late 1970s especially by the developed nations. However, PCDDs (dioxins) and PCDFs (furans) were never produced commercially, but are formed in small quantities as byproducts of combustion of various industrial as well as natural processes. Due to their persistent, bioaccumulative and toxic properties, residues of these compounds are found in every component of the global ecosystem (Lipnick *et al.*, 2001; Kodavanti *et al.*, 2008). Some PCBs (coplanar PCBs), dioxins, and furans are three structurally and toxicologically related families of compounds that are classified as the most toxic synthetic chemical substances to a variety of animal species including humans (Tucker *et al.* 1983; Loganathan *et al.*, 1995; ATSDR, 1998). Production of PCBs was banned during the 1970s; however, already produced PCBs are still causing environmental and health problems (Loganathan *et al.*, 2008; Sajwan *et al.*, 2008). Fortunately, these compounds were never used as chemical warfare agents, weapons of mass destruction, or agents of threat or terror by contamination of air, water, food/feed, etc. However, inadvertent poisonings of these chemicals have caused significant environmental and health problems. In this chapter, historical background, chemical characteristics, analysis, pathways of human exposure to these compounds, and toxic effects associated with the exposures are presented.

II. BACKGROUND

PCBs were first synthesized in the early 1880s (Schmidt and Schultz, 1881) and commercial production began in 1929. Biphenyls were reacted with Cl_2 in the presence of ferric chloride catalyst, where some of the hydrogen atoms are replaced by chlorine atoms. PCBs were produced as complex mixtures potentially containing 209 congeners formed by chlorinating biphenyl with 1 to 10 chlorines (Figure 18.1). The amount of chlorination of biphenyls corresponded to the duration of the chlorination process. For example, Aroclor 1221, 1242, 1248, 1254, 1260, and 1268 are commercial preparations that were formerly produced by the Monsanto Chemical Company in the USA (St Louis, MO) that contain 21, 42, 48, 54, 60, and 68% chlorine by weight, respectively, as indicated by the last two digits in the numerical designation (Giesy and Kannan, 1998). The PCB mixture formulations were different depending on the country of origin, and were produced in Germany (Clofen), France (Phenoclor and Pyralene), Japan (Kanechlor), Italy (Fenclor), Russia (Sovol), and Czechoslavakia (Delor). PCB mixtures were produced for a variety of uses such as fluids in electrical transformers, capacitors, heat transfer fluids, hydraulic fluids, lubricating and cutting oils, and as additives in plastics, paints, copying paper, printing inks, adhesives, and sealants (Loganathan *et al.*, 1989; Safe, 1990).

Dioxins and furans are not produced deliberately, but are produced unintentionally as byproducts of combustions of organic matter in the presence of chlorine. Dioxins and furans consists of 135 possible chlorinated dibenzofuran and 75 chlorinated dibenzo-p-dioxins with from 1 to 8 chlorine substituents (Figure 18.2). PCDDs/DFs are found as byproducts during the manufacture of some industrial chemicals such as PCBs, polychlorinated naphthalenes, chlorinated phenols, chlorinated phenoxyacids, polychlorinated diphenyl ethers, polyvinyl chlorides, and chlorinated phenoxy-2-phenols (Hutzinger *et al.*, 1985; Hryhorczuk *et al.*, 1986; ATSDR, 2001; Masunaga *et al.*,

Generalized structures of highly toxic chlorinated organic compounds

Compound	Molecular mass	Chemical structure
PCBs	188-498	PCDDs	218-460	PCDFs	202-444	
FIGURE 18.1. Generalized structures of PCBs, dioxins, and furans.

2001a). These compounds are also formed during incineration of industrial and municipal waste, forest fires, fireplaces, and combustion engines (Loganathan *et al.*, 1997; Feil and Larsen, 2001). Due to anthropogenic as well as natural processes, PCBs, dioxins, and furans are widely dispersed in the global environment and their presence was reported in air, water, soil, sediment, aquatic and terrestrial organisms including human tissues (Loganathan and Kannan, 1994; Safe, 1994; Giesy and Kannan, 1998; Masunaga *et al.*, 2001b; Ogura *et al.*, 2001).

III. HUMAN EXPOSURE TO PCBs, PCDDs, AND PCDFs

Direct human exposure to PCBs/PCDF occurred due to inadvertent poisoning by consumption of PCB contaminated food: Yusho and Yucheng poisoning (oil disease) in Japan and Tailwan during 1968 and 1979, respectively are examples of such food poisoning. The Yusho Support Center Report (2007) states that ''39 years have passed since the outbreak of YUSHO, the PCB/dioxin tragedy – the most unprecedented incident in the history of mankind whereby people ingested toxic chemicals unknowingly, directly through food''. The outbreak of a strange disease ''Yusho'' (Kanemi Oil Poisoning) occurred in the western part of Japan in 1968. The major symptoms and signs of the disease consisted of acne form eruptions, pigmentation of the skin, nails, and conjunctivae, increased discharge from the eyes, and numbness in the limbs (Yao *et al.*, 2002; Yusho Support Center Report, 2007). The epidemic was identified later (1969) to be an unprecedented mass food poisoning caused by the ingestion of commercial brand rice oil that had been contaminated by PCBs and their related compounds. The number of people who were reported to have ingested the rice oil was about 14,000 and 1,867 persons were designated as Yusho victims. A similar outbreak ''Oil Disease'' occurred in Taiwan in 1979. Toxicological studies revealed that PCDF congeners, including 2,3,4,7,8-pentachlorodibenzofuran, played an important role in the manifestation of the above mentioned diseases. Research conducted on Yusho victims revealed harmful effects of exposure which continued for two generations (Yusho Support Center Report, 2007).

Direct human exposure to dioxin occurred in southern Vietnam and also in Seveso, Italy. It was estimated that southern Vietnam has been contaminated by 160 to 600 kg of dioxin as a result of 80 million liters of defoliant herbicides (Agent Orange, a 50:50 mixture of 2,4,5-T and 2,4-D) being sprayed by the US military over a large area of forests and crops of southern Vietnam from 1962 to 1971 (Westing, 1984; Schecter, 2006; Le Hong Thorn, 2007). The defoliant was contaminated with a very toxic form of dioxin (TCDD) known to have caused adverse effects on human health. Dioxin may cause harmful effects on whole body and can affect separately the functioning of systems such as the nervous system, immune responses, carcinogenicity, hepatotoxicity, metabolic and enzyme toxicity (Le Hong Thorn, 2007). Another example of direct human poisoning of dioxin was the food poisoning of Mr Viktor Yushchenko (See Figure 18.3), the Ukrainian presidential candidate, in 2004. Dioxin poisoning caused a mysterious illness that resulted in his face becoming pockmarked and ashen (www.Mindfully.org). Manahan (1989) classified dioxin (2,3,7,8-TCDD) as super toxic in comparison with other known toxic substances (Table 18.1).

FIGURE 18.3. Dioxin poisoning – Ukrainian former Prime Minister and presidential candidate Mr Viktor Yushchenko, with his face disfigured by illness due to dioxin poisoning. Photo source: www.mindfully.org; date: November 19, 2004 (accessed on July 13, 2008).

TABLE 18.1. Toxicity level of various chemical compounds (prepared from Manahan, 1989)

Toxicity level	Compounds	LD_{50} estimated from laboratory animals[a]
Slightly toxic	Ethyl alcohol	10,000 mg/kg
	Sodium chloride	5,000 mg/kg
Moderately toxic	Malathion (organophosphorus pesticide)	1,000 mg/kg
	Chlordane (termite exterminator)	500 mg/kg
Very toxic	Heptachlor (pesticide)	100 mg/kg
	Parathion (pesticide)	10 mg/kg
Extremely toxic	Dioxin (2,3,7,8-TCDD)	5 mg/kg (hamster)
	Tetraethyl pyrophosphate (pesticide, raticide)	1 mg/kg
	Tetrodotoxin (toxin of blowfish)	0.1 mg/kg
Super toxic	Dioxin (2,3,7,8-TCDD)	0.0006 mg/kg (guinea pig)
	Botulin (toxin of botulinum)	0.00001 mg/kg

[a] LD_{50} are rough values estimated form oral-dose experiment on laboratory animals (usually rats). Unit: mg/kg food

IV. PHYSICOCHEMICAL PROPERTIES AND GLOBAL DISTRIBUTION

The unusual industrial versatility of PCBs was directly related to physical and chemical properties which include resistance to acids and bases, compatibility with organic materials, resistance to oxidation and reduction, excellent insulating properties, nonflammability, and thermal stability (Hutzinger, 1985). Physical and chemical stability of PCBs is vital to the industrial applications and the same properties have been responsible for global environment contamination. In addition, multimedia releases and volatility lead to long-range environmental transport, both via water and atmosphere, resulting in widespread environmental contamination of humans and wildlife at sites distant from their use (Lipnick and Muir, 2001; Loganathan *et al.*, 2008). In PCBs, dioxins, and furans, the properties vary widely and depend on the number and position of chlorine atoms attached to the molecule. In general, vapor pressure, water solubility, and biodegradability decrease with the increasing number of chlorine atoms. Lipophilicity adsorption capacity shows a reverse trend (Loganathan and Kannan, 1994). Because of these unique properties, PCBs, dioxins, and furans have been detected in air and water (rivers, lake ecosystems) (Pearson *et al.*, 1997; Loganathan *et al.*, 1998a, b, 2001). Apart from this, these compounds were recorded in fish, birds, and marine mammals of several other ecosystems such as Atlantic, Baltic, and Pacific ocean (Kawano *et al.*, 1988; Loganathan *et al.*, 1999). They have been identified in processed fish and other food products (Kannan *et al.*, 1997; Patandin *et al.*, 1999). Further, the residues of these contaminants were found in human adipose tissue, blood, and milk and also in numerous other matrices (Loganathan *et al.*, 1993, 1998a, b, 1999; Petreas *et al.*, 2001; Czaja *et al.*, 2001). Because of the large production and indiscriminate use of PCBs in industries, these contaminants extended their boundaries of distribution over the global environment and this was evidenced by their detection even in pristine environmental media and biota such as the Arctic and Antarctic atmosphere, hydrosphere, and biosphere (Muir *et al.*, 1988; Corsolini *et al.*, 2002; Kumar *et al.*, 2002). The discovery of the widespread environmental occurrence, the increased general environmental concern, and the apparent link to carcinogenesis and other health disorders prompted public outcry which resulted in prohibition of PCBs as well as chlorinated pesticides in several developed nations during the early 1970s. The following section deals with the chemical analysis of PCBs, dioxins, and furans in environmental and biological samples.

V. ANALYTICAL METHODS

PCBs and PCDDs/DFs consist of a total of 419 individual congeners. These congeners have quite a variety of toxicity and some, especially planar dioxins, furans, and dioxin-like PCBs (non-*ortho* chlorine substituted coplanar PCBs), are extremely toxic even at very low concentrations (Table 18.1). Therefore, determination of some toxic congeners to a very low concentration (parts per trillion) has become important.

Congener-specific determination was required for those congeners that have toxic equivalency factors (TEFs), namely 2,3,7,8-chlorine substituted dioxins and dioxin-like PCBs (Table 18.2). Thus, they are analyzed using high-resolution gas chromatography–high-resolution mass spectrometry (HRGC-HRMS). A schematic flow chart of the representative analysis procedure for environmental and biological samples is shown in Figure 18.4 based on standard analytical methods such as US EPA Method 1613, 1668, 1668a and JIS K0312 (US EPA, 1994, 1997, 1999; JISC, 2008).

Biological samples are either freeze dried or dewatered (homogenized) with anhydrous sodium sulfate salt and spiked with internal standards (cleanup spike) and then extracted using Soxhlet apparatus. Obtained extracts are concentrated and their solvents are changed to an appropriate solvent such as hexane. Then, the sample extracts are taken through a series of cleanup procedures to remove lipid and other interfering chemicals. Then eluates are concentrated again and spiked with internal standards. The prepared sample extracts were injected into HRGC-HRMS and monitored by multiple ion monitoring mode. Concentrations of target analytes are calculated by the isotope dilution method. Stable isotope labeled target compounds are used as internal standards and spiked into samples. Calibration with internal standards and determination by isotope dilution are necessary to obtain reliable data under very low concentration and after repeated pretreatment and cleanup procedures.

Solid samples such as soil and sediments are air dried and extracted using Soxhlet/Dean-Stark apparatus. Aqueous samples are separated into solids and filtrates by filters. Solids are Soxhlet extracted similar to biological samples and filtrates are liquid–liquid extracted. These extracts are then cleaned up and injected into HRGC-HRMS, similar to biological samples.

In cases when congener-specific information is not necessary, other simpler methods can be used. EPA Methods 608 and 8082a use GC/ECD to determine the concentration of PCBs in terms of Aroclor (Federal Register, 1984; US EPA, 2007). EPA Method 680 (US EPA, 1985) uses GC/MS (low resolution mass spectrometry) to determine the homolog concentration of PCBs.

VI. MECHANISM OF ACTION AND TOXICITY

The toxicity of PCBs and PCDDs/DFs is complicated by the presence of large numbers of congeners, each with its own toxicity. Commercial PCB mixtures elicit a broad spectrum of toxic responses that are dependent on several

factors including chlorine content, purity, dose, species, age and sex, and duration of exposure. Immunotoxicity, carcinogenicity, and developmental toxicity as well as biochemical effects of commercial PCB mixtures have been studied extensively in various laboratory animals, fish, and wildlife (Giesy and Kannan, 1998). Several studies have confirmed the common receptor mediated mechanism of action of toxic halogenated aromatics and have resulted in the development of a structure–activity relationship for this class of chemicals (Safe, 1990). The most toxic halogenated aromatic compound is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) which is assigned the maximum toxicity factor of 1, and the relative toxicities of individual halogenated aromatics have been determined relative to TCDD (i.e. toxic equivalents). The 17 congeners of PCDD/DFs and the 12 congeners of dioxin-like PCBs are assigned TEFs lower than TCDD (Table 18.2). In June 1997, the World Health Organization established the levels of toxicity factors (WHO-TEFs) to be applied to evaluating the risks for humans and animals (WHO-TEF, 1998). The WHO consultation set the tolerable daily intake (TDI) between 1 and 4 pg TEQ/kg body weight, emphasizing that the aim was to lower the TDI to a level under 1 pg TEQ/kg body weight (Guerzoni and Raccanelli, 2004). The most toxic PCB congeners are those that have chlorine substitution in most of the non-*ortho* positions such as 3, 4,

TABLE 18.2. Toxic equivalency factors (TEFs) for dioxins and dioxin-like PCBs

TEF SYSTEM	I-TEF	WHO-TEF (1998)			WHO-TEF (2006)

and 5 in each ring. These coplanar PCB congeners (Figure 18.2) are structurally similar to highly toxic 2,3,7,8-TCDD and exhibit similar toxic responses (Ah-receptor mediated toxicity) (Figure 18.5). 2,3,7,8-TCDD and structurally related halogenated aromatic compounds induce a variety of microsomal enzymes primarily in the liver. 2,3,7,8-TCDD evokes dose-related induction of cytochrome-P-450-associated AHH (aryl hydrocarbon

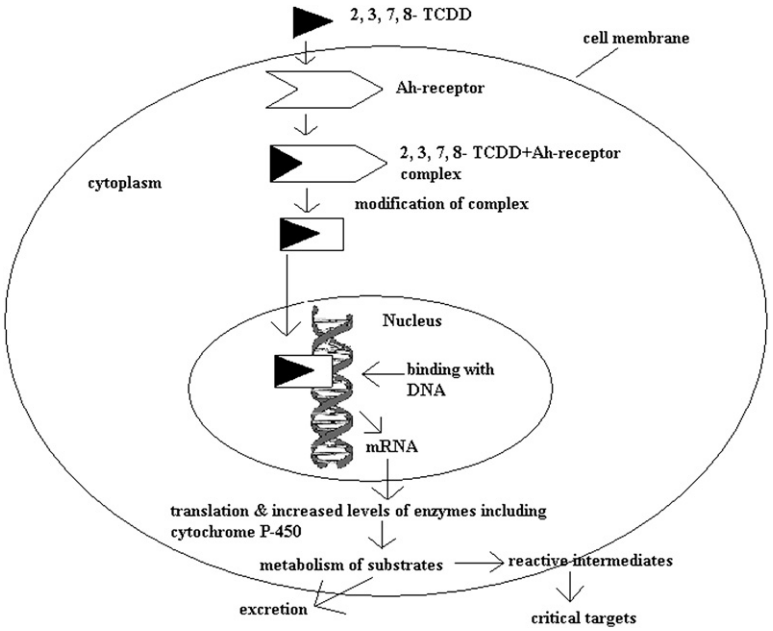

FIGURE 18.5. Possible mechanism of toxic action of 2,3,7,8-TCDD.

hydroxylase) activity. The most widely studied of these responses is the induction of AHH and EROD (markers of CYP1A activity) in mammalian cell cultures and in laboratory rodents (Goldstein and Safe, 1989).

Ah-receptor mediated toxicity resulted in wide range of biological responses, including alterations in metabolic pathways, body weight loss, thymic atrophy, impaired immune responses, hepatotoxicity, chloracne and related skin lesions, developmental and reproductive effects, and neoplasia.

VII. CONCLUDING REMARKS AND FUTURE DIRECTION

PCBs, dioxins, and furans are persistent organic pollutants (POPs) which have negative effects on the environment and health of humans including skin toxicity, immunotoxicity, neurotoxicity, negative effects on reproduction, teratogenicity, endocrine disruption, and a predisposition to cancer. A major pathway of exposure to these chemicals is through consumption of food contaminated by these chemicals. The Committee of Experts on Food of the European Commission proposed a dose called ''Tolerable Weekly Intake'' (TWI) given by the total of dioxins and PCBs of 14 pg TEQ per kg of body weight, that is an average of 2 pg TEQ/day/kg of body weight (Guerzoni and Raccanelli, 2004). By reducing the environmental contamination, we can diminish the food chain accumulation and ultimately we can reduce the intake levels of PCBs and dioxins and their toxic effects.

CHAPTER 19

Cyanide Toxicity and its Treatment

R. BHATTACHARYA AND S. J. S. FLORA

I. INTRODUCTION

Cyanide refers to a highly toxic chemical compound containing one atom of carbon and nitrogen each. Deaths due to cyanide poisoning are relatively rare largely due to its limited availability (Musshoff *et al.*, 2002). However, the name cyanide and its toxic characteristic have long been a source of dread for humans. The first reported isolation of hydrocyanic acid from Prussian blue was by the Swedish chemist C.W. Scheele in 1782 and he was reported to be the first victim of this poison in 1786 when he accidentally broke a vial of the chemical in the laboratory and died from vapor poisoning (Ballantyne, 1987).

Since the days of ancient Rome, cyanide and its derivatives were used in weapons (Sykes, 1981). Nero used cherry laurel water, which contained cyanide as its main toxic component, to poison members of his family and others who displeased him. Napolean III proposed the lacing of soldiers' bayonets with cyanides during the Franco-Prussian War. Hydrogen cyanide (HCN) was not very successful as a chemical warfare agent during World War I because it was not persistent. During the same period, the French army employed artillery shells under the name Vincennite (50% HCN, 30% arsenic trichloride, 15% stannic chloride, and 5% chloroform) but due to high volatility of HCN, these munitions could not be used effectively. Also, German soldiers were adequately equipped to protect themselves from HCN exposure. In 1916, the French experimented with cyanogen chloride which was heavier and less volatile than HCN. The effect of cyanogen chloride was similar to HCN. Additionally, it caused marked lacrimation, rhinorrhea, and bronchial secretions similar to phosgene. However, these effects were considered to be of little military importance compared to its tissue effects. During World War II, the Nazis used Zyklon B (briquettes of calcium sulfate impregnated with 40% HCN) made by IG Farben, Germany, to exterminate millions of civilians and enemy soldiers in the death camps (Robinson, 1971; Baskin, 1998). It is also reported that in the late 1980s, there was the possible use of cyanide against the inhabitants of the Syrian city of Hama, the inhabitants of the Kurdish city of Halabja, Iraq, and in Shahabad, Iran, during the Iran–Iraq war (Baskin and Rockwood, 2002). Cyanide gas precursor compounds were found in several subway restrooms in Tokyo following the release of sarin in Tokyo in 1995 (Sidell, 1996). Allegedly, cyanide was added to the explosives used in the first attack on the World Trade Center in New York (Brennan *et al.*, 1999).

The use of cyanides for murder, suicide, and accidentally has been passably reviewed by Gee (1987). In 1973, 109 passengers and in 1980, 303 pilgrims were feared killed in Paris and Riyadh, respectively, due to inhalation of HCN from smoldering plastic inside aircraft which accidentally caught fire (Mohler, 1975; Weger, 1983). In 1985, the explosion of a Boeing 737 during take-off at Manchester, England, revealed that 20% of the 137 victims who escaped had dangerously high levels of carbon monoxide, while 90% had significantly elevated levels of cyanide. Similarly, short circuits in electrical wires also caused fire on ships which led to the combustion of plastic materials releasing HCN, which resulted in severe poisoning (Levine *et al.*, 1978). The murders of two Ukrainians, Mr Rebet (1957) and Mr Bandera (1959), were committed by a Soviet agent in Munich using a gas pistol containing cyanide (Anders, 1963). In September 1982, seven people in Chicago died when cyanide (acetatminophen, manufactured by McNeill Consumer Products Co., Fort Washington, PA), was illicitly placed in bottles of Tylenol (Wolnick *et al.*, 1984). In 1978, 912 members of a religious sect in Port Kaituma, Guyana, committed mass suicide after consuming a grape-flavored drink laced with cyanide (Thompson *et al.*, 1987; Sidell *et al.*, 1997). The first case of illegal euthanasia in Spain was reported when a tetraplegic patient, whose repeated legal requests for euthanasia were refused, consumed potassium cyanide (KCN) (Blanco and Garcia, 2004).

The toxicology of cyanide and its treatment modalities have been extensively discussed by many authors (Vennesland *et al.*, 1981; Way, 1984; Ballantyne and Marrs, 1987; Gonzales and Sabatini, 1989; Borowitz *et al.*, 1992; Salkowski and Penney, 1994; Marrs *et al.*, 1996; Baskin and Brewer, 1997). Additionally, over the years thousands of research articles on cyanide have appeared. Cyanide and its effects, being such an old poison, seem to be known universally. But most of the crucial molecular mechanisms underlying cyanide toxicity have been elucidated only in the recent past (Gunasekar *et al.*, 1996; Sun *et al.*, 1997;

Borowitz *et al.*, 2001). Cyanide is a very interesting molecule; it has always fascinated researchers, and is the reason for further study. This chapter attempts to enlighten the reader with the known facts about cyanide and some of the recent advances made in its toxicology and antagonism.

II. SOURCES OF EXPOSURE

The use of cyanide for military purposes has been very insignificant and most of the cases of poisoning have involved civilians, for example in the case of fires and industrial accidents. The human to cyanide interaction is very common due to its wide industrial applications. Worldwide industrial consumption of cyanide is estimated to be 1.5 million tons per year, and occupational exposures account for a significant number of cyanide poisonings (Cummings, 2004). Cyanide poisoning may occur from a broad range of exposures and is summarized in Table 19.1. Some of the major sources of poisoning are as follows.

A. Fire Smoke

Residential fires may result in life-threatening poisoning (Megarbane *et al.*, 2003). In a closed space, fire induces a combination of oxygen deprivation directly related to combustion, and simultaneous intoxication by asphyxiant and irritant gases (Baud, 2007). Cyanide can be liberated during combustion of products containing carbon and nitrogen. These products include wool, silk, polyurethane, polyacrylonitriles, melamine resins, and synthetic rubber (Vogel *et al.*, 1981; Bismuth *et al.*, 1987; Homan, 1987). It is estimated that significant levels of cyanide are present in almost 35% of all fire victims (Clark *et al.*, 1981; Barillo *et al.*, 1994; Sauer and Keim, 2001). Carbon monoxide is also an important component of fire smoke and its concomitant exposure with HCN is known to exacerbate the toxicity as both cause tissue hypoxia by different mechanisms (Barillo *et al.*, 1994).

TABLE 19.1. Various possible sources of cyanide poisoning

Fire smoke	Smoke generated after combustion of silk, polyurethanes, polyacrylonitriles, nylon, melamine resins, plastics, etc., in accidents including industrial, residential, car, aircraft, ship fire
Industrial exposure	Plastics production, dyeing, printing and photography, fumigation of pesticides/ rodenticides, synthetic rubber production, fertilizer production, metal polish, tanning in leather industry, electroplating, metallurgy, paper and textile manufacture
Drugs	Sodium nitroprusside, Laetrile, Succinonitrile
Dietary	Cassava, lima beans, linseed, bamboo sprout, macadamia nuts, hydrangea, Rosaceae family (plum, peach, pear, apple, bitter almond, cherry), *Sorghum* species (Johnson grass, sorghum, Sudan grass, arrow grass), *Linum* species (flax, yellow pine flax)
Others	Cigarette smoking, phencyclidine synthesis, ingestion of nail polish remover, suicide, homicide, terrorist attack, chemical warfare, capital punishment

B. Industrial Exposure

Occupational exposures to cyanide in industry have caused serious problems (Blanc *et al.*, 1985; Peden *et al.*, 1986). Cyanide is used in many chemical syntheses, plastics and rubber processing, gold and silver extraction, tanning, metallurgy, photography, and fumigation of pesticides/ rodenticides (ATSDR, 1997). Cyanide poisoning can also occur following contamination of the skin with cyanide solution or inhalation of released HCN during electroplating in jewelry polishing (Sullivan and Krieger, 2001; Megarbane *et al.*, 2003). Exposure to silver brightener, which contains cyanide, has also caused death. Subsequent to initial lethal inhalation of cyanide, an extensive post-mortem transcutaneous diffusion of cyanide was also shown to occur (Seidl *et al.*, 2003). Cyanogens are complex nitrile-containing materials which can generate free cyanide of toxicological significance. Many of the cyanogens occur naturally or are produced synthetically. The synthetic cyanogens have a variety of industrial, domestic, and therapeutic uses (Ballantyne, 1987). Some of the synthetic cyanogens include acetonitrile, acrylonitrile, adiponitrile, malononitrile, propionitrile, succinonitrile, sodium nitroprusside, tetremethyl succinonitrile, etc. Fires involving nitrogen-containing polymers, often found in fibers used in fabrics, upholstery covers, and padding, produce HCN (Tsuchiya and Sumi, 1977).

C. Drugs

Cyanide is a metabolic product of amygdalin (Laetrile®) which was introduced as an antineoplastic agent in the 1950s, and was responsible for several cyanide poisoning cases (Hall *et al.*, 1986; Bromley *et al.*, 2005). Intestinal beta-d-glucosidase digests the amygdalin, releasing HCN. Also, iatrogenic exposure to cyanide may result following the use of sodium nitroprusside, an anti-hypertensive agent (Vesey and Cole, 1985) and succinonitrile, an antidepressant (Ryan, 1998). Sodium nitroprusside is used medicinally as Nipride® and its intravenous infusion is used to lower blood pressure in hypertensive emergencies. This application of sodium nitroprusside occasionally causes classical cyanide toxicity (Kurt, 1983). Death due to mercuric

cyanide or mercuric oxycyanide poisoning was reported due to possible ingestion of an antiseptic or a hair lotion commercialized in France (Labat *et al.*, 2004).

D. Dietary

Cyanide occurs naturally in cassava (*Manihot esculenta* Crantz) as linimarin, a cyanogenic glycoside. Cassava roots are a major source of energy for millions of people in the tropics. However, chronic ingestion of cassava-based foods accounts for several toxicological effects, including various neuropathies, amblyopia, etc. (Rosling, 1989; Kamalu, 1995). Several common plants also contain cyanogenic glycosides and their ingestion can result in death due to improper processing (Conn, 1988). The family Rosaceae, which includes plum, peach, pear, apple, bitter almond, and cherry, is responsible for many cases of cyanide poisoning (Ryan, 1998).

E. Other Sources

There are numerous other instances of cyanide poisoning which include illicit synthesis of phencyclidine, ingestion of nail polish remover (acetonitrile), in terrorist attacks, as suicidal, homicidal, and chemical warfare agents, and in capital punishment. HCN was considered to be a notorious chemical warfare agent because of its rapid lethal actions. It was used as a war gas in World War I (Gee, 1987), World War II (Williams and Wallace, 1989), and in the Iran–Iraq War (Lang *et al.*, 1986; Heylin, 1988). Due to poor persistence of HCN in the environment and lack of delivery system, cyanides were not optimistically considered for future use in wars. However, its possible use in local terrorist actions cannot be overlooked. Because cyanide can be released from both synthetic and natural materials, terrorist acts with explosives or incendiaries, which could cause fire in enclosed spaces, make cyanide and cyanogenic compounds potential threats for terrorism (Rotenberg, 2003). During the last decade, Japan has experienced the largest burden of chemical terrorism-related events in the world, which included the Nagano cyanide incident in 1998, and two intentional cyanide releases in Tokyo subway and railway station restrooms, which were thwarted in 1995 (Okumura *et al.*, 2003). Because of the natural cyanide found in tobacco, cigarette smokers show significant increase in blood cyanide levels as compared to nonsmokers. Visual abnormalities of tobacco amblyopia are usually associated with heavy smoking and vitamin B_{12} deficiency (Wilson, 1983; Homan, 1987).

III. TOXIC LEVELS OF CYANIDE

It is not easy to determine the lethal doses of cyanide to man. Morbidity or mortality depends upon the magnitude of poisoning, which varies with the dose and form of cyanide and the route of poisoning. The maximum permissible concentration for HCN in human is 11 mg/m^3 (Ballantyne, 1974). Taken orally the fatal dose of HCN to adults is estimated at 50–100 mg, and for KCN about 150–250 mg (DuBois and Geiling, 1959). Figures estimated in terms of body weight for HCN vary from 0.7 to 3.5 mg/kg (Hallstrom and Moller, 1945). However, victims ingesting as much as 3.0 g of KCN have been saved with immediate therapy (Van Heijst *et al.*, 1987). Table 19.2 shows that inhalation of HCN at a concentration of 300 mg/m^3 (approximately 270 ppm) will be immediately fatal while at 20–40 mg/m^3 mild symptoms will appear after several hours of exposure (Rumack, 1983; FOA, 1992). Victims having a blood cyanide level of 2.5–3.0 μg/ml frequently succumb to respiratory cessation within 20–30 min of exposure or may survive even up to 3 h (Ballantyne, 1974; Van Heijst *et al.*, 1987). Oral ingestion of cyanide may also produce rapid onset of symptoms because many human doses far exceed the minimal lethal dose. Studies on experimental animals have shown that absorption of cyanide decreases with a more alkaline stomach and that normally most cyanide is absorbed within 2–3 h of ingestion (Ryan, 1998). However, substances such as nitrile compounds and amygdalin from plants require enough time for conversion to cyanide before they can produce symptoms of toxicity (Ryan, 1998). Laeterile is synthesized from amygdalin. One gram of laterile contains the equivalent of 60 mg of cyanide, and each laeterile tablet may contain up to 100 mg of laeterile. A 12- to 18-tablet laeterile overdose is sufficient to produce severe metabolic acidosis and convulsions (Ellenhorn *et al.*, 1997). The lethal toxicity of HCN and its alkali salts by different routes for different species of animals and sexes has been largely discussed elsewhere (Ballantyne, 1984, 1987). A study carried out in rabbits revealed the following order of decreasing toxicity of KCN administered by different routes: intravenous > intramuscular > intraperitoneal > per oral > instillation into conjunctival sac > percutaneous (Ballantyne, 1984). The comparative per oral LD_{50} values of KCN for different species of animals are given in Table 19.3. Rabbit was found to be more susceptible than rat and mouse.

TABLE 19.2. Toxicity of hydrogen cyanide by inhalation

Concentration		
mg/m^3	**ppm**	**Effects**
20–40	18–36	Slight symptoms after several hours
50–60	45–54	Endurable for 20–60 min without effect
120–150	110–135	Very dangerous (fatal) after 30–60 min
150	135	Lethal after 30 min
200	181	Lethal after 10 min
300	270	Immediately lethal

TABLE 19.3. Acute lethal toxicity of KCN by oral route for different species of animals

Species	Sex	LD_{50} (mg/kg)	Reference
Mouse	Male	8.50	Sheehy and Way, 1968
	Male	12.5	Bhattacharya *et al.*, 2002
Rat	Male	10.0	Hayes, 1967
	Female	7.49	Ballantyne, 1984
	Female	14.1	Bhattacharya and Vijayaraghavan, 2002
Rabbit	Female	5.82	Ballantyne, 1984

IV. DETECTION AND ESTIMATION OF CYANIDE

Determination of cyanide or its metabolites in biological fluids is necessary for forensic, clinical, military, research, and veterinary purposes. The choice of analytical methods depends on a variety of factors like sensitivity, specificity, rapidity, convenience, facilities, and expertise. The selection of biological sample, time of sampling, time to analyze and storage conditions, and interfering substances are other factors which influence the choice of analytical methods (Troup and Ballantyne, 1987). There are several convenient and sensitive methods for measuring cyanide in biological fluids but many of them have limitations. Some of the methods are summarized below.

One of the most common procedures includes diffusion and trapping of cyanide in the alkaline media prior to colorimetric analysis in pyridine–pyrazolone mixture (Epstein, 1947). This method was subsequently modified for microdiffusion analysis of cyanide (Feldstein and Klendshoj, 1954). This procedure is widely used during the treatment of cyanide intoxication and thiosulfate is known to interfere in the colorimetric estimation, which was subsequently resolved (Morgan *et al.*, 1979). A rapid (about 20 min), specific, and sensitive spectrophotometric method for whole blood cyanide assay has also been developed (LaForge *et al.*, 1994). All these procedures are based on the König reaction, which starts with the production of cyanogen chloride. A spectrofluorometric determination of cyanide and thiocyanate based on modified König reaction in a flow-injection system was also reported with detection limits of 30 nM for both anions (Tanaka *et al.*, 1992). Spectrophotofluorometry is also a convenient, sensitive method provided prior microdiffusion is carried out to isolate and concentrate the cyanide. The fluorometric methods using pyridoxal are more sensitive and require fewer and more stable reagents than the colorimetric method (Takanashi and Tamura, 1970). However, sodium thiosulfate is known to interfere with the chemical conversion of the fluorophore and it is possible to circumvent the interference by using acetate buffer (pH 5.2) as the acidifying agent. Another fluorescent method with an advantage over pyridoxal uses para-benzoquinone and this method is not known to have any extraneous interference (Guilbault, 1976).

The potentiometric determination of cyanide using ion selective electrodes has become yet another very popular technique, because it is convenient, rapid, and sensitive method of analysis (Frant *et al.*, 1972). Microdiffusion of biological samples containing cyanide is recommended prior to potentiometric determination. The use of a cyanide ion-selective electrode in combination with the Conway microdiffusion method for the measurement of cyanide concentrations in human red blood cells and plasma was reported with remarkable recovery of cyanide (Yagi *et al.*, 1990). Ion chromatographic determination of sulfide and cyanide in real matrices by using pulsed amperometric detection on a silver electrode was reported by Giuriati *et al.* (2004).

The measurement of HCN directly by gas chromatography has also been reported but this method lacks sensitivity with most detectors (Valentour *et al.*, 1974). Gas chromatographic techniques are not widely used for measuring cyanide because other methods are more convenient. A simple and sensitive method was devised for determining cyanide and its major metabolite, thiocyanate, in blood using an extractive alkylating agent (pentafluorobenzyl bromide). The detection limits of cyanide and thiocyanate were 0.01 and 0.003 μmol/ml, respectively (Kage *et al.*, 1996). Rapid quantitation of cyanide in whole blood by automated headspace gas chromatography was performed on clinical samples from fire victims. This method could detect a wide concentration of blood cyanide (30–6,000 μg/l) in about 17 min (Calafat and Stanfill, 2002).

A direct and sensitive isotope dilution-mass spectrometry determination of blood cyanide by headspace gas chromatography was developed with the detection limit of 0.3 μmol/l (Dumas *et al.*, 2005). This method was also compared with other techniques in a round robin exercise. Cyanide can also be measured by indirect atomic absorption spectrometry where a metal–cyanide complex is formed which is then extracted in organic solvent to determine the metal content (Manahan and Kunkel, 1973). An original high-performance liquid chromatographic-mass spectrometric (HPLC-MS) procedure was developed for the determination of cyanide in whole blood. The limits of detection and quantitation were 5 and 15 ng/ml, respectively (Tracqui *et al.*, 2002). Also, several other methods including HPLC, using post-column derivatization with *o*-phthalaldehyde (Sumiyoshi *et al.*, 1995), capillary electrophoresis with fluorescence detection (Chinaka *et al.*, 2001), polyphenol oxidase/clay biosensors (Shan *et al.*, 2004), capillary electrophoresis microchip (Lu *et al.*, 2004), ICT-based probes (Badugu *et al.*, 2005), and micro-chemiluminiscence (Lv *et al.*, 2005) have been reported for different environmental or biological samples. However, their utility to detect cyanide in blood samples is yet to be ascertained.

A technique to detect cyanide currently utilized by water treatment facilities was employed to rapidly detect concentrations of cyanide in the clinically important range (Rella *et al.*, 2004). The CYANTESMO test strips accurately and rapidly detect cyanide greater than 1 μg/ml. A paper test for cyanide (CYANTOSNO) in whole blood is now commercially available in the USA (Ellenhorn *et al.*, 1997).

V. TOXICOKINETICS OF CYANIDE

A. Absorption

Oral absorption of cyanide is rapid, and toxic effects can occur within minutes. When salts of cyanide are ingested, hydrochloric acid in the stomach causes the release of HCN, which is readily absorbed as cyanide ion (CN^-). Cyanide (hydrocyanic acid, HCN) is a small molecule with good lipid and water solubility. It is rapidly absorbed irrespective of route of exposure owing to its low molecular weight (Borowitz *et al.*, 2001). It is mainly absorbed by the respiratory and gastrointestinal mucosa and through skin and eyes on prolonged contact (Ballantyne, 1974; Ellenhorn *et al.*, 1997; Ryan, 1998). In experimental rabbits, cyanide introduced into the conjunctival sacs was quickly absorbed in significant quantities to produce systemic toxicity (Ballantyne, 1983). Dermal exposure is rare but large surface area of the skin facilitates absorption of toxic consequences. Nitriles are more readily absorbed through the skin but the onset of toxicity is delayed.

B. Distribution

After absorption, cyanide distributes to a volume of approximately 40% total body weight. The distribution is rapid and is completed within 5 min after a single intravenous dose (Sylvester *et al.*, 1983). Cyanide is rapidly transported in the body by blood and about 60% is bound to plasma proteins, a small amount is present in the red blood cells (RBC), and the remainder present as free cyanide (Ryan, 1998). The concentration of cyanide in RBC is estimated to be at a RBC/plasma ratio of 100/1 (Ellenhorn *et al.*, 1997). After acute exposures, the plasma elimination half-life of cyanide was observed to be 14.1 min (Egekeze and Oehme, 1979). After oral poisoning, a significant amount of cyanide was traced in the brain, blood, kidney, stomach wall, liver, and urine (Ansell and Lewis, 1970). This indicates that after absorption, cyanide is widely distributed in all the tissues.

C. Elimination

Cyanide is rapidly detoxified in mammals. The detoxification rates of cyanide following intravenous administration in humans, dogs, guinea pigs, and rabbits are 0.017, 0.020, 0.04, and 0.008 mg/kg body weight/min, respectively (Hinwich and Saunders, 1948; NIOSH, 1975). The major pathway of cyanide detoxification (approximately 80%) is through enzymatic transulfuration to thiocyanate (SCN^-), which is nontoxic and excreted in the urine (Lang, 1933). This reaction is catalyzed by an enzyme, rhodanese (thiosulfate cyanide sulfur transferase; EC.2.8.1.1). Rhodanese uses a precursor like thiosulfate which is a source of sulfane sulfur (divalent ionized sulfur bound to another sulfur atom). The endogenous supply of this substance is very limited. Therefore, detoxification of cyanide largely depends on an exogenous supply of thiosulfate (Westley *et al.*, 1983). However, cyanide detoxification by this pathway is often debated because rhodanese is located principally in the mitochondria and penetration of the cell wall and mitochondrial membrane by thiosulfates is very slow (Bhat and Linell, 1983). It is presumed that the sulfane sulfur binds first to the serum albumin to yield a sulfane sulfur albumin complex which eventually reacts with cyanide to form thiocyanate (Way, 1984; Westley *et al.*, 1983). In normal metabolism of cyanide, the serum albumin–sulfane complex may be the primary detoxification mechanism (Sylvester *et al.*, 1983). Unlike other chemical warfare agents, cyanide appears biologically in blood, urine, and expired breath (Lundquist *et al.*, 1988). Cyanide is eliminated from the body by several mechanisms. After 3 h, approximately 90% of injected cyanide has been shown to be eliminated in the dog model (Sylvester *et al.*, 1983). A small amount of cyanide is excreted in the urine and via the lungs after being incorporated into cyanocobalamin (vitamin B_{12}), oxidated to formate and carbon dioxide, and incorporated with cystine (Ballantyne, 1987). Other minor pathways of detoxification include enzymes like mercaptopyruvate sulfurtransferase, thiosulfate reductase, and cystathionase γ-lyase or disulfide cystine, 2-iminothiazolidine-4-carboxylic acid (2-ICA) or its tautomer, 2-aminothiazolidine-4-carboxylic acid (2-ACA) (Wood and Cooley, 1956; Baskin *et al.*, 2004). Cyanide reacts with cystine to produce β-thiocyanoalanine, which spontaneously undergoes ring closure to form 2-ICA and 2-ACA, depending on the pH in the cells (Borowitz *et al.*, 2001). To determine the effect of species on cyanide metabolism, toxicokinetics of cyanide was studied in rats, pigs, and goats after oral dosing of KCN (Sousa *et al.*, 2003). The study showed that metabolism of cyanide and its main metabolite, thiocyanate, is species linked, with goat being the most sensitive to the toxic effects of cyanide.

VI. MECHANISM OF ACTION

The toxic effect of cyanide is attributed predominantly to the production of anoxia following inhibition of the metal-containing enzymes. The critical interaction appears to be the inhibition of the terminal respiratory chain enzyme, cytochrome oxidase a_3 (containing iron) within the mitochondria. The enzyme is essential for the production of adenosine triphosphate (ATP). As a result, aerobic oxidative

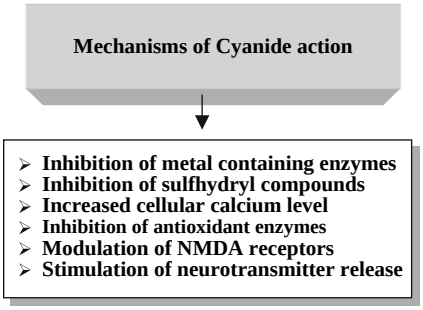

FIGURE 19.1. Mechanisms for the toxic manifestations of cyanide exposure.

metabolism and phosphorylation are impaired leading to cellular hypoxia. The pyruvate that is produced can no longer be used and is now reduced to lactate. The shunt from aerobic to anaerobic metabolism leads to profound lactic acidosis (Solomonson, 1981). Cyanide toxicity may not be ascribed solely to a single biochemical lesion but a complex phenomenon. Cyanide reacts with several metalloenzymes, carbonyl groups of different enzymes, coenzymes, and substrates, resulting in inhibition of normal activity. Cyanide also interacts with sulfhydryl compounds like cystine, mercaptopyruvate, reduced glutathione, and oxidized glutathione to form different complexes (Way, 1984; Borowitz *et al.*, 1992). Cyanide also strongly interacts with iron in protein molecules, inhibiting enzymes including carbonic anhydrase and succinic dehydrogenase (Ballantyne, 1987). Formation of cyanhemoglobin by interaction of cyanide with ferric iron abolishes the ability of hemoglobin to carry oxygen (Way, 1984). The mechanism of cyanide toxicity is summarized in Figure 19.1.

Cyanide is regarded as a selective neurotoxin and its toxicity has frequently been associated with elevated levels of cellular calcium (Johnson *et al.*, 1986), inhibition of antioxidant defense enzymes in the brain (Ardelt *et al.*, 1989), and generation of reactive oxygen species, leading to lipid peroxidation (Ardelt *et al.*, 1994; Kanthasamy *et al.*, 1997). Cyanide raises intracellular calcium through activation of voltage-sensitive calcium channels (Johnson *et al.*, 1987), direct redox modulation and enhancement of *N*-methyl-D-aspartate (NMDA) receptor function (Patel *et al.*, 1992; Sun *et al.*, 1997), and mobilization of intracellular calcium stores (Yang *et al.*, 1997). It was proposed that elevated cytosolic calcium activates proteases, which in turn converts xanthine dehydrogenase to xanthine oxidase. In the presence of oxygen, xanthine oxidase can catalyze the formation of superoxide radicals that initiate lipid peroxidation (Figure 19.2) (Chan and Fishman, 1985). Modulation of NMDA receptor has been widely implicated in cyanide-induced neurotoxicity. Nitric oxide and reactive oxygen species generation after NMDA receptor activation was found to mediate cyanide-induced neurotoxicity (Gunasekar *et al.*, 1996). Several other studies also showed activation of NMDA receptors during cyanide toxicity (Patel *et al.*, 1992; Sun *et al.*, 1997). Cyanide can stimulate release of glutamate from intracellular stores resulting in elevation of cytosolic Ca^{2+} through NMDA receptor activation. There is also evidence that cyanide may interact directly with NMDA receptor to enhance NMDA receptor-mediated Ca^{2+} influx (Patel *et al.*, 1994; Sun *et al.*, 1995). It was further shown that cyanide selectively interacted with NMDA subunits, possibly by formation of thiocyanate adduct with a cysteine residue located in NR1 receptor subtype (Arden *et al.*, 1998). Cyanide is also known to

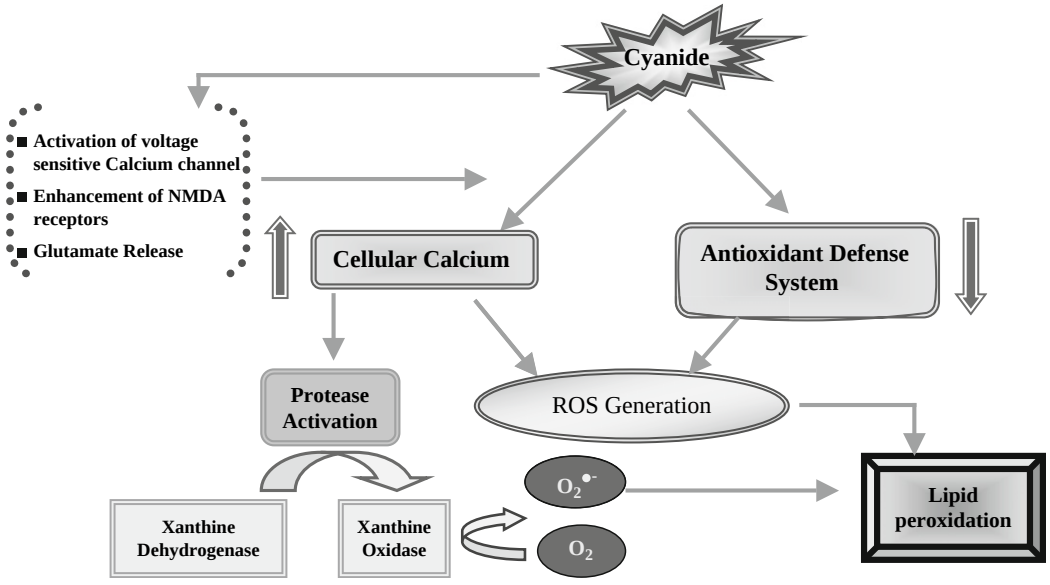

FIGURE 19.2. Pathway of cyanide-induced oxidative stress. Abbreviations used: ROS – reactive oxygen species; O_2 – Oxygen; $O_2^{\bullet-}$ – superoxide anion.

interact with cystine to produce 2-ICA and 2-ACA, and the former is responsible for memory loss, convulsions, and loss of consciousness (Bitner *et al.*, 1991). Cyanide can produce dopaminergic toxicity characterized by loss of dopaminergic neurons in the basal ganglia that is accompanied by impaired motor function (Kanthasamy *et al.*, 1994). Cyanide is also known to stimulate neurotransmitter release in both the central and peripheral nervous systems (Kanthasamy *et al.*, 1991). It is suggested that the convulsive effects of cyanide are due to changes in the levels of dopamine (Cassel, 1995). It has also been opined that protein kinase C, calmodulin, and nitric oxide (NO)-dependent cyclic guanosine monophosphate (GMP)-dependent enzymes may contribute to the induction of convulsions. ATP depletion may also contribute in part to the development of cyanide-induced convulsions (Yamamoto, 1995). Other biochemical processes that may mediate or at least influence cyanide toxicity include lactic acidosis, mitochondrial ADP ribosylation, and hyperammonemia (Borowitz *et al.*, 1992). It is possible that some of these mechanisms are independent of cellular energy deficit but produce severe effects on the cells. Overall, it appears that oxidative stress plays a crucial role in cyanide-induced neurotoxicity (Ardelt *et al.*, 1989; Kanthasamy *et al.*, 1994). Another important aspect of cyanide toxicity is its cardiotoxic manifestations. However, it has been excluded from the present chapter as it has been adequately discussed by others (Baskin, 1991; Borowitz *et al.*, 1992).

VII. DIAGNOSIS AND CLINICAL FEATURES OF CYANIDE POISONING

Signs and symptoms of acute cyanide poisoning are often nonspecific and vary in both time and intensity depending upon the scale of exposure (Ballantyne, 1987; Ellenhorn *et al.*, 1997). Low concentrations may produce delayed and various nonspecific symptoms like headache, dizziness, nausea, vomiting, confusion, coma, and incontinence of feces and urine, but exposure to high concentrations may lead to a series of events like dyspnea, incoordination of movements, convulsive seizures, coma, and cardiac and/or respiratory failure culminating in death (Ballantyne, 1974; Way, 1984). Pathologically, no particular lesions can define cyanide toxicity, although animal experiments indicate that the lesions are principally in the central nervous system (CNS), particularly necrosis in the white matter (Ballantyne, 1974). Probably the most widespread pathologic condition attributed to chronic cyanide poisoning is tropic ataxic neuropathy following cassava consumption (Rosling, 1989; Kamalu, 1995). Other effects associated with cassava consumption include tropical pancreatitis (Gee Varghese, 1985), tropical neuropathies (Banea *et al.*, 1997), and endemic goiter (Abuye *et al.*, 1998). Repeated or prolonged skin contact to low concentrations of KCN dust may lead to dermatitic effects (cyanide rash) characterized by itching and skin eruptions (NOHSC, 1993).

TABLE 19.4. Whole blood cyanide levels and clinical signs and symptoms

Whole blood cyanide		
µg/ml	**µmol/l**	**Signs and symptoms**
0–0.5	8–20	No symptoms
0.5–1.0	20–38	Tachycardia, flushing, headache, hyperpnea, dizziness
1.0–2.5	48–95	CNS depression including giddiness, tachypnea, nausea, vomiting feeling, suffocation, confusion
2.5–3.0	95–114	Respiratory depression, convulsion, coma, cyanosis, apnea, circulatory collapse, fixed dilated pupils
≥3.0	114	Death

While the signs and symptoms of cyanide poisoning are well documented, more than 55 signs and six biochemical idiosyncrasies are known to possibly occur during cyanide poisoning (Hall *et al.*, 1987). Signs and symptoms of acute cyanide poisoning reflect cellular hypoxia and are often nonspecific. Onset of symptoms depends on dose, route, and duration of exposure. In general, the signs and symptoms correlate with the whole blood cyanide level, and are usually tachycardia, flushing, headache, hyperpnea, and dizziness (Table 19.4). Laboratory tests suggestive of cyanide intoxication include: arterial blood gases (metabolic acidosis with normal PO_2), serum electrolytes (elevated anion gap), central venous percent O_2 saturation (elevated), calculated arterial percent O_2 saturation (normal), and measured arterial percent O_2 saturation (decreased). Quantitative determination of cyanide in whole blood, urine, gastric contents and tissues, and plasma thiocyanate levels are also important (Ballantyne, 1983). Unfortunately, these tests take several hours and the results may not be available to the clinician during the acute phase of poison management. Usually the ''Lee-Jones test'' is a quick bedside test that can qualitatively detect cyanide in gastric aspirate but may give false positive cases with many drugs (Hall *et al.*, 1987).

VIII. TREATMENT OF CYANIDE POISONING

The onset of toxicity after cyanide poisoning is very fast. The prognosis of the victim depends on termination of further exposure, supportive care, and institution of immediate and aggressive specific treatment. Early diagnosis and clinical information would enhance the chances of recovery. The first principle of therapy is termination of further exposure, which can be facilitated by the following: (a) remove the victim from the contaminated atmosphere,

(b) apply a protective mask for the patient as soon as possible to prevent further inhalation, (c) remove off any liquid on skin or clothing as soon as possible, (d) remove all contaminated clothing; rinse skin with soap and copious amounts of water or water alone if there is liquid on the skin, and (e) gavage and administer activated charcoal if cyanide was ingested (Baskin and Brewer, 1997).

A. Supportive Therapy

The details of supportive therapy are presented in Table 19.5. Briefly, prior to specific therapy, the patient is given supportive aid. This includes mechanical airway support, artificial ventilation with 100% oxygen, possibly delivered via an Ambu bag containing the contents of two ampoules of amyl nitrite (0.6 ml), and cardiac monitoring (Van Heijst *et al.*, 1987). Anecdotal evidence suggests that hyperbaric oxygen augments the protective efficacy of nitrite–thiosulfate therapy (Goodhart, 1994). Lactic acidosis resulting from anaerobic metabolism and convulsions should be treated with intravenous administration of sodium bicarbonate and diazepam, respectively (Van Heijst and Meredith, 1990; Baskin and Brewer, 1997). The use of antidotes should be restricted to patients in deep coma with respiratory insufficiency.

B. Specific Antidotal Therapy

Patients who are critical and do not satisfactorily respond to supportive therapy should be administered specific cyanide antidotes as outlined in Table 19.5. Cyanide antidotes have been classified into three main groups based on their mechanism of action: (1) methemoglobin inducers, (2) sulfur donors, and (3) cobalt compounds. The definitive treatment of cyanide poisoning differs in various countries due to different medical practices and guidelines. The safety and efficacy of all the antidotes are still debated upon. There is no worldwide consensus for treatment of cyanide intoxication.

1. Methemoglobin Inducers

The basic aim of rapid detoxification of cyanide is prevention or reversal of inhibition of cytochrome oxidase by cyanide. This is usually facilitated by providing a large pool of ferric iron in the form of methemoglobin to complex cyanide. Cyanide preferentially competes with the Fe^{3+} of methemoglobin as compared to that of cytochrome oxidase, and eventually binds with the former to form cyanmethemoglobin. Thereby, the activity of inhibited cytochrome oxidase is restored (Baskin *et al.*, 1992). The various methemoglobin inducers employed as cyanide antidotes are discussed below.

a. Amyl Nitrite

Although inhalation of amyl nitrite as a first aid measure to cyanide poisoning has been known for many years (Pedigo, 1888), its efficacy as a methemoglobin inducer is often disputed due to its inability to generate methemoglobin greater than 6% (Jandorf and Bodansky, 1946). About 15% of methemoglobin is required to challenge one LD_{50} of cyanide (Van Heijst *et al.*, 1987). The protective effect of amyl nitrite is attributed to its vasodilatory effect which can reverse the early cyanide-induced vasoconstriction (Van Heijst and Meredith, 1990). Artificial ventilation with amyl nitrite broken into Ambu bags has been reported as a life-saving therapy in cyanide poisoned dogs, prior to induction of significant levels of methemoglobinemia (Vick and Froehlich, 1985).

b. Sodium Nitrite

Sodium nitrite is the most prevalent drug for cyanide poisoning. It takes about 12 min to generate approximately

TABLE 19.5. Supportive therapy and specific antidotal therapy for acute cyanide poisoning

	Agents	Drug category and action
Supportive therapy	100% oxygen or hyperbaric oxygen	Oxygen: Potentiates the efficacy of nitrite–thiosulfate therapy
	Sodium bicarbonate	Alkalizing agent: Corrects lactic acidosis
	Diazepam	Anticonvulsant: Depresses CNS activities
	Epinephrine	Sympathomimetic: Improves coronary and cerebral blood flow, corrects anaphylactoid reactions
Specific antidotal therapy	Amyl nitrite Sodium nitrite 4-Dimethylaminophenol	Methemoglobin inducers: Converts hemoglobin to methemoglobin which binds with cyanide to form cyanmethemoglobin. In the presence of sodium thiosulfate cyanide is excreted as thiocyanate
	Sodium thiosulfate	Sulfur donors: Facilitates enzymatic conversion of cyanide to thiocyanate
	Dicobalt edetate Hydroxocobalamin	Cobalt compounds: Forms stable metal complexes with cyanide

40% of methemoglobin after intravenous administration of the recommended dose (Van Heijst *et al.*, 1987). In spite of this delay in inducing a significant level of methemoglobinemia, a reasonable protection offered by sodium nitrite can be attributed to its vasodilatory effects (Van Heijst and Meredith, 1990). A major drawback with sodium nitrite is that it causes serious cardiovascular embarrassment, particularly in children (Berlin, 1970). Since methemoglobinemia impairs oxygen transport, sodium nitrite cannot be recommended for fire victims where concomitant exposure of HCN and carbon monoxide usually occurs. Since carbon monoxide also reduces the oxygen carrying capacity of blood, administration of sodium nitrite would further aggravate the underlying hypoxic condition. Sodium nitrite is also contraindicated for individuals with glucose-6-phosphate dehydrogenase (G6PD) deficient red cells because of the possibility of serious hemolytic reactions (Way, 1984). Excessive levels of methemoglobin are known to be reverted by intravenous administration of 30 ml of 1% methylene blue solution (Van Heijst *et al.*, 1987). In the USA, the Lilly Cyanide Antidote Kit (manufactured by Eli Lilly and Company, Indianapolis, IN) includes 10 ml ampoules of 3% sodium nitrite solution and 50 ml of 25% sodium thiosulfate solution. The kit also contains amyl nitrite encased in glass ''pearls'' which are meant to be broken so the drug could be inhaled. In India, a similar kit is manufactured by Troikaa Pharmaceuticals Ltd, Thiol.

c. 4-Dimethylaminophenol

The relatively slow rate of methemoglobin formation by sodium nitrite prompted the development of rapid methemoglobin formers like aminophenols. 4-Dimethylaminophenol (DMAP) is the treatment of choice for cyanide poisoning in Germany. Given intravenously, a dose of 3.25 mg/kg DMAP was reported to produce methemoglobin levels of 30% within 10 min and 15% methemoglobinemia was attained within 1 min without any immediate effect on the cardiovascular system (Kiese and Weger, 1969). However, there are differences in individual susceptibility to DMAP which may result in undesirable levels of methemoglobin even after normal therapeutic doses (Van Dijk *et al.*, 1987). Intramuscular injection of DMAP results in local abscess and fever. Its clinical utility remains limited on account of its other toxicological implications like nephrotoxicity (Weger, 1983).

2. Sulfur Donors

After the initial therapy of methemoglobin inducers, the cyanide has to be converted to thiocyanate which is eliminated in urine. This enzymatic detoxification of cyanide is facilitated by a sulfur donor like sodium thiosulfate. The mechanism of this reaction was discussed earlier under elimination of cyanide. High tissue oxygen markedly potentiates the effects of this reaction. In cases where methemoglobin formation is not desirable, sodium thiosulfate together with oxygen alone is sufficient. The utility of thiosulfate alone is limited because of its short biological half-life and its small volume of distribution (Sylvester *et al.*, 1983). Also, thiosulfate is contraindicated in patients with renal insufficiency as the thiocyanate formed may cause toxicity (Van Heijst and Meredith, 1990).

3. Cobalt Compounds

The cobalt ion, which forms a stable metal complex with cyanide, is an effective therapeutic agent against cyanide poisoning (Evans, 1964; Hillman *et al.*, 1974; Linell, 1987). Various cobalt-containing compounds known to antagonize cyanide poisoning are discussed below.

a. Dicobalt Edetate (Kelocyanor)

This compound chelates cyanide as cobalticyanide. This drug is known to antagonize cyanide more quickly than the nitrites but its clear superiority has not been established. Intravenous administration of 300 mg of dicobalt edetate in glucose solution is the current treatment of choice in France and the United Kingdom. Serious side effects like vomiting, urticaria, anaphylactoid shock, hypotension, and ventricular arrythmias have been reported in patients receiving Kelocyanor (Van Heijst and Meredith, 1990).

b. Hydroxocobalamin (Cyanokit)

With the exchange of the hydroxy group of hydroxocobalamin (vitamin B_{12a}) for cyanide, nontoxic cyanocobalamin (vitamin B_{12}) is formed (Hall and Rumack, 1987). An injectable solution of hydroxocobalamin (5 g in water) has been used in France and Germany. In France a 4 g hydroxocobalamin solution in 80 ml of sodium thiosulfate has also been used (Van Heijst and Meredith, 1990). EMD Pharmeceutical Company has produced a lyophilized packaging of 2.5 g of hydroxocobalamin that can be readily reconstituted in a 100 ml sodium chloride solution. This product is pending FDA approval. It has been in use in Europe since 1996 as the Cyanokit™. Hydroxocobalamin is also used in other countries, including Sweden, Denmark, Spain, Japan, and Hong Kong. Now, sodium thiosulfate or hydroxocobalamin has also been recommended for empiric treatment of cyanide poisoning (Hall *et al.*, 2007). There are several disadvantages in the clinical use of this drug. It has a relatively short half-life as it decomposes in light, and the dose required to counter cyanide poisoning is quite large. Also, recorded side effects include anaphylactoid reactions and acne (Van Heijst and Meredith, 1990). However, in a case study, clinical laboratory data did not show any evidence of toxicity (Borron *et al.*, 2007).

C. Investigational Drugs

Numerous agents analogous to the specific antidotes or compounds belonging to different pharmacological classes have also been evaluated against experimental cyanide poisoning. The cardiovascular implications and poor pharmacokinetics of nitrite led to evaluation of yet another group

of methemoglobin formers like aminophenones and derivatives. Out of all these compounds, *p*-aminopropiophenone (PAPP) was considered to be the most suitable agent for prophylaxis (Marrs and Bright, 1986; Bright, 1987). Hydroxylamine was examined as a rapid methemoglobin former with anticonvulsive properties, which conferred significant protection against acute cyanide poisoning (Kruszyna, *et al.*, 1982). Combinations of sodium nitrite with DMAP or hydroxylamine were found to provide sustained prophylaxis against acute cyanide poisoning in rats by virtue of rapid, protracted, and desired levels of methemoglobinemia (Bhattacharya *et al.*, 1991, 1993). However, toxicity of these regimens prevented their further use (Bhattacharya *et al.*, 1995). A number of 8-aminoqunoline analogs of primaquine (e.g. WR242511) were also studied as potential prophylactic drugs because they induced elevated levels of methemoglobin for a longer duration (Steinhaus *et al.*, 1990). Stroma-free methemoglobin solution (SFMS) was yet another alternative treatment proposed for cyanide poisoning (Ten Eyck *et al.*, 1985). SFMS was formed by oxidizing outdated human blood and intravenous administration of this solution did not impair the oxygen carrying capacity of blood as caused by most other methemoglobin formers. It was shown to directly sequester cyanide to protect a 4 × LD_{90} dose of sodium cyanide in rats. Among sulfur donors, several compounds containing sulfane sulfur, like polythionates, thiosulfonates, persulfides, etc., were examined as cyanide antidotes (Isom and Johnson, 1987). Compounds containing more lipophilic sulfane sulfur (e.g. ICD1021) or those which can be actively transported into the cells to mediate enzymatic detoxification of cyanide were synthesized as new anti-cyanide drugs (Baskin *et al.*, 1999). Antagonism of cyanide intoxication with murine carrier erythrocytes containing bovine rhodanese and sodium thiosulfate has been demonstrated (Cannon *et al.*, 1994; Petrikovics *et al.*, 1995). Exogenous supplementation of the enzyme has been reported to accelerate the transulfuration of cyanide to thiocyanate. However, stability and sensitivity of the enzyme remain to be addressed. Several cobalt compounds were also evaluated against experimental cyanide poisoning but none of them except cobalt edetate and hydroxocobalamin could be put to human use (Way, 1984; Linnell, 1987; McGuinn *et al.*, 1994).

Cyanide is a nucleophile known to react with various carbonyl moieties like ketones and aldehydes to yield cyanohydrin derivatives (Morrison and Boyd, 1976). Sodium pyruvate (Schwartz *et al.*, 1979), α-ketoglutarate (Moore *et al.*, 1986), pyridoxal-5′-phosphate (Keniston *et al.*, 1987), and many other carbonyl compounds and their metabolites or nutrients which interact with cyanide to form cyanohydrin complexes (Way, 1984; Niknahad *et al.*, 1994; Bhattacharya and Tulsawani, 2008) have been reported to afford significant protection against acute cyanide poisoning *in vitro* or *in vivo*. Out of all these agents, α-ketoglutarate, either alone or with sodium thiosulfate, has been considered to be a promising antidote for cyanide (Borowitz *et al.*, 1992). In a recent study, α-ketoglutarate and *N*-acetyl cysteine were found to protect rat pheochromocytoma (PC12) cells from cyanide-induced cytotoxicity and altered energy metabolism (Satpute *et al.*, 2008). *N*-acetyl cysteine, a free radical scavenger, was earlier found to attenuate cyanide-induced cytotoxicity and DNA damage in isolated rat thymocytes (Bhattacharya and Lakshmana Rao, 1997). Also, in several other acute (Tulswani and Bhattacharya, 2007) and subacute studies (Tulsawani *et al.*, 2005), α-ketoglutarate was found to antagonize cyanide poisoning in experimental animals. This agent is being actively pursued as an oral treatment for cyanide poisoning, particularly in instances where nitrites are not recommended (Bhattacharya, 2004). At present, phase-I clinical trials with α-ketoglutarate are being conducted in India.

There are several other compounds which are regarded as nonspecific cyanide antidotes, and their mechanisms have been only tentatively explained. These compounds are usually not very effective *per se* but as adjuncts significantly augment the efficacy of conventional antidotes. Chlorpromazine (phenothiazine), phenoxybenzamine (α-adrenergic blocker), centrophenoxine (neuroregulator), etomidate (nonbarbiturate hypnotic and anticonvulsant), naloxone (morphine antagonist), and flunarizine, verapamil, and diltiazem (calcium-channel blockers) are some of the compounds (Way, 2004; Marrs, 1988; Bhattacharya, 2000). Additionally, a few more compounds have been found to antagonize cyanide poisoning in the recent past. They include protein kinase C inhibitor (Maduh *et al.*, 1995), nitric oxide generator (Sun *et al.*, 1995), endothelium-derived relaxing factor/nitric oxide releasers or calcium ionophore A23187 (Baskin *et al.*, 1996), local anesthetic, procaine hydrochloride (Jiang *et al.*, 1998), and antioxidants like melatonin, a pineal hormone (Yamamoto and Tang, 1996) and its metabolite, 6-hydroxymelatonin (Maharaj *et al.*, 2003). In general, antioxidants are found to be good adjuncts to nitrite–thiosulfate therapy. Another study has shown that ATP, encapsulated in unilamellar fusogenic lipid vesicle when injected intraperitoneally in mice prior to cyanide, significantly increased the survival time and the fatal dose of cyanide (Chiang *et al.*, 2004). Above all, extracorporeal filtering or hemodialysis has also been found to supplement specific cyanide antidotes. This would hasten the elimination of cyanide and its metabolites. Hemodialysis achieved dramatic response in patients with severe acidosis (Wesson *et al.*, 1985). This is only an anecdotal case report and has not been substantiated further.

IX. CONCLUDING REMARKS AND FUTURE DIRECTION

In today's scenario, cyanide is considered to be neither an important CW agent nor an agent of choice for suicidal or homicidal purposes. However, threat from its possible use in local terrorism cannot be overlooked. Also, the occupational

hazard of cyanide is likely to increase with its escalating industrial use. Serious epidemiological studies and reporting in poison control centers can be observed in many developed nations. But many cases of fatal cyanide poisoning from fire smoke, drug side effects, dietary sources, and industrial exposures may go undetected due to poor surveillance in many countries. Cyanide toxicity is mainly ascribed to its ability to inhibit cytochrome oxidase, an end-chain enzyme of cellular respiration. Numerous new mechanisms of action of cyanide unfold the complex toxic phenomena occurring at cellular and molecular levels. Many of these mechanisms have been the target for pharmacological interventions. Although very primitive, the combination of sodium nitrite and sodium thiosulfate still continues to be the most favored treatment for cyanide poisoning. Hydroxocobalamin has also been used as a cyanide antidote with considerable success in the recent past. If we could circumvent the side effects of this drug, possibly it would be the most successful second-generation antidote for cyanide. Cyanide antagonism by scavengers like carbonyl compounds, particularly α-ketoglutarate, has also been very encouraging in animal models. Further clinical trials would determine its safety for human use. Also, the stability of this molecule needs to be addressed. Perhaps these kinds of molecules could be of use for occupational exposures, chronic dietary cyanide poisoning or as prophylaxis for fire-fighters/personnel engaged in evacuation operations in cyanide-contaminated areas. Another area of interest would be the development of field-based detection systems for rapid diagnosis of cyanide poisoning or for retrospective detection of cyanide in biological samples. This is a prerequisite for effective therapeutic measures.

Acknowledgment

The authors thank Dr R. Vijayaraghavan, Director, Defence Research and Development Establishment, Gwalior, India, for his keen interest and critical suggestions in the preparation of this chapter.

CHAPTER 20

Carbon Monoxide: From Public Health Risk to Painless Killer

DAYA R. VARMA, SHREE MULAY, AND SYLVAIN CHEMTOB

Carbon monoxide causes more health problems and death every year than any other poison or many together.
Lewin (1920) – Translation from German, Pankow (2000)

I. INTRODUCTION

The colorless carbon monoxide (CO) is everywhere. Wherever there is combustion there is CO; it is the predominant product above 800°C. The concentration of CO might vary from 0.1 ppm in clean atmosphere to 5,000 ppm in the proximity of domestic wood fire chimneys (Fawcett *et al.*, 1992) and is present in significant quantities in cigarette smoke (Hartridge, 1920; Hoffman *et al.*, 2001). The atmospheric lifetime of CO is 1 to 2 months, which allows its intercontinental transport (Akimoto, 2003).

The universal presence and unsuspecting inhalation of CO make it the most common source of poisoning in the modern world and the leading cause of unnatural death in the USA. However, CO is not on the list of chemicals used as chemical weapons in wars (Elsayed and Salem, 2006) although there are reports that the Nazis used CO gas against Jewish people in and around 1941 since CO was cheaper than bullets.

Mysterious illnesses, strange visions, and inexplicable deaths of entire households, generally attributed to haunted houses, are most likely due to malfunctioning chimneys resulting in carbon monoxide poisoning. Even nonlethal concentrations of CO can exert dramatic effects in the presence of pre-existing cardiac diseases. Continued exposure to relatively high, yet nonlethal, concentrations of CO can adversely affect a pregnant woman and her fetus. CO is a contributory factor in the adverse effects of smoking (Akrawi and Benumof, 1997; United Nations Environment Program and WHO, 1979); moreover smokers occasionally set the entire home afire producing excessive quantities of CO (Sacks and Nelson, 1994).

CO is also endogenously generated. Indeed, CO is a bit like other endogenous gases of great physiological and pathological significance like O_2, NO, and hydrogen sulfide (H_2S). CO also shares some properties with hydrogen cyanide (HCN) in so far as both produce hypoxia.

Given the toxicological and epidemiological importance of CO, it has been the subject of several books and monographs since 1920 (Bouletreau, 1970; Bour and Ledingham, 1967; Buchwald *et al.*, 1979; Coburn *et al.*, 1977; Cooper, 1966; Drinker, 1938; Flandin and Guillemin, 1942; Gras, 1967; Grut, 1949; Hamilton, 1921; IPCS, 1999; Jain, 1990; Lewin, 1920; Mannaioni *et al.*, 2006; Nicloux, 1925; Pankow, 1981; Penny, 1996; Putz *et al.*, 1976; Raymond and Vallaud, 1950; Shephard, 1983; Tiunov and Kustov, 1980; Von Oettingen, 1944). CO has also been a subject of numerous reviews some of which are referred to here (Beck, 1927; Blumenthal, 2001; Ernst and Zibrak, 1998; Fenn, 1970; Goldsmith and Landow, 1968; Gorman *et al.*, 2003; Kao and Nanagas, 2006; Killick, 1940; Lawther, 1975; Lilienthal, 1950; McGrath, 2006; Morandi and Eisenbud, 1980; Penny, 1990; Piantadosi, 2002; Prockop and Chichkova, 2007; Pugh, 1959; Raub *et al.*, 2006; Root, 1965; Ryter and Otterbein, 2004; Thom and Keim, 1989; Von Berg, 1999; Weaver, 1999; Winter and Miller, 1976).

During the last 20 years, however, the attention of researchers has shifted from the toxicity of CO to its physiological role (Snyder and Ferris, 2000; Wu and Wang, 2005). As a result the toxicity of CO is sometimes not mentioned as much as it should be. For example, the first edition of the textbook *The Pharmacological Basis of Therapeutics* by Louis Goodman and Alfred Gilman published in 1941 (MacMillan, New York) devoted five and one-quarter pages to carbon monoxide; the 11th edition of the same book edited by L.L. Brunton, J.H. Lazo, and K.L. Parker and published in 2006 (McGraw-Hill) mentions nothing under the heading of carbon monoxide; the word carbon monoxide appears only in relation to the therapeutic uses of oxygen. Similarly, the *Pharmacological Reviews* had the subject reviewed twice – first in 1950 (Lilienthal, 1950), when CO was known for its toxicity, and the second 55 years later (Wu and Wang, 2005), which only deals with its physiological role.

The pharmacology of CO spans a broad spectrum, from public health risk to endogenous modulator of important biochemical events to lethal poison. Given the theme of this

book, this chapter will mainly focus on the toxicology of CO. However, for the sake of completeness, physiological roles of endogenous CO are also presented. CO relates to all forms of life; however, its roles in microorganisms (Frankland, 1927) and plants (Han *et al.*, 2008; IPCS, 1999; K. Liu *et al*., 2007; Muramoto *et al.*, 2002; Wilks, 1959) are not covered in this chapter.

II. HISTORICAL BACKGROUND

An adequate amount was known about carbon monoxide at the beginning of the 20th century; Haldane (1922) devoted 14 pages on the history of carbon monoxide in his book titled *Respiration*; it occupied almost the same number of pages in the second edition 13 years later (Haldane and Priestley, 1935). An excellent description of the history of CO is contained in an article by Pankow (2000). Since most of the pioneering work on CO was done in Germany, and Pankow is based in Halle, Germany, he has been able to do justice to the celebrated first book on CO by Lewin (1920) and other related literature. There is another book called *Carbon Monoxide: The Silent Killer* by the University of Toronto Professor Roy J. Shephard. The title contains every ingredient of the history and toxicology of this mysterious poison – not invented by humans but made by nature itself like arsenic or cobra venom.

CO has always been a part of the universe. However, atmospheric CO has increased over time. When volcanoes erupted, continents collided, and winds embraced the trees sparking fires millions of years ago, all this contributed to the stock of CO. However, when CO first made a significant presence in the air we breathe, humans lived in the open. A very long time must have passed by before humans inhabited caves or built enclosures for protection from the effects of the weather or the tyranny of predators. In the process, however, humankind invited the unwanted guest – carbon monoxide, the silent killer. So where there is smoke, there is not only fire but also CO; in terms of human cost, the latter is more dangerous than the former. Yet it must have taken several thousands of years to tame the fire, and over those years CO has claimed many innocent victims who went to sleep after a hearty meal never to wake up. The knowledge of these mysterious events has been unraveled over time.

Just as concoctions of cinchona, bark of willow, and leaves of the common foxglove plant were used during ancient times without knowing that they contained, respectively, quinine, aspirin, or digoxin, so is the story of CO. The toxicity of CO was recorded by Aristotle (384–322 BC) in the third century BC; by the first century BC, charcoal fumes were used for suicide and executions without any knowledge of the exact nature of the killer (Lewin, 1920; Shephard, 1983). Byzantine emperor Julian the Apostate and his successor, Jovian, were poisoned in AD 363 and 364, respectively, because coal was used to heat their braziers (Lascaratos and Marketos, 1998).

The industrial revolution in Britain and Europe, and the discovery of the New World introduced coal for domestic heating and cooking. In 1700, Bernardino Ramazzini (1633–1714), a physician and professor at the University of Modena, published the book *De Morbis Arteficium Diatriba* (*Diseases of Workers*) which was translated from the original Latin text into Italian, French, German, English, and Dutch. Ramazzini recognized that fumes from burning coal by confectioners caused headache and dyspnea, and miners encountered ''noxious vapors''; burning coals, unless vented out, could ''Kill a man on the instant'' (Pankow, 2000; Shephard, 1983).

In their review, Prockop and Chichkoa (2007) write ''CO was first prepared by the French chemist de Lassone in 1716. Because it burned with a blue flame, de Lassone thought it to be hydrogen.'' In his book *Carbon Monoxide: The Silent Killer* (page 7), Shephard (1983) attributes this episode to the illustrious British chemist Joseph Priestley (1733–1804) who mistook this ''noxious vapor'' for hydrogen for the same reason – it burned with a bright blue flame. However, both Prockop and Chichkoa (2007) and Shephard (1983) agree that the identity of this noxious vapor was evaded until Cruikshank demonstrated that the gas which burned with the blue flame was indeed an oxide of carbon (CO) that could be converted into a dioxide of carbon (CO_2) by exploding it with oxygen.

Because the cause of CO poisoning which often resulted in death was unknown, myths emerged. Friedrich Hoffmann (1660–1742) of Halle, Germany, recounts that two farmers and a student used charcoal fire on a Christmas night; the farmers died and the student was found very sick; theologians, who claim to possess great knowledge, opined that it was a divine curse (Pankow, 2000).

French physiologist Claude Bernard (1857) was perhaps the first to describe the toxicity of carbon monoxide. In 1846, he forced a dog to inhale CO; of course the dog died and on autopsy he noted that the blood was crimson color in all the heart chambers as well as in the veins (Bernard, 1865). Claude Bernard correctly assumed that the crimson color was due to excess of oxygen in the blood. It was left to the celebrated British physiologist J.S. Haldane (1860–1936), to whom this chapter is dedicated, to identify carboxyhemoglobin (COHb) and determine its chemical nature (Haldane, 1895a).

By the end of the 19th century, Haldane had not only described the effects of exposure to various concentrations of CO on himself and mice but also discovered that the symptoms of CO poisoning could be alleviated by oxygen (Haldane, 1895a; Haldane and Priestley, 1935), which remains the most effective antidote against CO toxicity to date (Sluijter, 1967; Tibbles and Edelsberg, 1996). Haldane (1895a) also noted that ''symptoms of poisoning occur far more rapidly in mice than in man [himself]'' because the relationship of the body mass to surface area is

such that the mouse ''produces [CO] in an hour 10 grammes per kilo body weight, while man produces only about half a gramme''. Haldane was the first to use mice for the detection of CO in mines until canaries took over this service in 1921. By 1987 chemical methods for the detection of CO replaced the fate of the canaries.

Haldane worked out the physical chemistry of the CO–hemoglobin interaction; his First Law states: ''When a solution containing hemoglobin is saturated with a gas mixture containing O_2 and CO the relative proportions of the haemoglobin which enters into combination with the two gases are proportional to the relative partial pressures of the two gases, allowing for the fact that the affinity of CO for hemoglobin is about 3 times greater than that of O_2.'' This law is valid today; however, Haldane underestimated the affinity of CO for hemoglobin.

III. EPIDEMIOLOGICAL CONSIDERATIONS

Morbidity and mortality from CO poisoning vary from country to country because of the different standards of surveillance, extent of urbanization, housing conditions, source of energy, and so on. The major source of CO in the modern era is from the burning of petrol gas. Naturally, megacities with a population of over 10 million have a much higher level of atmospheric CO than smaller cities and rural areas.

Demography is changing rapidly in many countries especially in the two countries with populations of over one billion each – China and India; with surging economies in both countries the number of automobiles is fast increasing. In China, for example, the number of automobiles has been increasing at a rate of 13% per year since the 1980s; there were 18 to 21 million automobiles in China in 2000 compared with 11 million barely three years earlier in 1997; it is estimated that 3,000 kg of CO is discharged from every 1,000 automobiles each day (Chen and Wang, 2000).

In most countries, CO accounts for the maximum number of unintentional deaths in peace time. The estimated annual number of emergency admissions due to unintentional CO poisoning is approximately 40,000 in the USA (Weaver *et al.*, 1999), 5,000–8,000 in France (Annane *et al.*, 2001), 6,000 in Italy (Gandini *et al.*, 2005), and 523 in Poland (Sokal and Pach, 2000). Annual unintentional deaths from CO poisoning are approximately 600 in the USA (Cobb and Etzel, 1991) and 1,500 in the UK (Hamilton-Farrel and Henry, 2000).

Atmospheric CO is related to human civilization; consequently, its concentration varies markedly from east to west and from the south to north. Also, CO in the atmosphere varies greatly within different regions of the same country denoting uneven industrialization. In order to highlight these variables, we deal with this subject under two separate headings – the external source and the endogenous source of CO; details can be found in an excellent article by Vreman *et al.* (2000).

It is common knowledge that death due to CO poisoning is painless. The generation of CO in an enclosed space is also well known. Consequently, CO poisoning has emerged as the method of choice for suicides in favor of hanging and firearms.

IV. TOXICOKINETICS AND TOXICODYNAMICS

A. Sources of CO

There are two main sources of CO, exogenous and endogenous. While the atmospheric CO is the principal cause of CO toxicity, the endogenous source is physiologically very important (Maines, 1997; Marks *et al.*, 1991; Wu and Wang, 2005), and under certain conditions may even become pathological (Nezhat *et al.*, 1996).

1. External Sources of CO

Carbon monoxide is a product of incomplete combustion as encountered in the operation of vehicles, heating, coal power generation, and biomass burning (Godish, 2003). Natural geographical events such as volcanic eruptions, emission of natural gases, degradation of vegetation and animals, and forest fires all contribute to atmospheric CO. Approximately 40% of global CO comes from these natural sources. Human intervention such as fossil fuel consumption, garbage disposal, tobacco smoke, charcoal fires, etc., contribute to the remaining 60% of global CO (Jain, 1990; Vreman *et al.*, 2000). Because human activity and density differ from place to place due to socioeconomic factors, atmospheric CO varies greatly from place to place. CO emission in the USA in 2001 was 120.8 million short tons of which 74.8 million came from on-road vehicles (McGrath, 2006).

Apart from various other changes, the developing countries are characterized by increasing migration of rural population to slums and shanty towns on the outskirts of cities like São Paulo, Mexico, Johannesburg, Mumbai, Shanghai, etc.; this is associated, among other things, with an increase in atmospheric CO. Fortunately, atmospheric CO has not exceeded safety levels globally, or in any specific areas including, for example, Mexico City and Los Angeles, but it can. It is reassuring that many efforts are being made by government agencies to reduce CO emissions.

2. Endogenous sources of CO

The knowledge that CO is normally present in the body dates back to 1894 when Grehant (1894) detected a combustible gas in blood. By 1898, this combustible gas was suspected to be carbon monoxide (De Saint Martin, 1898; Nicloux, 1898). At the time, methods did not exist to ascertain if the CO in the blood was generated inside the

body or was derived from the air. It was not until 1949 that the evidence for endogenous production of CO was firmly established (Sjorstrand, 1949). Tenhunen *et al.* (1968, 1969, 1970) elaborated on the role of heme oxygenase in the generation of CO.

The major source of endogenous CO in a healthy individual is from the degradation of heme by heme oxygenase (HO) – HO-1 and HO-2. The enzyme HO-1 is inducible and HO-2 is constitutive; heme oxygenase degrades heme into CO and biliverdin and the latter is rapidly converted into bilirubin (Coburn, 1979; Coburn *et al.*, 1963, 1967; Mores and Sethi, 2002). Current literature emphasizes only a physiological role for endogenously generated CO (Boehning and Snyder, 2003; Choi and Otterbein, 2002; Mannaioni *et al.*, 2006; Ryter and Otterben, 2004; Wu and Wang, 2005) although it is quite likely that it could add to the toxicity of inhaled CO.

Heme oxygenase is the rate-limiting step in the production of CO and its activities account for 86% of endogenous CO production; the remaining 14% is derived from nonheme sources. The lifespan of red blood cells is approximately 120 days; the older the erythrocyte the greater is its CO output. In neonates, red blood cells have a shorter lifespan and relative to erythrocytes of adults, they produce two to three times more CO (Fallstrom, 1968). HO-2 is activated during neuronal stimulation by phosphorylation by the enzyme CK2 (Boehning *et al.*, 2003).

The rate of COHb formation is a function of inhaled CO concentration and duration (Figure 20.1). The rate of CO production and excretion parallels the rate of bilirubin production; hence a measurement of COHb serves as a measure of heme degradation and bilirubin production.

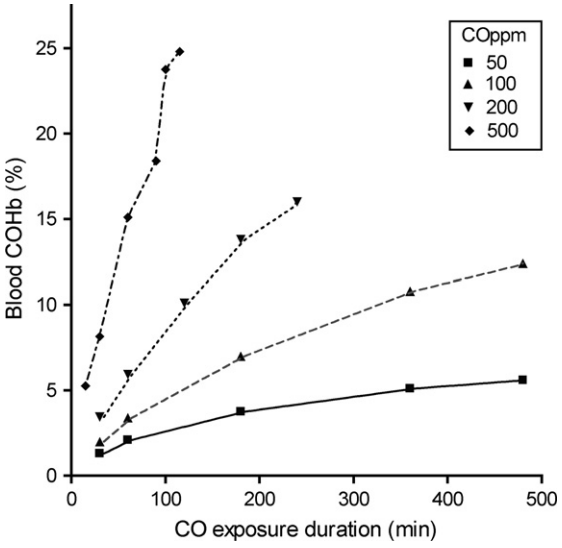

FIGURE 20.1. Relationship between the duration of exposure to different concentrations of carbon monoxide and blood carboxyhemoglobin (COHb) in healthy volunteers. The plot is based on data of Stewart and Peterson (1970).

Indeed, a measurement of end-tidal CO in breath corrected for inhaled CO is used as a measure of assessing infants at risk of severe hyperbilirubinemia because CO and bilirubin are produced in equimolar amounts (Bartoletti *et al.*, 1979).

A small fraction (20%) of endogenous CO is derived from other hemoproteins such as myoglobin and many other iron-containing enzymes (Coburn, 1970; Vreman *et al.*, 2000). This serves as an example of the use of endogenous CO monitoring for diagnostic purposes.

In addition to the major exogenous and endogenous sources of CO described above, certain medical procedures within the body can also generate CO. For example, laser and bipolar electrocautery during laparoscopy can generate over 200 ppm CO in the body cavity, which finds its way into the circulation increasing COHb levels (Wu *et al.*, 1998), sufficient to induce toxicity (Nezhat *et al.*, 1996). Anesthetic machines equipped with drying material like soda lime or barium hydroxide were found to generate CO (Baum *et al.*, 1995; Moon *et al.*, 1992) from several anesthetic agents (Fang *et al.*, 1995). Likewise pulmonary function tests based on determining the CO diffusion capacity as a means of determining the alveolar-capillary diffusion capacity for gases can also elevate CO and in turn COHb (Vreman *et al.*, 2000).

B. Physicochemical Properties of CO

CO is a colorless, odorless, tasteless, noncorrosive stable diatomic molecule in the atmosphere. Unlike hydrogen peroxide (H_2O_2) or superoxide ($O^{\bullet}$), CO is not a radical. CO has low water solubility and negligible quantities dissolve in blood at normally encountered pressure (Shephard, 1983). CO has a shorter inter-atomic distance ($\sim$1.13 Å) than would be anticipated for a single bond. It has a high heat of formation from the constituent atoms (bond strength 2.07 MJ/mol) and the electric charge is distributed rather uniformly between the carbon and oxygen atoms. Pauling (1960) postulated that under normal circumstances CO existed as a hybrid containing roughly equal proportions of three structures. According to the modern atomic theory, carbon atoms have the first shell filled with two electrons in S orbitals, while the second shell contains two electrons in the S orbital and two in the P orbital (Shephard, 1983). The general properties of CO are presented in Table 20.1.

C. Methods for CO Measurement

Appropriate techniques exist for the quantitation of CO both in gaseous and tissue samples. In either case caution needs to be exercised to ensure that CO concentration is not altered by interaction with the sample vessel during storage and transport. For example, Vacutainer tubes were found to greatly alter CO levels when used for storage of blood samples (Vreman *et al.*, 1984). Furthermore, routine monitoring of air for public health requires a simple and yet reliable sample collecting system. Ambient CO levels at the

TABLE 20.1. Physicochemical properties of carbon monoxide

Property	Description
Chemical structure	
Molecular weight	28.01
Critical point	−140°C at 3495 kPa
Melting point	−199 °C
Boiling point	−191.5 °C
Fundamental vibration transition	2143.3 cm^{-1} (4.67 μm)
Density at 25°C, 101.3 kPa	1.145 g/l
Specific gravity relative to air	0.967
Solubility in water at 0°C	35.4 ml/l
Solubility in water at 25°C	21.4 ml/l
Explosive limit in air	12.5–74.2%

workplace can be very low requiring sensitive analytical techniques. With the recognition of the hazardous nature of CO and its almost universal presence, several sophisticated methods for quantifying CO have been developed (IPCS, 1999; Vreman *et al.*, 2000).

1. Measurement of Blood CO

Haldane (1895b) wrote: ''In view of the very poisonous nature of carbonic oxide, and the comparative frequency with which cases of poisoning by this gas occur, much attention has been given to its detection and estimation … The method now to be described is very simple, and depends on the fact that when a hemoglobin solution is well shaken with air containing carbonic oxide and the proportion of hemoglobin, which finally combines with carbonic oxide, varies with the percentage of carbonic oxide in the air. By determining colorimetrically the proportion of the hemoglobin which has combined with the carbonic oxide it is thus possible to infer the percentage of carbonic acid in the air.''

''The bottle containing the blood solution and sample air must be covered with a cloth during the process of shaking, and (although this is by no means so important) very bright light should be avoided during the process of titration with the carmine solution'' (Haldane, 1896).

The currently employed method of quantifying blood CO and the precaution that is needed for accuracy are simply refinements of the method described by Haldane (1895b, 1896) more than a century ago; colorimetric detection was soon replaced by the spectroscopic detection method (Hartridge, 1912) and has undergone further sophistication since then. Both gas chromatography and spectrophotometry are considered appropriate although the former is favored (Coburn *et al.*, 1964; Collison *et al.*, 1968; Constantino *et al.*, 1986; Kane, 1985; Vreman *et al.*, 1984, 1998). However, blood CO is still measured by determining COHb levels, which are normally undetectable but might be involved in the transfer of CO between cells. The measurement of COHb is useful not only in the quantification of CO but also to detect neonatal hemolysis (Necheles *et al.*, 1976; Ostrander *et al.*, 1982).

COHb is quite stable and its concentration does not change over a long period (up to 6 months) if the blood sample is stored in the dark and under sterile conditions. Blood levels of COHb are not expected to exceed 5% at ambient levels of CO. IPCS (1999) focuses on methods which can accurately measure COHb below 10%. A method which simply requires finger-prick blood is convenient for mass screening and is described in detail by Commins and Lawther (1965); in this method, the sample is diluted in ammonia solution, which is divided into two parts; from one of these, CO is displaced by oxygen and the COHb containing part is placed in the sample beam of a spectrophotometer so that the instrument records the difference between the absorbance of COHb and oxyhemoglobin.

Several techniques for measuring COHb exist (IPCS, 1999). The sensitive techniques require the release of CO from hemoglobin into a gas phase; CO can then be detected directly by a number of methods such as infrared absorption, difference in thermal conductivity between CO and the carrier gas, amount of ionization following conversion of CO to methane, or the release of mercury vapor resulting from interaction of CO with mercuric oxide.

The conventional method of expressing CO in blood samples is as percent COHb and it is determined by the formula:

$$\%\text{COHb} = [\text{CO content}/(\text{HB} \times 1.389)] \times 100$$

where CO content is the CO concentration in ml/100 ml blood, Hb is hemoglobin in g/100 ml blood and 1.389 is the combining capacity of CO for Hb in ml of CO per gram Hb.

The blood level of COHb as a percent of total hemoglobin is directly related to the exposure duration at any concentration of CO (Figure 20.1).

Blood COHb measurements have been used to monitor exposure of populations to atmospheric CO; which also functions as a measure of air pollution; using this approach, New Hampshire, Vermont, and the city of St Louis, Missouri were found to have blood COHb levels in the range 1 to 1.5% in the early 1970s (Davis and Ganter, 1974; Kahn *et al.*, 1974).

a. Ambient Air CO

Because CO concentration in ambient air and at workplaces is usually quite low, reliable methods for sample collection and transport as well as highly sensitive methods for its measurement are needed (IPCS, 1999; Smith and Nelson, 1973). The sampling method recommended by WHO (IPCS, 1999) comprises a sample introduction system

consisting of a sampling probe, an intake manifold, tubing, and air remover. Known gas concentration is periodically collected to verify the method.

According to IPCS (1999), the analyzer system consists of an analyzer as well as sample preconditioning components fitted with a moisture control system such as the Non-Dispersive-Infrared (NDIR) analyzer. The infrared absorption near 4.6 μm, characteristic of CO, is used to measure its concentration. The most sensitive analyzers can detect CO concentrations as low as 0.05 mg/m^3 (0.044 ppm). The NDIR analyzer designed by Luft (1962) is considered appropriate because it is little affected by flow rate, requires no wet chemicals, has a short response time, and is sensitive over wide concentration ranges.

Other analyzers include gas chromatography, which is a sensitive, automated, and semi-continuous technique in which CO is separated from water, CO_2, and hydrocarbons (other than methane) by a stripper column and CO is passed through a catalytic reduction tube where it is converted to methane. The converted CO is passed through a flame ionization detector; its sensitivity range is 0.026 to 43.7 ppm (IPCS, 1999). Other methods such as small personal exposure monitors (PEMs) can measure CO concentrations on a continuous basis and store data on internal digital memories (Ott *et al.*, 1986).

b. Home Detectors

Residential CO detectors are designed like smoke detectors and provide protection from excessive CO concentrations inside homes by sounding alarms. They are based on an interactive-type sensor, such as tin oxide, artificial Hb that relies on an interaction between CO, and the sensitive element to generate an alarm. The alternate current powered home detectors have a metallic sensor that reacts with CO; the battery-powered ones have a chemically treated gel that darkens upon exposure to CO. They are designed to sound the alarm within 90 min at CO concentrations of 100 ppm; within 35 min at 200 ppm or within 15 min at 400 ppm (IPCS, 1999). CO concentration of 400 ppm can increase COHb to 10%, above which CO toxicity is observed.

c. CO in Expired Breath

Measurement of CO in the expired breath is based on the assumption that CO in alveolar air is in equilibrium with the partial pressure of CO in blood which in turn is in equilibrium with CO bound to Hb, that is COHb (Douglas *et al.*, 1912).

D. Absorption, Distribution, and Elimination of CO

Atmospheric carbon monoxide can travel thousands of kilometers from its source and has a half-life of 1–2 months (Akimoto, 2003). Although the biological effects of CO differ depending upon whether it is inhaled or endogenously produced, the ultimate fate of CO is the same regardless of its source.

Exogenous CO reaches the body solely by pulmonary absorption. Once inhaled, CO combines reversibly with hemoglobin and to a smaller extent with myoglobin and other iron-containing macromolecules. Because most of the CO in the body is bound to hemoglobin, the relative affinities of CO and oxygen for hemoglobin are of critical significance in terms of both its toxicity and excretion. This relationship was first described by Haldane (1912), in what is known as Haldane's first law, represented by the following equation:

$$(PO_2 \times \mathrm{COHb})/(P\mathrm{CO} \times \mathrm{O_2Hb}) = \mathrm{M}$$

where M is the affinity constant, thought to be between 208 and 245 at 37°C, and PCO and PO_2 are the partial pressures of CO and oxygen, respectively.

Haldane had conducted the experiments on himself and found that he needed to inhale 0.07% CO in the air containing 20.9% oxygen in order for Hb to achieve 50% oxygen and 50% CO saturation. On this basis he calculated the relative affinities of CO and oxygen for Hb as 1.299. While more refined techniques have estimated the affinity of CO for Hb to be much higher (Ernst and Zibrak, 1998; Roughton and Darling, 1944; Sendroy and Liu, 1930), the fundamental relationship proposed by Haldane (1912) remains valid and has been discussed in detail by others (Forster, 1970; Roughton, 1970); this relationship between CO, oxygen, and hemoglobin explains both the high toxic potential of CO and the need of hyperbaric oxygen to treat CO overdose (Jay and McKindley, 1997; Pace *et al.*, 1950; Peterson and Stewart, 1970).

Under normal physiological states there is almost always a certain amount of COHb even when breathing CO-free air, because the breakdown of Hb results in endogenous production of CO, which can result in 0.5 to 0.8% COHb in normal blood (Lawther, 1975). At any CO concentration in the air, COHb will attain an equilibrium (16% at 100 ppm ambient CO and 1.7% at 10 ppm CO); it follows that if CO in the air is lower than that required for a given COHb% at equilibrium, CO will leave COHb and be exhaled until a new equilibrium is established. This has practical implications. For example, a smoker with a relatively high COHb at equilibrium may exhale CO. Also, if the basal COHb is high an equilibrium at a high CO concentration in the air will be achieved more quickly than it would be at an initial low COHb.

The reaction of CO with ferrous iron is relevant to its pharmacology. Shephard (1983) provides the following description of this reaction. When reacting with ferrous iron, carbon atoms of CO form a sigma bond, involving also a D-orbital electron from the third shell of Fe^{2+}. In the body, Fe^{2+} also has four nitrogen linkages that contribute a substantial electron density; the effective valency is less than Fe^{2+}, enabling a more readily reversible reaction with both oxygen and carbon monoxide.

The solubility of CO in water is about 20% less than that of O_2 such that it is practically absent from the solution in blood.

Reaction of CO with hydroxyl radicals ($OH^{\cdot}$) is the major method of removing CO from the atmosphere (IPCS, 1999). The cycle of hydroxyl radicals is coupled to cycles of CO, methane, water, and ozone; they are produced by the photolysis of ozone followed by the reaction of the excited oxygen atoms with water vapor to produce two hydroxyl radicals: ($O(^1D) + H_2O \rightarrow OH^{\cdot} + OH^{\cdot}$). A small proportion of atmospheric CO is removed by the soil.

Carbon monoxide is eliminated from the body almost exclusively via the lungs. When respiring room air, the elimination half-life of CO in a healthy adult is approximately 4 h, which can be reduced to 1 h when breathing oxygen at normal atmospheric pressure (Bartlett, 1968; Pace *et al.*, 1950; Roughton and Root, 1945); high concentration of COHb can shorten the elimination half-life of CO (Haldane, 1985a; Henderson and Haggard, 1921) and low concentration can increase it (Petersen and Stewart, 1970). On the other hand, half-life for a drug is a meaningful feature only if it is not dose independent; which is not the case with CO (Jay and McKindley, 1997).

V. MECHANISM OF TOXICITY

Wu and Wang (2005) chose to name endogenous CO as ''Dr Jekyll'' and not ''Mr Hyde'' because it is good rather than bad; if they are correct, then this mysterious gas proves more than any other agent the correctness of the dictum of Paracelsus (1493–1541) that: ''All substances are poisonous. Only the dose differentiates a poison from a remedy.'' If Paracelsus had known about the views of Wu and Wang (2005) regarding CO, he might well have added – not only the ''dose'' of the substance but also its source.

There are very few agents like the anticoagulant warfarin whose toxicity and therapeutic effects are produced by the same mechanism. In most cases beneficial and harmful effects recruit different mechanisms of action. As far as CO is concerned not only does its mechanism of toxic and physiological actions differ, but the source from where it is derived matters too. So the mechanisms of action of inhaled- and heme-generated CO also seem to differ. Since the focus of this chapter is CO toxicity, we will attempt to elaborate the mechanism of its toxicity more than the mechanism of its physiologic actions.

The French physiologist Claude Bernard (1857) and the British physiologist Haldane (1895a) inferred that the toxicity of CO was caused by its interaction with hemoglobin. In his review of carbon monoxide, Lilienthal (1950) writes: ''It has been said many times that the effect of CO on man may be attributed to two actions and, in essence, to these two actions alone: (a) occupation of the Hb molecule by CO, with a resultant decrease in the O_2 transport capacity of the blood; and (b) alteration of O_2Hb dissociation

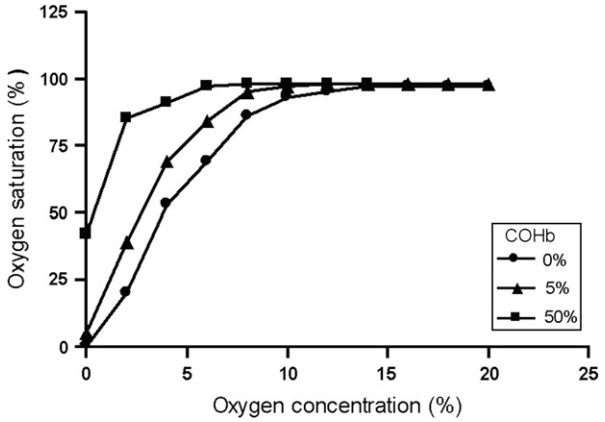

FIGURE 20.2. Effect of carboxyhemoglobin (COHb) upon the shape of the oxyhemoglobin dissociation curve in healthy males. Based on data of Haldane and Priestley (1935) as presented by Shephard (1983).

characteristic produced by COHb, with a resultant impaired unloading of O_2 at the tissues.'' The O_2Hb dissociation curve is shown in Figure 20.2.

Both features described by Lilienthal (1950) boil down to hypoxia as the principal mechanism of CO toxicity thereby confirming the basic observations of Claude Bernard and J.S. Haldane made 150 years earlier and working out details of CO–hemoglobin interaction. Haldane (1894a, 1896) knew that the affinity of CO for hemoglobin was greater than that of oxygen, even if he underestimated it. The color of COHb is red, which explains the cherry-like discoloration of CO victims; this is generally but erroneously believed to be a specific characteristic of cyanide poisoning. Obviously, any time oxygen is not fully extracted from the arterial side, the venous blood will become cherry-red.

More sophisticated techniques than the ones used by Haldane have established that CO binds to hemoglobin with an affinity 200 times greater than that of oxygen (Ernst and Zibrak, 1998; Roughton and Darling, 1944; Sendroy *et al.*, 1930). Carbon monoxide diffuses from the alveoli to the blood in pulmonary capillaries across the alveoli–capillary membrane, which is composed of pulmonary epithelium, the capillary epithelium, and the fused basement membranes of the two. The uptake of CO by Hb is very rapid and the transfer of CO is diffusion limited (Prockop and Chichkoa, 2007).

The greater the duration of the exposure to CO, the concentration of CO in the inhaled air, and the alveolar ventilation, the greater the total amount of COHb. While the uptake of CO by Hb is very rapid, the release of CO from COHb complex is extremely slow. As the concentration of COHb increases the formation of oxyhemoglobin at any concentration of oxygen in the inhaled air decreases. There is a strong case for using COHb concentration as a predictor of CO toxicity (Renwick and Walton, 2001).

There is yet another mechanism by which CO produces hypoxia. COHb shifts the dissociation curve of the

remaining oxyhemoglobin to the left, which further decreases the release of oxygen (Douglas *et al.*, 1912; Roughton and Darling, 1944), which causes headaches when mild and death when it is extreme. Douglas *et al.* (1912) also observed that ''the presence of a small proportion of oxygen may greatly increase the formation of CO–haemoglobin, and *vice versa*'' and this ''paradoxical effect explains the favorable physiological effect sometimes produced by carbon monoxide in conditions of great anoxhaemia''. The studies of Pace *et al.* (1950) on human volunteers demonstrated that the release of CO bound to hemoglobin and its expiration can be increased by inhalation of hyperbaric oxygen (Figure 20.3).

However, the data of Goldbaum *et al.* (1975, 1976) imply that formation of excess of COHb might not account for the lethal effects of CO; these researchers found that dogs breathing 13% CO died within 1 h after achieving COHb levels between 54 and 90% but transfusion of blood containing 80% COHb, which resulted in 57 to 64% COHb in the recipient dog, did not cause marked toxicity. It would thus appear that the toxicity of CO results from a combination of tissue hypoxia due to COHb plus other effects of CO, which would explain why COHb levels do not always correlate with the severity of clinical effects (Brown and Piantadosi, 1992; Myers, 1984; Norkool and Kirkpatrick, 1985; Rottman, 1991).

Besides hemoglobin, CO binds to many heme-containing proteins such as myoglobin, guanylyl cyclase, and cytochrome oxidase (Chance *et al.*, 1970; Hill, 1994; Kao and Nanagas, 2006; Omaye, 2002). However, the affinity of CO for cytochrome oxidase is very low and this interaction would require a dose far exceeding the lethal dose of CO (Prockop and Chichkoa, 2007). On the other hand, even at sublethal concentrations binding of CO to cytochrome may

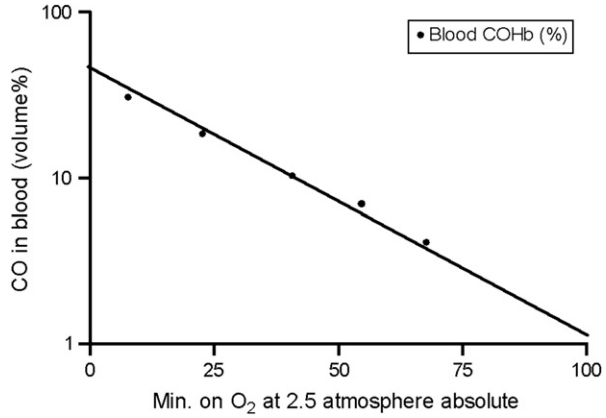

FIGURE 20.3. Data are from a healthy male volunteer, who breathed a low concentration of carbon monoxide and then oxygen at 2.5 atmospheric pressure, absolute. Blood was collected at different times after starting oxygen. Data points are taken from Pace *et al.* (1950) and may not be exactly the same as in their figure. Each point is the mean of triplicate determination and intercept indicates CO level at time zero prior to oxygen therapy.

lead to the generation of superoxides (Hardy and Thom, 1994; Zhang and Piantadosi, 1992) and interfere with cellular respiration. Cellular metabolism remains inhibited even after COHb levels decline to normal range (Brown and Piantadosi, 1992; Olson, 1984; Piantadosi *et al.*, 1995).

The interaction of CO with myoglobin can explain some of its toxic effects; it might impair oxygen supply to the mitochondria, which can result in myocardial ischemia. Patients with underlying cardiac conditions are therefore at a high risk of cardiac arrhythmias following exposure to CO (DeBias *et al.*, 1976; Olson, 1984; Sangalli and Bidanset, 1990) as well as chest pain and even death. A study of Swiss soldiers accidentally exposed to CO noted a substantial number had developed chest pain some time after exposure to CO (Henz and Maeder, 2005). The interaction of CO with skeletal muscle myoglobin can cause muscle weakness (Herman *et al.*, 1988; Richardson *et al.*, 2002; Wolf, 1994).

Nitric oxide (NO) and NO donors as well as phosphodiesterase inhibitors increase gyanylyl cyclase and hence cGMP causing marked vasodilatation; patients on nitrates for angina are well aware that the drug may cause dizziness and loss of consciousness. CO also activates guanylyl cyclase and there is always a possibility that the resulting hypotension and cerebral vasodilatation may lead to a loss of consciousness; it is therefore prudent also to treat an increase in cGMP as a potential toxic effect and not only as a physiological activity of CO or proof of a neurotransmitter role for CO as suggested by many (Verma *et al.*, 1993; Snyder and Ferris, 2000; Wu and Wang, 2005).

Any event that leads to hypoxia can lead to reperfusion and secondary hyperoxia especially if vascular autoregulation is not fully developed such as in premature births and certain animal models (Chemtob *et al.*, 1991; Hardy *et al.*, 1997, 2000). Hyperoxia leads to generation of superoxides and other radicals, which are involved in a number of pathologies (Brault *et al.*, 2007; Kowluru *et al.*, 2001; Pryor *et al.*, 2006). Recent studies suggest that hypoxia caused by the formation of COHb may also be followed by reperfusion injury on the top of that produced by the initial hypoxia. The oxidants generated during reperfusion can oxidize essential proteins and nucleic acid and can cause lipid peroxidation leading to demyelination of CNS lipids and other effects (Ernst and Zibrak, 1998; Prockop and Chichkoa, 2007).

In addition, CO can promote neutrophil adhesion to the microvasculature resulting in the activation of xanthine oxidase and generation of oxidative radicals which ultimately culminate in brain lipid peroxidation, which is the likely cause of delayed neurological sequelae (Gilmer *et al.*, 2002; Hardy and Thom, 1994; Ischiropolous *et al.*, 1996; Thom, 1990, 1993; Thom *et al.*, 1994, 1997, 2001). The observed brain lipid peroxidation in CO poisoning is likely to be caused by changes in cerebral blood flow plus oxidative damage (Hardy and Thom, 1994; Ischirpolous *et al.*, 1996; Thom, 1990, 1992; Thom *et al.*, 1997; Zhang and Piantadosi, 1992).

CO might also alter myelin basic protein, which may react with lipid peroxidation products to produce immunologic cascade (Thom *et al.*, 2004). Other events that could contribute to CO toxicity include glutamate-induced neuronal injury (Ishimaru *et al.*, 1992; Penny and Chen, 1996; Piantadosi *et al.*, 1997), atherogenesis (Lightfoot, 1972; Thom *et al.*, 1999), and apoptosis (Piantadosi *et al.*, 1997).

The model of carbon monoxide toxicity proposed by Kao and Nanagas (2006) combines the cascade of changes resulting from three primary events – binding to HB, direct cellular injury, and increased NO activity. CO is not a radical but many of the injuries produced by it are those that are caused by oxidative stress, which is secondary to hypoxia. In the model of Kao and Nanagas (2006), the oxidant is NO, which contributes to oxidative damage to the brain and produces the clinical syndrome of delayed neurologic sequelae (Thom *et al.*, 1997).

VI. TOXICITY OF CARBON MONOXIDE

A. Acute Toxicity

All chemicals produce toxicity; however, only a few of them cause death every time if taken in overdose; carbon monoxide is one of them. The toxicity of CO has been extensively reviewed (Drinker, 1938; Gorman *et al.*, 2003; Hamilton, 1921; Kao and Nanagas, 2006; Lilienthal, 1950; Mannaioni and Vannacci, 2006; McGrath, 2006; Prockop and Chichkova, 2007; Putz *et al.*, 1976; Robkin, 1997; Ryter and Otterbein, 2004; Samoli *et al.*, 2007; Thom and Kleim, 1989) or contained in monographs (IPCS, 1999; Penny, 2000; Shephard, 1983).

The acute toxicity of CO spans from dizziness to death. Symptoms of CO poisoning begin at approximately 20% COHb and death occurs between 50 and 80% COHb (Ryter and Otterbein, 2004); The relationship between blood COHb and toxic signs and symptoms is presented in Table 20.2.

Haldane (1895a) provided the first description of the relationship of CO in inhaled air to its toxic effect on humans. In the first experiment on himself and a mouse, Haldane inhaled 0.5% CO for 11.5 min with no obvious symptoms except ''hyperapnea after running upstairs''. In the second experiment, Haldane and his mouse inhaled 0.39% CO; at 15 min his COHb was 23% but he had no symptoms while the mouse started panting after 1.5 min and lay helplessly on its side by 15 min; at 29 min his pulse was 120 beats/min and he felt distinctly ''abnormal'' while the mouse lay on its back with hyperapnea; at 30.5 min the COHb was 39% and he stopped inhaling CO but felt giddy and had palpitations after running up 24 steps and could not see well; upon resting for 2–3 min, Haldane felt better and hyperapnea disappeared; 45 min after stopping the inhalation of CO, COHb was 23%, at 105 min 18% and at 186 min 5%.

Not satisfied with the data Haldane had so far collected he did nine more experiments (total of 11) with his companion mouse; aside from all other facts, Haldane came to the conclusion that mice are more sensitive than humans to CO toxicity and COHb remains elevated for a long time.

The higher sensitivity of mice than of humans led to the introduction of canaries in the coalmines. To our knowledge, CO toxicity on humans was again experimentally determined 75 years after Haldane's experiments (Hosko, 1970; Peterson and Stewart, 1970; Stewart *et al.*, 1970). Stewart *et al.* (1970) exposed 25 human volunteers to CO concentrations from <1 to 1,000 ppm for variable time periods and determined COHb as well as subjective symptoms and objective signs (EEG recording, EECG, hand and foot reaction); the main conclusions of these researchers was that even exposure up to 100 ppm CO for up to 24 h did not produce detectable subjective or objective changes; exposure to 200 ppm CO caused mild frontal headache in 4 h and headache was experienced within 1 h at 500 ppm. Full recovery took place in all cases when subjects were transferred to a hyperbaric oxygen chamber; COHb strongly correlated with inhaled CO concentration reaching approximately 20% at 100 ppm and 30% at 200 ppm CO (Peterson, 1970; Peterson and Stewart, 1970). Hosko (1970) found that at COHb greater than 20%, visually evoked responses were altered in human volunteers; at high altitudes even a much smaller increase in COHb (5–10%) can exert similar effects (Lilienthal and Fugit, 1945).

The data cited above and the relationship of COHb to CO toxicity presented in Table 20.2 clearly show that the acute toxicity of CO is concentration dependent; this is of great

TABLE 20.2. Relationship of carboxyhemoglobin (COHb) to toxicity in humans following exposure to carbon monoxide

COHb %	Signs and symptoms
<10	No effects in healthy individuals[a]
10–20	Mild headache, exertional dyspnea, cutaneous vasodilation
20–30	Throbbing headaches, nausea
30–40	Severe headaches, dizziness, visual disturbance, fatigue
40–50	Tachypnea, tachycardia, collapse, syncope
50–60	Coma, convulsions, Cheyne-Stoke's respiration
60–70	Cardiorespiratory depression, possible death
>70	Respiratory failure and death

[a]Symptoms may appear in subjects with cardiovascular disease. Concentration of COHb depends upon the duration of exposure to any concentration of CO in the air and therefore not included in the table. Exposure to approximately 200 ppm for 2 h results in 10% COHb; ~12,000 ppm CO would produce lethal concentrations of COHb within 2–3 breaths. Based on data from Goodman and Gilman (1941); Renwick and Walton (2001)

relevance in setting permissible or desirable atmospheric CO concentration standards. However, the binding affinity of CO for Hb is 200 to 300 times greater than that of oxygen to Hb; the effects of CO therefore must be considered cumulative. Prolonged exposure to CO would increase COHb more than can be accounted for by its ambient concentration; likewise a long period of CO-free atmosphere would be needed for COHb to return to normal levels as also revealed by the data of Haldane (1895a). As a caution it should be noted that toxic symptoms of CO poisoning do not necessarily correlate with COHb levels; for example, seizures in a four-year-old child were noted at COHb levels of approximately 25%, while 40% is the usual level for such symptoms (Herman, 1998). Putz *et al.* (1976) exposed 30 volunteers for 4 h to 5–70 ppm CO and found that 5% COHb (achieved following exposure to 70 ppm CO) impaired coordination, response time to light, and auditory acuity. However, exposure to CO during sleep, which increased COHb to 12.5, did not impair performance after awakening although it had some effect on sleep pattern (O'Donnell *et al.*, 1971).

Air pollution, which consists of particulate matter, CO, sulfur oxide, nitrogen oxide, hydrogen sulfide, acid gases like HF and HCl, volatile organic solvents, radiation, etc., is estimated to be responsible for 800,000 annual deaths worldwide (Cohen *et al.*, 2005); a review of the health effects of these pollutants found that respiratory and cardiovascular mortality was consistently associated with particulate matter and CO (Curtis *et al.*, 2006). A large study of the effect of air pollution on mortality was investigated in 19 European cities under the APHEA (Air Pollution and Health: A European Project) project. Samoli *et al.* (2007) found a significant association of CO both with total and cardiovascular mortality. However, because CO is not the only noxious air pollutant, such epidemiological studies fail to categorically establish a role of CO because it is also possible that CO toxicity is aided by the presence of other pollutants. Purser (1996) analyzed scenarios in the event of fire in aircraft which release a host of toxic gases including CO and concluded potentially serious consequences in terms of performance of the crew and the survival of passengers.

It is of interest that big cities like Mexico City and Los Angeles harbor not only high concentrations of CO in the air but also an excess of noise and there are both clinical and experimental data (Cary *et al.*, 1997; Fechter *et al.*, 1988) to show that noise increases the toxicity of CO as well as of other noxious chemicals.

Edmund Hillary and Sherpa Tenzing conquered Mount Everest on May 29, 1953; this sparked great enthusiasm about mountain climbing. However, at high altitudes the partial pressure of oxygen is low and even a small amount of CO can be fatal. For example, two healthy men died at a height of about 6,000 m in Alaska from exposure to CO generated just by a cooking stove in their tent (Foutch and Henrichs, 1988). Even a 5–10% increase in COHb can cause appreciable deterioration in flicker fusion frequency at high altitudes (Lilienthal and Fugit, 1945). Also, altitude exaggerates CO toxicity in subjects with coronary artery disease (McGrath, 2006).

Atmospheric CO is the main source of exposure to the population; for this reason WHO has set the following limits for CO exposure (IPCS, 1999):

100 mg/m^3 (87 ppm) for 15 min
60 mg/m^3 (52 ppm) for 30 min
60 mg/m^3 (26 ppm) for 60 min
10 mg/m^3 (9 ppm) for 8 h (the usual working period per day).

B. Delayed Toxicity

The delayed CO toxicity is also referred to as the interval form of toxicity (Mannaioni *et al.*, 2006) with significant effects on the central nervous system (Raub and Benignus, 2002). The interval form refers to neuropsychiatric symptoms within several days or even weeks after asymptomatic existence following recovery from unconsciousness caused by exposure to CO. The most common symptoms of the ''interval form'' of delayed CO toxicity are lethargy, behavior changes, forgetfulness, memory loss, and Parkinsonian symptoms (Yoshii *et al.*, 1998). These symptoms are attributed to diffuse demyelinization of cerebral white matter in specific regions of the brain (Hsiao *et al.*, 2004; Mannaioni *et al.*, 2006; Okeda et al., 1981; Yoshii, *et al.*, 1998). Neurological symptoms were found to accompany lesions in the brain as detected by magnetic resonance imaging in several other studies (Hsiao *et al.*, 2004; Parkinson *et al.*, 2002).

Daily exposure of dogs for 11 weeks to 100 ppm CO resulted in persistent ECG changes as early as 2 weeks and cardiac muscle degeneration at the end of the study; observed disturbances in gait and posture were attributed to lesions in the cerebral cortex (Hamilton and Hardy, 1974). Visual disturbances following recovery from a period of CO-induced unconsciousness have also been reported (Kelly and Sophocleus, 1978). Moderate to severe CO poisoning can shorten lifespan because of myocardial injury (Henry *et al.*, 2006).

A lack of close correlation between COHb levels and the severity of CO toxicity is well recognized (Mannaioni *et al.*, 2006); this clearly suggests the involvement of other factors. These other factors most probably include xanthine oxidase-derived reactive oxygen species, which are produced due to hyperperfusion following the initial hypoxia. This inference is supported by several animal studies (Sokal and Kralkowska, 1985; Thom, 1992; Zhang and Piantadosi, 1992).

CO and cyanide have certain similar toxicities, which are a consequence of hypoxia such as disruption of cochlear functions (Tawackoli *et al.*, 2001). CO has been found to cause hearing loss both in humans (Goto *et al.*, 1972; Makishima, 1977; Morris, 1969; Sato, 1966) and in animal

models (Douglas *et al.*, 1912; Fechter *et al.*, 1988; Liu and Fechter, 1995).

C. Cardiovascular Toxicity

CO can cause as well as exacerbate underlying cardiovascular diseases (Atkins and Baker, 1985; Thom and Kleim, 1989). CO seems to affect each step in the course of ischemic heart disease (Goldsmith and Aronow, 1975; Turino, 1981). CO has been found to exacerbate the atherogenic potential of cholesterol in monkeys (Webster *et al.*, 1970). Inhalation of CO during treadmill exercise in patients with coronary artery disease hastens the onset of anginal symptoms and causes a prolongation of ECG changes (Anderson *et al.*, 1973; Aronow and Cassidy, 1975). A number of deaths from myocardial infarction have been recorded at COHb levels much lower than the levels required to produce neurological effects (Atkins and Baker, 1985; Scharf *et al.*, 1974). The potential of CO to aggravate myocardial pathology is understandable since the disease is associated with relative decrease in oxygen supply to the myocardium; at any concentration CO can only further increase hypoxia as well as interfere with any compensatory mechanism. Given that cardiac disease is common in the developed world, which also has more than the usual level of CO in the atmosphere, important public health measures would be required to deal with this issue.

Anemia will exert a profound effect on CO saturation and its toxicity because most, if not all, of CO in the blood is bound to hemoglobin. This subject assumes special importance because anemia is quite common in the general population, particularly in slum dwellings in developing countries. Anemic subjects approach equilibrium levels of COHb more rapidly than those with normal hemoglobin at any level of exposure to CO. For example, a 4 h exposure of subjects with hemoglobin levels of 7 g/100 ml could attain COHb concentrations of 4–5% compared with an anticipated level of 2.5% for normal individuals; this fact coupled with greater production of endogenous CO would pose a greater threat of toxicity in anemic than in normal subjects (United Nations Environmental Program and WHO, 1979).

D. Maternal, Fetal, and Infant Toxicity of CO

Carbon monoxide crosses the placenta freely. Blockage of maternal and fetal hemoglobin by CO places the fetus at serious risk especially in the final weeks of gestation (Sheppard, 1983). Maternal and fetal hemoglobins are not identical. Fetal hemoglobin has a higher affinity for CO than the maternal hemoglobin. Almost 2 days are needed to achieve equilibrium in maternal and fetal hemoglobin and at equilibrium fetal COHb is slightly higher than the maternal COHb (Longo, 1970; Hill *et al.*, 1977).

Smoking is a well-recognized risk factor during pregnancy (Rogers, 2008). Norman and Halton (1990) analyzed 60 cases of exposure of pregnant women to CO and concluded that severe acute exposure to CO can lead to fetal deaths as well as anatomical malformation and functional alterations. Cigarette smoke has also been found to decrease fetal weight in rats (Carmines and Rajendran, 2008). Cigarette smoke contains 4,800 identified chemicals including CO, HCN, and of course nicotine; there is no difference in the toxicities of different brands of cigarettes (Hoffmann *et al.*, 2001). The well-established adverse effects of smoking on the fetus may be contributed by CO. While effects of chronic exposure to CO at levels that can be delivered by smoking CO have not been clearly documented, several animal studies and studies with embryos reviewed by Robkin (1997) suggest that the adverse effects of smoking on fetal development are due to factors other than CO.

CO poisoning of pregnant women can cause fetal death and malformation (Norman and Halton, 1990; Rogers, 2008). Several reports document that exposure to CO from ambient air pollution during pregnancy can decrease fetal weight and lead to preterm births (Gilboa *et al.*, 2005; Leem *et al.*, 2006; S. Liu *et al.*, 2007; Mannes *et al.*, 2005; Ritz *et al.*, 2002; Wilhelm and Ritz, 2005; Ziaei *et al.*, 2005). However, a large study conducted in 96 counties in the USA between 1999 and 2002 examined the effect of air pollution on pregnancy outcome; the study analyzed 3,538,495 births including 6,639 infant deaths and air composition of particulate pollutants >2.5 μm as well as CO, SO_2, and O_3; the study concluded that infant mortality was contributed by particulate matters and not by CO (Woodruff *et al.*, 2008).

In animal models, exposure to low levels of CO during pregnancy, which does not reveal obvious signs of fetal toxicity at birth, results in neurological and other abnormalities in later life (Annau and Fetcher, 1994; Benagiano *et al.*, 2005; Carratu *et al.*, 1997; Giustino *et al.*, 1999). The commonly encountered behavioral abnormalities in children could be due to prenatal exposure to low concentrations of CO; this possibility is very much real, and, if so, the prophylaxis is a monumental task and a major public health challenge since people have no choice but to breathe the air around them.

E. Tolerance to CO Toxicity

Hypoxia is the principal mechanism of CO toxicity. Hypoxia can also be produced by the low partial pressure of oxygen at high altitudes. The fact that people living at high altitudes do not exhibit signs of hypoxia implies adaptation to low oxygen pressure. It is thus no surprise that continuous exposure to CO also leads to adaptation (Killick, 1948). In one of the earliest studies on adaptation to CO, mice were exposed to successively higher concentrations of CO for 6–15 weeks; by the end CO concentration was nearly 3,000 ppm and COHb 60–70%; symptoms of this very high COHb were far less in the adapted than in the nonadapted mice (Killick, 1937); the underlying mechanism of this adaptation seems increased synthesis of hemoglobin (IPCS,

1999). These data have been confirmed by other researchers (Clark and Otis, 1952; Wilks *et al.*, 1959).

Adaptation to CO toxicity also seems to occur in humans. Doing experiments on herself, Killick (1940) found diminished symptoms and lower COHb on chronic exposure to CO than in the beginning, which is in accord with the data of Haldane and Priestley (1935). Adaptation to hypoxia is the reason why people living at high altitudes feel perfectly normal while a visitor from the plains may feel quite unwell. Indian and Pakistani soldiers are facing one another in Siachen of Kashmir, the highest place for any military confrontation in the world. Unless the soldiers are acclimatized before they go to Siachen, many develop fatal pulmonary edema; if they are acclimatized, the incidence of pulmonary toxicity is considerably reduced.

VII. PHYSIOLOGICAL ROLES OF CARBON MONOXIDE

The primitive earth atmosphere was composed of CO_2, CO, nitrogen, and water, and somehow radiation, heat, and sparks contributed to the generation of amino acid from these basic materials (Kobayashi *et al.*, 2002; Miyakawa *et al.*, 2002). If this is true, it should be possible to experimentally prove this; we are not aware whether this has been done. However, if it is true, nothing could be physiologically more important than CO, nitrogen, and H_2O.

Furchgott and Zawadzki (1980) made the seminal observation that vascular endothelium was essential for the vasorelaxant effect of acetylcholine; soon after, this vasorelaxant substance was identified as nitric oxide (Palmer *et al.*, 1987). It was subsequently found that NO increases guanylyl cyclase activity and cGMP and performs numerous physiological functions (Moncada *et al.*, 1991; Culotta and Koshland, 1992). The study of the physiological role of CO is relatively recent but it would not be surprising that in years to come CO may be on a par with NO. The excellent and extensive review of the physiological role of CO by Wu and Wang (2005) most certainly paints a rosy picture of CO; one can interpret the review to imply that the infamous CO is about to become a cure for many maladies.

NO and CO have several common properties; both are gases; both are putative neurotransmitters; both cause vasorelaxation; both increase cGMP; both inhibit platelet aggregation; both increase cGMP albeit from different pools; and both are synthesized endogenously although CO also had an exogenous source (Hartsfield, 2002; Snyder and Ferris, 2000). Being gases, neither CO nor NO directly depends upon plasma membrane transporter or channels for its entry into cells. Also, there exists a certain interdependence between CO and NO. NO augments HO-1 gene expression and consequently CO formation (Hartsfield, *et al.*, 1997); in its turn heme oxygenase can decrease NO synthesis (Maines, 1997). On the basis of data from our laboratory, we have proposed that *trans*-arachidonic acid increases the activity of heme oxygenase-2 leading to the generation of CO, which increases cGMP and thereby causes relaxation of cerebral microvasculature of rats as depicted in Figure 20.4 (Kooli *et al.*, 2008).

At the same time there are differences between CO and NO. For example, NO is an unstable gas and radical while CO is a stable gas and not a radical. CO binds only ferrous heme but NO binds to both ferrous and ferric hemoprotein (Hartsfield, 2002). The combination rate of NO with hemoglobin is faster and dissociation slower than that of CO (Sharma and Ranney, 1978) so that the affinity of NO for hemoglobin is ~1,500 times that of CO (Foresti and Motterlini, 1999). Formation of endogenous CO in a variety of tissues has been demonstrated (Marks *et al.*, 2002). Given the complexity of colocalization and activities of heme oxygenase and nitric oxide synthase, it has been speculated that ''CO and NO could function in a synergistic, compensatory, and/or counterregulatory way'' (Hartsfield, 2002).

The source of endogenous CO and NO and the enzymatic mechanisms in their synthesis differ (Hibbs *et al.*, 1987; Marletta *et al.*, 1988; Moncada *et al.*, 1991; Wu and Wang, 2005). There is no common mechanism of coordinating the release and activities of these two molecules; it is therefore difficult to conceptualize what would be the ultimate physiological effect of any interaction between the two molecules. Usually, if a substance has physiological effect, its excess or deficiency manifests in some physical disorder. While there is strong evidence that decreased formation of NO can affect blood pressure homeostasis, no condition has yet been identified which can be attributed to an excess or deficiency of endogenous CO. In contrast the toxic effects of exogenous CO are well characterized and there is no reason to assume that the source of this molecule makes fundamental difference in its pharmacology. In any case, this chapter focuses on CO toxicity. Putative physiological functions of endogenous CO have been extensively reviewed (Baringa, 1993; Choi and Otterbein, 2002;

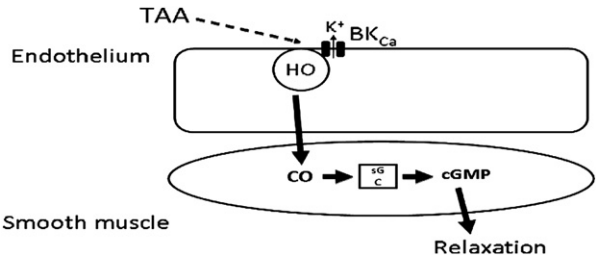

FIGURE 20.4. A model depicting the involvement of CO in mediating relaxation of brain pial microvessels of rats by trans-arachidonic acid (TAA). In this model TAA acts on calcium-dependent potassium cannels (BKca) leading to activation of hemeoxygenase-2 (HO-2), which releases carbon monoxide (CO). CO activates guanylyl cyclase (sGC) activity; the resulting increase in cGMP causes dilation of rat brain pial microvessels. Reproduced from Kooli *et al.* (2008) with permission from *Free Radical Biology & Medicine*.

Mannaioni and Vannacci, 2006; Marks *et al.*, 1991; Snyder and Ferris, 2000; Wu and Wang, 2005). A brief account of the postulated physiological roles of CO is presented below.

A. CO as a Putative Neurotransmitter

The colocalization of heme oxygenase-2 (HO-2), the enzyme responsible for the release of CO from COHb, and guanylyl cyclase in discrete brain areas lacking NOS coupled with changes in cGMP by agents and procedures that alter CO, has been advanced as evidence for a putative neurotransmitter role for CO (Verma *et al.*, 1993). However, these workers (Verma *et al.*, 1993) did not test whether or not changes in cGMP were associated with any changes in neuronal activity, nor did Baringa (1993) feel any need for such details in their commentary in the same issue of *Science*. In further support for neurotransmitter role for CO, Boehning *et al.* (2003) demonstrated that HO-2 is activated by phosphorylation of CK2 (casein kinase 2) during neuronal depolarization and that CK2 activation is essential during CO-mediated nonadrenergic noncholinergic relaxation of the smooth muscle. Also, a role of heme oxygenase and CO has been demonstrated in olfactory neurons in culture (Ingi and Ronnett, 1995; Ingi *et al.*, 1996), myenteric plexus (Zakhary *et al.*, 1996), and vas deferens (Burnett *et al.*, 1998).

The researchers cited above have provided strong evidence that CO is released during heme breakdown and that liberated CO can increase cGMP. However, according to the established criteria, a neurotransmitter, among other things, must transmit a message across a synapse; unless clear evidence is presented for an effect of CO on neuronal transmission, CO ought to be treated only as a putative but not a proven neurotransmitter.

B. Other Physiologic Effects of CO

Brune and Ullrich (1987) demonstrated that CO increases the activity of guanylyl cyclase like NO and inhibits platelet aggregation triggered by a variety of agents. CO was found to dilate coronary arteries and increase coronary blood flow in rats (McFaul and McGrath, 1987; McGrath and Smith, 1984); these researchers did not examine if this was associated with an increase in cGMP but they excluded involvement of an adrenergic system. Similar vasodilator effects of CO have been found on porcine coronary artery (Graser *et al.*, 1990), rabbit cerebral arteries (Brian *et al.*, 1994), rabbit aorta (Furchgott and Jothianandin, 1991), and rat aorta (Lin and McGrath, 1988). CO produces similar effects on cerebral blood flow; this subject has been reviewed by Koehler and Traystman (2002). CO has been shown to relax cerebral microvasculature (Leffler *et al.*, 1997) and pulmonary as well as systemic vessels (Villamor *et al.*, 2007) of newborn pigs. The vasorelaxant effect of CO is endothelium independent (Vedernikov *et al.*, 1989; Wang *et al.*, 1997) and exerted via K^+ channels (Graser *et al.*, 1990; Wang and Wu, 1997), in a manner similar to the oxidant OCl^- (Varma *et al.*, 2006), which is also endogenously produced (Weiss *et al.*, 1985, 1986). Also, CO can increase cerebral blood flow in rats (MacMillan, 1975), rabbits (Meyer-Witting *et al.*, 1991), and fetal sheep (Rosenberg *et al.*, 1986).

Heme oxygenase activation as well as CO induce the synthesis of vascular endothelial growth factor (Dulak *et al.*, 2002) but suppress its induction by hypoxia (Liu *et al.*, 1998). Heme oxygenase-1 plays a protective role against vasoconstriction and proliferation (Duckers *et al.*, 2001; Lee *et al.*, 1996; Sammut *et al.*, 1998), regulates vascular cGMP (Morita *et al.*, 1995), suppresses endothelial cell apoptosis (Brouard *et al.*, 2000), and activates mitogen-dependent protein kinase pathway (Otterbein *et al.*, 2000). Paradoxically, CO can prevent ischemic lung injury by suppressing fibrinolysis (Fujita *et al.*, 2001).

A number of studies have examined the anti-inflammatory activities of CO (Abraham *et al.*, 1988; Mannaioni *et al.*, 2006). An activation of the heme oxygenase system and exposure to CO *in vitro* (Chauveau *et al.*, 2005; Gibbons and Farrugia, 2004; Otterbein *et al.*, 1999, 2000; Pae *et al.*, 2004; Sethi *et al.*, 2002) and *in vivo* (Dolinay *et al*, 2004; Nakao *et al.*, 2003; Neto *et al.*, 2004; Otterbein *et al.*, 1999) revealed anti-inflammatory activity in animal models but not in humans (Mayr *et al.*, 2005). CO can inhibit apoptosis of endothelial cells (Soares *et al.*, 2002). There is some evidence that upregulation of HO-1 might be beneficial in inflammatory diseases (Willis *et al.*, 1996). In any case, the ability of CO to inhibit platelet aggregation and inflammation has important therapeutic implications and needs to be explored.

Liver is a site for cytochrome P450 synthesis as well as degradation of senescent erythrocytes and consequently catabolism of hemoglobin and heme oxygenase, which mediates the generation of endogenous CO. Since oxyhemoglobin can capture CO, it would reduce available CO, which could and has been shown to increase hepatic vascular resistance (Suematsu *et al.*, 2000). There is some evidence that endogenous CO formation in the hypothalamus might modify hypothalmo-pituitary-adrenal axis (Mancuso *et al.*, 1997).

In conclusion, there is definite evidence that endogenously produced CO exerts biological effects. If these are important physiological effects, one can assume that a deficiency in endogenous CO generation might manifest as a disease state or worsen existing diseases. Vascular NO is thought to be of relevance in maintaining vascular tone and its deficiency can cause hypertension or platelet aggregation. Diseases caused by a deficiency of hormones or neurotransmitters are ameliorated by substitution therapy. There is no reason to think that exogenous CO cannot substitute for a deficiency of endogenous CO. For example, endogenous CO deficiency increases acid-dependent bile flow; this can be corrected by exogenous CO (Shinoda *et al.*, 1998; Suematsu *et al.*, 2000). A lower

incidence of Parkinson's disease among smokers than in nonsmokers is attributed to nicotine in cigarettes (Quick, 2004). Fortunately, the beneficial effects of nicotine in cigarettes have not led to promoting smoking. Hopefully, any useful role for CO would also not lead to promoting the therapeutic value of cigarettes, which is a rich source of CO.

VIII. TREATMENT OF CARBON MONOXIDE OVERDOSE

A. Oxygen

When Humphrey Bogart rescued Audrey Hepburn from a garage where she had turned on the ignition keys of several cars in the film *Sabrina*, she knew that exhaust fumes could kill and he knew that fresh air could save life. The treatment of CO intoxication by oxygen was elaborated by Haldane (Haldane, 1895a, 1922; Haldane and Priestley, 1935). Perhaps the general public is aware of this therapy.

It was implicit in Haldane's studies that oxygen at high pressure would be more effective than at atmospheric pressure. However, there was a reluctance to resort to this practice because of the fear of oxygen toxicity. End and Long (1942) successfully demonstrated the value of oxygen at high pressure to treat CO overdose in laboratory animals. To our knowledge the first controlled study on the value of hyperbaric oxygen against CO poisoning was done by Pace *et al.* (1950) on ten human volunteers, five men and five women; data of these workers show that changing ambient pO_2 from 0.2 to 2.5 atmospheric pressure absolute increased the rate constant (k) of elimination of CO from 0.0028 to 0.0315 min, which would alter the half-life of CO elimination from 246 to 21 min.

B. Other Therapeutic Measures

CO poisoning leads to several abnormalities such as generation of oxidants, lipid peroxidation, disturbance in glucose metabolism, and so on, which compound the toxic effect of CO caused by hypoxia; measures other than oxygen are intended to deal with these secondary changes.

1. Allopurinol and *N*-Acetylcysteine

There is strong evidence that some of the toxic effects of CO poisoning are produced by release of reactive oxygen metabolites and xanthine oxidase plays a major role in these processes (Sokal and Kralkowska, 1985; Thom, 1992; Zhang and Piantadosi, 1992). Xanthine oxidase is a nicotinamide adenine dinucleotide (NAD)-dependent dehydrogenase, which is converted to oxidase under ischemic conditions utilizing molecular oxygen in place of NAD and in the process generates superoxide radicals and hydrogen peroxide. Allopurinol is a xanthine oxidase inhibitor and *N*-acetylcysteine is a sulfhydryl donor. The efficacy of these agents against neuronal injury caused by CO has been documented (Thom, 1992; Howard *et al.*, 1987).

2. Insulin

Hyperglycemia, which follows stroke or myocardial infarction, worsens the resulting neurological insult. Acute CO poisoning is also characterized by hyperglycemia, which has been found to worsen brain dysfunction in rats (Penny *et al.*, 1990). Similar observations have also been made in CO-poisoned patients (Pulsinelli *et al.*, 1980). Moreover, neurological complications of CO poisoning in diabetic patients seem worse than in healthy individuals. There is evidence that insulin treatment is effective in reducing neuronal damage caused by stroke or cardiac arrest, and similar encouraging results have been found after CO poisoning in humans (White and Penny, 1994).

3. Other Measures

Due to the role of excitatory amino acids in ischemic neurodegeneration, Ishimura *et al.* (1991) studied the effect of several agents including NMDA receptor antagonists against CO poisoning in mice with encouraging results. We are not aware of any clinical studies on the efficacy of NMDA receptor antagonists in reducing neurological toxicity in humans after CO poisoning. Cerebrolysin, produced by enzymatic breakdown of lipid-free proteins of porcine brain, have been found to offer protection against certain neurological changes after CO poisoning in animal models. Hypothermia has also been found of benefit in CO poisoning (Peirce *et al.*, 1972).

IX. CONCLUDING REMARKS AND FUTURE DIRECTION

We have attempted to deal with most though not all aspects of the pharmacology, toxicology, and physiology of carbon monoxide. The literature on CO is immense and dates back to 1857 or even earlier. The omnipresence of this colorless, odorless, tasteless, and nonirritating gas, generated by incomplete combustion and ever present in megacities, has traveled a long way from being a leading cause of unintentional death and an agent of choice for suicide to finding a physiological role as big as a neurotransmitter like nitric oxide.

Many currently used drugs like acetyl salicylic acid, digitalis, nitrates, and quinine have existed for a long time, and so have many poisons like cyanide and neurotoxins. However, their mechanism of action was not known until the middle of 20th century or even later. CO is unique. The details of its mechanism of toxicity were published by Haldane as early as 1895 and subsequent work has only elaborated these details while affirming its correctness. The generation of COHb is the principal cause of CO toxicity; however, it is not the only one. Much research has been done to elaborate these additional mechanisms of CO

toxicity but we have not discussed them in detail, just as we have not gone into detail about the physiological role of endogenous CO as one of the many warfare chemicals.

If detected in time, CO poisoning can be treated with hyperbaric oxygen plus other supplementary measures. However, safeguarding against chronic toxicity, if it results from chronic exposure to low levels of CO, is a difficult challenge. Many megacities are highly polluted with CO. Burning petroleum in automobiles as the chief source of CO in the modern world would most probability increase rather than decrease atmospheric CO, ozone, nitrogen, and hydrogen sulfide, etc.; this poses one of the great challenges of modern times to public health care. It is the responsibility of the environmental toxicologists, other scientists, and a socially conscious population to do whatever they can to ensure that measures are taken to protect the citizenry from hazardous chemicals in the air we breathe.

Acknowledgments

We thank Ms Emily Gibson for compiling and checking references. This article is dedicated to the memory of Professor John Sanderson Haldane, FRS (1861–1936), who conducted experiments on himself with poisonous carbon monoxide to save the life of miners, and whose laws on the exchange of gases remain valid even today.

CHAPTER 21

Methyl Isocyanate: The Bhopal Gas

DAYA R. VARMA AND SHREE MULAY

I. INTRODUCTION

Methyl isocyanate (MIC) is the smallest member of the isocyanate family and the most reactive and toxic of all. MIC was almost unheard of until the fateful night December 3, 1984, when nearly 30 metric tons of this poisonous chemical spewed out of the Union Carbide India Ltd (UCIL) pesticide plant within a period of 45–60 min (Jayaraman, 1984). Bhopal turned into a ''city of death'', wrote the fortnightly *India Today* (December 30, 1984). The journal *Nature* (Opinion, 1984) vented its anger thus: ''… the anguish vividly carried round the world by the television cameras seems not to have matured into the anger, even hysteria, there would have been had the [Bhopal] accident occurred on the edge of a European city – or in Connecticut'' (the headquarters of Union Carbide was in Danbury, Connecticut, USA).

There was only one scientific report on MIC toxicity (Kimmerle and Eben, 1964) until the Bhopal disaster; this led *Lancet* (Editorial, 1984) to comment: ''In a year's time we will have learnt a lot more about methyl isocyanate – at an appalling price.'' As is to be expected, the Bhopal disaster evoked immense interest among journalists, scientists, the corporate world, lawyers, social activists, and the Indian government. A discussion of the toxicology of MIC necessitates a narrative of different events specific to the Bhopal disaster. However, this chapter mainly focuses on four aspects. One, why did MIC escape in such huge amounts and can this reoccur at other places where MIC is manufactured and stored? Two, what are the physicochemical characteristics of MIC that make it the most toxic of all isocyanates and deadlier than cyanide? Three, what is the toxicity profile of MIC? Four, what was done and not done to deal with the tragedy? Other aspects such as social cost, legal implications, and issues of rehabilitation (Budiansky, 1985; Dhara and Dhara, 1995; Varma, 1986) are equally important; however, these aspects are not being discussed.

II. BACKGROUND

At the time of the disaster the population of Bhopal was approximately 800,000; more than one-quarter of the population was exposed to toxic gases. The toxicity of a chemical, barely tested in animal models, was suddenly being observed on unsuspecting thousands of children, women, and men. The magnitude of the disaster was so enormous that some called it the Nagasaki and Hiroshima of peace time. ''This may be how the world will end – not with a bang but with an ecological whimper'', wrote Abu Abraham in the *Sunday Observer*, Bombay, December 23, 1984. ''India's disaster – The night of death'' was displayed on the front cover of the *Time* magazine (December 17, 1984, New York). *Nature* (Opinion, 1984) expressed its dismay at the lack of international concern for this tragedy. *Chemical and Engineering News* (1985) published a special issue ''Bhopal the continuing story''. A British medical student, who had arrived just one day earlier in Bhopal to start her elective, had this to say (Sutcliffe, 1985): ''The dead and dying arrived by the truckload, others came by rickshaw or were carried by relatives. For some the effort of the journey itself proved too much, and they died soon after arrival.''

Bhopal is known as the city of the world's worst industrial disaster. That might be why the 20th anniversary of the Bhopal episode in 2004 was covered by news media all over the world. Commentaries appeared in *Nature Medicine* (Padma, 2005), *Science* (Crabb, 2004), *The Lancet* (Sharma, 2005) and other journals. By this time the story of MIC and Bhopal had been the subject of several books and monographs (Eckerman, 2005; Everest, 1985; Lapierre and Moro, 2001; Morehouse and Subramaniam, 1986; Sinha, 2007; Sufrin, 1985) and reviews (Bucher, 1987; Dhara and Dhara, 1995, 2002; Dhara *et al.*, 2002; Dhara and Gassert, 2002; Dhara and Kriebel, 1993; ICMR, 1985, 1986, 2004; Lepkowski, 1985; Marwick, 1985; Mehta *et al.*, 1990; Sriramachari, 2004; Sriramachari and Chandra, 1997; Varma, 1986; Varma and Guest, 1993; Varma and Varma, 2005; Varma and Mulay, 2006).

Given the social dimensions of the tragedy, a documentary ''Bhopal beyond genocide'', directed by Tapan Bose and Suhasini Mulay, was produced in 1986 by Cinemart Foundation, New Delhi. ''Bhopal: The Search for Justice'', directed by Peter Raymond and Lindalee Tracey, was produced by White Pine Pictures and the National Film Board of Canada in 2004. The play ''Bhopal'' by Rahul Varma was staged in Canada and its Hindi version titled ''Zahrili Hawa (poisonous gas)'' was staged in Indian cities under the direction of the renowned theater personality, Habib Tanweer.

Soon after the Bhopal accident, the government of India intervened in two important areas; first, it assumed all rights for negotiations about the liability of the Union Carbide Corporation and subsequently with its new owners Dow Chemical Corporation and, second, assured an investigation into the causes of the disaster as well as a comprehensive study of the acute and long-term effects of exposure of the Bhopal population to MIC or other gases. While the details of the negotiations are not integral to this chapter, the promised toxicological studies were scarcely done. Although the Indian Council of Medical Research (ICMR) released approximately $2 million for research on MIC toxicity, there is no indication that scientists were assigned to undertake a systematic study of different areas to unravel the complete picture of MIC toxicity.

As time passed, three important developments made the study of MIC toxicology problematic. First, there has been a significant movement of the population, which usually is not a characteristic of Indian cities. For example, out of 317 children identified in 1985 to have been exposed to the gas *in utero*, fewer than 100 could be traced 20 years later. Second, there is evidence of contamination of groundwater, which makes it difficult to distinguish between effects due to exposure to toxic gases and those due to ingestion of groundwater toxins. Third, people in Bhopal are looking for relief from their suffering and are not keen on being subjects of a researcher's inquisitiveness; therefore honest scientific inquiry necessitates a rapport with the population, which the government-commissioned scientists have not been able to establish.

III. THE MAKING OF A DISASTER

The specific details of how MIC escaped from Tank E-610 at the UCIL plant in Bhopal have been described in detail elsewhere (Varadarajan *et al.*, 1985; Varma, 1986; Varma and Varma, 2005). It is highly unlikely that an accident will repeat itself in exactly the same way it did in Bhopal on December 2–3, 1984. On the other hand, a brief description of the Bhopal episode is relevant to speculate how such accidents can occur and what needs be done to ensure that they do not happen elsewhere.

In the case of Bhopal, water entered into pipes on the floor of the factory during routine cleaning but safety slips had not been placed at the joints. Water reached Tank E-610. The exothermic reaction between water and MIC increased the temperature of the tank converting liquid MIC into gas. The increase in pressure forced open the vent valve letting most of the MIC escape to the outside as gas. Various safety measures to neutralize MIC, such as caustic soda scrubbers, were not functional or unserviceable. Even if safety measures had been in perfect workig order, they could not have handled such a big leak. Fortunately, MIC stored in the other two tanks (E-611 and E-619) was not affected; it was later converted to pesticide in what was termed ''Operation Faith'' during December 16–22, 1984. The disaster had frightened the people of Bhopal to such an extent that despite all assurances by the Indian government, almost one-half of the population left the town, some with their entire belongings, during this exercise.

An examination of the causes of the Bhopal disaster clearly indicates that the accident would not have occurred if all necessary precautions had been taken in the maintenance and operation of the Union Carbide Pesticide Plant. This required continued and apt maintenance, regular inspection by independent authorities, sufficiently well-trained staff, and location of the plant far away from residential areas and not just within 1 km of the railway station and within 3 km of two major hospitals, as was the case in Bhopal.

Around the time of the Bhopal disaster, MIC was used in the USA (West Virginia), Germany, and Japan; at none of these places was MIC stored in large quantities. One can assume that other cautionary measures were followed more rigorously in these places than in Bhopal, suggesting that developing countries with very poor regulatory processes require more stringent safety measures than in developed countries.

Whether or not the operation of hazardous industries can be both safe and profitable is debatable. What is not debatable is that safety must remain the top consideration. There is a strong case to demand state control of hazardous corporate operations (Varma and Varma, 2005) and global monitoring of potentially toxic materials (Baxter, 1986; Sriramachari and Chandra, 1997). Following the cyclohexane explosion in Flixborough in 1974, an Advisory Committee on Major Hazards was set up in the UK. The European Economic Council Directive (1982) was triggered by the Seveso accident of 1976 in Italy. However, the Bhopal disaster of 1984 was far worse than the Flixborough or Seveso accidents or for that matter any other in history which has not led to additional regulations outlining corporate and state responsibilities. MIC is dangerous and is to be treated on a par with nuclear establishments, requiring the utmost care in maintenance.

IV. TOXICOKINETICS OF ISOCYANATES

MIC is a member of the isocyanate family of chemicals. The high chemical reactivity of isocyanates is central to their toxicity as well as commercial uses. No clinical use of isocyanates has so far been demonstrated. In view of these considerations, this section will elaborate in some detail the relationship between the structure of MIC and other isocyanates, and between their physicochemical properties and toxicities.

A. Chemistry of Isocyanates

Organic isocyanates were first synthesized in 1849. Isocyanates (Table 21.1) are highly reactive heterocumulene

TABLE 21.1. Commonly used isocyanates

Isocyanates	MW	LC_{50} ppm[a]	Ceiling ppm[b]
Methyl isocyanate (MIC)	57	5.1	0.02
Hexamethylene diisocyanate (HDI)	168	55.9	0.02
Toluene diisocyanate (TDI)	174	49.0	0.02
Isophorone diisocyanate (IPDI)	222	28.5	0.02
Diphenylmethane diisocyanate (MDI)	250	36.0	0.02
Dicyclohexylmethane diisocyanate (SMDI)	262	–	0.01
1,5-Naphthalene diisocyanate (NDI)	210	–	0.02

[a] LC_{50} (lethal concentration killing 50 experimental animals) values are after 4 h exposure

[b] To convert ppm to mg/m^3, divide it by (24.4/MW); see review by Varma (1986)

chemicals. The general structure of isocyanates is R–N=C=O which is distinct from cyanate N≡C–O–H. The reactivity of organic isocyanates is due to the strain in the cumulative double bonds (–N=C=O) of isocyanates (D'Silva *et al.*, 1986; Varadarajan *et al.*, 1985; Westcott, 1985).

Most of the commercially used isocyanates are diisocyanates and R is an aromatic ring. MIC is an exception; its structure is H_3C–N=C=O. The physicochemical properties of MIC differ from those of other isocyanates (Lowe, 1970; Tse and Pesce, 1978; Westcott, 1985; Worthy, 1985). Because of high chemical reactivity of MIC with alcohols, it serves as an intermediate in the production of the pesticide carbaryl. Diisocyanates are primarily used for the manufacture of polyurethanes.

1. Synthesis of MIC

MIC (CH_3N=C=O) can be synthesized using different reactions. The commercial synthesis of MIC by the Union Carbide Corporation, Bayer, and Dupont is described below:

At Union Carbide Corporation, Bhopal, India:

$$CH_3NH_2 \text{ (monomethyl amine)} + COCl_2 \text{ (phosgene)} \rightarrow CH_3NCO + 2HCl$$

At Bayer, Germany:

$$CH_3NH\text{–}CO\text{–}NHCH_3 \text{ (dimethyl urea)} + (C_6H_5O)_2CO \text{ (diphenyl carbamate)} \rightarrow CH_3NCO + \text{byproducts}$$

At Dupont, USA:

$$CH_3\text{–}NH\text{–}CHO \text{ (methyl formamide)} + O_2 \rightarrow CH3NCO + H_2O$$

MIC was produced and stored in Bhopal. Other chemicals used for the production of carbaryl, such as chlorine, methylamine, caustic lye, and chloroform, were brought to Bhopal and stored in tanks. CO and phosgene were not stored but produced and utilized.

Various steps in the production of carbamate pesticide at Bhopal were (Varadarajan *et al.*, 1985):

1. Petroleum coke (2C) was reacted with oxygen to produce 2CO.
2. CO and chlorine were reacted to produce phosgene $(COCl_2)$–.
3. Phosgene and methylamine (CH_3NH_2) were reacted to form methylcarbamoyl chloride ($CH_3NHCOCl$) plus HCl.
4. Methylcarbamoyl was then pyrolyzed to yield methyl isocyanate (CH_3NCO) and HCl.
5. Finally, MIC was reacted with a slight excess of α-naphthol in the presence of a catalyst in carbon tetrachloride solvent to produce the desired pesticide carbaryl.

In the system used in Bhopal, the stored liquid MIC was transferred through pipes to one metric ton charged pots under nitrogen pressure of 16 psi. These charged pots were connected to two reactors where MIC and α-naphthol reacted to produce carbaryl (see below). The charging of α-naphthol was done by dissolving it in carbon tetrachloride at approximately 50°C in the presence of a catalyst trimethylamine. The reaction between MIC and α-naphthol is exothermic. The temperature was maintained at 70°C for efficient production of carbaryl.

$$CH_3N{=}C{=}O + \alpha\text{-Naphthol} \rightarrow 1\text{-Naphthyl-}N\text{-methyl carbamate (carbaryl)}$$

The alternate route of production of carbaryl involves reaction of α-naphthol with phosgene to generate α-naphthol chloroformate which upon reaction with methylamine leads to the formation of carbaryl.

2. Physicochemical Reactions with MIC

MIC can interact with a large number of molecules as well as with itself. Indeed, 21 identified (Varadarajan *et al.*, 1985) and almost ten unidentified chemicals (Sriramachari, 2004) were detected in the culprit MIC Tank E-610. An MIC trimer as well as other metabolites of MIC such as dimethyl isocyanurate and 2,4-dione of methyl isocyanate were identified in autopsy samples from Bhopal victims (Chandra *et al.*, 1991, 1994; Saraf *et al.*, 1995). Reaction of MIC with water is important because this will occur whenever MIC comes into contact with a body or environment, as happened in Bhopal. It is important to note that while excess water can neutralize MIC, a small quantity of water is sufficient to generate heat during the reaction, which would lead to vaporization of MIC, as actually happened in Bhopal. Some important interactions of MIC are enumerated below:

1. Polymerization (self-addition of many MIC molecules).
2. Trimerization:

$$3(CH_3N{=}C{=}O) \rightarrow \text{Trimethyl isocyanurate}$$

3. Dimerization is common with aromatic isocyanates but is rare with aliphatic isocyanates like MIC.
4. Additive reactions with molecules containing reactive hydrogen species, which migrate to the nitrogen of MIC.
5. General reaction of MIC with molecules containing hydroxylic groups:

$$CH_3N{=}C{=}O + ROH \rightarrow CH_3NHCOOR \ (\text{urethane})$$

6. Reactions with water:

$$CH_3NCO + H_2O \rightarrow CH_3NH_2 \ (\text{MMA}) + CO_2$$

$$2(CH_3NCO) + H_2O \ (\text{excess}) \rightarrow CH_3NHCONHCH_3 \ (\text{DMU}) + CO_2$$

$$3(CH_3NCO) \text{ in excess} + H_2O \rightarrow CH_3NHCON\ (CH_3)\ CONHCH_3\ (\text{TMB}) + CO_2$$

$$4(CH_3NCO) + H_2O \rightarrow \text{DMI} + (CH_3)2NH\ (\text{DMA}) + CO_2$$

7. Reaction with DMA:

$$CH_3NCO + \text{DMA} \rightarrow (CH_3)2N{-}CO{-}NH{-}CH_3\,(\text{TMU})$$

8. Reaction with alcohols and phenols (used by Union Carbide Corporation, India, to produce carbaryl pesticide):

$$CH_3NCO + \alpha\text{-Naphthol} \rightarrow \text{1-Naphthyl-}N\text{-methyl carbamate (carbaryl)}$$

9. Reaction with primary and secondary amines:

$$CH_3NCO + R{-}NH_2 \rightarrow CH_3{-}NH{-}CO{-}NH{-}R$$

10. Reaction with nitrates and nitrites: the reaction of MIC with nitrates and nitrites, which are normally present in water, can yield carcinogenic nitrosamines.
11. Decomposition into hydrogen cyanide (HCN): when MIC pyrolyzes into the gaseous phase in the range 427–548°C at 55–300 torr, the major decomposition product is HCN (Blake and Ijadi-Maghsoodi, 1982). This reaction is of relevance in view of the conjecture that the culprit gas in Bhopal was HCN. However, MIC does not degrade to HCN at low temperatures and pressures. The temperature in Tank 610 was estimated to have reached approximately 200°C, far below that required for conversion of MIC into HCN.
12. Reaction with HCN at normal temperatures leading to the formation of other cyanides (Slotta and Tschesche, 1927).
13. Reactions with body constituents.

In general, interactions between isocyanates and endogenous molecules are reversible (Axness and Fleeker, 1979; Gibson and Hickman, 1982; Newman and Farquhar, 1987; Tse and Pesce, 1978; Twu and Wold, 1973). MIC has been shown to cause greater interaction with macromolecules than aryl isocyanates because of the slower hydrolysis of the former than of the latter in biological medium (Brown *et al.*, 1987); indeed, this has been suggested to be the cause of sensory and pulmonary irritation with MIC and not with toluene diisocyanate (Ferguson *et al.*, 1986). Reversible conjugation of isocyanates with glutathione (Pearson *et al.*, 1990; Slatter *et al.*, 1991), which occurs both spontaneously and enzymatically (Brusewitz *et al*, 1977; Mennicke *et al.*, 1983), may have been the mechanism of distributing MIC molecules to different parts of the body and for its diffuse toxicity profile (Baillie and Slatter, 1991; Bruggeman *et al.*, 1986; Pearson *et al.*, 1991).

Kinetic analysis of hydrolysis revealed a half-life of 2 min for MIC in aqueous solution, which is much slower than that for aryl isocyanates (Brown *et al.*, 1987). Interaction of isocyanates with cholinesterases is reversible and MIC is far less potent than aryl isocyanates in this respect (Brown *et al.*, 1987). At the same time MIC can act as a hapten leading to generation of antibodies in both animals and humans, although it results in low titers (Karol and Kamat, 1988; Karol *et al.*, 1987).

A reactive *S*-(*N*-methylcarbamoyl) glutathione (SMG) has also been isolated from the bile of rats administered methyl isocyanate (Pearson *et al.*, 1990, 1991); the corresponding mercapturic acid has been isolated from the urine (Slatter *et al.*, 1991). Since MIC-SMG conjugate is reversible, it is likely that it serves as a method of transport of MIC to different organs. MIC can carbamylate macromolecules (Bhattacharya *et al.*, 1988; Ramachandran *et al.*, 1988; Segal *et al.*, 1989; Sriramachari *et al.*, 1991). MIC has been shown to be an effective anti-sickling agent *in vitro*, combining with α-amino groups of hemoglobin and thus increasing its oxygen binding affinity (Lee, 1976).

3. Quantification of MIC

The method of collection of MIC samples in the workplace, and under controlled experimental conditions, differs because its concentrations are in the range of parts per billion (ppb) in the former case and several orders of magnitude higher in the latter case.

The methods of sampling MIC in air at the workplace are mainly by pumped sampling in combination with impingers, reagent-coated or impregnated with sorbent tubes for collection of the analytes. The isocyanate thus collected is reacted with an amino-based reagent such as 1-(2-methoxyphenyl) piperazine (2MP) or other similar substances. Details of sampling and measurement of MIC are described in detail by others elsewhere (Henneken *et al.*, 2003; Von Zweibergk *et al.*, 2002). Sampling under controlled experimental conditions can be done using gas-tight syringes.

Several techniques have been used for the quantitative analysis of MIC. Kimmerle and Eben (1964) used the spectrophotometric method at 352–353 nm. Most studies following the Bhopal disaster used GC-MS equipped with appropriate detectors, while Adkins *et al.* (1987) used infrared spectroscopy between 3.3 and 3.6 nm. The method employed in Alarie's lab (Ferguson *et al.*, 1986) and by us (Varma *et al.*, 1987, 1988, 1990) used a Perkin-Elmer Model 3920 gas chromatograph equipped with a nitrogen–phosphorus detector; the column used for the chromatographic analysis of MIC was made of glass, packed with 3% OV-210 on Chromosorb WHP (SO/l00 mesh), run isothermally at 60°C, and permitted on-column injection of samples. Helium was passed through the column at 20 ml/min (inlet pressure: 60 psi). The injector and interface temperatures were both set at 200°C. Air and hydrogen passed into the nitrogen–phosphorus detector at 30 and 1 to 3 ml/min, respectively. An MIC calibration curve was prepared by injecting known volumes of pure MIC gas into glass vessels of 1,000 ml thus producing MIC of different dilutions. These vessels contained glass beads for mixing and were equipped with Teflon-coated septa, enabling the withdrawal of desired volumes for subsequent injection onto the chromatography column by gas-tight (Unimetrics) syringes. The absolute retention time for MIC under these conditions was approximately 1 min and sensitivity of the method was 0.8 ng MIC. Following calibration, samples were withdrawn from the animal exposure chamber with the same syringes. Samples were taken approximately every 3–5 min during the exposure period and the mean concentration was determined for each exposure. Coefficients of variation for each mean were under 20%, indicating low variation between samples analyzed during exposure.

V. MECHANISM OF ACTION

Physicochemical properties of MIC relevant to its toxicity are presented in Table 21.2. MIC exerts a wide spectrum of toxic effects, including sensory and pulmonary irritation (Alarie *et al.*, 1987; Ferguson *et al.*, 1986; Kamat *et al.*, 1985, 1992; Kimmerle and Eben, 1964), reproductive toxicity (Varma, 1987), ocular toxicity (Andersson *et al.*, 1984; Salmon *et al.*, 1985) and neurological toxicity (Bharucha and Bharucha, 1987; Sethi *et al.*, 1987). There is some evidence indicating teratogenic and carcinogenic effects of MIC (Goswami, 1986; Saxena *et al.*, 1988; Ghosh *et al.*, 1990; Dikshit and Kanhere, 1999). However, unlike the toxicity of pesticides or cyanide, which can be clearly attributed to inhibition of cholinesterase (Taylor, 1980) or cytochrome oxidase (Goldstein *et al.*, 1968), respectively, specific biochemical mechanisms, which can explain these diverse toxic effects of MIC, have so far not been identified. The paucity of data on MIC toxicity at the time of the Bhopal disaster was because of a lack of systematic study of the clinical toxicity of MIC and the incompleteness of documents of Union Carbide (1978).

TABLE 21.2. Physicochemical properties of methyl isocyanate (MIC) and toluene diisocyanate (TDI)

Properties	MIC	TDI
Appearance	Colorless liquid	Colorless to yellow liquid
Flammability	Flammable	Not flammable
Specific gravity (water = 1) at 20°C	0.96	1.22
Boiling point (°C)	39.1	251
Autoignition temperature (°C)	535	–
Vapor density (air = 1)	1.97	6.0
Vapor pressure at 20°C (mbar)	464	0.06
Weight (mg/m^3) = 1 ppm	2.5	7.12

The immediate effect of exposure to MIC in Bhopal was lacrimation, choking sensation, and difficulty in breathing followed in many cases by death. There was a lag period of 4–6 h between exposure to MIC and death in Bhopal (Varma, 1986). Delayed death was also observed in experimental animals (Varma *et al.*, 1988; Dodd *et al.*, 1986, 1987; Fowler *et al.*, 1987a; Bucher *et al.*, 1987a, b; Boorman *et al.*, 1987; Stevens *et al.*, 1987; Fowler and Dodd, 1987a, b; Alarie *et al.*, 1987). It would thus appear that the lethal effects of MIC were caused by pulmonary complications; these complications could be attributed to pulmonary irritation, which could ultimately lead to fluid exudation and pulmonary edema (Alarie *et al.*, 1987), tissue hypoxia (Fowler *et al.*, 1987b), or acidosis (Fedde *et al.*, 1987). Hypoxia does not seem to result from inhibition of oxygen utilization as is the case with cyanide (Alarie *et al.*, 1987). There is some evidence that at high concentrations MIC can reversibly inhibit cholinesterase (Brown *et al.*, 1987; Troup *et al.*, 1987); this could cause pulmonary edema. However, other characteristic signs of excess acetylcholine such as papillary constriction or skeletal muscle paralysis were not reported in Bhopal victims.

1. There are reports of biphasic death in Bhopal. The first phase – within 2 days of exposure – was followed by a second phase of deaths during subsequent months and years (Varma, 1986; Varma and Guest, 1993; Varma and Mulay, 2006). Interestingly, the pattern of death in experimental animals (rats, mice, and guinea pigs) following exposure to MIC was similar to that observed in Bhopal; even excessively high concentrations (3,506 ppm for 15 min) of MIC were not lethal to rats within 10 min but 1,000 ppm killed 69% of animals between 4 and 6 h (Dodd *et al.*, 1987). Qualitatively

similar data have been reported by others at MIC concentrations that could have been achieved in Bhopal (Bucher *et al.*, 1987b; Varma *et al.*, 1988; Ferguson and Alarie, 1991). Exposures to MIC have consistently led to a significant decline in body weight within 24–48 h (Dodd *et al.*, 1986; Bucher *et al.*, 1987b; Varma, 1987; Varma *et al.*, 1988), suggesting significant loss of body fluid. Overall, both clinical observations in Bhopal and experimental data suggest that initial deaths were caused by hypoxemia resulting from pulmonary edema plus alveolar obstruction, and delayed deaths were the result of pulmonary complications.

2. It is possible that high chemical reactivity of MIC leads to its interaction with and disorganization of tissue macromolecules; this could also explain numerous other biological effects of MIC. There is evidence that MIC can deplete key components, which can contribute to death (Kolb *et al.*, 1987).

In the experiments conducted by Kimmerle and Eben (1964), human volunteers were exposed to unadulterated MIC; the symptoms observed in these volunteers are identical to those noted in Bhopal, albeit far less severe because as the concentration of MIC was increased to 21 ppm, volunteers could not tolerate it even for seconds. We are not aware of any studies examining whether MIC and HCN toxicities are additive or synergistic; on purely theoretical grounds at least an additive effect can be predicted.

In summary, while MIC can cause specific effects, its overall toxicity seems to result from its ability to physically damage any cell or organ it comes in contact with and the ultimate effects, including death, are secondary to the physical insult inflicted by MIC.

VI. THE CYANIDE CONTROVERSY: MIC OR HCN?

There was strong contention that the lethal as well as persistent maladies in Bhopal were caused by hydrogen cyanide and not MIC. Even though the proponents of the cyanide theory do not say so, their thesis does imply that MIC by itself is neither lethal nor capable of exerting long-term effects. Nothing could be further from truth. The mechanism of toxicities of MIC and HCN differ in another important way. Because the toxicity of HCN depends upon interaction with ferric ion, conversion of ferrous to ferric form in the hemoglobin by nitrites or supplying molecules with greater affinity for the CN^- ion than provided by F^{3+} such as by thiosulfate acts as an antidote against cyanide. Neither sodium nitrite nor sodium thiosulfate was found to reduce the toxicity of MIC (Bucher *et al.*, 1987a; Varma *et al.*, 1988) nor did exposure to MIC cause any decrease in oxygen utilization (Alarie *et al.*, 1987).

The lethal effects of MIC were due to hypoxemia primarily because of pulmonary effects. HCN also causes death by hypoxemia by a well-known mechanism and the brain is the most susceptible organ. In this sense there is a superficial similarity between MIC- and HCN-induced fatalities. Indeed deaths due to many toxins and disease states result from pulmonary failure. However, data taken together with extensive information in literature (Ballantyne and Marrs, 1987; Curry, 1963; Goldstein *et al.*, 1968; Way, 1984) strongly contradict the HCN hypothesis (Varma, 1989).

At a temperature range of 427–548°C and a pressure range of 55–300 torr, MIC has been shown to decompose into HCN (Blake and Ijadi-Maghsoodi, 1982). However, the temperature inside the culprit MIC-containing tank was estimated to be only 250°C (Varadarajan *et al.*, 1985) at which temperature MIC does not degrade into HCN. There is evidence that MIC can combine with HCN even at low temperatures (Slotta and Tschesche, 1927); however, this reaction can only reduce toxicities of both HCN and MIC and not make more ''lethal cyanogens'' as speculated by Sriramachari (2004) because the toxic potency of cyanides depends upon the dissociation of the –CN ion (Goldstein *et al.*, 1968).

The possible decomposition of MIC into HCN has been treated as evidence that toxicity in Bhopal was caused by HCN (Mangla, 1989). However, a meticulous study by D'Silva *et al.* (1986) did not detect any HCN in the residue of Tank 610 (from which MIC escaped) nor did they observe the formation of HCN from MIC by experimentally duplicating the conditions that led to the disaster.

Notwithstanding the negative data about the presence of any HCN, if some MIC did decompose into HCN, the quantity of HCN generated as well as of unconverted MIC would be lower than it would be if no breakdown of MIC took place; in either case it would reduce the toxicity of both MIC and HCN. There is yet another point that needs to be considered. Once the vent valve of the tank containing MIC was forced open by the pressure, the escaping vapor was ejected upwards. Even if it is assumed that most of the MIC was converted into HCN, it is highly unlikely that significant amounts will descend onto the ground since the relative vapor density of HCN is 0.9 relative to 1.0 of air. Even if somehow HCN did descend to the ground, it is unlikely that it will achieve a fatal concentration in an area of approximately 40 km^2 in which the population was affected. Moreover, profuse lacrimation, which was witnessed in Bhopal residents, is not a characteristic of HCN poisoning.

Contrary to popular belief, cyanide is not a potent killer although it is an extremely fast killer if the dose is high enough (Goldstein *et al.*, 1968). HCN, the most potent of all cyanides, is lethal only at concentrations well over 200 ppm (Table 21.3). Alarie *et al.* (1987) exposed guinea pigs, which are more sensitive to MIC than rats or mice (Fowler and Dodd, 1987a), to as high as 340 ppm for a short period and all animals recovered. In contrast, MIC could be fatal at as low as 3 ppm and kill a majority of animals at 30–40 ppm for three to four exposures. Because of the relatively low

TABLE 21.3. Properties of methyl isocyanate (MIC) and hydrogen cyanide (HCN)

Property	MIC	HCN
Molecular weight	57	27
Appearance	Liquid	Liquid/gas
Boiling point (°C)	39.1	25.7
Vapor density (air = 1)	1.97	0.95
Threshold limit value (ppm)	0.02	10.0
Lethal level 1 h exposure (ppm)	3.0	100
Concentration immediately fatal (ppm)	Undetermined	>270
Antidote	None	Sodium thiosulfate
Long-term effects	Many	None identified

toxic potency of HCN, its threshold limit for an 8 h exposure is set at 10 ppm for HCN compared with 0.02 ppm for MIC (Table 21.3). It would be impossible to work in an atmosphere of 10 ppm MIC.

Almost no deaths occurred in Bhopal until 4 h after the MIC leak; indeed, most deaths occurred between 24 and 48 h after the discharge of the poisonous gas (Varma, 1986). This was followed by delayed deaths months and years after the accident (Varma and Mulay, 2006). This pattern of fatalities characterized by delayed and not immediate deaths in Bhopal (Varma, 1986) is mimicked by exposure of experimental animals to MIC (Boorman *et al.*, 1987; Bucher *et al.*, 1987a, b; Dodd *et al.*, 1987; Fowler and Dodd, 1987a, b; Stevens *et al.*, 1987; Tepper *et al.*, 1987; Uraih *et al*, 1987; Ferguson and Alarie, 1991). In contrast, at lethal concentrations, HCN would cause deaths almost immediately; if deaths do not occur within 4 h, it is highly unlikely that they would occur at all.

Also, there is definite evidence of long-term effects in survivors of the Bhopal disaster (Varma and Guest, 1993; Dhara and Dhara, 2002; Ranjan *et al.*, 2003; Sriramachari, 2004; Varma and Varma, 2005; Varma and Mulay, 2006) and in animals exposed to MIC (Boorman *et al.*, 1987; Fowler and Dodd, 1987; Karol *et al.*, 1987; Stevens *et al.*, 1987; Bucher *et al.*, 1987a, b; Varma *et al.*, 1988; Ferguson and Alarie, 1991). On the other hand, a single dose of cyanide is not known to produce long-term effects in survivors (Goldstein *et al.*, 1968), although continued ingestion, as a result of cyanogenic foods, can cause chronic toxicity (Cliff *et al.*, 1984).

The cyanide theory was triggered by the following events. First, in response to an enquiry from Bhopal immediately after the effects of the gas leak were felt in Bhopal, a senior official at the Union Carbide Plant in West Virginia is reported to have advised administration of sodium thiosulfate; although the instruction was soon withdrawn, the impact of the initial misinformation was not lost. Second, Dr Chandra of the Gandhi Memorial Hospital at Bhopal reported observing cherry-red venous blood at autopsy, characteristics of cyanide poisoning; although the characteristic almond odor of the breath and stomach contents was not reported, his suggestion that poisoning was caused by cyanide gained further currency. Third, the cyanide theory gained momentum in the Indian and international press after the release of the finding of ICMR's double-blind study that sodium thiosulfate exerted beneficial effects and increased urinary excretion of thiocyanate; indeed the Supreme Court of India intervened to instruct in August 1985, that is 7 months later, the ''mass detoxification'' of Bhopal victims with sodium thiosulfate. The cyanide theory acquired further credence because in an exemplary humanitarian gesture, the German toxicologist Dr Daunderer brought a generous supply of sodium thiosulfate ampoules and supervised its use in Bhopal victims (Sriramachari, 2004). Finally, in the midst of chaos and confusion caused by a disaster of the magnitude of Bhopal, rumors are bound to find their way. Even during the Tokyo subway episode when miscreants released organophosphate sarin, cyanide poisoning was suspected until the identity of the incriminating chemical was quickly established.

There are two aspects to the cyanide controversy. One, was the poisoning in Bhopal caused or significantly contributed by HCN? Two, did sodium thiosulfate provide relief? The overall evidence clearly indicated that the major culprit in the Bhopal disaster was MIC and not HCN. If the findings of cherry-red venous blood led to a suspicion of cyanide poisoning, autopsy blood (not liver or lungs) samples could have been tested for cyanide, even days or weeks after the accident (Ballantyne *et al.*, 1974), which was not done. The possibility that MIC itself can lead to underutilization of oxygen and thus give rise to cherry-red venous blood was critically examined by Salmon (1986) using a UV spectrometer following addition of MIC to rat blood; they found a role for methylamine, a hydrolysis product of MIC in color change, which can be misinterpreted when examined by the naked eye as was done in Bhopal.

As to the second question concerning the beneficial effects of sodium thiosulfate, the answer is not simple, but neither does it indicate that the disaster in Bhopal was caused by MIC being converted into HCN.

Sodium thiosulfate is well known as an effective antidote against cyanide poisoning, for which purpose it should be administered almost immediately and not several days and months later (Chen and Rose, 1956; Goldstein *et al.*, 1968); at the same time experimental data show that it is not an antidote against MIC (Alarie *et al.*, 1987; Nemery *et al.*, 1985b; Varma *et al.*, 1988). It is reasonable to assume that administration of sodium thiosulfate provided some relief to Bhopal residents but this does not prove that the poisoning in Bhopal was caused by HCN.

Cyanide has been part of the environment of living organisms during the evolutionary process and the body is endowed with a specific enzyme, thiosulfate-cyanide sulfurtransferase ''rhodanese'' (EC 2.8.1.1), which can convert cyanide into relatively nontoxic thiocyanate. Cyanide in the body can arise from several sources; its levels in normal human blood may be as high as 0.15 mg/l (~6 µmol/l) and might be even higher in patients with renal and respiratory disease (Cailleux *et al.*, 1988). Cyanide can be sequestered in the body from certain foods, ''cyanogenic glucosides'', as well as smoking, and other environmental factors. The cyanide content in 200 g of moist peach seed is 88 mg, greater than a fatal dose of HCN. Chronic toxicity of HCN can result from chronic (and not single) ingestion of the poison especially in workers in many industries where HCN can be a normal pollutant. Bhopal residents who were most severely affected by the disaster lived in shanty towns in highly polluted areas and cooked with charcoal or firewood, and many were smokers. It is therefore very likely that their normal cyanide blood concentration was significant; this would explain the relief experienced by them following injection of sodium thiosulfate at any time – days and months after the disaster. The double-blind study by ICMR, which recommended the routine use of sodium thiosulfate in Bhopal victims, is of dubious merit; of course the drug will relieve some symptoms better than the placebo. For the same reason administration of sodium thiosulfate would increase urinary thiocyanate. What ICMR should have done is to perform the same study on a population in shanty towns in other cities of India to determine if sodium thiosulfate is more beneficial in Bhopal than, say, in Mumbai or Kolkata.

No drug, including sodium thiosulfate, should be administered without clear indication. Like all other drugs, sodium thiosulfate is also not without its own toxicity. Sodium thiosulfate can even be converted into cyanide by the enzyme thiosulfate oxidase (Goldstein and Reiders, 1951), which is the reason why its overzealous use in cases of cyanide poisoning can lead to recurrence of symptoms.

VII. TOXICITY OF ISOCYANATES

MIC is less frequently used than toluene diisocyanate (TDI), diphenylmethane diisocyanate (MDI), naphthalene diisocyanate (NDI), hexamethylene diisocyanate (HDI), and other isocyanates. In order to highlight the distinctiveness of MIC toxicity, the toxicity of diisocyanates is described briefly.

Although organic isocyanates were first synthesized in 1849, their use, mainly for the manufacture of polyurethanes, increased after World War II. The toxicity of isocyanates can be due to direct irritant effect on lungs, eyes, skin, and exposed mucosa as well as secondary to pulmonary toxicity, allergic response, and nonpulmonary direct effects. The direct effects can be instantaneous as is the case with MIC, or ensue after a lag period of hours.

By the year 1956, more than 100 cases of illnesses and four cases of death due to poisoning by TDI were reported (Baader, 1956). In view of the increased use of isocyanates, the National Institute of Occupational Safety and Health, USA, projected as early as 1978 that approximately 50,000 to 100,000 workers would be exposed to these chemicals within 2 years (NIOSH, 1978); this estimate was based on exposure at the workplace in polyurethane production, upholstery work, wire coating, and spray painting in the absence of any accidental spill (Axford *et al.*, 1976; Editorial, 1966; Fuchs and Valade, 1951; Hill, 1970; Williamson, 1965).

The routine exposure of workers to isocyanates is by inhalation rather than oral ingestion; their toxicity is greater following inhalation than following oral ingestion as well as if they produce both pulmonary and sensory irritation than if they only cause sensory irritation (Weyel *et al.*, 1982). MIC is both a sensory and pulmonary irritant (Ferguson *et al.*, 1986). The smaller the isocyanate molecule, the greater its toxicity (Carney, 1980; Rye, 1973), which makes MIC the most toxic of all isocyanates (Varma, 1986). Also, the toxicity of isocyanates is directly related to their volatility and vapor pressure (Rye, 1973).

TDI seems to be the most toxic of diisocyanates. Eosinophilia, pulmonary emphysema, and right-sided heart failure were observed in some cases of TDI poisoning (Brugsch and Elkins, 1963). TDI can cause inflammatory changes at exposed mucous membranes in experimental animals (Sangha and Alarie, 1979; Sangha *et al*, 1982; Schmidt-Nowara *et al.*, 1973; Stevens *et al.*, 1987; Weyel *et al.*, 1982; Weyel and Schaffer, 1985; Wilson and Wilson, 1959; Wong *et al.*, 1985; Zapp, 1957). Repeated exposure to a dose of TDI as low as 5–10 ppm can be lethal in animals (Henschler *et al.*, 1962). Human toxicity of TDI has been documented by several workers (Adams, 1970; Axford *et al.*, 1976; Baader, 1956; Brugsch and Elkins, 1963; Bruckner *et al.*, 1968; Charles *et al.*, 1976; Editorial, 1966; Fuchs and Valade, 1951; Le Quesne *et al.*, 1976; Wilson and Wilson, 1959). Specific antibodies against TDI have been demonstrated in rabbits (Scheel *et al.*, 1964), guinea pigs (Karol, 1983), and humans (Karol, 1981), which would explain precipitation of symptoms following a second exposure to TDI in subjects who had recovered from previous exposure (Editorial, 1966).

In summary, all isocyanates are toxic and lungs are the main but not the only targets of their toxicity. The toxicity of isocyanates may range from transient reversible to long-term irreversible damage and may prove fatal.

A. Toxicity of Methyl Isocyanate

Experimental study on the toxicity of MIC vapor on rats, mouse, rabbits, and guinea pigs as well as on human volunteers was first reported in 1964 (Kimmerle and Eben,

1964). For the next 20 years from 1964 to 1984 no follow-up of these studies was done. The world had to have its worst industrial disaster in the last month of 1984 to prompt a renewed interest in the toxicology of MIC; this provoked *The Lancet* (Editorial, 1984) to comment: ''In a year's time we will have learned a lot more about methyl isocyanate – at an appalling price.'' It is to the credit of Kimmerle and Eben (1964) that their stringent observations were confirmed by all the studies since 1984. On the other hand, acute toxicity studies are not predictors of long-term effects (Salmon, 1985).

It is tragic that the toxicity of poisons is tested on humans during wars, and far too often by the most developed countries. It is unfortunate that human toxicity of chemicals is observed during industrial accidents or environmental neglect. In this sense, Bhopal offered the most expansive opportunity to observe and investigate the toxicity of MIC on such a large scale on a human population as well as on livestock and vegetation. Surprisingly, however, most of the obvious questions raised in the aftermath of the Bhopal disaster have not been investigated in a rigorous manner and the answers to many questions remain at best anecdotal.

Whereas inhalation is the commonest mode of entry of MIC into the body, its toxicities have been demonstrated following injections (Jeevarathinam *et al.*, 1988; Meshram and Rao, 1988; Pearson *et al.*, 1990; Varma, 1987); there is evidence that the toxicity of MIC is not contributed by its metabolites (Jeevaratnam *et al.*, 1992a).

For the sake of simplicity, data on the toxicity of MIC on humans and animals are presented separately. It is worth mentioning, however, that almost all the data derived from animal studies seem to confirm what has been observed in humans in Bhopal.

1. Toxicity of MIC In Animal Models

a. Mortality

Barely 4 h after the disaster, Bhopal, on the morning of December 3, 1984, was littered with dead animals – 790 buffaloes, 18 bullocks, 84 calves, 270 cows, 483 goats, 90 dogs, and 23 horses (Varma, 1986). According to autopsy reports, dead animals showed swollen livers and lymph nodes, bloated digestive tracts, engorged blood vessels, edema, necrosis in lungs with blood clots, and congested heart and kidney (Varma, 1986). House flies survived probably because they stood still and MIC did not enter into the body in sufficient concentrations through the wings and skin.

The lethal effect of MIC was first reported by Kimmerle and Eben (1964) who estimated an LC_{50} value of 5 ppm in rats following a 4-h exposure, and 21 ppm following a 2-h exposure. Unlike cyanide, deaths followed several hours after exposure and continued up to 18 days. In later studies it was found that a 10 min exposure to as high as 3,506 ppm was not immediately lethal (Dodd *et al.*, 1987) although guinea pigs died during exposure to high concentrations of greater than 500 ppm. In general, deaths following exposure to MIC occur 1 to 2 days later and a second phase of mortality follows after a week or longer (Alarie *et al.*, 1987; Boorman *et al.*, 1987; Bucher *et al.*, 1987a, b; Dodd *et al.*, 1987; Fowler *et al.*, 1987; Fowler and Dodd, 1987a, b; Stevens *et al.*, 1987; Varma *et al.*, 1988). There seem to be species differences in lethal toxicity of MIC; guinea pigs being more sensitive than rats (Dodd *et al.*, 1987). Experimental studies during the first 2 years have been reviewed by Nemery *et al.* (1987).

b. Pulmonary Toxicity

Kimmerle and Eben (1964) reported that MIC caused lacrimation, mucosal irritation, and pulmonary edema in rats, mouse, rabbits, and guinea pigs; death followed acutely after a few hours as well as after several days (up to 18 days). The LC_{50} in rats following a 4 h exposure was 5 ppm; it was 21 ppm following a 2 h exposure. Later studies found that MIC causes both sensory and pulmonary irritation; if death did not ensue, the recovery from these pulmonary effects was very slow (Alarie *et al.*, 1987; Ferguson *et al.*, 1986). Exposure to MIC caused concentration-dependent degenerative changes in bronchiolar and alveolar epithelium in rats and guinea pigs resulting in plugging of major airways and atelectasis (Nemery *et al.*, 1985a; Fowler *et al.*, 1987), increase in lung weight (Bucher *et al.*, 1987a; Stevens *et al.*, 1987), pulmonary (Boorman *et al.*, 1987; Bucher *et al.*, 1987a; Dutta *et al.*, 1988; Fowler and Dodd, 1987a, b) as well as olfactory epithelial necrosis (Uraih *et al.*, 1987), airway obstruction (Stevens *et al.*, 1987; Tepper *et al.*, 1987), and a compromised cardiopulmonary function (Tepper *et al.*, 1987) in surviving animals.

c. Ocular Toxicity

As was the case in humans, lacrimation has also been found to be one of the earliest effects of MIC vapor in experimental animals (Bucher *et al.*, 1987; Dodd *et al.*, 1986, 1987; Ferguson and Alarie, 1991; Gupta *et al.*, 1987; Kimmerle and Eben, 1964; Varma *et al.*, 1988). However, exposure of rats to 3, 10, or 30 ppm MIC for 2 h, which approximates the situation in Bhopal, was not found to cause any damage to cornea although copious lacrimation was observed up to 3 months. Similar findings have been reported in mice (Boorman *et al.*, 1987). On the other hand, exposure of lens explants to MIC *in vitro* has been shown to cause opacity (Harding and Rixon, 1985). It is very likely that profuse lacrimation acted as a protective mechanism by both chemically inactivating MIC and offering physical protection.

d. Reproductive Toxicity

Exposure of mice on day 8 of gestation (gestation period 19 days) to 2, 6, 9, and 15 ppm MIC for 3 h or 1–3 ppm for 6 h on days 14–17 of gestation caused concentration-dependent fetal loss and maternal mortality (Varma, 1987; Varma *et al.*, 1987, 1990); lengths of different fetal bones

were significantly reduced following exposure of mice to 9 and 15 ppm MIC (Varma, 1987). MIC also caused maternal and fetal toxicity in rats; pregnancy loss accompanied sudden decrease in progesterone although it could not be determined which of the two events occurred first (Varma *et al.*, 1990). Given the extensive nature of MIC toxicity, it is difficult if not impossible to determine if MIC-induced reproductive toxicity is a direct effect on the conceptus or a consequence of general toxicity; however, several observations indicate the possibility of a direct effect.

Radio-labeled MIC rapidly reaches the fetus (Ferguson *et al.*, 1988). Intraperitoneal injection of MIC also caused reproductive toxicity of a similar magnitude as following inhalation (Varma *et al.*, 1990). Moreover, MIC metabolites methylamines also produced reproductive toxicity without other obvious effects on pregnant mice (Guest and Varma, 1991); of the three amines tested, monomethylamine, dimethylamine, and trimethylamine, the last one was most toxic *in vivo* as well as in mouse embryos in culture (Guest and Varma, 1991, 1992; Guest *et al.*, 1994). Interestingly, administration of trimethylamine during mouse pregnancy resulted in stunting of male but not female progeny (Guest and Varma, 1993), similar to that reported years later in Bhopal victims (Ranjan *et al.*, 2003). Another metabolite of MIC, *S*-(*N*-methylcarbamoyl) GSH, exerted marked toxicity on cultured mouse embryos (Guest and Varma, 1994; Guest *et al.*, 1992) as well as yolk sac and limb bud (Guest and Varma, 1994). However, exposure of male and female mice to low concentrations (1–3 ppm) of MIC did not seem to affect their reproductive performance one week post-exposure (Schwetz *et al.*, 1987).

e. Genetic and Immunotoxicity

MIC has been found to generate specific antibodies in guinea pigs following both inhalation and subcutaneous injections (Karol *et al.*, 1987). However, immunologic response to 3 ppm MIC in mice was considered minimal by one group (Tucker *et al.*, 1987) but not by another group of investigators (Dwivedi *et al.*, 1988). In consideration of the socioeconomic status of the victims, Saxena *et al.* (1991) studied B lymphocyte cell activity in protein-deficient rats and found no evidence of significant effects on immune response; likewise, Luster *et al.* (1986) did not observe appreciable compromise in immune function in mice exposed up to 3 ppm MIC for 4 consecutive days.

Conner *et al.* (1987) did not observe any effect on sister chromatid exchange in bone marrow, alveolar macrophages, and lymphocytes of mice exposed to MIC; however, cell cycling of lymphocytes and bone marrow cells from mice exposed to >15 ppm MIC was almost completely suppressed. On the other hand, MIC was found to be genotoxic in rats (Dutta *et al.*, 1988) and caused dose-related increases in sister chromatid exchange as well as chromosomal aberrations in hamster ovary cells in addition to cell cycle delay in mice (Shelby *et al.*, 1987). MIC has also been reported to be mutagenic in mammalian and bacterial cell cultures (Caspary and Myhr, 1986; Meshram and Rao, 1988); MIC has been estimated to have a 76.6% probability of being a genotoxic carcinogen but only in tests with low specificity (Ennever and Rosenkranz, 1987).

f. Other Toxic Effects

MIC caused dose-dependent necrosis of brain cells and muscle cells (Anderson *et al.*, 1988) of rats in culture; these findings could explain neuromuscular complaints in Bhopal victims. Exposure of mice to 1–3 ppm MIC was found to inhibit erythroid precursors, pluripotent stem cells and granulocyte-macrophage progenitor; recovery from this inhibitory effect was found within 3 weeks after 1 ppm but not after 3 ppm (Hong *et al.*, 1987). At higher concentrations of 6–15 ppm, MIC inhibited cell cycling in bone marrow, alveolar cells, and T lymphocytes (Conner *et al.*, 1987; Shelby *et al.*, 1987); similar data were reported by others (Tice *et al.*, 1987; Mason *et al.*, 1987). MIC can inhibit bone marrow cell proliferation in mice (Meshram and Rao, 1988). MIC can cause necrosis in whole-brain cell cultures (Anderson *et al.*, 1990) and inhibit differentiation in muscle cell cultures (Anderson *et al.*, 1988).

Exposure of rats, mice, and guinea pigs to MIC vapor caused dramatic body weight decrease in the first 2 days, which was followed by incomplete to complete recovery (Bucher *et al.*, 1987a; Dodd *et al.*, 1987; Fowler and Dodd, 1987a, b; Varma 1987). The most likely cause of the rapid decrease in body weight is fluid loss, which may also explain the increase in hematocrit. A decrease in food intake may contribute to the persistence of decreased body weight.

MIC also caused an increase in creatinine kinase, hemoglobin, hematocrit, reticulocytes, neutrophils, and blood PCO_2 in rats and guinea pigs (Bucher *et al.*, 1987b; Dodd *et al.*, 1987; Troup *et al.*, 1987) and a decrease in blood pH and PO_2 (Fedde *et al.*, 1987; Jeevaratnam *et al.*, 1991; Maginniss *et al.*, 1987; Troup *et al.*, 1987). MIC can cause hyperglycemia, lactic acidosis, and hypothermia in rats (Jeevaratnam *et al.*, 1992c) as well as inhibit mitochondrial respiration (Jeevaratnam *et al.*, 1992b) and disrupt erythrocyte membranes (Jeevaratnam and Vaidyanathan, 1992). MIC was found to be a weak reversible inhibitor of cholinesterase (ChE) *in vitro* (Brown *et al.*, 1987; Troup *et al.*, 1987) but not *in vivo* (Troup *et al.*, 1987); both groups of workers concluded that ChE inhibition could not have contributed to fatalities in Bhopal. Mishra *et al.* (1991) exposed rats to different concentrations of MIC vapor for 8 min and measured drug metabolizing enzymes in lungs and found that aminopyrene demethylase and aniline hydroxylase activities were inhibited but glutathione-*S*-transferase activity was increased.

2. Toxicity in Humans

The human toxicity of the noxious gases that engulfed Bhopal on the night of December 2–3, 1984 has been reviewed by several investigators (Dhara and Dhara, 2002;

Mehta *et al.*, 1990; Sriramachari, 2004; Varma and Guest, 1993; Varma and Mulay, 2006). Dureja and Saxena (1987), two of the earliest physicians who were involved in the rescue, graded symptoms into four categories: (1) minor eye ailments, throat irritation and cough; (2) severe conjunctivitis, keratitis, acute bronchitis and drowsiness; (3) severe pulmonary edema; and (4) convulsions followed by cardiorespiratory arrest. Similar findings were reported by others (Kamat *et al.*, 1985; Misra *et al.*, 1987).

The human cost is vividly narrated in the various books mentioned in Section II of this chapter. While there is no doubt that the major toxic chemical responsible for acute and chronic toxicity in Bhopal was MIC, there is also ample evidence that the toxic fumes contained other noxious substances. Whether or not these additional chemicals exerted additive or synergistic effects on MIC toxicity cannot be stated categorically. It is reasonable to assume that major effects, both acute and chronic, were due to MIC.

a. Acute Toxicity

i. Nonlethal Effects Eye irritation, lacrimation, choking sensation, and difficulty in breathing were first reported by Kimmerle and Eben (1964) who exposed human volunteers to MIC vapor; the observation of these workers was confirmed on thousands of people following the Bhopal disaster. Also, many of the victims lost consciousness; some but not all regained it (Varma, 1986).

ii. Fatal Effects Although the precise number of people who died after being exposed to MIC is still not known, our estimate based on fatalities in 3,270 households surveyed to determine effects on pregnancy (Varma, 1987) would suggest 6,000–8,000 deaths within 24–72 h after the gas leak in Bhopal. Deaths can be attributed to pulmonary edema. As mentioned earlier, deaths did not occur as quickly as is characteristic of cyanide poisoning but after a delay of several hours.

b. Subacute and Chronic Toxicity

i. Mortality Anecdotal reports suggest that the Bhopal disaster resulted in approximately 20,000 deaths over approximately a 2-year period. Since late deaths have been observed by several workers in animal models (Alarie *et al.*, 1987; Boorman *et al.*, 1987; Bucher *et al.*, 1987a, b; Dodd *et al.*, 1987; Fowler *et al.*, 1987; Fowler and Dodd, 1987a, b; Stevens *et al.*, 1987; Varma *et al.*, 1988), the reports of late deaths in humans are a reasonable assumption. It is very likely that severe lung damage accounted for most of the late deaths although a contributory role of dehydration, internal hemorrhage, and other complications cannot be ruled out.

c. Pulmonary Complications

Examination of 500 exposed people within 3 days of the Bhopal disaster identified alveolar edema in 40% and destructive lesions in 8% (Sharma and Gaur, 1987); similar data have been reported by others (Bhargava *et al.*, 1987). A retrospective study of 978 patients found 7.14% mortality, breathlessness, and cough in 95%, irritation and choking in the throat in 46% and chest pain in 25% (Misra *et al.*, 1987). Evidence of necrotizing lesions in the respiratory tract (ICMR, 1985) as well as radiological changes and compromise in lung function have been documented (Gupta *et al.*, 1988; Misra and Nag, 1988). Since the prevalence of compromise in lung function was higher in the population closer to the pesticide plant than in the population further away, it is very likely that it was a result of exposure to the toxic gases rather than preexisting bronchitis, tuberculosis or emphysema. A follow-up of 113 exposed patients revealed worsening of pulmonary symptoms at 2 years relative to those at 1 year; forced expiratory flow (FEF) between 25 and 75% declined progressively over a 2-year period (Kamat *et al.*, 1985, 1987, 1992; Patel *et al.*, 1987), a 1–7 year period (Vijayan and Kuppurao, 1993; Vijayan and Sankaran, 1996; Vijayan *et al.*, 1989, 1995), and a 10-year period (Acquilla *et al.*, 1996; Dhara *et al.*, 2002). Likewise, other workers found direct relationship between pulmonary function compromise and inflammatory alveolitis and the severity of exposure (Vijayan *et al.*, 1989, 1995). A causative relationship between the intensity of exposure to toxic gases and a decrease in $FEF_{25\%–75\%}$ is also suggested by another follow-up study of 454 adults conducted 10 years after the disaster (Cullinan *et al.*, 1996, 1997).

Persistent airway hyperreactivity after a single exposure to chemical irritant has been termed Reactive Airways Dysfunction Syndrome (RADS) (Brooks et *al*., 1985). There is a strong likelihood of RADS among the victims of the gas exposure at Bhopal (Nemery, 1996); however, whether or not the exposed Bhopal population suffers from RADS has not been carefully studied.

A study by Avashia *et al.* (1996) (the medical director of the Union Carbide Institute at West Virginia Plant in 1984) concluded that prolonged low exposure of workers to MIC did not cause any pulmonary complications; the level of exposure was not quantified. Even in Bhopal people who lived far away from the pesticide plant and were exposed to very low concentrations of MIC did not develop pulmonary complications because no chemical produces detectable toxicity at all doses.

d. Ocular Toxicity

There are reports that eye irritation and some level of lacrimation was a common experience of workers of the pesticide plant. Indeed, because of these frequent episodes of eye irritation, workers initially believed that they did not initially suspect something unusual was happening in the early morning of December 3, 1984. It would seem that eyes are most sensitive to MIC toxicity since eye irritation was experienced even by people who lived quite far from the pesticide plant and seemed not to have experienced pulmonary and other symptoms (Varma, 1986). Exposure to

MIC produced ocular burning, watering, pain, and photophobia (Andersson *et al.*, 1984, 1985, 1988; Dwivedi *et al.*, 1985), conjunctivitis, and corneal opacity (Maskati, 1986). Within the first 2 weeks of disaster Anderson *et al.* (1988) found no case of blindness in a community-based survey; surprisingly, the incidences of photophobia and interpalpebral erosion were highest in areas where the death rates were lowest.

Two-year follow-up studies revealed persistent eye watering, itching, redness, photophobia, burning, Bitot spots, and even corneal opacity (Andersson *et al.*, 1986, 1990; Khurrum and Ahmad, 1987; Raizada and Dwivedi, 1987). It is noteworthy that in a gas-exposed cohort of 232 children admitted to the Pediatric and Eye Ward of the Hamidia Hospital, Bhopal, extensive evidence of respiratory and cardiac complications was not accompanied by equally serious eye injuries (Dwivedi *et al.*, 1985). It is very likely that poor living conditions, which favor infection, especially in children, further worsened ocular toxicity (Crabb, 2004; Dhara and Dhara, 2002). On the other hand, it was feared at the time of the accident that a large number of survivors might be left with severe visual impairment; fortunately this does not seem to be the case, which does indicate that profuse watering, a toxic effect of MIC, also had the effect of minimizing ocular toxicity.

e. Reproductive Toxicity

A follow-up of 865 pregnant women living close to the pesticide plant at the time of the Bhopal disaster found that 379 (43.8%) did not give birth to live babies (Varma, 1987). Another follow-up study of 2,566 pregnant women from 18,978 households also found pregnancy loss in 23.6% women as compared to 5.6% in 1,218 control cohorts (Bhandari *et al.*, 1990). Kanhere *et al.* (1987) found that exposure to toxic gases resulted in decreased placental and fetal weights, in addition to the increased loss of pregnancy; infant death within 1 month, 2 years, and 5 years after birth was approximately 14% compared with 2.6–3% within the pre-accident period (Varma, 1987, 1991). Other effects of exposure to MIC in women include leucorrhea, suppression of lactation, pelvic inflammatory diseases, and irregular menstruation (Varma, 1986). No effect on spermatogenesis was detected within 6 months after the Bhopal disaster (Daniel *et al.*, 1987).

f. Genotoxicity

In a study involving 43 gas-exposed females and 40 gas-exposed males 3 years after the disaster, a significant increase in chromosomal aberration was reported; these aberrations included breaks, gaps, and dicentric rings, which were more marked in females than in males (Ghosh *et al.*, 1990). Chromosomal aberrations (Goswami *et al.*, 1985, 1990; Ghosh *et al.*, 1990) and cell cycle abnormalities have been identified in Bhopal victims (Deo *et al.*, 1987).

g. Carcinogenicity

A cancer registry was initiated by the Indian Council of Medical Research (ICMR) in 1986. However, no conclusive evidence of an increase in cancer in the exposed population has been documented. Dikshit and Kanhere (1999) analyzed the incidence of cancer in gas-exposed males during1987–1992 but found no significant increase in cancer. On the other hand, these researchers (Dikshit and Kanhere, 1999) predicted that a true estimate of any increase in the incidence of cancer can only be made ‘‘15–20 years’’ after the accident, but no such study has since been published.

h. Immunotoxicity

Saxena *et al.* (1988) studied 31 exposed adults and found a significant increase in abnormal lymphocytes; however, there was no middle ground in humoral and cellular immunity in the exposed population in Bhopal. Anti-MIC antibodies were detected in blood samples from gas-exposed subjects but the clinical implications are not clear (Karol *et al.*, 1987).

i. Neurotoxicity and Psychological Effects

Soon after the Bhopal disaster there were displays of bizarre and starkly different drawings by the surviving children almost all of them depicting gusts of flames going upwards. Many of these drawings reflected loss of parents or other family members or friends. While these drawings are unlikely to be specific to MIC, they most probably reflected the children’s response to unanticipated horror. Psychological trauma was experienced by adults similar to that experienced by soldiers returning from combat missions. One study categorized the post-disaster psychological impact into four categories – post-traumatic stress disorder characterized by anxiety, restlessness, and sleep disorder; pathological grief reactions expressed as suicidal tendencies, and helplessness at not being able to save family members; emotional reaction to physical problems imposed upon them; and exacerbation of preexisting problems (Murthy and Isaac, 1987). A survey of 164 gas-exposed children 105 days after the disaster found them apprehensive and jittery (Irani and Mahashur, 1986).

The authors of this chapter encountered a volunteer at Sambhavana Trust Clinic located near the now decommissioned pesticide plant. This young man was perfectly normal on the many occasions we saw him but other members of the clinic told us that from time to time he would become very depressed; his parents had died during the disaster. One day in 2007 we received a message from Bhopal that he had committed suicide. There are reports of other such cases although it is never possible to causally link such tragic events with exposure to MIC.

Sethi *et al.* (1987) reported that a large number of survivors suffered from organic neurological problems including neuroses, anxiety states, and accentuation of previous psychological problems. Bharucha and Bharucha

(1987) also observed neurological and neuromuscular abnormalities in both adults and children and concluded that the incidence was lower than to be expected following a disaster of such magnitude; 24 of the 47 children examined by these authors experienced coma lasting for a maximum duration of 24 h. Neurological problems have also been reported by others (Gupta *et al.*, 1988; Kamat *et al.*, 1985; Misra and Kalita, 1997). Raphael and Middleton (1988) have suggested that 30–59% of those exposed to a disaster may suffer from traumatic neuroses.

j. Other Toxic Effects

Soon after the disaster, Bhopal was flooded with vendors selling all kinds of pills and buyers who hoped for a cure. Some did not know what to expect in the days following the accident and hoped that the pills would safeguard against existing ailments such as loss of appetite, weakness, breathlessness, and so on, and prevent complications. This scenario is typical of developing countries.

Twenty five years later, victims of the disaster still occupy the hospital beds and clinics and visit private practitioners of all branches of medicine complaining of vague to specific symptoms. In general, however, it is difficult to relate many of the symptoms, such as weakness, loss of appetite, and menstrual problems, to exposure to MIC. However, many subjects continue to suffer from pulmonary and visual problems.

As mentioned before, most of the victims of the disaster belonged to economically disadvantaged groups and lived in poor housing with nonexistent sanitary facilities. They thus suffered from many chronic diseases including bronchitis, tuberculosis, malaria, and so on. The Bhopal disaster certainly worsened these maladies.

VIII. TREATMENT

By their very nature disasters involving chemicals pose special problems because they involve a large number of people in a state of panic. Most places are not equipped to deal with such a situation especially if there is confusion about the nature of the chemical. If the chemical is a pulmonary irritant, as is the case with MIC, there is a good likelihood of cyanide poisoning as happened in Bhopal and for a short period in Japan when miscreants exploded organophosphates in the subway. The other reason for mass confusion is the erroneous belief that there exist antidotes for every poison.

People are usually unaware that supportive therapy rather than antidotes is the cornerstone to managing drug overdose or poisoning; a few exceptions include cyanide, narcotic analgesics, acetaminophen, methanol, organophosphates, digitalis, and CO. It was legitimate for the media and people in Bhopal to demand an antidote. Therefore conveying accurate information to the panicking population was vital. In the case of Bhopal, nondisclosure of the nature of, and lack of proper information about, the chemical involved, leading to improper cautionary measures proved as harmful as the poison itself. For example, if the community had been warned not to run away and encouraged to cover their faces with a wet cloth, the benefits would have been significant. In the midst of all this confusion, the doctors in Bhopal worked out as rational a treatment as possible, which comprised atropine, antibiotic eye drops, and antispasmodics. Treatment of pulmonary edema requires hospitalization and positive pressure respiration; Bhopal had neither enough beds nor equipment to provide this.

Long-term treatment is also supportive and is unrelated to the initiating factor. For example, the treatment of pulmonary, ophthalmic, or neurological complications has nothing to do with whether these are the late effects of poisoning by MIC or phosgene. Cyanide, unless ingested on a regular basis from the environment or food, does not produce long-term disability if death has not occurred.

A redeeming feature of the Bhopal tragedy was the overwhelming response of the citizens. Hundreds had flocked into Bhopal on the morning of December 3 from nearby villages and some came from further away. Doctors performed a commendable job working for long hours without a break. In contrast, the medical team dispatched by Union Carbide arrived 10 days later and tried to assure everyone that MIC is rapidly destroyed and no long-term effects are to be expected. The government of India failed both to summon a high level medical team to deal with the disaster and to provide any sort of ongoing aid. Voluntary groups and nongovernmental organizations shared the major burden of assuring people and helping in both the treatment and rehabilitation.

IX. TOXIC POTENTIAL OF MIC BEYOND THE BHOPAL DISASTER

Bhopal was the first case of mass exposure of humans, animals, and vegetation to MIC. Several factors influenced the toxicity of MIC such as the living conditions of the victims. Under identical conditions in a developed country the consequences would most likely be different. At the same time, the exposure of the Bhopal population was to a specific concentration of MIC and for a specific duration.

Accidental release of MIC can happen wherever the chemical is stored. A minor leak occurred from the Union Carbide plant in West Virginia only a few months after the Bhopal disaster and a nearby school had to be evacuated. Exposure to MIC at higher concentrations and for a longer duration than happened in Bhopal can also occur and can be fatal to a substantially greater percentage of population regardless of where it happens. The fact that MIC is heavier

than air makes it a potentially highly hazardous chemical both in enclosed and open spaces.

If animal experiments were solely performed to answer questions relating to the Bhopal disaster, the use of excessively high concentrations of MIC (Dodd *et al.*, 1987; Troup *et al.*, 1987; Fedde *et al.*, 1987; Fowler *et al.*, 1987) and repeated exposures would not have much relevance. However, workers are likely to encounter repeated exposure to MIC; indeed, anecdotal reports suggest that the impending disaster was not expected because workers were used to minor leaks and consequently eye irritation in the Union Carbide plant. Although no worker died inside the plant in Bhopal, because MIC spewed outside the factory, an accident worse than Bhopal cannot be ruled out, especially in an enclosed space.

Confusing instructions and the lack of transparency about the identity of the poison by the authorities at the Union Carbide headquarters only accentuated the tragedy. It can be assumed that whenever a full-scale disaster occurs, rumors are likely to spread. Even in the Japan subway tragedy where the incriminating agent was the organophosphate nerve agent sarin, rumors had it that the substance was cyanide.

X. CONCLUDING REMARKS AND FUTURE DIRECTION

We have described the chemistry, pharmacology, and toxicology of methyl isocyanate in the context of more commonly used diisocyanates. Combatants and civilians have been subjected to lethal and debilitating chemical agents during war. However, no poisonous chemical other than MIC has the notoriety of killing nearly 8,000 people within 72 hours and many more in the subsequent years on a scale as large as happened in Bhopal. Unlike the 9/11 tragedy where total casualties are accurately known, no one is still certain about the exact death toll immediately after and in the subsequent months and years in Bhopal. While acute deaths were most likely caused by pulmonary edema, only a well-planned epidemiological study coordinated by official agencies could have determined the nature and the magnitude of long-term effects. Unfortunately, this was not the case and many of the long-term effects cannot be identified retroactively. Carcinogenicity and genotoxicity require long-term follow-up of a large population. So far the results have been disappointing.

MIC toxicity amply demonstrates that the full dimension of the toxicity of a chemical (also its therapeutic potential) cannot be predicted from its chemical structure but can be approximated by careful and painstaking studies. Such an enquiry into MIC would be well deserved.

India may be the 12th largest economy in the world but the victims of Bhopal do not benefit from it. In February to May 2008, children, women, and men marched a distance of 800 km to the Indian capital Delhi with meager demands for clean water, appropriate therapy, and rehabilitation. The last time this was done was 2006; some promises were made but not fulfilled. What will happen this time, only time will tell.

Acknowledgments

Studies by the authors quoted in this article were supported by the Faculty of Graduate Studies and Research, McGill University and the Canadian Institutes for Health Research. In particular, we thank Sambhavana Trust Clinic, Bhopal, its managing trustees, Satinath Sarangi, and the entire staff who have been of invaluable help not only in epidemiological research but also in welcoming our interns who used its facilities for knowledge. This chapter is dedicated to the victims of the Bhopal disaster of 1984.

CHAPTER 22

Chlorine

SYLVIA S. TALMAGE

I. INTRODUCTION

Chlorine is the most abundant naturally occurring halogen. When formed experimentally, chlorine is a greenish-yellow, diatomic gas (Cl_2) with a pungent, irritating, or suffocating odor. The vapor is 2.5 times heavier than air and will form a cloud in the vicinity of a release. Solubility in water is low, approximately 4.4 g/l. Chlorine is extremely reactive and enters into substitution or addition reactions with both inorganic and organic substances. Other relevant chemical and physical properties are listed in Table 22.1. Because chlorine is so reactive, it is normally detected in the environment at only very low levels. Moist chlorine unites directly with most elements. Chlorine is a strong oxidizer; reaction with water produces hydrochloric (HCl) and hypochlorous acid (HOCl) as follows (ATSDR, 2007; O'Neil *et al.*, 2001; Teitelbaum, 2001):

$$Cl_2 + H_2O \leftrightarrow HCl + HOCl$$

Chlorine is used in the manufacture of a variety of nonagricultural chemicals. The major use of chlorine is in the manufacture of ethylene dichloride, which in turn is used to make vinyl chloride and subsequently polyvinyl chloride. Other uses include a bleaching agent in the paper industry [along with chlorine dioxide (ClO_2)], commercial and household bleaching agents [in the form of chlorates (ClO_3) and hypochlorites (OCl)], and a biocide in water purification and waste treatment systems (CEH, 2005; Teitelbaum, 2001).

As of July 2005, more than 500 companies produced chlor-alkali (chlorine and sodium hydroxide from brine) at over 650 sites worldwide with a total annual capacity of about 55.6 million metric tons of chlorine. About half of all plants are located in Asia. Global consumption of chlorine in 2004 was nearly 50 million metric tons. Consumption is greatest in the USA followed by Western Europe, China, and Japan (CEH, 2005).

The odor of chlorine is pungent and irritating (ATSDR, 2007). According to Amoore and Hautala (1983), the odor threshold is 0.31 ppm with a range of 0.2–0.4 ppm in other studies. There is considerable variation in detecting the odor among subjects; for many individuals, the ability to perceive the odor decreases over exposure time (NIOSH, 1976).

This chapter summarizes the known human health effects of chlorine, including information from studies with laboratory animals. Where quantitative data were available, the relationship of exposure concentration and exposure duration to toxicity is explained. Emphasis is on acute exposures.

II. HISTORICAL BACKGROUND

Chlorine gas was used as a chemical warfare agent during World War I (Withers and Lees, 1985; Haber, 1986; Salem *et al.*, 2008). During the early years of the war, both the Germans and the Allies used irritant gases as chemical weapons. By early 1915, Fritz Haber, a German chemist, proposed using chlorine as a chemical weapon. By this time, the German army had advanced into Belgium and France. During February and March 1915, trenches were dug and gas cylinders containing chlorine were installed to the north and northeast of Ypres, Belgium. Allied shelling resulted in some breached cylinders and a few German gas casualties during this time. By early April 1915, over 5,000 chlorine-containing cylinders containing about 168 tons of chlorine had been placed along a four-mile frontline near Ypres. On April 22, 1915, as a strong wind blew in the direction of the Allies, the valves were opened, and the released chlorine drifted as a cloud toward the French and Canadian lines. Allied protective gear was rudimentary, and estimated casualties for the battle ranged from 3,000 to 15,000 killed or wounded. Following this attack, the Germans led repeated chlorine gas attacks near Ypres but failed to capture the town. The concentrations that caused casualties are unknown.

III. TOXICOKINETICS

Chlorine is considered a direct-acting irritant to the target tissues, the eyes and respiratory tract. Death is due to acute respiratory failure. Chlorine gas reacts at the site of contact and very little of the chemical is absorbed into the bloodstream (Eaton and Klaassen, 2001). Any chlorine that is absorbed becomes part of the body pool of chlorine, and toxicokinetics is not involved in the mechanism of action.

TABLE 22.1. Chemical and physical data

Parameter	Value	Reference
Synonyms	Bertholite; hypochlorite; hypochlorous acid	ATSDR (2007)
Molecular formula	Cl_2	O'Neil *et al.* (2001)
Molecular weight	70.9	O'Neil *et al.* (2001)
CAS registry number	7782-50-5	O'Neil *et al.* (2001)
Physical state	Gas	O'Neil *et al.* (2001)
Color	Greenish-yellow	O'Neil *et al.* (2001)
Solubility in water	4.4 g/l @ 25°C	O'Neil *et al.* (2001)
Vapor pressure	5025 mm Hg @ 20°C	Matheson Gas Co. (1980)
Vapor density (air = 1)	2.48 @ 20°C	ATSDR (2007)
Density (water = 1)	1.56 at boiling point	Teitelbaum (2001)
Melting point	−101°C	O'Neil *et al.* (2001)
Boiling point	−34.05°C	O'Neil *et al.* (2001)
Flammability	Nonflammable	Matheson Gas Co. (1980)
Conversion factors	1 ppm = 2.9 mg/m^3 1 mg/m^3 = 0.34 ppm	ATSDR (2007)

IV. MECHANISM OF TOXICITY

The toxicity of chlorine is related to its oxidizing capacity (ATSDR, 2007). As noted, chlorine gas combines with water in the epithelial lining of the upper respiratory airways forming hydrochloric and hypochlorous acids. Hydrochloric acid is 33 times less potent as a sensory irritant than chlorine (Barrow *et al.*, 1977; Barrow and Steinhagen, 1982); whereas an aerosol of sodium hypochlorite and chlorine at equivalent air concentrations induces similar decreases in respiratory rate and changes in lung function parameters in mice (Morris *et al.*, 2005). This suggests that the oxidant properties of chlorine alone are sufficient to account for the observed responses. The precise mechanism of the interaction of chlorine or its reaction products with cellular components resulting in pulmonary edema is not known.

At low concentrations, e.g. 9 ppm, only sensory receptors are affected, triggering changes in respiratory dynamics such as a decreased respiratory rate. At irritant concentrations, the mechanistic response to chlorine is due to stimulation of the trigeminal nerve endings in the respiratory mucosa which results in a decrease in respiratory rate (Alarie, 1981). In studies with the mouse, this response is usually measured as the RD_{50}, the concentration of a chemical that decreases the respiratory rate by 50%. Another reaction, reflex bronchoconstriction, is a local reaction in which cholinergic-like agents bind to respiratory tract cell surface receptors and trigger an increase in the intracellular concentration of cyclic guanosine monophosphate, which in turn facilitates contraction of the smooth muscles that surround the trachea and bronchi. Contraction of these muscles causes a decrease in airway diameter and a corresponding increase in resistance to airflow which may result in wheezing, coughing, a sensation of chest tightness, and dyspnea (Witschi and Last, 2001).

HOCl, the reaction product of chlorine gas in the respiratory tract, reacts with thiol groups present in enzymes (Smith *et al.*, 2008). Results of *in vitro* studies show that enzymes containing thiol groups (glutamylcysteine synthetase, cysteine, and methionine) were 100 times more reactive to HOCl than amino acids that did not contain thiol groups. Inactivation of enzymes involved in antioxidant defenses would render the cell vulnerable to oxidative stress. Cellular glutathione, a cysteine-containing tripeptide, is also reduced by exposure to HOCl. Decreased glutathione may impair the ability of tissues to suppress lipid peroxidation reactions.

V. TOXICITY

Chlorine is an eye and respiratory tract irritant and, at high doses, has direct toxic effects on the lungs. Although only moderately soluble in water, inhaled chlorine is soluble in the epithelial lining of the respiratory tract by five orders of magnitude over its physical solubility (Nodelman and Ultman, 1999). At high concentrations the scrubbing capacity of the upper airways is saturated and chlorine reaches the lungs where it causes edema and hemorrhage. The irritant properties of chlorine have been studied in human volunteers and the acute, repeat-exposure, and chronic inhalation toxicity has been studied in several laboratory animal species.

A. Human Exposures

The irritant properties of chlorine have been documented in studies with healthy human volunteers as well as in individuals with airway hypersensitivity (Table 22.2).

TABLE 22.2. Summary of irritant effects in humans[a]

Concentration (ppm)	Exposure duration	Effect	Reference
0.5	8 h[b]	Perception of odor, no discomfort, no effects, no changes in pulmonary function measurements for healthy individuals, some changes for an atopic individual	Anglen (1981); Rotman *et al.* (1983)
1.0	8 h	Irritation (itchy eyes, runny nose, mild burning in throat); transient changes in pulmonary function measurements; asthmatic-like response in an atopic individual	
2.0	15 min to 4 h	No perceptible irritation at 30 min; throat irritation at 1 h; no significant changes in pulmonary function at 2 h; at 4 h irritation characterized as nuisance	
1.0	2 h	No noticeable effect	Joosting and Verberk (1974)
2.0	2 h	Very slight irritation of eyes, nose, and throat; no changes in pulmonary function tests	
4.0	2 h	Nuisance level of throat irritation, perceptible to nuisance level of nose irritation	
0.4	1 h	No changes in pulmonary function parameters in subjects with airway hyperreactivity/asthma	D'Alessandro *et al.* (1996)
1.0	1 h	Modest changes in pulmonary function parameters (FEV_1 and R_{aw}) for both healthy and asthmatic subjects	
0.5	15 min	NOAEL for nasal airway resistance and pulmonary peak flow in healthy subjects; change in nasal airway resistance for rhinitic subjects	Shusterman *et al.* (1998)
1.0	15 min	Increase in nasal air resistance for subjects with allergic rhinitis subjects greater (49% from baseline) than controls (10%); older subjects responded with greater increase than younger subjects; no gender difference	Shusterman *et al.* (2003)
0.5	6 h/day, 3 days	NOAEL for pulmonary function changes	Schins *et al.* (2000)

[a]The Anglen (1981) and Joosting and Verberk (1974) studies were performed with healthy adults. Atopic individuals were included in the Shusterman *et al.* (1998, 2003) and Rotman *et al.* (1983) studies, and healthy subjects as well as asthmatics were included in the D'Alessandro *et al.* (1996) study

[b]Eight-hour studies were composed of two segments with a 30-min or 1-h break after 4 h

FEV_1 = forced expiratory volume at 1 second

R_{aw} = airway resistance

A concentration of 0.4–0.5 ppm for up to 8 h is generally considered a no-adverse-effect level for nose and eye irritation (Anglen, 1981; Rotman *et al.*, 1983; D'Alessandro *et al.*, 1996). Nasal airway resistance and pulmonary peak flow are not affected at 0.5 ppm (Shusterman *et al.*, 1998; Schins *et al.*, 2000). At 1 ppm, some subjects report slight nose, throat, and eye irritation, and transient alterations in pulmonary function tests may occur. A concentration of 4 ppm was considered a ''nuisance'' level of nose and throat irritation (Joosting and Verberk, 1974).

Volunteers showed differing sensitivity to chlorine exposure. Following a 15-min exposure to 0.5 ppm chlorine, unmedicated subjects with seasonal allergic rhinitis had increased nasal air resistance, but no change in allergy symptoms or pulmonary peak air flow (Shusterman *et al.*, 1998). In the Rotman *et al.* (1983) study, a subject with obstructive airway disease, who was defined by the authors as ''atopic'' suffered an asthmatic-like attack following the exposure to 1.0 ppm for 4 h. Healthy subjects as well as subjects with airway hyperreactivity (defined by response to a methacholine challenge) showed no change in pulmonary function parameters following a 1-h exposure to 0.4 ppm chlorine (D'Alessandro *et al.*, 1996). Following a 1-h exposure to 1.0 ppm, there were statistically significant changes in FEV_1 (forced expiratory volume in 1 second) and R_{aw} (airway resistance) for both normal and hyperreactive subjects compared to baseline values, with hyperreactive subjects showing a greater relative decrease in FEV_1 (16%) than healthy subjects (4%) and a greater relative increase in R_{aw} (108%) than normal subjects (39%). For all subjects, return to baseline occurred by 24 h post-exposure.

The lethal effects of chlorine in humans are well documented, but lethal concentrations can only be estimated. Death is due to pulmonary edema. Probit analysis of available information on the lethality of chlorine to animals and man was used by Withers and Lees (1985) to estimate a concentration lethal to 50% of the population (LC_{50}). Their model incorporated the effects of physical activity, inhalation rate, the effectiveness of medical treatment, and the lethal toxic load function. The estimated 30-min LC_{50} at a standard level of activity (inhalation rate of 12 l/min) for the regular, vulnerable, and average (regular + vulnerable) populations, as described by the authors, were 250, 100, and 210 ppm, respectively. The LC_{10}s for the three populations were 125, 50, and 80 ppm, respectively.

B. Laboratory Animal Studies

Acute lethality studies in rodents are listed in Table 22.3. Thirty-min LC_{50} values range from 504 ppm in the mouse to 700 ppm in the rat (Zwart and Woutersen, 1988). The 60-min LC_{50} and LC_{01} values for the rat were 455 ppm and 288 ppm, respectively (Zwart and Woutersen, 1988).

TABLE 22.3. Summary of acute lethal inhalation studies with laboratory animals

Species	Concentration (ppm)	Exposure duration	Effect	Reference
Rat	5500	5 min	LC_{50}	Zwart and Woutersen (1988)
	2841		No deaths	
	1946	10 min	LC_{50}	
	700	30 min	LC_{50}	
	547		No deaths	
	455	60 min	LC_{50}	
	288		LC_{01}	
	322		No deaths	
Rat	293	60 min	LC_{50}	MacEwen and Vernot (1972)
	213		No deaths	
Mouse	290	6 min	No deaths	Bitron and Aharonson (1978)
		11 min	LC_{50}	
		15 min	80% mortality	
	170	55 min	LC_{50}	
		2 h	80% mortality	
Mouse	302	10 min	LC_{50}	Alarie (1980)
Mouse	1057	10 min	LC_{50}	Zwart and Woutersen (1988)
	754		No deaths	
	504	30 min	LC_{50}	
Mouse	137	60 min	LC_{50}	MacEwen and Vernot (1972)
Mouse	200	60 min	LC_{01}	O'Neil (1991)
	150		No deaths	

LC_{50} = the concentration that results in 50% mortality
LC_{01} = the concentration that results in 1% mortality

TABLE 22.4. Summary of acute nonlethal inhalation studies with laboratory animals

Species	Concentration (ppm)	Exposure duration	Effect	Reference
Rat	1,500	2, 10 min	Edema, metaplasia of lung	Demnati *et al.* (1995)
	500	5 min	Slight perivascular edema of lung	
	100	2 min	No effect	
Rat	25	10 min	RD_{50}	Barrow and Steinhagen (1982)
Rat	10.9	6 h	RD_{50}	Chang and Barrow (1984)
Rat	9.1	6 h	Lesions of the nasal passages, less severe lesions of the lower respiratory tract	Jiang *et al.* (1983)
Mouse	9.3	10 min	RD_{50}	Barrow *et al.* (1977)
Mouse	3.5	60 min	RD_{50}	Gagnaire *et al.* (1994)
Mouse	9.1	6 h	Lesions of the nasal passages; less severe lesions of the lower respiratory tract	Jiang *et al.* (1983)

RD_{50} = concentration that lowers the respiratory rate by 50% during a 10-min exposure

The 30-min LC_{50} for the mouse was much lower than for the rat, 137 ppm (MacEwen and Vernot, 1972).

Exposure to extremely high concentrations for short periods of time is tolerable in laboratory rodents (Table 22.4). In the rat, exposure to 1500 ppm for 2 min produced only slight effects including mild perivascular edema and occasional small clusters of polymorphonuclear leukocytes in the mucosa of large airways (Demnati *et al.*, 1995). The concentration that lowers the respiratory rate by 50% (RD_{50}), a measure of extreme irritation, is 9.3 ppm (Barrow *et al.*, 1977). The RD_{50} is a standard 10-min test conducted with male Swiss-Webster mice (ASTM, 1991). When this approximate concentration (9.1 ppm) was extended to a 6-h duration, moderate to severe lesions of the respiratory tract and peribronchiolitis were observed in rats and mice (Jiang *et al.*, 1983). Lesions of the lower respiratory tract were less severe. The lower mouse RD_{50} value of Gagnaire *et al.* (1994) may be due to the use of a different strain of mice.

In chronic studies, male and female rats and mice tolerated up to 2.5 ppm chlorine gas for 6 h/day, 5 days/week for 2 years (CIIT, 1993; Wolf *et al.*, 1995). Concentration-dependent lesions confined to the nasal passages were observed in all animals. These lesions were most severe in the anterior nasal cavity and included respiratory and olfactory epithelial degeneration, septal fenestration, mucosal inflammation, respiratory epithelial hyperplasia, squamous metaplasia and goblet cell hypertrophy and hyperplasia, and secretory metaplasia of the transitional epithelium of the lateral meatus. Body weight was depressed compared to controls but no early deaths occurred. A similar lack of lower respiratory tract effects was seen in monkeys exposed to 2.3 ppm chlorine for 6 h/day, 5 days/week, for 1 year (Klonne *et al.*, 1987). At these concentrations, chlorine is effectively scrubbed in the anterior nasal passages as indicated by the absence of lesions in the lung.

VI. RISK ASSESSMENT

Young children, especially children with asthma, are of concern in that they may experience increased sensitivity to irritants than asthmatic adults. However, children with asthma, ages 1–17, reacted in a similar manner to methacholine challenge (Avital *et al.*, 1991) as asthmatic adults challenged with histamine (Crockcroft *et al.*, 1977). The methacholine challenge is a medical test used to assist in the diagnosis of asthma. Breathing nebulized methacholine provokes narrowing of the airways, detected during a spirometry test. Reaction to histamine is similar. Although children were not tested, Shusterman *et al.* (2003) reported that airway resistance in the youngest group of tested subjects, ages 18–34 years, responded in a less pronounced manner to chlorine exposure than older subjects, ages 52–69 years.

Clinical studies with volunteers have shown that asthmatics or persons with airway hypersensitivity have increased sensitivity to the irritant effects of chlorine. The clinical studies of Anglen (1981), Rotman *et al.* (1983), D'Alessandro *et al.* (1996), and Shusterman *et al.* (1998, 2003) show that individuals with airway hyperreactivity or asthma react with increased sensitivity to the presence of chlorine. Taken together the studies show that human subjects exposed to 1.0 ppm chlorine for up to 8 h/day show some evidence of sensory irritation and transient respiratory tract changes. No such changes were reported in volunteers exposed to 0.5 ppm chlorine. These studies have been used by various agencies to develop standards and guidelines for chlorine exposure in emergency as well as occupational settings (Table 22.5).

Of interest in risk assessment is the relationship between concentration (C) and exposure duration (t) for a set endpoint such as irritation or death. This relationship can be described by $C^n \times t = k$, where k is a constant (ten Berge *et al.*, 1986). ten Berge and Vis van Heemst (1986) analyzed

TABLE 22.5. Standards and guidelines for chlorine

	Exposure duration				
Guideline	**10 min**	**30 min**	**1 h**	**4 h**	**8 h**
AEGL-1[a]	0.5 ppm	0.5 ppm	0.5 ppm	0.5 ppm	0.5 ppm
AEGL-2	2.8 ppm	2.8 ppm	2.0 ppm	1.0 ppm	0.71 ppm
AEGL-3	50 ppm	28 ppm	20 ppm	10 ppm	7.1 ppm
ERPG-1[b]			1 ppm		
ERPG-2			3 ppm		
ERPG-3			20 ppm		
EEGL[c]					3 ppm
IDLH[d]		10 ppm			
PEL – Ceiling[d]					1 ppm
REL – Ceiling[d]					0.5 ppm
TLV-TWA[e]					0.5 ppm
TLV-STEL					1.0 ppm
MAK[f]					0.5 ppm
MAK – Peak Limit					1.0 ppm
MAC – Ceiling[g]					1.0 ppm

[a]AEGLs (Acute Exposure Guideline Levels) (NRC, 2004) represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h. Three levels – AEGL-1, AEGL-2, and AEGL-3 – are developed for each of five exposure periods (10 and 30 min, 1 h, 4 h, and 8 h) and are distinguished by varying degrees of severity of toxic effects. The three AEGLs are defined as follows:

AEGL-1 is the airborne concentration [expressed as parts per million or milligrams per cubic meter (ppm or mg/m^3)] of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure.

AEGL-2 is the airborne concentration (expressed as ppm or mg/m^3) of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape.

AEGL-3 is the airborne concentration (expressed as ppm or mg/m^3) of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening health effects or death.

[b]ERPG (Emergency Response Planning Guidelines) (AIHA, 1997) also represent guidelines for the general public. Three ERPG levels are defined, each for a period of 1 h:

The ERPG-1 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing other than mild, transient adverse health effects or without perceiving a clearly defined objectionable odor.

The ERPG-2 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing or developing irreversible or other serious health effects or symptoms that could impair an individual's ability to take protection action.

The ERPG-3 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing or developing life-threatening health effects.

[c]EEGL (Emergency Exposure Guidance Level; NRC, 1984) is the concentration of contaminant that can cause discomfort or other evidence of irritation or intoxication in or around the workplace, but avoids death, other severe acute effects and long-term or chronic injury. EEGLs were developed for healthy military personnel. The EEL (Emergency Exposure Limit) for chlorine was set in 1966 and 1971 on the basis of nasal and eye irritation. After a review of the Rotman *et al.* (1984) data, the 8-h EEL was kept at 3 ppm but the 24-h EEGL was lowered to 0.5 ppm.

[d]IDLH (Immediately Dangerous to Life and Health; NIOSH, 2005) represents the maximum concentration from which one could escape within 30 min without any escape-impairing symptoms, or any irreversible health effects.

NIOSH REL-Ceiling (Recommended Exposure Limits – Ceiling; NIOSH 2005) is a 15-min ceiling.

OSHA PEL-TWA (Occupational Safety and Health Administration, Permissible Exposure Limits – Time Weighted Average; NIOSH, 2005) is defined analogous to the ACGIH-TLV-TWA, but is for exposures of no more than 10 h/day, 40 h/week.

[e]ACGIH TLV-TWA (American Conference of Governmental Industrial Hygienists, Threshold Limit Value – Time Weighted Average; ACGIH, 2001) is the time-weighted average concentration for a normal 8-h workday and a 40-h workweek, to which nearly all workers may be repeatedly exposed, day after day, without adverse effect.

The ACGIH TLV-STEL (Threshold Limit Value – Short Term Exposure Limit; ACGIH, 2001) is defined as a 15-min TWA exposure which should not be exceeded at any time during the workday even if the 8-h TWA is within the TLV-TWA. Exposures above the TLV-TWA up to the STEL should not be longer than 15 min and should not occur more than four times per day. There should be at least 60 min between successive exposures in this range.

[f]MAK [Maximale Arbeitsplatzkonzentration (Maximum Workplace Concentration)] (Deutsche Forschungsgemeinschaft (German Research Association), 2007) is defined analogous to the ACGIH-TLV-TWA. Two exposure peaks/work shift above the MAK are allowed, but the TWA must be maintained.

MAK Spitzenbegrenzung (Peak Limit) (German Research Association, 2007) constitutes the maximum average concentration to which workers can be exposed for a period up to 30 min with no more than two exposure periods per work shift; total exposure may not exceed the 8-h MAK.

[g]MAC [Maximaal Aanvaarde Concentratie (Maximal Accepted Concentration)] (SDU Uitgevers (under the auspices of the Ministry of Social Affairs and Employment), The Hague, The Netherlands, 2000) is defined analogous to the ACGIH-TLV-TWA.

the data of Anglen (1981) on irritation response in humans. Regression analysis of the percent of subjects reporting a nuisance irritation response to concentrations of 1 and 2 ppm over exposure durations of 30 and 120 min resulted in an *n* value of 1.9. Thus, the nuisance irritation response for longer and shorter exposure durations can be calculated. Probit analysis of the 5-, 10-, 30-, and 60-min LC_{50} values for the rat in the study by Zwart and Woutersen (1988) yields an *n* value of approximately 1.

VII. TREATMENT

According to IPCS (2008), patients without immediate symptoms may require no treatment, but a full physical examination and a record of respiratory peak flow may be of use in assessing any subsequent respiratory effects. Patients with mild effects require a full physical examination including peak flow before discharge and are advised to return if symptoms recur or develop over the following 24 to 36 h. Patients showing immediate moderate or severe effects should be checked for lung function and the chest should be x-rayed. Oxygen and bronchodilators such as salbutamol, orally or inhaled, may be used for bronchospasm. Pulmonary edema should be treated with positive end expiratory pressure, or constant positive airway pressure. Corticosteroids may inhibit the inflammatory response and should be considered in severe cases. Arterial blood gases should be monitored and hyperchloremic acidosis should be treated. Patients with preexisting respiratory disease should be assessed and considered for hospital admission for at least 24 h.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

The database on chlorine is robust. The irritant properties and toxicity of chlorine have been studied with controlled human exposures as well as with multiple species of laboratory animals. Exposure durations range from acute to chronic. Subjects with rhinitis or asthma appear to be more sensitive to the irritant effects of chlorine than healthy individuals. Thus, risk assessment addresses the potential for greater effects in these sensitive populations.

Chlorine is a direct-acting irritant to the eyes and respiratory tract. The mechanisms of action for both irritation and lethal effects are described. Toxicokinetics is not involved in the mechanism of action. The relationship between concentration and exposure duration for the set endpoints of irritancy and mortality can be described mathematically. There are no recommendations for further research.

CHAPTER 23

Phosgene

CHERYL B. BAST AND DANA F. GLASS

I. INTRODUCTION

Phosgene is a colorless gas at ambient temperature and pressure. Its odor has been described as similar to newly mown hay (Leonardos *et al.*, 1968). This mild odor and the weak acute irritant properties, however, provide little warning of its presence (Lipsett *et al.*, 1994).

Phosgene is manufactured from a reaction of carbon monoxide and chlorine gas in the presence of activated charcoal. Manufacture of phosgene is approximately 1 million tons per year in the USA; it is used in the manufacture of isocyanates, polyurethanes, polycarbonates, and pharmaceuticals and involves more than 10,000 workers (Currie *et al.*, 1987a). Manufacture of phosgene in the USA is almost entirely captive, in that >99% is used in the manufacture of other chemicals within a plant boundary (US EPA, 2003). The odor threshold is between 0.5 and 1.5 ppm (NIOSH, 1976); unfortunately, the odor threshold is inadequate to protect against toxic inhalant exposure as damage to the deep respiratory tract can take place at lower concentrations (Sidell *et al.*, 1997). Phosgene has an odor safety classification rating of ''E'' which indicates that fewer than 10% of attentive persons can detect the TLV (Amoore and Hautala, 1983).

Inhalation is the most important route of exposure for phosgene. Because of its mild upper respiratory, eye, and skin irritancy, and a mildly pleasant odor, an exposed victim may not actively seek an avenue of escape before lower respiratory damage has occurred (Currie *et al.*, 1987a; Lipsett *et al.*, 1994). Small amounts of phosgene can be irritating to the eyes (lacrimation) and throat (coughing) as phosgene undergoes hydrolysis to create hydrochloric acid which acts as an irritant. Far more dangerous, however, is the pulmonary edema that can develop after a latent period of 1–24 h post-exposure. Exercise can increase the extent of pulmonary edema (Marrs *et al.*, 1996). If severe clinical signs are not present after 48 h, then chances for full recovery are great. Physical and chemical properties of phosgene are summarized in Table 23.1.

II. BACKGROUND

Phosgene was first made in 1812 and was eventually used as a chemical warfare agent in WWI. Because of its higher density compared to air, phosgene gas can accumulate in low-lying areas; thus concentrated pockets within war trenches caused significant exposure in WWI. German troops in WWI used phosgene gas as a chemical warfare agent against the British troops. Possibly up to 85% of the deaths in WWI were a result of phosgene gas exposure (Ministry of Defence, 1987). Sandall (1922) examined 83 British soldiers 3 years after phosgene exposure. Shortness of breath upon exertion (70%), cough with expectoration (54%), tight feeling in chest (25%), sporadic giddiness (14%), and nausea (12%) were the most frequently reported complaints. No physical lung abnormalities were noted in 53% of the men.

The concept of a ''death product'' was introduced by Haber to explain the relationship between the extent of exposure to phosgene and death (Haber, 1924). According to ''Haber's law'', the biological effect of phosgene is directly proportional to the exposure expressed as the product of the atmospheric concentration (C) and the time of exposure (T) or $CT = k$, where k can be death, pulmonary edema, or other biological effects of phosgene exposure (US EPA, 1986). Haber's law has subsequently been shown by other investigators to be valid for both nonlethal and lethal effects within certain limits. There appears to be little species variability with regard to lethality between rats, mice, and guinea pigs, and the $CT = k$ relationship appears to be generally valid (although at very high or very low concentrations or exposure times so short that the animal can hold its breath, the $CT = k$ relationship may not hold).

III. TOXICOKINETICS

Following inhalation exposure, a small portion of phosgene hydrolyzes to hydrochloric acid (HCl) and carbon dioxide (CO_2) in the mucous coating of the upper respiratory tract (Diller, 1985), but in the moist atmosphere of the terminal spaces of the lungs more extensive hydrolysis is thought to occur (Beard, 1982). Although phosgene is only slightly soluble in water, once in solution it rapidly hydrolyzes to HCl and CO_2. However, phosgene reacts even faster with other functional groups such as amino, hydroxyl, and sulfhydryl groups (Jaskot *et al.*, 1991; Diller, 1985). Because of the affinity for lung tissue and the hydrolysis and acylation

TABLE 23.1. Physical and chemical data

Parameter	Data	Reference
Synonyms	Carbonyl chloride, carbon oxychloride, carbonic dichloride, chloroformyl chloride	Lipsett *et al.* (1994); US EPA (1986)

Molecular weight	98.92	Lipsett *et al.* (1994)
CAS registry no.	75-44-5	Lipsett *et al.* (1994)
Physical state	Colorless gas at room temperature	Budavari *et al.* (1989)
Odor threshold	0.5–1.5 ppm	NIOSH (1976)
Odor description	Pleasant, like newly mown hay	Dunlap (2001)
Vapor pressure	1215 mm Hg at 20°C	Budavari *et al.* (1989)
Vapor density	3.5 (air = 1)	NIOSH (2005)
Specific gravity	1.92 (water = 1)	*CRC Handbook* (1988)
Melting/boiling/flash point	−118°C/8.2°C/nonflammable	NIOSH (2005)
Water solubility	Slightly soluble in water, decomposes rapidly ($t_{1/2}$ = 0.26 s)	NIOSH (2005); US EPA (2003)
Reactivity	Reacts with alcohols, alkalis, ammonia, and copper	NIOSH (2005)
Conversion factors in air	1 ppm = 4.1 mg/m^3 1 mg/m^3 = 0.25 ppm	NIOSH (2005)

that take place in the pulmonary system, very little, if any, phosgene is dispersed to other locations in the body.

IV. MECHANISM OF ACTION

The toxicity of phosgene is due to both hydrolysis and acylation, with the latter being most important.

Diller (1985) accumulated data and described the clinical signs associated with phosgene exposure. Phosgene inhaled at concentrations of >1 ppm triggers a transient vagal reflex and causes shallow, rapid respiration with a decrease in respiratory volume and capacity, a decrease in arterial oxygen partial pressure, and bradycardia. The intensity varies greatly between individuals. Phosgene at >3 ppm becomes moderately irritating to the eyes and upper airways (cough) as some of the phosgene undergoes hydrolysis producing HCl.

The acylation reaction of phosgene with nucleophiles, such as amino, hydroxyl, and sulfhydryl groups, also occurs rapidly causing lipid and protein denaturation, irreversible membrane changes, and disruption of enzymatic function. These acylation effects observed at exposures >30 ppm·min produce pulmonary edema as the blood–air barrier becomes more permeable to blood plasma after a clinical latent period (1–24 h). This is called the clinical edema phase which is characterized by increasing inefficiency of gas exchange as more defects in the blood–air barrier occur allowing more accumulation of a protein-rich fluid. Clinical signs in this phase are labored breathing and a frothy expectorant. Progression usually results in death from paralysis of the respiratory center due to anoxemia with secondary cessation of heart function. If anoxemia is controlled, circulatory shock may still occur. At very high concentrations (>200 ppm), phosgene may cause death within a few minutes from ''acute cor pulmonale'' (acute overdistention of the right heart) often before pulmonary edema can develop.

Phosgene depletes lung glutathione, while glutathione reductase and superoxide dismutase increase as a result of the lung's response to injury. Upon exposure to phosgene, cellular glycolysis, oxygen uptake, intracellular ATP, and cyclic AMP are decreased and associated with increased permeability of pulmonary vessels leading to pulmonary edema. Phosgene exposure also causes increased lipid peroxidation and leukotriene synthesis, with no change in cyclooxygenase metabolism (TEMIS, 1997).

V. TOXICITY

A. Human

1. Noncancer

Reports of human phosgene poisonings present a relatively consistent set of clinical effects and sequelae (Stavarakis, 1971; Bradley and Unger, 1982; Misra *et al.*, 1985; Hegler, 1928; Delephine, 1922; Everett and Overholt, 1968; Regan, 1985; Galdston *et al.*, 1947a, b; Diller *et al.*, 1979; Herzog and Pletscher, 1955; Henschler, 1971; Kaerkes, 1992; Wells, 1985; Cordasco *et al.*, 1986). After acute phosgene exposure, brief (20 min) ocular and throat irritation, cough, nausea and vomiting, and dizziness are experienced, followed by a period (24 h) of apparent well-being. After this clinical latent phase, cough accompanied by expectoration,

a sensation of pain or tightness of the chest, shortness of breath, and a choking sensation are experienced. Clinical findings may include hemoconcentration, leukocytosis, rales, and pulmonary edema. After recovery, rapid, shallow breathing, shortness of breath on exertion, and a sense of decreased physical fitness may persist for months. Pulmonary emphysema may occur with repeated exposure to phosgene.

Diller and Zante (1982) identified ocular irritation, throat irritation, and cough as acute irritative effects of phosgene. In a follow-up analysis, Borak and Diller (2001) also performed an extensive literature review concerning human phosgene exposure, and concluded the following: the smell has no warning property; immediate irritation is not prognostic; pulmonary edema can appear several hours after exposure and the length of clinical latency can be used as a prognostic indicator (i.e. the shorter the time to effects, the worse the prognosis). The data also show that while concentration is the primary driver for the onset and severity of symptoms, duration of exposure also plays a role. Information synthesized from these reviews is presented in Table 23.2.

2. Cancer

Epidemiology studies have shown no increase in cancer in workers exposed to phosgene compared to controls. Polednak (1980) and Polednak and Hollis (1985) examined a cohort of chemical workers exposed to chronic low levels of phosgene as well as daily exposures above 1 ppm. Approximately 35 years after exposure to phosgene, no increase in overall mortality or mortality from cancer or respiratory disease was noted.

B. Animal

1. Noncancer

Animal studies with phosgene show a steep concentration–response curve for pulmonary edema and mortality. Acute animal studies also indicate little species variability as rats, mice, sheep, pigs, and dogs exposed developed similar clinical signs (dyspnea, labored breathing, pulmonary edema after a latent period) and histopathological lesions in the lungs. While there are no chronic animal data, subchronic studies indicate little accumulation of phosgene or increased severity of lesions with continuous exposure.

Bronchoalveolar lavage (BAL) fluid analysis may be used to assess pulmonary edema/lung injury following acute inhalation exposure to phosgene (Pauluhn *et al.*, 2007). Maximum protein concentrations in BAL fluid typically occur within one day post-exposure, followed by a latency period up to 15 h. For acute exposures, the *CT* relationship is constant over a wide range of concentrations. However, following noncontinuous, repeated exposure, increased tolerance to subsequent exposures is observed. Although limited, the longer-term data indicate that effects do not increase in severity over time, but do with increased concentration; suggesting that chronic toxicity is dependent on an acute pulmonary threshold dose. A comparison of BAL fluid constituents from acute inhalation studies in rats and dogs suggests that dogs are three to four times less sensitive to phosgene than rats (Pauluhn *et al.*, 2007).

A summary of selected lethal and nonlethal animal toxicity studies is presented in Tables 23.3 and 23.4, respectively.

2. Animal Cancer

A study by Selgrade *et al.* (1989) showed that exposure to very low levels of phosgene enhances the susceptibility of mice to lung tumor formation. Female C57BL/6 mice were exposed for 4 h to 0.01 ($N = 13$), 0.025 ($N = 28$), or 0.05 ppm phosgene ($N = 35$) and injected intravenously with syngeneic B16 melanoma cells on the following day. Controls were injected with tumor cells and exposed to air. The lungs were removed 2–3 weeks after tumor cell injection and the tumors were counted. Compared with controls, there was

TABLE 23.2. Summary of major signs and symptoms of phosgene inhalation exposure in humans (Diller and Zante, 1982; Borak and Diller, 2001)

Exposure					
Concentration	**Duration**	***C* × *T* product (ppm·min)**	**Acute effect**	**Time to onset of pulmonary edema**	**Time to death**
3 ppm	''Acute''	–	Throat irritation	–	–
4 ppm	''Acute''	–	Ocular irritation	–	–
4.8 ppm	''Acute''	–	Cough	–	–
1 ppm	20 min	20	–	–	–

12, 15, 16, 17, or 25	30 min	Mouse	LC_{50} = 19 (m) and 11.5 (f) ppm	Zwart *et al.* (1990)
1.0, 2.0, 3.0, 6.0, 9.0, or 13.5	30 min	Mouse	LC_{50} = 5.1 ppm	Kawai (1973)
Various	32 min	Mouse	LC_{50} = 15 ppm	Boyland *et al.* (1946)
6.4, 8.8, 9.0, or 12	60 min	Mouse	LC_{50} = 9.5 (m) and 5.0 (f) ppm	Zwart *et al.* (1990)
Various	64 min	Mouse	LC_{50} = 7 ppm	Boyland *et al.* (1946)
Various	8 min	Guinea pig	LC_{50} = 43 ppm	Boyland *et al.* (1946)
Various	32 min	Guinea pig	LC_{50} = 13 ppm	Boyland *et al.* (1946)
Various	64 min	Guinea pig	LC_{50} = 11 ppm	Boyland *et al.* (1946)

a statistically significant ($p < 0.05$) increase in the number of B16 melanoma tumors in the lungs of mice treated with 0.025 or 0.05 ppm phosgene. Exposure to 0.025 ppm was considered the lowest-observed-effect level. Extending the exposure time from 4 to 8 h did not alter the susceptibility to B16 tumors at 0.01 ppm.

VI. RISK ASSESSMENT

Many inhalation regulatory and guideline levels have been derived for phosgene. These values are summarized in Table 23.5, and the definitions and basis for the values are described in the footnotes to Table 23.5.

VII. TREATMENT

Treatments that have been proposed to prevent pulmonary edema in exposed-asymptomatic persons include steroids, ibuprofen, *N*-acetyl cysteine, and positive pressure airway ventilation. However, there is no known antidote for phosgene poisoning, and although animal studies suggest that these treatments may be effective, no clinical data are available to verify efficacy in humans (Borak and Diller, 2001). Asymptomatic individuals exposed to phosgene should be observed and evaluated to determine if symptoms develop. Vital signs and lung auscultation should be evaluated every 30 min and serial chest x-rays should be performed starting 2 h post-exposure. If no clinical signs occur and no signs of pulmonary abnormalities are detected on the x-ray after 8 h, patients may be discharged. If no x-ray is available, patients should be observed for 24 h post-exposure. If signs develop, patients should be treated. Therapy for the cardiogenic pulmonary edema may include positive airway pressure and monitoring (endotracheal intubation and mechanical ventilation with high oxygen concentrations), steroids, theophylline, diuretics, and antibiotics (in patients who develop bacterial pulmonary infections) (Borak and Diller, 2001).

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

Phosgene is a colorless gas at ambient temperature and pressure, and inhalation is the most important route of exposure for phosgene. Phosgene's odor has been described as similar to newly mown hay. Because of its mild upper

0, 0.1, 0.2, 0.5, or 1.0	240 min	Rabbit and guinea pig	LOAEL = 0.5 ppm based on ↑ LFP NOAEL = 0.2 ppm	Hatch *et al.* (1986)
0 or 1.0	240 min	Rat	LOAEL ≥ 1.0 ppm based on ↓ body wt, ↑ lung wts	Franch and Hatch (1986)
0 or 1.0	240 min	Rat	LOAEL ≥ 1.0 ppm based on ↑ pulmonary edema	Frosolono and Currie (1985)
0 or 1.0	420 min	Rat	LOAEL ≥ 1.0 ppm based on ↑ lung wts	Franch and Hatch (1986)
0.125 or 0.25	4 h/day, 5 days/week for 17 days	Rat	LOAEL = 0.25 ppm based on ↑ lung wts and ↑ NPSH and G6PD activity NOAEL = 0.125 ppm	Franch and Hatch (1986)
0, 0.1, 0.2, 0.5, or 1.0	0.1 ppm for 5 days/week; 0.2 ppm for 5 days/week; 0.5 ppm for 2 days/week; 1.0 ppm for 1 day/week All exposed 6 h/day for up to 12 weeks	Rat	LOAEL = 0.1 ppm based on reversible lung histopathology; ↑ lung displacement volume NOAEL = none	Kodavanti *et al.* (1997)
0, 0.1, 0.2, or 0.5	0.1 and 0.2 ppm for 5 days/week; 0.5 ppm for 2 days/week All exposed 6 h/day for up to 12 weeks	Rat	LOAEL = 0.1 ppm based on ↓ bacterial clearance after infection with *S. zooepidemicus* NOAEL = none	Selgrade *et al.* (1995)

LOAEL – lowest observed adverse effect level; LFP – lavage fluid protein; BAL – bronchoalveolar lavage; NOAEL – no observed adverse effect level

TABLE 23.5. Standards and guidelines for phosgene

	Exposure duration				
Guideline	**10 min**	**30 min**	**1 h**	**4 h**	**8 h**
AEGL-1[a]	NA	NA	NA	NA	NA
AEGL-2[a]	0.60 ppm	0.60 ppm	0.30 ppm	0.08 ppm	0.04 ppm
AEGL-3[a]	3.6 ppm	1.5 ppm	0.75 ppm	0.20 ppm	0.09 ppm
ERPG-1[b]	NA				
ERPG-2[b]	0.2 ppm				
ERPG-3[b]	1.0 ppm				
EEGL (NRC)[c]			0.2 ppm		0.02 ppm (24 h)
NIOSH IDLH[d]	2 ppm				
NIOSH STEL[e]	0.2 ppm (15 min ceiling)				
NIOSH REL[e]					0.1 ppm (10 h)
OSHA PEL-TWA[f]					0.1 ppm
ACGIH TLV[g]					0.1 ppm
MAK (Germany)[h]					0.02 ppm
MAC (Netherlands)[i]					0.02 ppm
RfC[j]					7.33×10^{-5} ppm

[a]AEGL (Acute Exposure Guideline Levels) (NRC, 2002) represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h. Three levels – AEGL-1, AEGL-2 and AEGL-3 – are developed for each of five exposure periods (10 and 30 min, 1 h, 4 h, and 8 h) and are distinguished by varying degrees of severity of toxic effects. The three AEGLs tiers are defined as follows.

AEGL-1 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure. The AEGL-1 is not recommended for phosgene because the odor threshold is at the concentration approaching AEGL-2 values, and odor cannot be used as a warning.

AEGL-2 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape. The AEGL-2 for phosgene is based on chemical pneumonia in rats (Gross *et al.*, 1965).

AEGL-3 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening health effects or death. The AEGL-3 is based on concentrations causing no death in rats or mice (Zwart *et al.*, 1990).

[b]ERPG (Emergency Response Planning Guidelines, American Industrial Hygiene Association) (AIHA, 2006).

The ERPG-1 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing other than mild, transient adverse health effects or without perceiving a clearly defined objectionable odor. The ERPG-1 for phosgene is not derived.

The ERPG-2 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing or developing irreversible or other serious health effects or symptoms that could impair an individual's ability to take protective action. The ERPG-2 for phosgene is based on pulmonary pathology and function studies suggestion that concentrations exceeding 0.2 ppm may produce serious pulmonary effects in some individuals.

The ERPG-3 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing or developing life-threatening health effects. The ERPG-3 for phosgene is based on acute animal inhalation data indicating that concentrations exceeding 1 ppm for 1 h may by expected to produce pulmonary edema and possible mortality in a heterogeneous human population.

[c]EEGL (Emergency Exposure Guidance Levels, National Research Council) (NRC, 1985). The EEGL is the concentration of contaminants that can cause discomfort or other evidence of irritation or intoxication in or around the workplace, but avoids death, other severe acute effects, and long-term or chronic injury. The EEGL for phosgene is based on the ''most relevant animal exposure studies'' (Gross *et al.*, 1965; Rinehart and Hatch, 1964) and studies suggesting that animals do not tolerate phosgene at 0.2 ppm administered 5 h/day for 5 days (Cameron and Foss, 1941; Cameron *et al.*, 1942).

[d]IDLH (Immediately Dangerous to Life and Health, National Institute of Occupational Safety and Health) (NIOSH, 2005) represents the maximum concentration from which one could escape within 30 min without any escape-impairing symptoms, or any irreversible health effects. The IDLH for phosgene is based on acute inhalation toxicity data in humans (Diller, 1978).

[e]NIOSH REL-STEL (Recommended Exposure Limits – Short Term Exposure Limit) (NIOSH, 2005) is defined analogous to the ACGIH TLV-TWA.

[f]OSHA PEL-TWA (Occupational Health and Safety Administration, Permissible Exposure Limits – Time Weighted Average) (NIOSH, 2005) is defined analogous to the ACGIH-TLV-TWA, but is for exposures of no more than 10 h/day, 40 h/week.

[g]ACGIH TLV-TWA (American Conference of Governmental Industrial Hygienists, Threshold Limit Value – Time Weighted Average) (ACGIH, 2006) is the time-weighted average concentration for a normal 8-h workday and a 40-h workweek, to which nearly all workers may be repeatedly exposed, day after day, without adverse effect. The ACGIH TLV-TWA was derived from the marked potential for pulmonary irritation after exposure to phosgene at concentrations greater than 0.1 ppm; this conclusion was based on two studies. Gross *et al.* (1965) found that phosgene at 0.5 ppm for 2 h caused some pathologic changes in the lungs of rats and Cameron *et al.* (1942) found that 0.2 ppm, 5 days/week for 5 consecutive days caused pulmonary edema in 41% of animals exposed (goats, cats, rabbits, guinea pigs, rats, and mice).

[h]MAK [Maximale Argeitsplatzkonzentration (Maximum Workplace Concentration)] Deutsche Forschungsgemeinschaft (German Research Association) 2000 is defined analogous to the ACGIH-TLV-TWA.

[i]MAC [Maximaal Aanvaaarde Concentratie (Maximal Accepted Concentration)]. SDU Uitgevers (under the auspices of the Ministry of Social Affairs and Employment), The Hague, The Netherlands 2000 is defined analogous to the ACGIH-TLV-TWA.

[j]US EPA (US Environmental Protection Agency Reference Concentration) (US EPA, 2005). The RfC is an estimate of a continuous inhalation exposure concentration to people (including sensitive subgroups) that is likely to be without risk of deleterious effects during a lifetime. The RfC was developed by using incidence of the lung histopathological findings from Kodavanti *et al.* (1997) in a benchmark dose analysis.

respiratory, eye, and skin irritancy, and a mildly pleasant odor, an exposed victim may not actively seek an avenue of escape before lower respiratory damage has occurred (Currie *et al.*, 1987a; Lipsett *et al.*, 1994). Pulmonary edema is the cause of death after a clinical latent period of 24 h (Franch and Hatch, 1986). Phosgene exhibits a steep concentration–response curve, and little species variability with regard to lethality. Recent data (Pauluhn, 2006a, b, c; Pauluhn *et al.*, 2007) suggest that with regard to physiology of the respiratory tract and acinar structure of the lung, dogs are more similar to humans than rodents. Thus, it may be most appropriate to base future phosgene risk assessments on data extrapolation from dogs to humans when dog data are available.

CHAPTER 24

Other Toxic Chemicals as Potential Chemical Warfare Agents

JIRI BAJGAR, JIRI KASSA, JOSEF FUSEK, KAMIL KUCA, AND DANIEL JUN

I. INTRODUCTION

For the development of new chemical weapons (CWs), a number of criteria are necessary: a research base including scientists and equipment, access to information, chemical and arms industries, and of course financial support. It is noteworthy that the development of CWs is possible not only for states but also for terrorists. It is necessary to stress that the intention of this chapter is not to describe new CWs or chemical warfare agents (CWAs) but to comment on a number of trends in toxicology with the aim that these chemicals may be proposed for inclusion in the Chemical Weapons Convention (CWC) verification mechanisms. However, the text of the CWC is comprehensive and covers practically all chemicals that may be misused as CWs.

The objective of this chapter is to briefly describe a number of chemicals that could be used as toxic compounds or CWAs against humans.

II. GENERAL

A. Chemical Weapons Convention: Article II, Definitions and Criteria

1. ''Chemical weapons'' means the following, together or separately:
   (a) Toxic chemicals and their precursors, except where intended for purposes not prohibited under this Convention, as long as the types and quantities are consistent with such purposes;
   (b) Munitions and devices, specifically designed to cause death or other harm through the toxic properties of those toxic chemicals specified in subparagraph (a), which would be released as a result of the employment of such munitions and devices;
   (c) Any equipment specifically designed for use directly in connection with the employment of munitions and devices specified in subparagraph (b).

2. ''Toxic chemical'' means:

Any chemical which through its chemical action on life processes can cause death, temporary incapacitation or permanent harm to humans or animals. This includes all such chemicals, regardless of their origin or their method of production, and regardless of whether they are produced in facilities, in munitions or elsewhere.

Therefore, CWAs can be characterized as toxic chemicals. Initially, it is difficult to differentiate between the research aimed at protection against (defensive) and development of new CWAs (offensive). Both actions deal with the synthesis of chemicals, based on either information or ideas, or incidentally synthesized toxic compounds. A typical example is the synthesis of organophosphates (OPs) by G. Schrader, originally dedicated to the development of new pesticides. Another example of the development of a new CW would be the synthesis of OP compounds of the V series. After synthesis, the compound in question will be characterized chemically and biologically, and sometimes modified to increase its military properties (toxicity, physicochemical properties, e.g. stability, volatility, etc.). Then the compound can be studied in detail for its pharmacological and toxicological characteristics by using more convenient species and routes of administration, etc. At this stage, it is practically impossible to decide if the research is offensive or defensive though some indications would lead to the opinion that the direction is offensive, e.g. when attention is given to its efficacy following percutaneous or inhalation administration. Studied methods of dispersion under field conditions are an indication of an offensive approach; testing for protective qualities under real conditions can be regarded as a defensive approach. However, further steps like production of large quantities and weaponization are clearly offensive. It is useful to compare the time from synthesis to production or use of certain CWs. After the synthesis of phosgene and diphosgene (1812 and 1887), their use in 1916 was observed; a similar situation was observed for mustard (1866–1917); for CS, this period was shortened (synthesis in 1928 and use in 1950); VX was synthesized in the early 1960s and weaponized in 1968. The big question is, what is meant by

large quantities? This can be solved using the approach contained in CWC. Quantities would be also compared with the contamination density prescribed for different CWAs – for yperite it is 19 tons/km^2 for percutaneous administration and 4 tons/km^2; for VX (percutaneous) it is 2 tons/km^2; for sarin and BZ (by inhalation) this value is about 0.5–0.6 tons/km^2 (Robinson, 1985). Of course, it does not apply to the synthesis or production for terroristic purposes.

Apart from this ''classic'' approach, it would be possible to ''improve'' the properties of known CWs, e.g. microencapsulation so that less stable or highly volatile substances can be used. Nanotechnology offers new possibilities, as described recently by Price and Peterson (2008). The other option is to improve penetration using known enhancers like dimethyl sulfoxide (DMSO). While the percutaneous toxicity (expressed as LD_{50} in rats) of one of the toxic organophosphates – *O*-isopropyl *S*-2-diisopropylaminoethyl methyl phosphnothiolate – is 59.1 μg/kg, in mixture with DMSO this value is decreased to 10.1 μg/kg (Bajgar, 1989).

Binary technologies are also acknowledged; however, the development of other methods of synthesis is not excluded (the more steps there are involved in synthesis the more difficult it is to control the process). An alternative is to search for compounds either used or synthesized already. From the groups of highly toxic chemicals these could be fluorophosphorylcholines (unstable) or toxic silatrans. In the group of medicaments, there are also highly toxic chemicals like cardiac glycosides (digoxin), sympathomimetics (noradrenalin), and myorelaxans (succinylcholine, curare derivatives). The other compounds to be included are insulin, cantharidin, aconitin, galantamine, pancuronium, pipecuronium, some derivatives of vitamin D (cholecalcipherol), some antibiotics, cytostatics drugs, etc. It is necessary to point out that their use is limited, e.g. parenteral administration of insulin or delayed acute effect of cytostatics. A possible candidate would be centrally acting alpha 2-adrenergics having antihypertensive and sedative properties. All bioregulators are of great interest especially in connection with the increased possibility of obtaining significantly sufficient quantities for military and terroristic purposes. All these examples are more or less hypothetical and require further testing. There exist some groups of compounds whose misuse is more probable and some of these chemicals are under suspicion (not proved) of being introduced into military arsenals. An illustrative but not exhaustive list of warfare agents is given below.

III. SPECIFIC AGENTS

A. Carbamates

Compounds in this group have a broad spectrum of toxicities – from relatively slightly toxic (carbaryl) to highly toxic compounds comparable with nerve agents (T-1123)

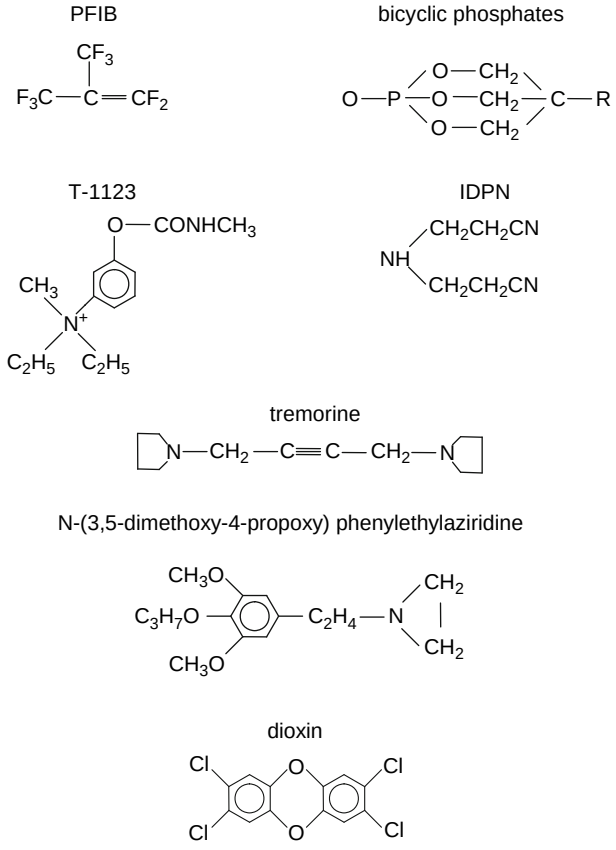

FIGURE 24.1. Chemical formulae of some toxic chemicals.

(Figure 24.1). As described by Robinson (1971), carbamates including T-1123 had been studied by British and Canadians as CW agents since 1940. Other carbamates were described in detail by Badawi and Hassan (1995). They are well absorbed by the lungs, gastrointestinal tract, and the skin. The clinical representation of poisoning is similar to that for nerve agents; perhaps with more expressed peripheral signs because of quaternary nitrogen in the molecule (T-1123) and therefore penetration through blood–brain barrier is difficult (Bajgar and Patocka, 1976; Fusek *et al.*, 1996a). The basic mechanism of action is reversible inhibition of cholinesterases. However, inhibition in case of carbamates is based on carbamylation of the active center of the acetylcholinesterase (AChE). Spontaneous decarbamylation is a relatively quick process (ca 24 h) and carbamylated cholinesterases are resistant to the effect of reactivators. Therefore, the treatment is symptomatic, preferably using only atropine. These difficulties would be reasons for military use (Patocka, 1990).

B. Dioxin

Dioxin is one of the most toxic low molecular weight compounds (Figure 24.1). Its oral LD_{50} for guinea pigs is 2–20 µg/kg, for monkeys 2 µg/kg, for rats 18–60 µg/kg and the dose assessed for humans (subcutaneous administration) is about 107 µg/kg (Bajgar, 2006; Patocka, 2004). Dioxin interferes with the metabolism of porphyrins (and the main symptom of poisoning is derived from an increase of porphyrins in the organism – porphyria cutanea tarda) by induction of delta aminolevulate synthetase. Dioxin also has carcinogenic, hepatotoxic, nephrotoxic, terratogenic, and embryotoxic effects and causes dermal changes (except porphyria cutanea tarda), including chloracne, followed by development of cachexia. There is no specific antidote, making treatment very difficult and symptomatic. Effects of dioxin following acute administration are relatively delayed. This is a limiting factor for its use as a CW. It should be mentioned that dioxin is one of the polychlorinated biphenyls and dibezofuranes that appears to be problematic for the environment (Bajgar, 2006; Sofronov *et al.*, 2001). Dioxin was used to poison Ukraine's President Viktor A. Yushchenko.

C. Bicyclic Phosphates

These compounds were used as flame retardants, antioxidants, stabilizers, or for spectroscopic studies. At present, they are being replaced by other compounds that are not so highly toxic. In a chemical structure (Figure 24.1), when R is substituted by isopropyl, toxicity is very close to sarin ($LD_{50} = 0.18$ mg/kg, i.m. in rat). Bicyclic phosphates act rapidly, in minutes following parenteral administration. Clinical symptoms include behavioral perturbation, muscle weakness, hyperactivity, muscle tremor, and later convulsions passing to paralysis. Intoxication is slightly similar to poisoning with nerve agents but with a different mechanism of action, i.e. probably connected with GABA receptors. Specific antidotal therapy does not exist but a relatively good effect was observed following administration of benzodiazepines (Bajgar, 2006; Patocka, 2004).

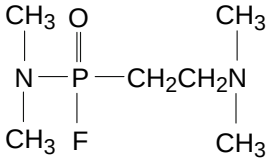
D. PFIB

PFIB is a chemical 2 of the CWC and therefore contained in Schedule 2A. Its chemical structure is shown in Figure 24.1. PFIB is produced by thermal decomposition of Teflon, and has high inhalation toxicity characterized by pulmonary edema. PFIB has been characterized in more detail in an *ASA Newsletter* (Patocka and Bajgar, 1998). Therapy is symptomatic.

E. Organophosphates

There are other known OPs having relatively high toxicity like amiton (Tetram®), Armin®, dimefox (Hanane, Terrasytam®), paraoxon (E 600®), TEPP (Tetron®), etc. These compounds could be used for military and terrorist purposes; however, for the military to replace these substances would be uneconomic. However, a new group of OP compounds has been described and characterized. This class of OPs can be described in general as 2-dialkylaminoalkyl-(dialkylamido)-fluorophosphates. In their chemical formulae, structural similarities with the group of so-called G-compounds (i.e. sarin, soman, tabun) and V-compounds (i.e. VX and others) are found. These chemicals were designated as GP or GV compounds (Bajgar, 1992; Bajgar *et al.*, 1992; Fusek *et al.*, 1996b; Halámek *et al.*, 1995). The toxicities of the most toxic derivatives are shown in Table 24.1. Intoxication with this compound has practically the same syndromes as observed with nerve agents. Treatment with atropine and reactivators is difficult because of the absence of the ability to reactivate

TABLE 24.1. LD_{50} values of GV in mice and rats following various routes of administration

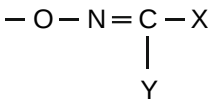


LD_{50} (µg/kg) with their 95% confidence limits

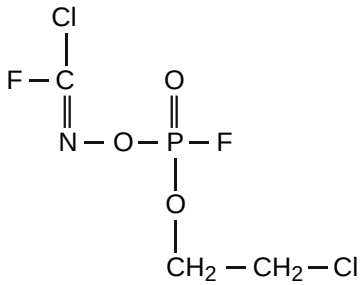
Route of administration	Mice	Rats
i.v.	27.6 (25.6–29.4)	11 (8.5–17.6)
i.m.	30.5 (28–55)	17 (15.5–23.6)
s.c.	32 (29–53)	21 (18–26)
p.o.	222 (194–255)	190 (881–272)
p.c.	not tested	1366 (881–3,138)

inhibited cholinesterases by common oximes (Fusek *et al.*, 1996b; Kassa, 1995; Kassa *et al.*, 2006; Kuca *et al.*, 2006). The lack of reactivation is different from that observed for soman (aging, dealkylation) and it is probably caused by steric hindrance in the cavity of cholinesterase. The volatility of GV compounds is between VX and sarin and therefore these agents are effective when penetrating through uniforms. This is an example of an intermediate volatility agent.

There are sources of information that suggest a new nerve agent known as Novichok or Novichok 5. In 1982, the Soviets began a secret CW development program codenamed Foliant. The program had the apparent goal of developing new binary nerve agent weapons. Novichok has been described as a new toxic agent and it is very difficult to treat the poisoning (practically impossible; the toxicity was about ten times greater than VX agent). Its exact chemical structure is unknown. The Novichok class of chemicals almost certainly belongs to the organophosphorus compounds containing the dihaloformamide group (Bajgar, 2006):



where X and Y are Cl, F, Br or even a stable pseudohalogen like –CN. An example of Novichok could be as follows:



F. Toxins

Toxins are prohibited by the Biological Weapons Convention [Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on their Destruction, signed in London, Moscow, and Washington on April 10, 1972]. Their isolation from natural sources is sometimes difficult but some toxins are possible to synthesize using biotechnology. Their toxicity is very high, e.g. inhalation LD_{50} of botulinum toxin and tetanotoxin lies in tens of $mg/kg/m^3$. Some other known toxins are saxitoxin, tetrodotoxin, batrachotoxin, etc. They are highly effective by other routes of administration as well. A quick effect is observed during 10–20 min, beginning with muscle weakness, insensitivity of tongue, fingers and mouth, followed by muscle paralysis, including respiratory muscles. Specific therapy is unknown, so it is necessary to save basic life functions (using artificial ventilation, etc.). When death is not observed within the first 24 h after exposure, the prognosis is relatively good.

Other types of toxins are mycotoxins – mostly trichothecenes. Their production is straightforward by fermentation, they are highly stable and therefore may be stored for a long time. They are effective by all routes of administration, including inhalation and percutaneous absorption. Their toxicity is not very high and the effect is prolonged. Symptoms of intoxication are vary greatly, including fever, hemorrhagic eruption, bleeding, necrotic angina, decrease of leukocytes, sepsis, etc. Some toxins are carcinogenic, teratogenic, mutagenic, and hepatotoxic, while some of them also have a neurotoxic effect. There is no specific therapy and treatment is symptomatic only (Patocka, 2004). They caused an epidemic (alimentary toxic aleukia) in the former USSR and were the subject of discussion for possible use in Asia (yellow rain).

In August 1981, based on limited physical evidence, the USA announced that trichothecene mycotoxins had been used – but the findings were less than convincing to the scientific community and the issue became extremely contentious. This controversy was never totally resolved and no definitive evidence was found (Bajgar, 2006).

The question of neurotoxins and neurotoxicity mechanisms was extensively described by Segura-Aguilar and Kostrzewa (2006). Some of them are described below.

1. Aziridines

These are 2-(trisubstituted phenyl) ethyl aziridines that induce changes in behavior and motoric influencing neurotransmission. Their toxicity is not very high and they play a role in modeling a number of diseases. The effect is long lasting, and mostly irreversible without specific antidotal treatment. Some aziridines, e.g. *N*-(3,5-dimethoxy-4-propoxy) phenylethylaziridinium (Figure 24.1), have convulsive properties. Convulsions are treatable with benzodiazepines (Herink, 1977, 1995).

2. Tremorine

This relatively simple compound (Figure 24.1) is known to induce symptoms similar to Parkinson's disease in mice and monkeys. The onset of symptoms, such as salivation, miosis, lacrimation, muscle weakness, bradycardia, was evident within 15–30 min after tremorine administration. Typical symptoms are muscle twitch or fine tremor of the head and extremities, decrease in body temperature, and analgesia. This stage usually lasts for a few hours. Therapy is symptomatic only and not very effective (Bajgar, 2006; Patocka, 2004).

3. IDPN

This is one of the compounds (Figure 24.1) isolated from *Lathyrus sativus*, also called lathyrogenic substances. The toxicity of IDPN (and also of aziridines and tremorine)

expressed as LD_{50} is not very high, as it lies in the range of tens of mg/kg. Following administration of lower doses of IDPN, a condition called ''waltzing syndrome'' is characterized by a circling movement in both directions, and sometimes movement of the head similar to chorea (also hyperkinetic syndrome). High doses of IDPN are known to produce conjunctivitis and edema of the eyelids. In severe cases, it causes hemorrhages in the retina with the possibility of blindness. Hyperkinetic syndrome is irreversible and does not react to therapy (Bajgar, 2006).

G. Bioregulators

A variety of agents have the potential to be used as weapons of bioterrorism. These weapons have been used in wars from the start of recorded history (Metcalfe, 2002). The development of technologies on a modern militarily significant scale was initiated in several countries during the period between the two world wars (Roffey *et al.*, 2002). However, as a result of modern technology, the risks are greater now and the outcomes are more serious (Henderson, 1999). Today, agents include not only different toxins but also a new group of compounds and bioregulators. Bioregulators are naturally occurring organic compounds that regulate diverse cellular processes in all organisms. There are substances normally found in the body that regulate normal biological processes, such as blood pressure, heart rate, breathing, muscle contraction, temperature, mood control, consciousness, sleep, emotions, immune responses, and other critical functions. Their characteristics include activity in extremely low doses and they frequently have rapid effects. Unlike traditional disease-causing biowarfare agents that take hours and days to act, bioregulators can act within minutes after administration. There is comprehensive knowledge available on these compounds, because all these compounds work as regulators and modulators of all vital biochemical pathways, linked with physiological functions of living organisms. If bioregulators were exploited for the purpose of terrorism, they could potentially cause profound pathophysiological effects. The main group of bioregulators under discussion includes different biochemicals such as neurotransmitters, hormones, proteolytic enzymes, and others. The common property of all bioregulators is their ability to induce biological effects and a consequential rapid fall in their concentrations in tissues. The problem is their route of administration (Patocka and Merka, 2004).

A brief description of some bioregulators from a military viewpoint is given below. These peptides have been chosen based on the criteria of bioregulators intended for terrorism and warfare agents (Bokan *et al.*, 2002).

1. Angiotensins

Angiotensins regulate blood pressure and participate in sustaining hypertension (Mazzolai *et al.*, 1998). The principal effect of angiotensin is to stimulate the synthesis of aldosterone and elevate blood pressure via vasoconstriction of smooth muscles in arterioles.

2. Bombesin

Bombesin is a tetradecapeptide isolated from the skin of the amphibian frog *Bombina bombina* (Anastasi *et al.*, 1971). It has been proposed that bombesin-related peptides may be released from the gastrointestinal tract in response to ingested food, and that they bridge the gut and brain via neurocrine means to inhibit further food intake (Merali *et al.*, 1999).

3. Bradykinin

Bradykinin is a vasoactive nonapeptide which is the most important mediator generated by the kinin system and it is involved in inflammation processes (Calixto *et al.*, 2000). Kinins so far identified include bradykinin and kallidin. They cause local increases in the permeability of small blood vessels. Bradykinin is a potent stimulator of pain receptors in the skin and has a powerful influence on stimulating smooth muscle contraction, inducing hypotension, and increasing blood flow and permeability of capillaries (Cyr *et al.*, 2001).

4. Endorphins

Endorphins are peptides which bind to the neuroreceptors in the brain to give relief from pain (Terenius, 1992). Beta-endorphin is the most active, and it is about 20 times more potent than morphine.

5. Endothelins

Endothelins constitute a family of peptides (Hart and Hart, 1992). They are very potent endogenous vasoconstrictors and vasopressors and are secreted by various cells and tissues in the human body. Of the three isoforms, endothelin-1 (ET-1) is one of the most potent contractors of vascular smooth muscles (Miller *et al.*, 1993). Endothelins have very similar structures and biological properties to sarafotoxins (Kloog and Sokolovsky, 1989), and the toxic peptides are obtained from the venom of mole vipers (Atractaspidae).

6. Enkephalins

Enkephalins are endogenous pentapeptides. Two enkephalins have been identified: Met-enkephalin and Leu-enkephalin. Both enkephalins are relatively weak analgesics, which activate all opioid receptors, but appear to have the highest affinity for the delta-receptors. In the CNS, enkephalins have been found in many areas but predominantly those associated with nociception (Przewlocki and Przewlocka, 2001).

7. Histamine Releasing Factor (HRF)

HRF is one of the many immune system protein molecules called cytokines that trigger allergic reactions. Unlike other cytokines, HRF stimulates basophils to release histamine (MacDonald, 1996).

8. Neuropeptide Y (NPY)

NPY is the most abundant neuropeptide in the brain. Its concentration is many times higher than the other neuropeptides. It is a member of a family of proteins that include pancreatic polypeptide, peptide YY, and seminalplasmin. In addition to its function of stimulating feeding behavior, several other physiologic roles have been assigned to NPY, including involvement in circadian rhythms, sexual function, anxiety responses, and vascular resistance (DiBona, 2002; Halford and Blundell, 2000).

9. Neurotensin

Neurotensin is an endogenous peptide neurotransmitter inducing a variety of effects, including analgesia, hypothermia, and increased locomotor activity. It is also involved in regulation of dopamine pathways. Neurotensin is found in endocrine cells of the small intestine, where it leads to secretion and smooth muscle contraction (Moore and Black, 1991).

10. Oxytocin

Oxytocin in a nine amino acid peptide that is synthesized in hypothalamic neurons and transported down through axons of the posterior pituitary for secretion into blood. Oxytocin has three major physiological effects: stimulation of milk ejection, stimulation of uterine smooth muscle contraction at birth, and establishment of maternal behavior.

11. Somatostatin

Somatostatin is a cyclic tetradecapeptide hormone, characterized as the major physiological inhibitor of growth hormone released from the pituitary, but inhibits the release of many other physiologically important compounds, including insulin, glucagon, gastrin, and secretin (Wolkowitz, 1994).

12. Substance P

Substance P is an 11 amino acid polypeptide, and physiologically significant member of a family of three related peptides known as neurokinins. The best known of these is substance P. The specific receptor subtypes corresponding to these three neurokinins are known (Sandberg and Iversen, 1982). These neurotransmitters appear to play a key role in the regulation of emotions, and antagonists of their receptors may be novel psychotropic drugs of the future. Koch *et al.* (1999) demonstrated that substance P, in combination with thiorphan, administered as an aerosol, is highly potent and extremely toxic. Exposure to the substance at extremely low air concentrations may result in incapacitation of humans.

H. Vasopressin

Vasopressin, also called antidiuretic hormone (ADH), is a cyclic nonapeptide hormone, which is released from the posterior pituitary. Its primary function in the body is to regulate extracellular fluid volume by affecting renal handling of water. Specific actions include inhibition of diuresis, contraction of smooth muscles, stimulation of liver glycogenesis, and modulation of ACTH release from pituitary gland. ADH belongs to the family of vasoactive peptides involved in normal and pathological cell growth and differentiation.

I. Thyrotropin, Thyroliberin, or Thyroid-Stimulating Hormone (TSH)

Thyrotropin, thyroliberin, or thyroid-stimulating hormone (TSH) is a peptide released by the anterior pituitary gland that stimulates the thyroid gland to release thyroxine (Ladram *et al.*, 1994). The release of TSH is triggered by the action of thyrotropin-releasing factor (TRF), a peptidic substance found in the hypothalamus of the brain and influencing the secretion of glandula thyroidea.

Not long ago, most bioregulators had been unavailable in the amount needed for terroristic attacks or military operations. However, by the end of the 20th and beginning of the 21st century there had been intensive developments in biomedical sciences, biotechnology, and chemical engineering in the pharmaceutical industry, and because of the revolution in the science and technology of drug discovery, the control of bioregulators will be significantly complicated.

In the near future, genomic and proteomic methods will stimulate increasing use of computer modeling techniques to identify new biologically active compounds and then determine their mode of action. Currently, new compounds are being generated in large numbers by combinatorial methods and assayed for potential activity, and it seems likely that genomic and proteomic methods will make these compounds accessible in amounts necessary for terroristic use. This is a very disagreeable situation and quite a new problem for the control of chemical and biological weapons.

IV. NONLETHAL WEAPONS

Nonlethal weapons can be of a chemical, physical, or pharmacological character (Hess *et al.*, 2005). Nonlethal weapons are designed and primarily employed so as to incapacitate personnel or material while minimizing fatalities, permanent injury to personnel, and undesired damage to property and the environment (Pearson, 2006). Weapons used for physically immobilizing personnel include lasers, microwave impulses, ultrasound, electric current, nets, solidifying foams, and sliding gels. For chemical weapons, immobilizing gases and irritants and smelly bombs can be considered. For pharmacological immobilization, ketamine, benzodiazepines, and onset accelerators are the compounds of real interest. Basic requirements for the use of immobilizing drugs are necessary, such as minimal cardiovascular and respiratory side effects; easy administration, primarily by inhalation; rapid onset; high biological accessibility and well-controlled effects; and specific antagonists which can

be used within a large therapeutic range. These drugs are used for animal immobilization, using narcotizing blowpipes, darts, or guns. This group is also called calmatives. The compounds considered include ketamine and phencyclidine, alpha-2-agonist, opioids – etorphine, fentanyl, carfentanyl – and muscle relaxants (Hess *et al.*, 2005; Patocka and Cabal, 2001; Patocka and Fusek, 2004).

A. Genetic and Ethnic Weapons

Another possible threat is modification of the effects of commonly used chemicals or biological agents. The first administration produces no toxic effect but the second administration of the same or another compound causes damage.

The present genetic material of a human population could be misused. Recent advances in biological research could eventually lead to the creation of new types of chemical weapon targeting a specific group of human beings with common genetic characteristics, as is perhaps the case with certain ethnic groups. Biologically, there are more similarities than differences between human beings. However, differences do exist and if the data on ethnic differences are known, the selective effect of different chemicals to the groups cannot be excluded. Some examples are cited here to support this contention. Glucoso-6-phosphate dehydrogenase, the enzyme that catalyzes dehydrogenation of glucoso-6-phosphate to 6-phosphogluconate, has been genetically determined and found to be low or nonexistent in some groups (more frequently black people or Scandinavians). It is connected with the male chromosome and in these men, hyperbilirubinemia is observed. Following administration of some normal medicaments, like acetylsalicylic acid, sulfadimidine, chinine, chloramphenicol, etc., a hemolytic syndrome is induced. Individuals with other pathologic states, e.g. chronic methemoglobinemia, will be more sensitive to drugs that are able to increase the level of methemoglobin. These drugs include analgesics, antipyretics, nitrates, etc. Deficiency of alpha-1-antitrypsine can cause increased sensitivity to asphyxiation agents. Plasma cholinesterase activity is also genetically determined and individuals with decreased cholinesterase activity are more sensitive to myorelaxants. It is very probable that these people will be more sensitive to nerve agents (Bajgar, 2006).

V. CONCLUDING REMARKS AND FUTURE DIRECTION

This chapter describes that misuse of knowledge of pharmacology and toxicology is possible and can be applied to all activities of humankind. The task is to be well informed in cases where it is important to know the best protection and therapeutic means, and to control all activities connected with the synthesis and possible availability of chemical weapons/chemical warfare agents to nonqualified as well as qualified persons.

CHAPTER 25

Ricin and Abrin

MANASHI BAGCHI, SHIRLEY ZAFRA-STONE, FRANCIS C. LAU, AND DEBASIS BAGCHI

I. INTRODUCTION

Human toxicity of castor beans (ricin) and jequirity seeds (abrin) has been acknowledged throughout medical history, worldwide. Ricin and abrin are natural protein toxins isolated from plant seeds *Ricinus communis* and *Abrus precatorius*, respectively (Olsnes *et al.*, 1974). Ricin and abrin share extensive identity and structural similarities of two polypeptide chains: an A-chain subunit and a larger B-chain subunit linked by a disulfide bond (Rutenber and Robertus, 1991; Rutenber *et al.*, 1991; Weston *et al.*, 1994). The mechanisms of toxic action of abrin and ricin are also similar in which the B-chain achieves cellular recognition and binding function to facilitate toxin transport across the cell membrane whereas the A-chain, once internalized by the cell, blocks protein synthesis by catalytically modifying the ribosomes. Both toxins ultimately kill target cells in animal or cell culture models by both necrosis and apoptosis (Rutenber and Robertus, 1991; Rutenber *et al.*, 1991; Weston *et al.*, 1994; Tahirov *et al.*, 1995). The toxicity of ricin and abrin causes severe irritation to the eyes and adnex causing congestion and conjunctivitis after administration of very dilute solutions in microgram quantities of toxins (Audi *et al.*, 2005). Ricin and abrin are toxic to mice by injection in the range 1–20 μg/kg body weight (Stirpe and Battelli, 1990). Along with their toxic potential, the relative ease of ricin and abrin production makes them potential chemical warfare agents or terrorists' weapons.

II. BACKGROUND

A. Botanical Description

Ricin was found by Stillmark in 1889 as the first plant lectin derived from the seeds of the castor plant, *Ricinus communis* L., a member of the Euphorbiaceae or spurge family. Other members of this family include the popular houseplants poinsettia (*E. pulcherrima*), and the croton species. The term ''castor bean'' is used commonly to refer to both the plant and seed of *R. communis*. *Ricinus communis* commonly grows along streams and riverbeds in addition to subtropical locations high in nutrients. *Ricinus communis* is a coarse perennial, 10–13 m tall in the tropics, with a stem 7.5–15 cm in diameter, but usually found as an annual in the temperate regions at 1–3 m tall. Castor beans are ovoid, glossy, 0.5–1.5 cm long, carunculate, and vari-color with base colors white, gray, brownish-yellow, brown, red, or black, with the outer pattern gray or brown to black. The pattern varies from fine to coarse, veined or finely dotted to large splotches (Reed, 1976). Castor beans are glossy, oval in shape, and speckled with black or brown and white spots, and yield an average 50% oil content (Reed, 1976). Castor beans are processed throughout the world to make castor oil. India currently produces the largest amount of castor oil, followed by China and Brazil (Oil World, 2006). Castor oil is yellowish in color and is used for either medicinal applications or industrial processing of paints, varnishes, and sebacic acid (Kim *et al.*, 1999; Jackwerth and Bruening, 2007; Twilley *et al.*, 1967).

Ricin can be made from the waste material left over from processing castor oil. It can be made in either powder, mist, or pellet form, or it can be dissolved in water or weak acid. Ricin is a stable substance under normal conditions, but can be inactivated by heat above 80°C.

Abrin is derived from the plant *Abrus precatorius* L., a member of the Fabaceae (Leguminosae) or pea family. Common names include jequirity seed, rosary pea, crab's eye, precatory pea, and licorice vine. Other names include Gunga or Goonteh or Indian licorice. Originating in India and other parts of tropical Asia, *A. precatorius* is a high-climbing, twining, or trailing woody vine with slender herbaceous branches. The seeds have a remarkably uniform weight of 1/10th of a gram, and were used ancient times for the purpose of weighing gold.

Abrin can be made in the form of a powder, a mist, a pellet, or it can be dissolved in water. Powdered abrin is a stable substance yellowish-white in color.

B. Historical Uses of Ricin and Abrin

Since ancient times, *R. communis* and *A. precatorius* have been used to treat numerous aliments worldwide. Castor beans have been found in Egyptian tombs dating from 4,000 BC and Egyptian temple gardens dating from 1,500 BC (Jacob and Jacob, 1993). In the pharmacopeia of ancient Egypt, castor oil, bean, and root were also mentioned in

medical papyri. The products of castor plant were used in medicinal recipes to treat headaches, stomach ache, tooth ache, skin disease, and constipation. Purified castor oil has also been ingested as a human nutritional supplement, emetic, or purgative (Scarpa and Guerci, 1982; Olsnes, 2004).

In folk medicine, the products of *A. precatorius* have been used orally as a herbal remedy to quicken labor, induce abortion, as an oral contraceptive, and as treatment for diabetes, eye inflammation, kidney inflammation, and pain relief. Jequirity seeds are also used in the manufacture of rosaries, necklaces, and other ornamental articles. However, alongside their beneficial applications for human health, the plants that harbor ricin or abrin are also closely associated with death. Ricin and abrin seeds have been used in Asia for centuries to kill animals, chiefly cattle and other livestock, and have a notorious history as an agent in criminal poisoning (Olsnes, 2004). Over 750 cases of human poisoning with castor beans or ricin, including homicide and suicide attempts, have been reported during the 20th century (Balint, 1974; Rauber and Heard, 1985). One of the most famous cases of ricin poisoning was in 1978 when Georgi Markov, a Bulgarian dissident, was poisoned by an injection of ricin pellet with an improvised umbrella (Balint, 1974; Rauber and Heard, 1985). Most documented case reports involving abrin poisoning involve accidental or intentional ingestion of jequirity seeds.

C. Ricin Use in Warfare

Several aspects of ricin, such as its potent toxicity, lack of specific antidote, and wide availability in large quantities from castor bean meal, have contributed to the international regulation of the toxin as a potential ''weapon of mass destruction''. If made into a partially purified material or refined into a terrorist or warfare agent, ricin could be used to expose people through air, food, or water.

During World War I, the US War Department investigated ricin for chemical warfare use (Audi *et al.*, 2005). At that time it was being considered for use either as a toxic dust or as a coating for bullets and shrapnel. However, the toxic dust concept could not be adequately developed, and the coated bullet/shrapnel concept would violate the Hague Convention of 1899. The war ended before it was weaponized.

During World War II, the USA and Canada resumed the study of ricin, now given the military symbol Whiskey (W), for use in cluster bombs (Audi *et al.*, 2005). Although different bomb concepts were produced, the end conclusion was that it was no more economical than using phosgene, a highly toxic colorless gas used to manufacture pesticides.

Despite ricin's extreme toxicity and utility as an agent of chemical/biological warfare, it is extremely difficult to limit the production of the toxin. Therefore, ricin is currently monitored as a Schedule 1 toxic chemical under the Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and on Their Destruction (CWC), and the international use of ricin or abrin as weapons is prohibited under the 1972 Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on Their Destruction (BTWC) Procedural Report and Rolling Text: Ad Hoc Group 23rd session (April 23–May 11, 2001).

In the USA, the Centers for Disease Control and Prevention (CDC) lists ricin on its second highest priority list as an agent for terrorism. Therefore, possession or transfer of ricin, abrin, or genes encoding functional forms of these toxins is regulated by the CDC Select Agents and Toxins Program, US Department of Health and Human Services. Ricin is also categorized as a biological agent under the federal Biological Weapons Anti-Terrorism Act of 1989, which can impose lifetime prison sentences and unspecified fines for its production, acquisition, or possession (CDC, 2003).

III. TOXICOKINETICS

As relatively large proteins, ricin and abrin are not likely to be extensively absorbed from the gastrointestinal tract. In animal studies, ingested ricin was absorbed within 2 h and accumulated mainly in the liver and spleen (Ishiguro *et al.*, 1983, 1992). In mice, intravenously injected ricin was distributed mainly to the spleen, kidneys, heart, and liver, while intramuscularly injected ricin was found to localize in draining lymph nodes (Fodstad *et al.*, 1976; Griffiths *et al.*, 1986). When injected post-intravenously in rodents, 70% of ricin was excreted and less than 2% was recovered in feces or urine over the first 24 h (Blakey *et al.*, 1988; Ramsden *et al.*, 1989). When ricin is post-ingested, approximately 20 to 45% is excreted unchanged in the feces over the first 72 h (Ishiguro *et al.*, 1983, 1992). In rodent studies, ricin was eliminated as degraded proteins, with majority excretion in the urine (Blakey *et al.*, 1988; Ramsden *et al.*, 1989).

Similar to ricin, abrin is poorly absorbed from the intestine, due to its high molecular weight (approximately 65 kDa). Some studies have suggested that abrin is slowly absorbed in which the majority of the toxin was digested within 3 h (Gunsolus, 1955; Lin *et al.*, 1970). However, even a small amount of undigested toxin is still sufficient to cause severe complications and death. After parenteral injection, abrin has been shown to be considerably more toxic than oral administration (Gunsolus, 1955). When injected post-intravenously in mice, abrin is widely distributed in tissues with the greatest percentage found in the liver, followed by the blood, lungs, spleen, kidneys, and heart (Fodstad *et al.*, 1976). When injected into rats via intraperitoneal route, the highest percentage was found predominantly in the liver, followed by the kidneys and blood (Lin *et al.*, 1970). In rodent studies, abrin elimination is almost exclusively renal

as low molecular weight degradation products (Fodstad *et al.*, 1976).

IV. MECHANISM OF ACTION

A. Structural Description

Ricin and abrin share extensive structural similarities. They are composed of two polypeptide chains: an *N*-glycosidase A-chain subunit or effectomere and a larger lectin B-chain subunit or haptomere, linked by a disulfide bond. The A-chains of abrin and ricin have a 102 conserved amino acid homology (Rutenber and Robertus 1991; Rutenber *et al.*, 1991; Weston *et al.*, 1994). Ricin and abrin belong to a group of type 2 RIPs (ribosome-inactivating protein) toxins which inhibit protein synthesis by specifically inactivating eukaryotic 28s ribosomes (Frigerio and Roberts, 1998; Ishiguro *et al.*, 1964a, b; Nicolson and Blaustein, 1972). Other type 2 RIPs toxins include bacterial and plant toxins such as viscumin, pulchellin, modeccin, and volkensin. Abrin-c shares an 86% identical primary amino acid sequence of the A-chains with pulchellin, a highly potent toxin produced in the seeds of *Abrus pulchellus* (Silva *et al.*, 2005; Olsnes, 2004).

Ricin, also known as ricin-D or *R. communis* agglutinin, is a 60–65 kDa globular protein that makes up 1–5% by weight of the castor bean (Ishiguro *et al.*, 1964a, b; Funatsu and Funatsu, 1970; Stirpe and Battelli, 2006). The ricin B-chain is composed of 262 amino acid residues (approximately 34 kDa) containing two lectins capable of binding to galactose-containing glycoproteins and glycolipids expressed on the cellular surface (Lord *et al.*, 1994, 2003). The ricin A-chain is an *N*-glycosidase composed of 267 amino acid residues (approximately 32 kDa) (Lord *et al.*, 1994, 2003). Both chains are glycoproteins containing mannose carbohydrate groups. Ricin A-chain and B-chain are held together by a single interchain disulfide bond, which, upon reduction, remains a relatively weak, noncovalent association (estimated dissociation constant of 10^{-6} M) (Lewis and Youle, 1986).

B. Mechanism of Toxic Action

The mechanisms of toxic action of abrin and ricin are similar. The B-chain attains cell recognition and binding function to facilitate toxin transport across the cell membrane, whereas the A-chain, once internalized by the cell, blocks protein synthesis by catalytically modifying the ribosomes. Both toxins ultimately kill target cells in animal or cell culture models by both necrosis and apoptosis.

Ricin facilitates entry into the cytosol by binding glycoproteins to the cell surface using the galactose binding property of its ricin B-chain (Olsnes, 2004; Olsnes *et al.*, 1974a,b; Sandvig and Olsnes, 1982). The ricin A-chain inhibits protein synthesis by irreversibly inactivating eukaryotic ribosomes through removal of a single adenine residue from the 28S ribosomal RNA loop contained within the 60S subunit. This process prevents chain elongation of polypeptides in protein synthesis and leads to cell death (Olsnes, 2004; Olsnes *et al.*, 1974a,b, 1975; Sandvig and Olsnes, 1982). Ricin toxicity results from the inhibition of protein synthesis, but other mechanisms, including apoptosis pathways, direct cell membrane damage, alteration of membrane structure and function, and release of cytokine inflammatory mediators are also noted (see Figure 25.1) (Day *et al.*, 2002; Hughes *et al.*, 1996).

Abrin exerts its toxic action in the same way as ricin. The abrin B-chain avidly binds to a variety of cell types, in particular reticuloendothelial cells which bear the appropriate mannose receptors. The abrin B-chain also binds to the galactosyl-terminated receptors on the cell membrane to allow the entry of the abrin A-chain. Once internalized, the abrin A-chain is transported from the cell membrane to the ribosomes, where it catalytically inactivates the 60S ribosomal subunit by removing adenine from positions 4 and 324 of 28S rRNA, thereby inhibiting protein synthesis and causing cell death (Stripe and Barbieri, 1986).

Ricin and abrin poisoning can also be explained by hemagglutination. *Ricinus communis* and *A. precatorius* contain the glycoprotein lectins known as ricin communis agglutinin (RCA) and abrus agglutinin, respectively. Their toxic effect is due to its affinity for the red blood cell and other parenchyma cells, such as liver and kidney cells, leading to agglutination and subsequent hemolysis (Lin *et al.*, 1981; Hart, 1963; Lord *et al.*, 1994; Barbieri *et al.*, 1993). Compared to ricin, RCA is a relatively weak cytotoxin due to its poor gastrointestinal absorption (Olsnes *et al.*, 1974a,b); however, it is a powerful hemagglutinin shown to cause clinically significant hemolysis only after intravenous administration (Balint 1974; Olsnes *et al.*, 1975). Another route is endothelial cell damage or vascular leak syndrome, which causes an increase in capillary permeability causing fluid and protein leakage and tissue edema (Baluna *et al.*, 1999). The A-chain causes organ and tissue lesions that might be the result of vascular disturbances induced by the toxin rather than a direct effect of the toxin itself. Regardless of the route of administration, clinical trials have shown that administration of ricin or abrin A-chain immunotoxin caused vascular syndrome characterized by hypoalbuminemia and edema (Baluna *et al.*, 1999).

V. TOXICITY

Numerous laboratory studies in mammals have demonstrated that ricin and abrin are highly toxic and potentially fatal to animals and humans. Major symptoms of both ricin and abrin poisoning are dependent on the route of exposure, the dose (or number of beans) received, or the content of toxin in the seed (or age of seed). Upon ingestion, toxicity is dependent on the degree of mastication: if the bean was

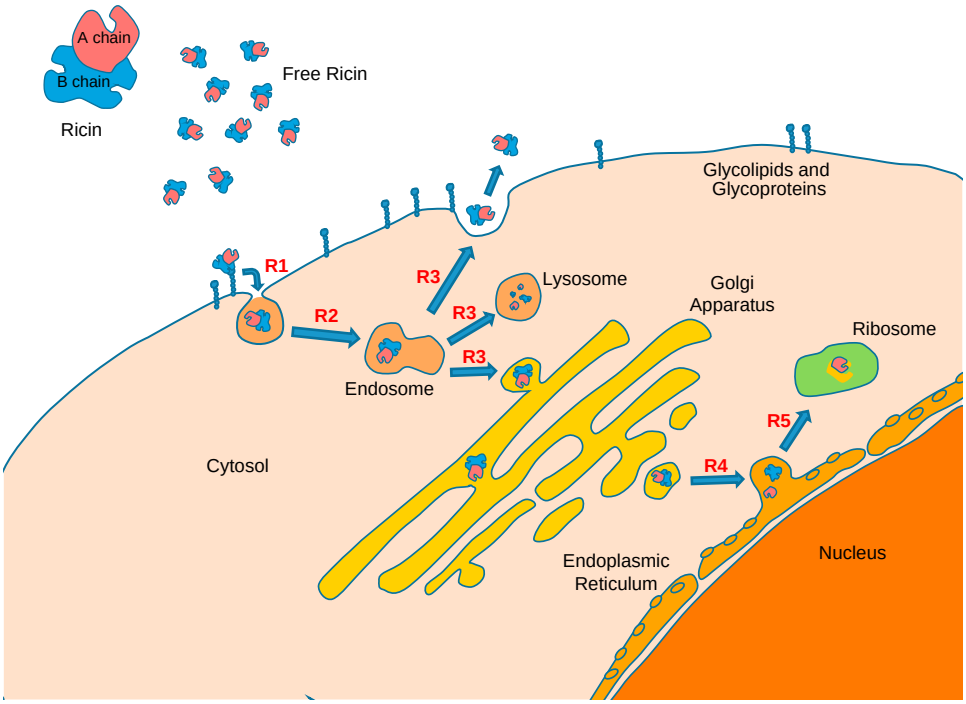

FIGURE 25.1. Mechanism of toxic action of ricin. Ricin B-chain binds to a range of cell surface glycolipids or glycoproteins possessing specific galactose residues and enters the cell by endocytosis (R1); ricin is transported into early endosomes (R2); ricin acquires one of three routes (R3): separation from the endosomal membrane to undergo exocytosis, dissociation from the endosomal binding sites for degradation in the lysosome, or transport to the Golgi apparatus to undergo retrograde transport; from the Golgi apparatus the ricin is transported to the endoplasmic reticulum. The disulfide bond is reduced and the ricin A-chain is separated from the ricin B-chain. It is still unclear as to whether reduction occurs in the endoplasmic reticulum or in the reducing environment of the cytosol (R4) (Lord *et al.*, 2003); ricin A-chain is translocated into the cytosol where it interacts with the ribosome to catalyze the depurination reaction with the rRNA by removing an adenine from position 4324 of the 28S rRNA in the 60S ribosomal subunit. The rRNA is incapable of binding protein elongation factors and thus protein synthesis is disabled (R5).

damaged before consumption or swallowed whole. Intact jequirity seeds are likely to pass through the gastrointestinal tract without harm, due to its impervious shell-like coating, while if the seed was chewed, damaged or even immature, the toxin may be readily absorbed (Davis, 1978; Hart, 1963; Gunsolus, 1955).

A. Experimental/Animal Data

1. Oral Administration

In oral administration of ricin in mice, the approximate LD_{50} dose is 20 mg/kg with time to death up to 85 h (Fodstad *et al.*, 1979). In a rat study, ricin was absorbed in the lymphatic blood vessels and largely distributed in the spleen and liver within 2 h of ingestion (Ishiguro *et al.*, 1983). The study also demonstrated that up to 72 h after ingestion, approximately 20–45% of ricin is excreted in the feces (Ishiguro *et al.*, 1992).

Few animal studies exist on the toxicity of orally administered abrin. The majority of reports indicate jequirity seed poisoning in humans, which is discussed later in the chapter.

2. Parenteral Administration

Ricin and abrin are toxic to mice by parenteral routes in the range 1–20 µg/kg body weight (Stirpe and Battelli, 1990). Injected ricin has been shown to kill laboratory animals in a concentration and time-dependent manner with steep lethality curves. In laboratory mice, the approximate LD_{50} dose and time to death are, respectively, 5 µg/kg and 90 h by intravenous injection, 22 µg/kg and 100 h by intraperitoneal injection, and 24 µg/kg and 100 h by subcutaneous injection (Godal and Fodstad, 1984; Fodstad and Olsnes, 1976). In rats administered 5 µg ricin intramuscularly, LD_{50} dose and time to death are 33–50 µg/kg body weight and a maximum of 35 h, respectively (Leek *et al.*, 1989). The minimum lethal doses via intravenous injection range from 0.7 to 2 µg/kg in mice and 1 to 1.75 µg/kg in dogs (Fodstad *et al.*, 1979). When the dosage of ricin injected intravenously (120 µg/kg body weight) to mice is exceeded, results show hemolytic uremic syndrome, such as thrombotic microangiopathy, hemolytic anemia, and acute renal failure (Fodstad *et al.*, 1979).

With the exception of mice, abrin exposure via intravenous routes demonstrates a significant interspecies variation

in susceptibility: rats 0.35–0.5 μg/kg; guinea pigs 0.4–0.5 μg/kg; rabbits 0.03–0.06 μg/kg; and dogs 1.2–1.35 μg/kg with a dose-dependent survival time of 10 h maximum (Fodstad *et al.*, 1979). The minimum lethal dose in mice was 0.7 μg/kg (Gill, 1982). Intravenous administration of abrin to mice and dogs caused weakness, shivering, anorexia, weight loss, edema, ascites, and rectal bleeding (Fodstad *et al.*, 1979). Intraperitoneal injection of abrin LD_{50} was found to be 0.02 mg/kg body weight in mice (Budavari, 1989). Subcutaneous injection of abrin into mice, guinea pigs and rats caused increases in the AST, ALT, and isocitric dehydrogenase activities are indicative of liver damage (Niyogi, 1977).

3. Inhalation Exposure

Lung deposition and lethality after ricin or abrin inhalation are significantly influenced by particle size, in which low micron-sized particles can deposit deeper into the respiratory tract resulting in higher mortality (Griffiths *et al.*, 1995a, b). Mice exposed to ricin particle sizes less than 5 μm have an LD_{50} about 3–5 μg/kg, while the LD_{50} of rats is 3.7 μg/kg. In laboratory mice, the time to death was 60 h by inhalation (Fodstad *et al.*, 1979). Toxicity results from direct injury to the epithelial membrane with primary toxicity occurring to the type I and II pneumocytes (Griffiths *et al.*, 1995a, b; Brown and White, 1997). In mice, rats, and primates, high doses of inhaled ricin cause death due to hypoxemia resulting from massive pulmonary edema, acute destructive alveolitis as well as necrosis/apoptosis of the lower respiratory tract epithelium (Wilhelmsen and Pitt, 1996; Roy *et al.*, 2003; Gareth *et al.*, 1995). Primates exposed to inhaled ricin developed progressive dyspnea 20–24 h after 21–42 μg/kg dosing of 1–2 μm size particles with mortality occurring within 48 h (Wilhelmsen and Pitt, 1996). Postmortem findings included diffuse pulmonary edema with multifocal areas of necrosis and inflammation (Griffiths *et al.*, 1995a, b; Brown and White, 1997). All injury was significantly worse in the distal airways and alveoli.

The LD_{50} in rats for abrin inhalation was 3.3 μg/kg (Griffiths *et al.*, 1995a, b). Rats exposed to varying concentrations of abrin by inhalation remained clinically well for 18–24 h, then developed general malaise, as well as lethargy, anorexia, piloerectation, and respiratory difficulties. In severely poisoned animals, blood-stained fluid exuded from the nostrils. Examination showed that inhaled abrin caused pulmonary edema, alveolitis, diffuse airway inflammation, necrosis, and diffuse alveolar flooding. Interestingly, ricin caused abundant apoptotic figures in the lung, which were absent following the inhalation of abrin (Griffiths *et al.*, 1995a, b).

4. Dermal and Ocular Exposure

In animal studies, low ricin concentrations caused irritation and the development of conjunctivitis. In ocular exposure, pseudomembranous conjunctivitis occurred following application of ricin solutions in concentrations of 1:1,000–1:10,000 (Audi *et al.*, 2005). In rabbits administered 0.5 μg of ricin, conjunctivitis occurred lasting one week after introduction, while after 1.5 μg of ricin was administrated, corneal lesions with keratitis occurred lasting 11 days after exposure (OSRD, 1946). In dermal exposure of ricin to mice, toxicity was observed at the 50 μg spot. Few animal studies exist on the toxicity of abrin via dermal or ocular exposure. However, clinical reports show abrin exposure to the eye causes severe inflammation of the conjunctiva, along with localized necrosis.

B. Human Data/Clinical Observations

Data about the effects of ricin and abrin poisoning on humans are limited. Due to initial symptoms resembling gastroenteritis or respiratory illness, it is often difficult to discern from other illnesses. Therefore, it is important to observe for epidemiological signs indicative of chemical release.

1. Oral Administration

Most literature reports refer to castor bean or jequirity seed ingestion, with very few reports on ingestion of pure ricin or abrin. As mentioned earlier, toxicity via ingestion of castor bean or jequirity seed is dependent on the degree of mastication. Intact jequirity seeds are likely to pass through the gastrointestinal tract without harm, while if the seed was chewed or damaged the toxin may be readily absorbed (Davis, 1978; Hart, 1963). In human ingestion of castor beans, the lethal dose (LD_{50}) is estimated to be 1–20 mg ricin/kg of body weight, or approximately eight beans for adults (Challoner and McCarron, 1990). In children, one to three seeds can be fatal (Wedin *et al.*, 1986). However, other clinical reports have shown symptomatic poisoning in patients ingesting 15 to 30 beans, and death associated with only two beans ingested (Challoner and McCarron, 1990).

In clinical observations, symptoms may occur approximately within 4–6 h and as late as up to 10 h (Challoner and McCarron, 1990; Klaim and Jaeger, 1990; Rauber and Heard, 1985; Kopferschmitt *et al.*, 1983; Bispham, 1903). Initial symptoms include vomiting, bloody diarrhea, heartburn, abdominal pain, and oropharyngeal irritation. Other less common symptoms include melena and hematemesis. Subsequent features suggest fluid and electrolyte loss, with dehydration, sweating, hypotension, and circulatory collapse. Upon lab testing, abnormalities may include leukocytosis, elevated transaminases and creatinine kinase, hyperbilirubinemia, renal insufficiency, and anemia. In fatal cases, death occurs on the third day or later. Postmortem findings revealed that ingestion of castor beans mainly caused diffuse intestinal hemorrhagic lesions as well as histology consistent with the appearance of apoptotic cell death seen in both humans and animals (Balint, 1974; Challoner and McCarron, 1990; Klaim and Jaeger, 1990;

Rauber and Heard, 1985; Kopferschmitt *et al.*, 1983; Bispham, 1903).

In ingestion of jequirity seeds, the human fatal dose is estimated to be 0.1–1.0 μg/kg of body weight, or approximately one fully masticated jequirity seed may be fatal in either adult or child (Houston, 1982). Children attracted to the brightly-colored seeds are usually exposed to the abrin poison and may chew, suck, or swallow them. However, other reports have shown symptomatic poisoning in patients ingesting 10 to 20 beans, and death associated with only two beans ingested (Swanson-Biearman *et al.*, 1992). In clinical observations, initial symptoms may occur in less than 6 h but usually are delayed for 1–3 days. Early features commonly include nausea, severe vomiting, bloody diarrhea, abdominal pain, and colic. Gastrointestinal bleeding and/or hematemesis may also follow. Patients may exhibit tachycardia, headaches, dilated pupils, irrationality, hallucinations, drowsiness, and weakness. Tetany, tremors, seizures, fever, and dysarrhythmias have also been noted (Davis, 1978; Fernando, 2001). In fatal cases, death has occurred up to 4 days after the onset of symptoms. Postmortem findings revealed that ingestion of jequirity seeds mainly affected the gastrointestinal tract, with hemorrhage, erythema, and edema (Davis, 1978; Fernando, 2001).

2. Parenteral Exposure

Parenteral exposure is one of the most lethal routes of ricin and abrin exposure. In humans, the estimated lethal dose of ricin is 1–10 μg/kg body weight following inhalation or injection (Smallshaw *et al.*, 2002). In clinical observations, onset of symptoms can be delayed for as much as 10–12 h with weakness developing as early as within 5 h of injection. Symptoms can include dizziness, nausea, anorexia, fever, headache, hypotension, and abdominal pain (Fodstad *et al.*, 1976, 1979), and may persist for 8–10 days (CDC, 2006; Fine *et al.*, 1992). Intramuscular injection causes severe local necrosis of muscle and regional lymph nodes with moderate visceral organ involvement. In fatal cases, death has occurred within 3 days. In laboratory testing, results may include increased levels of liver transaminases, amylase, creatinine kinase, hyperbilirubinemia, myoglobinuria, and renal insufficiency (Fine *et al.*, 1992; Targosz *et al.*, 2002). Postmortem findings, in both animal studies and clinical reports, include focal hemorrhage in the intestines, brain, myocardium, and pleura (Godal *et al.*, 1984; Klaim and Jaeger, 1990; Fodstad *et al.*, 1976). Necrosis, hemorrhaging, and edema of the lymph nodes, kidneys, and intestines were also found.

Several cases of ricin exposure via parenteral routes were documented. A 20-year-old man was admitted to the hospital 36 h after subcutaneously injecting castor bean extract. Symptoms were characteristic of nausea, weakness, dizziness, and myalgias. He developed anuria and hypotension, followed by hepatorenal and cardiorespiratory failure, and died 18 h following admission. In another report, a 36-year-old chemist extracted ricin from a castor bean and self-administered intramuscular injections for the purpose of scientific curiosity. He developed fever, nausea, anorexia, mild elevation of liver function tests, and tissue damage at the site of injection. Symptoms persisted for approximately 8–10 days and then improved, at which point he was discharged from the hospital. Finally, the most famous report of ricin poisoning was the ‘‘umbrella murder’’ in which Georgi Markov, a Bulgarian dissident, was thought to have been assassinated with an extremely small amount of ricin. His symptoms included immediate pain at the injection site, weakness within 5 h, and fever and vomiting within 24 h. His clinical course worsened to include shock, multiorgan failure, and death over the next 3 days (Romano *et al.*, 2007).

Human parenteral toxicity for abrin is approximately 0.1–1 μg/kg (Romano *et al.*, 2007). However, based on clinical trials on abrin-immunotoxin use for cancer treatment, the human minimum lethal dose by intravenous injection was estimated to be >0.3 μg/kg without occurrence of serious adverse effects (Gill, 1982).

3. Inhalation Exposure

In humans, inhalation is another one of the most lethal forms of ricin and abrin exposure. In clinical reports, inhalation of ricin typically leads to cough and respiratory distress followed by pulmonary edema, respiratory failure, and multisystem organ dysfunction. Weakness and influenza-like symptoms of fever, myalgia, and arthralgia were also reported (Ellenhorn and Barceloux, 1997; Kortepeter and Parker, 1999; Eitzen *et al.*, 2001). Initial symptoms may occur as early as 4–6 h after exposure, but serious symptoms could also occur as late as 24 h after exposure. The initial symptoms include difficulty breathing, shortness of breath, chest tightness, and cough. The symptoms of ricin poisoning are likely to progress rapidly (generally over 12–24 h) and include problems such as worsening respiratory symptoms and pulmonary edema, and eventually respiratory failure. This rapid progression of symptoms and illness is noticeably different than what typically occurs with most common colds and cough-type illnesses (Ellenhorn and Barceloux, 1997; Kortepeter and Parker, 1999; Eitzen *et al.*, 2001).

A case reported in the 1940s accounted for the unintentional aerosol exposure of ricin in humans. The symptoms were characterized by the onset of the following within 4–8 h: fever, chest tightness, cough, difficulty breathing, nausea and arthralgias, followed by diaphoresis. In another report, workers exposed to castor bean dust from castor oil processing plants developed an allergic set of symptoms which was characterized by nasal and throat congestion, eye irritation, hives and skin irritation, chest tightness, and, in some severe cases, wheezing. Another recent incident occurred in February 2008, in which inhaled ricin resulted in a 57-year-old man becoming comatose for one month. In Las Vegas, Nevada, a large quantity of ricin contained in vials was found in the victim’s hotel room, along with castor beans,

''anarchists' cookbooks'' marked at sections detailing how to make ricin, and firearms. The victim summoned an ambulance, complaining of respiratory distress, where he later developed kidney failure and slipped into a coma for a month. The ricin-exposed man's cousin was later indicted alleging he tried to conceal the production and possession of ricin when attempting to collect the evidence during the investigation (Ellenhorn and Barceloux, 1997; Kortepeter and Parker, 1999; Eitzen *et al.*, 2001; CNN, 2008).

Symptoms of abrin inhalation are similar to ricin exposure. Initial symptoms of abrin poisoning by inhalation may occur within 8 h of exposure. Symptoms include respiratory distress, fever, cough, nausea, and tightness in the chest. Heavy sweating may follow as well as pulmonary edema. Finally, low blood pressure and respiratory failure may occur, leading to death (Ellenhorn and Barceloux, 1997; Kortepeter and Parker, 1999; Eitzen *et al.*, 2001).

4. Dermal and Ocular Exposure

Allergic reaction may occur after handling an intact castor bean plant or exposure to the castor bean dust (Metz *et al.*, 2001; Thorpe *et al.*, 1988). There are no reports of human toxicity by skin contact with abrin. Abrin in powder or mist form can cause redness and pain of the skin and the eyes.

C. Oxidative Stress and DNA Damage by Ricin and Abrin

Preliminary studies indicate that ricin induces an oxidative stress in the livers of mice (Muldoon and Stohs, 1991). Few studies have examined other biochemical alterations that may be associated with ricin toxicity. Oxidative stress, induced by free radicals and reactive oxygen species, has been widely implicated as a mechanism in the toxicity of ricin (Muldoon and Stohs, 1991; Omar *et al.*, 1990).

It is well known that lipid peroxidation, DNA single-strand breaks, and other forms of DNA damage occur in response to oxidative stress (Ames *et al.*, 1982). Depletion of reduced glutathione also commonly precedes or accompanies lipid peroxidation and oxidative stress (Muldoon and Stohs, 1991; Omar *et al.*, 1990). In an *in vivo* study, the effects of ricin administered orally on hepatic lipid peroxidation, nonprotein sulfhydryl content, and DNA single-strand breaks were assessed in mice (Muldoon *et al.*, 1992). The incidence of hepatic DNA damage increased 2.9-, 2.8-, and 2.4-fold relative to control values at 24, 36, and 48 h post-treatment with ricin, respectively. Hepatic nonprotein sulfhydryl concentration decreased significantly from 51 to 65% to control values at 24, 36, and 48 h post-treatment (Figures 25.2 and 25.3).

Earlier studies have also shown that ricin induces oxidative stress in mice, resulting in increased urinary excretion of MDA and formaldehyde (FA) (Muldoon *et al.*, 1994). Other toxicants have been shown to induce oxidative stress by macrophage activation with subsequent release of reactive oxygen species and tumor necrosis factor alpha (TNF-α).

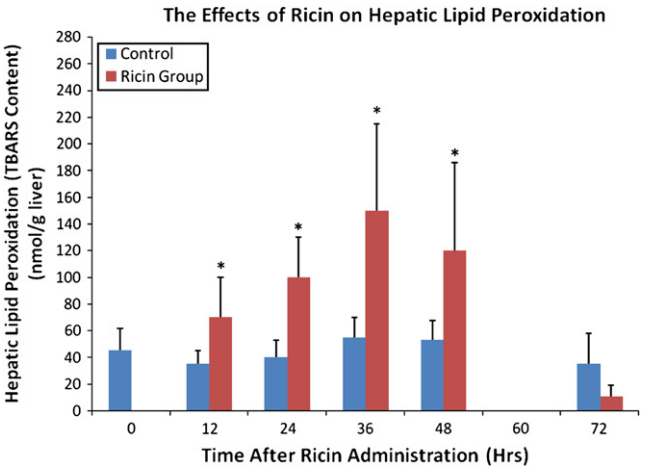

FIGURE 25.2. The effects of ricin on hepatic lipid peroxidation. Concentration of thiobarituric acid reactive substances (TBARS) in the liver was compared between control (untreated) mice and mice treated with 25 μg ricin/kg. Values are the averages of 4–10 animals ± SD. *$p < 0.05$ with respect to corresponding control group.

Therefore, the ability of TNF-α antibody to modulate ricin-induced urinary carbonyl excretion as well as hepatic lipid peroxidation, glutathione depletion, and DNA single-strand breaks was assessed (Muldoon *et al.*, 1994). Ricin-induced urinary MDA and FA were reduced significantly in mice receiving antibody (15,000 U/kg) 2 h before treatment with ricin (5 μg/kg). At 48 h following ricin treatment, MDA and FA concentrations in the urine of TNF antibody-treated

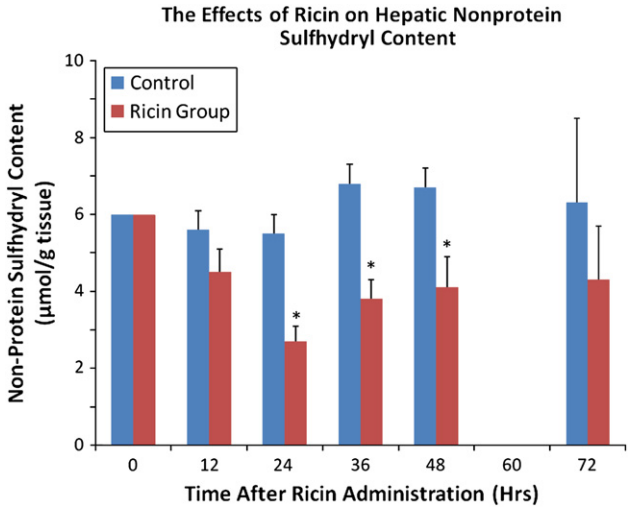

FIGURE 25.3. The effects of ricin on hepatic nonsulfhydryl content. Concentration of nonsulfhydryl content in the liver was compared between control (untreated) mice and mice treated with 25 μg ricin/kg. Protein was removed by precipitation with 2% TCA final concentration. Values are the averages of 3–7 animals ± SD. *$p < 0.05$ with respect to corresponding control group.

mice decreased 25.7 and 53.2%, respectively, relative to ricin-treated mice receiving no antibody (Figures 25.4 and 25.5). In addition, anti-TNF-α (1,500 U/kg) significantly decreased hepatic lipid peroxidation and DNA single-strand breaks, induced by 5 μg ricin/kg, by 49.3 and 44.2%, respectively (Table 25.1). The results suggest that macrophage activation and subsequent release of TNF-α are involved in ricin toxicity.

D. *In Vitro* Studies and Chemoprotectants

The abilities of potential chemoprotectants to inhibit cytotoxicity of ricin have been determined *in vitro*, using the macrophage cell line J744A.1. Six compounds were tested: α- and β-galactopyranosylamine; *N*-bromoacetyl-α-D-galactopyranosylamine; *N*-bromoacetyl-β-D-galactopyranosylamine; *N*-bromoacetylglucopyranosylamine; and *N*-bromoacetylmannopyranosylamine (Figure 25.6) (Hassoun *et al.*, 1992, 1996). Of the six compounds tested, only *N*-bromoacetyl-α-D-galactopyranosylamine and *N*-bromoacetyl-β-D-galactopyranosylamine exhibited significant activity against ricin toxicity, as indicated by the release of lactate dehydrogenase (LDH) and aspartate aminotransferase (AST) (Figures 25.7a and b and 25.8a and b). Enzyme assays were performed within 1 week of media collection. Assays for determining activities of LDH and AST were performed according to the method of Moss *et al.* (1986). The α-isomer provided greater protection against ricin toxicity and also exhibited less inherent cytotoxicity in the absence of ricin, as compared to the β-isomer. Neither the α- and β-galactopyranosylamines nor the glucose and mannose analogs were promising as potential chemoprotectants (Hassoun *et al.*, 1992, 1996).

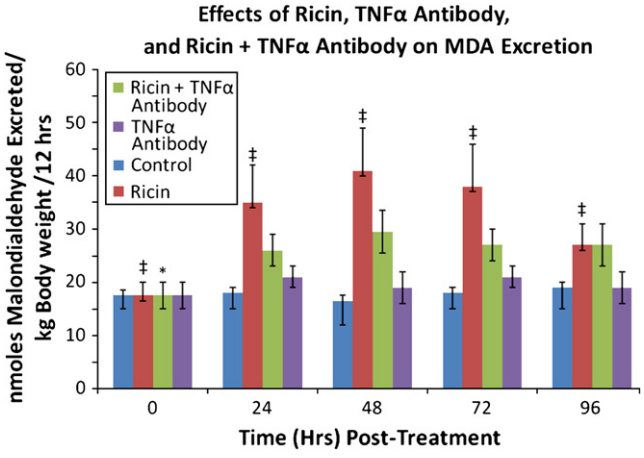

FIGURE 25.4. The effects of ricin (5 μg/kg), TNF-α antibody (15,000 U/kg), and ricin plus TNF-α antibody on malondialdehyde (MDA) excretion. Animals treated with TNF-α antibody plus ricin received the antibody 2 h before ricin. Appropriate vehicle controls were substituted in each of the other regimens. Each value is the mean ± SD of four mice in each group. Values with nonidentical superscripts at each time point are significantly different ($p < 0.05$).

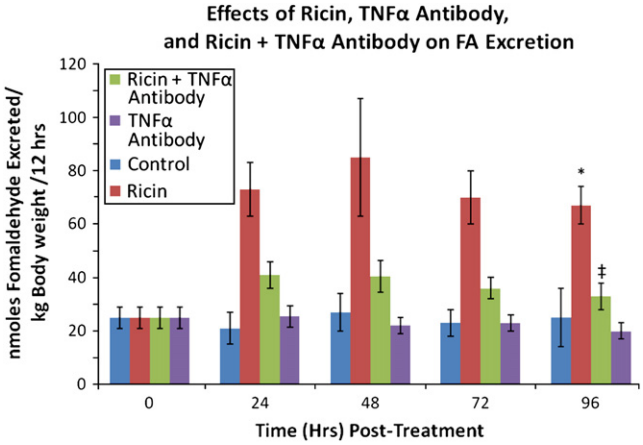

FIGURE 25.5. The effects of ricin (5 μg/kg), TNF-α antibody (15,000 U/kg), and ricin plus TNF-α antibody on formaldehyde (FA) excretion. Animals treated with TNF-α antibody plus ricin received the antibody 2 h before ricin. Appropriate vehicle controls were substituted in each of the other regimens. Each value is the mean ± SD of four mice in each group. Values with nonidentical superscripts at each time point are significantly different ($p < 0.05$).

Previous investigations have suggested that deoxynucleoside analogs may be effective in decreasing the toxicity of ricin (Hassoun *et al.*, 1996). The effects of 3′-azido-3′-deoxythymidine (AZT) and 2′,3′-dideoxycytidine (DDC) in decreasing the cytotoxicity of ricin in J774A.1 macrophage and Chinese hamster ovary (CHO) cells in culture by assessing the release of lactate dehydrogenase (LDH) and asparate aminotransferase (AST) from the cells, as well as decreased cell viability, were examined. Results demonstrated that DDC provided partial protection against ricin toxicity in both cell culture systems based on the leakage of LDH and AST. Concentration-dependent effects between 10^{-10} and 10^{-4} g/ml were produced. Under similar conditions, AZT had no effect on the toxicity of ricin in these two cell culture systems. When assessing cell viability, DDC almost doubled the viability of both CHO and J774A.1 cells at a concentration of 10^{-4} g/ml in the presence of ricin. These results demonstrated that DDC but not AZT exhibits a chemoprotective effect against ricin toxicity in the two cell culture systems that were tested (Hassoun *et al.*, 1992, 1996).

VI. RISK ASSESSMENT

Upon exposure to ricin or abrin, the clinical signs, symptoms, and pathological manifestations in intoxicated victims depend on the route of exposure. When inhaled as a small particle aerosol, ricin produces symptoms within 8 h. Respiratory distress, fever, cough, dyspnea, nausea, and chest tightness are followed by profuse sweating, the development of pulmonary edema, cyanosis, hypotension, and finally respiratory failure and circulatory collapse. Ingestion of ricin causes gastrointestinal signs and intestinal

TABLE 25.1. Effects of TNF-α antibody (TNF-α Ab) on ricin-induced lipid peroxidation, NPSH content, and DNA-SSB

Treatment	Lipid peroxidation (nmol MDA/g liver)	DNA-SSB [elution constants ($\times 10^{-3}$)]
Control	64.3 ± 11.9^a	6.0 ± 0.8^a
Ricin (5 μg/kg)	115.9 ± 22.2^b	15.0 ± 2.6^b
Ricin (25 μg/kg)	162.0 ± 4.9^c	19.7 ± 0.9^c
TNF-α Ab (1,500 U/kg)	102.3 ± 41.1^b	6.3 ± 1.2^a
TNF-α Ab (15,000 U/kg)	69.5 ± 8.8^a	5.8 ± 0.9^a
Ricin (5 μg/kg) + TNF-α Ab (1500 U/kg)	60.2 ± 12.8^a	7.8 ± 0.9^c

Each value is the mean ± SD of at least four animals 24 h after treatment. Values with nonidentical superscripts are significantly different from one another ($p < 0.05$)

hemorrhage with necrosis of liver, spleen, and kidneys. Intramuscular intoxication causes severe localized pain, muscle and regional lymph node necrosis, and moderate involvement of visceral organs. Transient leukocytosis appears to be a constant feature in humans, whether ricin intoxication is via injection or oral ingestion. Children are more sensitive than adults to fluid loss, due to vomiting and diarrhea, and can quickly become severely dehydrated and die. If death has not occurred in 3–5 days, the victim usually recovers (CDC, 2008).

The major symptoms of abrin poisoning also depend on the route of exposure and the dose received, though many organs may be affected in severe cases. Initial symptoms of abrin poisoning by inhalation may occur within 8 h of exposure. Following ingestion of abrin, initial symptoms may occur in less than 6 h but usually are delayed for 1–3 days. Within a few h of inhaling significant amounts of abrin, symptoms would be respiratory distress, fever, cough, nausea, and tightness in the chest. Heavy sweating may follow as well as pulmonary edema. Excess fluid in the

lungs would be diagnosed by x-ray or by listening to the chest with a stethoscope (CDC, 2008). Symptoms of abrin ingestion include bloody vomiting and diarrhea. Severe dehydration may also result, followed by low blood pressure. Other signs or symptoms may include hallucinations, seizures, and blood in the urine. Within several days, impairment of the liver, spleen, and kidneys may occur resulting in death. Symptoms of skin and eye exposure to abrin include redness and pain (CDC, 2008). Symptoms of exposure to inhaled abrin include suddenly developed fever, cough, and excess fluid in the lungs followed by severe breathing problems.

Differential diagnosis of ricin exposure shows early inhalational ricin poisoning and will have primarily respiratory signs and symptoms, whereas ingested ricin will probably present early with gastrointestinal symptoms.

TABLE 25.2. Epidemiological clues for determining the release of concealed ricin, abrin, or any chemical agent or a biological toxin

- an unusual increase in the number of patients seeking a toxin-related illness
- unexplained illness or death among relatively healthy or young people
- detection of unexplained odors on presenting patients
- similar symptoms in groups of people who have common characteristics (i.e. common workplace, common source of drinking water)
- rapid onset of symptoms
- unexplained death of plants, fish or animals
- presence of a particular syndrome known to be associated with a chemical agent or biological toxin

Referenced from: US Public Health Service, Health Studies Branch, National Center for Environmental Health Centers for Disease Control and Prevention. January 27, 2004

Differential diagnoses of inhaled ricin poisoning show staphylococcal enterotoxin B, exposure to pyrolysis byproducts of organofluorines such as Teflon or Kevlar, nitrogen oxides, phosgene, influenza, anthrax, Q-fever, and pneumonic plague (Schier, 2004). Differential diagnosis of ricin poisoning by ingestion shows enteric pathogens such as salmonella or shigella, mushrooms, caustics, iron or other metals, arsenic, and colchicines (Schier, 2004).

Several methods of detection of exposure to ricin include use of enzyme-linked immunosorbent assay (ELISA) testing of blood or other body fluids or immunohistochemical techniques may be useful in confirming ricin intoxication (Poli *et al.*, 1994). No widely available, reliable test exists to detect and confirm exposure to abrin.

In determining the concealed release of ricin, abrin, or any chemical agent or biological toxin, certain epidemiologic clues should be evident (Schier, 2004) (Table 25.2). If clinical findings of ricin- or abrin-associated poisoning are evident, the proper public health authorities including the regional poison control center and local and state health departments should be contacted immediately. The Centers for Disease Control and Prevention and public health laboratories in the Laboratory Response Network are able to detect ricin in environmental samples. Environmental testing may document the potential or affirm the nature of the exposure (Schier, 2004). Unfortunately, effective countermeasures and real-time detection of ricin and abrin are not yet viable options.

VII. TREATMENT

There is no specific treatment for ricin or abrin. Therefore the only recommendation is to rid the body of the toxins as quickly as possible. Ricin and abrin poisoning is treated by giving victims the appropriate supportive medical care to minimize the effects of the poisoning. Cases of gastrointestinal exposure are best managed by vigorous gastric decontamination with activated charcoal, followed by use of cathartics such as magnesium citrate (CDC, 2008). Replacement of gastrointestinal fluid losses is crucial. In cases of aerosol or inhalant exposure, patients are managed for intensive respiratory therapy, fluid and electrolyte replacement, anti-inflammatory agents, and analgesics (CDC, 2008). Other types of supportive medical care would include providing medications to treat conditions such as seizure and low blood pressure, flushing the stomach with activated charcoal, or washing eyes and skin if exposed ocularly or dermally (CDC, 2008).

Gross decontamination of the patient should also follow in the event of a recognized release or exposure. This would include removal of all suspected contaminated clothing, including jewelry and watches, and washing off any obvious contamination with soap and copious amounts of water. Contaminated clothing removed from the victim should be double bagged and labeled as contaminated and then secured in a safe location until it can be safely disposed of. Environmental surfaces or medical equipment can be cleaned with soap and water or a 0.1% sodium hypochlorite solution (CDC, 2008).

Candidate vaccines under development are immunogenic and confer protection against lethal aerosol exposures. Recent animal studies have shown that either active immunization or passive prophylaxis may be effective against intravenous or intraperitoneal intoxication with ricin (Poli *et al.*, 1994). In the case of inhalational exposure, active immunization or prophylactic administration of aerosolized specific anti-ricin antibody may also be effective (Poli *et al.*, 1994). Unfortunately, these applications may not be clinically available since they are still under investigation.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

Ricin and abrin have played important roles in the history of clinical medicine and biomedical research. Ricin is commonly used as a part of immunotoxins for clinical tumor research and application, although the detailed mechanism of its function is still under investigation (Stirpe and Battelli, 2006; Rao *et al.*, 2005). At present, a major effort in biomedical research is under way to target the toxins and pursue malignant cells. Novel *in vitro* approaches of using ricin toxins in cancer therapy have proven successful; however, further *in vitro* and animal studies are needed to confirm its potential (Wang *et al.*, 2007).

Interestingly, the hope for a vaccination in the treatment against abrin toxicity may be not that far away. In a recent *in vitro* and *in vivo* study, antibodies specific to the recombinant abrin A-chain were shown to rescue cells from toxicity. Importantly, the antibody also protected mice from lethal doses of the toxin. The neutralizing effect of the antibody

was shown to be due to interference with abrin attachment to the cell surface (Surendranath and Karande, 2008). This study along with our understanding of ricin and abrin may bring us closer to the development of a long awaited protective vaccine.

CHAPTER 26

Trichothecene Mycotoxins

WANDA M. HASCHEK AND VAL R. BEASLEY

I. INTRODUCTION

The ideal biologic warfare agent is lethal, easy, and inexpensive to produce in large quantities, stable as an aerosol for dispersion over wide areas, without effective treatment or vaccination, and communicable between people. The trichothecene mycotoxins possess all these properties with the exception of the last. The potent acute toxicity and chemical stability of T-2 toxin, diacetoxyscirpenol (DAS) and, possibly, DON make them candidates for bioterrorism (Stark, 2005). Mycotoxins may already have been used for weapons based on toxicity syndromes, typical for exposure to trichothecene mycotoxins, associated with ''yellow rain'' incidents in southeast Asia and Afghanistan (Heyndrickx *et al.*, 1984; Mirocha *et al.*, 1983; Spyker and Spyker, 1983; Tucker, 2001; Watson *et al.*, 1984). The Soviet Union was alleged to have provided mycotoxins to the armies of Vietnam and Laos for use against resistance forces in Laos and Cambodia and to have used mycotoxins in combat operations in Afghanistan (Haig, 1982; Tucker, 2001). Confirmation of this use of mycotoxins has been difficult and controversial. T-2 toxin, nivalenol, and DON were identified in vegetation at affected sites and both T-2 toxin and HT-2 toxin, a metabolite of T-2 toxin, were found in urine and blood samples from victims of alleged attacks (Mirocha, 1983; Heyndrickx *et al.*, 1984). T-2 toxin was also reportedly found in high concentrations in spots found on rocks and gas masks. While mycotoxins are considered impractical as tactical weapons, crude preparations could be readily produced and used by terrorist organizations to contaminate food or water supplies, or be released as an aerosol in small crowded areas (Stark, 2005).

The government of the USA has created several overlapping lists of potential bioterrorism agents and diseases that are considered a possible threat to the health and safety of the public, animals, and plants. These agents are federally restricted through regulation of their possession, use, and transfer. T-2 toxin is on the current (2007 revision) Overlapping (Human and Livestock) Select Agents and Toxins list for the Center for Disease Control, Department of Human Health Services (CDC, DHHS) and the Animal and Plant Health Inspection Service, United States Department of Agriculture (APHIS, USDA). T-2 toxin is toxic on ingestion with enhanced toxicity by the inhalation route; it is toxic to the skin and can be absorbed across intact skin. Diacetoxyscirpenol (DAS), which is similar to T-2 toxin in mechanism of action and potency, is only on the HHS Select Agents and Toxins list; less information is available about this toxin. DON is on neither list but has been mentioned as a possible bioweapon because its acute toxicity is similar to T-2 toxin. However, it is much less toxic than T-2 toxin (mouse LD_{50} for T-2 toxin is 0.25 mg/kg as compared to 78 mg/kg for DON; Stark, 2005). This chapter will review information on these three trichothecenes with most attention given to T-2 toxin. The review will focus on swine research, since the pig is an excellent model for man, and other information pertinent to human exposure.

II. BACKGROUND

Trichothecene mycotoxins are a family of tetracyclic sesquiterpenoid substances (12,13 epoxytrichothecenes) comprising over 200 compounds of widely varying toxicity. The epoxy group at C-12 and C-13 is considered essential for toxicity. Trichothecenes are broadly divided into two groups, the macrocyclic and nonmacrocyclic, based on the presence or absence of a macrocyclic ring linking C-4 and C-15 with diesters (roridin series) and triesters (verrucarin series). The nonmacrocyclic trichothecenes, such as T-2 toxin, HT-2 toxin, diacetoxyscirpenol (DAS, anguidine), deoxynivalenol (DON, vomitoxin), and nivalenol, are produced primarily by field fungi of the genus *Fusarium*. The macrocyclic trichothecenes, such as roridins, verrucarins, and satratoxins, are produced primarily by *Stachybotrys* and *Myrothecium* spp. Other genera that have been reported to produce trichothecenes include *Trichoderma*, *Trichothecium*, *Cephalosporium*, *Cylindrocarpon, Verticimonosporium*, and *Phomopsis* (Scott, 1989).

Trichothecenes occur worldwide in grains and other commodities grown in cooler climates. Colonization and toxin production by *Fusarium* spp. occur in the field; however, some toxin production can also occur in storage. Mild temperatures tend to encourage fungal growth and cool temperatures increase toxin production (0–15°C). Trichothecenes tend to be produced in toxic concentrations in years of wet weather when harvests are delayed and prolonged.

The primary fungal species producing the trichothecene mycotoxins are listed in Table 26.1. T-2 toxin is produced primarily by *Fusarium sporotrichioides*, with highest concentrations generally occurring in small grains such as barley and wheat. T-2 toxin may occasionally occur in corn, and forages are sometimes contaminated. Diacetoxyscirpenol is produced by *Fusarium roseum* (*Gibberella zeae*, *F. graminearum*) and several other species of *Fusarium*. Deoxynivalenol (DON, vomitoxin) is also produced primarily by *F. roseum*, with corn, oats, barley, and wheat, as well as other small grains being important sources of exposure to livestock. Macrocyclic trichothecene mycotoxins can be produced by fungi such as *Stachybotrys chartarum* (previously *S. atra*), a black fungus that grows in wet forages and/or straw as well as in water-damaged building materials and wet wood in air ducts.

Trichothecenes are potent inhibitors of protein synthesis due to binding to the 60S ribosomal unit and this is believed to be the main mechanism of toxicity. However, recent experimental data suggest that activation of the mitogen-activated protein kinases (MAPKs) through the ribosomal stress response could be another mechanism that operates via apoptotic and proinflammatory processes.

Trichothecenes can cause problems in livestock and humans ingesting contaminated grains or hay. In the USA and Canada, deoxynivalenol appears to be the most significant member of the group despite its comparatively low toxicity. This is based on agricultural losses in exports and swine production. However, both T-2 toxin and DAS occasionally cause outbreaks of toxicoses in animals in North America as well as Japan. T-2 toxin has been implicated in widespread epidemics of alimentary toxic aleukia (ATA) in humans in the Soviet Union that occurred in the 1930s and 1940s.

Trichothecenes cause apoptosis and/or necrosis in the lymphoid, hematopoietic, and gastrointestinal systems resulting in leukopenia, vomiting, and diarrhea that can be lethal. In addition, trichothecenes are toxic to the skin and testes. Immune suppression and increased susceptibility to infection may occur, especially in the late phase of the disease. The toxic effects from trichothecenes largely resemble those following radiation exposure (radiomimetic) due to effects on rapidly dividing cells in the intestine, bone marrow, and testis.

Lethality due to ingestion of food contaminated by trichothecenes has been reported in horses (Rodricks and Eppley, 1974), cattle (Hsu *et al.*, 1972), and humans (Joffe, 1974). General clinical signs include emesis, food refusal and weight loss, dermal effects, and immune suppression with secondary infection. Clinical signs are dependent on the specific trichothecene involved, the dose, species, route of exposure, as well as the nature of the exposure. Spontaneous and experimental exposures may give somewhat different results, as can exposure to field contaminated materials, when compared to purified toxin. In the case of field contamination or experimental use of crude extracts, multiple mycotoxins, both known and unknown, may be present at the same time.

TABLE 26.1. Partial listing of trichothecene toxins and their comparative toxicity

			Acute LD_{50} values (mg/kg)[a]				Lethal dose (mg/kg)
Group	**Main producer**	**Trichothecene**	**Mouse i.v. or i.p.**	**Mouse oral/p.o.**	**Mouse inhalation[b]**	**Pig i.v.**	**Pig inhalation[c]**
A	*Fusarium* spp.	T-2 toxin	3.0–5.3	3.8–10.5	0.16	1.21	1.5–3.0
		HT-2 toxin	6.5–9.0				
		Diacetoxyscirpenol (DAS)	9.6–23.0	15.5–46.0		0.37	
		Monoacetoxyscirpenol					
B	*Fusarium* spp.	Deoxynivalenol (DON, vomitoxin)	70.0–76.7	46.0			
		Nivalenol	4.0–6.3				
		Fusarenon X	3.4	4.5			
C	*Cephalosporium* spp.	Crotocin	700–810	1,000			
D	*Myrothecium* spp.	Verrucarins					
		Verrucarin A and B	0.5 (A)–7.0 (B)				
		Roridins					
		Roridin A	1.0 (A)				
	Stachybotrys spp.	Satratoxins					

[a]Information largely from Trenholm *et al.* (1989), Ueno (1985)
[b]24 h LD_{50}, in saline solution, Cresia and Lambert (1989)
[c]Estimated retained dose (20–30%) using dry aerosol of T-2 toxin, all animals died within 18 h, Cresia and Lambert (1989)

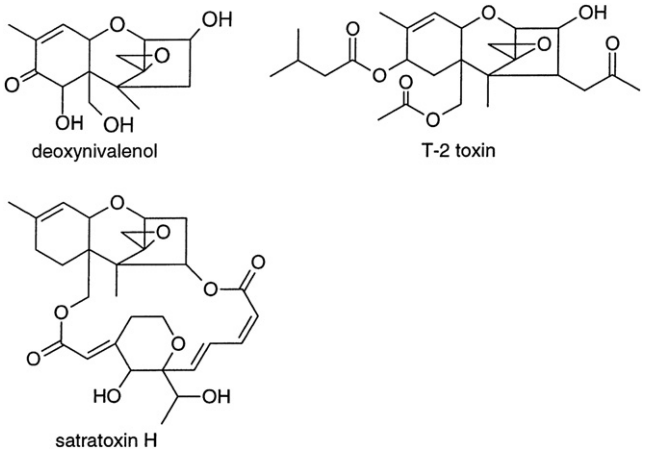

FIGURE 26.1. Chemical structure of trichothecene mycotoxins from group A, T-2 toxin; group B, deoxynivalenol (DON); and group D (satratoxin H). From Haschek *et al.* (2002).

All trichothecene mycotoxins have a basic tetracyclic sesquiterpene structure with a six membered oxygen-containing ring, an epoxide group in the 12,13 position, and an olefinic bond in the 9,10 position. Trichothecenes have been classified into four groups based on substitutions at five positions of the trichothecene skeleton (Figure 26.1). Group A trichothecenes possess hydroxyl or esterified hydroxyls at the C-3, 4, 7, 8, or 15 position and include T-2 toxin, HT-2 toxin, DAS, and monoacetoxyscirpenol. *Fusarium sporotrichoides* and *F. poae* cultures are used most commonly to produce these toxins. Group B trichothecenes contain a keto group at C-8 and a hydroxyl group at C-7, in addition to the other functional groups in group A, and include DON and nivalenol. These trichothecenes are less toxic than those classes without the C-8 keto substitution. Group C trichothecenes typically have a second epoxide ring at C-7, 8, are not produced by *Fusarium* spp., and include crotocin. Group D trichothecenes have a macrocyclic ring linking C-4 and C-15 and include macrocyclic trichothecenes, such as verrucarins and satratoxins, that are produced by *Myrothecium* and *Strachybotrys* spp., respectively. While fungi frequently produce several toxins, most species tend to produce group A, B, or D toxins. However, several different types of toxins may be produced by a single fungal species. For example, *F. roseum*, a primary producer of zearalenone, can synthesize both group A and B toxins.

III. TOXICOKINETICS

Trichothecenes can be absorbed through the gastrointestinal tract, the lungs, and the skin (Madsen, 2001). Most of the information on toxicokinetics is based on i.v. administration because of the powerful emetic effects of these toxins. Limited information is available on oral and inhalation routes of exposure. Inhalation would be the most likely route of exposure for weaponized mycotoxins since this approach would result in many people being affected in a short time. For example, in mice, lethality was present within 5 h when T-toxin was given by inhalation for 10 min (Cresia *et al.*, 1987). Oral or parenteral administration of trichothecenes does not result in their accumulation in the body to any great extent and any residues are rapidly excreted over several days of exposure. In contrast, topical application of T-2 toxin results in delayed absorption and sustained metabolism and excretion due to the skin and subcutaneous fat acting as a reservoir in swine (Pang *et al.*, 1987d).

The trichothecenes undergo all four basic reactions in xenobiotic metabolism, i.e. hydrolysis, oxidation, and reduction in phase I metabolism, and glucuronide conjugation in phase II metabolism. These reactions occur in tissues except for reduction of the 12,13-epoxide which occurs through microbial action in the gastrointestinal tract (Swanson *et al.*, 1988; Swanson and Corley, 1989). Reduced toxicity generally follows T-2 metabolism with deacetylation of T-2 toxin to HT-2 (at C-4), to 4-deacetylneosolaniol, and to T-2 tetraol. T-2 toxin is considered 1.5 to 1.7 times as toxic as HT-2, which is 4.8 times as toxic as T-2 tetraol (Ueno *et al.*, 1973). Both human and bovine liver homogenates can deacetylate T-2 toxin *in vitro* to HT-2 toxin (Ellison and Kotsonis, 1974). Rapid excretion occurs via the biliary system (feces) and urine without significant accumulation of orally administered trichothecenes in the body. Enterohepatic recirculation may occur. Reviews of trichothecene toxicokinetics are provided by Swanson and Corley (1989), and Mostrom and Raisbeck (2007) for agricultural species.

In swine, following intra-aortic administration, the disappearance of parent T-2 toxin followed a two compartment open model with mean elimination phase half-life of 13.8 min and mean apparent specific volume of distribution of 0.366 l/kg (Beasley *et al.*, 1986). Parent T-2 toxin was not detected in plasma, urine, or liver but was transiently present in lymphoid tissues. T-2 toxin and metabolites were eliminated as glucuronide conjugates into bile, undergoing deconjugation in the intestinal tract by microbial action and then underwent enterohepatic recirculation (Corley *et al.*, 1985).

Diacetoxyscirpenol (DAS) is rapidly and extensively metabolized in rats, pigs, and cattle. Pharmacokinetic studies of DAS given i.v. to swine 48 h after anesthesia, indicated a large volume of distribution of 1.58 ml/kg, high total body clearance of 119.4 ml/min/kg, and elimination phase half-life of 10.2 min (Coppock *et al.*, 1987). Less than 1% of parent compound was detected in urine. The major metabolites were monoacetoxyscirpenol and scirpenetriol.

Because deoxynivalenol (DON) commonly contaminates grains and swine are the most susceptible species, toxicokinetics for DON have been extensively studied in this species (Coppock *et al.*, 1985b; Prelusky *et al.*, 1988, 1990; Prelusky and Trenholm, 1991; Goyarts and Danicke, 2006). Intravenously administered DON (1 mg/kg body weight) distributed rapidly to all tissues and body fluids, and declined to negligible levels within 24 h except in urine and bile

(Prelusky and Trenholm, 1991). The half-life of DON in swine was between 2.08 and 3.65 h after i.v. injection of 0.5 mg DON/kg body weight. This suggested that 97% of the DON would be eliminated in 10.1 to 18.3 h (Coppock *et al.*, 1985b). DON concentrations decreased biphasically with terminal elimination half-lives ($t_{1/2}$ β) of between 4.2 and 33.6 h (Goyarts and Danicke, 2006). Orally administered DON is rapidly and nearly completely absorbed from the stomach and proximal small intestine (Danicke *et al.*, 2004). Pigs given DON in one oral dose or chronically dosed (via a diet containing DON at 5.7 mg/kg diet for 4 weeks) rapidly absorbed >50% of administered DON. The toxin rapidly left the blood (apparent volume of distribution exceeded the total body water), with serum elimination half-lives of 5.3 and 6.3 h, respectively, and total elimination time (97%, five elimination half-lives) of 26.5 and 31.5 h, respectively. The majority of the DON was eliminated via the urine and feces with urine excretion of unmetabolized DON accounting for most of the compound.

IV. MECHANISM OF ACTION

Trichothecenes inhibit synthesis of protein, RNA and DNA as well as mitochondrial and electron transport chain function; stimulate lipid peroxidation; alter cell membrane function; induce apoptosis; modulate immune responses; activate mitogen-activated protein kinases (MAPKs) and induce gene expression of numerous chemokines and cytokines; and alter neurotransmitter levels.

Although trichothecenes vary to some extent in their chemical structure and the biological effects that they produce, all trichothecenes target the 60S ribosomal subunit suggesting that the major mechanism of toxicity is translational inhibition. Inhibition of protein synthesis occurs through interference with peptidyl transferase activity, with an intact C-9,10 double bond and the C-12,13 epoxide required for this inhibition (McLaughlin *et al.*, 1977). Inhibition takes place in the translational stage that occurs in the polysomes of the endoplasmic reticulum. All three translational processes, initiation, elongation, and termination, can be affected by the trichothecenes. However, the inhibitory potency and major site of action during translation vary among trichothecenes. Prevention of polypeptide chain initiation or elongation has been demonstrated in cell-free models, and partial translational inhibition was found in cell cultures and in laboratory animals (Azcona-Olivera *et al.*, 1995; Bamburg, 1983; Carter and Cannon, 1977; Thompson and Wannemacher, 1986; Ueno, 1984).

Trichothecenes can be divided into two groups based on their site of action on protein synthesis. Trichothecenes with hydroxyl and acetyl substitutions at both C-3 and C-4, such as T-2 toxin, DAS, verrucarin A, preferentially inhibit initiation while DON, trichodermin, crotocin, and verucarol inhibit elongation and/or termination (McLaughlin *et al.*, 1977). Trichothecenes inhibit both DNA and RNA synthesis in *in vitro* systems, presumably secondary effects of protein synthesis inhibition (Thompson and Wannemacher, 1986). Mitochondrial protein synthesis and electron transport was inhibited both *in vitro* and *in vivo* by high doses of T-2 toxin (Pace, 1983; Pace *et al.*, 1988).

Trichothecenes and other translational inhibitors which bind to ribosomes can also rapidly activate MAPKs and induce apoptosis in a process known as the ''ribotoxic stress response''; this could be another pathway for trichothecene-induced apoptosis (Laskin *et al.*, 2002; Pestka, 2007). MAPKs modulate processes such as cell growth, differentiation, and apoptosis, and are critical for signal transduction in the immune response (Dong *et al.*, 2002). Trichothecenes activate p38, Jun N-terminal kinase (JNK) and extracellular signal regulated kinase (ERK) MAPKs *in vitro* and *in vivo* (Chung *et al.*, 2003; Moon and Pestka, 2003; Moon *et al.*, 2003; Yang *et al.*, 2000; Zhou *et al.*, 2003a, b, 2005a, b). Both proinflammatory cytokine up-regulation as well as apoptosis are mediated by trichothecene-induced MAPK activation (Pestka *et al.*, 2004; Zhou *et al.*, 2003b, 2005b). MAPK activation was correlated with and preceded apoptosis induced by trichothecenes in an *in vitro* system, with cytotoxic potency being satratoxin G, roridin A, verrucarin A >T-2 toxin, satratoxin F, H >nivalenol and DON (Yang *et al.*, 2000).

Apoptosis is now recognized as a major mechanism for trichothecene-induced toxicity. It should be recognized that the majority of studies examining trichothecene toxicity were carried out prior to the recognition of apoptosis as a toxic response. In retrospect, the early morphologic changes described as necrosis in the lymphoid, hematopoietic, and intestinal tract are consistent with apoptosis. Later studies of trichothecene toxicity *in vivo* have verified this for T-2 toxin-induced bone marrow and thymic changes using DNA fragmentation in addition to morphology (Islam *et al.*, 1998, Shinozuka *et al.*, 1998). More recently, T-2 toxin-induced apoptosis of neuroepithelial cells in fetal rats was shown to be preceded by expression of oxidative stress-related genes (e.g. heat shock protein 70) and subsequent activation of MAPKs and caspase-2, important factors in cell signaling pathways for apoptosis (Sehata *et al.*, 2004). Similarly, satratoxin G-induced apoptosis of olfactory sensory neurons was associated with elevated expressions of the proapoptotic genes Fas, FasL, p75NGFR, p53, Bax, caspase-3, and CAD in the olfactory epithelial lined ethmoid turbinate (Islam *et al.*, 2006). Based on these findings, trichothecenes may be able to drive both extrinsic (death receptor-mediated) and intrinsic (mitochondrial-mediated) apoptotic pathways.

Some biological effects may be mediated by reaction of the epoxy groups of trichothecenes with sulfhydryl groups on enzymes and binding of certain trichothecenes to membrane components. T-2 toxin rapidly affected glucose, nucleotide and amino acid transporters as well as calcium/potassium channel activities *in vitro* indicating alteration of cell membrane functions independent of protein synthesis inhibition (Brunner and Morris, 1988). In pigs, DAS was

found to be cytotoxic to cells with specialized ion pumps, namely renal tubular cells, gastric parietal cells, and salivary ducts (Coppock *et al.*, 1985a). Parietal cell toxicity was also identified in rats treated with T-2 toxin (Bratich *et al.*, 1990). Other effects of trichothecenes may be mediated via lipid peroxidation. For example, following oral T-2 toxin administration, rats on antioxidant-deficient diets had increased thiobarbituric acid reactive substances as well as decreased glutathione and superoxide dismutase activity in liver, while mice had increased plasma and organ malondialdehyde (MDA) content and decreased plasma vitamin E levels (Rizzo *et al.*, 1994; Vila *et al.*, 2002).

Recent studies indicate that some trichothecenes can bind covalently. Satratoxin G, a macrocyclic trichothecene, forms covalent adducts with proteins and potentially other cellular macromolecules (Gregory *et al.*, 2004; Yike *et al.*, 2006). The ability of satratoxin G to bind to albumin provides a potential biomarker of exposure to the toxin as well as to *Stachybotrys chartarum*.

Trichothecenes can be immunostimulatory or immunosuppressive depending on dose, exposure frequency, and timing relative to sampling for immune assays (Holt *et al.*, 1988; Pestka *et al.*, 2004; Taylor *et al.*, 1989). Low level exposure promotes, in hormetic fashion, the expression of numerous cytokines and chemokines (Holt *et al.*, 1988; Warner *et al.*, 1994). Both transcriptional and post-transcriptional mechanisms are involved in trichothecene-induced cytokine mRNA expression (Pestka *et al.*, 2004, 2008). One example of cytokine up-regulation is DON-induced IgA dysregulation in mice which results in glomerulonephritis that closely resembles human IgA nephropathy (Pestka *et al.*, 1989). At higher doses, trichothecenes given orally, intravenously, by inhalation, and topically are well known to be cytotoxic to lymphocytes in lymphoid tissues, including the thymus and Peyer's patches, as well as in the leukocytes of bone marrow, collectively resulting in immune suppression (Connor *et al.*, 1986; Coppock *et al.*, 1985a; Islam *et al.*, 1998; Pang *et al.*, 1987a, b, c, 1988; Pestka *et al.*, 2004; Shinozuka *et al.*, 1998). Similar effects have been observed with macrophages, where low doses of trichothecenes up-regulate expression of inflammation related genes including COX-2, proinflammatory cytokines and numerous chemokines, while high doses induce apoptosis thereby suppressing innate immune function (Pang *et al.*, 1987b; Pestka *et al.*, 2004; Yang *et al.*, 2000; Zhou *et al.*, 2005a).

Some trichothecene-induced effects may be due to neurotransmitter alteration in the central nervous system. Emesis or vomiting, which occurs with many of the trichothecenes when given at high doses, has been attributed to the stimulation of the chemoreceptor trigger zone in the area postrema of the medulla oblongata. However, studies with T-2 toxin in cats indicated that other mechanisms, such as the neural afferent pathways from the abdomen, implicated in radiation-induced emesis, may also be involved (Borison and Goodheart, 1989). DON alters serotonin activity in the central nervous system of swine which is important in regulation of food intake (Prelusky *et al.*, 1992). This may be the mechanism for reduction of food consumption found at low levels of DON exposure. In addition, alterations in norepinephrine and dopamine were identified in specific areas of the brain (Prelusky *et al.*, 1992).

V. TOXICITY

LD_{50} values, which may differ based on route of exposure and species exposed, can be used to compare the toxicity of trichothecenes (Table 26.1). For example, the LD_{50} values for i.p. exposure in the mouse are 5.2 mg/kg for T-2 toxin and 23 mg/kg for DAS, while for i.v. exposure in the pig they are 1.21 mg/kg for T-2 toxin and 0.37 mg/kg for DAS (Ueno, 1985). For T-2 toxin, oral LD_{50} values are not markedly different across species (Ueno, 1985); however, T-2 toxin was 10- to 50-fold more toxic when inhaled than when administered orally (Marrs *et al.*, 1986). For DON, pigs are the most sensitive, followed by mice then rats. For DON in pigs, the main clinical effect at high levels is vomiting and at low levels reduced food intake or food refusal. Such responses apparently limit exposure and thus toxic manifestations.

Trichothecene toxicosis is manifested by a broad spectrum of clinical disorders, which vary according to the specific causative toxin or mixture of toxins. Species differences in response are generally related to severity of the response, and young animals are more susceptible than adults. Toxicosis can be acute or chronic, with clinical signs remaining fairly similar. A comprehensive review of the pathophysiology of spontaneous and experimentally induced trichothecene mycotoxicosis is available (Beasley, 1989).

Vomiting (emesis), reduced feed intake, and feed refusal are associated with most trichothecenes, with swine being the most sensitive species (reviewed by Schiefer and Beasley, 1989). Vomiting is an acute reaction that may occur rapidly after either parenteral or oral administration, depending on the dose. Vomiting is believed to be a result of central nervous stimulation, although gastric irritation cannot be ruled out. Reduced food intake and food refusal lead to decreased weight gain. T-2 toxin and DAS cause cytotoxicity in many cell types such as skin or oropharyngeal epithelia that are directly exposed, as well as hematotoxicity and immune suppression due to effects on rapidly dividing cells and, in some cases, neurotoxicity (Beasley, 1989). Abortion and retarded growth rate of offspring have been reported (Francis, 1989).

The ability of the trichothecenes to produce dermal toxicity is rather unusual for toxins. While only the more potent trichothecene mycotoxins have this effect, the cytotoxicity produced on contact with feed may result in lesions on the snout, muzzle, lips, and tongue of animals. Similar dermal effects have been reported in humans and in swine following topical application of T-2 toxin. T-2 toxin, DAS,

and other trichothecenes, especially the macrocyclic toxins produced by *Stachybotrys chartarum* which have been recognized primarily in Europe, have dermal effects although systemic effects are more important. Deoxynivalenol does not produce dermal effects.

Insufficient data are available to draw a firm conclusion regarding the mutagenicity or carcinogenicity of the trichothecenes, including T-2 toxin (reviewed by Haschek, 1989). Trichothecenes are not mutagenic in bacterial assays, although chromatid breaks have been induced by DON in Chinese hamster cells (Hsia *et al.*, 1988). Carcinogenesis bioassays have been largely negative while data from weakly positive studies could be explained by secondary effects of trichothecenes such as altered immune function (Haschek, 1989). Evaluation by IARC (1993, updated online 1997) of available data has concluded that the trichothecenes are not classifiable as to their carcinogenicity to humans (Group 3). Trichothecenes have not been shown to be teratogenic in mammals except at maternally toxic doses. At these doses, embryolethality and anomalies in the nervous and skeletal systems were observed (Francis, 1989).

A. T-2 Toxin and Diacetoxyscirpenol (DAS)

The toxic effects of T-2 toxin and DAS are similar irrespective of route of exposure and species, with ingestion, parenteral administration, and inhalation resulting in lymphoid necrosis, hematotoxicity, and gastrointestinal toxicity (Table 26.2, Figures 26.2 and 26.3). Shock secondary to cardiovascular collapse occurs at high doses. T-2 toxin and DAS also cause dermal and mucous membrane injury on contact.

Ingestion of feed naturally contaminated with T-2 toxin and DAS has caused serious toxicoses mainly in cattle, swine, and poultry, but also occasionally in horses, dogs, cats, and humans. Signs most often include increased incidence of infection, reduced food intake or food refusal, vomiting and diarrhea, and necrosis of skin and oral mucosa. With more severe toxicosis, lesions include hemorrhage and necrosis of the gastrointestinal mucosa (high doses), destruction of hemopoietic tissue and lymphoid necrosis (high doses), and meningeal hemorrhage (massive doses). Shock and death can follow (massive doses). Clotting disorders and reproductive problems also have been reported with T-2 toxin, but the former have not been readily reproduced experimentally. At doses toxic to the dam, embryotoxicity and fetotoxicity, and possibly abortion may occur. In males, testicular damage may occur at high doses.

1. Swine

In early studies, the LD_{50} values for DAS and T-2 toxin administered i.v. in swine were determined to be 0.37 and 1.3 mg/kg, respectively (Weaver *et al.*, 1978a, b). Acute effects included vomiting, lethargy, frequent defecation, and posterior paralysis. Following the ''yellow rain'' incidents in Southeast Asia, extensive studies funded by the Department of Defense were conducted at the University of Illinois in the 1980s using the pig as a model for humans. Exposures were by intravenous, inhalation, and dermal routes. In previous studies of T-toxin and DAS, exposure was mainly by ingestion due to the major concern being natural contamination of food. Using an i.v. LD_{50} dose of 1.2 mg T-2 toxin/kg or above, pigs developed a shock syndrome which was followed by death within 12 to 16 h (Lorenzana *et al.*, 1985a, b). Clinical signs included vomiting, ataxia, collapse, and diarrhea. The same syndrome was induced with DAS at a similar i.v. dose and following inhalation exposure to T-2 toxin. Following i.v. exposure to T-2 toxin, shock was characterized by reduction in cardiac output and aortic blood pressure and increased plasma concentrations of epinephrine, norepinephrine, thromboxane B_2, 6-keto-$PGF_{1\alpha}$, and lactate. Pulmonary vascular resistance and heart rate increased. An initial leukocytosis was followed by leukopenia with both neutrophils and lymphocytes affected. Coagulation assays were normal.

Extensive pathology evaluation was conducted as part of these studies (Pang *et al.*, 1986, 1987c). Lesions included hemorrhages of the lymphoid tissues, gastrointestinal tract, heart, pancreas, adrenal gland, and meninges. Degeneration and necrosis of the lymphoid tissues, necrosis of the surface and crypt epithelium of the gastrointestinal tract (Figures 26.2 and 26.3), and necrosis of the bone marrow confirmed previous findings in pigs and other species. Subsequent reevaluation of lesions supports the findings of apoptotic cell death as well as oncotic necrosis. In addition, scattered necrosis of the pancreatic acinar cells, heart, adrenal cortex, and tubular epithelial cells of the renal medulla were found, as well as a mild interstitial pneumonia. Ultrastructural examination indicated that the endoplasmic reticulum of the pancreatic acinar cells was affected. These changes may have caused release of myocardial depressant factor which would have augmented T-2 toxin-induced cardiac dysfunction. In the heart, myofibrillar lysis and contraction band formation were present (Figure 26.4, Pang *et al.*, 1986). These lesions are consistent with catecholamine-induced changes.

Inhalation of T-2 toxin with endotracheal exposure to a nebulized dose of 9 mg/kg (20–30% retention, 1.8 to 2.7 mg/kg) resulted in clinical signs, and hematologic and morphologic changes similar to those occurring following i.v. exposure but with more severe interstitial pneumonia (Pang *et al.*, 1987b). Two of 17 pigs died or were euthanized (when moribund) within 8 to 10 h of dosing, the remainder were euthanized over a 7 day period. There was a transient reduction in alveolar macrophage viability and phagocytic ability as well as a transient reduction in mitogen-induced blastogenic response by pulmonary, but not peripheral blood, lymphocytes. When pigs were exposed to T-2 toxin at 8 mg/kg and evaluated over 28 days, T-2 toxin did not cause death but caused transient decreases in mitogen-induced (Con A, PHA, and PWM) blastogenic responses of

TABLE 26.2. Target organ toxicity of T-2 toxin and DAS

Tissue	Exposure route	Organ	Clinical signs, hematology	Pathology
Lymphoid	Parenteral, inhalation, ingestion, dermal	Thymus	Immune suppression, lymphopenia	Apoptosis (T-cell), lymphoid depletion
	Parenteral, inhalation, ingestion, dermal	Spleen, lymph nodes	Immune suppression, lymphopenia	Apoptosis, lymphoid depletion, B-cell primarily
	Parenteral, inhalation, dermal	Mucosa associated lymphoid tissue (MALT)	Immune suppression, lymphopenia	Apoptosis, lymphoid depletion, B-cell primarily
Bone marrow	Parenteral, inhalation, ingestion		Leukopenia, anemia, thrombocytopenia	Apoptosis, necrosis – all cell types
Gastrointestinal	Parenteral, inhalation, ingestion	Stomach	Vomiting, dehydration	Ulceration, parietal cell injury
	Parenteral, inhalation, ingestion	Small intestines	Diarrhea, dehydration	Apoptosis, epithelial cell, both surface and crypt
Gall bladder	Parenteral, inhalation, ingestion	Gall bladder		Edema, hemorrhage
Skin	On contact, dermal		Irritation, vesicles, desquamation	Necrotizing dermatitis
Mucous membrane	On contact, oral	Oral and buccal mucosa	Oral/buccal vesicles, ulcers	Stomatitis
Pancreas (pig only)	Intravenous, inhalation, dermal	Exocrine pancreas Endocrine	 Hyper- or hypo-glycemia	Acinar cell necrosis Islet cell necrosis (DAS, i.v.)
Cardiovascular system	Parenteral, inhalation		Decreased cardiac output and aortic blood pressure (T-2 toxin, pig, rat) Hypotension (DAS, human)	Myocardial hemorrhage and necrosis (T-2 toxin, pig i.v., inhalation, and rat i.p.)
Central nervous system	Parenteral, inhalation		?Vomiting	None
	Parenteral, inhalation		Somnolence, confusion, ataxia (DAS, humans), dizziness, vertigo (‘‘yellow rain’’, humans)	Not examined
	Parenteral, dermal		Ataxia, posterior paresis (pig)	Capillary endothelial cell necrosis and hemorrhage (DAS, i.v.)
Reproductive system	Parenteral	Testis	Infertility	Necrosis of germinal epithelium

peripheral blood mononuclear cells and hemagglutination titers to sheep red blood cells (Pang *et al.*, 1988). Therefore, both cell-mediated and humoral immunity were affected as shown in other species.

Trichothecene mycotoxins are highly irritating to the skin and mucous membranes in all species. Skin irritation was experienced by laboratory workers accidentally exposed to trichothecene producing fungal cultures or crude extracts of T-2 toxin. Skin irritation has also been used as a basis for a semiquantitative bioassay to detect these toxins (Bamburg *et al.*, 1968; Ueno *et al.*, 1970). T-2 toxin was applied topically to pigs to characterize its effects by the dermal route and to evaluate therapeutic intervention (Pang *et al.*, 1987a, d). Topical treatment of pigs with T-2 toxin up to 50 mg/kg did not result in any deaths. Clinical signs in pigs followed for 14 days following topical application of T-2 toxin at 15 mg/kg included lethargy, anorexia, posterior weakness or paresis, persistent fever, and pruritis. Severe erythema was present within 24 h and necrotizing dermatitis developed within 3 days (Figure 26.5). By day 14 there was sloughing of

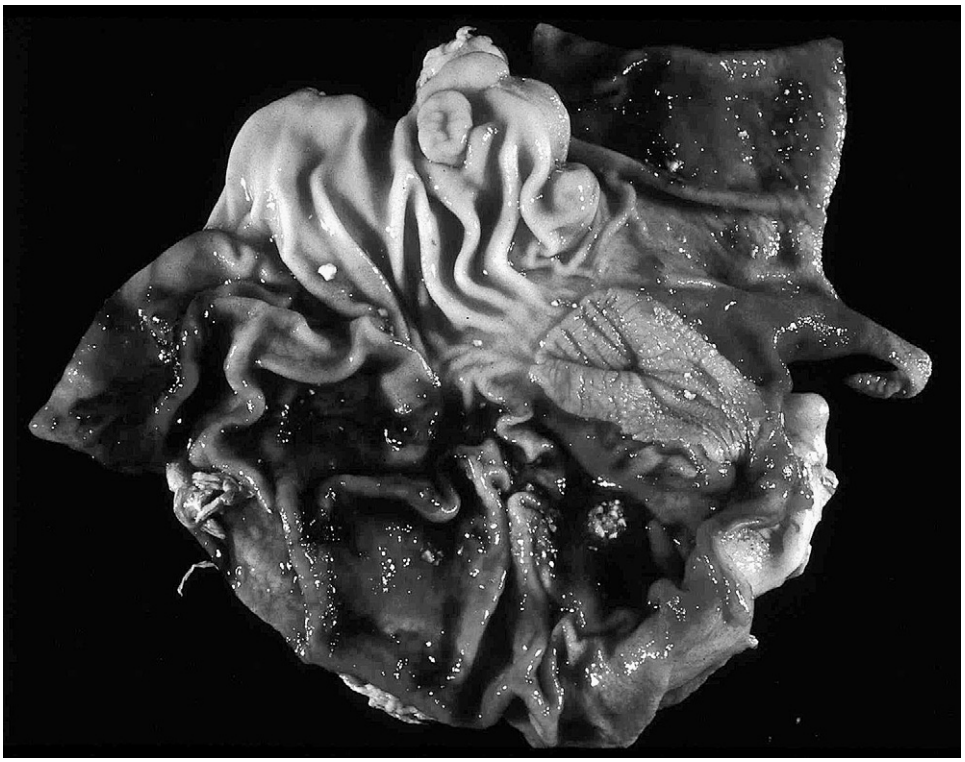

FIGURE 26.2. Stomach from a pig given T-2 toxin at approximately 2 mg/kg as a single inhalation exposure 8 h previously. There is severe necrohemorrhagic gastritis especially in the fundic portion. From Haschek *et al.* (2002).

the necrotic dermis with hyperplasia of the subjacent regenerating epidermis. In addition, there was mild apoptosis of the lymphoid tissues and pancreatic acinar cell necrosis. The skin and subcutaneous tissues appeared to serve as a depot and site of metabolism for T-2 toxin as significant amounts of the toxin and its metabolites were present at the dose site up to 7 days but were not detected systemically (Pang *et al.*, 1987a). In a second study conducted over a 35 day period, the skin lesions had healed by day 21. Prominent leukocytosis, due to neutrophilia, with transient lymphopenia, and increased serum globulin were observed. These leukocyte changes were consistent with a corticosteroid-altered leukogram, potentially related to stress. Decreases in mitogen-induced (Con A, PHA and PWM) blastogenic responses of peripheral blood mononuclear cells were present but not in hemagglutination titers to sheep red blood cells (Pang *et al.*, 1987d). Therefore, cell-mediated immunity was affected by topical application of T-2 toxin.

2. Humans

In Japan, red mold disease or ''Akakabi-byo'' of wheat due to *F. graminearum* infection was reported to cause gastroenteritis in humans (Saito and Ohtsubo, 1974). In China, 60% of people who ate rice contaminated with T-2 toxin were reported to have nausea, dizziness, vomiting, chills, abdominal distension, abdominal pain, thoracic stuffiness, and diarrhea with a latent period of 10 to 30 min (Wang *et al.*, 1993).

Severe disease known as alimentary toxic aleukia (ATA) occurred in humans who had eaten overwintered grains in the former USSR during the 1930s and 1940s, and also earlier (Joffe, 1974, 1983). The primary toxin thought to be responsible for ATA is T-2 toxin although this cannot be confirmed. Four stages have been described with ATA. Stage 1 lasted from 3 to 9 days post-ingestion. It was characterized by a burning sensation of the mouth and irritation of the gastrointestinal tract resulting in hypersalivation, vomiting, diarrhea, dizziness, and tachycardia. This stage correlates with gastrointestinal lesions especially necrosis of crypt epithelial cells. Stage 2 lasted from 2 weeks to 2 months with eventual recovery if exposure stopped. It was characterized by progressive leukopenia with granulocytopenia and a relative lymphocytosis. Anemia, icterus, and impaired resistance to infections were observed. This stage correlates with acute damage to the mitotic cells in the hematopoietic system with clinical signs delayed until the lifespan of the mature cells is exceeded. Abnormalitites in the central and autonomic nervous system were also described. Stage 3 was characterized by more severe leukopenia and anemia, as well as hemorrhages due to thrombocytopenia and fibrinogenemia. Necrotic lesions were observed in the oral cavity with secondary bacterial infections and some individuals died with glottal stenosis, indicating penetrating injury or interference with normal epithelial repair processes. Stage 4 lasted 2 or more months as the hematopoietic system recovered. During this time, individuals were very susceptible to various infections. A similar syndrome was reproduced in cats exposed to repeated doses of T-2 toxin (Lutsky *et al.*, 1978).

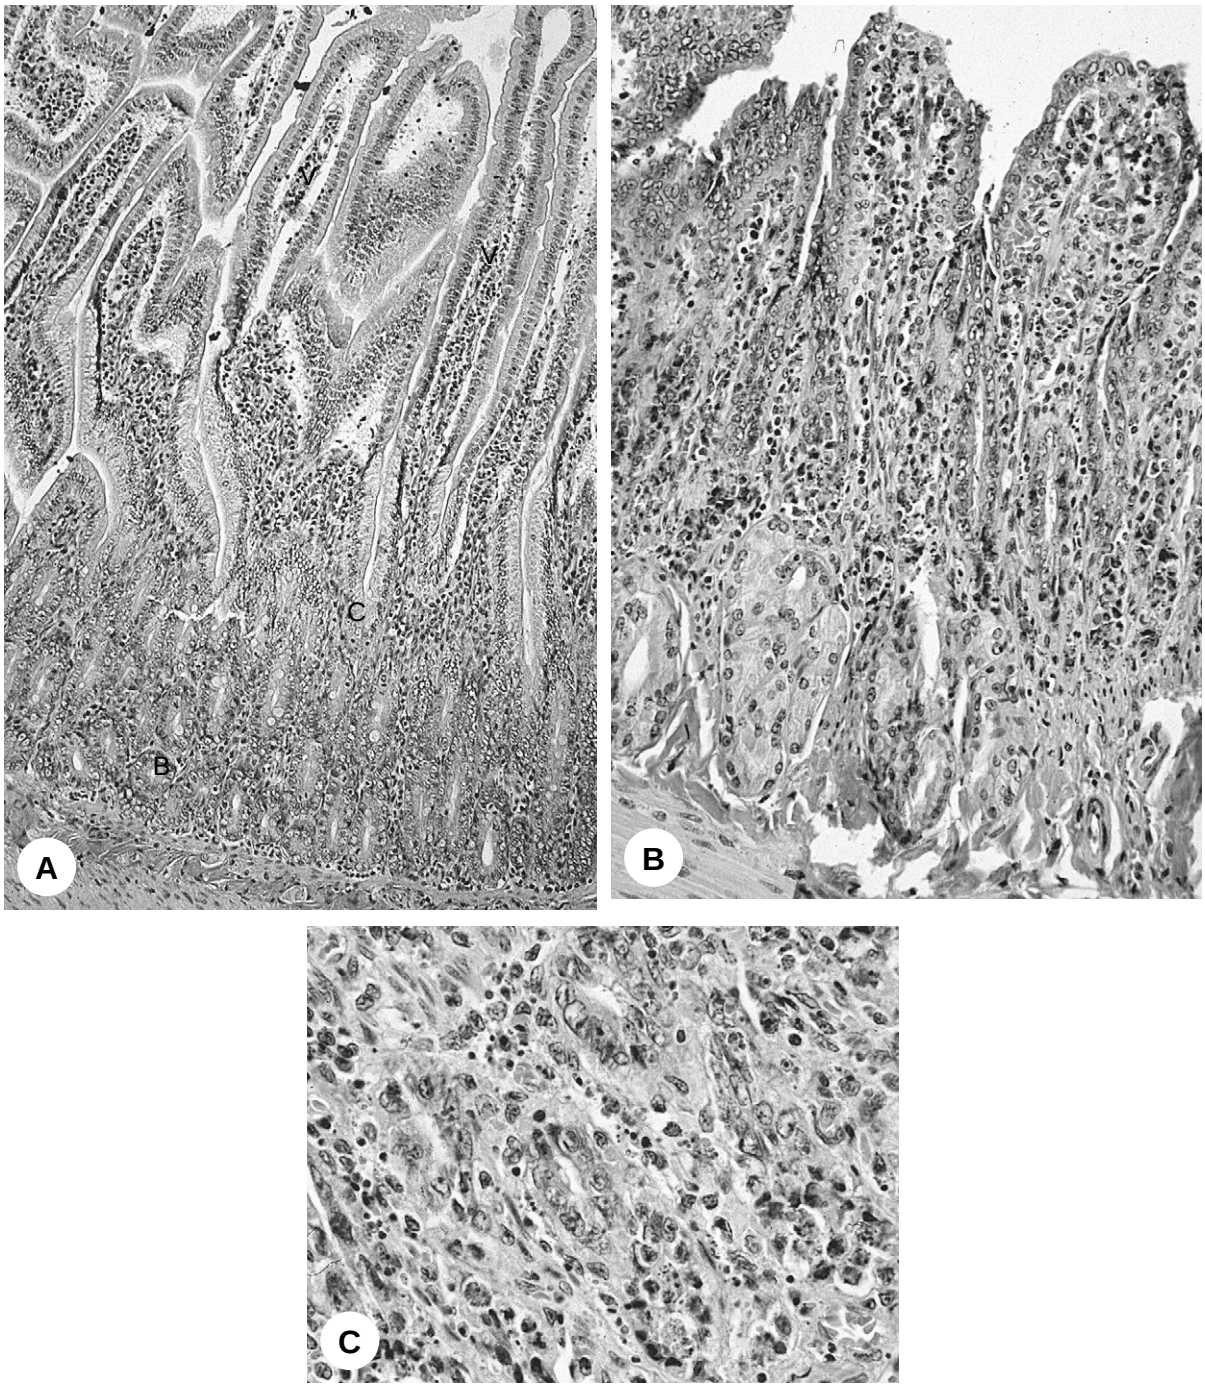

FIGURE 26.3. Intestine from Sprague–Dawley rats given T-2 toxin at 25 mg/kg as a single oral dose 12 h previously (H&E). From Haschek *et al.* (2002). A. Duodenum from a control rat. The mucosa consists of normal elongated villi (V), crypts (C), and Brunner's glands (B) located at the base of the mucosa (×100). B. Duodenum from a treated rat. The intestinal villi are short and blunted. The villous epithelial lining is segmentally ulcerated. Bruner's glands and crypts are largely destroyed (×100). C. Higher magnification of B. Extensive apoptotic necrosis of crypt cells is present. Cellular debris and mononuclear inflammatory cells are present in the lamina propria (×400).

Diacetoxyscirpenol (DAS), also called anguidine, was evaluated as a potential chemotherapeutic agent for cancer treatment (reviewed by Jarvis and Acierto, 1989). While the therapeutic efficacy was insufficient to develop DAS as an anticancer drug, valuable information was obtained in the preclinical toxicology studies, conducted using beagle dogs and rhesus monkeys, and in the phase I and II clinical studies in humans. In the preclinical studies, lethality of DAS was similar in dogs and monkeys based on mg/m^2 but on an mg/kg basis, monkeys tolerated about eight times

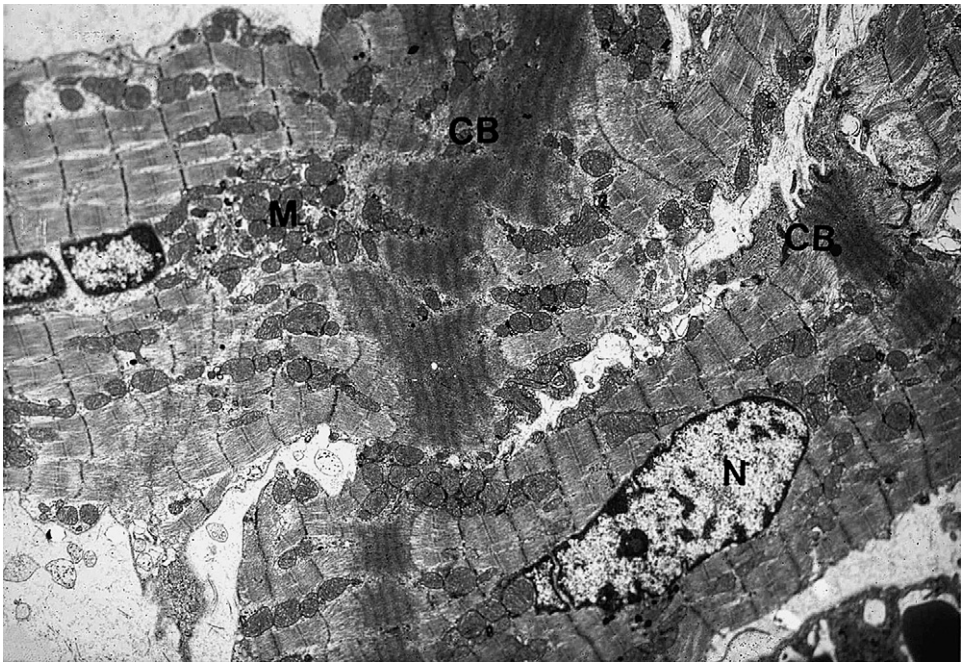

FIGURE 26.4. Heart from a pig given T-2 toxin i.v. at 2.4 mg/kg 4 h previously. Prominent contraction bands (CB) of electron-dense contractile material with adjacent mitochondrial accumulation (M) are present. Edema is present between myocytes (×6,700). From Haschek *et al.* (2002).

more DAS than dogs before lethality occurred. The highest nontoxic dose (HNTD, dose at which no hematologic, chemical, clinical, or morphologic drug-induced alterations occur) in monkeys was 0.125 and for dogs 0.016 mg DAS/kg/injection (Q1DX5, dosed daily for 5 days). Toxic effects were similar to those reported in other species for type A trichothecenes, including vomiting and diarrhea that led to dehydration; and hematopoetic effects that included leukopenia, anemia, and mild thrombocytopenia. All effects were reversible and occurred more consistently in dogs than monkeys.

Cancer patients received DAS i.v. up to 10 mg/m^2 in phase I and II clinical studies (Goodwin *et al.*, 1978; Yap *et al.*, 1979). Deaths were reported but antineoplastic activity was not observed. In phase I clinical trials (Goodwin *et al.*, 1978), toxic effects following i.v. administration of 5 μg/kg to 6 mg/kg body weight included nausea, vomiting, myelosuppression, hypotension, diarrhea, central nervous system dysfunction (including somnolence, confusion, and ataxia), fever, chills, stomatitis, erythema, and thrombocytopenia. CNS toxicity and hypotension were dose limiting. Dosage recommendations for phase II clinical trials were 3.0 to 5.0 mg/m^2 i.v. daily for a period of 5 days. In phase II clinical trials (Yap *et al.*, 1979), hematologic toxicity consisting of mild myelosuppression was deemed substantial but not prohibitive. One patient died of sepsis. Clinical signs were the same as in phase I studies with hypotension being the most significant side effect.

B. Deoxynivalenol (DON, Vomitoxin)

DON causes much less severe toxicity than T-2 toxin. Among domesticated animals, swine appear to be most susceptible, but cattle, horses, dogs, and poultry are all reported to be susceptible (reviewed by Mostrom and Raisbeck, 2007; Pestka, 2007). Though not among the more acutely toxic trichothecenes, deoxynivalenol has caused great economic loss to the livestock industry. The predominant sign associated with contaminated feed is reduced feed intake (or occasionally feed refusal) and decreased rate of gain. In swine, DON in feed at 4 ppm caused a 2% reduction in feed intake while at 40 ppm a 90% reduction was observed. In the field, however, concentrations of DON associated with feed refusal may be as low as 1 ppm. Other signs may include soft stools, diarrhea, failure to thrive, and a predisposition to other disease entities and poor nutrition. Vomiting, which occurs at higher levels of exposure, is infrequently seen. With repeated exposure, pigs may develop a resistance to DON and make compensatory gains. Specific lesions are not observed under field conditions. However, a mild thickening of the squamous mucosa of the stomach has been noted experimentally in swine (Schiefer and Beasley, 1989).

C. Macrocyclic Trichothecenes (Stachybotryotoxicosis)

Stachybotrys chartarum (previously also called *S. atra*), the fungal cause of stachybotryotoxicosis and sick building syndrome, is a black mold. There are two toxic ‘‘chemotypes’’ of *S. chartarum*, one elaborating highly toxic macrocyclic trichothecenes and the other less toxic atranones and simple, but not macrocyclic, trichothecenes (Andersen *et al.*, 2002). Exposure may be by ingestion, e.g. exposure to contaminated straw, or inhalation as when mold grows in water-damaged homes or air ducts.

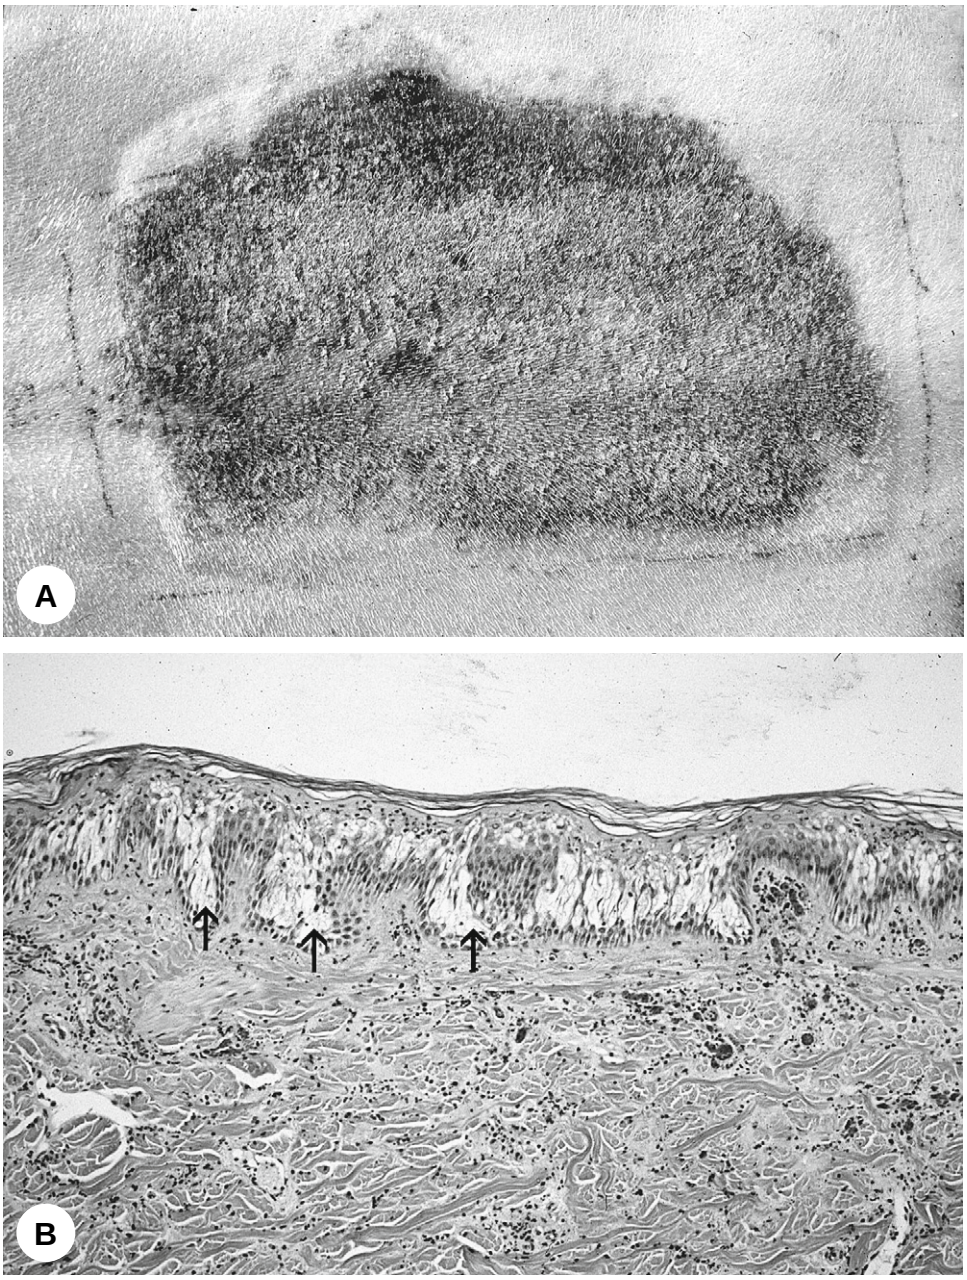

FIGURE 26.5. Skin from a pig given T-2 toxin at 15 mg/kg as a single dermal application. From Haschek *et al.* (2002). A. At 3 days after application, the area was markedly reddened and edematous. B. At 1 day after application, there is multifocal ballooning degeneration of the epidermis, as well as edema and mild cellular infiltration around congested vessels in the dermis (H&E ×10).

Consumption of straw or hay contaminated with the highly toxic trichothecenes has resulted in toxicoses, termed stachybotryotoxicosis, in horses and farm workers (reviewed by Beasley, 1992; Mostrom and Raisbeck, 2007). It has been reported in the USSR and adjacent countries, as well as Finland and South Africa, in humans, horses, ruminants, swine, and poultry. The fungi causing the disease are *Stachybotrys chartarum* and possibly *Myrothecium* and *Dendrodochium* spp., which produce macrocyclic trichothecenes including satratoxins, roridin, and verrucarin on straw or hay. These toxins are directly toxic to mucosal membranes causing necrosis and edema of the lips, tongue, and buccal membranes, and later diarrhea due to gastrointestinal toxicity. Hematopoietic toxicity follows and is characterized by leukopenia, thrombocytopenia, and coagulopathy, which can result in systemic hemorrhage, septicemia, and death. Consumption of large amounts of contaminated feed, at least in horses, results in nervous signs, circulatory collapse, and death (Beasley, 1992). In some affected horses, a ''shocking'' form of stachybotryotoxicosis has been reported. Dermal toxicity due to contact with infected material can occur and has been reported in humans. In addition, respiratory distress, epistaxis (nose bleeds), and eye irritation have been reported in humans, possibly from inhalation exposure.

When mold grows in water-damaged homes or air ducts, exposed humans may show acute or chronic health effects (Peraica *et al.*, 1999; Smoragniewicz *et al.*, 1993).

Stachybotrys chartarum is one of the most commonly noted agents associated with so-called ''sick building'' or ''damp building-related'' syndrome and ''damp building-related illnesses'' (DBRI). While upper and some lower respiratory tract symptoms have been accepted as causally linked to human exposure to moldy damp indoor environments, other reported effects, including airflow obstruction, chronic obstructive pulmonary disease, pulmonary hemorrhage, neurologic effects and cancer, have not (Institute of Medicine, 2004). An excellent recent review of *S. chartarum*, associated trichothecene mycotoxins, and DBRI is available (Pestka *et al.*, 2008).

Experimentally, the macrocyclic trichothecenes satratoxin G, isosatratoxin F, and roridin A have been shown to cause nasal and pulmonary toxicity when administered intranasally or intratracheally to mice. Intranasal exposure of satratoxin G and roridin A induced apoptosis of olfactory sensory neurons resulting in atrophy of the olfactory epithelium and olfactory nerve layer of the olfactory bulb in the frontal brain (Islam *et al.*, 2006, 2007). Alveolar-type II cells and alveolar macrophages were injured following intratracheal instillation of isosatratoxin F or *Stachybotrys* spores with marked changes in surfactant synthesis and secretion (Rand *et al.*, 2002).

VI. RISK ASSESSMENT

The toxic effects of mycotoxins in humans have been reviewed by Peraica (Peraica *et al.*, 1999). Toxins produced by *F. sporotrichioides,* with T-2 toxin believed to be the principal toxin, were implicated with the human disease alimentary toxic aleukia (ATA). Alimentary toxic aleukia was recognized prior to 1900 in the USSR, with thousands of people developing ATA and many dying after consuming cereals that overwintered in fields during and after World War II.

Human exposure to trichothecene mycotoxins was also alleged to occur in Southeast Asia from exposure to a chemical warfare agent named ''yellow rain''. T-2 toxin, DON, nivalenol, and DAS were implicated as components of yellow rain and were detected in low concentrations in blood, urine, and tissue samples of alleged victims (Mirocha *et al.*, 1983; Watson *et al.*, 1984). Clinical signs included vomiting, diarrhea, headache, fatigue, dermatitis with focal alopecia, and generalized malaise. These toxins were also implicated in several outbreaks of gastrointestinal disease in China and India that followed a single ingestion of bread containing contaminated flour or rice (Bhat *et al.*, 1989; Peraica *et al.*, 1999; Wang *et al.*, 1993).

In the 1970s, DAS (anguidine) underwent phase I and II clinical trials in humans for treatment of cancer, but minimal antitumor activity was reported (Goodwin *et al.*, 1978; Yap *et al.*, 1979). This allowed documentation of clinical signs and hematopoetic effects. Clinical signs included nausea, vomiting, diarrhea, hypotension, and CNS disturbances. Myelosuppression was observed but was not the limiting factor in dose setting.

A more recent concern with trichothecenes for humans is stachybotryotoxicosis from macrocyclic toxins produced by *S. atra* and other non-*Fusarium* spp. These fungi grow on organic matter rich in cellulose, such as straw or hay, and in water-damaged homes or airducts (''sick building syndrome''). Sick building syndrome consists of clinical signs including vomiting, diarrhea, headache, fatigue, dermatitis with focal alopecia, and generalized malaise (Peraica *et al.*, 1999; Smoragiewicz *et al.*, 1993). One study from Montreal, Canada, identified T-2 toxin, diacetoxyscirpenol, roridine A, and T-2 tetraol (Smoragiewicz *et al.*, 1993). Farm workers in contact with infected litter or feed developed skin rashes, respiratory distress, nose bleeds, and eye irritation.

Risk assessment for humans is difficult due to limited toxicokinetic and toxicodynamic data available and the paucity of cases of human illness reported from consumption of food derived from heavily contaminated grains. Risk assessment from nondietary routes of exposure in humans is also complicated by lack of epidemiological data.

VII. TREATMENT

Respiratory, skin, and eye protection is required for personnel working with trichothecenes. There are no specific therapies for trichothecene toxicoses. Neither vaccines nor specific antidotes are readily available. Treatment in people and animals is symptomatic and supportive, and the only known prophylactic measure is avoidance of exposure (Fricke and Poppenga, 1989; National Academy of Science, 1983). T-2 toxin is stable in the environment, and resistant to heat and ultraviolet light.

The first step in suspected toxicosis is to stop exposure. If ingestion is the source of contamination, the food source needs to be changed. If exposure is environmental, exposed individuals should have their outer clothing removed and exposed skin decontaminated by washing thoroughly with soap and water. Prompt soap and water wash within 5 to 60 min of exposure significantly reduces the development of dermal effects. Exposed eyes should be treated with copious saline or water irrigation. If exposure has been through ingestion, superactivated charcoal may be used to bind trichothecenes and prevent further absorption.

Various potential treatments have been examined experimentally (reviewed by Fricke and Poppenga, 1989). The only treatments that have shown some success are orally administered activated charcoal (an adsorbent), steroidal anti-inflammatory agents (supportive treatment), and monoclonal antibodies. Activated charcoal has been successful in multiple species, including rats and pigs, when administered prior to or shortly after experimental acute exposure to T-2 toxin (Bratich *et al.*, 1990; Fricke and Poppenga, 1989; Poppenga *et al.*, 1987b). Steroidal

anti-inflammatory agents such as methylprednisolone and dexamethasone have significantly prolonged survival time (Fricke and Poppenga, 1989; Poppenga *et al.*, 1987a). Large doses of monoclonal antibodies directed against T-2 toxin and its metabolites have shown prophylactic and therapeutic efficacy in the rat (Feuerstein *et al.*, 1985). Ascorbic acid was effective in mice but not in rats (Fricke and Poppenga, 1989). For topical T-2 toxin exposure, soap and water applied within 60 min significantly reduced dermal toxicity in swine (Biehl *et al.*, 1989).

Appropriate samples, such as serum, nasopharyngeal swabs and urine, should be collected from exposed individuals and sent for toxin identification or confirmation. Currently, there are no commercially available rapid field diagnostic tests for identification of trichothecene exposure. Confirmation of exposure requires testing of blood, tissue, and environmental samples using GC-MS techniques.

Decontamination of clothing, equipment, and the environment can be performed since T-2 toxin is sensitive to standard household bleach (soaking for 30 min) especially when the solution is alkalinized (Castegnaro *et al.*, 1991; Madsen, 2001). For environmental decontamination, the use of a chlorine bleach solution under alkaline conditions such as 1% sodium hypochlorite (1 part bleach and 4 parts water) and 0.1 M sodium hydroxide solution with a 1 h contact time is recommended. Other trichothecenes should also be sensitive to this decontamination procedure.

In domestic animals, when a history includes food refusal and failure to thrive, mycotoxins should be included in the differential diagnosis, and food should be submitted for a mycotoxin screen. Specific quantitative assays are available for a limited number of trichothecenes, e.g. the Neogen Corporation assay for T-2 toxin has a range of 25 to 250 ppb. Trichothecenes are not found at high concentrations in tissues, although stomach contents may contain detectable levels if the animals were eating contaminated feed prior to death. As for humans, there are no specific antidotes for trichothecene toxicoses in domestic animals. A change in diet and supportive and symptomatic treatment are indicated. For low level chronic exposure, cessation of exposure by removal of contaminated food generally results in recovery. Prevention of absorption of trichothecenes from contaminated feed by use of binders, such as clay and zeolitic products, has not been shown to be effective.

Detection methods for T-2 toxin and other *Fusarium* toxins have been recently reviewed (Krska *et al.*, 2007; Ler *et al.*, 2006). Trichothecene analysis can be done by screening methods such as thin layer chromatography (TLC) and ELISA or analytical methods such as gas chromatography (GC) and high performance liquid chromatography (HPLC). GC instrumentation has been the most frequently used method for experimental work with trichothecenes. Newer methodologies, such as GC-MS and LC-MS, have an excellent lowest level of detection (LOD) of 5 ng/g for T-2 toxin in cereals and food, and wheat flour respectively (Ler *et al.*, 2006). Improved sensitivity for detection of T-2 and HT-2 toxins in cereal grains by HPLC using different fluorescent labeling reagents with similar LOD has also been recently described (Lippolis *et al.*, 2008). For future work LC-MS and LC-MS/MS (liquid chromatography with tandem mass spectrometry) will be the methods of choice given their lack of derivitization requirement, high sensitivity, high selectivity, high specificity, and capability to identify and quantify unknown agents simultaneously in a short time frame. However, the sophisticated instrumentation and high cost are major drawbacks to use in many laboratories. Emerging methods include fluorescence polarization immunoassays and dipsticks, and even newer methods such as biosensors and noninvasive methods based on infrared and acoustic techniques are being developed (Krska *et al.*, 2007).

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

Our understanding of the mode of action and effects of trichothecene mycotoxins has been greatly expanded over the last few years. This has been primarily due to the importance of these compounds in agriculture, e.g. DON, and in human health, e.g. toxins produced by *Stachybotrys* spp. However, the major expansion of knowledge of the trichothecene toxins, especially T-2 toxin, was in the 1980s because of their potential use in chemical warfare. Major gaps still remain in our knowledge base and this has been emphasized by the concern of their potential use for bioterrorism. The primary trichothecene toxins of concern are T-2 toxin and DAS which are on the select agents list.

Recent trichothecene research in the USA has focused on DON since it is the most commonly encountered and most economically important agricultural mycotoxin (Pestka, 2007). The elegant studies by Pestka and colleagues have made important strides in unraveling the mechanism of toxicity for this toxin. It is presumed that similar mechanisms operate for other trichothecenes such as T-2 toxin and DAS; however, additional work needs to be done to evaluate the relevancy of these mechanisms. T-2 toxin is of greater concern agriculturally in Europe than in the USA since increased levels of T-2 toxin have been recently found in grain. This is attributed to the increased use of no till farming and to climate change. Because of the increasing human health concerns related to wet and moldy buildings, e.g. following hurricane Katrina in Louisiana, emphasis has also been placed on toxins produced by *Stachybotrys* spp. Recent advances in the understanding of the mechanisms of toxicity caused by *Stachybotrys* toxins have been made by Pestka and Harkema, but much remains to be done in this area (Pestka *et al.*, 2008). Appropriate therapeutic regimens can only be developed once mechanisms of toxicity are understood. This would also allow development of methods for the early diagnosis of the health effects of mycotoxins,

particularly the detection of early changes that occur before the development of irreversible effects.

General research needs lie in the areas of detection, decontamination, and treatment. Better and cheaper methods need to be developed for the rapid detection and measurement of mycotoxin levels be it in food or tissues. In regard to bioterrorism, better methods need to be developed for the identification and measurement of mycotoxins in human and animal tissues, body fluids, and feces. Availability of mycotoxin reference samples to provide comparability of analytical results obtained between laboratories within a country as well as in different parts of the world would be helpful.

CHAPTER 27

Toxins of Cyanobacteria

J.F. HUMBERT

I. INTRODUCTION

Cyanobacteria (or blue-green algae) are photosynthetic prokaryotes, which like the higher plants contain pigments that allow them to perform oxygenic photosynthesis. These microorganisms are distributed worldwide, and they colonize terrestrial, marine, and freshwater (rivers, lakes, ponds, and estuaries) ecosystems (Mur *et al.*, 1999; Whitton and Potts, 2000). Many cyanobacterial species are able to synthesize a wide range of toxins. These toxins have been involved in cases of fatal human poisoning, for example in a recent case affecting a hemodialysis center in Brazil (Azevedo *et al.*, 2002; Carmichael *et al.*, 2001; Jochimsen *et al.*, 1998). Moreover, many cases of poisoning events leading to the death of nonhuman mammals have also been reported in the past few years (see reviews by Briand *et al.*, 2003; Puschner and Humbert, 2007).

In aquatic ecosystems, cyanobacteria abundance can reach very high levels when environmental conditions are appropriate for their growth. Cyanobacterial blooms usually occur in eutrophic environments, which are characterized by high concentrations of mineral nutrients, and more particularly of phosphorus (Humbert *et al.*, 2001). When toxic cyanobacterial species proliferate they can synthesize large quantities of cyanotoxins, in particular of microcystins, during blooms, and these could be potentially extracted. It is also easy to cultivate some cyanobacterial species intensively, and this has already been done, for example, for nontoxic *Spirulina* strains, which are used to produce a human food supplement. However, some toxic strains belonging to the *Anabaena* and *Aphanizomenon* genera could be also cultivated under the same conditions or in smaller bioreactors, in order to obtain large amounts of cyanotoxins (Miyamoto *et al.*, 1988; Moreno *et al.*, 2003). Large biomasses of cyanobacteria can also be harvested from natural ecosystems, as described by Carmichael *et al.* (2000) for *Aphanizomenon flos-aquae* from Lake Klamath.

Saxitoxin is the only cyanobacterial toxin that is included in Schedule 1 of the Chemical Weapons Convention. However, other cyanotoxins would in fact be easier to obtain, due to the fact that they are produced by a wider range of species, and occur in many aquatic ecosystems. For this reason, in this chapter we will consider all the hepatoxins and neurotoxins synthesized by cyanobacteria.

II. BACKGROUND

The morphology of cyanobacteria varies widely, and they include spherical, ovoid, and cylindrical unicellular species, as well as multicellular colonial and filamentous forms (e.g. Couté and Bernard, 2001). Some species differentiate to form various specialized cells, such as heterocysts, which are able to fix nitrogen in water under N-limited conditions, and akinetes, which allow them to survive when environmental conditions are not favorable for growth. This high phenotypic plasticity makes it rather difficult to identify cyanobacteria to the species level.

In aquatic ecosystems, cyanobacteria can grow in the water column (pelagic species) or live attached to rocks, sand, or plants (benthic species). The parameters that can limit their growth are light (due to their photosynthetic metabolism), nutrients (particularly phosphorus), water temperature, and water column stability. When environmental conditions are favorable for their growth, blooms can produce very large biomasses in freshwater ecosystems within a few weeks. During these blooms, the vertical and horizontal distribution of cyanobacteria is often very heterogeneous, which makes it difficult to survey blooms and estimate biomasses.

It is also impossible to predict the potential toxicity of a cyanobacterial proliferation since even within a given species known to be potentially microcystin producing, for example, genotypes known to be toxin-producing and nontoxin-producing can occur in proportions that vary considerably not only from one ecosystem to another, but also over the course of a proliferation (Briand *et al.*, 2008). In addition, the quantity of microcystins produced by the toxin-producing cells can vary considerably, depending on the rate of cell growth (Sivonen, 1990; Briand *et al.*, 2005). Little information is available about other cyanotoxins, but it also looks as though here too the toxin-producing capacity can vary considerably from one strain to another in the species known to produce toxins.

Cyanobacteria can be fairly cultured under laboratory conditions, ranging from small batch cultures to high-volume bioreactors (Marxen *et al.*, 2005; Richmond *et al.*, 1993), but they can also be grown outdoors, in tubular bioreactors or large ponds. For example, the nontoxic species *Arthrospira platensis* (also known as Spirulina) has been cultured in

450 m^2 ponds in the south of Spain (Jimenez *et al.*, 2003), demonstrating that the outdoor industrial production of this species is possible in the Mediterranean climate, and several papers have reported different systems for outdoor mass cultures (see the review of Chaumont, 1993). Toxic genera, such as *Microcystis* or *Planktothrix* are more difficult to produce in large quantities, but high biomasses of these genera very frequently occur in aquatic ecosystems, which could be used to provide large quantities of toxins.

III. STRUCTURE, MECHANISM OF ACTION, AND TOXICITY OF CYANOTOXINS

The two main families of cyanotoxins that could potentially be used for chemical warfare are the hepatotoxins and the neurotoxins. Chemical structures of some of these toxins are shown in Figure 27.1.

A. Hepatotoxins

Three families of toxins mainly target the liver: the microcystins, which include more than 80 variants, the nodularins, and the cylindrospermopsins.

1. Microcystins and Nodularins

Microcystins (MC) are widely distributed cyanotoxins, and have often been implicated in accidental human and animal poisonings. They are produced by several genera, including the planktonic *Microcystis*, *Planktothrix*, *Anabaena* species, and the benthic *Oscillatoria*. Nodularins are only produced by the species *Nodularia spumigena,* which occurs in brackish waters, essentially in the Baltic Sea, Australia, and New Zealand.

These two families of toxins are both cyclic peptides (Figure 27.1A and B), with the same basic cyclic structure involving an amino acid known as ADDA (3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4,6-dienoic acid), and four (nodularins) or six (microcystins) other amino acids (Chorus and Bartram, 1999). Only six nodularins have so far been identified. In contrast, microcystins have two variable amino acids (X and Z), two groups (R1, R2) and two demethylated positions (3 and 7), and as a result there are more than 80 known microcystins, ranging in molecular weight from 800 to 1,100 daltons.

These hepatotoxins range from extremely toxic compounds, such as microcystin-LR ($LD_{50} = 50$ µg/kg body weight, i.p. in mice) (Chorus and Bartram, 1999; Wolf and Frank, 2002) and nodularin ($LD_{50} = 30$ µg/kg body weight, i.p. in mice), to nontoxic microcystins (Rinehart *et al.*, 1994). The oral toxicity in mice has been reported to be 30- to 100-fold lower than the toxicity after i.p. injection, depending on the microcystin(s) present (Falconer *et al.*, 1994).

Clinical signs of microcystin or nodularin intoxication in mammals are diarrhea, vomiting, piloerection, weakness, and pallor (Elleman *et al.*, 1978; Falconer *et al.*, 1981). Acute episodes of gastroenteritis due to oral contamination by microcystins have been observed in Australia and Brazil (Rao *et al.*, 2002). Moreover, in one case, 76 human deaths were recorded in Brazil after dialysis patients had been exposed to water contaminated by microcystins and cylindrospermopsin (Azevedo *et al.*, 2002; Carmichael *et al.*, 2001; Jochimsen *et al.*, 1998). We are not aware of any case of human poisoning attributable to nodularins.

Microcystins probably enter the boodstream from the ileum via the bile acid transporter system (Eriksson *et al.*, 1990; Runnegar *et al.*, 1991, 1995). Microcystins and nodularins have been shown to be potent inhibitors of serine/threonine protein phosphatases 1 and 2A (Honkanan *et al.*, 1994; MacKintosh *et al.*, 1990), and this leads to hyperphosphorylation of the proteins associated with the cytoskeleton in hepatocytes (Toivola *et al.*, 1997). The rapid loss of the sinusoidal architecture and of cell attachment is followed by intrahepatic hemorrhage, and progressive liver necrosis leading to the death if the dose is sufficient. Lower doses of microcystins cause progressive changes in liver tissue, including chronic inflammation, focal degeneration of hepatocytes, and the accumulation of metabolites such as bilirubin in the blood (Elleman *et al.*, 1978; Hermansky *et al.*, 1990a).

The liver appears to be the main target organ for microcystin accumulation, but microcystins may also be found in the intestine and kidneys after i.p. and i.v. administration of microcystin-LR. On the other hand, following oral administration of microcystins in mice, less than 1% of microcystins are found in the liver, where they are detoxified in three metabolic products (Chorus and Bartram, 1999).

Microcystins do not seem to be genotoxic, but they do have carcinogenic activity as demonstrated in various rat and mouse studies. For example, Ito *et al.* (1997) demonstrated that neoplastic nodules were induced in mouse liver by repeated intraperitoneal injections of MC-LR, and Humpage *et al.* (2000) detected an increase in the area of aberrant colon crypt foci in the mouse after chronic oral ingestion of MC for several months. In the same way, nodularin may have hepatic tumorigenicity, as detected in rats by Ohta *et al.* (1994).

2. Cylindrospermopsins

To date, cylindrospermopsins are only known to be produced by *Cylindrospermopsis raciborskii* (Hawkins *et al.*, 1985), *Aphanizomenon ovalisporum* (Banker *et al.*, 2000; Shaw *et al.*, 1999), *Umezakia natans* (Harada *et al.*, 1994), and *Raphidiopsis curvata* (Li *et al.*, 2001), mainly in tropical areas. Cylindrospermopsin (CYN) has been identified in New Zealand field extracts, but the toxin-producing cyanobacterium was not identified (Stirling and Quilliam, 2001).

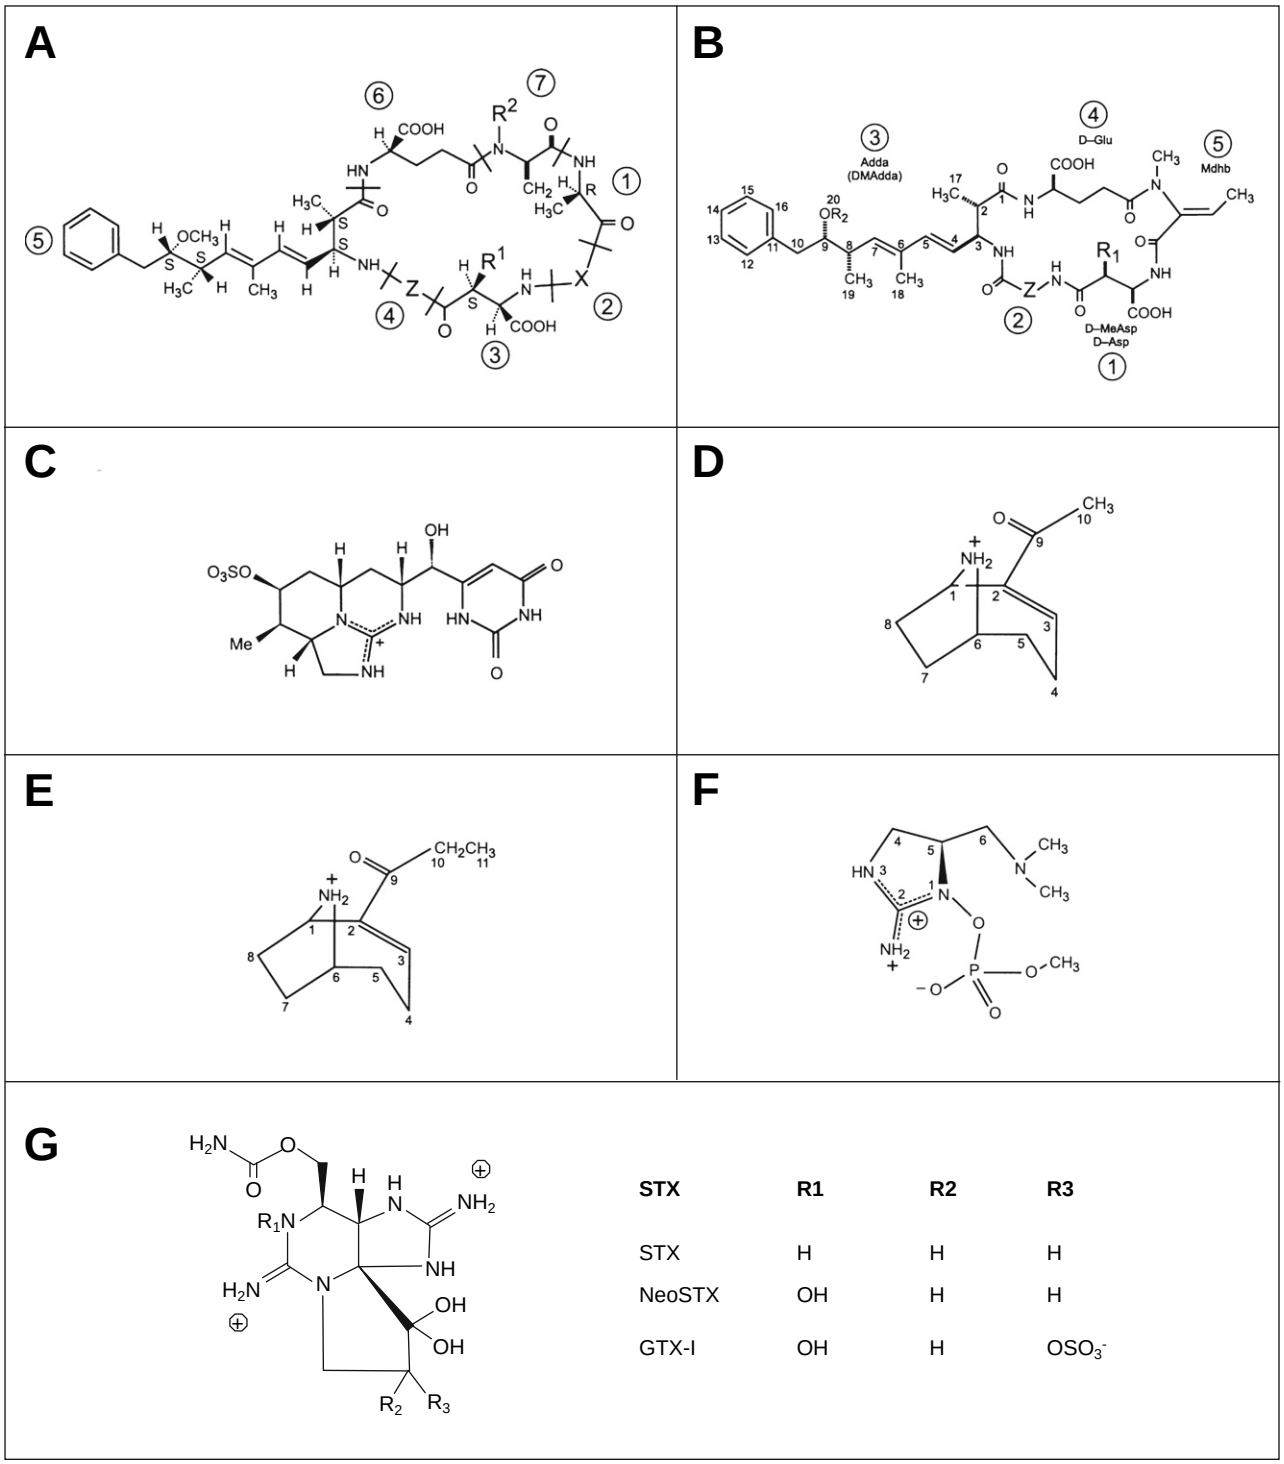

FIGURE 27.1. Chemical structures of A: microcystins, B: nodularins (X and Z are variable amino acids, R = H or CH_3), C: cylindrospermopsin, D: anatoxin-a, E: homoanatoxin-a, F: anatoxin-a(s), G: saxitoxin (STX), neosaxitoxin (NeoSTX); and gonyautoxin-I (GTX-I).

Cylindrospermopsin (CYN) is an alkaloid containing a tricyclic guanidine combined with hydroxymethyl uracyl (Figure 27.1C) with a molecular weight of 415 daltons. Intraperitoneal injection of cells containing CYN in mice is followed by diarrhea, anorexia, irregular respiration, and death if the dose is sufficient (Hawkins *et al.*, 1985). This molecule acts mainly by inhibiting protein synthesis, but other actions have also been described (Falconer, 1998; Terao *et al.*, 1994). The LD_{50} of CYN is 2,100 µg/kg body weight in mice at 24 h, but only 200 µg/kg at 5–6 days by

i.p. injection (Ohtani *et al.*, 1992). However, in the present context it should be noted that a number of papers have reported that crude extracts of *Cylindrospermopsis raciborskii* can have greater 24-h toxicities than would be expected from the known CYN content (Falconer *et al.*, 1999; Hawkins *et al.*, 1997). The oral toxicity is about 30-fold less than the i.p. toxicity (Seawright *et al.*, 1999). CYN has two known derivatives, one of which is toxic, 7-epicylindrospermopsin (Banker *et al.*, 1997), and the other virtually nontoxic, deoxy-cylindrospermosin (Norris *et al.*, 1999).

The main target of this toxin is the liver, but unlike the microcystins, CYN can also affect other organs such as the kidneys (tubular necrosis), thymus (atrophy), or heart (subepicardial and myocardial hemorrhage). Gastroenteritis and hepatitis can be generated by oral exposure (Duy *et al.*, 2000), and acute poisoning induces death probably due to heart failure, as suggested by Seawright *et al.* (1999). At toxic concentrations, the development of lesions is relatively minor compared to the rate of clinical progress. Recently, CYN has been found to display genotoxic activity (Humpage *et al.*, 2000; Shaw *et al.*, 2000). From the experimental data available, CYN appears to be slower acting and less toxic than microcystins.

B. Neurotoxins

The neurotoxins known to be produced by freshwater cyanobacteria include anatoxin-a and homoanatoxin-a, anatoxin-a(s), and saxitoxins. Their target is the neuromuscular system, and they can paralyze peripheral, skeletal muscle, including respiratory muscles. Death ensues as a result of respiratory arrest within a few minutes to a few hours (see reviews by Duy *et al.*, 2000; Kuiper-Goodman *et al.*, 1999).

1. Anatoxins

Anatoxins are produced mainly by *Anabaena* species, but also by *Aphanizomenon*, *Planktothrix*, *Cylindrospermum*, *Microcystis*, and the benthic *Oscillatoria* and *Phormidium* (Sivonen and Jones, 1999).

Anatoxin-a is a bicyclic secondary amine (Figure 27.1D) with a molecular weight of 165 daltons. It is a cholinergic agonist that binds to nicotinic acetylcholine receptors (nAChRs) in nerves and at neuromuscular junctions (NMJs). Subsequent depolarization that opens voltage-sensitive Ca^{2+} and Na^{+} channels can lead to muscle paralysis and death by asphyxiation (Falconer, 1998). The LD_{50} is 200 µg/kg body weight in mice by i.p. injection. The oral toxicity of a sonicated suspension of anatoxin-a-containing Anabaena cells is about 100 to 1,000 times higher (Carmichael, 1992), and the LD_{50} values in several species range from 1 to 10 mg/kg. Homoanatoxin-a is an anatoxin-a homolog (Figure 27.1E), with a molecular weight of 179 daltons, and lower potency ($LD_{50} = 250$ µg/kg body weight in mice by i.p. injection).

No documented case of human anatoxin-a poisoning has been found in the literature, whereas numerous cases of animal poisoning have been reported. In France, for example, the death of several dogs has been attributed to the consumption of benthic anatoxin-a-producing cyanobacteria (Gugger *et al.*, 2005).

The chemical structure of anatoxin-a(s) is not related to that of anatoxin-a because it is a unique *N*-hydroxyguanidine methyl phosphate ester (Figure 27.1F) with a molecular weight of 252 daltons. Anatoxin-a(s) is an acethylcholinesterase (AChE) inhibitor with a mechanism similar to that of the organophosphorus (OP) insecticides. There is no oral study of this metabolite, but it appears to be considerably more toxic than anatoxin-a, with an LD_{50} in mice of only 20 µg/kg body weight by i.p. injection (Falconer, 1998). The neurological effects in mice given acute doses are muscle weakness, respiratory distress (dyspnea), and convulsions (effect on seizure threshold), culminating in death. In pigs and mice, anatoxin-a(s) can cause viscous mucoid hypersalivation. Death often occurs as a result of respiratory arrest (Matsunaga *et al.*, 1989). The ''s'' in the name of the toxin stands for ''salivation'', because of the additional hypersalivation observed in mice.

2. Saxitoxins

Saxitoxins are well-known marine toxins produced by dinoflagellates, especially *Alexandrium* spp. and *Gymnodinium* spp. (Van Dolah, 2000; Wright and Cembella, 1998), and by some heterotrophic bacteria (Gallacher *et al.*, 1997). PSPs (paralytic shellfish poisons) have recently been identified in five freshwater cyanobacterial species: *Aphanizomenon flos-aquae* (Ferreira *et al.*, 2001; Ikawa *et al.*, 1982; Mahmood and Carmichael, 1986; Pereira *et al.*, 2000), *Anabaena circinalis* (Humpage *et al.*, 1994; Negri *et al.*, 1995), *Lyngbya wollei* (Carmichael *et al.*, 1997; Onodera *et al.*, 1997), *Cylindrospermopsis raciborskii* (Lagos *et al.*, 1999), and *Planktothrix* sp. (Pomati *et al.*, 2000). Saxitoxins (STXs) have also been identified in Danish freshwater field extracts, but without unambiguous identification of toxin-producing species (however, *Anabaena lemmermannii* is very common in these lakes) (Kaas and Henriksen, 2000).

The saxitoxins or paralytic shellfish poisons (PSPs) consist of a family of carbamate alkaloids (Figure 27.1G) containing more than 20 molecules with a tetrahydropurine structure (molecular weights from ranging from 241 to 491 daltons). They can be divided into four groups, depending on the substitutions in the five variable positions R1 to R5: saxitoxins (STX, dcSTX, neoSTX) (Humpage *et al.*, 1994; Ikawa *et al.*, 1982; Kaas and Henriksen, 2000; Lagos *et al.*, 1999; Mahmood and Carmichael, 1986; Negri *et al.*, 1995; Pereira *et al.*, 2000; Pomati *et al.*, 2000), gonyautoxins (GTX 1 to 6) (Humpage *et al.*, 1994; Kaas and Henriksen, 2000; Lagos *et al.*, 1999; Negri *et al.*, 1995; Pereira *et al.*, 2000), and dcGTX 2 and 3 (Humpage *et al.*, 1994; Negri *et al.*, 1995; Onodera *et al.*, 1997), C-toxins (C1 and 2) (Ferreira *et al.*, 2001; Humpage *et al.*, 1994; Negri and

Jones, 1995), and variants identified in American strains of *Lyngbya wollei* (LWTX 1 to 6) (Onodera *et al.*, 1997). Depending on the variants, the toxicity in the mice can differ considerably. Saxitoxin is the most potent PSP ($LD_{50} = 10$ µg/kg mouse, i.p.), and LWTX 1, 4, and 6 can be more than 165 times less toxic (Oshima, 1995).

All these toxins act in the same way: nervous transmission is blocked when the PSP binds to site 1 of the sodium channels (Catterall, 1980), and this induces muscle paralysis. In animals, typical neurological effects induced by this toxin include nervousness, jumping, jerking, ataxia, convulsions, and paralysis. The paralysis of respiratory muscles is fatal within a few minutes (Runnegar *et al.*, 1988). Saxitoxins are toxic both by ingestion and by inhalation, and they could be dispersed as aerosols and inhaled, and so lead to rapid respiratory collapse and death.

Saxitoxins have been involved in numerous cases of human poisoning as a result of consuming marine shellfish, but no documented cases have been recorded in freshwater environments.

IV. RISK ASSESSMENT

A. What are the Potential Routes of Contamination?

The two routes by which human beings could be deliberately contaminated by cyanotoxins involve either the ingestion of cells containing these toxins, or the direct ingestion of the free toxins in water. This means that for the purpose of deliberate poisoning with these toxins, the potential routes of contamination consist essentially of water or other dietary constituents to which cyanotoxins have been added, or the ingestion of cells in the form of a powder or capsules, for instance, after replacing a nontoxic strain with a toxin-producing strain.

In the case of the water-borne route, it would not be possible to envisage manipulating the cyanobacterial populations in natural aquatic ecosystems so as to replace nontoxic populations of cyanobacteria by toxic populations. Similarly, attempting to add toxins to these ecosystems would require far too much toxin to produce a sufficient level of risk; even without taking into account the fact that a fair proportion would be destroyed either naturally or during water treatment processes. The greatest threat would therefore seem to be likely to come either from the contamination of potable water supplies intended for human populations after they have been treated, or contaminating water intended for dialysis of hospital patients, for instance. The contamination of liquids intended for human consumption is another possible threat. The stability of these toxins is variable, depending on the compound concerned. In the natural setting, the microcystins seem to be fairly stable, and they are not very vulnerable to photodegradation, whereas anatoxin-a is much more sensitive to light, and this makes it much less stable. In a natural environment, microcystins have been detected in an ecosystem 21 days after they had been released into the water (Van Apeldoorn *et al.*, 2007).

With regard to dietary products, it would be possible to culture toxin-producing strains of cyanobacteria in bioreactors, or to harvest them from ecosystems undergoing natural cyanobacterial blooms, and then to process the biomasses obtained so that they can be supplied as dietary complements for use in slimming diets or high-protein diets, in the same way as spiruline is already administered. Furthermore, marketing these products online, and the lack of toxicity tests could make it even easier to use toxic strains of cyanobacteria to cause deliberate harm. Finally, the threat is increased by the fact that intracellular toxins are very stable once the cells have been freeze-dried, which means that they can pose a toxic risk extending over a very long period of time.

B. How can Cyanotoxins be Detected?

The methods required to detect and identify cyanotoxins can be time consuming, complicated, and expensive. In the case of the microcystins, for a long time, the method usually used involved first extracting the toxins in 100% methanol, and then using high-performance liquid chromatography (HPLC) coupled to a photo diode array detector (or possibly a mass spectrometer) to carry out specific identifications of the different variants (Nicholson and Burch, 2001). The main problem encountered in using HPLC was linked to the fact that only a fairly limited range of microcystin standards was available on the market, despite the large number of known variants. Subsequently, ELISA tests were used to carry out immunodiagnosis of these substances, and an indirect test was used to measure the toxicity by estimating the inhibition of the protein phosphatase PP2A. Very recently, a quick microcystin immunodetection kit has come onto the market, which takes less than 30 min to test a liquid sample and find out whether the concentrations of microcystins are above a threshold value. The detection of nodularins, which have a molecular structure similar to that of the microcystins, is based on the same type of approach.

The methods for detecting anatoxin-a and homoanatoxin-a are based either on bioassays, either a rather nonspecific mouse test or a slightly more specific neuroblastoma tests, or on chromatography after extracting these substances. There are several different methods of extracting these substances, as well as several different chromatographic methods for assaying them, based either on the use of HPLC, coupled with a UV or fluorescence (FL) detector, or with a mass spectometer, or on gas chromatography coupled with a mass spectrometer. There is an excellent review of all these methodologies in the paper of Osswald *et al.* (2007).

Finally, in the case of the saxitoxins (STXs), their extraction is based on the use of acetic acid, and preliminary concentration can be carried out on graphitized carbon black

cartridges (Nicholson and Burch, 2001). The identification and quantification are based on the use of HPLC-FL using either precolumn or postcolumn oxidation, and derivatization of the STXs. Hydrophilic interaction LC (HILIC)-MS and LC-EISI-MS-based methods are increasingly being used to assay these substances in water or in cells (Dell' Aversano *et al.*, 2004).

V. TREATMENT

Very few data are available about possible treatment protocols for use following cyanotoxin poisoning. Thus, in the case of the microcystins, Rifampin seems to be an effective chemoprotectant and antidote against MCLR toxicity, as shown by Hermansky *et al.* (1990b). Other drugs have also demonstrated protective effects, such as cyclosporin-A and silyramin (Rao *et al.*, 2004). However, in a recent article, Weng *et al.* (2007) point out that there is no effective treatment available for the liver damage caused by microcystins. Physostigmine and high concentrations of 2-PAM appear to be the only effective antagonists against a lethal dose of anatoxin-a(s) (Hyde and Carmichael, 1991). Finally, there is no specific treatment or antidote for saxitoxins, although Benton *et al.* (1998) have shown that saxitoxin-induced lethality can be reversed by 4-aminopyridine administered during the early stages of respiratory depression.

VI. CONCLUDING REMARKS AND FUTURE DIRECTION

No terrorist attack involving cyanotoxins has been reported to date. However, cyanobacteria and their toxins cannot be discounted as a potential threat, because large quantities of toxins sometimes exist under natural conditions in aquatic ecosystems, and in most cases, it would be quite easy to extract them. However, it is not always easy to culture cyanobacteria on a large scale, and this could considerably restrict their large-scale use. Furthermore, the lower toxicity observed after oral ingestion of several cyanotoxins, compared to their toxicity by the i.p. route, means that large quantities of toxins would potentially be required to contaminate large drinking water reservoirs, and this constitutes a second restriction on their use by terrorists. The main threat from cyanotoxins would therefore seem to be their use in relatively small-scale terrorist attacks, for example involving the contamination of food supplies or of small reservoirs of drinking water.

CHAPTER 28

Radiation and Health Effects

JOHN A. PICKRELL

I. INTRODUCTION

Radiation cannot be seen; however, its interaction with matter is partially understood at a theoretical and an experimental level. Its effects in humans have been extensively explored in large studies (Harley, 2001, 2008). These studies were those in which large numbers of people had been exposed; the doses and responses were as well known as in any branch of toxicology or chemical safety (Harley, 2008). These studies included the radium dial painters, survivors of the atomic bomb, patients with ankylosing spondylitis, children treated for ringworm (tinea captis), the workers and residents around Chernobyl and uranium miners exposed to radon soil gas, and to the short-lived radon daughter isotopes. The major health effect so far at the lowest doses has been cancer. Only at higher doses [>0.5 seivert (Sv); 500 milliSv (mSv); 50 roentgen equivalent in man (rem)] have some heart and digestive diseases been noted in atom bomb survivors (Harley, 2001, 2008).

Models of radiation damage have been explored and are well developed. For many years, accidental releases of ionizing radiation have been universally feared. Alternatively, radiation has been used in controlled, defined amounts as a therapy for certain tumors in both companion animals and humans. Taken together, all studies provide a cohesive and comprehensive picture of radiation toxicity. There are sufficient details of radiation effects to make credible estimates of risk resulting from radiation exposure (Harley 2001, 2008).

Since acute radiation toxicity responses become apparent shortly after exposure, history is an important criterion in determining whether the radiation is related to the cause of a particular complication or adverse effect. As with any attempt to specify a dose–response relationship, the dose is an important component. In contrast, late radiation toxicity in organs such as the kidneys, liver, or central nervous system (CNS) will not be seen until months or perhaps even years after radiation exposure (Center for Drug Evaluation, 2005). The integrated response is often to the radiation response and attempts to heal any radiation damage that has been caused.

Natural background radiation is substantial. Attempts to determine if there were subtle effects from this background irradiation have only begun to yield information about these worldwide effects; techniques for such estimation have increased in sensitivity and reliability.

II. BASIC RADIATION CONCEPTS

The four main types of irradiation are x-rays, gamma rays, electrons (negatively charged beta particles or positively charged positrons), and alpha particles. An atom can decay by the loss of mass (helium – loss of two protons and neutrons), or the loss of positively or negatively charged electrons (beta particles or positrons). Gamma irradiation occurs when excess energy is released from the nucleus, usually after an alpha, beta, or positron transition (Harley, 2001, 2008).

A. Radiation Energy

$$\text{Energy} = \left\{\frac{1}{2}\right\}(\text{Particle mass})(\text{Particle velocity})^2$$

Both high amounts of mass and high velocity can be used experimentally (artificially) to contrive releases of large amounts of energy such as neutron activation by bombarding an atom.

As particles approach the speed of light estimations of their energy must be corrected for relativity using

$$\text{E} = 0.511(1 - \text{Particle velocity}^2/\text{Light velocity}^2) + 0.511$$

Alpha particles have sufficiently low velocity relative to the speed of light that no correction is required for relativity (the velocities ratio is very small and approaches 0).

Gamma rays are pure electromagnetic radiation with energy = (6.626×10^{-34} joules/second – Planck's constant) (frequency of the radiation). Conventional units of radiation to be considered are one electron volt (eV) = 1.6×10^{-19} joules and one million electron volts (MeV) (Harley, 2001, 2008).

B. Alpha Particles

Alpha particles are a helium nucleus (two protons and two neutrons) ejected from the nucleus of a radioactive element

$$^{226}\text{Radium}_{86} \text{ decomposes to } ^{222}\text{Radon}_{84}$$
$$\text{and an alpha particle } (^{2}\text{He}_{2}^{++}) + \text{Energy (5.2 MeV)}$$

Most alpha particles are in the range 4–8 MeV. There are several, discrete monoenergetic alphas emitted from most alpha emitters, not just a continuous spectrum of emissions (Harley, 2001, 2008).

C. Beta Particles, Positron and Electron Capture

Beta particles are emitted when a neutron is converted to a proton plus an electron and the electron is lost. Unlike the discrete energy emissions from the decay of alpha particles, beta particles are emitted along a spectrum of energies, because energies are shared between positive and negative electrons. Positrons are emitted when a proton becomes a neutron and decays by beta emission or an electron is captured. These are competing processes, and both occur with about the same frequency (Harley, 2001, 2008).

D. Gamma Ray (Photon) Emission

Gamma ray emission is mostly secondary to an alpha, beta, or positron emission or electron capture. When all of the energy is not used by the emission, the nucleus is in an excited state with energy available for emission. This excitation energy is emitted as a photon when the particle is emitted. In many cases the photon will not be emitted, but bind to an electron which is ejected as a mono-energetic particle equal to the photon energy minus the binding energy. This latter process is called internal conversion (Harley, 2001, 2008).

III. INTERACTION OF RADIATION WITH MATTER

Ionizing radiation loses energy by producing ion pairs (an electron and a positively charged atom). About 33.85 eV is needed to produce an ion pair. This is twice the energy needed for ionization, which is lost in the ion pair formation. Alpha and beta particles and gamma rays lose energy in somewhat different ways (Harley 2001, Harley 2008).

A. Alpha Particles

An alpha particle is heavily charged with a mass equal to 7,300 times that of an electron. Yet energy can be transferred to particles going only twice as fast as the alpha particle. Since it requires 33.85 eV to produce an electron pair, a 5 MeV can produce ~7,400 pairs within 1 micron (micrometer) of the decay. One micron (1/1,000,000 meters; 1/1,000 millimeters; 15% of the diameter of a human red blood cell) is much thinner than a sheet of paper. This linear energy transfer (LET) is said to be much greater than is needed to have DNA strand breakage. Thus, it is said to have a high LET.

B. Beta Particles

Energy loss in matter cannot be simplified as it can in alpha particles because:

1. Even low energy beta emitters are traveling near the speed of light and must be corrected for mass increase by the term

$$0.511(1 - \text{Particle velocity}^2/\text{Light velocity}^2) + 0.511$$

2. Electrons are interacting with particles of the same mass; large energy losses are possible
3. Radiative (Bremstrahlung) energy losses from particles slowing down are appreciable (Harley, 2001, 2008), while with alpha particles they are not.

C. Gamma Rays

$$\text{E in MeV } \text{m}^2/\text{kg} = \text{Mass energy absorption coefficients } (\text{m}^2\ \text{g}^{-2})(\text{initial photon energy})$$

Mass energy absorption coefficients in air and in muscle are somewhat similar between 0.01 to 3.0 MeV. Energy loss/unit length is obtained by multiplying absorption coefficients by density (kg/m^3). This LET particle can penetrate much further into tissue. Thus, radiation dose is distributed over much greater areas, tending toward diffuse as opposed to focal distribution (Harley, 2001, 2008).

If lead shielding were used, density would be much greater, and penetration would be much less beyond the lead shield. If energy emitted is sufficiently low penetration can be taken to be negligible. A lead shield is often used when obtaining diagnostic x-rays as a safety feature which greatly reduces the exposure to gamma irradiation. Some fraction of energetic gamma emitters (e.g. ^{60}cobalt) irradiation can penetrate even lead and added earth shielding. This radiation leakage is usually measured to determine external radiation from a source and shielding. It may be as high as 1–10% of the source strength depending on the amount of shielding used if therapeutic gamma instead of x-irradiation is used.

IV. ABSORBED DOSE

A. Total Dose and Dose Rate

Total dose is the total energy absorbed per unit of mass; this measurement is independent of the time taken to deliver it (the dose rate) (Harley, 2001, 2008). If the dose is delivered quickly in a single exposure at a high dose rate, there is almost no time to repair radiation damage and damage/unit of dose absorbed is high (Harley, 2008). Alternatively, if the total dose is delivered quite slowly at a lower dose rate, or in divided dose fractions, say over the lifespan of the animal,

there is more time to repair radiation damage and damage/unit of dose is much lower.

Very little time is required to initiate repair. For example, if multiple fractionated doses are delivered per hour, the damage/unit of total dose decreases significantly. In this instance, the radiation therapist can deliver higher doses to the area, but less total rem/h from the source or x-radiation machine. Because charges are frequently per rad, the use of fractionated radiotherapy is small, but does occur. Fractionated radiotherapy leads to the emergence of a more homogeneous population of live cells from cell repopulation and by the high degree of radiosensitivity of the G2 cells that is a decrease in the percentage of G2 cells.

Variations in the chromatin pattern of the cells may be explained by DNA repair processes (El-Khattabi *et al.*, 1997; Murata *et al.*, 1998; Harley, 2001). While these data may be relevant to higher radiation doses required for therapy where present tolerable doses are merely palliative, protraction does lengthen the time and therefore the cost required to deliver that dose.

Absorbed dose is a function of the mass and density of the media and is equal to the mean energy deposited in mass divided by the mass of the target organ. Sometimes absorbed dose is called kerma (kinetic energy released in matter). Dose is delivered to target organs. Because exposure and dose are often used interchangeably, dose is often confused with exposure level. For comparison, exposure level is radiation in air = total radiation ions (one sign) per unit mass of air (Harley, 2001, 2008).

B. Equivalent Dose and Cancer Risk

Alpha particles with large mass produce intense ionization tracks per unit distance relative to beta particles. Beta particles produce more intense ionization than do gamma rays. Linear energy transfer (LET) measures this transfer of energy per unit distance traveled by the emission from the radiation particle. In situations where dose is considered to be proportional to response, that dose must be normalized for LET. For a particular endpoint (e.g. cell death in mouse fibroblasts), frequently one calculates relative biological effectiveness (RBE). RBE = dose of radiation under study relative to the dose of gamma rays to achieve the same effect. Radiation with high LET will be expected to have an RBE of greater than 1.

We calculate equivalent dose as:

$$\text{Equivalent dose} = (\text{Dose})(\text{Weighting factor or relative biological effect (RBE)})$$

Weighting factors recommended are approximately 1 for x-rays, gamma rays, beta particles, and electrons and 20 for conventional neutrons (>>>0.1 to 2 MeV), protons, alpha particles and charged particles of unknown energy.

For example, the weighting factor and RBE of plutonium-238 (^{238}Pu) is about 10–30. Thus, the roentgen equivalent in man (rem) is 10–30 roentgen dose in air (rads). This radiation dose pattern following alpha emission is confined to an immensely small area because alpha irradiation travels only a short distance in tissue, but has a high LET. Because the dose is in a small area it is said to be focal as opposed to being diffuse if lower energy transfer were operating and penetration was greater. It is not uncommon to have focal dose correspond to focal response in alpha particle exposure (Harley, 2001, 2008). Thus, one might see millions of ''burned out zones'' or indicators of cell death following alpha emission if microscopic resolution were sufficiently good.

The term effective dose allows comparison of cancer and genetic risks from different partial body and whole body doses to be integrated for the purposes of estimating a whole body response. Some tissues (gonads weighting factor = 0.2) are more sensitive than others (red bone marrow, colon, stomach, and lung weighting factors = 0.12; bladder, breast, liver, esophagus, and thyroid weighting factors = 0.05). Skin and bone surface are the least sensitive (weighting factors = 0.01). Other tissues not specified are taken to have a weighting factor of 0.05 as a conservative estimate (Harley, 2001, 2008).

It is useful to calculate doses using the tissue weighting factor in protracted exposures (exposures over significant periods of time). Most nonexperimental companion or domestic animals do not receive protracted exposures. A major exception to this is the animal receiving repeated fractionated doses as radiation therapy, or the relatively rare animals in which radiation has been implanted so that it acts as an internal emitter of radioactivity (Harley, 2001).

C. Committed Equivalent Dose

Once radioactivity is placed internally it becomes an internal emitter. Internal emitters are used infrequently either therapeutically (actually implanted in a tumor) or with accidental exposure via ingestion or inhalation or penetration through skin; internal emitters may be removed only with varying degrees of difficulty (Harley, 2001). Usually, they cannot be removed simply or easily and an irreversible committed equivalent dose is said to exist.

For radionuclides with half-lives zero to 3 months the equivalent dose is equal to the annual dose of the year of intake (Harley, 2001). It is often convenient to estimate the fraction of the committed equivalent dose which remains. For a radionuclide with a half-life of 3 months, after 1 year of exposure, it had undergone the passage of four half-lives so that fraction of dose delivered was $(1 - ½^4) \sim 94\%$ of the total dose for all time. Thus, 94% of the possible dose had been delivered and only 6% remains to be delivered. Those with shorter half-lives would approach 100% more closely (half-life of 1 month $(1 - ½) \sim 99.98\%$ of the total dose for all time). In both cases, any effort to remove the particle will reduce the internal dose only minimally.

Alternatively, if the half-life was long, say 1, 10, or even 5,000 years, considerably less radioactive decay would have occurred. Thus, considerably more of the total dose would remain to be delivered $(1 - ½) \sim 50\%$, $(1 - ½^{1/10}) > 0\%$, and $(1 - ½^{1/5,000}) >>> 50\%$ and nearly 100%, respectively at the end of 1 year, making removal of the radioactive particulates of greater advantage at that time to the reduction of risk. It is a good idea to perform such analyses with each radionuclide to see how much of the dose remains to be delivered; thus, one can assess the relative advantage of going to considerable effort to remove the remaining dose.

D. Negligible Individual Risk Level (Negligible Dose)

Radiation is feared because its delivery cannot be seen, and is often not measured, because it is only in retrospect that one realizes that radiation exposure has occurred. We accept the concept of linear, nonthreshold cancer induction from ionizing radiation (Harley, 2001, 2008); this allows calculation of cancer risk regardless of how small (or large) the dose may be. Calculating very low risks leads to calculating a risk that one would consider acceptably low, that is a risk below the ability to detect a response (Harley, 2001).

The National Council for Radiation Protection (NCRP) has identified a negligible individual risk level (NIRL) as a level of annual excess risk of health effects attributable to irradiation below which further effort to reduce radiation to the individual is unwarranted. The NCRP emphasized that this level should not be confused with an acceptable risk level, a level of significance or a standard. The NCRP recommended a level around half the natural background radiation level; the final recommended NIRL level is 1 mrem; this level is now called negligible individual dose (NID) level (Harley, 2001, 2008).

Effective dose was a parameter used to assess biological risk related to radiation exposure, from dual-energy X-ray absorptiometry (DXA). Children are a worst case estimate because they absorb higher doses than adults. With the exception of the hip scans in 1- and 5-year-old children, the effective doses were below the negligible individual dose limit of 1 mrem per year (Thomas *et al.*, 2005).

The NCRP recommends an annual effective dose for continuous members of the public in some circumstances of 1 mSV (100 mrem). This value is in addition to natural background level of irradiation approximately twice that (2 mSv; 200 mrem). In this context, the NIRL was taken to be 1/100 of this level, or 0.01 mSv/year (1 mrem/year). This level of exposure was low enough to have a risk of <1 cancer/1,000,000 and the risk for lung cancer $<1/10,000,000$. The notation is negligible individual dose (NID) (Harley 2001, 2008).

E. Radiation Safety for Diagnostic Imaging

Diagnostic imaging with radiation must be performed with proper protection (Kahn and Line, 2005). Although exposure factors are substantially lower than with past diagnostic imaging, a considerable radiation dose may be delivered over time if proper protection is not worn. Lead gloves will lower external radiation dose $\sim$1,000-fold from scatter radiation, not in the direct radiation beam, but only 10-fold from radiation when directly in the beam of irradiation. Thyroid shields and eye shields are recommended. For example, upper limb and skull studies are especially likely to result in substantial exposure to anyone holding the film or restraining the animal (Kahn and Line, 2005; Pickrell, 2007).

V. MECHANISMS OF DNA DAMAGE AND MUTAGENESIS

A. Energy Deposition in the Cell Nucleus

Radiation is released and slows down by forming ion pairs (Harley, 2001, 2008). Different ion densities result in the formation of alpha particles, beta particles, or gamma rays. Tract structure is roughly characterized into sparsely populated (low LET) and densely populated (high LET) tracts. Each tract from the x-irradiation of gamma rays results in 70 events across the width of the nucleus for $\sim$0.5 rads [5 mGrey (mGy); 500 mrads]. Alternatively, a 400 MeV alpha track may produce 30,000 events across the same nucleus for $\sim$300 rads (3 Gy). Within the nucleus even low LET gamma radiation may produce some microregions of relatively dense ionizations in the DNA region. The threshold is very low for some single strand breaks (Panajotovic *et al.*, 2006, cited in Harley, 2008).

The ability to capture environmental CO_2 to form backbones of macromolecules such as DNA or proteins needed to be preserved robustly to sustain both memory (faithful reproduction) and contingency (variation), if both were to be permitted and preserved (Smith, 2008). A significant percentage, but far from all of the volume of the nucleus is expressed as fibers (flexible cylinders; worms) of DNA, indicating a higher level of organization (Jones, 2004). Both genetic and epigenetic processes occur in the nucleus.

Within a cell indirect effects occur at sites within nanometers of the direct effects. Bigger tracts are caused by radiation that is a high LET. Low doses of high LET result in a few cells being hit by a single track. Low LET radiation tends to be spread out over the cells more evenly. One gray of radiation will produce 1,000 single strand breaks and fewer double strand breaks ($\sim$40); intermediate levels of damage were seen in base damage (500 breaks) and deoxyribonucleic acid (DNA) protein crosslinks (150 breaks). About 30% of the double strand breaks are complex because of additional breaks (Harley, 2001, 2008).

In the past 15 years, research on epigenetic (nontargeted) effects has shown that the nucleus need not be irradiated for health effects to occur (Little, 2006, cited in Harley, 2008). Epigenetic effects include: genomic instability – increased genomic alterations; bystander effects – effects in cells not traversed by radiation, but very close by; cytoplasmic/membrane effects – bystander effects following cytoplasmic irradiation; clastogenic effects – detrimental effects from irradiated plasma; abscopal effects – whole organ damage resulting from partial volume irradiation; and trans-generational effects – instability passed through the germ line. Risk calculations are based on observed exposure response in human and animal populations. Thus, while contributing greatly to mechanistic and biological understanding, this new epigenetic information should not affect the risk calculations (Little, 2006, cited in Harley, 2008).

B. *In Vitro* Irradiation Studies

Small lymphocytes from horses were transformed into larger radioresistant lymphoblast-like cells following stimulation by phytohemagglutinin *in vitro*. One hundred rads x-irradiation killed all the small lymphocytes, but only around one-third of the lymphoblast-like cells (Dewey and Brannon, 1976). Horse lymphocytes were more radiosensitive than human lymphocytes. The ratios between doses inducing the same effect are 1.3, 1.7, and 9.4 for the number of binucleated cells with micronuclei, micronucleus frequency in binucleated cells, and DNA synthesis inhibition, respectively (Catena *et al.*, 1997).

In cattle, at any LET value, repair is much slower after heavy ion exposure than after x-irradiation. For ions with an LET of less than 10,000 keV/μm more than 90% of the strand breaks induced are repaired within 24 h. At the highest LET value (16,300 keV/μm) no significant repair is observed (Baumstark-Khan *et al.*, 2003). Thus, a steep dose–response effect is seen at higher doses.

The baseline frequency of SCEs was similar in the three species and no significant variation in human, cattle, or muntjac (deer) cells was seen even after administration of 400 rad of x-rays (Das and Sharma, 1983). Preirradiation of artificial vessel walls substantially decreased the wall's capabilities to resist fibrosarcoma-induced lysis and abilities of blood vessels to limit extravasation and perhaps invasion (Heisel *et al.*, 1984).

X-rays induce DNA damage including strand breaks that lead to the formation of micronuclei and chromosomal aberrations; x-irradiation was associated with an increased number of apoptotic cells (Konopacka and Rzeszowska-Wolny, 2006). This phenomenon was termed ''bystander effect''. A number of studies suggest that bystander effect appears to be associated with up-regulation of oxidative metabolism. The factors causing micronucleation by x-irradiation, oxidative DNA damage, and incomplete repair may be regulated by apoptosis-independent pathways (Konopacka and Rzeszowska-Wolny, 2006).

Immature B lymphocytes in the chicken bursa of Fabricius have previously been reported to undergo apoptosis by low doses of ionizing radiation. Increase in the number of pyknotic cells was observed at a dose of as little as 1 Gy. The chicken bursal cells are hypersensitive to x-irradiation with regard to induction of apoptosis, and the apoptotic bursal cells exhibit most of the ultrastructural features known to be typical of apoptosis (Arai *et al.*, 1996).

VI. ANIMAL EXPOSURES AND RADIATION TOXICITY

Animals may show acute irradiation-induced changes from high single doses of radiation from either external or internal emitters. Alternatively, irradiation regimens may be devised which have high radiation dose rates. Cells likely to be most sensitive to high doses of irradiation may be used to model the changes expected to be seen from these radiation doses. High external doses are most commonly accumulated from either an x-irradiation source or a ^{60}cobalt gamma ray source. Usually diagnostic x-irradiation will not be sufficiently high to produce acute symptoms. However, if therapeutic irradiation is given as a single dose high doses of external irradiation may be sustained. Most often very high doses of external irradiation given for therapeutic purposes are fractionated over several to many doses, allowing a more total radiation dose to be sustained without causing clinical signs of radiation toxicity to appear, because of the lower radiation dose rate. Mammary tumors are sometimes treated with external irradiation. The radiation field commonly includes the areas occupied by the intestines and lungs. Less commonly, fugitive releases (reactor accidents) may release radioactive iodine which localizes to irradiate the thyroid glands.

The highest levels of this type of radiation produce CNS changes. It is unlikely that anything but a gross miscalculation of radiation dose rate would lead to this high level of radiation. At ultra-high external irradiation doses, humans and animals die quickly (<1 week) with associated CNS nervous signs. Disruption of the blood–brain barrier (BBB) occurs after radiation injury; it is detectable by magnetic resonance imaging or horseradish peroxidase studies. For example, rats, irradiated at 60 Gy, that were serially sacrificed at 2 to 24 weeks showed a detectable disruption of the BBB at 2 weeks post-irradiation; disruption of BBB preceded white matter necrosis (Rubin *et al.*, 1994). In humans, one pilot study administered 55–60 Gy which as a single exposure would have been fatal; however, this dose was hyperfractionated in 110 cGy fractions. The hyperfractionation allowed completion of the course of radiotherapy. Tumor regression was noted, with minimal recurrence of tumors and no overt radiation toxicity (Fontanesi *et al.*, 1995). Thus, hyperfractionation allows delivery of high doses that were therapeutic to tumors.

At high levels of this type of irradiation, but below the levels capable of inducing CNS signs, the short-lived intestinal epithelial cells die in massive amounts and gastrointestinal (GI) mucosal changes are said to occur. Death usually occurs in 1–2 weeks. Again, only the worst radiation accident or miscalculation of dose would lead to exposures of this level. For example, Chernobyl had fatalities in 30 of ~3,000 staff members, but no record of GI changes being the predominant cause of death (Harley, 2001).

At lower levels there can still be appreciable clinical contributions from gastrointestinal mucosal changes; great effort is made to minimize the importance of these to people or animal survival. One such way of improving chances of survival from radiation therapy is directing the radiation toward the field of the tumor; we call this involved field radiation therapy (IFRT) (Albuquerque *et al.*, 2005). This is relatively simple to effect in large animals such as humans; it is more difficult to focus the beam sufficiently for the same advantages in smaller dogs. Twenty ovarian cancer patients treated with 50.4 Gy of directed radiation were 66% 5-year recurrence free and 33% disease free. Thus, directed beam radiation therapy that would have been fatal if not directed minimized the consequences of human ovarian cancer (Albuquerque *et al.*, 2005). After radiation treatment for gynecological cancer, patients gained more body fat than expected, e.g. Chilean women around menopause; the loss of fat-free mass observed during radiation treatment was probably associated with infrequent physical activity (Pia de la Maza *et al.*, 2004). The extent to which this effect occurs in older dogs has not been determined.

At still lower doses failure to renew blood cells from bone marrow aplasia or hypoplasia may occur. These occur at low enough doses that radiotherapy may induce them clinically. Hyperfractionation of radiation dose helps minimize the consequences of these changes by lowering the overall dose rate. When human external beam irradiation 50–70 Gy was combined with cisplatin chemotherapy to treat head and neck cancer 6% of the patients had groin hematomas requiring no treatment. In addition, 6% of the patients had mucosal events; hematologic changes were less frequent at 2% (Gemmette, 2003). Intensive induction chemotherapy combined with external beam irradiation therapy of children with brain stem gliomas produced objective improvements in 50% of cases; this treatment course also produced severe but manageable hematologic toxicities. Data suggested that future radiation therapy regimens may require hematologic toxicities to be managed (Benesch *et al.*, 2001). IL-17A is a T cell-derived proinflammatory cytokine required for microbial host defense (Tan *et al.*, 2006). *In vivo* expression profoundly stimulates granulopoiesis. Knockout mice establish IL-17A as an inducible mechanism that is required for recovery of granulopoiesis after radiation injury (Tan *et al.*, 2006).

Below 10 mSv/day (1,000 mrem; 1 rem per day) organisms show some indicators of response (Fliedner and Graessle, 2008). Between 10 and 100 mSv/day animals are capable of dealing with excessive cell loss. Above 100 mSv/day dogs have progressive shortening of their lifespan. The mechanisms are compatible with an excess cell loss (relative to steady state) that is a function of the daily dose rate. Once the stem cell pool is approaching exhaustion level, a ''turbulence region'' is reached and takes only a small amount of stress for the system to fail. It is important to understand the pathophysiology of the cell renewal systems in order to allow one to predict the development of radiation-induced lesions (Fliedner and Graessle, 2008).

Depending on dose, external irradiation may lead to different types of reproductive toxicity in the male companion animal (Scialli *et al.*, 1995, cited in Ellington and Wilker, 2006; De Celis *et al.*, 1996, cited in Ellington and Wilker, 2006). At very high doses, it may lead to permanent aspermia. At intermediate doses it may lead to reduction in sperm numbers. Finally, at lower doses external irradiation may lead to DNA alterations in sperm cells (Scialli *et al.*, 1995, cited in Ellington and Wilker, 2006; De Celis *et al.*, 1996, cited in Ellington and Wilker, 2006).

Finally, at lower levels, but with continuing irradiation, degenerative changes, for example cancer, are of the greatest concern. Usually, these changes are caused by fugitive releases of radiation (reactor accidents). The Chernobyl reactor accident released massive quantities of ^{131}iodine causing increased thyroid cancer in Belarus (>100 thyroid cancers/year). Less than one-third of this increase was seen in Ukraine and the Russian Federation (Harley, 2001). No such tumors are reported for companion dogs, but they were similarly exposed and some tumors may have occurred. Widespread radioactivity was released across much of Europe and has been recorded >10,000 miles around the world at Fiji atoll. Increased levels of ^{90}strontium and ^{131}iodine were in European cows' milk near the time of Chernobyl.

Thirteen dogs with invasive thyroid carcinoma were treated by four once-weekly fractions of 9 Gy of 4 MeV x-rays of external beam irradiation (Brearley *et al.*, 1999). Four of the dogs died from primary thyroid carcinoma and four from metastatic spread. Of the remaining five dogs, three died of unrelated problems, and two were still alive at the time of the census. Median survival time from first dose to death from either primary or metastatic disease was 96 weeks, with a range of 6 to 247 weeks. Radiation therapy should be considered an important modality for the control of invasive canine thyroid carcinoma (Brearley *et al.*, 1999).

Animals receiving fractionated external radiation therapy for mammary tumors may develop chronic pulmonary degenerative disease because the thorax is irradiated. To achieve the desired therapeutic effect, the dose may be too high to heal by primary intent; thus, they will heal by secondary intent – fibrosis. Type II cell proliferation is a common early event in radiation toxicity to the lungs.

Following 10–15 Gy of x-irradiation, the first wave of type II cell proliferation correlated with an increase in surfactant in alveolar fluids (Coggle, 1987). The second wave follows an additional delay allowing the alveolar epithelial continuity to be sufficiently compromised by the low rates of type I alveolar pneumocyte loss; type I cell loss triggered a compensatory wave of type II cell divisions that contrasted with the dramatic and immediate hyperplastic responses which many toxic irritants produce in type II epithelial cells (Coggle, 1987). At later times, fractionated external thoracic irradiation 1–2 times weekly to achieve 4,000 to 6,000 rads modestly increased total lung collagen (Pickrell *et al.*, 1975, 1983). Collagen production was initially increased, leading to an increase in total lung collagen; collagen metabolism returned to a more normal level at later times (Pickrell *et al.*, 1975, 1983).

Dogs exposed to ^{226}radium to establish coefficients for ^{239}plutonium produced data that showed the best way to translate data to humans was to use a two-mutation model to calculate radiation risks to supplement published risk estimates (Bijwaard, 2006; Bijwaard and Dekkers, 2007). The total exposure resulting from a 5 mCi administration of 18F fluoroethyl cyanophenoxy methyl piperidine 18F SFE as a tracer show it to be safe in human positron emission tomography (PET) imaging studies (Waterhouse *et al.*, 2006).

The relation of static compliance of excised lungs to collagen accumulation and histologic fibrosis was examined in Syrian hamsters inhaling sufficiently high LET $^{238}PuO_2$ particles to achieve initial lung burdens of 50 or 100 nCi (Pickrell *et al.*, 1983). Hamsters exposed to 50 nCi $^{238}PuO_2$ showed normal collagen content and static lung compliance with minimal histologic fibrosis 288 days after exposure. In contrast, hamsters exposed to 100 nCi had significant pulmonary fibrosis at that time and the highest incidence of dense scars at any time period. Such findings are consistent with a stiffening of lung parenchyma. Hamsters had increased total lung collagen, reduced lung compliance, and histologic evidence of diffuse interstitial fibrosis. The diffuse interstitial fibrosis developed by this injury resolves spontaneously as indicated by total lung collagen, compliance, and histology; dense fibrous scars, however, do not resolve (Pickrell *et al.*, 1983; Pickrell and Abdel-Mageed, 1995).

Total body irradiation-induced changes in expression of CD25 and CD71 activation markers on the surface of lymphocytes suggest that radiation may alter tumor surveillance. Taken together, the relative percentages and activation status of immune cell compartments support the conclusion that these total body irradiation-induced changes function to slow tumor progression.

VII. HUMAN EXPOSURES AND RADIATION TOXICITY

The major health effects at the lowest doses have been the production of cancer – such production has often been influenced by exposure to tobacco smoke. Only at higher doses [>0.5 seivert (Sv); 500 milliSv (mSv); 50 roentgen equivalent in man (rem)] have some heart and digestive diseases been noted in atom bomb survivors (Harley, 2001, 2008).

Six major studies in which dose and response were well characterized have been reviewed by Harley (2001, 2008). The worker and environmental populations have been studied to make certain that there is consistency in radiation risk data extrapolated from higher exposures.

A. Radium Exposures

The highest effects were seen in the radium dial painters who tipped their paint brushes during painting. The only late effect was osteogenic sarcoma; no leukemia was noted. Radium was retained in the body >1% after ~1,000 days (>2.5 years); loss of radium from the body matched the simple power function in several studies

$$R = 0.54t^{-0.52}$$

where t is the total time in days. The fit was good except at long times after exposure (Norris cited in Harley, 2008). Radium once taken up is somewhat similar to calcium. It is incorporated on the surface of the bone into the bone matrix. Raabe *et al.* (1980; cited in Harley, 2008) modeled dose and risk and found a practical threshold (a level sufficiently low that bone cancer will not appear) from these radium exposures in the normal human lifespan to be 0.04 Gy (4 rads/day) or a total dose of 0.8 Gy (80 rads) to the skeleton.

European children and adults were treated with ^{224}radium for tuberculosis or ankylosing spondylitis. Data analyzed together showed that they had an overall risk of 0.01 per Gy (100 rads) at a total dose of 1 Gy, which nearly doubled by a total dose of 10 Gy to 0.02 per Gy; no excess leukemias were noted (Harley, 2008).

B. Atom Bomb Survivors

The survivors from atomic bombs dropped in August 1945 were analyzed. Within 1 km of the epicenter 64,000 people were killed by the blast. From 1–2 km of the epicenter, people received doses as high as several Sv. At more than 2.5 km, irradiation was not significantly above background. Risk estimates are important because they are used for occupational exposure guidelines. The latest updates report that 5% of the solid cancer deaths and 0.8% of the noncancer deaths were estimated to be due to radiation exposure (>9,000 cancer deaths; >31,000 noncancer deaths; 47 years of follow-up).

Projected cancer incidences (>9,000 cancer deaths) for 100 mSv (0.1 Sv) were 0.8 and 1.3% (1.2 and 1.8% for a DS86 subcohort) for men and women, respectively. Looking at specific organs in this subcohort, incidence was as high as 0.52% for breast cancer in females and 0.23% for both liver and lung in males. Examination of smoking

interaction with lung cancer showed no interaction, that is smoking and atomic bomb radiation acted independently and not multiplicatively in lung cancer induction.

More than 31,000 excessive noncancer deaths were seen at doses higher than 0.5 Sv (500 mSv) as significant excesses of heart disease, stroke, digestive diseases, and respiratory diseases.

C. Children Irradiated with X-Irradiation for Ringworm (Tinea Captis)

More than 2,000 children who were irradiated for ringworm at New York University Medical Center over 20 years (age range 1–15 years) were compared to 1,380 control children. An additional 11,000 children (mean ages 7 to 8 years) irradiated for ringworm in Israel were also compared to control children. Significant increases in skin cancer, cancer of the scalp, and thyroid malignancies were noted. Risk of basal cell carcinoma of the skin was highest at 0.32 per Gy (100 rads). Total incidence was 0.01 per Gy for males and 0.04 per Gy for females. Total mortality from all sites was ~10% of the incidence (0.001 for males; 0.004 for females).

D. Chernobyl and Thyroid Cancers

The Chernobyl incident (April 1986) was the largest radiation exposure of recent times. Chernobyl resulted in a rapid increase in reactor power, vaporization of water in the reactor that blew the reactor core apart and destroyed most of the building. During that year, 220,000 people from areas near or surrounding the reactor were evacuated. Approximately 250,000 people were relocated from Belarus, the Russian Federation, and Ukraine.

About 280,000 persons were initially given status of liquidators; these were workers who took part in reactor mitigation or clean-up. This number would later increase to ~600,000.

Within the following few weeks 28 of the 32 acute deaths of exposed employees were judged due to radiation exposure. Thyroid cancer in children under 18 rose from an incidence of 0.5 of 100,000 (1986–1988; baseline) to more than ten times that level (5–8 per 100,000) in Belarus (1993–2002). Increases were just as consistent, but of less magnitude for Ukraine, going from 0.2 per 100,000 from 1986 to 1988 (baseline) to 5–10 times that level (1 to 2.2 per 100,000) from 1993 to 2002. There is little doubt that Chernobyl radiation caused thyroid cancer. In 2,000 there were 4,000 cases of thyroid cancer in children under 18 drinking milk contaminated with ^{131}I; in 2002 there were 12 deaths related to these exposures.

Many countries had large supplies of potassium iodide (KI) to block the uptake of ^{131}I. Had KI been available, and use of the contaminated milk been discontinued in favor of other sources, it is doubtful that large numbers of thyroid tumors would have occurred.

E. Patients Irradiated with X-Rays for Ankylosing Spondylitis

About 14,000 persons, mostly men, were exposed to x-rays to relieve and/or cure ankylosing spondylitis. Organs were partially and variably shielded; cancers occurred 6–20 years after exposure. Leukemia and cancer to the esophagus were significantly elevated relative to the control population but had relatively low risks of cancer [0.0011 and 0.007 per Gy (100 rads)]. Risk of lung cancer was about 2–3 times as high as that for esophagus or leukemia at 0.0022 per Gy. Noncancer deaths were about 30% higher than a carefully matched control population related to this cohort (Harley, 2008). Control populations were closely matched to those exposed, so that radiation effects might be investigated.

F. Underground Miners Exposed to Radon

Most cancers from radon were produced by radon daughter decay products (polonium – 3 isotopes; bismuth – 1 isotope; and lead – 3 isotopes). ERR (excessive relative risks) of cancers varied, ranging from 0.002 to 0.08 per working level months (WLM) of 170 h of exposure. One WLM is about 200 pCi per liter in a home and 300 pCi per liter in an underground mine. Relative risk increases from 1 to 10 at 2,500 WLM and 16 at twice that exposure level (5,000 WLM) in the Colorado cohort (Harley, 2008).

Aerosol size has an effect on the lung dose. Fine particles breathed through the mouth or the nose from 100 nm to 1,000 nm median size had 5–20 nGy per becquerel. Below 100 nm, this number more than doubled at 25–65 nGy per becquerel at 20 nm median size. Median sizes had an approximate geometric standard deviation of 2, so that the 95% confidence interval of particle sizes ranged from 0.25 to 4 times the stated median size. Very small particles deposited more efficiently in the airways. Lung cancer was related to radiation dose. These dose estimates are important determinants of lung cancer.

The greatest risk was at 5–15 years after initial exposure; later risk fell to 0.5 of that level and in those aged 55–64 to 0.4 of that level. Cancer fatalities were thought to be 0.0003 per working level month. Smoking may have had a modest effect. For example, there are 15,000 lung cancer cases in people exposed to radon and radon daughters, 10,000 in those who have smoked and 5,000 in those who have never smoked (Harley, 2008).

G. Natural Radioactivity and Background Radiation

The occupational, accidental, and wartime experiences have provided the basis for the estimation of risk to humans following radiation exposure. However, cosmic, cosmogenic, inhaled, and in-body radiation deliver total body effective doses of 3 becquerel per year total effective dose. The average radon concentration indoors is 40 becquerel

per m^3, resulting in an inhalation of 2 of the 2.1 (lung) and 3 (total tissue) mSv per year total effective dose (Harley, 2008). Thus, indoor air pollution is responsible for most of our total effective radon and total effective radiation dose from natural radioactivity and background radiation. Since radon is different for each indoor dwelling, this figure may vary considerably. This variation has led to the measuring of radon concentration in houses. Usually, natural radiation is not sufficiently high to produce clinical signs.

VIII. RADIATION HORMESIS

Hormesis is defined, originally in the field of toxicology, as a phenomenon in which a harmful substance gives stimulating (beneficial) effects to living organisms when the quantity is small (Sakai, 2006). Although radiation was thought to be harmful no matter how low the dose, recent investigations have revealed that radio resistance is induced by low dose irradiation given in advance. The stimulation of bioprotective functions includes antioxidant capacity, DNA repair functions, apoptosis, and immune functions as adaptive processes. The adaptive response is effective for chromosomal induction, acute death, and tumorigenesis induced by high doses of radiation. Radiation hormesis and adaptive responses provide a new scope in the risk assessment and medical application of ionizing radiation (Sakai, 2006).

The effect of low-dose irradiation of the immune system was investigated in mice (Ren *et al.*, 2006). When a 0.2 Gy (20 rad) dose of x-irradiation was administered every other day for a total of four times, the number of lymphocytes yielded by the liver, spleen, and thymus decreased by 10 days, but increased above the level of the control mice by day 28. The population of NK cells dramatically expanded, especially in the liver where primordial lymphocytes were present. Functional and phenotypic activation of these cells occurred at the recovery stage, raising the possibility that an initial activation of macrophages by low-dose irradiation mediated the innate immune system (Ren *et al.*, 2006).

Induction of hormesis and adaptive responses by low dose radiation have been extensively studied (Wang *et al.*, 2008). Pre-exposure of diabetic prone mice to low dose radiation (LDR) has reduced the incidence of alloxan diabetes and delayed the onset of hyperglycemia, although the mechanisms are unclear (Wang *et al.*, 2008). Low intensity laser (LIL) has stimulated healing in diabetes (Wang *et al.*, 2008).

Pre-exposure B6C3F1 hybrid male mice with low dose $^{12}C^{6+}$ ion beam or ^{60}Co gray (0.05 Gy; 5 rad) significantly alleviated the harmful effects of subsequent high dose irradiation (2 Gy; 200 rad) – reduction in serum follicle stimulating hormone, luteinizing hormone, testosterone, testis weight, sperm count, and sperm morphology (Zhang *et al.*, 2006). The effects were greater and the reversal nearly the same if $^{12}C^{6+}$ were used rather than ^{60}Co for irradiation. These data suggested that the low dose radiation pre-exposure could induce adaptive response(s) (Zhang *et al.*, 2006).

Thus, it would appear that low dose irradiation is fully capable of inducing adaptive responses so that the overall response is below that when the adaptive response was not induced. Advocates of hormesis suggest that we may be ignoring the benefits of radiation hormesis (the low level that produces adaptation necessary to combat higher levels of radiation) if we set our allowable radiation limits too high. The next study addresses this concept.

The hormesis theory proposes the low-dose beneficial and high-dose detrimental pattern existing for radiation has not been borne out at the level of our present radiation protection criteria (Zapponi and Marcello, 2006). A study of 400,000 power plant workers has shown there is a small risk at the limits of radiation protection and possibly below those limits. Thus, the hormesis theory-based criticism of current radiation protection, assumed to be excessively conservative, is not justified. Also not justified is the criticism that by dismissing hormesis, regulatory agencies such as the US EPA deny the public the opportunity for optimal health and avoidance of diseases. Analogical considerations are not necessarily logical ones and the single result should be considered in the whole context of radiation hormesis (Zapponi and Marcello, 2006).

Zapponi and Marcello (2006) report an interesting study, which says that if our low level adaptive response were to occur at just the level of the allowable radiation exposure limit, then the authors calculate that there is still some risk at or possibly below that level. To be a true adaptive response one would want to go below the level where there is significant risk. As these data point out, this level may be difficult to calculate. Moreover, it may be easy to interpret data in a variety of different ways.

Incidentally, the author is hardly unbiased with respect to hormesis and was far from convinced about its benefits (Pickrell and Oehme, 2002). After being asked to provide a critique he became a reluctant convert as he learned more about it (Pickrell and Oehme, 2002, 2005, 2006).

This leaves us with two possibilities; the first is that hormetic protection and adaptation do not exist. Three papers argue against this position (Zhang *et al.*, 2006; Wang *et al.*, 2008; Ren *et al.*, 2006). An alternative position might be that to achieve radiation hormesis, one might want to go below the allowable radiation protection limit. In three specific instances, the low level protective dose can produce beneficial responses (Zhang *et al.*, 2006; Wang *et al.*, 2008; Ren *et al.*, 2006). In the case of Zhang *et al.* (2006) the beneficial responses were phenotypical, and the measurements seemed relevant to the arguments of Zapponi and Marcello (2006).

Zapponi and Mastrello argue that at low level the allowable exposure limit would not provide the protection described by hormesis. I tend to agree. They go on to say that the critique which says that US EPA, by setting these limitations, is denying us the protection of radiation

hormesis and the opportunity for optimal health is not correct. Reluctantly, I must agree with them again, it is a matter of wording, and they are correct. However, their data do not say that there is not such a level, in this case below the allowable radiation exposure limit that would initiate an adaptive response and provide the protection of radiation hormesis and facilitate optimal health. In the interest of fairness, their data do not say that such a level exists either. However, the other three studies (Zhang *et al.*, 2006; Wang *et al.*, 2008; Ren *et al.*, 2006) I cited, especially that of Zhang *et al.* (2006), argue for this point and provide examples, of such a level, with measurements relevant to radiation risk assessments. Although future research will be needed to completely assess these arguments, we should keep our minds open to assessing the additional data.

IX. CONSEQUENCES OF RADIATION THERAPY

When x-ray therapy (XRT) has been given, radiation injury is often limited to organs within the radiation beams. The risk of radiation injury to an organ is determined by the organ's radiosensitivity and by the concentration time–activity curve of the agents in that organ or at a specific anatomical target. For example, late radiation effects can occur if the kidneys receive a significant radiation absorbed dose. The kidneys are known to have a relatively low radiation tolerance dose (23 Gy for conventionally fractionated XRT); therefore, late radiation nephritis may be a dose-limiting toxicity. Radiation fibrosis is a common sequela to XRT for lung cancer (Pickrell *et al.*, 1975, 1978; Pickrell and Mageed, 1995; Center for Drug Evaluation, 2005).

It is possible to predict the effect of treatment in cancer in a noninvasive manner by apoptosis imaging *in vivo* after radiotherapy by using ^{125}I-Annexin V. Brain tumors were implanted in susceptible (nude) mice. By 6 h after receiving levels of x-irradiation as low as 2 Gy both autoradiography and immunohistochemical staining showed more apoptosis in the tumors of irradiated groups than in the control group (Watanabe *et al.*, 2006).

Therapeutic brain irradiation can cause progressive decline in cognitive function, particularly in children, but the reason for this effect is unclear. Neocortical neurons of very young mice are more susceptible to radiation-induced apoptosis than are older mice. However, this sensitivity decreases rapidly after birth. By 14 days after parturition, acute cell loss due to radiation occurs primarily in non-neuronal populations (Nakaya *et al.*, 2005).

Poly (ADP-ribose) polymerase-1 (PARP-1) facilitates the repair of DNA strand breaks (Calabrese *et al.*, 2004). Inhibiting PARP-1 increases the cytotoxicity of DNA-damaging chemotherapy and radiation therapy *in vitro*. But classical PARP-1 inhibitors have limited clinical utility. AG14361 is, to our knowledge, the first high-potency PARP-1 inhibitor with the specificity and *in vivo* activity to enhance chemotherapy and radiation therapy of human cancer (Calabrese *et al.*, 2004). GR205171 has the most potent anti-emetic activity of any tachykinin NK1 receptor antagonist described to date. The compound is orally active in the ferret and dog, long-lasting, and warrants further investigation as a potential broad-spectrum anti-emetic agent (Gardner *et al.*, 1996).

Three-dimensional dose–rate/time/response surfaces for chronic exposure to carcinogens and ionizing radiation clarify the interactive roles of competing risks (Raabe, 1987). The three dimensions are average dose rate, exposure time, and risk. The improved conceptualization afforded by them contributes to the planning and evaluation of epidemiological analyses and experimental studies involving chronic exposure to radiation toxicants (Raabe, 1987).

X. CONCLUDING REMARKS AND FUTURE DIRECTION

Radiation is of concern because it cannot be seen, exposure is frequently not painful, but it can cause significant biological effects. Alpha and neutron particles are the largest radiation particles, they penetrate the least and deliver the highest radiation energy per unit distance. Their dose patterns resemble multiple tiny foci of radiation damage. When irradiation interacts with matter, alpha and neutron particles have 20 times the injurious cancer causing potential than beta irradiation and gamma rays have.

Cancer causing or apoptotic potentials are related to the interaction of ionizing radiation (neutron, alpha, beta, or gamma) with the critical target cell nucleus. In veterinary medicine, the greatest potential for acute radiation damage lies in accidents causing release of the contents of nuclear reactors such as Chernobyl in Belarus, radiation cancer therapy, most commonly for dog mammary tumors, or a gross miscalculation of irradiation dose needed for diagnostic imaging. Radiation fatalities at the highest dose can affect the CNS, perhaps by damaging the blood–brain barrier. At a lower dose they can damage intestinal epithelium with rapid turnover, causing the gastrointestinal syndrome. At a still lower level than can damage blood cells causing the hematologic syndrome.

Fractionating the radiation dose dramatically reduces the probability of an acute reaction from radiation therapy. If the dose is protracted over long time periods (months instead of hours to minutes), there is danger of chronic degenerative disease. For example, children who receive relatively low radiation doses appear to lose measurable cognitive function. The degree to which this is a lower dose manifestation of the CNS syndrome is not understood. When radiation is in the lung area, pulmonary fibrosis may develop; post-radiation nephritis is not uncommon. Dr Raabe's 1987 model for three-dimensional dose–rate/time/response surfaces after chronic exposure to ionizing

radiation by dose fractionation has helped us to understand the interactive roles of competing risks from therapeutic irradiation.

Acknowledgments

The author would like to thank Dr Priyadarshini Gadgil for her excellent literature review on irradiation of ground beef that I was privileged to read, Dr Larry Erickson, Chemical Engineering, Kansas State University, for his support in this effort, and Dr Frederick W. Oehme, Comparative Toxicology Laboratories, Department of Diagnostic Medicine/Pathobiology, Kansas State University, for his support, and for critically reading earlier versions of the manuscript. We acknowledge the support of the state of Kansas.

CHAPTER 29

Depleted Uranium

GEORGE C-T. JIANG AND MICHAEL ASCHNER

I. INTRODUCTION

Uranium (U) is a naturally occurring heavy metal that is both radioactive and ubiquitous (ATSDR, 1999; Harley *et al.*, 1999; Jiang and Aschner, 2006). Depleted uranium (DU) is the by-product of the enrichment process of uranium for its more radioactive isotopes. Enriched uranium (EU) is used for nuclear energy, whereas DU is used in other applications which require a heavy metal, such as aviation counterweights and naval ballasts. Because of its pyrophoric and dense metallic properties, DU is used primarily by the military in armor and ammunitions. DU retains 60% of its natural radioactivity and as such there are health hazards associated with exposure to the retained inherent radioactivity, but the radiological risks are less than those of natural uranium. However, the chemical toxicity of DU cannot be overlooked and the possibility that it exerts specific chemical toxicological effects separate from its radiological effects has been a subject of intense investigation.

There has been significant public concern regarding the use of DU by the military, and it has been hypothesized that DU may be a cause of Gulf War Syndrome. The public concern also stems from the lack of awareness regarding the specific physical chemistry and hazards of DU, and the belief that DU is still a form of uranium and therefore radiologically hazardous. These concerns have given rise to the belief that DU may be used as a weapon of mass destruction in the form of a dirty bomb, or as an agent of bioterrorism.

II. BACKGROUND

Small amounts of uranium are found in rock, soil, air, water, and food, and it is estimated that total annual intake of uranium by human adults approximates 460 μg by ingestion of food and water, and 0.6 μg by inhalation (Fisenne *et al.*, 1987; Pietrzak-Flis *et al.*, 2001; UNSCEAR, 2000a, b). Natural uranium is composed of three isotopes, ^{234}U, ^{235}U, and ^{238}U, in the proportions shown in Table 29.1.

DU is formed as a by-product of the enrichment of naturally occurring uranium for its most radioactive isotope ^{235}U. As such, DU contains significantly less ^{235}U and more ^{238}U. Enriched uranium (EU) contains much greater levels of ^{235}U, anywhere ranging from 3% to greater than 90%, while its ^{238}U content is decreased from anywhere less than 10% to 97%. For every one kilogram of uranium enriched to 3% ^{235}U during the enrichment process about 5 kg of DU (as a fluoride, UF_6) is produced (Bem and Bou-Rabee, 2004; Jiang and Aschner, 2006). It is estimated that 700,000 tons of UF_6 are stored in the USA, and that each year the mass of accumulated DU increases by 30,000 tons (Bem and Bou-Rabee, 2004; Hartmann *et al.*, 2000; Jiang and Aschner, 2006).

DU has 40% less radioactivity than natural uranium, but may contain trace levels of plutonium, neptunium, americium, technetium, and ^{236}U, which increase the radioactivity by 1% but are insignificant with respect to chemical and radiological toxicity (Force Health Protection & Readiness Policy & Programs, 2008; Sztajnkrycer and Otten, 2004; WHO, 2001). Because of the decreased radioactivity of DU, it is believed that DU is a safer form than natural uranium, while maintaining the same chemical properties. As the heaviest occurring element, uranium is extremely dense and both uranium and DU are often used in applications which require such dense metals.

This chapter describes depleted uranium and its applications in weapons of mass destruction. The DU exposure pathways, pharmacokinetics, health effects, toxicity, and available treatments are also reported.

A. Civilian Uses of DU

DU in civilian applications is marginal compared to its use in military applications (Bem and Bou-Rabee, 2004; Jiang and Aschner, 2006). As a heavy metal, DU is used as ballasts in yachts, counterbalances in commercial jets (Mould, 2001; Sztajnkrycer and Otten, 2004), shielding in radiation therapy, and as containers for transportation of radioactive materials (Jiang and Aschner, 2006). Considering ingestion, inhalation, and dermal exposure as the typical routes of exposure, typical civilian exposure to uranium from food, water, and air is considered minimal under normal circumstances (Fisenne *et al.*, 1988). These exposures fall well below the daily tolerable intake levels for soluble uranium (0.5 μg/kg body weight), insoluble uranium (5 μg/kg body weight), and inhaled uranium

TABLE 29.1. Forms of uranium and their respective isotope percentages

	Form of uranium		
Isotope	**Natural**	**Depleted**	**Enriched**
^{238}U	99.275%	99.8%	<10% to 97%
^{235}U	0.720%	0.2%	3% to >90%
^{234}U	0.0055%	0.001%	0.03%

(1 μg/m^3 in the respirable fraction), as set forth by both the WHO (2001) and ATSDR (1999). Because uranium is present in greater levels in war-ravaged regions, it is believed that uranium may pose a potentially greater exposure danger to civilians in these regions (Bem and Bou-Rabee, 2004).

B. Military Uses of DU

The major use of DU is by the military as an alloy in armor and ammunition. These applications take advantage of the unique metallic properties of DU, specifically the density and pyrophoric properties. Uranium is the heaviest naturally occurring element and is extremely dense. Uranium has a density 1.7 times the density of lead, and rods made of uranium are resistant to deformation (Bem and Bou-Rabee, 2004). Uranium shielding is therefore used in the armor of military armored vehicles, allowing the deflection of enemy projectiles. Furthermore, alloys of uranium that contain 2% molybdenum or 0.75% tungsten have a unique attribute such that they will sharpen themselves on impact with a hard target, which allows for greater penetration of uranium-based projectiles compared to traditional tungsten-based alloys (Jiang and Aschner, 2006). DU is also pyrophoric, such that particles will ignite at relatively low temperatures. Fine particles will burn rapidly at relatively low temperatures (150–175°C), while particles will spontaneously burn violently with air above 600°C, releasing heat and uranium oxide aerosols (Bem and Bou-Rabee, 2004; Harley *et al.*, 1999). These unique properties of uranium make it an excellent material for military applications.

During the 1991 Gulf War (Operation Desert Storm), it is estimated that 300 tons of DU were used in the aircraft rounds and tank-fired shells in Kuwait and southern Iraq over an area of 20,000 km^3 (Bem and Bou-Rabee, 2004). Studies have shown that DU penetrators hitting armored targets convert 17–28% of a projectile's mass into DU aerosols (Bem and Bou-Rabee, 2004; Force Health Protection & Readiness Policy & Programs, 2008; Harley *et al.*, 1999; Parkhurst, 2003). Of these aerosols, 83% are S-type (S for slow dissolution) oxides, while 17% are M-type (M for medium dissolution) oxides, and the respirable fraction (diameter <10 μm) may be 50% of the total mass of the aerosol (Harley *et al.*, 1999; Jiang and Aschner, 2006). This would mean that of 50 tons of tank-fired and 25 tons of aircraft-fired DU munitions, 10 tons of uranium oxides would have been released into the air in the form of respirable uranium (Jiang and Aschner, 2006).

The US Department of Defense (DOD) has conducted studies to evaluate distribution of aerosolized DU after destruction of an armored tank to assist in determing DU health risk (Force Health Protection & Readiness Policy & Programs, 2008; Harley *et al.*, 1999). The concentration of uranium inside a tank can reach hundreds or thousands mg/m^3 just after an explosion caused by a DU penetrator (Force Health Protection & Readiness Policy & Programs, 2008; Harley *et al.*, 1999). As uranium has such a high density, the aerosolized DU particles fall within 10 m of a burning tank. The US DOD estimates that the DU intake of a person in the vicinity of a tank hit by a single 120 mm DU-containing projectile is 0.1 mg uranium, and the maximum intake in traversing a cloud of smoke plume that is 200 m in length is 0.8 μg uranium (Bem and Bou-Rabee, 2004; Force Health Protection & Readiness Policy & Programs, 2008; Harley *et al.*, 1999; Parkhurst, 2003). These US DOD studies demonstrate that the risks of uranium inhalation are greatest for crews of damaged tanks and rescue teams (Jiang and Aschner, 2006). However, as the DU particulate matter can be carried by winds and deposited in soil and water, there are concerns that both civilian and military units may be exposed to DU dust, vapors, and aerosols, particularly as military conflicts continue. The concerns regarding the unknown exposure data of these individuals have spurred recent studies on war veterans and civilians living in war-ravaged regions to try to determine if DU has human health and environmental impacts.

III. EXPOSURE PATHWAYS AND BODY RETENTION OF DU

The chemical toxicity of DU is only an issue if the metal is internalized. The three traditional pathways of exposure are inhalation, ingestion, and dermal contact (Figure 29.1). Typically, in nonmilitary situations, the main routes of natural uranium uptake are by inhalation and ingestion. Because of the use of DU in ammunitions and armor by the military, the more important routes of exposure are inhalation and internalization of the DU (Figure 29.1). This internalization of the DU results from embedding of DU projectile fragments (shrapnel) due to explosions of DU-containing armor and ammunitions. Follow-up studies of 1991 Gulf War veterans with embedded DU shrapnel have attempted to determine if there are adverse health effects associated with internalized DU (Hodge *et al.*, 2001; McDiarmid *et al.*, 2000, 2001a, b, 2002, 2004a, 2006, 2007; Squibb and McDiarmid, 2006).

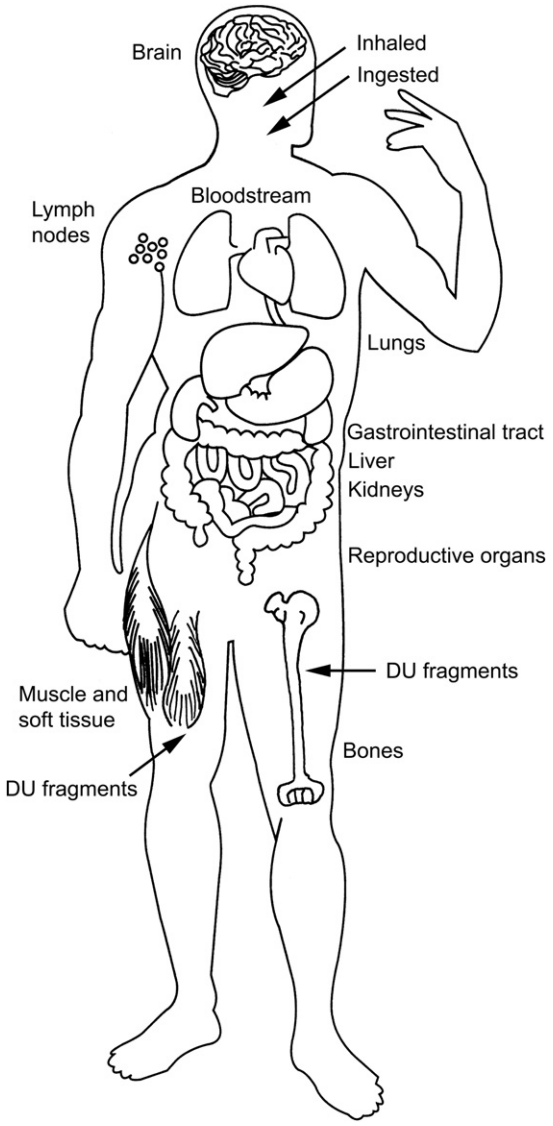

FIGURE 29.1. Routes of depleted uranium entry into the body and the corresponding target organs where DU has been shown to accumulate.

A. Inhalation

Inhalation is a likely route of intake of DU primarily due to its use in DU munitions, whereas naturally occurring uranium dust particles are only inhaled in very small quantities (ATSDR, 1999; Jiang and Aschner, 2006). Studies on people in New York City show that about 1 µg of uranium is inhaled each year by each person (ATSDR, 1999; Fisenne *et al.*, 1987; Harley *et al.*, 1999). Inhalation risk from DU is due to the aerosolization following the impact of ammunitions, forming DU oxides and particles. These particles become suspended in the air by the wind, or settle into the environment for later resuspension. For example, it was determined that the estimated mean annual concentration of suspended matter in ambient air in Kuwait following the 1991 Gulf War was 200 µg/dm^3, one of the highest concentrations in the world (Bem and Bou-Rabee, 2004).

The particle size of the aerosolized DU, and its correlated physical and chemical properties (e.g. solubility), have a significant impact on how far into the lungs the particles will penetrate, and if they will result in deposition in the respiratory tract (ATSDR, 1999; Jiang and Aschner, 2006). Only small particles less than 10 µm in diameter will reach and accumulate in the bronchioles and alveoli, while larger particles are effectively cleared by mucociliary clearance (Gwiazda *et al.*, 2004; Harley *et al.*, 1999; WHO, 2001). These respirable particles present a potential health hazard from uranium inhalation, but studies have shown than less than 1% of inhaled uranium actually reaches the kidneys (Gwiazda *et al.*, 2004; Harley *et al.*, 1999; Spencer *et al.*, 1990; WHO, 2001). These studies have demonstrated that of the uranium that is inhaled, 75% is exhaled and 25% is retained in the respiratory tract and lungs. Of the retained fraction of uranium in the lungs, 80% is removed by bronchial clearance, 15% is deposited in lymph nodes, and 5% actually enters the blood (Harley *et al.*, 1999; Spencer *et al.*, 1990).

B. Ingestion

Soil ingestion by children is an important exposure pathway, but typically for humans ingestion is only an important route of entry if food and drinking water are contaminated by DU (Jiang and Aschner, 2006). The average daily intake of uranium from food and water is estimated to be between 1 and 5 µg/day from uncontaminated areas (ATSDR, 1999; Harley *et al.*, 1999). In uranium mining areas, ingestion has been found to range between 13 and 18 µg/day (ATSDR, 1999; Harley *et al.*, 1999). Obviously, these concerns of adverse health effects from DU-contaminated food and drinking water are amplified in battlefield arenas, such as Iraq, Kuwait, the Balkans, and Afghanistan. A number of studies have demonstrated increased uranium levels in the soil in these sites several years after the conflict (Bem and Bou-Rabee, 2004; Danesi *et al.*, 2003; Di Lella *et al.*, 2004; Durante and Pugliese, 2003; Mitchel and Sunder, 2004; Oliver *et al.*, 2007; Sansone *et al.*, 2001; Spencer *et al.*, 1990). To date, there have been a number of studies that have attempted to link higher malignancy rates and genotoxic effects in these regions with varying degrees of correlation (Milacic *et al.*, 2004; Obralic *et al.*, 2004). Furthermore, bone ash data indicate significant baseline uranium differences across countries (Fisenne et al., 1980, 1983, 1987; Fisenne and Welford, 1986), and there is no clear indication as yet that these different levels of uranium have led to any adverse health consequences (ATSDR, 1999; Harley *et al.*, 1999).

The solubility of the uranium compound is an important consideration in determining adsorption and distribution as toxicity is related to uptake efficiency of the gastrointestinal (GI) tract. Generally, absorption is increased with the

increased solubility of the compound. Uranium oxides (U_3O_8 and UO_2) are relatively insoluble (Types M and S; M for medium and S for slow dissolution) while uranium trioxide (UO_3) is more soluble (between Type M and F; F for fast dissolution). These more insoluble forms are less likely to enter the bloodstream and cause toxicity. On the other hand, uranyl nitrate hexahydrate, uranium hexafluoride, or uranyl fluoride are all relatively soluble forms and tend to be absorbed through the GI epithelium. However, unlike other heavy metals, uranium is not efficiently absorbed through the intestinal lumen (ATSDR, 1999; Harley *et al.*, 1999; Spencer *et al.*, 1990). Studies in humans ingesting uranium nitrate in spiked grapefruit juice demonstrate only 0.5–5% absorption of the original dose (Karpas *et al.*, 1998) (IARC publication). Only 0.2–2.0% of uranium in food and water is absorbed by the GI tract, and of the amount that is absorbed, 67% will be filtered out by the kidneys and excreted in the urine within the first 24 h (ATSDR, 1999; Harley *et al.*, 1999; WHO, 2001).

C. Dermal Contact and Embedded Fragments

Dermal absorption has not been characterized in human studies, and there have not been any dermal effects reported from uranium miners, millers, or processors (ATSDR, 1999). There have also been no human deaths related to dermal exposure of uranium. Dermal contact is not an important route of exposure since DU does not pass through the skin into the blood unless there are open wounds or embedded fragments (Harley *et al.*, 1999; WHO, 2001).

Embedded DU-containing shrapnel, if not removed, is a permanent exposure source within the body, and will allow the DU to enter the systemic circulation. The DU Follow-Up Program at the Baltimore Veterans Administration Medical Center has been surveying a small population of approximately 230 soldiers since the 1991 Gulf War and reports from this program have shown that the uranium leaches into the circulation resulting in elevated urinary uranium levels compared to control patients (Ejnik *et al.*, 2000, 2005; Gwiazda *et al.*, 2004; Hodge *et al.*, 2001; McDiarmid, 2001; McDiarmid *et al.*, 2000, 2001a, b, 2002, 2004a, b, 2006, 2007; Squibb *et al.*, 2005; Squibb and McDiarmid, 2006).

IV. PHARMACOKINETICS

A. Adsorption

1. Ingestion

Uranium ingested from food and water ingestion ranges from 1–5 μg uranium in uncontaminated regions to 13–18 μg uranium in uranium mining areas (ATSDR, 1999). The absorption of uranium across the gastrointestinal tract is related to the solubility of the compound and generally increases with increased solubility. Only a small fraction is absorbed of even the relatively soluble uranium compounds, such as uranyl nitrate hexahydrate, uranium hexafluoride, or uranyl fluoride. For example, studies have shown that humans ingesting uranium nitrate hexahydrate or uranyl nitrate absorb only 0.5–5% of the original dose (Hursh *et al.*, 1969; Karpas *et al.*, 1998). In animal studies with uranyl nitrate and uranium dioxide directly intubated into the GI tract, only 0.77% and 0.11% of the total doses, respectively, were absorbed (Harrison and Stather, 1981). Studies in rats with an intragastrically applied relatively insoluble form of uranium, UO_2 (Type S dissolution), showed that uranium could not be detected in liver, kidney, muscle, bone, brain, blood, and urine, and that uranium was not absorbed or retained significantly in the epithelial cells of the intestinal wall (Lang and Raunemaa, 1991).

2. Inhalation

Typically, uranium is present in limited concentrations in the air, and uranium particle inhalation is minimal (ATSDR, 1999; Harley *et al.*, 1999). Uranium particle deposition in the respiratory tract is governed by the physical forces that effect particle behavior in the air, as well as the anatomy of the respiratory tract (ATSDR, 1999; Bleise *et al.*, 2003; Phalen and Oldham, 2006). The anatomy of the lungs is important as this affects the clearance mechanisms available to deal with deposited particles, and the degree of actual uranium absorption that will occur. In addition to the aerodynamic diameter (AD) of the particle, the solubility of the inhaled uranium is an important determinant as to how much uranium will be absorbed (Eidson, 1994; Lang *et al.*, 1994).

Most inhaled uranium particles have an AD that does not permit them to be carried to the deep lungs (ATSDR, 1999; Igarashi *et al.*, 1987). Studies have shown that only small uranium particles less than 10 μm in diameter will reach and accumulate in the bronchioles and alveoli, while larger particles are effectively cleared by mucociliary clearance (Gwiazda *et al.*, 2004; Harley *et al.*, 1999; WHO, 2001). These inhaled respirable particles do present a potential health hazard from uranium inhalation, but studies have shown than less than 1% of inhaled uranium actually reaches the kidneys (Gwiazda *et al.*, 2004; Harley *et al.*, 1999; Lang *et al.*, 1994; Morris *et al.*, 1990; Spencer *et al.*, 1990; WHO, 2001). Studies have demonstrated that of the uranium that is inhaled, 75% is exhaled and 25% is retained in the respiratory tract and lungs. Of the retained fraction of uranium in the lungs, 80% is removed by bronchial clearance, 15% is deposited in lymph nodes, and 5% actually enters the blood (Harley *et al.*, 1999; Spencer *et al.*, 1990).

3. Dermal

In animal studies, soluble uranium compounds have been shown to penetrate the skin of rats within 15 min of application (de Rey *et al.*, 1983). The penetration was as high as 7 g/kg body weight for ammonium uranyl tricarbonate while uranyl nitrate hexahydrate ranged from 0.5 to 7 g/kg body

weight. No penetration through the skin was observed when uranium dioxide, a more insoluble form, was applied (de Rey *et al.*, 1983). Two days after exposure, demally absorbed uranium was no longer localized to the epithelium, and rats either had significant weight loss or had died. Other studies have demonstrated that other uranium compounds (uranium tetrafluoride, uranium tetrachloride, and uranium trioxide) are absorbed through the skin of mice, rats, and guinea pigs at a rate of 0.1% of determally applied uranium, a relatively low absorption rate (Orcutt, 1949). These studies show that soluble uranium compounds can be absorbed through the skin. However, the concentrations of uranium applied to the skin were extremely high, and it is unlikely that humans would typically experience such exposures. Dermal absorption has not been characterized in humans (ATSDR, 1999).

B. Distribution

Once absorbed into the system circulation, uranium undergoes chemical transformations to complex with the blood. Uranium in the trivalent form will oxidize to the hexavalent species to form uranyl ions, which form soluble complexes with bicarbonate, citrate, or proteins in the plasma (Chevari and Likhner, 1968; Cooper *et al.*, 1982; Stevens *et al.*, 1980). The distribution of uranium in the blood is approximately 47% complexed with bicarbonate in plasma, 32% bound to plasma proteins, and 20% bound to erythrocytes (Chevari and Likhner, 1968, 1969).

Uranium is then distributed by the systemic circulation primarily to the bones and kidneys. Of the total absorbed uranium, 85% is associated with bone, where uranium replaces calcium in the hydroxyapatite complex (Donoghue *et al.*, 1972). Of the remaining 15% uranium, over 90% is associated with the kidneys, accumulating primarily in the proximal tubule (ATSDR, 1999). Uranium also distributes in detectable amounds to the liver, brain, testes, and spleen (Fitsanakis *et al.*, 2006; Leggett and Pellmar, 2003; Pellmar *et al.*, 1999a). The embedded uranium fragments continuously release uranium into the circulation, and the fragment size diminished with time.

Less soluble uranium compounds (Type M and Type S dissolution), which are not effectively absorbed, are distributed in bronchial lymph nodes as well as the lung tissue itself (Leach *et al.*, 1970).

C. Metabolism and Excretion

Once uranium is in the systemic circulation, it is transported as various complexes in the blood. The predominant form of uranium is as a bicarbonate complex, the stability of which is highly dependent on the pH of the solution (ATSDR, 1999; Chevari and Likhner, 1968). In the kidneys, the bicarbonate complex is filtered at the renal glomerulus and excreted in the urine (Adams and Spoor, 1974; ATSDR, 1999; Blantz, 1975; Bowman and Foulkes, 1970; Brady *et al.*, 1989; Foulkes, 1971). Protein-bound uranium will remain in the blood since little protein passes through the glomerulus.

Studies in humans have shown that approximately 66% of an intravenous injection of uranium is eliminated from the plasma within 6 min, while 99% of the uranium is eliminated from the plasma 20 hours after injection (ATSDR, 1999; Harley *et al.*, 1999; Luessenhop *et al.*, 1958). Another study has shown that the kidneys excrete over 90% of intravenously injected soluble hexavalent uranium salt, with less than 1% excreted in the feces; approximately 70% of the dose is excreted within the first 24 h (Bassett *et al.*, 1948).

1. Oral Exposure

The average gastrointestinal uptake of uranium is limited, and ranges from 1 to 5% in adult humans (ATSDR, 1999; Leggett and Harrison, 1995). Absorption generally increases with increasing solubility of the compound. It is highest for the soluble uranium compounds; nevertheless, only a small fraction of uranium is absorbed across the gastrointestinal epithelium. Uranium absorption takes place predominantly in the small intestine, with no absorption from the buccal cavity, stomach, or large intestine (Dublineau *et al.*, 2005). Measured with *ex vivo* techniques, the apparent uranium permeability was shown to be similar in various parts of the small intestine (Dublineau *et al.*, 2005). Uranium transport across the gastrointestinal epithelium likely occurs via a transcellular pathway. Approximately 90% of the ingested uranium in humans is excreted in the feces without being absorbed while the remainder is excreted in the urine (Oeh *et al.*, 2007a, b; Spencer *et al.*, 1990; Wrenn *et al.*, 1985). Studies in rats show similar excretion patterns to humans, of which the majority of ingested uranium (99%) is eliminated in the feces, and 95% of the absorbed uranium is excreted in urine within a 1 week of exposure, with a half-life of 2–6 days (Dublineau *et al.*, 2005; La Touche *et al.*, 1987; Wrenn *et al.*, 1985).

2. Inhalation Exposure

The rate of deposition and clearance of uranium-containing particles from the lung depends upon its chemical form and particle size. As previously discussed in the adsorption section, most of the larger uranium particles are transported out of the respiratory system by mucocilliary action, or swallowed and eliminated in the feces. Smaller particles with higher solubilities are more rapidly absorbed into the systemic circulation but can then be excreted in the urine.

The aerosol by-products of exploded DU munitions are primarily the uranium oxides with varying dissolution rates. Uranium trioxide (UO_3) is soluble like uranyl salts, and systemic absorption accounts for more than 20% of the exposure burden, with 20% of the excreted uranium being in the urine (Morrow *et al.*, 1964, 1972, 1982). UO_3, being soluble, has a fast dissolution rate (Type F), and is rapidly removed from the lung (half-life of 4.7 days). Uranium

dioxide (UO_2) and triuranium octaoxide (U_3O_8) are relatively insoluble and have slow dissolution rates (Type S) resulting in pulmonary clearance rates dominated by particle size and mucocilliary transport out of the lungs. In humans, studies of these insoluble uranium compounds suggest a two-phase clearance process, consisting of a short phase with a biological half-time of between 11 and 100 days and a slow phase of clearance with a biological half-time between 120 and 1,500 days (Eidson, 1994; Hodge, 1973; Taylor and Taylor, 1997).

3. Embedded Fragments Exposure

DU fragments from embedded shrapnel act as reservoirs to continuously release uranium into the circulation (Fitsanakis *et al.*, 2006; Jiang and Aschner, 2006; Leggett and Pellmar, 2003; Pellmar *et al.*, 1999a). Significant percutaneous diffusion of soluble uranium through intact skin has been described (de Rey *et al.*, 1983; Lopez *et al.*, 2000; Petitot *et al.*, 2007). In rats, the absorption of uranium via deep wounds was shown to depend on the chemical form of uranium. Upon intramuscular injection of uranium nitrate, approximately 98% of the uranium was in the blood (Houpert *et al.*, 1999). In contrast, after UO_4, 70 and 85% of instilled uranium was found in the blood after 1 and 3 days, respectively (Houpert *et al.*, 1999).

Surgical removal of fragments attempts to remove as many fragments as possible, but often there will be residual fragments that cannot be removed due to location and/or size. Over time the fragment sizes will decrease as the uranium leaches from these fragments; the body has no other way to effectively remove such embedded fragments.

V. MECHANISM OF ACTION

There have been many *in vitro* studies evaluating the toxic effects of uranium in different cell types, many of which demonstrate cytotoxicity. There is no specific mechanism that emerges to explain all the results, but the weight of evidence suggests that DU-induced cytotoxicity may result from oxidative stress and eventual cell death. Uranyl compounds have high affinity for phosphate, carboxyl, and hydroxyl groups, and easily combine with proteins and nucleotides to form stable complexes (Weir, 2004). DU can cause oxidative DNA damage by catalyzing hydrogen peroxide and ascorbate reactions, resulting in single strand breaks in plasmid DNA *in vitro* (Miller *et al.*, 2002a; Yazzie *et al.*, 2003). Evidence for induction of oxidative stress and reactive oxygen species (ROS) by DU has been shown by increases in NO (Abou-Donia *et al.*, 2002), lipid oxidation (Briner and Murray, 2005; Ghosh *et al.*, 2007; Jiang *et al.*, 2007), transcriptomic, and proteomic changes (Malard *et al.*, 2005; Prat *et al.*, 2005). Moreover, some studies indicate that heat shock proteins may be involved in the cellular response to DU exposure and acquired resistance to uranium rechallenge (Furuya *et al.*, 1997; Mizuno *et al.*, 1997; Tolson *et al.*, 2005). These data strongly suggest the possibility that uranium may result in the formation of reactive oxygen species, leading to cell death. An apoptotic mechanism has even been suggested following a study where significant apoptotic events were seen in mouse macrophage cells treated with 100 μM DU (Kalinich *et al.*, 2002).

VI. TOXICITY OF DEPLETED URANIUM EXPOSURE

Scientists in the mid-19th century first believed that natural uranium had homeopathic properties, and could be an effective treatment for diabetes and albuminuria after promising results in animals and humans dosed with uranium (Hodge, 1973; Jiang and Aschner, 2006). However, animal studies in the early 20th century showed that uranium was not therapeutic, and the misuse of uranium in humans was halted (Hodge, 1973). There is extensive literature on the toxicology of uranium, which now includes studies specifically on DU. The following section highlights a number of key *in vitro*, animal, and human studies of DU, as they relate to health effects from uranium exposure. Chemical toxicity of uranium only poses a threat if the metal is internalized.

A. Nephrotoxicity

The kidney is the major target organ for uranium toxicity (ATSDR, 1999; Harley *et al.*, 1999; Jiang and Aschner, 2006). Renal toxicity associated with uranium exposure results as the kidneys work to eliminate internalized uranium and this has been known for two centuries (Goodman, 1995). In the kidneys, the site of action is the proximal tubule where proton secretion degrades the bicarbonate complex of the uranyl ion. Uranium can then react with apical cell membranes of the tubule epithelium (Goodman, 1995; Harley *et al.*, 1999). Nephrotoxicity is clearly associated with uranium exposure and has been documented in animal studies at high exposure levels (Harley *et al.*, 1999; Leggett, 1989; Sztajnkrycer and Otten, 2004). Recent *in vitro* studies on renal cells demonstrated a concentration-dependent uranium toxicity (Carriere *et al.*, 2004; L'Azou *et al.*, 2002; Thiebault *et al.*, 2007). Any observed uranium nephrotoxicity results from acute exposure. Currently, there is no evidence that DU has any long-term effects on renal function, or that long-term renal impairments will develop if no acute effects are seen (ATSDR, 1999; Harley *et al.*, 1999; Jiang and Aschner, 2006). There is even evidence in animals and humans that there may be repair of damaged tubular epithelial tissue (Diamond *et al.*, 1989; Goodman, 1995; Harley *et al.*, 1999).

B. Carcinogenicity

1. Bones

Bones are the secondary target organ of uranium toxicity (ATSDR, 1999). The majority of absorbed uranium is distributed to the bones and not surprisingly the carcinogenic potential of uranium in bones has been explored in uranium workers and personnel living in or having served in the war-ravaged regions potentially exposed to DU (Abu-Qare and Abou-Donia, 2002; Boice *et al.*, 2003, 2007; Harley *et al.*, 1999; Obralic *et al.*, 2004; Storm *et al.*, 2006).

Animal studies to mimic Gulf War veterans' injuries and assess the chronic effects of internalized DU have utilized rats implanted with DU and control tantalum pellets (Arfsten *et al.*, 2007; de Rey *et al.*, 1984; Fitsanakis *et al.*, 2006; Hahn *et al.*, 2002; Leggett and Pellmar, 2003; Pellmar *et al.*, 1999a). Carcinogenicity of these surgically implanted DU fragments has been evaluated, and is related to the size of the fragments – DU fragments of sufficient size can cause localized proliferative reactions and soft tissue sarcomas (Hahn *et al.*, 2002). Urine and serum mutagenicity studies with rats implanted with DU demonstrated enhanced mutagenic activity in *Salmonella* TA98 strain and Ames II mixed strain (TA7001-7006) in a dose-dependent manner with excreted urinary concentration (Miller *et al.*, 1998b). There are numerous other studies which demonstrate the deleterious effects of DU on viability, micronuclei, chromosomal instability, and sister chromatid exchanges by human bronchial, bone marrow, and Chinese hamster ovary cells (Kadhim *et al.*, 1992, 1994; Kennedy and Saluga, 1970; Lin *et al.*, 1993; Miller *et al.*, 1998a, 2003; Nagasawa and Little, 1992; Schroder *et al.*, 2003). However, it is still unclear if the mutagenic and carcinogenic effects are a result of the chemical or radiological effects of DU, but it is believed that these effects are primarily due to the latter. Osteosarcoma risk has clearly been demonstrated to be related to the amount of radiation exposure and there is a wealth of *in vitro* studies on bone cells and in animal models that illustrate this (Ibrulj *et al.*, 2004, 2007; Miller et al., 2002b, 2003, 2005). However, many scientists believe that the amount of radiation emitted by DU is insufficient to raise a significant risk in humans, but may be more of a concern for children whose bones are growing rapidly (Brugge *et al.*, 2005; Jiang and Aschner, 2006).

2. Lungs

It is often difficult to pinpoint specific cancerous agents using epidemiological studies (Priest, 2001), but as the lungs are the primary portal of inhaled uranium numerous studies have examined the health effects of inhaled uranium. It has been known since the 1940s that the most soluble uranium compounds are the most toxic (Voegtlin and Hodge, 1949a, b). Indeed, early animal studies did not reveal significant animal mortality from inhalation unless very soluble forms of uranium were used. However, most of the effects of uranium on the lungs occur due to the insoluble forms of uranium. Researchers have found that the lungs and tracheobronchial lymph nodes are the major sites of uranium accumulation for large particles and relatively insoluble forms of uranium, and fibrotic changes in the lung tissue have been observed suggestive of radiation injury (Leach *et al.*, 1970, 1973). These insoluble particles deposited in the lungs have a long residual time and may result in increased risk for cancer (Hartmann *et al.*, 2000; Houpert *et al.*, 1999). Indeed, typical health effects seen in uranium inhalation studies are the development of pneumonia and chemically irritated passages, which are considered as early signs of lung cancer (Voegtlin and Hodge, 1949a, b, 1953a, b).

The mechanisms associated with lung injury in high-level uranium exposure are not well understood. Treatment of rat lung epithelial cells with uranyl (VI) acetate was shown to result in increased oxidative stress and decreased cell proliferation, which was attributed to loss of cellular redox (Periyakaruppan *et al.*, 2007). Effects of uranium on cytokine secretion and on the proteasome–ubiquitin system have also been advanced (Gazin *et al.*, 2004; Malard *et al.*, 2005). Several studies have also established the deleterious effects of DU on viability, micronuclei, chromosomal instability, and sister chromatid exchanges in cells (Lin *et al.*, 1993; McDiarmid *et al.*, 2001b; Miller *et al.*, 1998a, 2002c; Prabhavathi *et al.*, 1995; Schroder *et al.*, 2003; Wolf *et al.*, 2004). These effects are believed to be due more to the radiological properties of uranium than to the chemical effects (Bolton and Foster, 2002; Mould, 2001).

C. Reproductive/Developmental Toxicity

The reproductive effects of DU have recently been studied in various animal models (Arfsten *et al.*, 2001, 2005, 2006; Domingo, 2001; Linares *et al.*, 2005; Llobet *et al.*, 1991; Paternain *et al.*, 1989). Uranium has been shown to be a developmental toxicant when given orally or subcutaneously, resulting in decreased fertility, embryo/fetal toxicity including teratogenicity, and reduced growth of offspring, following uranium exposure at different gestation periods (Arfsten *et al.*, 2001, 2005; Bosque *et al.*, 1993; Domingo, 2001; Domingo *et al.*, 1989a, b; Ortega *et al.*, 1989b). It is still unclear what the exact mechanism of action is, although *in vitro* studies in Chinese hamster ovary cells showed DU-induced genotoxicity and cytotoxicity (Lin *et al.*, 1993). In humans, studies have evaluated the reproductive effects in male miners, uranium processors, and Gulf War veterans and show that these individuals have uranium in their semen, but do not otherwise show any detrimental reproductive effects (Abu-Qare and Abou-Donia, 2002; Arfsten *et al.*, 2006; Domingo, 2001; Harley *et al.*, 1999; Houpert *et al.*, 2007; Linares *et al.*, 2005; McDiarmid *et al.*, 2000; Priest, 2001; Squibb and McDiarmid, 2006; Voegtlin and Hodge, 1953a, b).

D. Neurotoxicity

As concerns mounted with regards to the cause of Gulf War Syndrome, a growing body of evidence suggested that DU may indeed be affecting the central nervous system (CNS). Animal studies demonstrated that uranium crosses the blood–brain barrier (BBB) and readily accumulates in the brain (Fitsanakis *et al.*, 2006; Gilman *et al.*, 1998a, b, c; Houpert *et al.*, 2007; Leggett and Pellmar, 2003; Lemercier *et al.*, 2003; Monleau *et al.*, 2005; Pellmar *et al.*, 1999a, b). Furthermore, studies in rats, and some follow-up studies in Gulf War veterans, suggested that DU may cause subtle changes in CNS function without any corresponding nephrotoxicity (McDiarmid, 2001; McDiarmid *et al.*, 2000, 2001b, 2002, 2004a, 2007; Pellmar *et al.*, 1999a, b). The public concern regarding the potential neurotoxic effects of DU has spurred recent novel scientific research to extensively evaluate if there are reasons to be concerned about DU exposure and neurotoxicity.

One of the earliest studies evaluating the specific effects of DU on the CNS demonstrated that uranyl nitrate facilitated the release of acetylcholine from the nerve terminals to potentiate muscle contraction in phrenic nerve preparations from mice (Lin *et al.*, 1988). It was then shown that uranium could cross the blood– brain barrier (BBB) *in situ* using rat brain perfusions (Lemercier *et al.*, 2003). Significant amounts of uranium accumulated in the brain after only a 2 min perfusion. Studies in rats embedded with DU and/or control tantalum pellets for 1 day, 6, 12, and 18 months confirmed previous biodistribution data that demonstrated kidneys and bone as the primary target organs, but also identified other sites in the lymphatic, respiratory, reproductive, and central nervous systems (Pellmar *et al.*, 1999a). High-dose (20 pellets) DU implantation resulted in significantly increased uranium levels in the skull (12.5 ng U/g skull tissue) after only 1 day compared to controls (1.41 ng U/g skull tissue) (Pellmar *et al.*, 1999a). By 6 months, there was a significant difference in the amount of uranium in brain samples from high-dose rats (approximately 5,000 ng U/g tissue) compared to tantalum control samples (approximately 50 ng U/g tissue) (Pellmar *et al.*, 1999a). Significant differences in brain region distribution of uranium were also found. Differences were also seen in electrophysiological studies in hippocampal slices of rats implanted with DU, the hippocampus being important in learning, memory consolidation, and spatial orientation functions. The 6-month and 12-month high-dose groups exhibited decreased neuronal excitability compared to controls, whereas rats in the 18-month DU-treatment groups did not show significant changes in neuronal excitability perhaps obscured by the aged rats (Pellmar *et al.*, 1999b). No significant differences in hippocampal weights of DU treated animals compared to controls were seen.

Generation of nitric oxide (NO) and evaluation of the central cholinergic system of male Sprague-Dawley rats following uranium exposure have also been studied (Abou-Donia *et al.*, 2002). Intramuscular injection of 0.1 and 1.0 mg/kg for 7 days, followed by a 30-day observational period, resulted in sensorimotor deficits in rat behavior, differential levels of NO, and increased acetylcholinesterase activity in the cortex of animals dosed with 1 mg/kg, suggesting multiple exposures to low doses of uranyl acetate caused prolonged neurobehavioral deficits in rats after the initial exposure has ceased, similar to the exposures of Gulf War veterans (Abou-Donia *et al.*, 2002).

Short-term and long-term differences in brain lipid oxidation and open-field behavioral differences in rats exposed to DU have been shown (Briner and Murray, 2005). After 2 weeks of DU exposure, brain lipid oxidation was increased and correlated with increases in line crossing and rearing behavior. While open-field behavior differences remained after 6 months of DU exposure, brain lipid oxidation could no longer be clearly correlated with the behavioral changes (Briner and Murray, 2005). Male rats were also more sensitive to the behavioral effects of DU compared to female rats (Briner and Murray, 2005). The gender differences may warrant further study to allay the fears of the public as the US armed forces deployment to Kosovo, Bosnia, and the Persian Gulf in 2000 were approximately 91% males (US Department of Defense, 2002). The results of both of these studies support previous studies which indicate that DU is a toxicant capable of crossing the BBB and producing prolonged behavioral/neurological changes.

Studies from our laboratory have recently addressed the cytotoxicity of uranyl acetate in primary rat cortical neuron cultures. We found no evidence that uranyl acetate at concentrations below 100 μM caused cytotoxicity (Jiang *et al.*, 2007). Furthermore, we failed to document a significant change in the levels of F_2-isoprostanes, biomarkers of oxidative stress, as well as thiol metabolite levels upon treatment with uranium. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction assays and lactate dehydrogenase (LDH) activity were also unchanged in neurons treated with uranyl acetate. In complementary studies in the nematode *C. elegans*, we found no evidence for neuronal degeneration using green fluorescent protein (GFP)-reporter strains corroborating the neuron culture results (Jiang *et al.*, 2007).

With respect to human subjects, Gulf War veterans subjected to friendly fire and embedded with shrapnel from DU projectiles have been followed (Hooper *et al.*, 1999; McDiarmid *et al.*, 2000, 2001a, b, 2002, 2004a, b, 2006, 2007). The fragments are a permanent exposure source inside the body and these veterans have demonstrated consistently higher urine levels of uranium, compared to controls without DU shrapnel, even after 10 years of exposure (Hooper *et al.*, 1999; McDiarmid *et al.*, 2000, 2001a, b, 2002, 2004a, b, 2006, 2007). These Gulf War veterans do not show evidence of kidney damage or dysfunction, but there was an indication that increased uranium exposure may be marginally correlated with decreased neurocognitive performance, as

measured by paper and pencil, and automated tests. In more recent follow-up studies, the initially identified neurological disabilities can no longer be detected. Many groups have called for further studies to examine the potential relationship between DU exposure and cognition (Bem and Bou-Rabee, 2004; Durakovic, 2001, 2003; Harley *et al.*, 1999; Priest, 2001; Sztajnkrycer and Otten, 2004; The Royal Society, 2001, 2002; US Department of Defense, 2000; WHO, 2001).

VII. TREATMENT

Currently, the treatments for uranium exposure are limited. Chelation therapy is used to prevent acute toxicity of high doses of uranium in the systemic circulation, typically resulting from some sort of ingestion. Chelating agents are used to competitively compete for the uranyl ion. Numerous studies have tested the efficacy of different chelating agents, such as gallic acid, 4,5-dihydroxy-1,3-benzenedisulfonic acid (Tiron), diethylenetriaminepentaacetic acid (DTPA), 5-aminosalicylic acid (5-AS), catechol-3,6-bis(methyleneiminodiacetic acid) (CBMIDA), and ethane-1-hydroxy-1,1-bisphoshonate (EHBP) (Durbin *et al.*, 2000, 1997; Fukuda, 2005; Fukuda *et al.*, 2005; Ortega *et al.*, 1989a). These chelating agents can be effective in removing uranium and providing protective effects from actute uranium toxicity with differing efficacy. However, the length of time before initiating chelation therapy for acute uranium intoxication greatly influences the effectiveness of this therapy (Domingo *et al.*, 1990).

For embedded DU fragments surgical removal is the best option to get rid of as much of the shrapnel as possible. Because shrapnel can be of different sizes and dispersed in multiple locations, it is often difficult to remove every piece. Large fragments and fragments that are easily accessible, such as in soft tissues, are removed where possible to minimize the amount of uranium that will remain in fragments in the body.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

Depleted uranium is an excellent metallic substrate for radiation shielding and for armor and ammunition by the military due to its density and pyrophoric properties. Furthermore, the unique ability of uranium-based ammunitions to sharpen themselves upon impact, allowing for deeper penetration of the ammunitions, also makes DU a better substrate for weapons of mass destruction. As such, it is not suprising that the use of DU in military applications is expected to grow. This increased use will no doubt be bolstered by recent scientific studies showing that DU exposure has relatively low adverse health effects, contrary to the public backlash and belief that DU is a harmful chemical and may be the cause of Gulf War Syndrome.

There has also been speculation that there is a potential black market use of DU as a weapon for bioterrorism, or as part of a dirty bomb. However, a thorough evaluation of the toxicology of uranium indicates that DU is relatively inert, compared to other potential materials and organisms that could be used to make an effective bioterrorism weapon or dirty bomb. Indeed, the reason why DU may still be considered to be an excellent bioterrorism agent is the public perception that DU is a harmful chemical, even though the toxicology of the chemical and radiological effects are relatively mild.

Recent studies have provided a great deal of new information about DU but there are still gaps in our understanding. For example, although we now know that uranium will cross the blood–brain barrier and accumulate in the brain, the functional changes associated with brain uranium accumulation remain to be seen. As such, although the evidence suggests that DU is relatively inert, the controversy still remains as to whether DU may be an agent that causes Gulf War Syndrome. Additionally, although there is not a great demand for pharmacological interventions, potential development of better chelating agents would be beneficial to assist in the treatment of uranium exposures, both acute and chronic.

CHAPTER 30

Botulinum Toxin

JAIME ANDERSON, PATRICK T. WILLIAMS, ALEXANDRE M. KATOS, MARK KRASNA, WHITNEY BURROWS, AND COREY J. HILMAS

Opinions, interpretations, conclusions, and recommendations are those of the author(s) and are not necessarily endorsed by the US Army.

I. INTRODUCTION

Botulism is a disease caused by anaerobic, spore-forming bacteria found in soil. Disease results from the actions of chemical toxins produced by these bacteria. The most common forms of human botulism include foodborne, infant, and wound. The main etiology of botulism in humans is foodborne; this form is caused by eating foods contaminated with botulinum spores, which germinate and multiply into bacteria to produce neurotoxin in the food. Commonly contaminated foods include improperly preserved home-processed foods such as honey, corn, green beans, and beets. Less likely sources are fish products and other commercially processed foods. Infant botulism is often associated with eating honey contaminated with spores, but new evidence suggests that soil and dust brought into the house from the outside may be a significant source of botulinum spores. Wound botulism occurs when spores contaminate a wound, germinate, and produce toxins absorbed into the bloodstream. Regardless of the form of botulism, disease results from the intoxicating effects of potent neurotoxins.

Botulinum neurotoxins (BoNTs) comprise a family of seven distinct neurotoxic proteins produced by immunologically discrete strains of the anaerobic bacteria. These spore forming, Gram-positive bacteria secrete deadly toxins with an estimated human LD_{50} of 1–3 ng/kg (Simpson, 2004; Sobel *et al.*, 2004). In fact, BoNTs are the most potent substances known to humankind. Due to their extremely high potency, ease of production and previous history of weaponization, the BoNTs have been designated as category A threat agents by the US Centers for Disease Control and Prevention (CDC). Category A agents are defined by the CDC as those that ''… result in high mortality rates and have the potential for major public health impact; might cause public panic and social disruption and require special action for public health preparedness''.
