hydrolyzing OPs along with other terms (such as PON1, paraoxonase, etc.) as they appear in original references.

The molecular weight of human A-esterases is between 43 and 45 kDa. Human A-esterase is a protein of 355 amino acids having two polymorph sites in which arginine or glutamine are located at position 192 and methionine or leucine at position 55 (La Du *et al.*, 1993; Li *et al.*, 1995). The former accounts for three genotypes (QQ, RR, and QR) relating to the catalytic properties of two forms of an enzyme (types R and Q allozymes), which hydrolyze certain organophosphates at different rates. Its three-dimensional structure is also known (Benning *et al.*, 1994; Vilanova and Sogorb, 1999). At the active site of A-esterases there are two metal cations connected via a common ligand, and most of the other protein groups are bound to this binuclear site through imidazolium side chains from histidine groups (Benning *et al.*, 1994). Activity of these enzymes largely depends on Ca^{2+} which represents a necessary factor for maintaining the function of active site and it is also possible that Ca^{2+} directly participates in catalytic reactions or maintains the conformation of amino acids at the active site. In addition, in the case of paraoxon, Ca^{2+} facilitates the release of diethylphosphate from the active site probably by polarizing bond P=O which makes phosphorus atoms much more sensitive to nucleophilic attack of hydroxyl ions (Vitarius and Sultatos, 1995). Human A-esterases can hydrolyze many OPs, among them paraoxon, soman, sarin, tabun, chlorpyriphos and chlorpyriphos oxon, DFP, dichlorvos, diazoxon, and pyrimiphos methyl oxon.

The R allozyme (Arg192) hydrolyzes the organophosphate paraoxon at a high rate; however, it has a low activity toward diazoxon, sarin, and soman. Lower activity means that more sarin would be bioavailable to exert its anticholinesterase effects. The Q allozyme, on the other hand, has high activity toward diazoxon, sarin, and soman (and low activity toward paraoxon). Thus, individuals with the Q allozyme (QQ or QR) are expected to have greater hydrolysis of sarin than individuals homozygous for the R allele (RR) (Costa *et al.*, 1999, 2005). In Caucasian populations, the frequency of the R allele is about 0.3, but the frequency is 0.66 in the Japanese population (Yamasaki *et al.*, 1997; Costa *et al.*, 2006). This would make individuals in the Japanese population more sensitive to the toxicity of sarin, a fact that may have contributed to their morbidity and mortality after the terrorist attacks in 1995. The concentration of PON1 in human plasma (about 60 mg/l) varies between individuals by as much as 13-fold. PON1 activity level is determined by a combination of complex genetic interactions and environmental/dietary factors, giving rise to a 40-fold variation in PON1 for a single individual (Rochu *et al.*, 2007). The relationship between paraoxonase polymorphisms and toxicity of OPCs was further discussed in an excellent article by Costa *et al.* (2006) and other papers from his team.

Paraoxonase (PON1) is a member of a family of proteins that also includes PON2 and PON3, the genes of which are clustered on the long arm of human chromosome 7 (q21.22). PON1 is synthesized primarily in the liver and a portion is secreted into the plasma, where it is associated with high-density lipoprotein (HDL) particles (Costa *et al.*, 2005). The primary physiological role of PON1 appears to be to protect low-density lipoproteins (LDL) from oxidative modifications (Mackness *et al.*, 1993; Aviram *et al.*, 1998; Vilanova and Sogorb, 1999; Rochu *et al.*, 2007). In addition to its role in lipid metabolism and cardiovascular disease and atherosclerosis, PON1 has been shown to play a role in the metabolism of drugs and xenobiotics containing aromatic carboxyl esters (Costa *et al.*, 2003). It is also suggested that PON1 hydrolyses various lactones including naturally occurring lactone metabolites.

The differences in the activity of A-esterases due to polymorphisms may have important effects on the toxicity of OP in humans who are occupationally or accidentally exposed. In this respect it was proposed that humans expressing lower activity of A-esterases could be more susceptible to toxic effects of OP and there were ideas that such individuals should not be exposed (Mackness, 1989). Hernandez *et al.* (2004) have confirmed this hypothesis suggesting the association of paraoxonase phenotypes with susceptibility of humans to anticholinesterase pesticides toxicity. However, additional studies are needed to fully understand the effects of A-esterase polymorphism on the capacity of detoxification and toxicity of OPs.

1. Toxicological Relevance of A-Esterases

For many years it had been suggested that activity of A-esterases in serum can serve as a protective factor in poisoning with OP and among them OP insecticides whose active metabolites are AChE inhibitors and, at the same time, substrates for A-esterases. An important finding in this respect was significantly higher toxicity of pyrimiphos methyl and diazinon in birds than in mammals (Brealey *et al.*, 1980; Walker and Mackness, 1987) (oral LD_{50} of pyrimiphos methyl in hens is 30 mg/kg, and in rats about 1,500 mg/kg). The difference in toxicity of these OPs was explained by protective effect of A-esterases in mammals that express relatively high activity of the enzymes, in contrast to birds, which have no or very low A-esterase activity and are more susceptible to OPs. A-esterase activity in rabbits is about seven-fold higher than in rats, and because of this the rats are about four-fold more susceptible to paraoxon. Direct confirmation of this hypothesis was obtained after administration of purified A-esterases from rabbit serum to rats which provided a significant protection in poisoning with paraoxon or chlorpyrifos oxon (Main, 1956; Costa *et al.*, 1990). Furthermore, it was shown that purified A-esterases given to mice significantly decrease inhibition of AChE in brain and diaphragm after administration of chlorpyrifos or its active metabolite chlorpyriphos oxon (Li *et al.*, 1993, 1995). The increased levels of A-esterases in the serum of mice were maintained for 2 days providing protective effects not only when the enzyme was given before chlorpyriphos but also when it was given 3 h after the insecticide (Li *et al.*, 1995). A-esterases

purified from *Pseudomonas diminuta* and given to mice decreased inhibition of AChE in brain and ChE in serum in poisoning with paraoxon and DFP, and this effect was less significant in poisoning with soman and sarin (Tuovinen *et al.*, 1994). These authors have also observed accelerated reactivation of serum ChE in mice that was inhibited with paraoxon and proposed possible cleavage of the bond between ChE and paraoxon (which provides the same effect as spontaneous reactivation of ChE) and destruction of paraoxon itself. Purified A-esterases have shown protective effect when given to mice before poisoning with tabun (Ashani *et al.*, 1991a). The availability of serum paraoxonase knockout mice has provided an *in vivo* system which enables more direct examination of the role of paraoxonase in detoxification of OPs (Furlong *et al.*, 2000b). These animals demonstrated highly increased sensitivity to chlorpyrifos oxon and diazoxon and moderately increased sensitivity to the respective parent compounds chlorpyrifos and diazinon.

A recent study investigated PON1 genotype and serum enzyme activity in a group of 25 ill Gulf War veterans and 20 controls (Haley *et al.*, 1999). Ill veterans were more likely than controls to possess the R allele (QR heterozygotes or R homozygotes) and to exhibit lower enzyme activity. This study raises the possibility that the R genotype (low sarin-hydrolyzing activity) may represent a risk factor for illness in Gulf War veterans. However, because of the very small size of the study, such findings necessitate further confirmation in a larger population (Furlong, 2000a). La Du *et al.* (2001) have also found reduced sarinase and somanase levels in plasma obtained from Gulf War veterans. In a similar study, in a group of 152 UK Gulf War veterans, the PON1 activity was lower in veterans than in a control group but the differences were independent of PON1 genotype (Mackness *et al.*, 2000). However, in both studies there were no indications about the extent of exposure to nerve agents and possible effects of such exposures.

Standard therapy of OP poisoning consists of the administration of a combination of atropine, oxime, and diazepam with other supportive measures when necessary. However, the possibility of addition of purified enzymes such as AChE, ChE, CarbE, and A-esterases to this therapeutic scheme has been considered and preliminary experiments in animals have shown much better protective effect after addition of exogenous enzymes. In this respect, protective effects of AChE, ChE, and CarbE are based on formation of covalent conjugates or phosphorylated enzymes in the stoichiometric ratio 1:1. Capacity for binding of these enzymes is limited by the number of active sites on the enzyme to which OP molecules can be bound. This means that more enzymes have to be administered in order to achieve better detoxification of OPs which may not always be possible due to adverse effects. This can also be influenced by differences in the extent of spontaneous reactivation of these enzymes inhibited by OP.

It is known that AChE spontaneously reactivates very slowly except when inhibited with dimethyl phosphates, which occurs relatively rapidly at the rate of 25% in 1.3 h (Gallo and Lawryk, 1991) or with a half-time of about 2 h for AChE of rat brain inhibited with dichlorvos *in vivo* (Reiner and Pleština, 1979). CarbE from rat plasma can be spontaneously reactivated at a much faster rate after inhibition with OPs having different structure (Jokanović *et al.*, 1996). However, A-esterases have a very important advantage in eventual therapeutic application in relation to other enzymes in that they can be given in low amounts since their catalytic activity is, in general, proportional to the substrate concentration. Relatively long persistence of exogenous A-esterases in circulation (more than 30 h) (Li *et al.*, 1995) and its considerable activity towards many OP compounds having different chemical structures certainly recommend them for further studies directed to possible addition of these enzymes to the standard therapy of OP poisoning. Possible applications of phosphotriesterases in the prophylaxis and treatment of OP poisoning were recently discussed by Sogorb *et al.* (2004).

Another possible application, probably in the near future, is that A-esterases may find a role in the destruction of large amounts of nerve agents and OP insecticides, and the degradation products formed are generally nontoxic. Eventual mutations on A-esterases can contribute to increased specificity towards substrates of special importance such as warfare nerve agents soman, sarin, and tabun.

B. B-Esterases

B-esterases are the group of enzymes that can be inhibited by OP compounds in the progressive reaction that is time and temperature dependent. This group of enzymes comprises CarbE (EC 3.1.1.1), AChE (EC 3.1.1.7), ChE (EC 3.1.1.8), chymotrypsin, trypsin, and some other enzymes. A common feature of these enzymes is that they have a serine hydroxyl group at the active site that enables them to react with OP in a similar fashion (Figure 69.1 in Chapter 65 of this book). AChE, ChE, and CarbE are members of the α/β hydrolase family and have a high degree of overall homology in their amino acid sequences, but they differ in several critical regions that produce differences in their biochemical properties. The most significant biochemical differences in these esterases are related to the extent of aging of the OP-inhibited esterase, the size of the active site, and the ability of the OP-inhibited enzyme to undergo spontaneous or oxime-induced reactivation (Doctor *et al.*, 2001).

1. Serum Cholinesterase (ChE; E.C. 3.1.1.8)

While the biological role of ChE is presently unclear, it is known that soman, sarin, tabun, and VX bind to ChE, without any apparent toxic effects, decreasing the amount of free agents available for inhibition of AChE in the central nervous system and erythrocytes. Pretreatment with human

plasma cholinesterase has protected laboratory mice (Ashani *et al.*, 1991b) and monkeys (Raveh *et al.*, 1997) from lethal and other acute toxic effects of VX exposure. Thus, variability in plasma cholinesterase activity is a parameter of concern for characterization of population susceptibility to nerve agent exposure. Selective inhibition of ChE had no effect on the acute soman toxicity to mice (Clement, 1984). Since VX reacts with ChE, and very slowly with CarbE due to its positively charged quaternary ammonium group, it appears that ChE may have a significant role in detoxification of VX. Wide variations in ChE activity seen in individuals not exposed to OPC, caused by genetic, physiological, and pathological conditions, as well as interactions with many drugs, may strongly influence the susceptibility of those individuals to OPs (Jokanović *et al.*, 1996). It is possible that individuals with lower ChE activity may be more susceptible to the effects of OPs including nerve agents.

2. Carboxylesterases (CarbEs; EC 3.1.1.1)

The mammalian CarbEs comprise a multigene family whose gene products are located in the endoplasmic reticulum (Hosokawa and Satoh, 2006). CarbEs are the enzymes that hydrolyze esters and thioesters or amide groups of carboxylic acids. They were also mentioned in the literature as aliesterases and esterase D. CarbEs have a very important role in metabolism of lipids, endogenous fatty acid esters, steroids, and a large number of ester-containing drugs and prodrugs such as salicylates, clofibrate, procaine, lorazepam, cilazapril and other angiotensin-converting enzyme inhibitors, narcotics (cocaine, heroin), and capsaicin. CarbEs also participate in detoxification of pesticides (carbofuran, pyrethroids, OPs), acrylates, mycotoxins (T2 toxin), and esters of nicotinic acid (Cashman *et al.*, 1996). Certain isoenzymes of hepatic microsomal CarbE are involved in the metabolic activation of some carcinogens and are associated with hepatocarcinogenesis (Hosokawa and Satoh, 2006). Similar enzymes to CarbEs are arylesterases (EC 3.1.1.2) that hydrolyze aromatic esters of carboxylic acids. However, this classification is not perfect since CarbEs hydrolyze some aromatic esters (i.e. phenyl valerate, phenyl butyrate) and arylesterases hydrolyze certain aliphatic esters. These two enzymes can be clearly differentiated according to their interaction with OPs since CarbEs are inhibited with OPs while arylesterases can hydrolyze some OPs that contain an aromatic group such as paraoxon and chlorpyriphos oxon, and because of this they were often confused with A-esterases.

The CarbE profile in humans is not well known. While CarbEs were considered to be absent from the blood plasma of humans (Li *et al.*, 2005), they are, indeed, present in human erythrocytes and monocytes as well as in human liver, kidney, lung, skin, and nasal tissue (Cashman *et al.*, 1996). Additional literature documents the presence of CarbEs in many human tissues and fluids, including brain, milk, mammary gland, pancreas, small intestine, colon, stomach, placenta, and plasma and serum (Chanda *et al.*, 2002; Kaliste-Korhonen *et al.*, 1996). The lung CarbEs are associated with alveolar macrophages (Munger *et al.*, 1991). Further, CarbEs are present in human tissues, and organs where exposure to nerve agent vapors would likely first occur (nasal tissues and the lung) would be distributed (erythrocytes, monocytes, plasma) and would generate effects (brain, stomach, colon, etc.). CarbE is also present in human serum. Chanda *et al.* (2002) indicate that full characterization of the OP-protective capabilities of CarbEs requires assessment not only of the amount but also of the affinity exhibited by CarbEs for the inhibitor as well as the total CarbE activity unlikely to be inhibited. The detoxification potential of CarbEs is apparently complex and is an area requiring further experimental characterization.

CarbEs are proteins of molecular weight between 47 and 65 kDa which can be found in microsomal fraction of many mammalian tissues (Satoh and Hosokawa, 1998). CarbEs are synthesized in liver and secreted into plasma (via the Golgi apparatus) where they are present in soluble form. Their physicochemical and immunological properties and the sequence of amino acids are very similar, while their specificity towards various substrates is different (Hosokawa *et al.*, 1995; Satoh and Hosokawa, 1998). CarbE belongs to the group of esterases having serine at its active site that hydrolyzes esters of carboxylic acids in a biphasic reaction. In the first phase carboxylic ester acylates the hydroxyl group of serine at the active site, and in the second phase serine is deacylated in the presence of water (Augustinsson, 1958). The active site of CarbE comprises a peptide isoleucine–phenylalanine–glycine–histidine–serine–methionine–glycine–glycine, with serine and histidine directly participating in biochemical reactions. Physiological substrate for CarbE is probably *O*-acetyl sialic acid (Satoh and Hosokawa, 1998). CarbE can be differentiated from other serine esterases, AChE (EC 3.1.1.7) and ChE (EC 3.1.1.8), in that AChE and ChE react with positively charged esters such as acetylcholine and butyrylcholine and can be inhibited with carbamates, while CarbEs do not react with positively charged esters and inhibition with carbamates occurs only at high concentrations. Inhibition of CarbE, except inhibition of neuropathy target esterase associated with organophosphate-induced delayed polyneuropathy, does not cause any known toxic effects. Classification and nomenclature of CarbEs were proposed by Satoh and Hosokawa (1998) and readers are referred to an excellent chapter in Hosokawa and Satoh (2006) for more details.

a. The Relationship Between CarbE Activity and Toxicity of Nerve Agents and Other OPCs

The first finding that made a connection between lower activity of CarbE and increased toxicity of OPs was given by Frawley *et al.* (1957) showing that EPN increases toxicity of malathion by inhibiting CarbEs that hydrolyze malathion. Murphy *et al.* (1959) have further shown that

TOCP, which is a specific inhibitor of CarbE and weak anticholinesterase agent, increases acute toxicity of malathion in rats from 1,100 mg/kg to 10 mg/kg by inhibiting CarbE. Mechanism of action of TOCP was explained by Eto *et al.* (1962) who found that TOCP itself is not a CarbE inhibitor and that under *in vivo* conditions it is converted to its active metabolite CBDP (2-/*o*-cresyl/-4H-1:3:2-benzodioxaphosphorin oxide) which is a potent and irreversible inhibitor of CarbE. Later experiments indicated that TOCP and CBDP strongly potentiate toxicity of other OPCs which do not contain a carbethoxy bond such as paraoxon (Lauwerys and Murphy, 1969), soman, sarin, and tabun (Bošković, 1978; Clement, 1984; Jokanović, 1989), but not of VX agent (Bošković, 1978) probably because VX in physiological conditions is positively charged and a weak inhibitor of CarbE (Maxwell, 1992). Bošković (1978) found that pretreatment of mice with CBDP increased the s.c. toxicity of soman by 19.1-fold, and its i.p. toxicity by 17.8-fold. For other nerve agents he observed an increase of s.c. toxicity of sarin, tabun, and VX by 11-, 5- and 0.24-fold, respectively. Clement (1984) observed that potentiation of soman toxicity in mice after previous administration of TOCP or CBDP was directly related to plasma CarbE and not to activity of CarbE in liver and other tissues. This effect of TOCP and CBDP was explained by phosphorylation of active sites at CarbE that occupies the binding sites for other OPs, increasing its concentration in circulation and therefore its acute toxicity. Binding of soman to CarbE in rodents occurs specifically with the most toxic stereoisomer of the agent (Cashman *et al.*, 1996).

The detoxification potential of endogenous CarbE to protect against the lethal effects of nerve agent exposure was tested by Maxwell (1992) who observed that a wide range in potentiation of toxicity of different OPs *in vivo* cannot be correlated with reactivity of these compounds towards CarbE showing that paraoxon and soman toxicity in rats with inhibited CarbE was potentiated by two- and six-fold, respectively, in spite of their similar inhibitory power for CarbE. It was concluded that detoxification of OP via CarbE is very important for highly toxic OPs such as soman, sarin, tabun, and paraoxon with an LD_{50} of <2 μmol/kg, while it is less important for less toxic OPs such as DFP ($LD_{50} = 9.75$ μmol/kg) and dichlorvos ($LD_{50} = 98.4$ μmol/kg). Having in mind that relatively higher concentrations of OP insecticides have to be achieved in circulation and tissues in order to exert toxicity, dominant factors in the detoxification of less toxic OPs are A-esterases since their catalytic activity is proportional to substrate concentration and their K_m value is in the millimolar range.

Contrary to these findings of decreased CarbE activity increasing the toxicity of many OPs, there are also data showing that increased CarbE activity can decrease toxicity of OPs. Activity of CarbE can be increased by about 80% after repeated administration of phenobarbital to rats and mice by a mechanism of enzyme induction which caused a decrease in soman and tabun toxicity by two-fold, while toxicity of sarin was not affected probably because plasma CarbEs inhibited with sarin spontaneously reactivate very rapidly *in vitro* and *in vivo* with the half-times of 18 and 120 min, respectively (Bošković *et al.*, 1984; Clement, 1984; Jokanović, 1989; Jokanović *et al.*, 1996).

Various OPs inhibit both CarbE and AChE at similar concentrations ranging from 1 to 1,000 nmol/l. CBDP, dichlorvos, DFP, and paraoxon show higher affinity towards CarbE *in vitro* and as a result their acute toxicity is lower in contrast to highly toxic OPs soman and sarin that have 4–6 times higher affinity for AChE. This relationship was confirmed *in vivo* after administration of 0.9 LD_{50} of these compounds (Maxwell, 1992). Rat plasma CarbE appears to be more sensitive to soman and sarin than CarbE in rat liver and brain, and can be completely inhibited at sublethal doses. Significant inhibition of CarbE in liver can be obtained only at multiple lethal doses (Bošković *et al.*, 1984). Even when two-thirds of rat liver was removed by partial hepatectomy 5 LD_{50} of soman was not sufficient for significant inhibition of rat liver CarbE (Jokanović, 1990). Somani *et al.* (1992) found that interspecies variation in response to some nerve agents may be accounted for largely by CarbE binding.

Involvement of CarbE in development of tolerance to paraoxon and DFP was investigated by Dettbarn *et al.* (1999) who found that rat plasma CarbE provides significant protection against paraoxon toxicity because its rapid reactivation can reduce the toxicity of repeated paraoxon applications and contribute to tolerance development. This same mechanism did not apply to DFP toxicity, as inhibition of CarbE of plasma, liver, and lung neither potentiated its toxicity nor prevented tolerance development. These findings confirmed previous observations that CarbE detoxification is of greater importance for highly toxic OPs such as nerve agents and paraoxon than for less toxic ones such as DFP.

In the study of the mechanism of interaction of CarbE with some OPs *in vitro* it was found that this reaction is not irreversible, but reversible due to rapid spontaneous reactivation of inhibited CarbE (Jokanović *et al.*, 1996; Jokanović, 2001). The highest rate of spontaneous reactivation was obtained for plasma CarbE inhibited with sarin and the half-time of reactivation was 18 min. These results were also confirmed in experiments *in vivo* in which rats were treated with 0.5 LD_{50} of soman, sarin, and dichlorvos (Jokanović *et al.*, 1996). Calculated half-times of reactivation for plasma CarbE of the rats treated with 0.5 LD_{50} dichlorvos, sarin, and soman were 1.2, 2.0, and 2.7 h, respectively. Similar results were reported by Gupta *et al.* (1987a) who found 50% of spontaneous reactivation of plasma CarbE 24 h after poisoning of rats with 100 μg/kg soman. Gupta *et al.* (1987b) also reported 94% of reactivation of plasma CarbE in rats treated with 200 μg/kg tabun, but 7 days after poisoning. Spontaneous reactivation of CarbE hydrolyzing phenyl valerate inhibited with paraoxon *in vitro* was observed by Barril *et al.* (1999).

b. The Role of CarbE in Detoxification of OPCs

CarbEs participate in detoxification in three different ways. The first is hydrolysis of ester bonds in OPs that contain them such as malathion (WHO, 1986; Fukuto, 1990). The second is binding of OP to CarbE and other proteins which decreases the concentration of free OPs in circulation that can react with AChE in vital tissues (Clement, 1984; Jokanović, 1989). The third role is related to all OPs that can phosphorylate CarbE by binding to the serine hydroxyl group at its active site (Jokanović *et al.*, 1996; Jokanović, 2001). During spontaneous reactivation this phosphoryl residue is separated from the enzyme, accepting the hydroxyl group from water as its new acyl radical. This newly formed OP (i.e. organophosphoric acid) is a much less potent, if at all, esterase inhibitor which represents nontoxic metabolites of the parent OP. In the case of nerve agents the corresponding metabolites formed EDMPA (for tabun), IMPA (for sarin), and PMPA (for soman) are shown in Figure 52.1. CarbE activity recovered in this reaction can be inhibited again by other OP molecules. The active role of CarbE in this process is in its involvement in metabolic transformation of OP to its nontoxic and biologically inactive metabolites. Because of rapid spontaneous reactivation of CarbE one active site at the enzyme can metabolize several molecules of OP and this reaction does not occur according to stoichiometric ratio 1:1 depending only on the stability of the bond between phosphorus from the OP and oxygen from the serine hydroxyl group. Tissues in which this ''turnover'' is fast, such as plasma, have higher capacity for detoxification of OPs than expected only on the basis of catalytic activity of CarbE. This reaction can be very important under conditions of repeated (subchronic or chronic) exposure to low doses of nerve agents and other OPs that could be detoxified through the reaction with CarbE without any apparent toxic effect.

The role of CarbE as a bioscavenger involved in the detoxification of nerve agents and other OPs was investigated. The ideal OP bioscavenger would have a fast rate of reactivity for a broad range of OP compounds, a slow rate of aging, and the ability to reactivate to increase its stoichiometry as a bioscavenger. Evaluation of CarbE on these criteria suggests that it is an important candidate as an OP bioscavenger (Doctor *et al.*, 2001). One of the most important advantages of CarbE is that OP-inhibited CarbE does not undergo the rapid aging that prevents oxime-induced reactivation of OP-inhibited cholinesterases. This means that OP-inhibited CarbE can be reactivated yielding an active enzyme, involved in further metabolism of OP molecules, and an inactive OP metabolite.

Another advantage of CarbE is the much greater size of its active site compared to AChE (10× difference) and ChE (6× difference) (Saxena *et al.*, 1999). The large active site volume of CarbE minimizes steric hindrance effects at the active site and maximizes the potential for reactivation. In a study investigating the structural specificity of AChE, ChE, and CarbE, Maxwell *et al.* (1998) found that AChE could accommodate OP inhibitors containing only one bulky group (e.g. isopropyl, pinacolyl, phenyl), ChE could accommodate OP inhibitors containing two of the smaller bulky groups (like isopropyl), while the active site of CarbE was sufficiently large to accommodate up to two of the largest bulky groups (e.g. phenyl groups). Therefore, CarbE had the ability to detoxify the broad spectrum of OP inhibitors. The only exception to this observation is due to fewer aromatic residues in the active site of CarbE in comparison to ChE and reduced affinity of CarbE for positively charged OP inhibitors (such as VX). This effect apparently has a small importance for nerve agents (except VX) and pesticides since only a few of them are positively charged (Doctor *et al.*, 2001).

IV. OTHER FACTORS INVOLVED IN METABOLISM AND DETOXIFICATION OF NERVE AGENTS

A. Protein Binding

Proteins are amphoteric structures containing anionic and cationic reactive sites. Proteins can also participate in other interactions with xenobiotics through the formation of hydrogen bonds, polarity, and electrostatic and van der Waals' forces. Many xenobiotics can bind to proteins from blood such as albumin and B-esterases. The high concentration of albumin in plasma (30–60 g/l) may balance the poor reactivity of this protein with OPs. However, the OP scavenging property of albumin *in vivo* has not yet been evaluated. Easy binding to proteins occurs with substances that are ionized at physiological pH and those soluble in lipids such as OP. After binding of OP to proteins such as CarbE, ChE, AChE, and other macromolecules, these agents are metabolized since their acyl radical is released and phosphoryl residue remains bound to proteins. This unspecific binding of OP to blood proteins decreases inhibitor concentration in circulation and tissues thus preserving AChE activity at target sites. Binding of OP to proteins can be limited by steric hindrance and protein conformation factors that do not allow OP molecules to access all binding sites at the protein. The involvement of secondary non-cholinergic targets (neuropathy target esterase, fatty acid amide hydrolase, arylformamidase, acylpeptide hydrolase, and other macromolecules) in OP toxicity was reviewed by Casida and Quistad (2004).

The recent study of Williams *et al.* (2007) found that sarin, soman, cyclosarin, and tabun phosphylate a tyrosine residue on albumin in human blood. The tyrosine adducts with soman and tabun were detected in guinea pigs receiving therapy 7 days following subcutaneous administration of five times the LD_{50} dose of the respective nerve agent. VX also forms a tyrosine adduct in human blood *in vitro* but only at high concentrations.

Li *et al.* (2008) have shown that soman covalently binds to albumin at tyrosine 411. The adduct is stable ($t_{1/2} = 20$ days). However, though the concentration of albumin in plasma is very high, its reactivity with soman is too slow to play a major role in detoxification of the agent. The authors concluded that soman–albumin adducts could be useful for the diagnosis of soman exposure. Tarhoni *et al.* (2008) also found that OP pesticides covalently bind to albumin and that the adduct is stable for more than 7 days.

B. Tissue Depots for Nerve Agents and Other OPs

Deposition of OP in fatty tissue is based on high lipid solubility of these compounds that are stored in its original form or as toxic metabolites. Fatty tissue may have high capacity for deposition of large amounts of OP particularly for phosphorothioates that are more lipophilic than corresponding phosphates. It is not known how significant deposition of nerve agents can be in relation to their toxicity. However, for other OPs it is known that their deposition in fatty tissue decreases concentration of free OP in blood preventing inhibition of AChE. From these depots OP can be mobilized under some physiological and pathological conditions in the form capable of inhibiting AChE in target tissues. Mobilization of these compounds from fatty depots may occur in stress situations for the body such as illness, repeated treatment with some drugs, increased physical activity (important for military personnel), changed dietary regimen, and increased lipid metabolism. This can be very important in patients poisoned with these compounds in which, after completion of the treatment for acute poisoning, release of OP from the depots may occur causing the recurrence of symptoms of OP poisoning. In this respect, Ecobichon *et al.* (1977) described a case of poisoning of a female patient dermally exposed to fenitrothion and its active metabolite fenitrooxon that were partly deposited in fatty tissue. Eight months after completion of the treatment for OP poisoning she tried to lose weight and symptoms of OP poisoning with inhibition of AChE and ChE reappeared because of the release of fenitrothion from fatty tissue where it was deposited for such a long time. Also, Davies *et al.* (1975) have described five patients poisoned with dichlorofenthion in which cholinergic symptoms of poisoning lasted up to 48 days, with the presence of this insecticide in fatty tissue and blood for more than 50 days.

There are some data in the literature indicating possible deposition of nerve agents in other tissues. Van Helden and Wolthuis (1983) and Van Dongen *et al.* (1986) suggested possible deposition of soman and its nontoxic analog called soman simulator (the difference between the two compounds is the methyl group in soman simulator instead of fluoride in soman) in muscles and particularly in the diaphragm. However, they did not further investigate what comprises this depot and its physiological role. In addition, Kadar *et al.* (1985) have observed significant accumulation of ^{3}H-soman in mouse lungs and skin indicating that this agent could be bound to alveolar epithelial cells in the lungs and keratinocytes of skin epidermis. Considerable accumulation of the label occurred in the urine, gall bladder, and intestinal lumen, suggesting that these were the main pathways of excretion.

V. CONCLUDING REMARKS AND FUTURE DIRECTION

After more than three decades of research on metabolism of nerve agents soman, sarin, tabun, and VX, it can be concluded that several enzymes have a significant role in this process. Enzymes capable of hydrolyzing these agents (A-esterase, PON1) were very efficient in breaking down the bond between phosphorus and acyl radical and their activity was proportional to substrate concentration. Esterases such as cholinesterases and carboxylesterases act by binding OP molecules to the hydroxyl group placed in their active site, decreasing free concentration of the agents in blood, thus preventing inhibition of acetylcholinesterase at target sites and subsequently their toxic effects. In addition, binding of OP to carboxylesterases is reversible indicating an active role of the enzyme in metabolic detoxification of nerve agents and other OPs. However, it is necessary to further investigate the role of these enzymes and other macromolecules in the detoxification of OP compounds. Important issues for further research in this field should be related to the assessment of the detoxification potential of carboxylesterases, the significance of A-esterase polymorphism on the capacity of detoxification and their possible application in prophylaxis and treatment of OP poisoning in humans.

Acknowledgments

I am grateful to my dearest friend and teacher Professor Matej Maksimović for his support. Research was supported in part by grants from the Serbian Ministry of Science (projects 145030 and 145035).

CHAPTER 53

On-Site Detection of Chemical Warfare Agents

YASUO SETO

I. INTRODUCTION

Chemical warfare agents (CWAs) were used in World Wars I and II, during the Cold War, and still continued to be produced and stockpiled (Somani, 1992). In the 1980s, Iraq used sarin (GB) and mustard gas (HD) in the Iran–Iraq conflict (Black *et al.*, 1994). In 1992, a treaty prohibiting the development, production, stockpiling and use of chemical weapons and mandating their destruction was ratified, and in 1997 it came into force (Organization of the Prohibition of Chemical Weapons, 2005). However, the Japanese doomsday cult group, AUM Shinrikyo, used GB in Matsumoto 1994 and in the Tokyo subway in 1995. As a result, many defenseless people were poisoned or killed (Seto *et al.*, 2000). The Tokyo subway sarin gas attack and the US postal anthrax letter attack in 2001 (Inglesby *et al.*, 2002) presented a threat of chemical and biological terrorism all over the world. To realize safe and secure society, the authorities should establish a more strengthened crisis management system at national level for civil defense (Seto, 2006a). In addition, various CWAs have been discovered from former Japanese military force facilities during land excavations (Ohashi, 2004). Injuries were reported due to the direct contact with CWAs leaked from containers in Samukawa (Hanaoka, 2004), and some complaints were received concerning damage to health (neurological disorders) as a result of drinking water contaminated probably with degradation products of arsenic vomiting agents in Kamisu (Ishii *et al.*, 2004).

In crisis management of chemical warfare terrorism cases and chemical weapon disposal, monitoring of CWAs in public places, security checks at territorial borders, airports, large event venues, executive facilities, and demilitarization spots of chemical weapons are performed for protection against terrorism and workers' health. With regard to consequence management, on-site detection is performed by first responders for personal protection; on-site samples are then transported to laboratories for analysis from the perspective of both investigation and emergency lifesaving. In incident management, laboratory analysis is performed to provide evidence for the court in order to prevent future crimes (Figure 53.1). Among these detection schemes, rapid on-site detection is most important for minimization of the disaster, because it takes a long time to carry specimens sampled on-site to a laboratory for analysis (Smith, 2002; Harris, 2002; Fittch *et al.*, 2003). Various kinds of measuring technologies have been used for on-site detection and laboratory identification of CWAs.

II. PROPERTIES OF CHEMICAL WARFARE AGENTS

CWAs are low-molecular weight synthetic compounds, which are fast acting and sometimes lethal, even at low levels (Somani, 1992; Stewart *et al.*, 1992; Marrs *et al.*, 1996), and in physical properties can be classified into gaseous ''blood agents'', gaseous ''choking agents'', volatile ''nerve gases'', volatile ''blister agents'', nonvolatile ''vomit agents'', and nonvolatile ''lacrimators (tear gases)''(Figure 53.2). The physicochemical and toxicological properties of CWAs are widely varied in molecular weight, melting point, boiling point (vapor pressure), vapor density, stability in air and water, lethal concentration, incapacitating concentration, smell, water solubility, effect on skin, and antidote possibility. In particular, except for slow-acting agents, which manifest toxicity after several hours such as phosgene (CG) and mustard gas (HD), CWAs are fast acting. Deadly poisonous nerve gases and toxic blister agents are registered as scheduled compounds in the Chemical Weapon Convention. Although CWAs show toxicity by skin contact and intake, in chemical warfare terrorism cases and chemical weapon disposal, inhalation toxicity against CWA vapor is mainly considered, and analytical technologies are aiming to detect CWAs in vapor phases. To measure the toxicity of a substance, a lethal concentration value (LCt_{50}, $mg \cdot min/m^3$) is used. This value indicates the vapor concentration leading to 50% death in humans with 1 min inhalation.

III. CONCEPT OF ON-SITE DETECTION

In chemical warfare terrorism countermeasures, we must consider the dispersion of various kinds of CWAs including

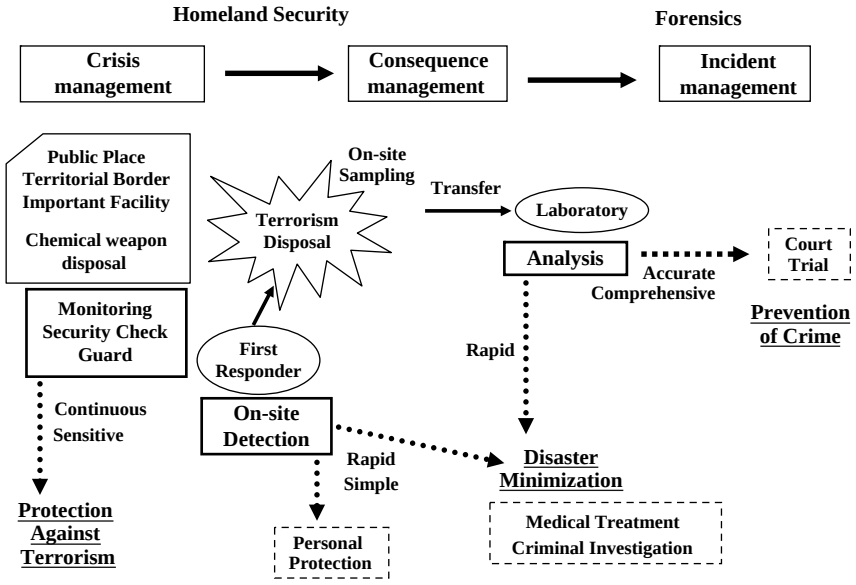

FIGURE 53.1. Detection and identification in chemical terrorism countermeasure and chemical weapon disposal.

toxic industrial chemicals (TIC) except for overt cases such as the previous notice of the criminal acts. If clear symptoms of the CWA-exposed casualties are manifest, it is possible to narrow the kinds of CWAs detected. On the other hand, in chemical weapon disposal, the kinds of the possible dispersed CWAs are apparent in advance. In a situation of exposure to CWA vapor and subsequent intoxication, monitoring technology is very important for exposure minimization and effective medical treatment. However, there is no clear idea of the required performance of the on-site detection technology, and it depends only on previous experience. Namely, the on-site monitoring of CWAs is largely an unknown area compared to the other monitoring situations, and so not only the researchers but also the first responders have little appreciation of how to detect CWAs on-site. The required on-site detection criteria are kinds of CWAs, limit of detection (LOD), response time, time required to start the detector, recovery time after the previous alarm, accuracy (interference, false positivity), state of alarm, operational performance (technology required, training required), maintenance, cost of introduction and maintenance, etc. In addition, machinery operational conditions, durability and portability should be considered.

When considering toxicity manifestation time and vapor dispersion, the detection sensitivity for vapor concentration is one hundredth of LCt_{50} within 1 min. In the case of GB, this required detection sensitivity is 0.15 mg/m^3, and at this level there is no odor and humans show no signs of toxicity. In the chemical weapon disposal situation, because the workers stay in one place for a long time, the time weighted average (TWA) values are the monitoring target for allowed operational conditions. These TWA values are approximately 1/100,000 of LCt_{50}. The desired alarm time is to be less than several minutes. There is a trade-off relationship between LOD, alarm time, detection accuracy and operation, and in detection equipment the mechanism raising the LOD leads to prolonged alarm time and an increased frequency of false positivity.

Before on-site detection technology had become as well developed as it is today, field damage and injury of the victims had been detected using the senses and by transferring on-site samples and victims' samples to specific laboratories and emergency medical hospitals, where CWAs were identified through laboratory analysis and diagnostics. To minimize damage from terrorist activity, it is vitally important to obtain information about the kinds and concentrations of dispersed CWAs using currently available technology. These laboratory analytical technologies have also been brought to the field. Figure 53.3 shows the concept of the determination of CWAs. ''Remote detection (stand-off detection)'' is the method employed to detect CWAs remote from the dispersed site using spectroscopic technology, which is divided into the following two types. ''Passive'' detection senses the (mostly the infrared) light emitted from the target. ''Active'' detection senses the secondary light emitted from the target into which the primary light was irradiated from the equipment remote from the site – usually laser is used as the irradiated light, and the reflected light, fluorescent light and absorbed light (ultraviolet, visible, infrared) are used as the emitted light. The vapor concentration of CWAs used for terrorism is low because of the high toxicity, and as terrorism is predicted to occur at civilian locations where various kinds of interfering compounds exist, it is difficult to fulfill the on-site detection requirement. ''Suction detection'' is the method to detect CWAs by directly measuring CWAs through the suction of vapor in the field, and is divided into the following types. ''Continuous monitoring'' continuously draws on-site air samples with fixed or movable equipment. ''Point detection'' is the method used to detect CWA vapor by first responders moving

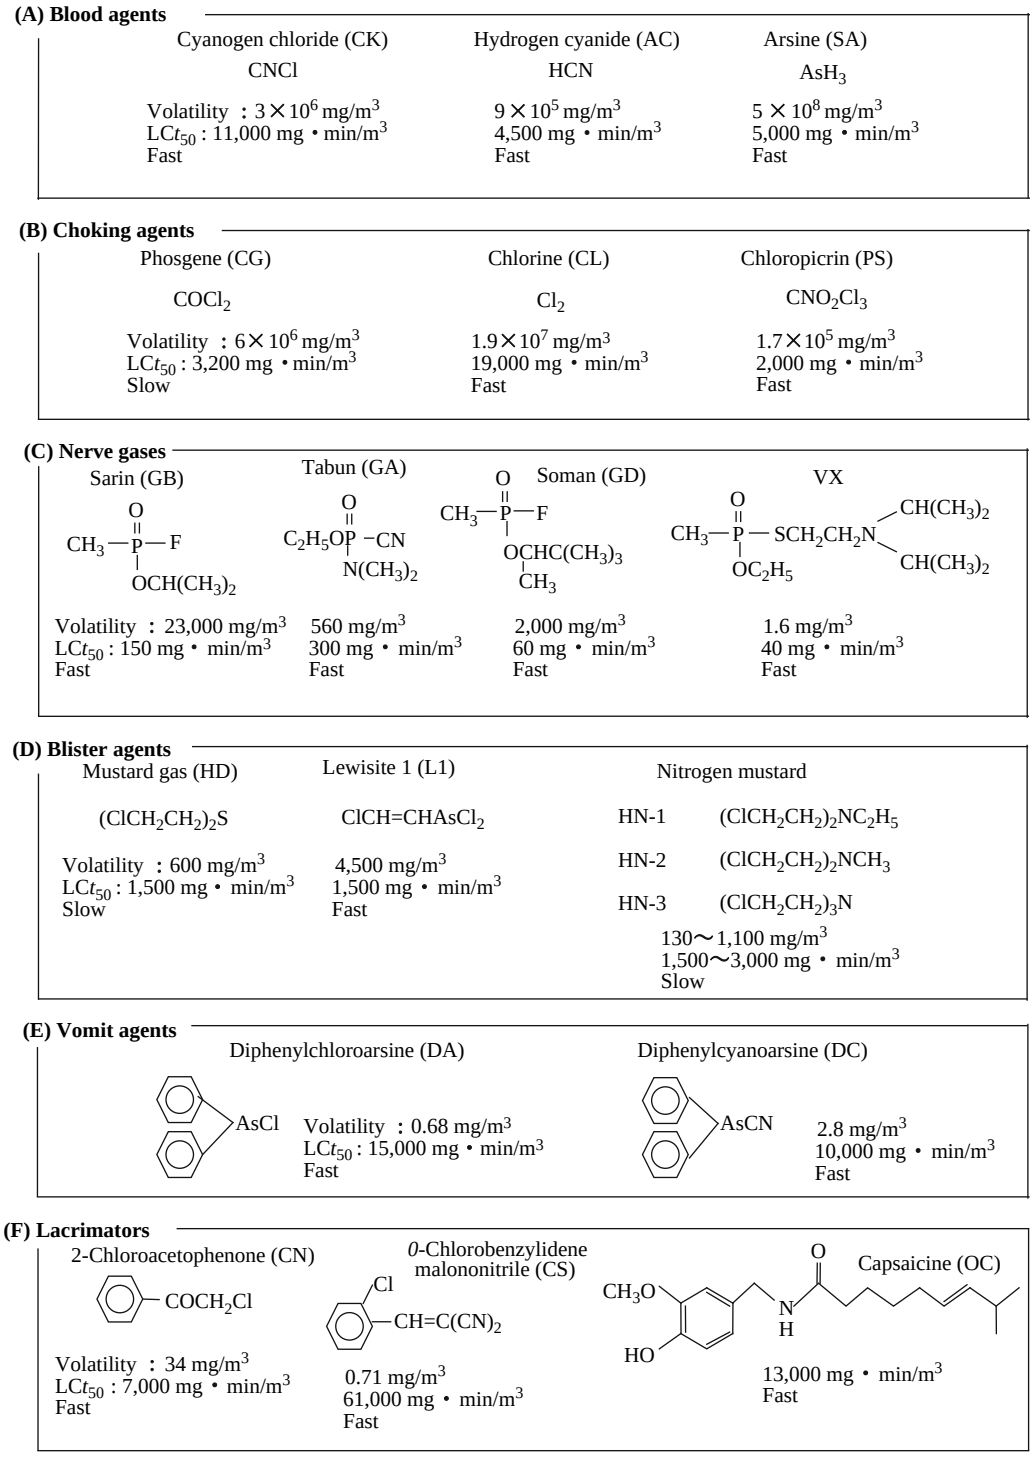

FIGURE 53.2. Chemical structures, volatility (at 25°C) and inhalation toxicity data of chemical warfare agents.

(A) Remote detection
active: LASER (reflection, absorption, excitation fluorescence)
passive: infrared, visible light
(B) Suction detection
continuous monitoring: real-time detection, collection detection, collection off-site analysis
point detection: real-time detection, collection detection, off-site analysis
(C) On-site sampling detection: real-time detection, sampling off-site analysis, sampling on-site analysis

FIGURE 53.3. Concept of on-site detection for chemical warfare agents.

in the field. ''Real-time'' detection detects CWAs by giving an alarm when continuously drawing the air, and ''collection detection'' detects CWAs by giving an alarm after the air sample is collected and detected further with cycling measurement. ''Collection off-site analysis'' detects CWAs in the laboratory from collected samples transferred from the field. As for the solid or liquid samples and the dispersed surface, CWAs are detected by directly contacting the detector, or the sampled or stripped specimens are measured by inserting into the detectors. ''On-site analysis'' uses a large trailer containing chemical laboratory equipped with analytical machines.

It is necessary to predict dangerous terrorist activity and chemical weapon disposal situations by detecting fast-acting CWAs quickly with low concentration levels (Sidell *et al.*, 2003). Any casualties are attended to with proper emergency treatment (securing aeration, antidote administration, etc.). First responders put on protective masks and clothing, and perform the zoning of the dangerous sites. For on-site detection, field deployability, rapid alarm capability, and ease of automated operation are most important – the low frequency of false positivity is a secondary requirement. However, frequent false positive alarms disrupt the responders in the performance of their duties in dangerous situations. Various types of on-site CWA detection devices have been used by military organizations all over the world (Fittch *et al.*, 2003), and some have been introduced for civil defense and counterterrorism such as mobile police teams, fire defense teams, and the coastguard.

CWAs are measurable as the chemicals and the detection technologies adopt different mechanisms depending on the target CWAs (Paddle, 1996). The discrimination level varies from screening to identification methods. At present, detection paper, gas detection tube, ion mobility spectrometer (IMS), flame photometric detector (FPD), photoionization spectrometer (PID), surface acoustic wave detector (SAW), Fourier transform/infrared spectrometer (FT/IR), gas chromatograph (GC), mass spectrometer (MS), and GC–MS are utilized as field equipment. Furthermore, chemical sensors, biosensors, and micrototal analysis systems (μTAS) have been extensively developed. Except for highly discriminating technologies such as chromatographic or spectrometric measurement, many detectors show only evidence of restricted chemical species. The representative species are ''nerve gases (nerve agents)'', ''blister agents'', ''blood agents'' including gaseous choking agents, and ''toxic industrial chemicals (TIC)''. The ''vomit agent'' and ''lacrimators'' are not considered, because of the mechanical impossibility of detecting such nonvolatile agents and their low toxicity. Nerve gas is the chief preferential agent, followed by blister agent and blood agent. So far, CWA detection technology has been developed and utilized for military missions, and so it is not guaranteed that such on-site equipment would work properly for real CWAs in civil defense siuations. Considering the present situation of terrorism countermeasures and on-site needs, on-site detection technology should be developed scientifically. Several research groups are engaged in the evaluation of commercially available detection equipment, and are developing new detection technology. Our laboratory has evaluated some commercially available detection equipment using authentic CWAs. In the following section, the evaluation results obtained in the author's laboratory are stated (Seto, 2006a, b; Seto *et al.*, 2005, 2007).

IV. THE PRESENT SITUATION OF THE DETECTION TECHNOLOGY

As for remote detection technology, passive methods of spectrophotometrically measuring specific infrared light emitted from the CWAs, and the built-in machines, are in part utilized by the military. The machine can detect CWA vapor instantaneously and continuously, but due to background interference practical utilization in the civilian market is far in the future. Active methods of measuring reflected light of the irradiated laser provide high sensitivity compared to the passive method, but the machine is too heavy (over 1 ton). Rapid is a typical machine manufactured by Bruker Daltonics (Germany). By analyzing the obtained spectra, the discriminating capability is significantly raised, and other than ultraviolet, visible and infrared lights, a wide range of other light such as mini-wave and tera-hertz wave light are now available, in addition to laser excitation and Raman scattering.

A. Classical Manual Method

As for suction detection, detection paper and gas detection tube are still used as the classical manual detection tools, which can detect CWAs by the appearance of color changes manifested with the reaction between the reagents and CWAs. ''Detection paper'' shows instant color change for liquid forms of CWAs with a sensitivity of several $\mu g/cm^2$ (Toyobo, Japan). Two kinds of pigments and a pH indicator are impregnated in the cellulose paper, and the paper turns to brown or orange when a droplet of GB, soman (GD), or tabun (GA) (G agent, G stands for Germany) is applied, red when a droplet of HD, lewisite 1 (L1) (H agent) is applied, and black or deep green when VX (V agent) is applied. This coloring reaction is based on the organic solvent solubility, and so almost all organic solvents except for water show false positivity. Dimethylmethylphosphonate, acetone, toluene, and ethyl acetate show G agent false positivity, 2-mercaptoethanol, carbon tetrachloride, and aniline show H agent false positivity, and diethylamine shows V agent false positivity. Due to too many false positivities, detection paper seems to be impractical for civilian defense missions (Seto *et al.*, 2005).

The ''gas detection tube'' shows a color change for vapor CWAs with a sensitivity of mg/m^3 concentration level. The

specific reagents are impregnated into the silica gel support in the glass tube. Both sides of the tube are opened by a cutter, the appropriate volume of the air sample is drawn, and the extent or length of coloring is ascertained using the naked eye. For the detection of blood and choking agents, commercial industrial-use gas detection tubes (Komyo Kika; Gastec, Japan) are available. However, for special agents such as nerve gases, the Dräger Safety gas detection tube (Germany) is adequate (Takayama *et al.*, 2007).

For nerve gases, the ''phosphoric acid ester'' tube shows a red color, which is based on the complicated sequential procedures of butyrylcholinesterase inhibition, substrate butyrylcholine hydrolysis, and pH indication. For HD, the ''thioether'' tube shows a yellow color, which is based on the reaction with silver chloride and chloramines. For L1, the ''arsine and organic arsenicals'' tube shows black; a sequential procedure involving two types of chemical reaction allows for separate detection of both inorganic and organic arsenicals, and based on the reduction by zinc and hydrochloride and a complex formation with gold and mercury, produces a gold colored colloid. For AC, the ''hydrogen cyanide'' tube shows a pink color, which is based on oxidation by mercury chloride and subsequent pH indication. For CK, the ''cyanogen chloride'' tube shows a pink color, which is based on the reaction with pyridine and barbituric acid. The limit of detection (the minimum concentration giving three positive results within three trials), the response time and interference of the stimulants and solvents are shown in Tables 53.1 and 53.2. The operation is a complicated procedure of breaking the inner liquid tube and subsequent incubation in a number of detection tubes. However, the procedure is rather tedious, and several minutes are required from the start of the operation until tube coloration was observed. The gas detection tube is recommended as the supplemental means for ascertainment of CWA species after IMS screening.

TABLE 53.1. Detection performance of Drager gas detection tubes

Agent	Gas detection tube	Limit of detection	Response time
Sarin	Phosphoric acid ester	0.002 mg/m^3	5–6 min
Soman	Phosphoric acid ester	0.02 mg/m^3	5–6 min
Tabun	Phosphoric acid ester	0.5 mg/m^3	5–6 min
VX	Phosphoric acid ester	2 mg/m^3	5–6 min
Mustard gas	Thioether	2 mg/m^3	2 min
Lewisite 1	(In)organic arsine	4 mg/m^3	2 min
Hydrogen cyanide	Hydrogen cyanide	0.3 mg/m^3	1 min
Cyanogen chloride	Cyanogen chloride	0.8 mg/m^3	3 min

Gas detection tube	Compound
Phosphoric acid	Dichlorvos, methomyl
Thioether	2-Chloroethylethylsulfide, 1,4-tioxane

B. Photometric Method

This type of detection is based on the photometric or electronic response manifested by the physicochemical reaction of CWAs. A flame photometric detector (FPD) detects CWAs by measuring the specific phosphorus or sulfur emission line produced through combustion with hydrogen gas. AP2C, a handy portable automated FPD, was manufactured by Proengin (France). This detector responds rapidly to both vapor and liquid forms of phosphorus containing CWAs in the ''GV'' mode and of sulfur containing CWAs in the ''H'' mode. Approximately 0.1 mg/m^3 and 1 mg/m^3 concentration levels of nerve gases and HD are detected in GV and H modes, respectively (Seto *et al.*, 2005, 2007). The simulants containing phosphorus or sulfur show false positivity, and CWAs which do contain neither phosphors nor sulfur show negative detection. The flame ionization detector (FID) detects nonspecifically combustible CWAs by measuring ionic production manifested by the combustion with hydrogen, and the limit of detection (LOD) is sub-mg/m^3 level of vapor concentration. The photoionization spectrometer (PID) detects all kinds of CWAs nonspecifically, which is based on the measurement of the produced ion current of charged gas ions by irradiation with ultraviolet light. RAE Systems (USA) manufactures ppb RAE, and the LOD is several tens of mg/m^3 level (Seto *et al.*, 2007).

Chemical sensor technology adopting acoustic waves (Harris, 2002) is also available for CWA on-site detection. The CWAs are adsorbed reversibly on the arrayed cells of the specific liquid phase polymer, and the acoustic wave numbers change according to the mass increase due to the CWA adsorption. CWAs can be detected and discriminated by analyzing the respective wave number changes (Harris, 2003; Grate, 2000). By increasing the number of the polymer cells, discriminating power is increased. Portable detector adopted arrayed surface acoustic wave (SAW) devices are commercially available. ChemSentry, manufactured by BAE Systems (USA), adopts ten different polymer cells, and detects CWAs as ''NERVE'' for nerve agents, ''BL'' for blister agents, and ''BLOOD'' for blood and choking agents. As shown in Tables 53.3 and 53.4 (Matsushita *et al.*, 2005), LOD is rather high, the response

TABLE 53.3. Detection performance of arrayed surface acoustic wave detector – ChemSentry

Agent	Alarm	Limit of detection	Response time	Recovery time
Sarin	NERVE	30 mg/m^3	12 s	235 s
Soman	NERVE	50 mg/m^3	12 s	234 s
Tabun	NERVE	100 mg/m^3	13 s	230 s
Mustard gas	BL	38 mg/m^3	8 s	236 s
Lewisite 1	NERVE	280 mg/m^3	109 s	272 s
	BL	57,000 mg/m^3	13 s	394 s
Hydrogen cyanide	BLOOD	28 mg/m^3	100 s	19 s
Cyanogen chloride	BLOOD	940 mg/m^3	103 s	27 s

BL – blister

and recovery time is long, and the false positive frequency is high. This chemo-adsorptive sensor technology provides the possibility of raised discrimination by adopting arrayed cells, but due to the strong adsorption of CWAs disturbs quick response of alarm and recovery.

C. Ion Mobility Spectrometric Method

The ion mobility spectrometer (IMS) is most frequently used for military and civil defense missions to detect not only CWAs but also explosives and illicit drugs (Cottingham 2003; Iceman and Stone, 2004). The drawn air sample is ionized by β emitter or corona discharge under atmospheric pressure, and the ionized water cluster molecules combine with CWA molecules in the reaction region. The produced cluster ions (positive or negative) are periodically traversed through the drift region, and detected on the collector. Ion mobility depends on their charge and molecular weight with a several millisecond cycle (Figure 53.4). CWAs are recognized according to the ion mobility of the peak or peaks, and semi-quantified according to the ion peak height (St Louis and Hill, 1990). In positive ion mode, a protonated water cluster combines with the targets, and in negative mode a water and carbon dioxide cluster attached with oxygen combines with the targets. As the dopant, ammonia or organic solvents are introduced into the drift region, which raises sensitivity and discriminating power. Easily ionizable nerve gases show high sensitivity, and weakly ionizable blister agents do not show high sensitivity. Low molecular weight, blood and choking agents do not produce characteristic cluster ions, and so the detection sensitivity is low. Because of atmospheric pressure ionization, the devices are manufactured in compact form, and the response time is fast. However, the resolution of the produced target ions is low compared to the mass spectrometer, leading to frequent false positivity by many kinds of organic solvents. To raise the sensitivity and accuracy, the ionization mechanism has been improved, by using electrospray, laser desorption, matrix-assisted laser desorption, and the development of new hardware (Cottingham, 2003; Kolakowski and Mester, 2007).

TABLE 53.4. Response of ChemSentry against organic solvents

Alarm	Compound
NERVE	Methanol, ethanol, *n*-propanol, 2-butanol, *t*-butyl alcohol, ethyl acetate, 1,4-dioxane, acetonitrile, acetaldehyde, *N*,*N*-dimethylformamide, pyridine
BL	Dichloromethane, 1,2-dichloroethane, chlorobenzene
BLOOD	Ammonia, acetaldehyde
CONFIDENTIAL	*t*-Butyl alcohol, acetone, diethylether, diethylamine, *N*,*N*-dimethylformamide, pyridine

An aspiration-type device is based on discrimination by the pattern recognition of the several IMS cells of different ion mobility and polarity. Environics OY (Finland) manufactures two types of IMS detectors. The M90 (type D1) is an aspiration-type 80 μCi ^{241}Am-bearing IMS, adopting six IMS cells and one semiconductor cell, and provides vapor detection of GB, GD, and GA (LOD: sub-mg/m^3) as a ''Nerve'' mode alarm with a false-positive alarm against vapors of dimethylmethylphosphonate and trimethylphosphate. HD and L1 vapor (LOD: several mg/m^3) caused a ''Blister'' mode alarm, but 2-mercaptoethanol and 2-chloroethylethylsulfide vapors also caused a false-positive alarm. AC or CK gas (1,000 mg/m^3) showed a false ''blood'' negative alarm (Seto *et al.*, 2004). The same Finnish aspiration-type IMS, ChemPro100 (version 6.2.5), adopts 16 IMS cells and one semiconductor cell, providing more reliable recognition. Tables 53.5 and 53.6 (Maruko *et al.*, 2006) show LOD, response and recovery time for CWAs, and interference. Blood agents were not detected easily, which is the reason for the false negativity and may be the influence of *n*-hexane used as CWA solvent in the detection experiment.

LCD-3.2E, a corona discharge-type IMS, which was developed by Smiths Detection (United Kingdom), is a handy detector showing two kinds of alarm: ''G'' for nerve gases and ''H'' for the other CWAs. Tables 53.7 and 53.8 (Sekioka *et al.*, 2007) show LOD, response and recovery time for CWAs, and interference. This machine adopts an ammonia dopant, raising sensitivity and discriminating power. Maintenance requires the sieve pack to be changed frequently for proper operation. SABRE 4000, manufactured by Smiths Detection, is a high-resolution IMS, providing agent name alarm. Air Sense (Germany) manufactures GDA2, which is a multisensor system consisting of IMS, semiconductor, metal oxide, and PID, enabling identification and quantification for not only

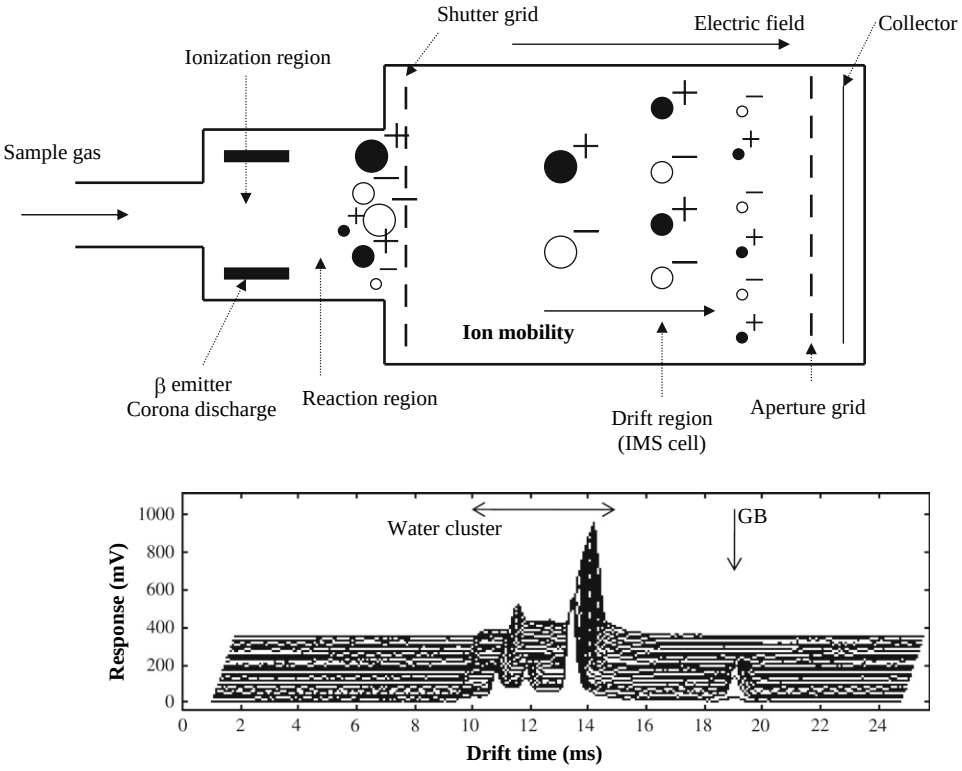

FIGURE 53.4. Ion mobility spectrometry. Detection mechanism and an exemplified spectrum. SABRE4000 (Smiths Detections Ltd, ionization ^{63}N detected GB).

CWAs but also TIC. These two machines need frequent maintenance.

D. Fourier Transform/Infrared Spectrometric Method

Fourier transform/infrared spectrometry (FT/IR) detects and identifies CWAs by measuring the infrared spectrum of the air sample noninvasively and instantly (Mukhopadhyay 2004). Considering the interference of water and carbon dioxide, characteristic absorbance peaks in the low-wave number region are used as the specific marker. Portable FT-IR equipment is commercially available. IGA-1700 (Otsuka Electronics, Japan) and DX-4000 (Temet, Finland) showed HD (1,200 cm^{-1}) and GB (1,000 cm^{-1}) detection with an LOD of 10 mg/m^3 after subtracting background water and carbon dioxide absorption. VIR-9500 (Japan Spectroscopy Co., Japan) showed L1 detection with an LOD (815 cm^{-1}) of 2 mg/m^3 using an 8 m light path gas cell.

E. Gas Chromatography

Gas chromatography (GC) detects CWAs by measuring the peak response appearing on the GC column. CWAs are discriminated with the retention time and the detectability by the specific detection devices (Henry, 1997). Combined with the automated air collection/thermal desorption system, GC provides very sensitive detection (lower than $\mu g/m^3$) for

TABLE 53.5. Detection performance of aspiration-type IMS detector – ChemPro100

Agent	Alarm	Limit of detection	Response time	Recovery time

nerve gases and blister agents every 10 min cycle. The OI Corporation (USA) manufactures Minicams.

F. Mass Spectrometry

By reducing the size of a laboratory-type mass spectrometer (MS), and making it portable and resistant to mechanical shock, the machine can be used to detect CWAs in the field (Wise and Guerin, 1997). MS provides high-resolution power, but to maintain the vacuum, the machine needs to be large, and its operation is complicated. Electron ionization is usually used because of the benefit of the abundant mass spectra data library. On-site MS adopts a hydrophobic membrane inlet system to eliminate oxygen and nitrogen from the ionization region. The adsorbed CWAs are then introduced to the ionization region. The small molecules and strong adsorptive compounds cannot be detected by this ionization-type MS. Field-portable MS, which has been developed for environmental TIC measurement (Horiba, Japan) and adopts time-of-flight mass analyzer and pattern recognition data analysis, detects high vapor levels of GB and HD.

TABLE 53.8. Response of LCD-3.2E against organic solvents

Alarm	Compound
G	Trimethylphosphate, triethylphosphate, *n*-propanol, diethylamine, triethylamine Tobacco smoke
H	2-Chloroethylethylsulfide, 1,4-thioxane, diethylether, acetic acid

The technology of GC–MS can be downsized for field usage and is now commercially available. Inficon (USA) manufactures a field-portable GC–MS, Hapsite. Vapor is withdrawn for 30 s into the Tenax preconcentration system, thermally desorbed into the apolar capillary column with elevated temperature control, and the separated components are finally analyzed by the electron ionization quadrupole mass spectrometer. GB, GD, GA, and HD are detected and identified within 12 min with postulated LOD values of 0.2, 0.5, 8, and 0.3 μg/m^3 (Sekiguchi *et al.*, 2006). Gaseous and weakly volatile (boiling temperature >250°C) CWAs cannot be detected.

G. Other Sensor Technologies

As for sensor technologies, biosensors utilizing the CWA target enzymes have been developed over the years (Guerrieri *et al.*, 2002; Zayats *et al.*, 2003; Walker and Asher,

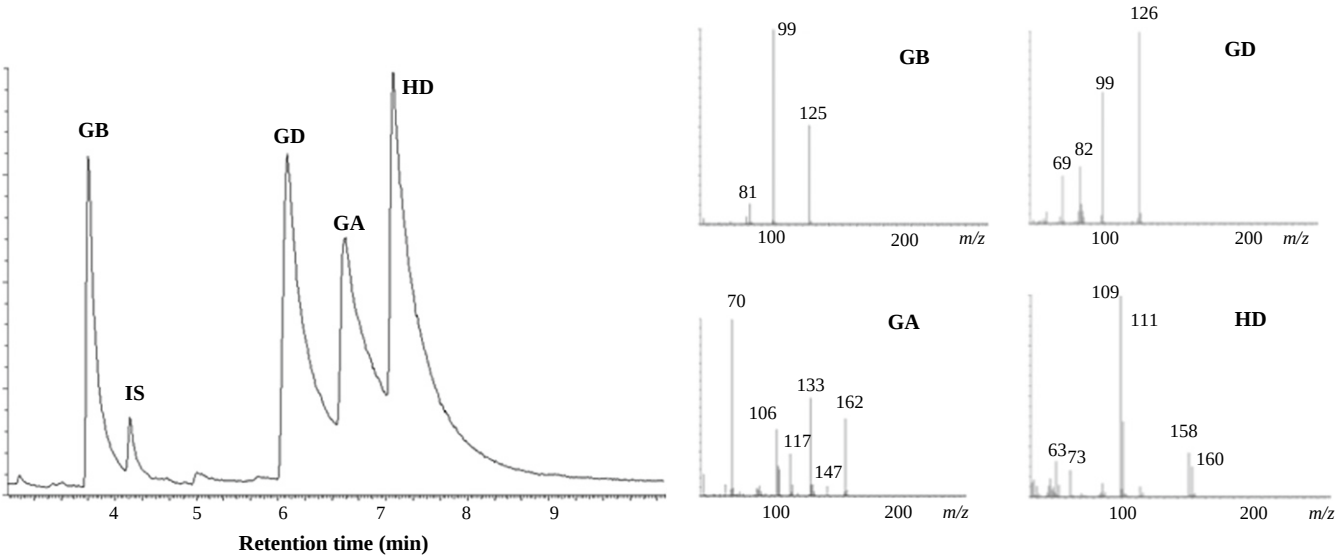

FIGURE 53.5. GC–MS data of portable apparatus, Hapsite. Left: total ion chromatogram; right: electron ionization mass spectra. GB, GD: 1 mg/m^3; GA: 3 mg/m^3; HD: 0.5 mg/m^3. IS: internal standard.

2005). To detect nerve gases, acetylcholinesterase is fixed on the sensor chip, and by the reaction with nerve gases, substrate hydrolysis velocity is lowered due to enzyme inhibition, and the resulting electric response such as hydrogen peroxide formation by choline oxidase is monitored (Palleschi *et al.*, 1992). A fluorescent sensor device utilizing organophosphorus hydrolase (Russell *et al.*, 1999) and a chemical sensor utilizing nerve gas-reactive fluorescent reagent (Zhang and Swager, 2003) have been developed. These types of sensors are still not practical to use. To detect AC, tyrosinase is fixed on glassy carbon, and after concentration of AC on the colloidal mineral the inhibited activity is monitored by electrochemically measuring polyphenol hydrolysis (Shan *et al.*, 2004). Nerve gases and blister agents easily hydrolyze to form the characteristic compounds, and the hydrolyzed CWAs can be analyzed in the wet system utilizing μTAS capillary electrophoresis (Wang, 2004).

V. COMPARISON OF THE EXISTING ON-SITE DETECTION TECHNOLOGIES

First responders require the following criteria: detection sensitivity, detection accuracy, response time, recovery time and operation; Table 53.9 compares these items. The numerical data are derived from our experiment. The evaluation is categorized into the three signs: ''OK'' means acceptable, ''Δ'' means improvement required, and ''X'' means not acceptable. There are no devices that meet all CBWA detection requirements. Low sensitivity, false alarms, and the strong adsorption of CWAs on certain devices are particularly serious problems. The gas detection tube system, permitting the detection of a wide range of CWA vapors, suffers from tedious operation and a slow response. The IMS-based detectors, which permit rapid and sensitive detection of nerve and blistering agents, show low sensitivity for gaseous agents, and a false positive for some compounds. The FPD-based detector, which permits rapid and sensitive detection of nerve gases and HD, shows false-negative detection for nonphosphorus and sulfur CWAs. The PID-based detector shows nonspecific and low sensitive detection. The SAW-based detector does not permit sensitive detection of CWAs. The FT-IR, which permits noninvasive and constant detection, shows inadequate sensitivity. The GC-based detector with concentration system, which permits sensitive detection of nerve gases and blister agents, suffers from tedious operation and a slow response, as does the GC–MS-based detector, which permits sensitive identification of only volatile nerve gases and HD. Nonvolatile vomit agents and lacrimators cannot be detected in any of the above devices.

VI. DEVELOPMENT OF NEW ON-SITE DETECTION TECHNOLOGIES

Figure 53.6 shows a performance map of the physical properties of on-site CBWA detection equipment. CBWAs are represented in terms of volatility and molecular weight, and the target agent territories and drawbacks of the detection equipment are shown. The detection of gaseous agents and nonvolatile CWAs needs to be improved. To enable more sensitive and continuous monitoring of both

TABLE 53.9. Comparison of detection performance of various chemical warfare agent detectors

	Gaseous agent	Nerve gas	Blister agent	Vomit agent Lacrimator	False alarm	Response time	Recovery time	Operation
Detection tube	OK 1 mg/m^3	OK 0.5 mg/m^3	OK 4 mg/m^3	X	Δ	X 1–5 min	–	X

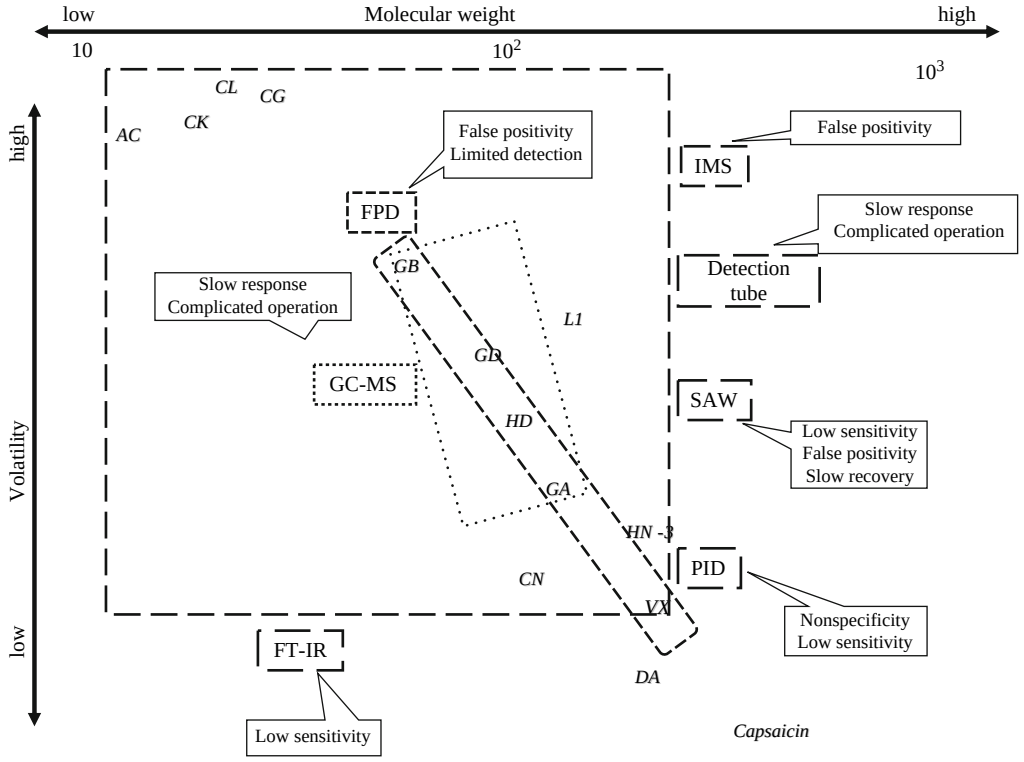

FIGURE 53.6. Performance of on-site chemical warfare agent detection equipment.

volatile and nonvolatile CWAs, our laboratory, coordinated with Hitachi Ltd, has developed on-site detection methods utilizing counterflow introduction atmospheric pressure chemical ionization MS (CFI-APCI-MS, Figure 53.7). CFI-APCI-MS technology provides soft ionization of the suctioned CWAs by corona discharge (APCI), and the introduction of the produced primary target ions into the mass analyzer; the secondary interfering ions are excluded from the ionization region (CFI). CFI-APCI technology is superior in noise ion reduction, realizing ultrasensitive detection (Takada, 2006). Explosive residues and illicit drugs are monitored with this type of machine. Adopting an

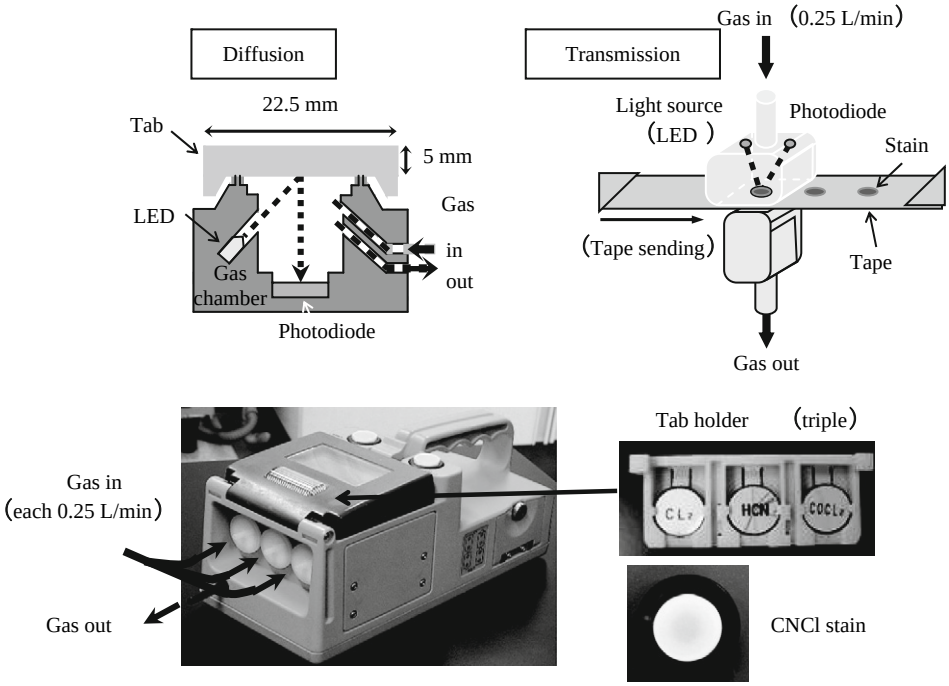

FIGURE 53.8. Monitoring tape method. Schematic detection mechanism of diffusion (upper left) and transmission (upper right) types of apparatus and arrayed diffusion-type detector (lower).

ion trap mass analyzer (MS^n function), all kinds of nerve gases, blistering agents, vomit agents and lacrimators are detected within several seconds with LODs in the sub-$\mu g/m^3$ region (DS-1000, Figure 53.7).

The monitoring tape method (Nakano, 2001) detects hazardous gases by spectrophotometrically measuring the color change on the tape or tab impregnated with specific reagents after the reaction with the suctioned air sample (Figure 53.8). The technology was developed by Riken Keiki Ltd (Japan), and machines are commercially available. Diffusion-type apparatus is used as the portable machine, and by selecting the tab the machine can monitor the desired gases. Transmission-type apparatus is used as the fixed monitor machine, which provides more sensitive detection. Riken Keiki and the author have developed the three tab arrayed detector (FP-100). Three kinds of gaseous CWAs can be detected simultaneously and specifically with LODs lower than 1 mg/m^3 within 1 min. Blood agents (AC, CK, and arsine), choking agents (CL, GC), and L1 can be detected.

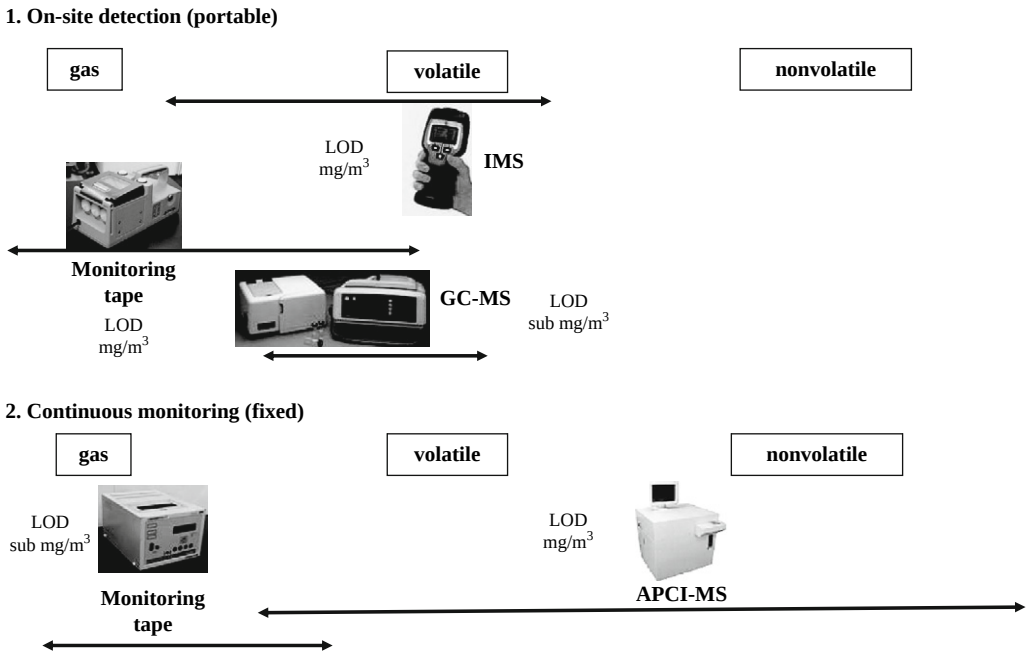

FIGURE 53.9. Recommended combination of on-site detection equipment.

VII. CONCLUDING REMARKS AND FUTURE DIRECTION

When considering on-site CWA detection requirements and the status of the present detection technologies, the recommended on-site detection system is shown in Figure 53.9. For portable-type detectors used by first responders, a combination of IMS and arrayed monitoring tape method machine is desirable. This combination covers gaseous to volatile CWAs. GC–MS helps to identify the detected CWAs. Nonvolatile CWAs are still unable to be detected by portable machines. For fixed-type detectors, highly sensitive detection equipment is necessary, and a combination of CFI-APCI-MS and a lined set of transmission-type monitoring tape method machines is almost perfect, covering all the CWAs with the required sensitivity. It is anticipated that new sensing technology will be developed in the future and will overcome the problems of large size, false alarms, low sensitivity and narrow detection coverage.

CHAPTER 54

Laboratory Analysis of Chemical Warfare Agents and Metabolites in Biomedical Samples

M. J. VAN DER SCHANS

I. INTRODUCTION

Chemical warfare agents (CWAs) are the most toxic compounds ever produced. In order to develop medical countermeasures against the effects of these agents, analytical procedures to analyze these agents in biological matrices are essential for a better understanding of the toxicological process. The need for the analysis of biomedical samples can have several purposes. First, the agents themselves may be detected in their intact form in the case of toxicokinetic studies. Toxicokinetic studies provide a quantitative basis for the development of new strategies for prophylaxis and therapy against intoxication with chemical warfare agents. Second, verification of exposure to CWAs is another goal that requires analytical methodology for biomedical samples. Verification of exposure is needed for several reasons:

1. In the case of chemical warfare military personnel who are exposed need a fast diagnosis to ascertain the level of exposure and the identity of the agent, in order to give victims adequate treatment.
2. Low-level exposures to nerve agents might be associated with unexplainable phenomena like the Gulf War Syndrome (CIA, 1997).
3. Despite the OPCW treaty, large stockpiles of intact agents still exist, waiting for destruction. Personnel in such destruction facilities might have an elevated risk of exposure; careful biomonitoring could minimize the risks associated with these activities.
4. In the case of a terrorist event, unambiguous verification is needed to verify the exposure.

Methodologies for the verification of exposure to chemical warfare agents have been published recently in special issues of the *Journal of Analytical Toxicology* (Barr, 2004, 2008; Black, 2008). Methodology of the clinical methods has also been reviewed by Noort *et al.* (2002), Black and Noort (2007), and Capacio *et al.* (2008). This chapter is not meant as a duplicate for these references. It will briefly discuss the analytical techniques that are needed for the analysis of biomedical samples. Most of the analytical methods still rely on chromatographic techniques like gas and liquid chromatography. The progress in instrument development on the detection site has been tremendous in the last few decades. Analyses based on mass spectrometry are now more or less routine. Single and triple quadrupole mass spectrometers have become affordable and automated standard configurations with mass spectrometers can now fulfill the analytical need for most type of analyses. However, analyses of chemical warfare agents might need some additional requirements. For example, it might be necessary to measure an intact agent at extremely low concentrations, because only these levels are relevant in view of the high toxicity of the agents. In that case, it might be considered to utilize large volume sample introduction. This puts higher demands on the analytical configurations because the introduction of larger sample volumes also increases the matrix effect, which puts extra demands on the selectivity of the analysis. In the special case of nerve agents, it might be desirable to distinguish the stereoisomers of these compounds from each other, which requires a rather complicated analytical configuration. In this chapter the methods for the bioanalysis of CWAs or their biomarkers will be briefly described and in case the instrumentation for a particular analysis is more sophisticated than a standard configuration, it will be discussed in more detail.

II. NERVE AGENTS

Nerve agents are organophosphorus (OP) compounds that inhibit acetylcholinesterase (AChE) extremely rapidly, which results in an accumulation of acetylcholine (ACh), leads to muscle fasciculations and paralysis, and finally results in death (Dacre, 1984). There are several strategies available to verify an exposure to nerve agents. It is not

feasible to measure the intact reagent, since the half-life of these agents is only a few hours, which means that they disappear within a day after exposure (Benschop and de Jong, 2001; Van der Schans *et al.*, 2008a). Metabolites, often alkylmethylphosphonic acids, are better biomarkers because they circulate for a longer period of time and are gradually excreted in urine (Shih *et al.*, 1994; Fredriksson *et al.* 1995; Nagao *et al.*, 1997; Noort *et al.*, 1998). Several methodologies have been published to analyze these metabolites, which were found in plasma and urine (see Table 54.1 for an overview). Most methods for determination of these compounds are based on liquid chromatography or gas chromatography which requires derivatization (Black and Muir, 2003). Selective MS–MS techniques facilitated by triple quad instruments or ion trap instruments enabled the detection of hydrolysis products down to the pg/ml range (Barr *et al.*, 2004; Riches *et al.*, 2005). This concentration is so low that hydrolysis products can be detected in urine up to 1 week after exposure (Riches *et al.*, 2005).

Nerve agents bind to proteins such as AChE and butyrylcholinesterase (BuChE). These proteins are not excreted or metabolized rapidly (typical half-life is 12 days for BuChE; Hall *et al.*, 1984), which means that adducts to proteins can serve as retrospective biomarkers for exposure to nerve agents (Fidder *et al.*, 2002; Van der Schans *et al.*, 2004a). The enzymatic measurement of AChE activity, known as the Ellman assay, is the easiest method to determine a nerve agent exposure (Ellman *et al.*, 1961; Halbrook *et al.*, 1992). The method is based on the enzymatic cleavage of the substrate acetylthiocholine into thiocholine, which converts 5,5′-dithiobis(2-nitrobenzoic acid) into nitrobenzoate, a yellowish product that can easily be measured with a low-cost colorimeter. Major drawbacks of the method are, first, that the identity of the nerve agents cannot be elucidated from this measurement. Second, the intra- and interpersonal variation of the ChE activity implies that a decrease of ChE activity must be relatively large to be significant (Brock, 1991). Third, the *de novo* synthesis of the enzyme restores the

TABLE 54.1. Major biomarkers for nerve agent exposure

VX	Blood	Adduct to BuChE	Peptic digest of BuChE	LC–MS–MS	Fidder *et al.* (2002)

enzyme activity within several days within the range of the control values. Low-level exposures to nerve agents or exposures that took place several weeks before the biosample could be taken cannot be detected using this method. Instead of looking for a decrease in AChE activity, it is more efficient to detect the ChE fraction that is inhibited by the nerve agent. In that case, it is also better to look at BuChE, which has several advantages over AChE. First, BuChE is a protein present in plasma, which is an easier sample matrix to process than whole blood. Second, the concentration of BuChE is approximately 80 nM, which is approximately ten times higher than the concentration of AChE in blood (Myers, 1952; De Jong and Wolring, 1984). This automatically means that the concentration of that biomarker is higher and therefore easier to detect. The most straightforward method to detect the adduct of nerve agent is the fluoride reactivation method (Polhuijs *et al.*, 1997). During incubation of a plasma sample with fluoride ions, the nerve agent adduct is released from the protein and can be extracted in a GC compatible solvent and subsequently analyzed with GC. The lowest detectable degree of inhibition that can be determined with this method depends on the type of GC detector. Typical reasonably priced detectors like the nitrogen phosphorus detector (NPD), flame photometric detector (FPD), and mass selective detector show absolute detection limits of about 1 pg, which means that a concentration of 1 ng/ml can be detected using an injection volume of 1 µl. A concentration of 1 ng/ml of nerve agent is equivalent to 5–7 nM, which corresponds with approximately 10% BuChE inhibition. In order to be able to determine lower degrees of inhibition, higher sample volumes have to be injected which puts higher demands on the selectivity of the separation and detection method.

A better chromatographic selectivity can be obtained by two-dimensional chromatography based on the heart cutting method, which will be discussed later (see Analysis of nerve agents, below). Another option is to improve the selectivity of the detector. Chemical ionization with ammonia as reaction gas is a relatively soft ionization mode, which ensures a more selective detection of only compounds with sufficient proton affinity (Degenhardt *et al.*, 2004; Jakubowski *et al.*, 2004; Holland *et al.*, 2008; Solano *et al.*, 2008). Another more expensive option is to use an HR–MS instrument, which can provide sensitivity and selectivity for the sensitive detection of low degree inhibition (Degenhardt *et al.* 2004; Solano *et al.*, 2008). When the large volume technique is utilized low degrees of inhibition down to 0.1% can be confirmed.

A major drawback of the fluoride reactivation method is that not all nerve agent adducts are amenable to fluoride reactivation, with the aged adduct of soman the best known example. This problem can be solved by looking at the BuChE enzyme itself. Fidder *et al.* (2002) published a method based on the LC–MS analysis of a nerve agent phosphylated nonapeptide derived after pepsin digestion of inhibited butyrylcholinesterase. The authors presented a procedure to extract BuChE from plasma using home fabricated procainamide gels. The phosphylated nonapeptide is best analyzed with an LC–MS–MS instrument using the single reaction monitoring (SRM) mode. The mass of the parent ion depends on the mass of the nerve agent that is conjugated to the peptide. During the fragmentation process, the phosphyl moiety of the nerve agent is removed first and the characteristic daughter ions are 778, 673, and 602, which are all fragments of the native peptide. This method and the fluoride reactivation method were both successfully applied on plasma samples that were taken from victims who had been exposed to sarin in the Tokyo subway in 1995 (Polhuijs *et al.*, 1997; Fidder *et al.*, 2002). Due to the low concentration of the biomarkers, the analyses are target directed because a full scan would be at the cost of sensitivity, which means that low-level exposures cannot be detected. However, this is a serious problem in the case where the identity of the nerve agent is not known beforehand. Recently, some progress has been made in solving this problem. The number of different OPs exceeds several thousand, but the number of different masses is only 170. Since the OPCW Schedule 1 nerve agents consist only of saturated alkyl groups with mass increments of 14 units the number of mass possibilities can be further reduced to 36 masses, which means that only 36 MRM transitions have to be recorded (Van der Schans *et al.*, 2008a). Another approach was recently published by Noort *et al.* (2006). The phosphylated serine residue of nerve agent inhibited BuChE can be converted under alkaline conditions into a dehydroalanine residue that can subsequently react with a generic tag, yielding a mutual product, whatever the identity of the nerve agent. The resulting product can be detected in the most sensitive single reaction monitoring mode of the mass spectrometer.

A. Analysis of Nerve Agents

1. G-Agents

The requirements for the analytical equipment of the analysis of nerve agents become more sophisticated when the fate of the nerve agents themselves is analyzed. The toxicokinetic studies create insight into the distribution and elimination of the agents and indicate until which time toxicologically relevant concentrations are still present in the circulation (Benschop and De Jong, 2001; Van der Schans *et al.*, 2008b). In view of the high toxicity of nerve agents, these toxicologically relevant concentrations are in the pg/ml range. Using gas chromatography, these levels can only be measured when large volume samples can be introduced on the column. With higher sample volumes, the matrix effect is increased as well and it places higher requirements on the selectivity of the analysis. Another challenging factor is that nerve agents are chiral compounds with an asymmetrical phosphorus atom (Benschop, 1975; Benschop and De Jong, 1988). The difference in toxicity of the two isomers is several orders of magnitude, the P(−)-isomers being the most toxic (Benschop *et al.*, 1984;

Benschop and De Jong, 1988). In the case of toxicokinetic studies, it is important to differentiate between the two isomers because it is essential to know which isomer is still present in the circulation. Chiral gas chromatography can fulfill this requirement for G-agents like sarin and soman. Soman has two asymmetric atoms, phosphorus and carbon in the pinacolyl group. Therefore, the compound consists of four different stereoisomers.

An optical active stationary phase like β-cyclodextrin can be used to separate the isomers of sarin (Spruit *et al.*, 2001). Chirasil-Val columns can be used to separate the four isomers of soman (Benschop *et al.*, 1981, 1985). The Chirasil-Val stationary phases were synthesized at the TNO Prins Maurits Laboratory. Smith and Schlager (1996) reported the use of commercially available gamma-cyclodextrin-based columns that are also capable of separating the four isomers of soman. In the case of toxicokinetic studies the chiral columns were installed in a two-dimensional GC configuration according to the heart cutting method (see Figure 54.2 for an outline). First, the introduction of large volume samples requires additional selectivity from the chromatographic system to alleviate the matrix effect. Second, the fragile optical active phase needs to be protected from the ''dirty'' extracts of the biosamples and the condensating solvent in the column. Samples are introduced by thermodesorption tubes filled with TENAX material. The components are cryo-focused in a cold trap and after a certain desorption time, flash injected into the first column. According to the heart cutting technique one small section of the effluent of the first column is collected in a cold trap and then reinjected on the second analytical column with the chiral selective phase. The isomers of soman could be detected in the blood of guinea pigs at levels down to 10 pg/ml blood (Benschop and De Jong, 1991). Figure 54.1 shows a chromatogram of the analysis of the four isomers of soman together with one isomer of deuterated soman [d_{13}-C(−)P(+)-soman] which was added as an internal standard.

2. VX

Efforts to separate the isomers of VX with gas chromatography have been unsuccessful so far. However, separation was achieved using normal phase liquid chromatography with a Chiracel OD-H column. The separation of the enantiomers of VX was first described by Kientz *et al.* (1994). They used a thermo-ionic detector for the selective detection of phosphorus compounds. Unfortunately, this technique was not robust enough. The same separation was also described by Van der Schans *et al.* (2003) using electrochemical detection. The mobile phase (hexane:ethanol 95:5) was mixed post-column with 0.1 M lithium perchlorate solution to ensure conductivity necessary for electrochemical detection. The system could be used to study the stereoselective degradation of VX in *in vitro* samples such as liver homogenates and plasma. Although the electrochemical detection was rather sensitive (absolute detection limit 25 pg), the method was not selective enough to measure low levels of VX in extracts of biological matrices at a relevant level (<10 ng/ml). Relevant levels of VX in blood could be detected down to 1 ng/ml using a two-dimensional off-line LC–GC separation. The enantiomers of VX were separated on the Chiracel OD-H column and collected in fractions of 100 µl. The mobile phase (hexane:ethanol 95:5) is GC compatible and can be directly injected onto the GC–NPD. Since VX can be sensitively detected using GC–NPD, the amount of VX in each fraction could be quantified and the analyses of ten consecutive fractions from the LC were sufficient to quantify VX and determine the ratio of the enantiomers (Bonierbale *et al.*, 1996; Van der Schans *et al.*, 2003). Smith (2004) published the same separation using a single quadrupole mass spectrometer using atmospheric pressure chemical ionization

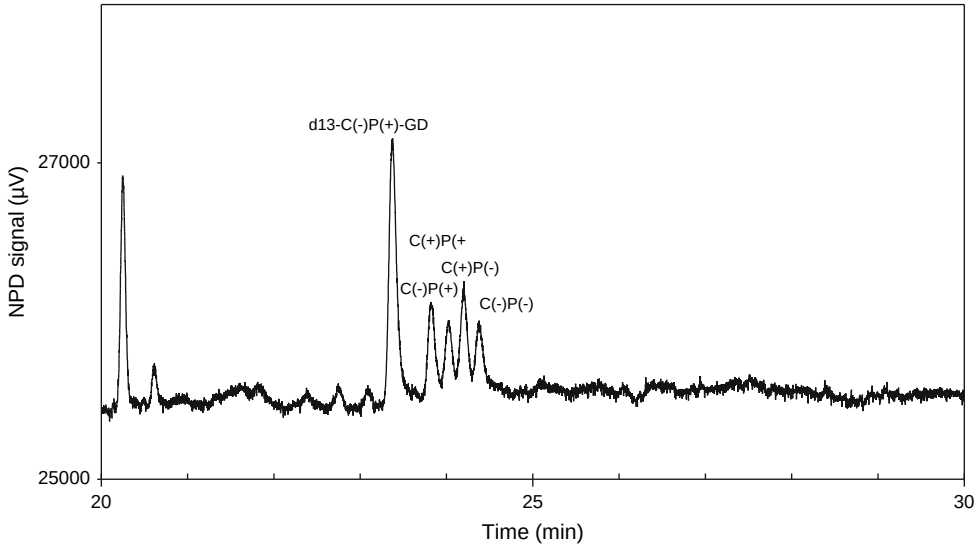

FIGURE 54.1. Large volume (200–400 µl) thermal desorption from TENAX (300 mg, TA 60–80 mesh) followed by 2D-GC and MS detection in EI mode. (1) Precolumn. (2) Analytical column. Small part of the chromatogram of the first column is reinjected on the second analytical column. From: Trap and Van der Schans (2007), Figures 3 and 4.

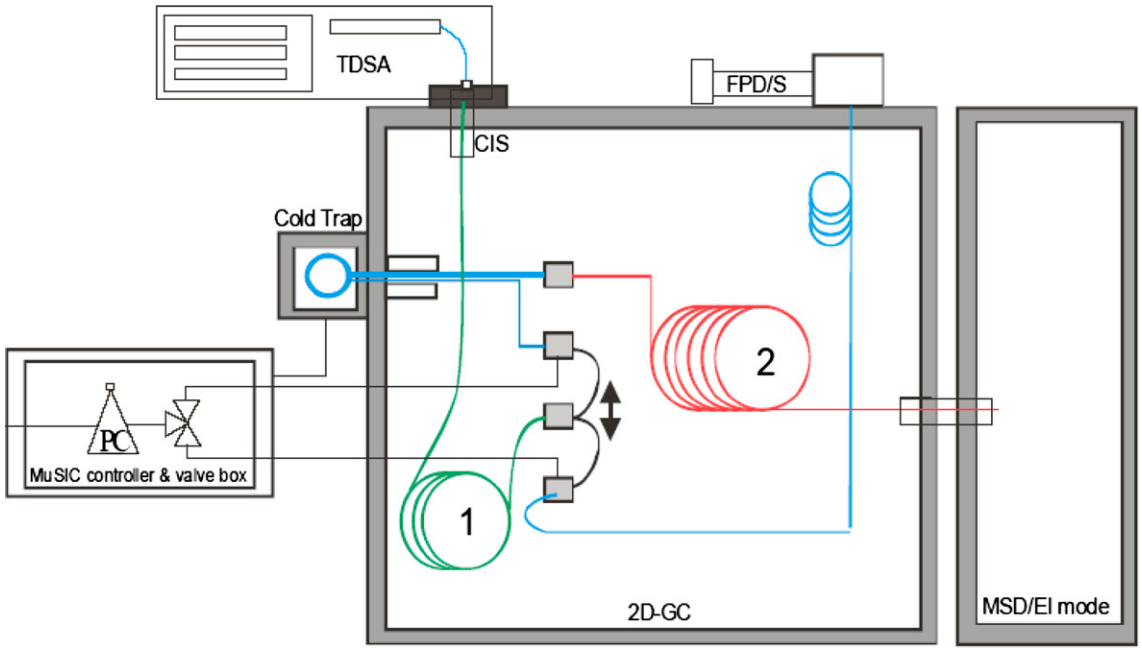

FIGURE 54.2. Typical separation of the stereoisomers of soman and internal standard d_{13}-C(−)P(+)-soman using the 2D-GC configuration. From: Trap and Van der Schans (2007), Figures 3 and 4.

(APCI). In that paper, he focused on the separation and detection of VX to study the stereoselective degradation of VX in plasma. The detection of low levels of VX was not mentioned. Recently, the chiral analysis of VX was performed using the same chromatographic system and connected to a triple quadrupole mass spectrometer with an APCI ionization source. Using this configuration VX isomers could be detected at levels down to 50 pg/ml blood.

TABLE 54.2. Biomarkers for sulfur mustard exposure

Matrix	Biomarker	Comment	Analytical technique	Reference
Urine	Thiodiglycol	Compound also present in nonexposed subjects (<2 ng/ml)	GC–MS	Black and Read (1988); Riches *et al.* (2007)

III. SULFUR MUSTARD AND LEWISITE

There is a variety of biomarkers that can verify an exposure to sulfur mustard. Table 54.2 shows an overview of these biomarkers. Analogous to the nerve agents, biomarkers can be distinguished in metabolites that are excreted in urine and adducts to proteins. A disadvantage of the major metabolite, thiodiglycol, is that this compound is also present in subjects that are not exposed to sulfur mustard (Black and Read, 1995; Boyer *et al.*, 2004). In that respect, the protein adducts are more reliable biomarkers for sulfur mustard exposure because these biomarkers direct unambiguously to an exposure to sulfur mustard. The sulfur mustard adduct to N-terminal valine of globin can be analyzed after a sample preparation procedure known as the modified Edman degradation (Fidder *et al.*, 1996a; Noort *et al.*, 2004a, b). Sulfur mustard binds also to cystein in albumin; this adduct can be analyzed as a tripeptide Cys-Pro-Phe with LC–MS–MS after a digestion with pronase (Noort *et al.*, 1999, 2004a, b). Analogous to the fluoride reactivation method, the sulfur mustard adduct can also be released from the protein by alkaline hydrolysis and measured as thiodiglycol. A precipitation step during the sample preparation removes endogenous thiodiglycol before it is released from the protein (Capacio *et al.*, 2004; Lawrence *et al.*, 2008).

Unlike the nerve agents, the analyses can be target directed and the mass spectrometer can be operated in the most sensitive SIM or SRM mode. Table 54.2 shows that most methods rely on analytical techniques such as gas and liquid chromatography combined with mass spectrometry. Most of the analyses can be performed with standard analytical configurations, without the utilization of large volume sample introduction. The LC–MS technique is already equipped to handle sample volumes up to 100 µl and the quality of the LC separation and tandem MS detection is normally sufficient. The concentrations of the biomarkers are normally so high that they can be detected with normal configurations. Smith *et al.* (2008) showed that after an accidental exposure to sulfur mustard, the albumin adduct could be measured up to several weeks after exposure. Typical detection limits using GC–MS configurations were in the pg range, which means that concentrations down to 1 ng/ml can be detected. This level is also sufficient to detect the levels several weeks after exposure. Noort *et al.* (2008) demonstrated that the sulfur mustard adduct on N-terminal valine in marmosets could be measured up to 4 weeks after exposure using GC–NICI–MS. However, in the case of toxicokinetic studies of sulfur mustard, typical concentrations at 10–100 pg/ml in blood were found and could not be measured with a normal GC–MS configuration. The utilization of large volume sample introduction by thermodesorption and two-dimensional chromatography (analogous to the configuration for chiral nerve agent analysis) enabled the detection of sulfur mustard levels down to 10 pg/ml (Oostdijk *et al.*, 2007).

TABLE 54.3. Biomarkers for lewisite exposure

Matrix	Biomarker	Analytical technique	Reference
Urine	Chlorovinylarsonous acid (CVAA)	GC–MS	Wooten *et al.* (2002)
Blood	CVAA bound to hemoglobin	GC–MS	Fidder *et al.* (2000)

In addition to the methods based on instrumental analysis, sulfur mustard exposure can be detected using immunoassays. Antibodies that can recognize DNA adducts have been raised. In an immunoslotblot assay exposures to sulfur mustard could be verified in DNA that is obtained from blood or skin (Benschop *et al.* 1997; Van der Schans *et al.*, 2004b).

The number of methods to verify an exposure to lewisite is limited. Chlorovinylarsonous acid (CVAA) can be found as the main metabolite in urine, while this compound can also be found as an adduct to hemoglobin (see Table 54.3). The analyte can be analyzed with GC–MS using normal configurations.

IV. CONCLUDING REMARKS AND FUTURE DIRECTION

The development of sophisticated analytical instruments, mainly based on mass spectrometry, enabled several analyses for bioanalysis of chemical warfare agents. Toxicokinetic studies at relevant levels (down to 10 pg/ml blood) can now be performed. Exposures to CWAs can be verified up to several weeks after exposure, because of the persistence of the biomarkers but also thanks to the sensitive and selective instrumentation. It is anticipated that future equipment will be even more sensitive, enabling exposures that occurred weeks after the event to be tracked down.

A better sensitivity is also desirable, in order to meet the criteria that are in place for identification of a compound meeting the forensic standards. Normally, identification by two techniques is needed. If these techniques are not available, special requirements to the MS spectra are demanded. A link with the doping control analysis can be made, which accepts that three ions in an SIM or SRM are needed, provided that the retention time is within a certain time window (Black, 2008). In the case of analyses with tandem MS detection, two transitions are also sufficient for forensic identification. When instrumentation becomes more sensitive it is possible that these requirements can be met. In that view, it will be interesting to watch the developments in miniaturization, such as lab-on-a-chip. Another interesting development is comprehensive GC–GC. Comprehensive GC–GC offers a great selectivity and resolution ideal for

complex samples such as biomedical samples. The combination with time of flight mass spectrometry offers the possibility to analyze in a full scan mode, not target directed, with the availability of a full mass spectrum that will meet the forensic standards. The utility has been demonstrated for the detection of CWAs in complicated matrices such as fuel, but it is expected that this technique will also be soon available for biomedical samples (Reichenbach *et al.*, 2003). Finally, it may be expected that the sample preparation will be more or less automated. Recently, a promising result was published by Carol-Visser (2008), describing the on-line digestion and analysis of sulfur mustard adducts on albumin and the sarin adduct to BuChE.

CHAPTER 55

Biosensors for the Detection of OP Nerve Agents

JUN-ICHI ANZAI

I. INTRODUCTION

Organophosphorus (OP) pesticides and nerve agents have been detected based on various principles including spectroscopy, chromatography, microgravimetry, and electrical and electrochemical techniques. Among the devices used for detecting OP agents, electrochemical devices such as modified electrodes are relatively inexpensive, small in size, and easy to operate. One of the characteristic features of electrochemical devices is that the function and performance of electrodes can be arbitrarily regulated by modifying the surface with functional molecules, proteins, DNA, etc. Thus, one can develop electrochemical devices that can be used for detecting chemicals in sample solutions and in gas phase. The modified electrodes whose surface is modified with proteins and other biological molecules are often called biosensors. For this reason, modified electrodes or biosensors have been widely used for detecting a variety of analytes including OP agents. So far, the majority of biosensors have been developed not for environmental and toxicological purposes but for biomedical or clinical use because of the large market. A typical example of a biomedical biosensor is a glucose biosensor used for monitoring glucose levels in the blood of diabetics. The present chapter describes recent progress in the development of electrochemical biosensors and related devices for detecting OP nerve agents and pesticides.

II. BIOSENSORS

It is well established that electrochemical techniques are useful for determining ions and molecules in solution and gas phases. Oxidizable and reducible chemical species dissolved in solution can be detected by measuring oxidation or reduction current that is produced upon electrolysis of the species on the surface of electrodes. Usually, the output current of the system depends on the concentration of redox species in the solution. Thus, one can quantitatively determine the concentration of the analyte. Another merit of electrochemical techniques is easy identification of analyte by recording redox potential of the analyte because the redox species can be characterized by its own redox potential. In other words, one has to apply an appropriate electric potential to the electrode to electrochemically oxidize or reduce specific ions or molecules for obtaining output signal from the electrochemical reaction. For example, hydrogen peroxide (H_2O_2) is known to be oxidized according to reaction (1) (Scheme 55.1) on the surface of metal or carbon electrode poised at 0.4–0.6 V, which often depends on the type of electrode material and on the solution conditions, while no oxidation current can be observed at the electrode potential lower than this value because H_2O_2 cannot be oxidized at the lower electrode potential. Thus, one can identify the redox species based on the redox potential applied to the electrode and quantitatively determine the concentration from the magnitude of the output current.

However, this is true only for the sample solutions which contain a single component, H_2O_2 in this case. The electrochemical response is more complicated if sample solutions contain two or more redox species because both species would be oxidized or reduced and thus contribute concurrently to the output current. This is often the case for the electrochemical determination of drugs and metabolites or other biological components in blood, because many kinds of redox-active species are intrinsically contaminated in blood. Ascorbic acid (vitamin C) and uric acid (UA) are redox species found in blood and these compounds often disturb electrochemical measurements of blood because the redox potential of vitamin C and UA overlaps with those of many kinds of drugs and biological components (Anzai *et al.*, 1998; Hoshi *et al.*, 2001). Another drawback of electrochemical measurements is that target analytes are often electrochemically inert and thus no electric signal can be obtained with an electrode. In other words, the redox potential of many target molecules is too high to be oxidized or reduced in the reasonable potential range. Operation of electrochemical systems in high electrode potential is impractical because oxidation of H_2O and reduction of dissolved O_2 often disturb the measurements. For these reasons, analytes and samples to which electrochemical

$$H_2O_2 \longrightarrow O_2 + 2H^+ + 2e^- \quad (1)$$

SCHEME 55.1. Electro-oxidation of H_2O_2

protocol can be successfully applied by using unmodified electrodes are rather limited.

Electrochemical biosensors are devices that are fabricated by combining proteins or other biological molecules and electrodes (Xu *et al.*, 2006; Ramanavicius *et al.*, 2006; Yun *et al.*, 2007). Usually, functional proteins are immobilized on the surface of metal or carbon electrodes to effect selective determination of analytes in sample solution. Figure 55.1 schematically shows the concept and structure of electrochemical biosensors, where the surface of the electrode is modified with biomaterial that can selectively bind target analyte in the sample solution contaminated with many interfering substances. It is also possible to substitute electrodes with other transducers such as thermistors and optical devices to prepare calorimetric and optical sensors. Among the biosensors developed so far, enzyme-based biosensors have been most extensively studied due to their high sensitivity and wide applicability in biomedical and environmental analyses. Enzyme-catalyzed reactions occur on the surface of electrode and the reaction products are oxidized or reduced electrochemically, resulting in generation of electric current as output signal. Thus, chemical signals (type of analyte and its concentration) can selectively be converted into electric signals through the enzyme/electrode interface. For example, the principle of operation of glucose biosensors is based on the glucose oxidase (GOx)-catalyzed oxidation reaction of glucose [reaction (2)] and electrochemical oxidation of reaction product of the enzymatic reaction (H_2O_2) [reaction (3)] (Scheme 55.2). It is clear that 2 moles of electron can be produced from 1 mole of glucose, and the concentration of glucose in the sample solution is related to electric current recorded. It should be noted here that oxidation or reduction potential of glucose is too high to be oxidized or reduced directly on unmodified electrodes. Consequently, electrochemical determination of glucose is not possible without using GOx-modified electrodes (or GOx biosensors). It is clear from reactions (2) and (3) that the role of enzyme in the function of biosensors is to catalytically produce redox-active species which can be electrolyzed by the electrode.

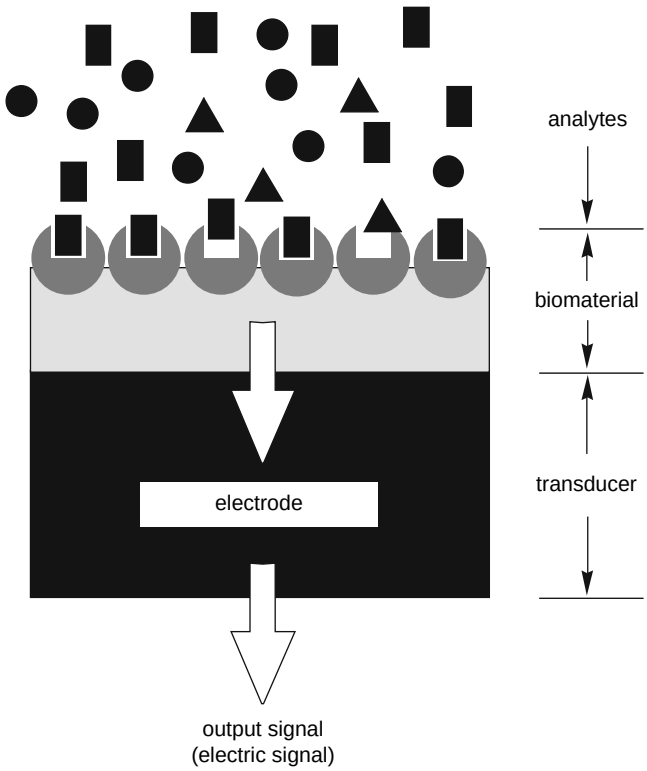

FIGURE 55.1. A schematic illustration of the structure of biosensors. (Reproduced from Anzai, 2006, with permission).

One of the merits of an enzyme biosensor is its versatility. The selectivity of biosensors directly relates to the type of enzyme used for constructing biosensors. Up to now, many kinds of enzyme sensors have been reported, other than glucose biosensors, using a variety of enzymes. A miniaturization of the sensor body is another possible merit of enzyme sensors. In fact, miniature sensors of micron size have been prepared for detecting target analyte in a single cell. The miniaturization of sensor body would make it possible to construct a sensor array on a single tip. However, one should keep in mind that the output current decreases with decreasing the size of electrode, resulting in a suppressed signal-to-noise ratio. For routine purposes, therefore, biosensors of pencil size are usually used for easy handling. A small disk of metal or carbon materials (3–5 mm diameter) is often mounted in an insulating plastic rod (~10 mm diameter and 50–100 mm length) to prepare disk electrodes.

Figure 55.2 illustrates an experimental set-up for biosensor measurements. Electrochemical measurements using biosensors require three electrodes, which are called the working electrode (enzyme-modified electrode), reference electrode, and counter electrode. In some cases, the three electrodes can be assembled into a single body electrode. It is also possible to eliminate the reference electrode and use the counter electrode as a pseudo-reference electrode for specific reasons, such as miniaturization. The experimental set-up shown in Figure 55.2 is a batch system, in which the electrodes are immersed in the sample solution to obtain output signal. For constructing flow systems, the electrodes are set at a suitable place in the fluidic device, which is often used for measuring a large number of samples.

In Section III, recent studies on the determination of OP nerve agents and pesticides based on electrochemical biosensors will be discussed. The electrochemical biosensors

used for detecting OP compounds can be divided into three types depending on the type of enzymes used for constructing biosensors: (1) choline esterase (ChE)–choline oxidase (ChOx) bienzyme-modified biosensors, (2) ChE-modified biosensors, and (3) organophosphorus hydrolase (OPH)-modified biosensors. Also, OP biosensors based on transducers other than electrochemical devices are discussed in this chapter.

III. ELECTROCHEMICAL BIOSENSORS FOR DETECTING ORGANOPHOSPHORUS COMPOUNDS

A. ChE–ChOx Bienzyme-Modified OP Biosensors

The primary objective of ChE–ChOx bienzyme biosensors was to determine neurotransmitter acetylcholine in biological samples (Chen *et al.*, 1998). The redox potential of acetylcholine (ACh) is too high to be determined directly using electrochemical reaction. For this purpose, acetylcholine esterase (AChE) was employed as ChE. AChE and ChOx were immobilized on the surface of the electrode to attain electrochemical analysis according to reactions (4) and (5) (Scheme 55.3).

The enzymatic reactions of AChE–ChOx bienzyme biosensor consist of AChE-catalyzed hydrolysis of ACh into choline and acetic acid [reaction (4)] and oxidation reaction

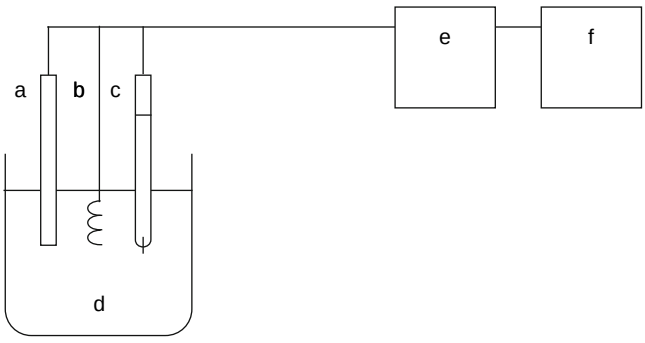

FIGURE 55.2. An experimental set-up for operation of electrochemical biosensors. (a) Biosensor, (b) counter electrode, (c) reference electrode, (d) sample solution, (e) potentiostat, and (f) recorder. (Reproduced from Anzai, 2006, with permission).

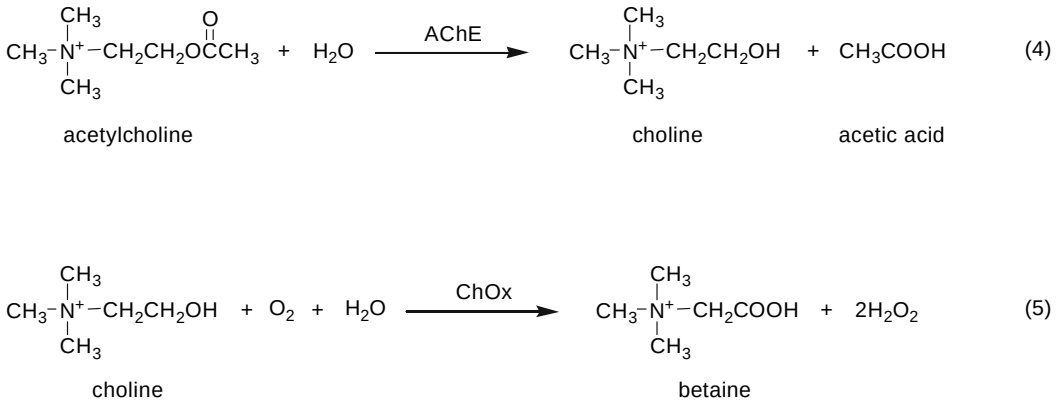
of choline catalyzed by ChOx [reaction (5)]. The latter reaction produces H_2O_2, which can be electrochemically oxidized on the electrode to generate output signal depending on the concentration of acetylcholine. It is also possible to use an oxygen electrode in place of a metal or carbon electrode because ChOx consumes dissolved O_2 during the oxidation of choline. Therefore, the O_2 consumption can be detected using a commercially available O_2 electrode. The reason why AChE–ChOx bienzyme biosensors can be used for detecting OP compounds is that the catalytic activity of AChE is inhibited by OP compounds. OP compounds are known to irreversibly bind to AChE to disturb its catalytic activity. It is thus clear that reaction (4) is suppressed in part depending on the concentration of OP and the rate of choline production becomes lower in the presence of OP compounds, resulting in reduced response in the output current of the sensor. In fact, the change in output current of the sensor upon addition of an OP-containing sample is detected in the presence of a known concentration of ACh, as illustrated in Figure 55.3. The ΔI value depends on the concentration of OP compounds in the sample solution. Butylcholine esterase (BChE) is sometimes used in place of AChE, in which butyrylcholine is used as substrate.

According to the above protocol, we have determined trichlorfon (Figure 55.4) in water samples using AChE–ChOx biosensors, which were constructed by a layer-by-layer deposition of the enzymes on the surface of a platinum disk electrode (Shi *et al.*, 2005). Response of the sensor to trichlorfon was evaluated by a successive addition of trichlorfon into the solution of 2 mM ACh. The output current of the sensor decreased with increasing the concentration of trichlorfon over the concentration range of $1 \times 10^{-8} - 2 \times 10^{-5}$ g/ml. The lower detection limit of the sensor was found to be ca. 1×10^{-9} g/ml (1 ppb). A key point for constructing high-performance OP sensors in bienzyme systems may be to suitably control the ratio of the catalytic activity of AChE and ChOx in the sensor. In the present case, the catalytic activity of ChOx should be higher than that of AChE – the overall rate of the reactions is determined by the rate of AChE-catalyzed reaction because OP compounds disturb this step. Therefore, usually, excess amounts of ChOx are mixed with AChE and the ChOx–AChE mixture is immobilized on the surface of the electrode to make the AChE-catalyzed reaction a rate-limiting step. In this situation, the overall reaction rate can be determined by the rate of the ChE-catalyzed reaction because the following



SCHEME 55.3. Enzyme reactions in AChE–ChOx bienzyme sensors.

electrochemical oxidation of H_2O_2 is sufficiently fast. On the other hand, in our sensors, ChE and ChOx were immobilized separately layer by layer for optimization of the amounts of enzymes.

ChE–ChOx bienzyme-modified biosensors have been widely used mainly for detecting OP pesticides, which are summarized in Table 55.1. AChE and BChE are often used as ChE enzyme. This type of ChE–ChOx sensor can be used conveniently for detecting OP compounds, and detection time for qualitative analysis is reasonably fast. For quantitative determination of OP compounds, however, operation of the sensor is somewhat time consuming because multiple steps (a measurement of response to acetylcholine and inhibition) are required.

B. AChE-Modified OP Biosensors

As described in the previous section, use of a bienzyme system sometimes induces complexity in the design of biosensors originating from different catalytic activity of the enzymes. In the ChE–ChOx systems, ChOx is used to oxidize choline that is generated through ChE-catalyzed reaction because the oxidation potential of choline is too high to be electrochemically directly oxidized. It is reasonable to assume that, if the reaction products can be oxidized on the electrode directly, one can remove the second enzyme ChOx from the sensor design, and a ChE-modified electrode may be used for detecting OP compounds. This concept was tested using an AChE-modified electrode as sensor in the presence of acetylthiocholine in place of acetylcholine as the substrate of AChE (Scheme 55.4). It was found that acetylthiocholine is decomposed into thiocholine and acetic acid [reaction (6)], and the resulting thiocholine can be electrochemically oxidized to its dimer (dithiobischoline) on the surface of electrode [reaction (7)]. Therefore, the output current of the sensor in the solution of a constant concentration of acetylthiocholine would be dependent on OP compounds in the solution. Thus, one can determine the OP concentration from the decrease in the output current, as shown in Figure 55.3.

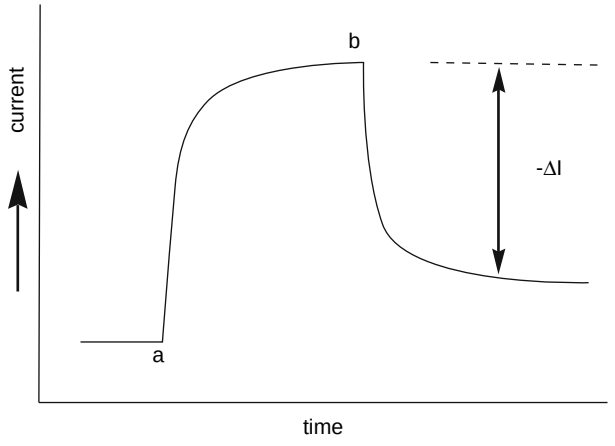


FIGURE 55.3. A typical response of inhibition-mode AChE–ChOx bienzyme OP sensors. (a) Addition of acetylcholine and (b) addition of OP sample. $-\Delta I$ corresponds to the output signal. (Reproduced from Anzai, 2006, with permission).

Table 55.2 collects some properties of AChE-modified biosensors based on acetylthiocholine. As shown in reaction (7), thiocholine can be directly oxidized to dithiocholine. However, oxidation potential of thiocholine is relatively high, ca. +0.7 V, and thus a high background current and a possible interference from oxidizable contaminants cannot be excluded. To circumvent this, electron transfer mediators (Med) are often used to oxidize thiocholine at milder potential as depicted in Figure 55.5, where thiocholine is oxidized by an oxidized form of the mediator, Med (ox), into dithiobischoline and the resulting reduced form of the mediator, Med (red), is oxidized at the electrode to generate output current. In this scheme, 1 mole of thiocholine generates 1 mole of electron. For example, Carlo and co-workers modified the surface of a screen printed carbon electrode with a thin layer of perfluorinated ion-exchanger films containing 7,7,8,8-tetracyanoquinodimethane (TCNQ) (Figure 55.6) as Med. It was found that the reduced form of TCNQ is oxidized at +0.4 V vs pseudo reference electrode (Ag wire) (Carlo *et al.*, 2004). The TCNQ-based biosensors were applied to

TABLE 55.1. AChE–ChOx bienzyme biosensors for detecting OP compounds

Sensor	Organophosphorus compound (lower detection limit)	Reference

Gold electrode	Trichlorfon (4 pM)	Shi *et al.* (2005)

a recovery test using egg, bovine meat, milk, and honey as food matrices. No false negative or false positive samples were detected in the assay. These results indicate that TCNQ-based biosensors may be useful as a prescreening device in the analysis of food safety.

Another recent topic in detection of OP compounds based on ChE-modified biosensors is to use carbon nanotubes (CNTs) as an electrode modifier. CNTs are known to exhibit excellent electrochemical properties originating from high catalytic activity of edge-plane-like graphite sites at CNT ends and a large effective surface area. Lin *et al.* (2004) have reported that stable CNT-modified glassy carbon (GC) electrodes can be prepared by coating the surface of GC electrode with a suspension of CNT and can be used for sensitive determination of thiocholine (Liu *et al.*, 2005). Voltammetric studies have demonstrated that thiocholine is oxidized at +0.15–0.20 V on CNT-modified GC electrodes as compared to its higher oxidation potential on unmodified GC (+0.7 V), carbon paste (+0.6 V), and gold electrodes (+0.9 V). A lower detection limit of 5×10^{-6} M thiocholine was obtained under the optimal batch conditions, while the detection limit was further improved down to 3×10^{-7} M by the electrochemical detection in flow injection analysis.

The same authors have further improved the CNT-modified biosensors for detection of OP compounds based on a layer-by-layer immobilization of CNTs, polymer, and AChE on the surface of GC electrodes (Liu and Lin, 2006). AChE was sandwiched with poly(diallyldimethylammonium chloride) layers on the surface of CNTs. The OP biosensor thus developed was used to detect paraoxon (Figure 55.7) as low as 4×10^{-13} M with a 6 min response time in flow injection analysis. A high stability of the sensors was also a merit of this biosensor; no deterioration in the response was observed after 1 week of continuous use of the sensor. Only a 15% decrease in the activity of the enzyme was observed after 3 weeks, though the authors

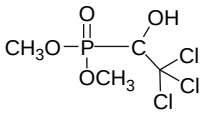

FIGURE 55.4. The chemical structure of trichlorfon.

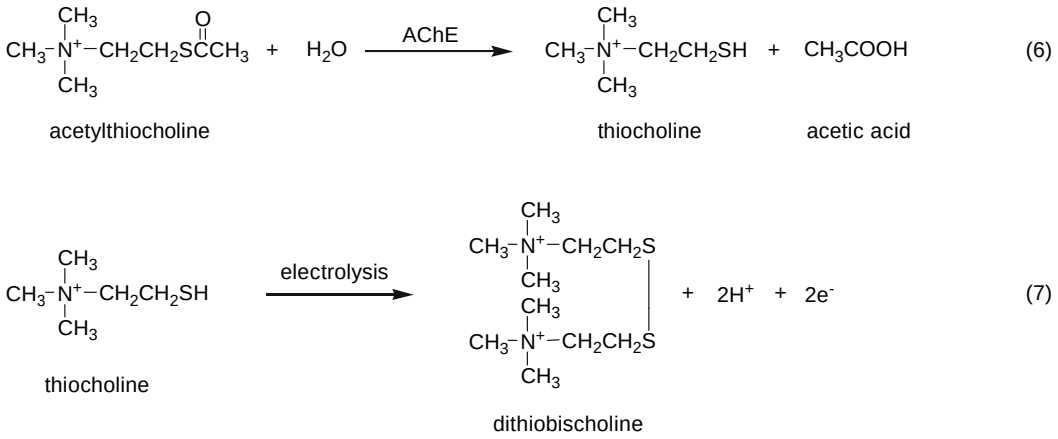
recommended recalibration after 2 weeks' operation. The high stability of the biosensors was ascribed to the assembling of enzymes in the sandwich-like layer structure, providing a favorable microenvironment to maintain the catalytic activity of the enzyme.

The effects of organic solvents on the performance of ChE-modified sensors were studied because OP compounds are sometimes extracted from samples using organic solvents. For this purpose, 4-aminophenyl acetate (Figure 55.8) was used as the substrate of the AChE enzyme in place of acethylthiocholine because of its high solubility in organic solvents and the redox-active nature of 4-aminophenol produced through enzymatic reaction (Scheme 55.5). Marty and co-workers prepared an AChE-modified carbon electrode by coating AChE-containing polymer film on the electrode (Andreescu *et al.*, 2002). 4-Aminophenol was found to be oxidized on the electrode at +0.1 V, while no redox response was observed in the 0–0.4 V range for 4-aminophenyl acetate. An AChE enzyme modified on the electrode retained ca. 80% catalytic activity even in the aqueous solution containing 1–5% acetonitrile or ethanol, though more than 20% organic solvent induced nearly complete deactivation of the enzyme, suggesting a possible use of the sensor in the presence of a small amount of water-miscible organic solvent in aqueous media. In fact, the AChE-modified sensor could be successfully used for determining 10^{-9}–10^{-8} M level of OP compounds in the aqueous solutions containing 1–5% acetonitrile and ethanol.

Model OP compounds are usually used for studying detection of nerve agents with biosensors because of the difficulty working with nerve agents. Recently, ChE-modified disposable electrodes have been used for detecting sarin and VX (Figure 55.9) in solution and in air stream. Arduini and co-workers have tested ChE inhibition in sarin and VX standard solution and found the lower detection limit of 12 and 14 ppb, respectively (Arduini *et al.*, 2007). For detecting sarin gas in air, the surface of the sensor which had been covered with a small amount of 0.05 M phosphate buffer was exposed to sarin stream for 30 s and then ChE inhibition of the sensor was evaluated in solution. The sensor was found to be effective to detect sarin gas at a concentration of 0.1 mg/m^3. Thus, low concentrations of sarin gas can be detected in a few minutes using ChE-modified electrochemical biosensors.



SCHEME 55.4. Enzyme and electrochemical reactions in acethylthiocholine-based sensors.

C. OPH-Modified OP Biosensors

The detection of OP compounds by biosensors modified with ChE–ChOx or ChE enzymes relies on an inhibition of catalytic activity of ChE enzymes by OPs. Therefore, it is a drawback of the sensors that the magnitude of the output signal correlates inversely with the concentration of OP compounds in the sample. The protocol in measurements is somewhat complicated because the substrate of ChE has to be added in the sample solution before measurements, resulting in multiple steps needed for OP detection. In addition, inhibition of ChE by OP compounds is usually irreversible and thus reactivation of ChE activity is required for repeated use of the sensors, although this problem can be circumvented by using disposable sensor tips.

In contrast to the inhibition mode of detection in the above biosensors, a direct detection of OP compounds has been proposed by means of organophosphorus hydrolase (OPH) enzymes, which hydrolyze OP compounds as shown in Scheme 55.6. OPH enzymes have a rather wide spectrum of substrate selectivity and hydrolyze many kinds of OP compounds including OP pesticides, VX, and sarin. It is obvious from the reactions shown in Scheme 55.6 that the reaction products such as 4-nitrophenol and 2-(diisopropylamino)ethanethiol can be electrochemically oxidized on the electrode to generate electric current as an output signal. Thus, OPH-modified electrodes directly detect OP compounds in a single step, as compared to two steps required for the biosensors constructed using ChE–ChOx and ChE enzymes.

Mulchandani and co-workers (1999) prepared V-type nerve agent biosensors by immobilized OPH on the surface of a CNT-modified carbon electrode (Joshi *et al.*, 2006). They used a mutant OPH that exhibits 20 times higher catalytic activity toward demeton-S (a frequently used mimic of V-type nerve agents) than wild-type OPH. The OP biosensors thus prepared exhibited an electrochemical response to demeton-S at $+0.4$ V, the higher and lower detection limits being 8.5×10^{-5} and 1×10^{-6} M, respectively, with a sensitivity of 8×10^{-6} A/mM. A high response of the biosensors to the hydrolysis product of R-VX [2-(diethylamino)ethanethiol, Figure 55.10] and mimic of the hydrolysis product of VX [2-(dimethylamino)-ethanethiol, Figure 10] was also demonstrated, suggesting

possible use for detecting VX and R-VX. A merit of this sensor is its high selectivity to demeton-S over many possible interfering compounds belonging to OP and carbamate families, excluding ''false positives'' in the field use of the biosensors. This biosensor was successfully applied to analyze lake water spiked with demeton-S. The same group developed a flow injection electrochemical detection system using an OPH-modified gold electrode. The response of the system depended linearly on the concentration of OP compounds over the range of 1×10^{-6}–1×10^{-5} M with a lower detection limit of 1×10^{-7} M. The authors suggested a possible use of the flow injection system for rapid screening of OP compounds (Wang *et al.*, 1999).

Wang and co-workers prepared OPH-modified carbon electrodes as a submersible biosensor for remote monitoring of OP compounds (Wang *et al.*, 1999). The biosensor mounted in a plastic tube was connected to a 50 foot long shielding cable via environmentally sealed rubber connectors. It was found that, despite the 50 foot long cable, the noise level of the sensor in the response to paraoxon and methyl parathion is very low. The authors suggested a possible use of the sensor for remote sensing of OP warfare agents in the field. The same group recently reported an interesting electrochemical/optical route for detection of OP nerve agents based on OPH-mediated biometallization (Arribas *et al.*, 2005). They found that the formation of cupric-ferrocyanide (CuFeCN) particles is accelerated by nitrophenol produced through OPH hydrolysis of OP agents. Therefore, the rate of formation of CuFeCN nanoparticles depended on the concentration of OP agents. The detection of CuFeCN particles can be carried out by either electrochemistry or optical measurement. CuFeCN is known to be redox active and CuFeCN

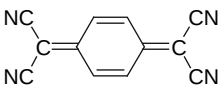

FIGURE 55.6. The chemical structure of TCNQ.

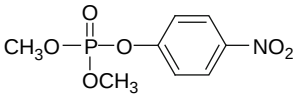

FIGURE 55.7. The chemical structure of paraoxone.

deposited on the surface of a carbon electrode exhibits an oxidation peak at ca. +0.7 V in its voltammogram, peak current being dependent on the concentration. Optical detection of OPs is also possible based on the color changes of the CuFeCN solutions. A light yellow color was observed in the absence of OP, while the solution became darker (orange–red) upon addition of OP due to the formation of a CuFeCN colloid. It is a merit of this system that no seed is required for CuFeCN biometallization in contrast to seed-induced growth of gold nanoparticles (see above).

Potentiometric OP biosensors were also prepared by coupling OPH and a glass pH electrode. The sensors were constructed by immobilizing OPH on the surface of a pH-sensitive layer of a commercially available pH electrode by crosslinking with bovine serum albumin (BSA) to form a thin film. This biosensor detects pH changes (or changes in electrode potential) originating from hydrolysis reaction of OP compounds catalyzed by OPH in the OPH–BSA film (Mulchandani *et al.*, 1999). The best sensitivity of the sensor was obtained in the operation in pH 8.5, 1 mM buffer, in which the sensor could detect as low as 2×10^{-6} M of OPs including paraoxon, ethyl parathion, and methyl parathion. In a similar mechanism of signal transduction, one can use a pH-sensitive field effect transistor (FET) for developing enzyme-modified FETs. Use of a FET provides superiority in miniaturization of the sensor body because a FET is usually produced through mass production on semiconductor materials (Simonian *et al.*, 2004).

An electrochemical OP sensor by the nonenzymatic route was reported based on chemical modification of the surface of a gold electrode with ferrocene derivative (Fc). For this purpose, the gold electrode was modified with dithioFc derivative to form an aminoFc-monolayer-modified electrode (Khan *et al.*, 2007). The principle of operation of the aminoFc-modified electrode for OP sensing is that chloro- or cyano-substitued OP compounds covalently bind to aminoFc moieties, by which the redox potential of the surface-confined Fc can be altered. In fact, ca. 110 and 60 mV shifts in the redox potential were observed, suggesting a possible use of the sensors for detecting OPs from the potential shifts.

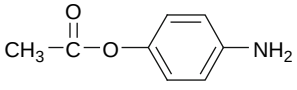

FIGURE 55.8. The chemical structure of 4-aminophenyl acetate.

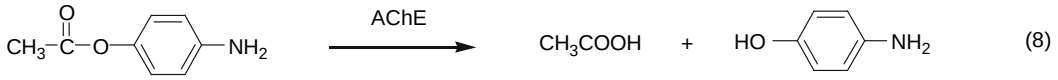

SCHEME 55.5. Hydrolysis reaction of 4-aminophenyl acetate by AChE.

IV. MISCELLANEOUS BIOSENSORS FOR OP DETECTION

Different types of transducers other than electrodes have also been used for constructing OP biosensors. Recent progress in the study of metal and semiconductor nanoparticles (NPs) stimulated researchers to apply these materials for detecting OP compounds. Willner and co-workers found that thiocholine-stimulated growth of gold NPs is inhibited by OP nerve agents depending on the concentration, enabling the NPs to be used for detecting OP compounds (Figure 55.11; Pavlov *et al.*, 2005). A visible absorption of gold NP solution at ca. 550 nm originating from the plasmon absorption band of NPs increased as a result of NP growth in the presence of AChE and acethylthiocholine because enzymatically produced thiocholine promotes growth of NPs. In the presence of 1×10^{-8}–1×10^{-6} M of OP compounds in the solution, however, the growth rate was significantly suppressed. NP seeds were confined on the surface of a glass plate for constructing an optical sensor system and the absorbance of the glass plate was monitored in the presence of OP agents. The NP-confined glass plate exhibited a maximum absorption at ca. 570 nm and the intensity and wavelength clearly depended on the concentration of OP agent in the sample solution. The optical sensor can detect 10^{-6} M level of OP compounds. Another merit of the NP-confined glass plate is the fact that the glass plate yields a blue-colored surface without OP agents while the OP agents generate a weak pale pink color, enabling OP compounds to be detected with the naked eye.

Polymer microbeads were also used for constructing an OP detection system using fluorescence response of the microbeads. Carboxylate-functionalized polymer microbeads that had been covered with a poly(vinylpyridine) (PVP) layer were modified with fluorescamine (FLA). When the microbeads were exposed to the vapor of diethyl chlorophosphate as a model OP, fluorescence of the microbeads increased rapidly as a result of formation of a phosphoramide of FLA (Figure 55.12; Bencic-Nagale *et al.*, 2006). A PVP layer on the surface of the microbeads served as an acceptor of HCl generated from phosphoramide formation. A potential use of the microbeads for constructing a sensor array was suggested for screening OP vapor.

Microgravimetry has often been used for studying mass changes on the surface using a quartz-crystal microbalance (QCM). A probe of QCM is a thin vibrating quartz resonator sandwiched between metal electrodes. The QCM detects adsorption of substance on the surface of the quartz resonator as changes in resonance frequency of the resonator. Thus, one can detect a nanogram level of mass changes on the surface. It is a great merit of QCM that it can be operated in air for detecting adsorption of gases as well as in solution for detecting dissolved analytes. For this reason, QCM is quite suitable for detecting nerve agents in air. Jiang and coworkers prepared a polymer film-coated quartz resonator for detecting dimethyl methylphosphonate (DMMP) vapor as a stimulant of nerve agents. The poly(vinylidene fluoride) (PVDF) film-coated quartz resonator was found to be sensitive to DMMP vapor in ppm level with a rapid and reversible response (Ying *et al.*, 2007). A zeolite film was also utilized as a coating of QCM for detecting DMMP (Xie *et al.*, 2005).

FIGURE 55.10. The chemical structures of 2-(diethylamino)ethanethiol and 2-(dimethylamino)ethanethiol.

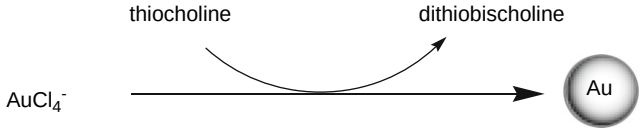

FIGURE 55.11. A thiocholine-induced growth of Au nanoparticles.

The progress in the development of microelectromechanical systems accelerated the use of microdevices for constructing biosensors. Microcantilevers (MCLs) have been chemically modified to use as sensitive probes for detecting OP compounds. It is known that adsorption of molecules on the surface of MCL induces bending of MCL due to changes in surface tension, depending on the amounts of mass adsorbed, in both gas and solution phases. Usually, one side of the MCLs is modified with functional materials to effectively induce bending of MCLs upon binding of analytes. Recently, the surface of V-shaped silicon MCLs, whose dimensions were 180 µm in length, 25 µm in leg width, and 1 µm in thickness, was modified with thin films containing OPH enzyme for preparing OP biosensors (Karnati *et al.*, 2007). The MCL-based sensors exhibited bending response to paraoxon with the dynamic range of 10^{-7}–10^{-3} M. The conformational changes of OPH enzyme associated with the catalytic reaction are suggested to be a main factor inducing the MCL bending. It was also possible to construct MCL-based OP sensors using organic polymers and metal oxides as surface coating in place of OPH enzyme. In these cases, adsorption OP compounds on the surface of MCLs induced bending, depending on the concentration of OPs, resulting in detection of DMMP as a model OP in air (Voiculescu *et al.*, 2005; Zhao *et al.*, 2006).

V. CONCLUDING REMARKS AND FUTURE DIRECTION

This chapter described recent developments of biosensors for detecting OP nerve agents. Different detection modes using different enzymes are applicable for constructing OP biosensors using electrochemical principles. Among them, use of OPH enzyme is superior to other protocols in view of the fact that OPH-based biosensors directly detect OP compounds in a single step as compared to the inhibition-mode biosensors based on ChE–ChOx and ChE enzymes which require a two-step operation. A merit of electrochemical biosensors in OP detection is that a portable device can easily be prepared for in-field analysis. The easy operation of biosensors is another merit as compared to chromatographic or spectroscopic measurements. Therefore, biosensors have high potential for fast on-site screening of OP nerve agents.

CHAPTER 56

Biomarkers of Exposure to Organophosphorus Poisons: A New Motif for Covalent Binding to Tyrosine in Proteins that have No Active Site Serine

OKSANA LOCKRIDGE, LAWRENCE M. SCHOPFER, AND PATRICK MASSON

I. INTRODUCTION

In 1954, Schaffer *et al.* (1954) reported the astonishing finding that the irreversible inhibition of eel acetylcholinesterase by the organophosphorus agent, diisopropylfluorophosphate, was the result of covalent binding to serine. In 1959, horse butyrylcholinesterase that had been inactivated by treatment with diisopropylfluorophosphate was found to have diisopropylphosphate-labeled serine in the sequence FGESAGAAS (Jansz *et al.*, 1959). Despite this evidence, serine was not immediately accepted as the esteratic site of cholinesterases, because the pKa of serine was so high that significant reaction with organophosphorus (OP) agents was not expected (Bergmann, 1955). The crystal structures of acetylcholinesterase and butyrylcholinesterase confirmed that organophosphorus agents make a covalent bond with serine. These structures also provided an explanation for the special reactivity of the active site serine (Nachon *et al.*, 2005; Sussman *et al.*, 1991). A nearby histidine and glutamic acid form a catalytic triad with serine that lowers the pKa of the serine, consistent with the expectation that the hydroxy-anion of serine is necessary to make a nucleophilic attack on the phosphorus. The oxyanion hole activates the OP for attack by the serine.

The covalent bond between OP and the active site serine of intact cholinesterase is stable, but not irreversible. Hydrolysis can occur with a half-life of between 10 and 35,000 min, depending on the enzyme, OP, temperature, pH, and buffer composition. The adduct becomes irreversibly bound to the enzyme after one of the alkyl groups on the OP is lost in a step called ''aging'' (Benschop and Keijer, 1966; Michel *et al.*, 1967). The dealkylated OP makes a stable salt bridge with the protonated histidine of the catalytic triad, so that histidine is no longer available for the dephosphorylation step that would otherwise have restored the enzyme to an uninhibited state. Hundreds of scientists have contributed to this understanding of the mechanism of OP inhibition of acetylcholinesterase and butyrylcholinesterase activity. Their studies are the foundation for use of acetylcholinesterase and butyrylcholinesterase as biomarkers of OP exposure.

OP-inhibited acetylcholinesterase and butyrylcholinesterase are the established biomarkers of OP exposure. The special features that make them good biomarkers are: (1) they react rapidly with OP at low OP concentrations; (2) symptoms of acute toxicity always correlate with inhibition of acetylcholinesterase and butyrylcholinesterase; (3) acetylcholinesterase is present in human red blood cells, while butyrylcholinesterase is present in human plasma, making it possible to test for OP exposure by measuring enzyme activity in a blood sample; (4) enzyme activity assays for acetylcholinesterase and butyrylcholinesterase are simple and inexpensive; (5) the OP adduct (nonaged and aged) for common pesticides and nerve agents is relatively stable making it possible to detect exposure days after the actual event; and (6) the mechanism of irreversible inhibition of acetylcholinesterase and butyrylcholinesterase activity by OP is understood.

II. USE OF ACETYLCHOLINESTERASE AND BUTYRYLCHOLINESTERASE BIOMARKERS IN THE CLINIC

Most hospitals and forensic laboratories are capable of performing cholinesterase activity assays. Two examples of the usefulness of acetylcholinesterase and butyrylcholinesterase activity assays are given below.

A. Tokyo Subway Attack with Sarin

Acetylcholinesterase and butyrylcholinesterase were useful biomarkers for identifying the poison that intoxicated 5,000

people in the Tokyo subway. In March 1995 members of the Aum Shinrikyo sect dispersed the nerve agent sarin in trains on the Tokyo subway. Japanese health workers identified the poison as a cholinesterase inhibitor within 2 h of seeing the first patient (Nozaki *et al.*, 1995). A cholinesterase inhibitor was suspected because victims had physiological signs of cholinergic intoxication including pinpoint pupils. Laboratory assays showed that red cell acetylcholinesterase and plasma butyrylcholinesterase activities were inhibited, thus confirming that the poison was a cholinesterase inhibitor. There are many cholinesterase inhibitors, including OP pesticides and carbamates. In the case of some OPs, AChE inhibiting compounds are precursor molecules that need bioactivation before they are toxic to humans. The rapid onset of toxic symptoms meant that the agent used in the subway was already activated or a direct AChE inhibitor was involved that needed no activation. The fact that people were becoming intoxicated by breathing the air meant the poison was volatile. These characteristics suggested that the poison was a nerve agent, and very likely sarin. The Forensic Science Laboratory used gas chromatography–mass spectrometry to identify sarin in crime scene samples (Seto, 2001). Identification of the poison as sarin was crucial to the police in their search for the perpetrators. Years later, new mass spectrometry methods were developed and used to retroactively identify sarin bound to red blood cell acetylcholinesterase (Nagao *et al.*, 1997) and to plasma butyrylcholinesterase from the Tokyo subway victims (Fidder *et al.*, 2002; Polhuijs *et al.*, 1997).

B. Suicide Attempts

Exposures to OP pesticides are declining in the USA following the banning of chlorpyrifos and diazinon for residential use in 2000 (Sudakin and Power, 2007). In 2004 the number of OP exposure cases reported to the American Association of Poison Control Centers was 7,181. The majority of these incidents resulted in either no symptoms or minor symptoms. The number of OP fatalities in the USA was four in 2006 (Bronstein *et al.*, 2007). Two adult males and two adult females intentionally ingested OP pesticides for the purpose of committing suicide. In contrast, ingestion of OP pesticides in attempted suicide is a frequent occurrence in rural communities of Sri Lanka, India, and China, where an estimated 200,000 persons die annually from OP pesticide poisoning (Eddleston *et al.*, 2008). Diagnosis is made on the basis of cholinergic signs of toxicity, smell of pesticides or solvents, and reduced butyrylcholinesterase and acetylcholinesterase activity in blood. Patients who survive the suicide attempt are monitored in hospital for several days; their plasma butyrylcholinesterase is assayed daily because recovery of butyrylcholinesterase activity is a marker of OP elimination from the body.

III. METHODS TO DETECT OP ADDUCTS ON ACETYLCHOLINESTERASE AND BUTYRYLCHOLINESTERASE

A. Cholinesterase Activity Assay

Exposure to a toxic dose of OP results in inhibition of acetylcholinesterase and butyrylcholinesterase activities. The most common method to measure OP exposure is to assay acetylcholinesterase and butyrylcholinesterase activities in blood using a spectrophotometric method (Ellman *et al.*, 1961; Wilson *et al.*, 2005; Worek *et al.*, 1999). The drawbacks of activity assays are that they do not identify the OP. They show that the poison is a cholinesterase inhibitor but do not distinguish between nerve agents, OP pesticides, carbamate pesticides, and tightly bound, noncovalent inhibitors like tacrine and other anti-Alzheimer drugs. In addition, low-dose exposure, which inhibits less than 20% of the cholinesterase, cannot be determined by measuring acetylcholinesterase and butyrylcholinesterase activity because individual variability in activity levels is higher than the percent inhibition.

B. Fluoride Reactivation Followed by Gas Chromatography–Mass Spectrometry

A new method for identifying exposure to nerve agents was introduced by Polhuijs *et al.* in 1997 (Polhuijs *et al.*, 1997). The method is based on the finding that incubation of sarin-inhibited butyrylcholinesterase with 2 M sodium fluoride at pH 4 results in release of sarin. Sarin is then extracted and analyzed by gas chromatography–mass spectrometry. Polhuijs *et al.* applied their new method to positively identify sarin in serum samples from Japanese victims of the Tokyo subway attack. This method has the advantage that it positively identifies nerve agents and other OPs (Van der Schans *et al.*, 2004). The method has been validated by Adams *et al.* (2004) who found that sodium fluoride released sarin and soman from human butyrylcholinesterase as well as from covalent attachment to human albumin.

C. Identification of OP–Butyrylcholinesterase Adducts by Electrospray–Ionization Tandem Mass Spectrometry

In clinical diagnosis of OP exposure, the tissue most readily available for study is blood. OP adducts of butyrylcholinesterase are better candidates for study than OP adducts on acetylcholinesterase for the following reasons. Human blood contains 5 mg of butyrylcholinesterase and 0.5 mg of acetylcholinesterase per liter. The butyrylcholinesterase is in plasma, whereas the acetylcholinesterase is bound to the membranes of red and white cells. Most OPs, with the exception of chemical warfare nerve agents, react more rapidly with butyrylcholinesterase than with acetylcholinesterase.

Fidder *et al.* introduced an electrospray–ionization tandem mass spectrometry method for diagnosing OP exposure by measuring the mass of the OP-labeled active site peptide of human butyrylcholinesterase (Fidder *et al.*, 2002). His starting material was 0.5 ml of human plasma from a victim of the Tokyo subway attack. The mass of the active site peptide was higher by 120 atomic mass units, compared to the mass of the unlabeled active site peptide. This added mass was exactly the added mass expected from sarin. The peptide's MS–MS fragmentation spectrum yielded the sequence of the peptide, and verified that the OP label was on serine 198, the active site serine. Examples of the MS–MS spectra from tryptic peptides of pure, OP-labeled human butyrylcholinesterase are shown in Figure 56.1.

Fidder *et al.* (2002) showed that this method could also detect human butyrylcholinesterase adducts of soman, dimethyl paraoxon, diethyl paraoxon, and pyridostigmine, when pure butyrylcholinesterase was treated with these poisons. Studies from other laboratories confirmed that OP–butyrylcholinesterase adducts from pure butyrylcholinesterase could be identified by this type of mass spectrometry (Li *et al.*, 2008b; Sun and Lynn, 2007; Tsuge and Seto, 2006). A technical difficulty with the method, in clinical settings, is the need to enrich plasma samples for butyrylcholinesterase to make it possible to detect the labeled peptide in the mass spectrometer. At least two purification steps must be employed, either affinity chromatography and HPLC or affinity chromatography and gel electrophoresis. While identification of OP–butyrylcholinesterase adducts is easy when the starting material is pure butyrylcholinesterase, it becomes a challenge when the starting material is plasma.

D. Antibody Detection

Sensors that use an antibody to detect OP–butyrylcholinesterase or OP–acetylcholinesterase adducts are being developed but are not yet commercially available.

IV. WHY ARE NEW BIOMARKERS NEEDED?

A. Not all OPs Inhibit Acetylcholinesterase and Butyrylcholinesterase

Tri-*ortho*-cresyl phosphate, the contaminant in a homemade liquor called ''Ginger Jake'', which is responsible for delayed neuropathy and paralysis of the legs, is bioactivated to a form that inhibits neuropathy target esterase but not acetylcholinesterase (Casida and Quistad, 2004; Glynn, 2006). Large structures with a 12–20 carbon alkyl chain on the phosphorus atom inhibit fatty acid amide hydrolase but not acetylcholinesterase (Casida and Quistad, 2004). These examples clearly show that OPs which do not affect cholinesterases can react with other proteins, sometimes generating toxic symptoms. These examples also suggest that additional, unknown OP targets may exist which are sensitive to OP that do not affect cholinesterases. In order to detect exposure to such OPs, biomarkers other than cholinesterases will be needed.

B. OP Doses Too Low to Inhibit Acetylcholinesterase Cause Toxicity

Workers in India ($n = 59$) engaged in the manufacture of quinalphos had normal red cell acetylcholinesterase activity, but complained of generalized weakness and fatigue. They had significantly low scores for memory, learning ability, and vigilance compared to controls. Plantar reflexes were abnormal in 50% of the workers. The average age of the workers was 30 ± 6 years and the average duration of exposure to quinalphos was 5.7 years. There was no history of acute poisoning. The plant was situated in large tin sheds without adequate ventilation (Srivastava *et al.*, 2000). The most logical explanation for their symptoms was low-dose exposure to OP.

Family tobacco farmers in Brazil ($n = 37$) used chlorpyrifos and acephate for 3 months a year, for 5.4 h a day. The average duration of exposure was 18 years. Their plasma cholinesterase activity was within the normal range and was not different between on- and off-exposure periods. Clinically significant extrapyramidal symptoms were present in 12 subjects during the pesticide application season, though this number was reduced to nine after 3 months without exposure. Generalized anxiety disorder was diagnosed in 13 subjects, and major depression in eight subjects. After 3 months without OP exposure, the number of subjects with psychiatric disorders declined to about half (Salvi *et al.*, 2003). The most logical explanation for their symptoms was low-dose exposure to OP.

More examples of chronic low dose, subclinical exposure to OPs in humans leading to chronic neurotoxicity are cited in reviews (Abou-Donia, 2003; Kamel and Hoppin, 2004).

Animal studies have been directed at understanding the mechanism of low-dose OP toxicity. The studies agree that doses too low to inhibit acetylcholinesterase activity nevertheless have adverse effects on the animals, including disruption of adenylyl cyclase signaling (Song *et al.*, 1997), hyperphosphorylation of calcium/cAMP response element binding protein (Schuh *et al.*, 2002), airway hyperactivity (Lein and Fryer, 2005), changes in expression levels of fibroblast growth factor in the brain (Slotkin *et al.*, 2007), changes in serotonin receptors (Slotkin *et al.*, 2008), and inhibition of acylpeptide hydrolase (Richards *et al.*, 2000).

Rats chronically treated with low doses of chlorpyrifos have long-term cognitive deficits in the absence of clinical signs of exposure (Jett *et al.*, 2001; Terry *et al.*, 2007). The mechanism for impairment of cognitive function may involve disruption of the microtubule transport of vesicles, organelles, and other cellular components which are

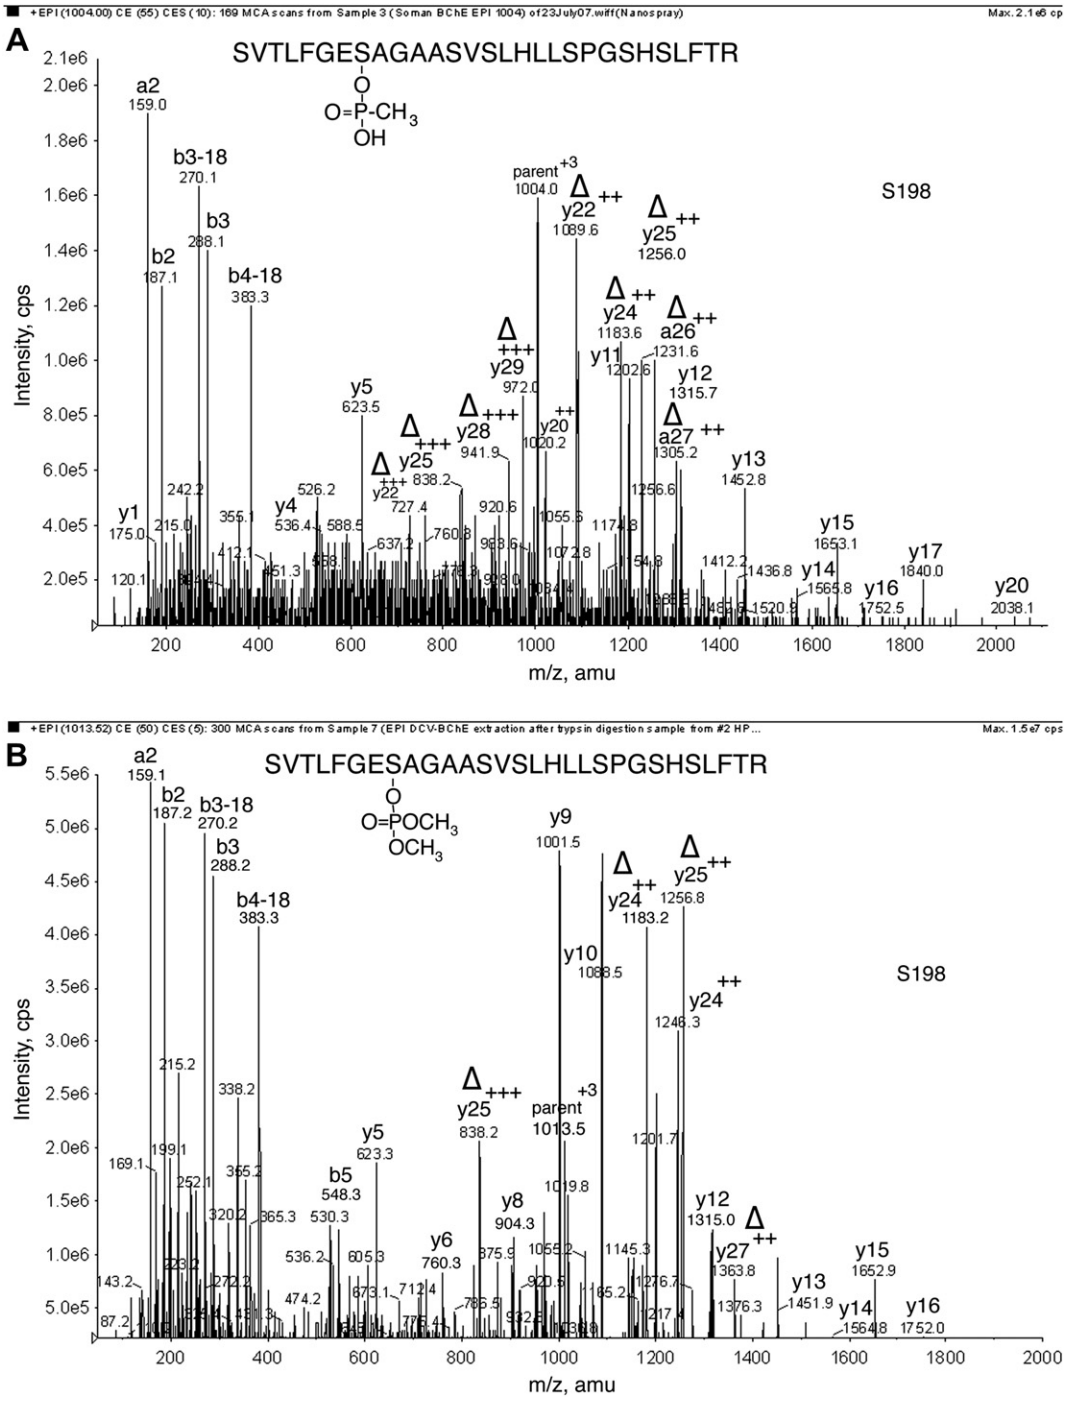

FIGURE 56.1. MS–MS spectra of peptide SVTLFGESAGAASVSLHLLSPGSHSLFTR from human butyrylcholinesterase labeled with aged soman (A), dichlorvos (B), or chlorpyrifos oxon (C). Spectra were acquired on the QTRAP-4000 mass spectrometer using low-energy, collision-induced dissociation. Ions marked with △ have lost the OP as well as a molecule of water, converting the active site serine to dehydroalanine. This type of fragmentation is typical when phosphoserine or organophosphoserine peptides are subjected to collision-induced dissociation in the mass spectrometer. (A) The parent ion for the aged soman-labeled peptide is the triply charged 1004.0 amu ion, where the added mass from aged soman is 78 amu. The scan has nine dehydroalanine masses and no masses other than the parent ion that retain methylphosphonate. (B) The parent ion for the dichlorvos-labeled peptide is the triply charged 1013.5 amu ion, where the added mass from dichlorvos is 108 amu. The scan has four dehydroalanine masses and one mass (y24++) where Ser198 retains dimethoxyphosphate. (C) The parent ion for the chlorpyrifos oxon-labeled peptide is the triply charged 1022.6 amu ion, where the added mass from chlorpyrifos oxon is 136 amu. The scan has four dehydroalanine masses and three masses (y22++, y24++, y25++) where Ser198 retains diethoxyphosphate. To obtain these data, pure human butyrylcholinesterase, accession # gi:158429457, was labeled with OP, digested with trypsin, and peptides were HPLC purified before mass spectrometry. (O. Lockridge, unpublished data)

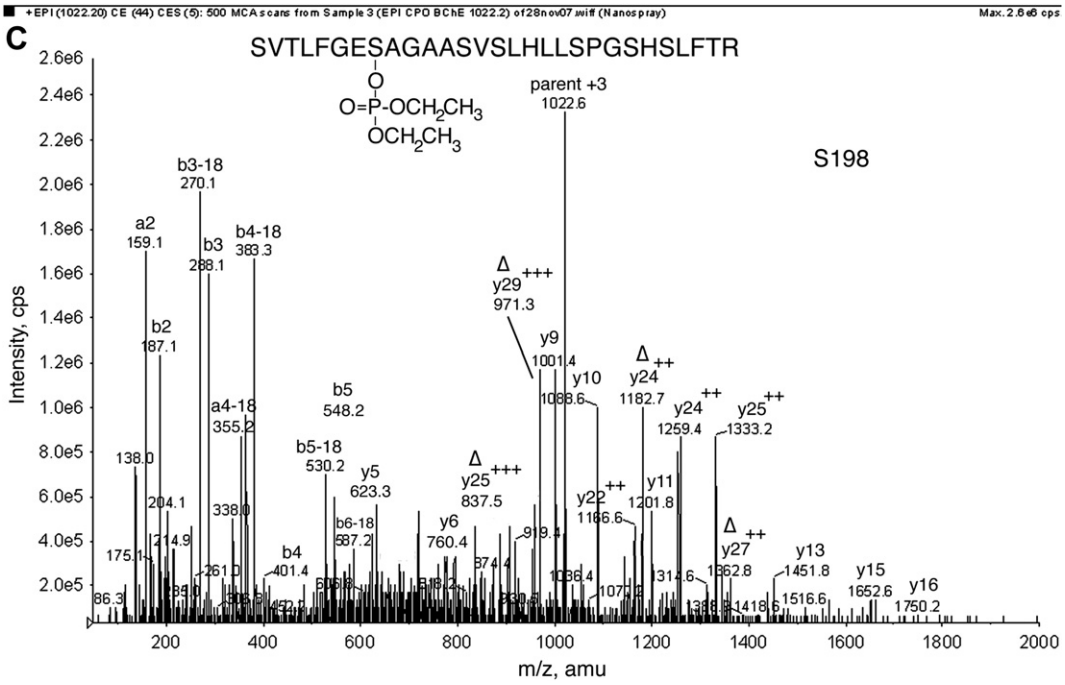

FIGURE 56.1. (*Continued*)

synthesized in the neuronal cell body and moved down long axons to presynaptic sites (Gearhart *et al.*, 2007).

A possible, noncholinesterase-based explanation for the neurotoxic symptoms observed in humans from the examples cited above is that workers were also exposed to a combination of chemicals including heavy metals, solvents, herbicides, and fumigants. The symptoms may actually have been caused by these chemicals and not by the OP (Kamel and Hoppin, 2004). However, the animal data cannot be explained this way because the animals were treated only with OP. In conclusion, OP targets that are not acetylcholinesterase or butyrylcholinesterase are involved in chronic neurotoxicity. These unknown targets bind OP at doses too low to inhibit acetylcholinesterase.

C. Only Some People have Symptoms

Not every person who has been chronically exposed to OP exhibits symptoms. For example, of 612 sheep dippers exposed to diazinon twice a year for 3 days at a time for 40 years, only 19% reported symptoms. In a control group of ceramics workers, who had not been exposed to OPs, 5% reported similar symptoms (Pilkington *et al.*, 2001).

The susceptibility of a minority of the population may be explained by genetic variation in genes affecting OP metabolism. The best studied example is paraoxonase, an enzyme that inactivates OPs (Furlong, 2007; La Du *et al.*, 2001). Paraoxonase polymorphism in humans is hypothesized to explain why some people are resistant to OP toxicity while others are susceptible. Another enzyme that may be involved in resistance to OP toxicity is butyrylcholinesterase. Butyrylcholinesterase scavenges OPs, eliminating the poison before it reaches sites where it could cause harm (Doctor *et al.*, 1991). Humans have a wide range of butyrylcholinesterase activities, with some people having no butyrylcholinesterase whatsoever, due to genetic variation (Manoharan *et al.*, 2007). It is possible, but unproven, that people with butyrylcholinesterase deficiency are more susceptible to OP toxicity. Polymorphisms in liver cytochrome P450 enzymes may also contribute to individual susceptibility to OP toxicity. Specific cytochrome P450 enzymes bioactivate the parent organophosphorothioates to the highly toxic oxon forms. Other cytochrome P450 enzymes detoxify OPs by dearylation (Hodgson and Rose, 2007). The concentration of each isozyme varies among individuals. Thus the relative rates for activation and detoxification will differ between individuals and the circulating levels of the toxic form of the OP will vary between individuals.

Another possibility for variable susceptibility in the population could be genetic variation in the yet unknown OP targets that are responsible for the symptoms. Some forms of these targets may be more sensitive to OPs than are others.

D. Toxic Symptoms Depend on the Identity of the OP

High doses of OPs cause similar toxic effects independent of the identity of the OPs. However, low-dose effects are not identical for all OPs (Moser, 1995). For example, a low dose of fenthion decreased motor activity in rats by 86% but did not alter the tail-pinch response, whereas a low dose of parathion did not affect motor activity but did decrease the

tail-pinch response. In another example, rats given doses of different OPs that inhibited acetylcholinesterase to similar levels had more severe toxicity when the OP was parathion than when it was chlorpyrifos (Pope, 1999). Toxicological studies such as these have led to the conclusion that sites in addition to cholinesterase are targets of OPs. New biomarkers for these effects of OPs are needed.

In summary, acetylcholinesterase and butyrylcholinesterase are not the only proteins modified by OP exposure in humans. Neurotoxicity from low doses of OPs may be explained by OP modification of heretofore unidentified proteins. Toxic symptoms from low-dose exposure to a particular OP are not identical to toxic symptoms from another OP, suggesting that the set of proteins modified by a particular OP does not overlap completely with the set of proteins modified by a different OP. Identification of new biomarkers of OP exposure could lead to new assays for OP exposure, and could lead to an understanding of the causes of low-dose toxicity.

V. NEW BIOMARKERS IN ANIMALS

A. Beta-Glucuronidase in Rat Plasma

A carboxylesterase in rat liver microsomes called egasyn is tightly complexed to beta-glucuronidase. When egasyn binds OP, it releases beta-glucuronidase into blood. A single oral dose of chlorpyrifos (10 mg/kg) increased the level of beta-glucuronidase activity in rat blood 100-fold within 2 h (Fujikawa *et al.*, 2005). The beta-glucuronidase activity decreased to control levels by 24 h. Thus, increased levels of beta-glucuronidase in plasma may serve as a biomarker for OP exposure. However, increase in plasma beta-glucuronidase activity has not been validated in other animal species or in humans.

B. Acylpeptide Hydrolase in Rat Brain

Acylpeptide hydrolase is a member of the serine hydrolase family. It deacetylates the acetylated N-terminus of polypeptides. Rat brain acylpeptide hydrolase was inhibited 93% at a dose of dichlorvos (4 mg/kg, i.p.) which inhibited acetylcholinesterase only 47%. The *in vitro* sensitivity of acylpeptide hydrolase to chlorpyrifosmethyl oxon, dichlorvos, and diisopropyl fluorophosphate (IC_{50}) was 6–10 times greater than that of acetylcholinesterase (Richards *et al.*, 2000). Acylpeptide hydrolase is also found in human erythrocytes where it could potentially serve as a biomarker for low dose exposure to OP in humans, though human cases of OP exposure have not yet been tested for OP-modified acylpeptide hydrolase.

C. Albumin in Mouse and Guinea Pig Plasma

Mice treated with a nontoxic dose of a biotin-tagged OP called FP-biotin had FP-biotinylated albumin in blood and muscle (Peeples *et al.*, 2005). *In vitro* experiments identified the site in human albumin for covalent attachment of a variety of OP as tyrosine 411 (Li *et al.*, 2007).

Guinea pigs treated with the nerve agents soman, sarin, cyclosarin, or tabun had nerve agent-labeled albumin in their blood (Williams *et al.*, 2007). The OPs were bound to tyrosine. The tabun–tyrosine and soman–tyrosine adducts were detected in blood 7 days post-exposure, indicating that the adducts are stable. The adducts did not undergo aging and were not released from tyrosine by treatment of the guinea pigs with oxime, which is a common treatment for OP exposure that induces release of OP from acetylcholinesterase.

These examples show that OPs can bind covalently to albumin under physiological conditions, and that the resultant adducts are relatively stable. OP–albumin adducts could therefore be useful as biomarkers of OP exposure. In addition, unlike cholinesterases, the soman–albumin conjugate does not age (Li *et al.*, 2008a), making it possible to discriminate between sarin and soman exposure. OP–albumin adducts have not yet been reported in humans exposed to OPs.

D. M2 Muscarinic Receptors in Heart and Lung

^{3}H-Chlorpyrifos oxon binds covalently to rat heart M2 muscarinic receptors (Bomser and Casida, 2001). The site of attachment has not been identified. When guinea pigs were treated with chlorpyrifos, diazinon, or parathion at doses too low to inhibit acetylcholinesterase activity, the M2 muscarinic receptors lost their ability to inhibit acetylcholine release from parasympathetic nerves, causing bronchoconstriction (Lein and Fryer, 2005).

VI. COVALENT BINDING OF OP TO TYROSINE

In a 1963 Pedler lecture, Sanger reported that ^{3}H-DFP makes a covalent bond with tyrosine in the sequence Arg-*Tyr*ThrLys from human and rabbit albumin (Sanger, 1963). Mass spectrometry of human albumin treated with soman, chlorpyrifos oxon, FP-biotin, dichlorvos, and DFP confirmed OP modification on Tyr 411 in peptide LVRY*TKKVPQVSTPTL (Li *et al.*, 2007, 2008a), where the underline shows Sanger's sequence and the * indicates the labeled tyrosine.

At the time we confirmed Sanger's observations we thought that albumin was a special case, though we were aware that papain and bromelain had also been reported to bind ^{3}H-DFP on tyrosine (Chaiken and Smith, 1969; Murachi *et al.*, 1965).

We soon learned differently. In a general search for proteins that bind OP, we treated live mice and mouse tissues with FP-biotin, a modified OP designed for identifying unknown targets of OP reaction. The FP-biotinylated

proteins were isolated on immobilized avidin, washed with 0.1% SDS, and separated on an SDS gel. Coomassie blue stained bands were excised, digested with trypsin and the proteins in the bands were identified by mass spectrometry. To our surprise the majority of proteins that were identified were not serine esterases or proteases, which are the classical targets for OPs, nor did the identified proteins contain the consensus sequence, GXSXG, which is characteristic of an active site serine. Typically, we found high abundance proteins such as albumin and tubulin.

Though biotin–avidin complexation has been used widely to isolate specific targets, it is notorious for generating false-positive identifications. To rule out the possibility that our results were an artifact we set out to find the OP-labeled peptide. We reasoned that convincing proof for OP labeling required identification of the labeled peptide and the labeled amino acid.

During years of mass spectrometry analysis, we had consistently identified OP-labeled tubulin in mouse brain. Therefore, we studied pure bovine tubulin (Cytoskeleton, Inc.) by treating it with soman, sarin, FP-biotin, DFP, chlorpyrifos oxon, and dichlorvos. We isolated the OP-labeled tryptic peptides and analyzed them by fragmentation in the QTRAP 2000 and QTRAP 4000 mass spectrometers. We identified five OP-labeled peptides in tubulin (Grigoryan *et al.*, 2008). In every peptide, the OP was covalently attached to tyrosine (Table 56.1).

Similar mass spectrometry experiments with pure human and mouse transferrin (Li *et al.*, 2008c), and with human kinesin showed that the OP label was consistently on tyrosine (Table 56.1). Studies with human plasma identified OP labeling on tyrosine in apolipoprotein and alpha-2-glycoprotein. Aggressive treatment of human albumin with FP-biotin and chlorpyrifos oxon led to identification of seven OP-labeled tyrosines (Ding *et al.*, 2008). Finally, we found that synthetic peptides made a covalent bond with DFP, chlorpyrifos oxon, and dichlorvos (Table 56.1). Mass spectrometry conclusively proved that the OP was attached to tyrosine.

VII. MOTIF FOR OP BINDING TO TYROSINE

Comparison of the sequences of the OP-labeled peptides in Table 56.1 shows no definite consensus sequence around the tyrosine to which the OP binds. What the peptides do have in common is the presence of a positively charged arginine, lysine, or histidine within 5 amino acids of the labeled tyrosine, most being within 3 amino acids. We suggest that these positively charged residues could interact with the phenolic hydroxyl of tyrosine to lower the pKa. Such ion-pair interactions have been shown to lower the pKa for the negatively charged partner, with a comparable rise of the pKa of the positively charged partner by as much as 4 pKa units (Johnson *et al.*, 1981). Tyrosines with a lower pKa value would be better nucleophiles and thus be better able to attack OPs.

Peptide SYSM has no positively charged residue in its sequence. Labeling efficiency on this peptide was poor at pH 8.3. MPCAEDYLSVVLN also contains no positively charged residue but this tyrosine was near a positively charged residue in the albumin structure.

In conclusion, most proteins that we have examined in detail, using sensitive mass spectrometry techniques, have shown the capacity to become labeled by OP on tyrosine. However, only certain tyrosines in a protein are labeled, i.e. those on the surface and near a positively charged residue that could potentially activate the phenolic hydroxyl group. The finding that even small synthetic peptides can be labeled by OP on tyrosine has led to the hypothesis that OP labeling on tyrosine is a general phenomenon. We propose that OP labeling on tyrosine is a new motif for OP binding to proteins.

VIII. CHARACTERISTICS OF OP BINDING TO TYROSINE

A. On Rate

Little is known about the rate of OP binding to tyrosine because the recognition of this OP binding motif is new with the writing of this chapter. Soman binding to Tyr 411 in human albumin has been measured and has been found to be slow with a bimolecular rate constant of $15 \pm 3\ M^{-1}\ min^{-1}$ (Li *et al.*, 2008a). We expect that other proteins will be identified whose rate of OP binding to tyrosine will be fast.

B. Off Rate

The OP adduct on tyrosine 411 of human albumin is stable. The half-life for decay of the soman–Tyr 411 adduct is 20 days at pH 7.4, 22°C (Li *et al.*, 2008a). The chlorpyrifos oxon–Tyr 411 adduct is even more stable (Ding *et al.*, submitted). After 7 months at 22°C in pH 7.4 buffer, 80% of the Tyr 411 was still labeled with diethoxyphosphate, which is the adduct formed by chlorpyrifos oxon. However, at pH 8.3 and 22°C, 50% had lost the OP label in 3.6 months. OP–albumin adducts stored at −80°C are stable indefinitely at pH 8.3, 7.4, and 1.5. One advantage of a stable OP–tyrosine adduct is that it will survive in an animal long enough to be useful for generation of antibodies. Another advantage of a stable OP–tyrosine adduct is that detection of OP can be made on samples long after exposure.

C. No Aging

OPs bound to tyrosine do not age. Aging of OP adducts on acetylcholinesterase and butyrylcholinesterase is defined as the loss of an alkoxy group from the phosphorus atom. Every OP–tyrosine adduct in Table 56.1 has been examined

For peptides derived from proteins, six residues on either side of the OP-labeled tyrosine are shown. Synthetic peptides are shown in their complete length. The labeled tyrosine is enclosed in a box.

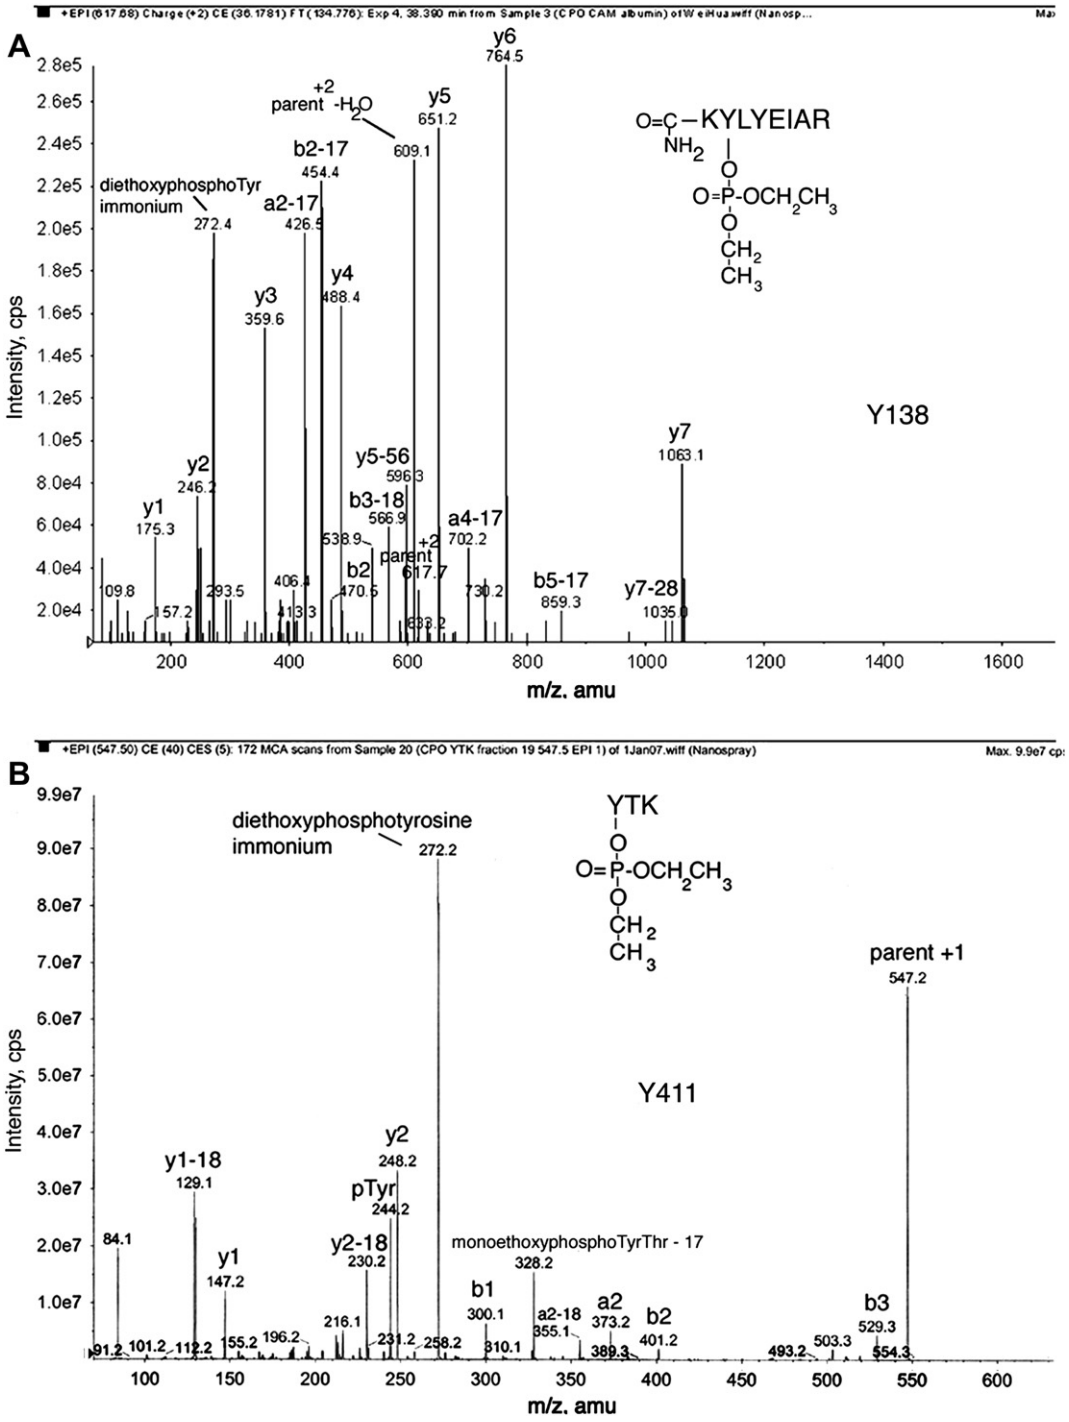

FIGURE 56.2. MS–MS spectra of human albumin peptides labeled on tyrosine with chlorpyrifos oxon. (A) The doubly charged parent ion (617.7 amu) for KYLYEIAR includes a mass of 136 amu from chlorpyrifos oxon and a mass of 43 amu from carbamate. Carbamylation was a by-product of denaturation in 8 M urea. The presence of diethoxyphosphate on Tyr 138 is supported by the masses y7, a2 minus amine (17 amu), b2 minus amine (17 amu), b3 minus water (18 amu), a4 minus amine (17 amu), and b5 minus amine (17 amu), all of which include the 136 amu added mass for diethoxyphosphate. The ion at 272.4 amu is consistent with the mass of the diethoxyphosphotyrosine immonium ion; its presence supports chlorpyrifos oxon labeling of tyrosine. (B) The singly charged parent ion (547.2 amu) for YTK includes an added mass of 136 amu from chlorpyrifos oxon. The presence of diethoxyphosphate on Tyr 411 is supported by the masses of the b1 ion, the y2 ion, and the parent ion, all of which include the 136 amu mass of diethoxyphosphate. Furthermore, the characteristic ions at 272.2 amu for the diethoxyphosphotyrosine immonium ion, at 328.2 amu for the monoethoxyphosphoTyrThr ion minus amine (17 amu), and at 244.2 amu for phosphotyrosine support labeling on tyrosine. Loss of one or both alkyl groups from the diethoxyphospho adduct during collision-induced dissociation in the mass spectrometer is a common observation. These data are original from our laboratory and have not previously been published.

for aging. No masses representing aged OP–tyrosine adducts have been found.

Aging can confound the identification of the original OP. For example, aged sarin and soman adducts on acetylcholinesterase are indistinguishable because they yield the same methylphosphonate derivative. The absence of aging for OP–tyrosine adducts results in a species that is suitable for discriminating between sarin and soman adducts because the unaged adducts have different masses. Absence of aging for OP–tyrosine adducts has also been reported by Williams *et al.* (2007).

IX. METHODS FOR DETECTING OP BINDING TO TYROSINE

A. Mass Spectrometry

If the identity of the OP-labeled protein is unknown, a tagged OP, for example a biotinylated OP, can be used to identify the protein (Schopfer *et al.*, 2005). After the identity of the OP-labeled protein is known, identification of the OP-labeled peptide depends on separating it from contaminating peptides. We have found that the OP-labeled peptide is frequently not found by mass spectrometry unless it has been extensively purified. In some cases it is possible to identify the labeled peptide simply by LC–MS–MS, where an enzymatic digest of the isolated protein is subjected to liquid chromatography on a C18 nanocolumn and the effluent from the column is electrosprayed directly into the mass spectrometer. For other cases, extensive HPLC purification of the enzymatic digest is necessary to obtain a purified fraction of peptides that can be introduced into the mass spectrometer.

Preliminary identification of the labeled peptides in HPLC fractions is made by mass, using MALDI mass spectrometry (MALDI TOF-TOF 4800 from Applied Biosystems). The MS-Digest algorithm on the Protein Prospector website at the University of California San Francisco is a useful tool for predicting the masses of peptides from a proteolytic digest with and without the added mass from a particular OP. Another indispensable tool is the Fragment Ion Calculator from the http://db.systemsbiology.net:8080/proteomicsToolkit/ website, which can be used to calculate the masses of ions generated during MS–MS fragmentation of a peptide. Our laboratory acquires MS–MS spectra with the QTRAP 2000 and QTRAP 4000 mass spectrometers (Applied Biosystems). Examples of MS–MS spectra for human albumin peptides labeled on tyrosine with chlorpyrifos oxon are shown in Figure 56.2.

B. Antibody

An elegant method for identifying OP-labeled tyrosine would be with an OP–tyrosine-specific antibody. A similar antibody toward phosphotyrosine is commercially available. Antibodies to OP–tyrosine adducts are not yet available, though their development is in progress.

X. CONCLUDING REMARKS AND FUTURE DIRECTION

A new motif for OP binding to tyrosine has been identified. Almost all proteins appear to be capable of binding OP covalently on tyrosine. Whether or not OP will bind to tyrosine *in vivo* will depend on the concentration of the protein, the concentration of the OP, and the ionization status of the tyrosine hydroxyl group. The latter factor appears to be dependent on the presence of nearby positively charged residues.

The importance of the first and third factors is amply demonstrated in the case of albumin. The concentration of albumin is so high (600 μM in human plasma) that albumin binds OP even though its rate of reaction is slow. The reaction of albumin's most sensitive tyrosine is aided by the presence of three positively charged residues within a five residue stretch surrounding that tyrosine.

Antibodies to OP–tyrosine will be made. These antibodies will be used to diagnose OP exposure in a biosensor assay with saliva, sweat, or urine. New biomarkers of OP exposure will be identified using mass spectrometry and the new OP–tyrosine antibodies. The identification of new biomarkers for low-dose OP exposure is expected to lead to an understanding of how neurotoxicity is caused by OP doses that are too low to inhibit acetylcholinesterase. For example, it is possible that disruption of microtubule polymerization by OP-adduct formation may explain cognitive impairment from OP exposure.

Identification of new biomarkers of OP exposure may also lead to an understanding of why some people are intoxicated by low doses of OP that have no effect on the majority of the population. The new motif for OP binding to tyrosine may lead to new antidotes for OP poisoning; for example, peptides containing several tyrosines and several arginines may be effective OP scavengers.

Acknowledgments

Mass spectra were obtained with the support of the Mass Spectrometry and Proteomics core facility at the University of Nebraska Medical Center. This work was supported by US Army Medical Research and Material Command W81XWH-07-2-0034 (to OL), NIH CounterACT U01 NS058056-02 (to OL), NIH Eppley Cancer Center grant P30CA36727, and DGA grant 03co010-05/PEA01 08 7 (to P.M.).

CHAPTER 57

Biomarkers and Biosensors of Delayed Neuropathic Agents

RUDY J. RICHARDSON, R. MARK WORDEN, AND GALINA F. MAKHAEVA

I. INTRODUCTION

Delayed neuropathic (DN) agents represent a new functional class of organophosphorus (OP) threats that have heretofore not been used in warfare or terrorist acts. Nevertheless, it is vital to develop effective defenses against them for three reasons. First, these materials can readily be produced by rather straightforward modifications of the structures of conventional nerve agents. Second, warning signs and symptoms of toxicity may be lacking until 1–4 weeks after exposure, when the permanent sensory deficits and paralysis associated with OP compound-induced delayed neurotoxicity (OPIDN) develop. Third, there are no established means of preventing or treating OPIDN. This chapter begins with a review of current understanding about the chemistry and mechanism of action of DN agents; it then describes how existing knowledge can be applied to generate biomarkers and biosensors for discriminating between conventional and DN agents; and it ends by indicating future work needed to address the threat of DN agents.

II. OP COMPOUNDS

A. Conventional Nerve Agents versus DN Agents

Conventional nerve agents, such as sarin and soman, are OP compounds of pentavalent phosphorus that are well known as threats in the context of warfare and terrorism (Sidell and Borak, 1992). These substances produce acute cholinergic toxicity and death via inhibition of acetylcholinesterase (AChE) in the central and peripheral nervous systems (Marrs *et al.*, 1996).

In contrast to conventional nerve agents, DN agents produce permanent neurological dysfunction in the form of OPIDN rather than cholinergic toxicity and death (Richardson, 2005). Like conventional nerve agents, DN agents are OP compounds of pentavalent phosphorus that are readily synthesized, but they are designed to inactivate neuropathy target esterase (neurotoxic esterase, NTE) in preference to AChE (Wu and Casida, 1995). Because of this selectivity, DN agents may elicit little or no warning signs of acute cholinergic toxicity, so that victims of DN agents might not know they have been exposed until OPIDN develops 1–4 weeks later.

Cholinergic toxicity from OP compounds can be elicited solely by inhibition of AChE (Thompson and Richardson, 2004). The AChE–OP conjugate can undergo loss of an OP ligand (''aging'') to yield a negatively charged phosphoryl adduct on the active site serine, but while this reaction has practical implications for therapy, it does not change the qualitative nature of the toxicity (Figure 57.1). On the other hand, if an OP compound is to be a DN agent, it must be capable of inhibiting NTE; moreover, it appears that the resulting NTE–OP conjugate must also be capable of undergoing aging (Figure 57.2) (Richardson, 1992, 2005).

Thus, DN agents are distinct from conventional nerve agents in several respects. Furthermore, especially in view of their ease of synthesis, absence of initial signs or symptoms of exposure, and lack of prophylactic or therapeutic measures, it is conceivable that rogue nations or terrorist groups might consider DN agents attractive as weapons of permanent incapacitation against military or civilian populations. Therefore, part of an effective chemical defense strategy is to develop methods for detecting DN agents via sensitive and selective biomarkers and biosensors (Makhaeva *et al.*, 2003; Malygin *et al.*, 2003).

B. OP Compounds of Pentavalent versus Trivalent Phosphorus

In this chapter, DN agents are defined as OP compounds of pentavalent phosphorus that produce OPIDN. Examples shown in Figure 57.3 are ethyl *n*-octylphosphonofluoridate (EOPF) and 2-(2-methylphenoxy)-4*H*-l,3,2-benzodioxaphosphorin-2-oxide [2-(2-methylphenoxy)-BDPO], the active metabolite of the archetypal DN agent, tri-*o*-cresyl phosphate (TOCP) (Wu and Casida, 1995).

However, there are also OP compounds of trivalent phosphorus that produce neurological injury. Examples

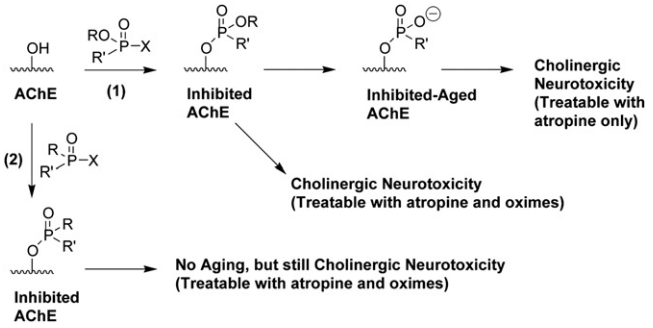

FIGURE 57.1. Reaction of acetylcholinesterase (AChE) with an organophosphonate in pathway (1) yields a phosphonylated (inhibited) enzyme, which can undergo net loss of an R-group to yield an inhibited-aged enzyme. Inhibition alone produces cholinergic toxicity that is treatable with both atropine to counteract excess acetylcholine at muscarinic acetylcholine receptors and oximes to reactivate AChE. Aging does not change the type of toxicity, but it renders the enzyme intractable to reactivation, so that treatment with oximes becomes ineffective. Reaction of AChE with an organophosphinate in pathway (2) yields a phosphinylated (inhibited) enzyme and produces cholinergic toxicity, but because of the stability of the C–P bonds linking the R- and R′-groups to phosphorus the phosphinyl moiety on AChE does not undergo aging, so that both atropine and oximes can be used in therapy. R, R′ = substituted or unsubstituted alkyl or aryl groups, which can be different or equivalent. X = primary leaving group, e.g. fluoride. Reproduced with permission from Richardson (2005).

shown in Figure 57.4 are triphenylphosphite and triphenylphosphine. Comparatively little is known about the neuropathic trivalent OP compounds, but the clinical course and spatial–temporal pattern of lesions that they produce vary from OPIDN, and the mechanisms of action of these compounds appear to differ from that of the DN agents. For example, triphenylphosphite produces a syndrome of delayed axonopathy and other neurodegenerative changes that could represent a variant of OPIDN, possibly via inhibition/aging of neuropathy target esterase (NTE) (Abou-Donia, 1992; Fioroni *et al.*, 1995; Padilla *et al.*, 1987; Tanaka *et al.*, 1990). However, although triphenylphosphite inhibits NTE *in vitro* and *in vivo*, the nature of the adduct formed with NTE has not been elucidated, and the aging reaction of triphenylphosphite-inhibited NTE has apparently not been studied. Triphenylphosphine is another trivalent OP compound that produces delayed axonopathy, but its pathogenesis and mechanism appear to differ from those of triphenylphosphite or neuropathic OP compounds of pentavalent phosphorus. Among other differences, triphenylphosphine does not inhibit NTE *in vitro* or *in vivo* (Davis *et al.*, 1999; Padilla *et al.*, 1987).

With the foregoing in mind, the remainder of this chapter will deal exclusively with OP compounds of pentavalent phosphorus.

III. OPIDN

OPIDN, also known as OP compound-induced delayed polyneuropathy (OPIDP), can be produced within 1–4 weeks of a single exposure to a DN agent; with compounds that are highly selective for NTE, the first week of this period can be clinically quiescent (Davis and Richardson, 1980; Lotti, 1992; Lotti and Moretto, 2005; Richardson, 2005). Pathogenesis involves progressive distal degeneration of sensory and motor axons in peripheral nerves and spinal cord tracts.

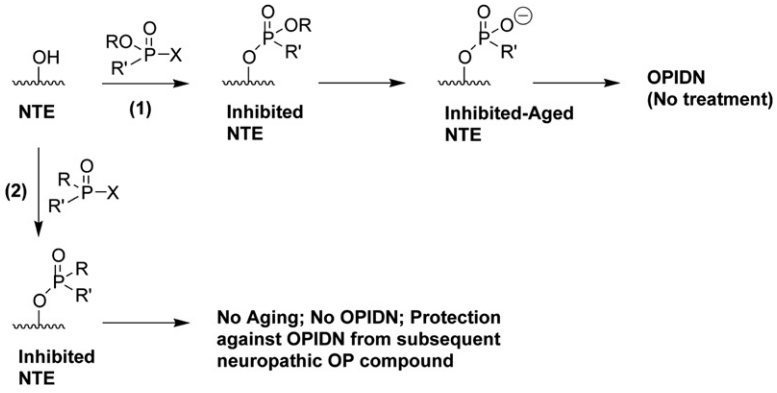

FIGURE 57.2. Reaction of neuropathy target esterase (NTE) with an organophosphonate in pathway (1) yields a phosphonylated (inhibited) enzyme, which can undergo net loss of an R-group to yield an inhibited-aged enzyme. Inhibition alone does not produce organophosphorus (OP) compound-induced delayed neurotoxicity (OPIDN); both inhibition and aging are required, and there is no treatment for the neuropathy. Reaction of NTE with an organophosphinate in pathway (2) yields a phosphinylated (inhibited) enzyme, but because of the stability of the C–P bonds linking the R- and R′-groups to phosphorus the phosphinyl moiety on NTE does not undergo aging, so that OPIDN does not occur. Inhibition of NTE with a nonaging inhibitor is not biologically inert – it protects against subsequent exposures to neuropathic (ageable) NTE inhibitors. R, R′ = substituted or unsubstituted alkyl or aryl groups, which can be different or equivalent. X = primary leaving group, e.g. fluoride. Reproduced with permission from Richardson (2005).

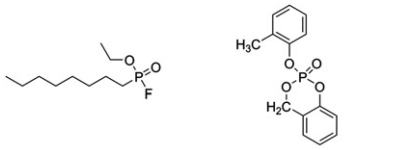

FIGURE 57.3. Examples of delayed neuropathic (DN) agents containing pentavalent phosphorus: ethyl *n*-octylphosphonofluoridate (EOPF) and 2-(2-methylphenoxy)-4*H*-l,3,2-benzodioxaphosphorin-2-oxide [2-(2-methylphenoxy)-BDPO], the active metabolite of the archetypal DN agent, tri-*o*-cresyl phosphate (TOCP) (Wu and Casida, 1995).

Accordingly, symptoms begin with paresthesias in the distal extremities followed by sensory loss, ataxia, and flaccid paralysis. Once the disease is initiated, it advances inexorably. In keeping with its unknown mechanism of neurodegeneration, there is no cure or treatment other than general supportive therapy. Over a period of months to years, some regeneration of peripheral nerve axons may occur to reinnervate muscle. Nevertheless, the concomitant persistence of injury to descending inhibitory pathways in the spinal cord prevents complete functional recovery and permits only a shift from flaccid to spastic paralysis (Richardson, 2005).

Because of the insidious onset and permanent debilitating effects of OPIDN, it is essential to be able to predict the potential of a given OP compound to produce this disease as opposed to causing acute cholinergic toxicity. Furthermore, it is important to develop specific and stable biomarkers and biosensors of exposure to DN agents and devise countermeasures against them (Makhaeva *et al.*, 2003; Malygin *et al.*, 2003). To accomplish these goals, it will be necessary to acquire a level of mechanistic understanding of interactions between DN compounds and target macromolecules akin to what has been achieved for conventional (anti-AChE) nerve agents. Although there is much left to be learned about the pathogenesis and mechanism of OPIDN, sufficient knowledge exists about the apparent initiating events, i.e. inhibition and aging of NTE, to provide a foundation for the development of biomarkers and biosensors of DN agents.

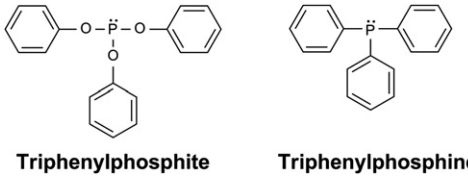

FIGURE 57.4. Examples of neuropathic organophosphorus compounds containing trivalent phosphorus: triphenylphosphite and triphenylphosphine (Eto, 1974).

IV. NTE

A. Definition of NTE and its Potential Normal or Pathogenic Roles

NTE (UniProtKB/Swiss-Prot Q81Y17; PLPL6_HUMAN) has recently been categorized as a lysophospholipase (EC 3.1.1.5), owing to its ability to hydrolyze phosphatidylcholine to glycerophosphocholine (UNIPROT, 2008). It is also known as patatin-like phospholipase domain-containing protein-6, whose gene name is PNPLA6, because the catalytic domain of NTE encompasses a region with sequence homology to patatin, a phospholipase found in potatoes and other plants. Thus, it appears that NTE can function biochemically as a phospholipase, but its precise physiological role remains to be firmly established.

The UniProt entry for human NTE lists three variants attributed to alternative splicing (UNIPROT, 2008). Although UniProt has adopted isoform-1 as the canonical sequence, this chapter defines human NTE as isoform-2, which is the sequence initially reported by Lush *et al.* (1998), consisting of 1,327 amino acids and having a molecular weight without posttranslational modifications of 146 kDa. The protein has a transmembrane domain near the N-terminus (residues 9–31) and three putative cyclic nucleotide binding domains (residues 163–262, 480–573, and 597–689), in addition to the patatin domain (residues 933–1,099), which contains the active site (Wijeyesakere *et al.*, 2007).

The three-dimensional structure of NTE has not been experimentally determined, but a homology model of the patatin domain indicates that the active site serine (Ser^{966}) is located on a ''nucleophilic elbow'' characteristic of serine hydrolases (Wijeyesakere *et al.*, 2007). Moreover, the model indicates that the catalytic site of NTE consists of a novel Ser-Asp catalytic dyad, as in patatin and mammalian cytosolic phospholipase A2 ($cPLA_2$), rather than the classical catalytic triad (Ser-Asp/Glu-His), as found in many serine hydrolases including AChE. Recently, mutations have been identified in NTE that are associated with motor neuron disease (Rainier *et al.*, 2008). The mutations occur within the catalytic domain of NTE, but it is not yet known if they affect the catalytic function of the enzyme or alter some other property of the protein in order to produce disease.

NTE was first identified as the presumptive target of neuropathic OP compounds in the initiation of OPIDN (Johnson, 1970). Its activity in cells and tissues is operationally defined as the enzymatic hydrolysis of the nonphysiological substrate, phenyl valerate, which is resistant to inhibition by diethyl 4-nitrophenyl phosphate (paraoxon) and sensitive to inhibition by *N,N′*-diisopropylphosphorodiamidic fluoride (mipafox) under specified conditions of preincubation with inhibitors and subsequent incubation with substrate (Johnson, 1977; Kayyali *et al.*, 1991; Makhaeva *et al.*, 2007).

Because the full-length protein is difficult to isolate or produce, human recombinant NTE esterase domain (NEST) has been used as an NTE surrogate for studies *in vitro* that require pure protein rather than a crude preparation containing NTE (Kropp *et al.*, 2004). NEST comprises residues 727–1,216 of NTE; it has been shown to be the shortest segment of NTE that retains esterase activity, and the catalytic properties of NEST, including its response to OP inhibitors, closely resemble those of full-length NTE (Atkins and Glynn, 2000; Atkins *et al.*, 2002; Kropp *et al.*, 2004; Van Tienhoven *et al.*, 2002). As noted below, NEST has been incorporated into a biosensor for detection of DN agents (Kohli *et al.*, 2007a).

B. Role of NTE in OPIDN

Early studies indicated that the initial molecular events in OPIDN are the concerted inhibition and aging of a threshold level (>70%) of NTE in the central and peripheral nervous systems (Glynn, 1999; Johnson, 1974, 1982; Lotti, 1992). As with other serine esterases, inhibition of NTE is thought to occur by nucleophilic attack of the active site serine (Ser^{966}) at the phosphorus of the OP compound, with displacement of a primary leaving group. Aging of the phosphylated enzyme presumably involves loss of a second ligand, leaving a negatively charged phosphyl moiety covalently attached to the active site. Note that ''phosphyl'' is used as a generic term for the various types of OP compounds that might be used as inhibitors of serine esterases, e.g. phosphates, phosphonates, phosphinates, and phosphoroamidates.

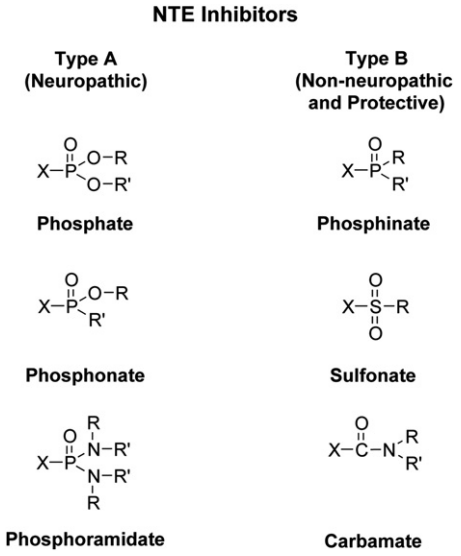

FIGURE 57.5. Subclasses of neuropathy target esterase (NTE) inhibitors. Type A inhibitors include phosphates, phosphonates, and phosphoramidates; these are neuropathic and capable of aging. Type B inhibitors include phosphinates, sulfonates, and carbamates; these are nonneuropathic and not capable of aging. However, inhibition of NTE with a type B inhibitor will protect against organophosphorus compound-induced delayed neurotoxicity (OPIDN) from subsequently administered type A inhibitors. Reproduced with permission from Richardson (2005).

The apparent necessity for aging of NTE as a trigger for OPIDN came about from analyses of structure–activity relationships. These studies revealed that NTE inhibitors fall into two functional categories, type A and type B (Davis and Richardson, 1980; Davis *et al.*, 1985; Johnson, 1975) (Figure 57.5). Type A inhibitors produce OPIDN and include certain phosphates, phosphonates, and phosphoramidates. When type A compounds inactivate NTE, it rapidly becomes intractable to reactivation by powerful nucleophiles, e.g. oximes or fluoride. This inability to be reactivated has been interpreted as evidence of aging. Because loss of reactivatability takes place within minutes of inhibition by type A inhibitors and OPIDN takes 1–4 weeks to develop, aging of NTE is not the rate-limiting step in this disease (Johnson, 1982). Type B inhibitors do not produce OPIDN and include certain phosphinates, carbamates, and sulfonates. NTE conjugates with type B compounds are considered not to undergo aging; those formed from carbamates and phosphinates can be reactivated, and carbamylated, phosphinylated, or sulfonylated NTE cannot undergo further reactions to produce a stable charged species. Despite the fact that inhibition of NTE by type B compounds does not result in OPIDN, this reaction is far from being biologically inert. Pretreatment of animals with type B inhibitors protects them against OPIDN from subsequently administered type A inhibitors, presumably by blocking the formation of aged NTE (Davis *et al.*, 1985; Johnson, 1990; Richardson, 1984) (Figure 57.2). Protection against type A inhibitors by type B inhibitors is effective as long as inhibition of NTE by type B compounds is >30%, thus preventing inhibition and aging of the >70% NTE required for induction of OPIDN.

It would appear that the ostensible requirement for aging of NTE in the development of OPIDN is not merely to ensure irreversible inhibition of the enzyme. Prolonged suprathreshold inhibition (>70%) of neural NTE *in vivo* by repeated dosing of nonaging inhibitors does not cause neuropathy (Johnson, 1970, 1974, 1982). Moreover, repeated low-level dosing with aging inhibitors to produce a prolonged steady-state inhibition that is below threshold (<70%) does not result in OPIDN until a higher single dose is superimposed that raises the inhibition level above threshold. In the latter scenario, there is still a delay of 10–14 days from the high point of inhibition (and presumed concomitant aging) until signs of neuropathy appear (Johnson and Lotti, 1980; Lotti and Johnson, 1980). These results suggest that simple loss of catalytic activity of NTE is not the damaging event in OPIDN. Thus, the notion has arisen that the ''biochemical lesion'' that triggers OPIDN is the formation of a chemically modified (aged) protein that has gained a toxic function in the neuron (Glynn, 2000; Richardson, 1984).

The pathogenic role of aged NTE is not known, but it is tempting to speculate that it may be involved in an axonal self-destruct program that has been proposed to be an important mechanism in neurodegenerative disorders, e.g. motor neuron disease (Raff *et al.*, 2002). Such a program might be triggered by chemically modified NTE acting through a toxic gain of function mechanism. On the other hand, conventional (Moser *et al.*, 2004; Mühlig-Versen *et al.*, 2005; Winrow *et al.*, 2003) and conditional (Akassoglou *et al.*, 2004) NTE knockout experiments, along with demonstrations of a likely role of NTE in membrane lipid metabolism (Quistad *et al.*, 2003; Van Tienhoven *et al.*, 2002; Zaccheo *et al.*, 2004), indicate that lethality or neuropathology can result from a loss of function of NTE (Glynn, 2006). Nevertheless, while the physiological and pathogenic roles of NTE are being deciphered, the fact that an excellent correlation exists between inhibition/aging of NTE and induction of OPIDN is sufficient to use this information for the development of biomarkers and biosensors for DN agents (Makhaeva *et al.*, 2003, 2007).

V. KINETICS OF OP INHIBITOR–SERINE HYDROLASE INTERACTIONS

A. Introduction

The inhibitory and postinhibitory steps in the interaction of an OP compound with a serine hydrolase (E-OH) such as NTE or AChE are illustrated in Figure 57.6. The mathematical relationships describing the kinetics of irreversible inhibition of serine esterases by OP compounds and postinhibitory reactions of the enzyme–inhibitor adduct (conjugate) summarized here were elegantly set forth in the classic work by Aldridge and Reiner (1972), and synopses are available in other sources (Clothier *et al.*, 1981; Main, 1980; Richardson, 1992). The equations featured below provide the foundation for determining the inhibitory potency of OP compounds against serine hydrolases as well as the rates of reactivation or aging of the inhibited hydrolases. Such approaches can be employed to assess the neuropathic potential of compounds and to distinguish conventional nerve agents from DN agents using biomarkers and biosensors.

B. Inhibition

The first step leading to inhibition is a reversible association of the OP compound (depicted in Figure 57.6 as a phosphonate) and enzyme to form a Michaelis-type complex (shown in square brackets); the associated rate constants for the forward (k_{+1}) and back (k_{-1}) reactions are shown on the double arrow. The active site serine hydroxyl of the hydrolase then engages in a nucleophilic attack on the phosphorus atom of the OP inhibitor, displacing the primary leaving group (X^-), resulting in a phosphonylated enzyme with net loss of HX. The primary leaving group, X^-, is typically a conjugate base of a strong acid, HX, such as HF. The phosphonylation rate constant is shown as k_2 (Richardson, 1992).

Considering only the first two steps in the reaction sequence, which is appropriate for most acylating inhibitors, the affinity of the inhibitor for the enzyme is given by the Michaelis-type equilibrium constant,

$$K_a = (k_{-1} + k_2)/k_{+1} \tag{57.1}$$

The overall progress of the reaction from E-OH and inhibitor to phosphonylated enzyme is characterized by the bimolecular rate constant of inhibition, k_i. This important measure of inhibitory potency is determined by measuring the activity remaining as a function of time of preincubation with various concentrations of inhibitor. The substrate is

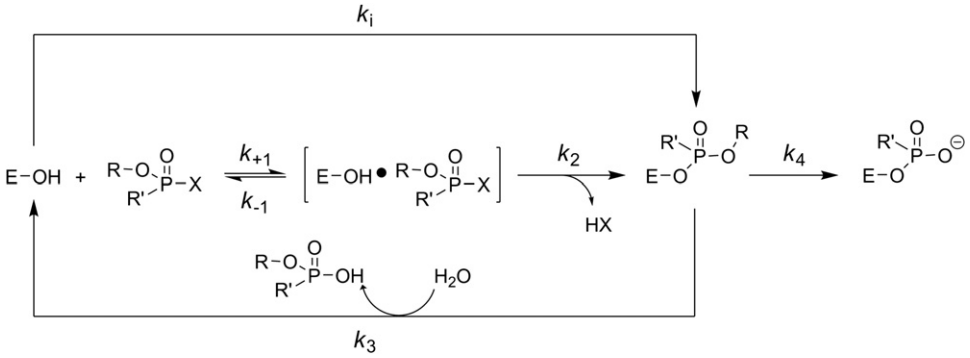

FIGURE 57.6. Reactions between a serine hydrolase and an organophosphonate inhibitor showing associated rate constants. The initial reversible reaction with forward (k_{+1}) and back (k_{-1}) rate constants forms a Michaelis-type complex. The complex can undergo phosphonylation (rate constant k_2) with expulsion of the primary leaving group, X. The overall progress of the reaction from enzyme to phosphonylated (inhibited) product is characterized by the bimolecular rate constant, k_i. The phosphonylated enzyme can undergo spontaneous reactivation (hydrolysis in the presence of excess water) described by the pseudo-first-order rate constant, k_3, or undergo net loss of the R-group (aging) characterized by the first-order rate constant, k_4 (Richardson, 1992).

added after the preincubation interval (Richardson, 1992). When the inhibitor concentration [OP] $<< K_a$,

$$k_i = k_2/K_a \tag{57.2}$$

So-called ideal first-order kinetics of inhibition are obtained under the commonly observed conditions when the concentration of the Michaelis-type complex is small, k_2 is high, k_3 is much smaller than k_2, and [OP] > 10[E-OH], where [E-OH] = concentration of native enzyme. In such cases,

$$\ln(v/v_0) = -k_2[\text{OP}]t/([\text{OP}] + K_a) \tag{57.3}$$

In Eq. (57.3), v is the rate of enzymatic hydrolysis of its substrate at time $= t$, and v_0 is the rate at time zero. Substituting (% activity/100) for (v/v_0) and letting $k' = k_2[\text{OP}]/([\text{OP}] + K_a)$ yields

$$\ln(\%\ \text{activity}/100) = -k't \tag{57.4}$$

Thus, primary plots of ln(% activity/100) versus t will be straight lines with slopes $= -k'$ as shown in Figure 57.7A. In addition, the experimentally determined dependence of % activity remaining on the preincubation time (t) and inhibitor concentration [OP] is

$$\ln(\%\ \text{activity}/100) = -k_i[\text{OP}]t \tag{57.5}$$

Setting Eq. (57.4) and Eq. (57.5) equal to each other gives

$$k' = k_i[\text{OP}] \tag{57.6}$$

Therefore, a secondary plot of $-k'$ versus [OP] will yield a straight line with slope $= k_i$ as shown in Figure 57.7B. The bimolecular rate constant thus obtained is an indication of the inhibitory potency of a given compound against a particular serine hydrolase. As stated above, k_i is a measure of the overall progress of the reaction between the inhibitor and enzyme to yield the organophosphylated product. However, it is important to realize as shown in Eq. (57.2) that k_i is a composite of K_a, which is an indication of the affinity of the inhibitor for the enzyme, and k_2, which is an indication of the rate of phosphylation of the enzyme by the inhibitor. Inspection of Eq. (57.2) and Eq. (57.5) shows that the units of k_i are $[\text{OP}]^{-1}t^{-1}$; for example, the k_i obtained for chlorpyrifos methyl oxon (CPMO) against hen brain microsomal NTE at pH 8.0 and 37°C (Figure 57.7) is $5.82 \times 10^4\ \text{M}^{-1}\,\text{min}^{-1}$ (Kropp and Richardson, 2003; Richardson, 1992).

Under certain conditions, it is possible to determine the K_a and k_2 components of k_i separately. For example, if the secondary plot is not linear, this is an indication of an appreciable concentration of a Michaelis-type complex. In this case, the K_a term must be included; by combining Eq. (57.3) and Eq. (57.4) and rearranging, we have

$$[\text{OP}]/k' = K_a/k_2 + [\text{OP}]/k_2 \tag{57.7}$$

Thus, a Wilkinson plot of $[\text{OP}]/k'$ versus [OP] will yield a straight line with slope $1/k_2$, a y-intercept of K_a/k_2, and an x-intercept of K_a. Moreover, from Eq. (57.2), $k_i = k_2/K_a$; therefore, the reciprocal of the y-intercept gives k_i (Richardson, 1992).

An especially useful relationship is given by substituting a percent activity of interest into Eq. (57.5) to yield the inhibitor concentration at a given time of preincubation with enzyme that would yield the particular percent activity. For example,

$$[\text{OP}]_{50} = I_{50} = \ln 2/(k_i \times t) \approx 0.693/(k_i \times t) \tag{57.8}$$

where $[\text{OP}]_{50} = I_{50} =$ the inhibitor concentration required to produce 50% inhibition of the enzyme at a given time, t, of incubation of enzyme and inhibitor at defined conditions of pH, temperature, and ionic strength before adding substrate. Note that the k_i and I_{50} are reciprocally related and that the I_{50} is time dependent. It is valid to calculate an I_{50} from a k_i value when ideal kinetics are observed. However, it is not valid to calculate a k_i from an experimentally determined fixed-time I_{50}, because the I_{50} alone contains no information

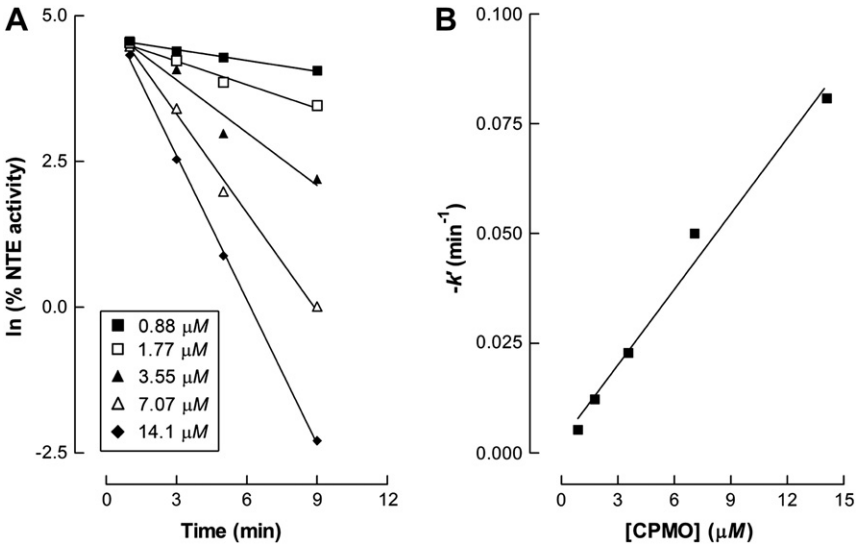

FIGURE 57.7. (A) Primary kinetic plots of ln(% NTE activity) versus time for various indicated concentrations of chlorpyrifos methyl oxon (CPMO). (B) Slopes ($-k'$) of primary kinetic plots versus inhibitor concentration. Data are for hen brain microsomal NTE at pH 8.0 and 37°C. Reproduced with permission from Kropp and Richardson (2003).

about the kinetic behavior of the inhibition reaction. In addition, if inhibitory potency is assessed by measuring fixed-time I_{50} values, it is essential to report the time of preincubation along with the concentration, because the I_{50} decreases as the preincubation time increases (Aldridge and Reiner, 1972; Clothier *et al.*, 1981; Richardson, 1992). For example, using Eq. (57.8), the 20 min I_{50} for chlorpyrifos methyl oxon against hen brain microsomal NTE at pH 8.0 and 37°C may be calculated from the k_i given above to be $0.693/(5.82 \times 10^4\ M^{-1}\ min^{-1})(20\ min) = 5.95 \times 10^{-7}\ M \approx 0.60\ \mu M$ (Kropp and Richardson, 2003).

C. Reactivation

The phosphonylated enzyme can undergo spontaneous reactivation via hydrolysis to yield free enzyme and a phosphonic acid, with an associated pseudo-first-order rate constant, k_3 (the reactivator, water, is present in great excess). The spontaneous rate constant of reactivation, k_3, can be obtained from the relationship

$$\ln(100/\%\ \text{inhibition}) = k_3 t \tag{57.9}$$

for which

$$\%\ \text{inhibition} = [(A - A_t)/(A - A_0)] \times 100 \tag{57.10}$$

where A is the activity of the control, A_t is the activity of the inhibited enzyme at time t, and A_0 is the activity of the inhibited enzyme at $t = 0$. In practice, reactivation is studied by preincubating the enzyme with a concentration of inhibitor that rapidly produces essentially complete inhibition. The inhibitor and enzyme are then rapidly separated or the preparation is diluted sufficiently to prevent further appreciable inhibition of free enzyme, and the return of enzyme activity is measured at timed intervals. The slope (k_3) of the least-squares best-fit line from a plot of ln(100/% inhibition) versus t is determined using linear regression from the initial linear portion of the curve. From Eq. (57.9), it can be seen that the units of k_3 are t^{-1}, e.g. min^{-1}, and that the half-life, $t_{1/2}$, the time required for 50% reactivation, can be determined to be

$$t_{1/2} = \ln 2/k_3 \approx 0.693/k_3 \tag{57.11}$$

The apparent half-life of reactivation can range from minutes to weeks, depending upon the enzyme, inhibitor, pH, and temperature. Reactivation can appear to be slow or nonexistent if aging has occurred, because the aged form of the phosphylated enzyme is stable to hydrolysis and will not reactivate (Jianmongkol *et al.*, 1999; Richardson, 1992).

D. Aging

The inhibited esterase can also undergo aging, e.g. via net loss of the R-group to yield the negatively charged phosphonyl adduct on the active site serine of the enzyme. Aging is characterized by a first-order rate constant, k_4, and the operational definition of this reaction is the time-dependent loss of the ability to reactivate the inhibited enzyme by powerful nucleophiles, such as fluoride ion or oximes. The method of determining aging is similar to that for reactivation. Enzyme is preincubated with a concentration of inhibitor sufficient to produce essentially complete inhibition in a relatively short time. Aliquots are then treated with a reactivator such as fluoride or an oxime and the amount of activity relative to a nonreactivated sample is measured. The first-order rate constant of aging, k_4, can be determined from the relationship

$$\ln[100/(\%\ \text{reactivation})] = k_4 t \tag{57.12}$$

for which

$$\%\ \text{reactivation} = [(AR_1 - AI_1)/(AR_0 - AI_0)] \times 100 \tag{57.13}$$

where AR_1 = activity of reactivated enzyme at t_{aging}, AR_0 = activity of reactivated enzyme at $t = 0$, AI_1 = activity of inhibited enzyme without reactivator at t_{aging}, and AI_0 = activity of inhibited enzyme without reactivator at $t = 0$. The slope (k_4) of the least-squares best-fit line from a plot of ln(100/% inhibition) versus t is determined using linear regression from the initial linear portion of the curve. From Eq. (57.12), it can be seen that the units of k_4 are t^{-1}, e.g. min^{-1}, and that the aging half-life, $t_{1/2}$, the time required for 50% aging, can be determined to be

$$t_{1/2} = \ln 2/k_4 \approx 0.693/k_4 \tag{57.14}$$

The apparent half-life of aging depends upon the enzyme, inhibitor, pH, and temperature. However, NTE inhibited with most neuropathic agents exhibits aging half-lives on the order of several minutes, so that the 1–4 week delay between exposure and appearance of signs of OPIDN is not due to the time required for aging of phosphylated NTE (Jianmongkol *et al.*, 1999; Johnson, 1982; Kropp and Richardson, 2007; Richardson, 1992).

E. Relative Inhibitory Potency (RIP)

The neuropathic potential of an OP compound depends upon its ability to inhibit NTE (and presumably for the NTE–OP conjugate to undergo aging). However, an OP compound will not be able to inhibit NTE to a sufficient degree to produce OPIDN if its cholinergic toxicity is too high to permit survival of a neuropathic dose. Therefore, neuropathic potential of an OP compound is a relative concept that depends upon the ability of the compound to inhibit NTE compared to its anti-AChE activity. Compounds can be screened *in vitro* for relative inhibitory potency (RIP) by measuring k_i or I_{50} values and calculating a ratio:

$$\text{RIP} = k_i(\text{AChE})/k_i(\text{NTE}) \tag{57.15}$$

Because of the reciprocal relationship between the k_i and I_{50} described by Eq. (57.8) above,

$$\text{RIP} = I_{50}(\text{NTE})/I_{50}(\text{AChE}) \qquad (57.16)$$

Thus, when the RIP > 1, the compound is a more potent inhibitor of AChE than NTE, and cholinergic toxicity would be expected to predominate over OPIDN. In fact, when the RIP > 1, the dose required to produce OPIDN tends to be greater than the median lethal dose (LD_{50}) for the compound (Kropp and Richardson, 2003; Richardson, 1992).

For example, although chlorpyrifos methyl oxon (CPMO), the active metabolite of the insecticide chlorpyrifos methyl, would seem to be a potent inhibitor of NTE, with $k_i = 5.82 \times 10^4\ M^{-1}\ min^{-1}$ and 20 min $I_{50} = 0.595\ \mu M$, it is a much more potent inhibitor of AChE, with a $k_i = 1.09 \times 10^7\ M^{-1}\ min^{-1}$ and 20 min $I_{50} = 3.18 \times 10^{-9}\ M$ (3.18 nM), so that the RIP for this compound is 187. This value is $\gg 1$, indicating that OPIDN could not be produced unless the dose were $\gg LD_{50}$ and aggressive therapy for cholinergic toxicity were instituted (Kropp and Richardson, 2003). In contrast, the compound di-*n*-pentyl 2,2-dichlorovinyl phosphate (*n*- pentyl DCV) has an RIP of 0.03 and produces OPIDN at a dose of 2 mg/kg, which is much lower than the LD_{50} dose of 26 mg/kg (Richardson, 1992). OP inhibitors with extremely high selectivity for NTE have been synthesized, e.g. ethyl *n*-octylphosphonofluoridate (EOPF) (Figure 57.3) (Wu and Casida, 1995), which has 20 min I_{50} values for mouse brain NTE and AChE of 0.02 and 54 nM, respectively, yielding an RIP value of 3.7×10^{-4} (i.e. about 2,700 times more potent for NTE than AChE) (Wu and Casida, 1996). Note that EOPF is a chiral compound, and the reported I_{50} and RIP values are for the racemic mixture. Given that inhibitory potency can vary considerably between *R* and *S* forms of OP compounds (Wu and Casida, 1994), it would be of interest to carry out such measurements on resolved isomers.

Because RIP values can encompass several orders of magnitude above and below 1, it is convenient to visualize such data by using log (RIP) as shown in Figure 57.8. It can readily be seen that higher positive numbers correspond to greater cholinergic propensity, as typified by the insecticide active metabolite, CPMO. Likewise, larger negative numbers correspond to greater neuropathic potential, as exemplified by the DN agent, EOPF. It is also interesting to see the steady progression from cholinergic to neuropathic tendency exhibited by the homologous series of dialkyl 2,2-dichlorovinyl phosphates (dichlorvos, DCV) compounds. In this and other series of alkyl OP inhibitors, increasing length of alkyl chains tends to produce decreasing potency against AChE and increasing potency against NTE until maximum selectivity is reached, after which potencies and selectivity decline (Richardson, 1992; Malygin *et al.*, 2003). The highest potency for NTE appears to have been achieved with certain phosphonofluoridates, where the sum of alkyl and alkoxyl chain length is 12–16 atoms, including O and P; in this series, EOPF has the highest potency and selectivity for NTE (Wu and Casida, 1995, 1996).

Determinations of RIP carried out *in vitro* using preparations of AChE and NTE can only assess the neuropathic potential of OP compounds that are direct-acting inhibitors, i.e. compounds that do not require metabolic activation. Such preparations would also not detect effects of detoxification that might occur *in vivo*. To account for the possibility of metabolic activation/deactivation, the system can be augmented by preincubating the compound of interest with xenobiotic metabolic enzymes (or chemical activators, e.g. bromine) before mixing with AChE or NTE preparations (Barber *et al.*, 1999). The concept of the RIP can also be extended to assaying AChE and NTE *ex vivo* and calculating activity ratios after dosing laboratory animals with the compound of interest. Because the adult hen is the species of choice for assessing the neuropathic potential of OP compounds, this species could also be used for *ex vivo* RIP determinations (Richardson, 1992; Richardson *et al.*, 1993). However, despite the fact that rats and mice are not as suitable as hens for studying the clinical and histopathological effects of DN agents, rodent species have AChE and NTE in their nervous systems and can therefore serve as sources of these enzymes for *in vitro* or *ex vivo* determinations of neuropathic potential (Novak and Padilla, 1986; Quistad *et al.*, 2003; Wu and Casida, 1996).

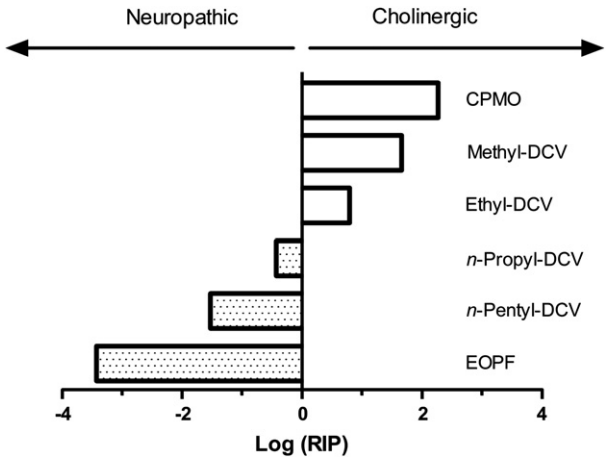

FIGURE 57.8. Spectrum of log values of relative inhibitory potency (RIP) = k_i(AChE)/k_i(NTE), where k_i = bimolecular rate constant of inhibition. As log(RIP) becomes more positive, cholinergic potential increases; as log(RIP) becomes more negative, delayed neuropathic potential increases. CPMO – chlorpyrifos methyl oxon. DCV derivatives refer to symmetrical dialkyl-2,2-dichlorovinyl phosphate (dichlorvos) compounds. EOPF – ethyl *n*-octylphosphonofluoridate. Data from Kropp and Richardson (2003); Richardson (1992); and Wu and Casida (1996).

VI. BIOMARKERS

A. Introduction

A widely quoted definition of ''biomarker'' is that it is ''a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention'' (Atkinson *et al.*, 2001). Although this definition was developed from the standpoint of pharmacology and therapeutics, it can easily be modified to apply to toxicology. In a toxicological setting, a biomarker would consist of an appropriate measure of a chemically induced pathological process, e.g. a response to a toxicant that could be considered injurious or diagnostic of potential injury. Ideally, a toxicological biomarker would represent a biological response that would be pathognomonic of a specific agent or at least a selective indicator of the effects of a class of agents. Thus, a biomarker of a DN agent would involve more than measuring the mere presence of the compound; instead, it would assess a distinctive and preferably early feature of the pathogenesis of OPIDN. Because the earliest known molecular events associated with OPIDN are the inhibition and aging of NTE, the appropriate biomarkers of DN agents would be measurements of these reactions, which could be done via determination of inhibition and aging using enzymology, or through identification of the resulting OP–NTE conjugates using mass spectrometry.

B. Enzymological Measurements of NTE Inhibition and Aging

NTE activity in lymphocytes and platelets was discovered by Dudek and Richardson (1978, 1982), characterized in human populations (Bertoncin *et al.*, 1985; Maroni and Bleecker, 1986), and used in animal (Makhaeva *et al.*, 2003; Richardson and Dudek, 1983; Richardson *et al.*, 1993; Schwab and Richardson, 1986) and human (Lotti *et al.*, 1983, 1986; McConnell *et al.*, 1999) studies to monitor exposures to potentially neuropathic OP compounds. NTE activity is not found in erythrocytes or in plasma or serum. These studies indicate that NTE in lymphocytes, platelets, or whole blood can be assayed and used as a biomarker of exposure to DN agents, particularly if the blood samples are taken within 24 h of acute exposures. Attempts to measure the aging of NTE in lymphocytes or platelets of exposed subjects have apparently not been done. However, given that aging of NTE inhibited by DN agents typically occurs within a half-life of a few minutes (Clothier and Johnson, 1979; Johnson, 1982), aging would be complete by the time that lymphocyte samples could be taken and assayed for activity. Nevertheless, as stated above, given the apparent requirement for aging as well as inhibition of NTE in OPIDN, to help rule out false positives arising from inhibition by Type B (nonaging) inhibitors (Figure 57.5), aging studies ought to be undertaken in future work. As noted below, mass spectrometry can be used to identify the phosphyl adduct on the inhibited enzyme, thus differentiating between inhibited and aged forms.

Recently, a lysophosphatidylcholine (LysoPC) hydrolase activity has been characterized in mouse and human erythrocytes (Vose *et al.*, 2007). This enzyme exhibits a similar inhibitory profile to that of NTE; therefore, it might be used along with lymphocyte or platelet NTE as an additional biomarker of exposure to DN agents. However, high inter-individual variation in LysoPC hydrolase was seen, possibly related to dietary lipids, which would require establishing pre-exposure baseline values for each subject.

In keeping with the concept of the RIP discussed under ''Relative Inhibitory Potency'', above, inhibition of lymphocyte and/or platelet NTE and possibly erythrocyte LysoPC hydrolase should be used in conjunction with inhibition of erythrocyte AChE and plasma butyrylcholinesterase (BChE) to assess the likelihood that an exposure to OP compounds would produce cholinergic and/or delayed neuropathic effects. Erythrocyte AChE inhibition has long been used as a biomarker of exposure to conventional nerve agents or OP insecticides (Lotti, 1995; Wilson and Henderson, 1992). BChE can be sensitive to both conventional and DN agents, and its inhibition could thus serve as a general biomarker for OP agents (Kropp and Richardson, 2007; Van der Schans *et al.*, 2008).

C. Identification of NTE–OP Conjugates using Mass Spectrometry

Mass spectrometry has proved to be an excellent tool for identifying the OP conjugates (adducts) of serine hydrolases such as AChE and BChE (Doorn *et al.*, 2000; Elhanany *et al.*, 2001; Jennings *et al.*, 2003; Kropp and Richardson, 2007; Li *et al.*, 2007; Van der Schans *et al.*, 2008). One approach is to reactivate inhibited esterases with fluoride and to detect the liberated OP fluoridate using gas chromatography–mass spectrometry; however, this technique cannot be used if the esterase conjugate has aged (Degenhardt *et al.*, 2004; Solano *et al.*, 2008). Because NTE inhibited with DN agents undergoes rapid aging (Johnson, 1982), it is important to be able to detect the aged adducts. Therefore, peptide mass mapping would be the current method of choice, whereby the active site peptide containing the phosphyl moiety on the active site serine is identified using mass spectrometry following digestion of the inactivated esterase with trypsin or other proteases (Doorn *et al.*, 2001b). Although some DN agents have extremely high potency and selectivity for NTE, in general there will be some degree of inhibitory overlap with other serine hydrolases (e.g. see Figure 57.8). Accordingly, in addition to examining NTE, it would be useful to acquire mass spectrometry data on OP conjugates of other potential esterase targets, such as AChE and BChE, with particular attention being paid to the aged species.

The classical view of the aging reaction of OP-inhibited serine esterases, based on studies of soman-inhibited AChE, is that aging involves an S_N1 reaction at a ligand carbon and transient formation of a carbocation that dissociates from the enzyme (Michel *et al.*, 1967; Shafferman *et al.*, 1996). The traditional model has been confirmed using mass spectrometry for BChE inhibited by a variety of phosphates and phosphonates and allowed to age in the presence of [^{18}O]-H_2O (Li *et al.*, 2007). Thus, it appears that cholinesterases inhibited by phosphates or phosphonates undergo aging via S_N1 cleavage of an O–C bond rather than S_N2 cleavage of a P–C bond.

However, it is important to realize that mechanisms of inhibition and aging can differ depending upon the esterase, inhibitor, and stereochemistry of the inhibitor. For example, the aging of AChE inhibited by ethyl *N*,*N*-dimethylphosphoramidocyanidate (tabun) was shown to proceed via hydrolytic P–N bond scission with loss of dimethylamine (Elhanany *et al.*, 2001). In addition, the mechanism of inhibition of AChE, BChE, and cholesterol esterase by the resolved stereoisomers of isomalathion has been shown to differ between the (1*R*) and (1*S*) forms, and the mechanism of aging in each case appears to proceed via S_N2 displacement of a secondary leaving group by water, involving cleavage of a P–S bond (Doorn *et al.*, 2000, 2001a, b, 2003). A subsequent study of BChE inhibited with racemic isomalathion confirmed that the major pathway for aging involved scission of the P–S bond, but relatively small peaks in the mass spectrum indicated that O–C and S–C cleavage could also occur as minor pathways (Li *et al.*, 2007).

For NTE inhibited by phosphates or phosphonates, the aging mechanism has been thought to be consistent with an S_N2 reaction at phosphorus (Johnson, 1982), although this hypothesis has not been rigorously tested. With respect to stereochemical influences on aging, limited studies indicate that both enantiomers of certain phosphonates inhibit NTE, but only one enantiomer undergoes aging (Johnson *et al.*, 1985, 1986). As expected, the isomer that inhibits NTE and ages produces OPIDN. In contrast, the isomer that inhibits NTE without aging does not produce OPIDN. Furthermore, the nonaging isomer protects against neuropathy from subsequent administration of a neuropathic OP compound (Johnson and Read, 1987; Johnson *et al.*, 1988). Some racemic phosphonates have been found to produce OPIDN at lower than expected threshold levels of inhibited/aged NTE (i.e. <70%), possibly because of potentiation or promotion of subclinical axonopathy by the nonaging enantiomer, presumably by the action of the nonaging enantiomer on one or more targets other than NTE that could be involved in repair or regeneration of neural lesions (Lotti, 1992).

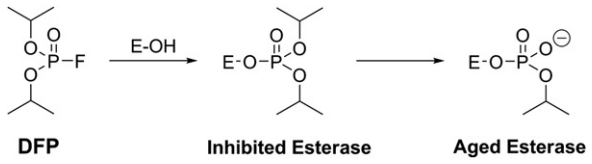

FIGURE 57.9. Inhibition and aging of serine esterases by diisopropylphosphorofluoridate (DFP). The active site serine is organophosphorylated in the inhibition step. Aging results in net loss of an isopropyl group to yield the monoisopropylphosphoryl esterase. This mode of inhibition and aging has been established for acetylcholinesterase (AChE), butyrylcholinesterase (BChE), and neuropathy target esterase catalytic domain (NEST) (Kropp and Richardson, 2007).

Perhaps the most thoroughly investigated compound with respect to inhibition and aging of serine hydrolases is diisopropylphosphorofluoridate (DFP). Using a variety of techniques, this compound has been shown to inhibit AChE (Clothier and Johnson, 1979; Kropp and Richardson, 2006; Millard *et al.*, 1999a, b; Ordentlich *et al.*, 1996, 1998), BChE (Kropp and Richardson, 2007; Li *et al.*, 2007; Masson *et al.*, 1997), NTE (Clothier and Johnson, 1979; Williams, 1983; Williams and Johnson, 1981), and NEST (Kropp *et al.*, 2004) by organophosphorylation of the active site serine followed by aging to yield a monoisopropylphosphoryl adduct, as shown in Figure 57.9. Esterase adducts have been directly demonstrated using mass spectrometry for AChE (Kropp and Richardson, 2006), BChE (Kropp and Richardson, 2007; Li *et al.*, 2007), and NEST (Kropp *et al.*, 2004), and in the case of BChE, the mechanism of aging has been unequivocally demonstrated to involve scission of an O–C bond in an isopropyl group (Li *et al.*, 2007). These results, taken together with those for soman-inhibited AChE (Michel *et al.*, 1967) and BChE inactivated with a variety of phosphonates and phosphates (Li *et al.*, 2007), indicate that it is reasonable to expect that aging of phosphonylated or phosphorylated serine esterases, including NTE and NEST, will proceed via O–C bond scission. This insight enables accurate prediction of the biomarker species to be sought in the mass spectra of serine esterases inhibited with phosphonates or phosphates.

Among the type A inhibitors of NTE (Figure 57.5), the phosphoramidates are perhaps the most enigmatic to be studied to date. For example, mipafox, the phosphoramidate analog of DFP, is capable of producing suprathreshold inhibition (>70%) of neural NTE *in vivo* and causing OPIDN (Davis and Richardson, 1980). Therefore, mipafox-inhibited NTE was expected to undergo aging (Davis *et al.*, 1985). Indeed, early studies showed that NTE inhibited by mipafox was intractable to reactivation, indicating the possibility of aging as a mechanism for yielding a nonreactivatable enzyme (Johnson, 1982). In the case of mipafox-inhibited NTE, however, nonreactivation was thought to be too rapid to measure by standard kinetic approaches (Johnson, 1982). Consequently, aging of mipafox-inhibited NTE had only been inferred and not directly demonstrated. Subsequently, Milatovic and Johnson (1993) showed that NTE inhibited by mipafox could be reactivated by prolonged treatment with KF at acidic pH. This surprising finding led to the conclusion that aging had not

occurred after all. Instead, it was surmised that an unusual property of the bond between the phosphoramidate and the active site serine was responsible for the stability of the complex as well as the perturbation of NTE that leads to OPIDN.

It had been known for some time that esterases inhibited by mipafox are resistant to reactivation, but conventional aging could not be proved or disproved by classical techniques. It is also known that the phosphoramido hydrogen on *N*-alkylphosphoramidates is acidic and that its removal yields a resonance-stabilized anion (Eto, 1974). Such a mechanism would explain the relative stability of phosphoramidated esterases in a manner that does not require loss of an alkylamino group to yield a negative charge on the adduct (Richardson, 1995). Moreover, reprotonation of the phosphoramide anion would generate a neutral species subject to attack by a nucleophile and account for the reactivation of mipafox-inhibited NTE at low pH. Under the acidic conditions usually employed for peptide mass spectrometry, the putative anion would be reprotonated. Thus, it can be hypothesized that the species attached to NTE after its inhibition by mipafox and allowing time for aging is the intact *N*,*N*′-diisopropylphosphorodiamido moiety. Such a result would indicate that the inhibited enzyme has not lost an isopropyl or isopropylamino group due to an aging process analogous to the net loss of an isopropyl group in the aging of DFP-inhibited NTE or NEST.

In contrast to the results for mipafox-inhibited NTE, early limited studies indicated that mipafox-inhibited BChE or AChE undergo irreversible aging, because the enzymes could be reactivated soon after inhibition, but not after 18 h (Milatovic and Johnson, 1993). The chemistry of phosphoramidates suggest that aging could involve hydrolytic loss of an alkylamino group. For example, acid-catalyzed P–N bond fission has been observed for certain *N*-alkyl phosphoramidates (Eto, 1974) and the aging of tabun-inhibited AChE has been shown to proceed via P–N bond scission with loss of dimethylamine (Elhanany *et al.*, 2001).

Considerations of probable mechanisms of aging for mipafox-inhibited serine esterases suggest that mass spectrometry studies would support a deprotonation mechanism for NTE or NEST and hydrolytic P–N bond scission for AChE and BChE. As summarized in Figure 57.10, these expectations were borne out for human recombinant NEST, which was used as a surrogate for NTE (Kropp *et al.*, 2004), and BChE, respectively (Kropp and Richardson, 2007). However, mipafox-inhibited AChE gave the surprising result, confirmed by immunoprecipitation and mass spectrometry, of loss of both isopropylamine groups to yield a simple phosphate adduct on the active site peptide (Kropp and Richardson, 2006). Thus, in the case of phosphoramidates, aging appears to be nonclassical for the three esterases investigated; moreover, the biomarker is distinctly different in each case.

VII. BIOSENSORS

A. Nanostructured Electrochemical Biosensors to Measure Enzyme Activity

Recently developed nanofabrication methods using layer-by-layer (LBL) self-assembly provide exciting new opportunities to design multilayered, functional, biosensor interfaces to measure enzyme activity. Since the LBL technique was first introduced (Decher and Hong, 1991), significant work has been done to fabricate polymer and organic thin films through alternating deposition of positively and negatively charged polyelectrolyte species on solid surfaces (Decher, 1997; Decher *et al.*, 1992; Lvov *et al.*, 1994; Ruths *et al.*, 2000; Schmidt *et al.*, 1999). Polyelectrolyte layers typically have a thickness on the order of a nanometer, allowing ultrathin interfaces to be fabricated that have minimal mass-transfer resistance. LBL self-assembly using polyelectrolytes is thus well suited for biosensor development studies, because, by minimizing

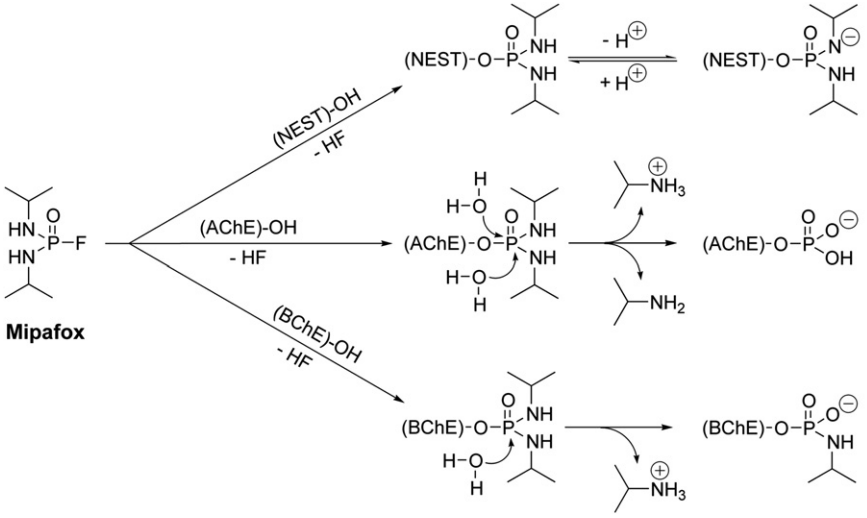

FIGURE 57.10. Inhibition and aging of serine esterases by *N*,*N*′-diisopropylphosphorodiamidic fluoride (mipafox). (A) Neuropathy target esterase catalytic domain (NEST) showing aging by reversible deprotonation of a phosphoramido nitrogen. (B) Acetylcholinesterase (AChE) showing aging by displacement of both isopropylamine groups by water. (C) Butyrylcholinesterase (BChE) showing aging by displacement of a single isopropylamine group by water. Reproduced with permission from Kropp and Richardson (2007).

mass-transfer resistances, the intrinsic enzyme kinetics can be measured. LBL assemblies of polyelectrolytes have been used to develop nanostructured biosensor interfaces that encapsulate enzymes (Hassler *et al.*, 2007; Kohli *et al.*, 2006, 2007a) and functional nanoparticles (Kohli *et al.*, 2005, 2007b). Electrochemical biosensors that measure the activity of a protein have been widely used to determine analyte concentrations, in both research and commercial applications (Prodromidis and Karayannis, 2002). Biosensors can detect protein activity either directly (Hassler and Worden, 2006) or indirectly through reaction coupling (Peteu *et al.*, 1996, 1998). The indirect approach greatly expands the range of enzyme activities that can be characterized using electrochemical biosensors. For example, reaction coupling has been used to measure NTE activity outside of the electrode, e.g. in blood samples (Makhaeva *et al.*, 2003, 2007) or AChE, BChE, and NEST activity incorporated into the electrode (Kohli *et al.*, 2007a).

B. Electrochemical Biosensor Arrays for High-Throughput Analysis

Microsystems technologies, particularly thin film deposition of microelectrodes and formation of microfluidic channels, have been widely applied to biological analysis systems (Bergveld, 1996; Urban, 2000), such as DNA-processing chips (Raisi *et al.*, 2004) and other lab-on-chip implementations (Kovacs, 2003; McFadden, 2002; Ziegler, 2000). Most of these devices rely on optical transduction mechanisms (Rabbany *et al.*, 1994; Vo-Dinh *et al.*, 2003) that often cannot quantitatively measure several important protein activities, such as redox reactions. In contrast, these parameters are readily measured using versatile electrochemical techniques. Traditionally, electrochemical measurements are performed at the ''beaker scale'', but newer technologies allow such systems to be miniaturized for improved performance and high-throughput analysis. Complete three-electrode electrochemical cells, including thin film Ag/AgCl reference electrodes, have been integrated on silicon surfaces (Yun *et al.*, 2004). Thin film reference electrode stability has been improved using Nafion or polyurethane coatings (Nolan *et al.*, 1997) and complex micromachined structures (Suzuki, 2000; Suzuki *et al.*, 1999). A remaining challenge is to adapt these new technologies to the construction of miniaturized electrochemical arrays for high-throughput protein activity characterization. Such biosensor array platforms must be compatible with the self-assembled biosensor interfaces, thus

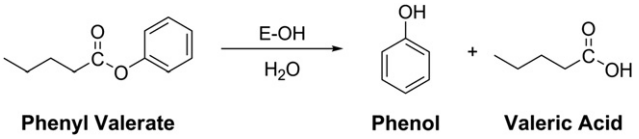

FIGURE 57.11. Reaction of a serine esterase with phenyl valerate to yield phenol and valeric acid (Kayyali *et al.*, 1991).

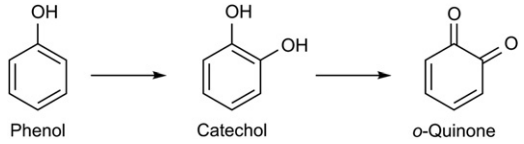

FIGURE 57.12. Reactions catalyzed by the two activities of tyrosinase. Phenol is first oxidized to catechol and then to *o*-quinone. Reproduced with permission from Kohli *et al.* (2007a).

establishing requirements for electrode materials, geometries, surface smoothness, and overall array architecture.

C. Assembly of Electrochemical Biosensor Interfaces for Serine Hydrolases

The natural reaction substrates and products of serine esterases are not electrochemically active. In order to transduce these esterase activities into an electrical signal, a two-enzyme reaction pathway can be assembled on a gold electrode. In the first reaction, the esterase of interest converts a phenyl ester (e.g. phenyl valerate) into phenol (Figure 57.11). In the second reaction, tyrosinase converts phenol first to catechol, and then to *o*-quinone (Figure 57.12), which can be electrochemically reduced back to catechol at an electrode, yielding a measurable current (Eq.57.17) (Kohli *et al.*, 2007a).

$$o\text{-Quinone} + 2H^+ + 2e^- \rightarrow \text{Catechol} \qquad (57.17)$$

Tyrosinase is a copper-containing oxidase (Coche-Guerente *et al.*, 2001; Forzani *et al.*, 2000), which possesses the two different activities illustrated in Figure 57.12. In the first step, referred to as the hydroxylase or cresolase activity, molecular oxygen is used to hydroxylate phenol to form catechol. In the second step, known as the catecholase activity, the enzyme oxidizes catechol to *o*-quinone, which is simultaneously oxidized by oxygen to its original form, with the production of water. The *o*-quinone is electrochemically active and can be reduced back to catechol, as illustrated above in Eq. (57.17).

By co-immobilizing tyrosinase with a serine esterase on a gold electrode, it is possible to establish a multistep reaction pathway that allows the activity of the esterase to be determined indirectly via measurement of *o*-quinone reduction at the electrode. The molecular architecture of a bi-enzyme sensor interface is shown schematically in Figure 57.13.

In practice, the fabrication of these bi-enzyme biosensors is relatively straightforward. Gold electrodes are scrupulously cleaned in ''Piranha solution'' [(concentrated) H_2SO_4: 30% (w/w) H_2O_2, 7:3 (v/v)] and then dipped in a 5 mM solution of thioctic acid in ethanol for 30 min. The electrodes are washed with ethanol, dried under nitrogen, and dipped in positively charged poly-L-lysine (PLL) solution for 45 min. The PLL solution is prepared by adding

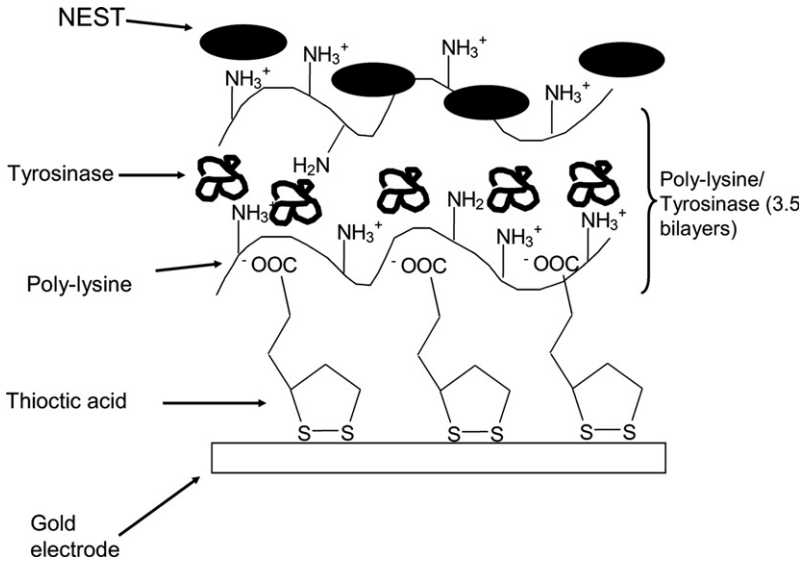

FIGURE 57.13. Molecular architecture of bi-enzyme biosensor electrode containing tyrosinase and neuropathy target esterase catalytic domain (NEST). Reproduced with permission from Kohli *et al.* (2007a).

12 mg of PLL in 50 ml of 20 mM phosphate buffer (pH 8.5). The electrodes are then rinsed with water and dipped in an aqueous solution of negatively charged tyrosinase (0.2 mg/ml) for 1 h. The last two steps are repeated 3.5 times to create 3.5 PLL-Tyr bilayers, with PLL being the topmost layer. The electrodes are washed with water and dipped in a 0.1 mg/ml solution of a serine esterase (e.g. AChE, BChE, or NEST) in 100 mM phosphate buffer, pH 7.0, for 1 h. The electrodes are then washed with water, dried under nitrogen, and dipped in phosphate buffer (0.1 M, pH 7.0) for testing. All steps are done at room temperature (approximately 22°C) (Kohli *et al.*, 2007a).

D. Electrochemical Measurements of Serine Esterase Activity

The electrochemical properties of serine esterase-containing biosensor interfaces are readily characterized. Each biosensor is immersed in a stirred buffer solution and maintained at a potential of −100 mV (vs an Ag/AgCl reference electrode). For example, NEST activity was measured indirectly via the output current of the electrode for a variety of phenyl valerate concentrations. As shown in Figure 57.14, the first step involves the diffusion of the ester (e.g. phenyl valerate) through a stagnant film from bulk solution to the enzyme layer. The NEST enzyme then hydrolyzes phenyl valerate to phenol, which is then oxidized to *o*-quinone by tyrosinase. Reduction of *o*-quinone at the surface of the electrode generates a current and regenerates catechol, which can then be reoxidized by tyrosinase. This internal recycling between catechol and *o*-quinone provides a mechanism for signal amplification, thereby enhancing biosensor sensitivity (Kohli *et al.*, 2007a).

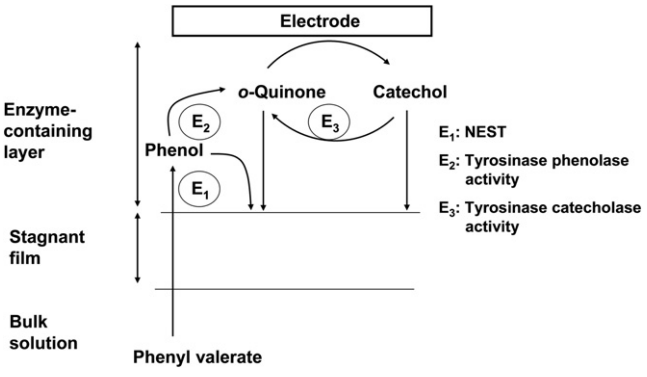

FIGURE 57.14. Schematic representation of the pathway that leads to the generation of current in the bi-enzyme biosensor containing tyrosinase and neuropathy target esterase catalytic domain (NEST). Reproduced with permission from Kohli *et al.* (2007a).

The response of the biosensor to aliquots of ester can be measured at a variety of pH values and applied potentials. For a typical NEST biosensor, the highest signal-to-background ratio is obtained at pH 7.0 and a working electrode potential of −0.1 V relative to an Ag/AgCl reference electrode. At this potential, addition of phenyl valerate to a stirred aqueous solution triggers a rapid increase in the NEST biosensor signal, with a time constant of about 5 s. BChE can be substituted for NEST, with a similar current vs time response using phenyl valerate as substrate. For AChE, phenyl acetate is a better substrate than phenyl valerate. Current increases linearly with phenyl acetate concentration ($R^2 = 0.989$) in the range of 0.5 to 16 µM, reaching saturation at approximately 40 µM. Current vs time response and concentration calibration curves similar to those obtained for NEST and AChE can be obtained for BChE in the bi-enzyme electrode. Sensitivities of the electrodes obtained from the slopes of the initial linear portions of the concentration calibration curves were found to be 180,

25, and 87 $nA\mu M^{-1}\,cm^{-2}$ for AChE, BChE, and NEST, respectively, where AChE used phenyl acetate, and BChE and NEST used phenyl valerate as substrate. Control experiments were also done in which each of the substrates was delivered to a gold electrode containing only PLL-Tyr bilayers. The current sensitivities obtained in these control experiments were negligibly small – always less than $0.5\ nA\mu M^{-1}\,cm^{-2}$, indicating that the signal is mediated by the esterase activity (Kohli *et al.*, 2007a).

The ability of the biosensors to detect chemical agents was confirmed by adding a known serine esterase inhibitor, phenylmethylsulfonyl fluoride (PMSF), to the solution. The electrode response decreased in a concentration-dependent manner (Kohli *et al.*, 2007a). Using a combination of biosensors containing different target enzymes, e.g. AChE and NEST, it would be possible to obtain real-time differential data that could be used to distinguish exposures to conventional versus DN agents.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

DN agents have not yet been used in warfare or terrorism. However, their possible use must be seriously considered, because it is straightforward to design and synthesize the compounds based on established methods in OP chemistry. Thus, a conventional nerve agent can be reengineered to produce a DN agent. The use of DN agents would be catastrophic, because there are no accepted means of prophylaxis or treatment, and the effects are devastating and permanent. NTE is the presumptive target for initiation of OPIDN. Accordingly, lymphocyte NTE has been used as a biomarker of exposure, and the NTE catalytic domain (NEST) has been incorporated into a biosensor for detection of DN agents. However, the precise physiological function of NTE and its role in the pathogenesis of OPIDN remain to be elucidated. Therefore, further mechanistic understanding is needed in order to improve upon existing biomarkers and biosensors as well as to develop preventive and therapeutic measures.

CHAPTER 58

Monitoring of Blood Cholinesterase Activity in Workers Exposed to Nerve Agents

DANIEL JUN, JIRI BAJGAR, KAMIL KUCA, AND JIRI KASSA

I. INTRODUCTION

Determination of the activity of blood cholinesterases (erythrocyte, RBC acetylcholinesterase, AChE, EC 3.1.1.7 and plasma butyrylcholinesterase, BuChE, EC 3.1.1.8) is currently the most important manner for conformation of the diagnosis of organophosphate (OP) poisoning, for monitoring of the recovery of intoxicated person, or for forensic study purposes (Bajgar, 2004, 2005; Eddleston *et al.*, 2003; Karalliedde *et al.*, 2003; Pope *et al.*, 2005). It is necessary to examine the whole picture of intoxication, i.e. not only biochemical examinations but clinical signs allowing more precise assessment of the prognosis of the intoxication. The evidence supporting AChE as the primary site of both OP nerve agents and pesticides action has been summarized by many authors (Bajgar, 1985, 1991; Lotti, 2000; Marrs, 1993; Mars *et al.*, 1996; Taylor, 1985). Their findings include the following observations: symptoms of OP poisoning are similar to those of the AChE inhibitor physostigmine; the *in vivo* LD_{50} value for a variety of OPs correlates well with the inhibition efficacy to AChE determined *in vitro*; and cholinesterase reactivators (e.g. oximes), anticholinergics (e.g. atropine), and reversible AChE inhibitors (e.g. carbamates) can attenuate OP toxicity. However, there are ample documented data showing that AChE inhibition is not the only important biochemical change during intoxication. These data have described many other changes accompanied by the development of intoxication that might contribute to OP toxicity. They have included changes of other enzymes, neurotransmitters, immune changes, anaphylactoid reaction, behavior, etc. The evidence includes the data indicating that prophylactic/therapeutic drugs might also have multiple sites of action similar to those observed during intoxication (Bajgar, 1991, 1992; Bardin *et al.*, 1987a, b; Cowan *et al.*, 1996, Kassa, 1998). Nevertheless, the first reaction of OP is interaction with cholinesterases in the blood stream (Bajgar, 1985, 1991; Benschop *et al.*, 2001) and then in the target tissues – the peripheral and central nervous system (Bajgar, 1985, 1991; Bardin *et al.*, 1987; Green, 1958, 1983; Marrs, 1993; Mars *et al.*, 1996). The delayed neurotoxic effect is caused by a reason other than cholinesterase inhibition. The neurotoxic esterase has been described as the target site for this symptom; however, only some OPs are neurotoxic in that sense (Abou-Donia *et al.*, 1990; Lotti, 1992; Johnson, 1990, 1992; Johnson and Glynn, 1995; Slotkin *et al.*, 2008).

The mechanism of AChE inhibition for all the OP nerve agents is practically the same, i.e. phosphorylation or phosphonylation of the esteratic site of AChE.

Monitoring the cholinesterase changes during the intoxication is at present the best indication of the severity of OP poisoning as well as a basis for antidotal therapy.

Both the toxicodynamics and toxicokinetics of OP nerve agents can be explained by their biochemical characteristics of interacting with cholinesterases and other hydrolases. Inhibition of cholinesterases in the blood is the first target for OPs according to the principle of ''first come, first served'' (Benschop and de Jong, 2001).

AChE and BuChE differ in their enzymatic properties and physiological function (Massoulié *et al.*, 1993; Darvesh *et al.*, 2003). However, there are other types of cholinesterases such as benzoylcholinesterase, propionylcholinesterase, etc. AChE splits neurotransmitter acetylcholine (ACh) at the cholinergic synapses. A similar reaction is also observed in erythrocytes but its function is not yet known in detail, as is also the case with the function of BuChE activity in plasma, though there is evidence that BuChE plays an important role in cholinergic neurotransmission and could be involved in other nervous system functions, in neurological diseases, and in nonspecific detoxification processes (Darvesh *et al.*, 2003).

II. DETERMINATION OF CHOLINESTERASES

Determination of cholinesterase activity is based on a number of principles. In general, an enzyme is added to the buffered or unbuffered mixture and the enzymatic reaction is initiated by adding the substrate. Different parts of the reaction mixture are determined (continually or noncontinually), i.e. unhydrolyzed substrate or reaction products, either directly or indirectly (Augustinsson, 1971; Holmstedt, 1971; Witter, 1963). The conditions must be

chosen very carefully because of different factors influencing the activity (Reiner and Simeon-Rudolf, 2000, 2006).

According to the procedure and laboratory instrumentation, the most common methods of cholinesterase determination are as follows: electrometric (e.g. Michel, 1949), titration (e.g. Nenner, 1970), manometric (e.g. Witter, 1963), colorimetric detection of the unhydrolyzed substrate (e.g. Hestrin, 1949), measurement by the change of pH using an indicator (Winter, 1960), spectrophotometric (e.g. Siders *et al.*, 1968; Voss and Sachsse, 1970; Worek *et al.*, 1999a), fluorimetric (e.g. Sasaki 1964; Kusu *et al.*, 1990), radiometric (e.g. Israel and Lesbats, 1987), calorimetric (Konickova and Wadso, 1971), polarographic (Fiserova-Bergerova, 1969), enzymatic (Abernethy *et al.*, 1986; Israel and Lesbats, 1987), and others, e.g. near infrared spectroscopy (Domjan *et al.*, 1998). These methods are also suitable for the detection of cholinesterase inhibitors using biosensors (Brimijoin and Rakonczay, 1986; Cremisini *et al.*, 1995; De Jong *et al.*, 1988; Walker *et al.*, 2007) or immunochemical assay for detection of chemical warfare agents (Lenz *et al.*, 1997a, b).

A very sensitive and commonly used method for cholinesterase determination was described by Ellman *et al.* (1961), based on hydrolysis of the thiocholine substrates acetyl- and butyrylthiocholine or others. After enzymatic hydrolysis, the relevant acid and thiocholine are released and thiocholine by its SH-group is detected using 5,5′dithiobis-2 nitrobenzoic acid forming 5-mercapto-2-nitrobenzoic acid determined spectrophotometrically at 412 nm (Figure 58.1).

Sometimes this method is used with specific inhibitors (tetraisopropyl pyrophosphoramide for BuChE inhibition and BW284C51 for AChE inhibition) and there are many modifications described in the literature. This method is in good correlation with other methods. It is sufficiently specific and sensitive and it is used for different purposes in many laboratories around the world. Expression of the activity varies greatly, usually as µmoles of substrate hydrolyzed per minute (time) per ml of material examined (e.g. plasma, serum) or per mg of weight tissue or tissue protein. From these values, the expression of the activity in units can be derived (it is the quantity of enzyme catalyzing µmol of substrate per minute at standard conditions). In the clinical laboratory, the enzyme activity can be also expressed as 1 mol of substrate hydrolyzed per liter or kg (cat/l, kg) per second, which is the hydrolysis of 1 mol of substrate hydrolyzed per second per liter or kg ($mol \cdot s^{-1} \cdot l^{-1}$ or kg^{-1}). There are many publications dealing with the review and modifications of cholinesterase determination. One of the last methodical works improving Ellman's method (Ellman *et al.*, 1961), including a description of the methods, is a paper published by Worek *et al.* (1999a).

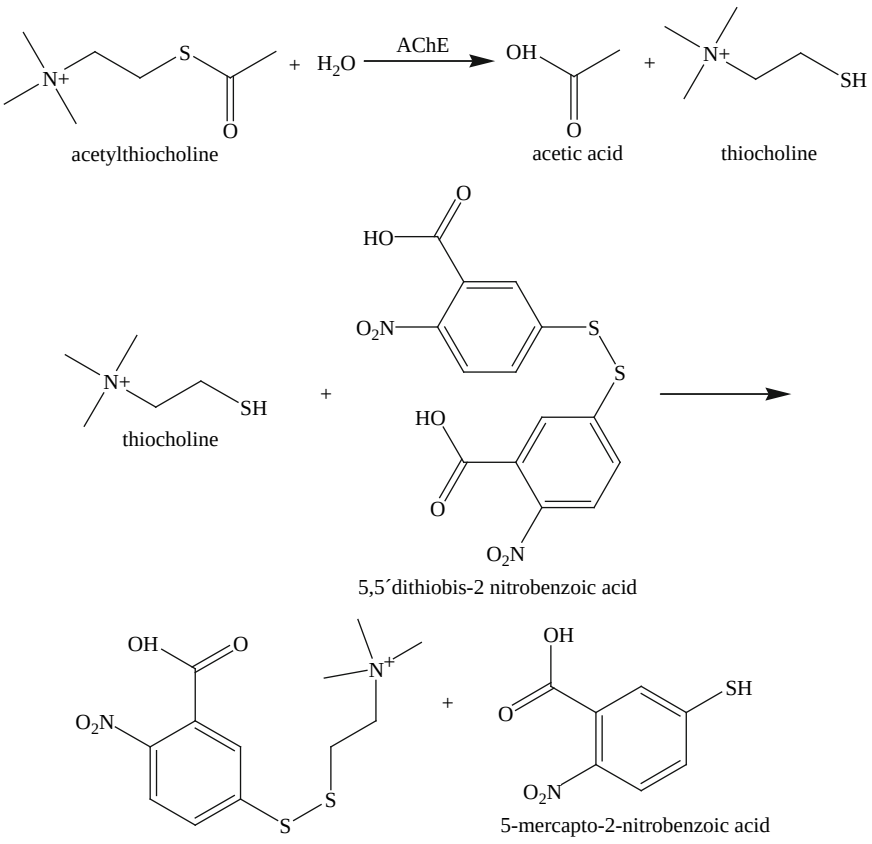

FIGURE 58.1. Acetylthiocholine is hydrolyzed by AChE to acetic acid and thiocholine, which forms yellow 5-mercapto-2-nitrobenzoic acid after reaction with Ellman reagent.

III. FACTORS INFLUENCING ACTIVITY OF CHOLINESTERASES

The influencing of BuChE activity by gamma irradiation, stress, gravidity, certain neurological and psychiatric disorders, hormones, and medical drugs has been demonstrated (Bajgar, 1985, 1998; Brown *et al.*, 1981). The elevation of BuChE activity is not so frequent; an increase in children with nephritic syndrome has been observed; an elevated ratio of BuChE/LDL cholesterol indicates an increase in the risk of cardiovascular diseases (Kutty, 1980; Navratil and Bajgar, 1987). The involvement of BuChE with the fat (cholesterol) metabolism has been suggested by Van Lith *et al.* (1991) and Van Lith and Beynen (1993). The relationship between BuChE activity and experimentally induced diabetes mellitus in rats was also mentioned (Annapurna *et al.*, 1991).

In clinical biochemistry, BuChE determination in the plasma or serum is more frequently used than that of AChE in the red blood cells. Except for intoxication with OP or carbamates (CMs), a BuChE decrease indicates either a reduced enzyme synthesis or a decrease in the number of production of cells in the liver (Masopust, 1983). A special case of diminished BuChE activity is the hereditary affected by the presence of atypical variants of BuChE (Brown *et al.*, 1981; Whittaker, 1980).

There are many other factors influencing BuChE activity and the diagnostic importance of diminished BuChE activity is important for the following states – except hereditary decrease of the activity and poisoning with OP nerve agents and OP/CM pesticides, congenital deficiency, liver damage, acute infection, chronic malnutrition, metastasis (especially liver), myocardial infarction, dermatomyositis, intoxication with carbon disulfide or mercury, and obstructive jaundice (Bajgar, 1991; Bardin *et al.*, 1987a, b; Kutty, 1980; Molphy and Ratthus, 1964; Wyckoff *et al.*, 1968).

Determination of AChE activity is not so widely used in clinical laboratories. A decrease in red blood cell AChE activity in pernicious anemia has been demonstrated; diminished erythrocyte AChE activity is typical for paroxysmal nocturnal hemoglobinemia and ABO incompatibility (Rakonczay, 1988). AChE activity in the erythrocyte membrane can be considered as an indicator of erythrocyte membrane integrity. Increased AChE activity in rectal biopsy is of great diagnostic significance in Hirschsprung's disease, especially in the presence of its atypical molecular form (Bajgar and Hak, 1979; Rakonczay, 1988). There are other publications demonstrating increased AChE activity in the amniotic fluid during pathologic development of the neural tube (Bonham and Attack, 1983). AChE activity in erythrocytes and cerebrospinal fluid is also diminished in some endogenous depressions and other psychiatric disorders; however, the results presented are not quite clear at present (Bajgar, 1985; Bohnen *et al.*, 2007; Martucciello, 2008; Rakonczay, 1988; Skau, 1986).

IV. DIAGNOSIS OF OP POISONING

The determination of cholinesterases in the blood is the basic method for diagnosis and therapy monitoring for OP poisoning though some doubts exist, some preferring the clinical signs of poisoning as a leading tool for OP poisoning diagnosis and monitoring (Bardin *et al.*, 1987a, b). The determination of AChE and BuChE activity in the whole blood is possible. The decrease in these activities is a good marker but the diagnostic validity is limited to the statement that some factors causing a decrease in blood cholinesterases are present. In connection with the anamnestic data (exposure to OP), this is important information. The determination of the red blood cell AChE or plasma BuChE is more informative. There are some discussions dealing with AChE and BuChE activity but which is more important for the diagnosis? In general, AChE activity in the red blood cell can be considered to be more important for diagnosis with nerve agents than plasma BuChE activity. However, there are some discussions dealing with the validity of the BuChE determination. This enzyme was described as a not very good marker of OP poisoning and its determination was proposed for exclusion from the recommended biochemical procedures (Bardin *et al.*, 1987a, b; Molphy and Ratthus, 1964; Wyckoff *et al.*, 1968). The temporal profile of BuChE was studied in a cohort of 25 OP-poisoned patients to examine their relationship to the development of intermediate syndrome. The study suggests that BuChE reflects the clinical course of poisoning and that intermediate syndrome may be associated with a persistent BuChE inhibition (Khan *et al.*, 2001). Israeli authors also described a direct correlation between the degree of BuChE inhibition levels and the severity of intoxication with OP pesticides (Weissmann-Brenner *et al.*, 2002). According to Aygun *et al.* (2002), in the acute phase of OP poisoning, low levels of AChE support the diagnosis of OP poisoning but do not show a significant relationship to the severity of poisoning. The preference of AChE determination has been demonstrated by Worek *et al.* (1999b) – BuChE activity determination for diagnosis and therapeutic monitoring provides no reliable information on AChE status. This is in good agreement with our experimental results (Bajgar, 1998). Plasma BuChE activity is in some cases a good marker for diagnosis of OP pesticide poisoning. It is necessary to exclude a diminishing of BuChE activity caused by other reasons. In all cases, the simple cholinesterase determination provides us with information about the decrease of enzyme activity without specification of the factor causing this phenomenon. A more detailed specification is possible using special methods not available in all clinical laboratories.

For the purposes of occupational medicine, the determination of cholinesterases in the blood of workers intoxicated with OP is obligatory. A decrease in activity below 70% of normal values is an indicator that the worker should

not come into contact with OP. However, the normal values varied within the laboratories depending on the method of determination.

For practical purposes (individual and interindividual variation), determination of individual norm activity is recommended (this approach is better than that of calculating the decrease from an average value) as well as separate determination of cholinesterases, the red blood cell AChE and plasma BuChE. The activity determined in the whole human blood corresponds to about 10% of BuChE and 90% of AChE. This is different to rats where this ratio is 29% of BuChE and 71% of AChE (Bajgar, 1972). Erythrocyte AChE activity seems to be more useful for these purposes than BuChE activity in plasma.

There are other biological materials available for special purposes – amniotic fluid, cerebrospinal fluid, and bioptic materials. From these samples, tissue obtained by rectal biopsy is used most frequently (diagnosis of Hirschsprung's disease). An elevated AChE activity in the rectal tissue/homogenate (detected histochemically/biochemically) is one of the good diagnostic markers indicating a need for surgical treatment of Hirschsprung's disease and a criterion for diagnosis and management of obstipation (Kobayashi *et al.*, 2002). The presence of an unusual AChE band after electrophoretic separation supports the diagnosis (Bajgar and Hak, 1979; Rakonczay, 1988). The same (either AChE elevation or the presence of a new electrophoretic AChE form) in the amniotic fluid can be applied for the diagnosis of malformation of the neural tube development during pregnancy (Bonham and Attack, 1983). AChE activity in cerebrospinal fluid is also changed in some pathological states; however, the diagnostic validity is not so high and can be considered as a complementary examination (Koponen and Riekkinen, 1991).

In OP poisoning, it is necessary to check vital functions (cardiac, ventilation) and other clinical signs and according to the symptoms to apply different biochemical examinations and treatment. Diagnostic criteria are mostly based on anamnesis and the state of ventilation (Bardin and Van Eeden, 1990; Bardin *et al.*, 1987a, b). Serum electrolytes (especially potassium), BUN, and creatinine are indicated to assess the degree of volume depletion by secretory losses. Arterial blood gas, blood pH, glucose, lactate, and pyruvate allow us to assess the degree of hypoxia/hypercapnia/acidosis in the presence of respiratory distress. The neurological examination involves, e.g. recording of muscle action potential of abductor digiti minimi after stimulation of nerve ulnaris. A quantitative correlation is shown between red blood cell AChE activity and paraoxon concentration in plasma. In these cases, muscle function was severely disturbed when the red blood cell AChE activity was inhibited by more than 90% (Thiermann *et al.*, 2002).

Direct determinations of the toxic agent (OP nerve agent or pesticide) in the circulating system are also possible. However, the parent compound will circulate intact for a short period of time and detection will not be possible for more than approximately a few hours after exposure. Metabolites circulate for a longer time and are mostly excreted in urine. A metabolite of sarin (*O*-isopropyl methylphosphonic acid) could be traced in urine and plasma from victims after the Tokyo subway sarin terrorist attack (Noort *et al.*, 1998, 2002). For some OP pesticides (parathion, paraoxon), detection of *p*-nitrophenol in urine is an indicator of exposure (Bajgar, 1985). However, the retrospectivity of these methods is limited. Detection using an immunoassay of nerve agents is now in progress. The antibodies against soman may have the appropriate specificity and affinity for immunodiagnosis of soman exposure (Lenz *et al.*, 1997a, b; Miller and Lenz, 2001).

Methods for the determination of blood cholinesterase inhibition (AChE and BuChE) do not allow for the identification of the OPs and do not provide reliable evidence for exposure at inhibition levels less than 10–20%. Moreover, they are less suitable for retrospective detection of exposure due to *de novo* synthesis of enzymes. Recently, a method was developed which is based on reactivation of phosphylated cholinesterase and carboxylesterase (CarbE) by fluoride ions. Treatment of the inhibited enzyme with fluoride ions can inverse the inhibition reaction yielding a restored enzyme and a phosphofluoridate which is subsequently isolated and quantified by gas chromatography and phosphorus-specific or mass spectrometric detection (De Jong and Van Dijk, 1984; Polhuijs *et al.*, 1997a, b). Human (and monkey) plasma does not contain CarbE but its BuChE concentration is relatively high (70–80 nM; Myers, 1952; De Bisschop *et al.*, 1987), much higher than the concentration of AChE in blood (ca. 3 nM; Heath, 1961). The plasma of laboratory animals, such as rats and guinea pigs, contains considerable concentrations of CarbE in addition to cholinesterases. This method allows partial identification of the OP whereas the lifetime of the phosphylated esterase (and consequently the retrospectivity of the method) is only limited by spontaneous reactivation, *in vivo* sequestration, and aging. The rate of the latter process (aging) depends on the structure of the phosphyl moiety bound to the enzyme and on the type of esterase. Phosphylated CarbEs generally do not age. Based on this method for retrospective detection of exposure to OP, the exposure of victims of the Tokyo incident to an OP, probably sarin, could be established from analysis of their blood samples (Fidder *et al.*, 2002; Polhuis *et al.*, 1997a, b). Fluoride-induced reactivation of OP-inhibited AChE is a reliable and retrospective method to establish OP exposure. It is limited to compounds that regenerate with fluoride ions. A novel and general procedure for diagnosis of exposure to OPs, which surpasses the limitations of the fluoride reactivation method, was described (Van der Schans *et al.*, 2002). It is based on the rapid isolation of BuChE from plasma by affinity chromatography, digestion with pepsin followed by liquid chromatography with the mass spectrometric analysis of phosphylated nonapeptides resulting in the digestion of inhibited BuChE with pepsin. The method can be applied

for the detection of exposures to various OP pesticides and nerve agents including soman. This approach is very valuable and represents a new field for the improvement of diagnosis with OP nerve agents and pesticides. A comprehensive review of the methods for retrospective detection of exposure to toxic scheduled chemicals has been published by Noort *et al.* (2001, 2002).

As was mentioned previously, a decrease in cholinesterase activity is the factor indicating (after the exclusion of other factors) an exposure to OP nerve agents or other cholinesterase inhibitors. This simple determination does not allow us to make certain decisions dealing with the antidotal therapy (especially the repeated administration of reactivators) and has low prognostic validity. Therefore, a new test of the reactivation has been described (Bajgar, 1991). The principle of the reactivation test is double determination of the enzyme, the first without and the second with the presence of a reactivator in the sample. The choice of reactivator is dependent on the availability of the oxime; however, in principle it is necessary to have in these parallel samples the same concentrations of reagents. The concentration of the reactivator (usually trimedoxime, but other oximes such obidoxime, pralidoxime or HI-6 are also possible) must be no higher than the oxime concentration which causes the hydrolysis of the substrate (acetyl- or butyrylthiocholine), i.e. the oxime concentration is lower than 10^{-3} M because these higher oxime concentrations cause artificial hydrolysis of the substrate (Patočka *et al.*, 1973).

OP poisoning is very complex and there exist many biochemical changes to be registered. Though the assessment of sensitivity and specificity was rather subjective, it is clear that there are two or three parameters that are most sensitive: cholinesterase determination (depending on the type of OP, either AChE or BuChE), the possible determination of OP metabolites in the blood and determination of the phosphonyl moiety on the target enzyme (if possible). In the case of developed intoxication when convulsions occurred, tension of the blood gases is also a good marker; however, these changes are not very specific. The same approach can be applied to lactate. This is not surprising because of the existence of convulsions including hyperactivity of the diaphragm (and thus disturbed ventilation, low oxygen saturation, and an increase in acid metabolites). It should also be mentioned that the validity of these parameters is changed during intoxication. The changes in transaminases, LDH and γ-GT, indicating liver damage can be caused by solvents used in commercially available OP insecticides. A low validity in the number of RBC or leukocytes is also indicated. As for CS and TAT stress markers, it is clear that OP intoxication represents a stress situation. In this context, an increase in ALT can also be considered as a stress marker and not indicative of liver damage.

Determination of AChE or BuChE molecular forms is interesting and useful for improvement of the diagnosis of OP poisoning. It was demonstrated that these forms are inhibited in different manners – some of the forms are resistant (a low molecular weight), and some of them are very sensitive (a high molecular weight). When the total AChE activity is determined, the value obtained is a ''mean'' of the activities of these forms. The changes in the cyclic nucleotides are interesting but not valid for blood. They were determined during animal experiments with toxic OPs and are of more interest in connection with the nervous system. Esterases and AP, generally hydrolases, are sensitive but the inhibition potency of different OPs is very variable: for nerve agents these hydrolases are not valid, and, for some OP insecticides like malathion, they are sometimes more sensitive than cholinesterases. In conclusion, diagnosis of OP poisoning represents a serious problem. The development of the new specific methods mentioned (fluoride reactivation, tandem MS analysis of enzymatic digests of BuChE) is of high importance for more precise diagnosis of OP nerve agent poisoning. The extensive review of Noort *et al.* (2002) dealing with biomonitoring of exposure to chemical warfare agents (not only nerve agents) is strongly recommended. From a practical point of view in the clinical laboratory, it is necessary to monitor basic physiological functions, cholinesterases, and other biochemical parameters not only for diagnostic purposes but also preferably for the regulation of treatment.

V. MONITORING OF BLOOD CHOLINESTERASE ACTIVITY IN WORKERS WITH NERVE AGENTS

For the purposes of occupational medicine, the determination of cholinesterases in the blood of workers intoxicated with OP is obligatory. However, the normal values varied within the laboratories depending on the method of determination. Systematic monitoring of workers with nerve agents was performed at our department from 1962 to 1963; however, the results presented contain determinations during 40 years (1964–2004). Because of the large number of results, the results are limited to RBC AChE only although plasma BuChE activity was also determined.

A. Methods for Determination

Modified Hestrin's method (Hestrin, 1949) was used initially. This method is based on colorimetric detection of unhydrolyzed substrate, ACh. Acetylcholine reacts with hydroxylamine quantitatively in alkaline solution after reaction with $FeCl_3$. The activity was determined in RBC hemolysate with distilled water (1:20). The method was modified and activity was expressed as μmoles of hydrolyzed acetylcholine per minute and per ml.

From 1964, a method described by Winter (1960) using an autoanalyzer (Technicon, USA) system was evaluated. The method is based on determination of acetic acid

released from the substrate hydrolyzed (ACh) and detected with phenol red. AChE activity in RBC hemolysate with distilled water (1:10) was determined (pH 7.6, phosphate buffer 37°C). The activity was expressed as µmol of acetic acid per 10 min.

From 1972 to 1975, Ellman's method (Ellman *et al.*, 1961), modified for the autoanalyzer, was used. The activity was expressed as ncat/liter. The same method was used for this determination using kinetic methods and instruments, Vitatron (Eefde, Holland) (1976–1990) and Uvicon 952 (Kontron Instruments, Switzerland), from 1991 to 2004.

B. Correlation Among Methods

To achieve comparable results (unification of the activity, i.e. one scale), all the activities were recalculated to ncat/liter. Recalculation of the activities was performed simply using: U/liter = 16.6667 ncat/liter. However, in the case of different substrates (esters of choline and thiocholine), correction was made according to correlation analysis ($y = 2.0188x + 2.2458$ and $r_{xy} = 0.9998$). Moreover, this correlation was demonstrated previously including not only Ellman's and Winter's methods (Ellman *et al.*, 1961; Winter, 1960) but also the potentiometric method.

C. Subjects

International inspectors: 28 males (two determinations, 2000 and 2002), seven selected (more determinations), age unknown.

Students: 21 medical students, 10 female, 11 male, age 19–20.

Workers in the department: 18 males, from these nine selected for long-term study, and 23 females, from these 13 selected for long-term study. Last determination was performed at age 60 (female) and 65 (male), respectively.

Ages at the beginning of study: 24 to 40 years for males, and 19 to 48 years for females. All determinations were performed during the years 1964 to 2004.

D. Data Analysis and Findings

Because of the large number of examinations, the results are demonstrated only for the RBC AChE. The first step was a simple survey of AChE activities divided between females and males. The next step was analysis of individual results and trends. Some attempts to detect a decrease of AChE activity in the case of potential exposure to nerve agents were made. The results are not fully evaluated and can be considered as preliminary.

The results of Hestrin's method (Hestrin, 1949) are documented as an average activity of the RBC AChE. Normal AChE activity was determined to be 104.9 ± 8.5 ncat/l and the coefficient of variation was 27.1%. The method was relatively difficult and is shown for information only. The results of AChE activities for all persons are shown in Figure 58.2. Selected results of RBC AChE activity determination are shown in Table 58.1.

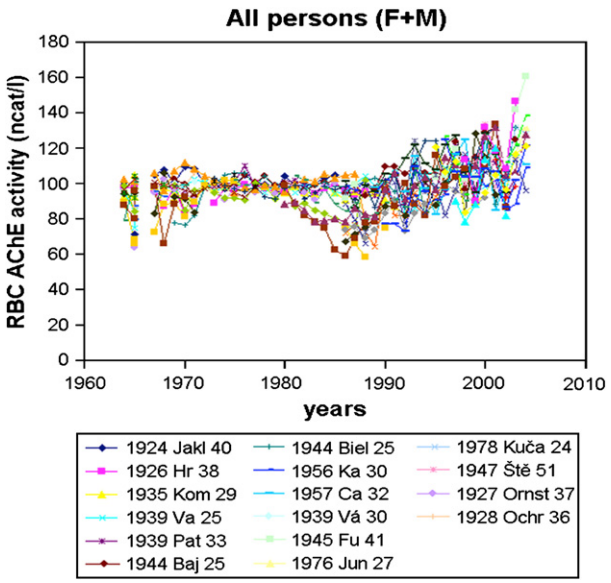

FIGURE 58.2. AChE activities of all monitored persons.

The correlation of activities in hemolysate and whole blood is shown in Figure 58.3.

In general, there were certain tendencies to decrease cholinesterase activity (especially RBC AChE activity) during their work at the department. Some rare examples of suspect intoxications were observed in the cholinesterase monitoring as well as an RBC AChE decrease in workers during their work with high concentrations of nerve agents (e.g. inhalation exposure experiments) (Figure 58.4).

In a practical way, the best appreciation of cholinesterase was performed using individual norms for RBC AChE. It seems to be the most sensitive parameter for monitoring cholinesterase changes in exposed workers, followed by a sensitivity for whole blood hemolysate. Plasma BuChE activity is not so specific and is a sensitive parameter. A decrease of 30% of individual norms seems to be critical for further consideration. In conclusion, cholinesterase determination in blood (especially RBC AChE) is a good parameter for monitoring and laboratory examination of

TABLE 58.1. Selected results of RBC AChE activity determination

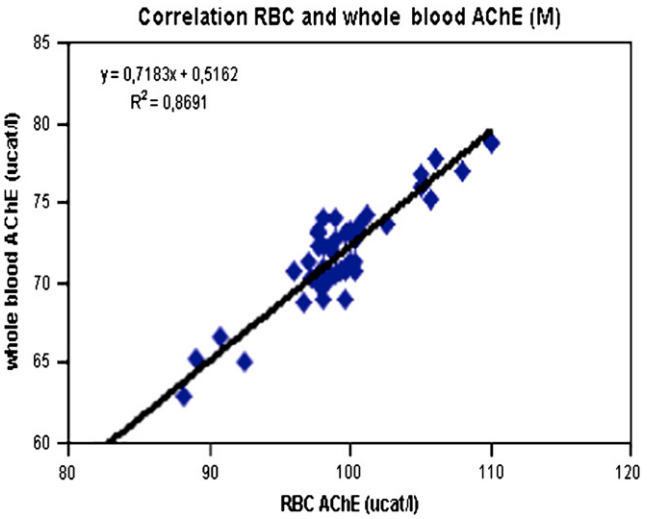

FIGURE 58.3. Correlation between RBC and whole blood AChE.

workers with highly toxic nerve agents, reflecting possible exposure to these agents.

Variation of RBC AChE is relatively high. Therefore individual levels were considered to be better, and the decrease of 30% under individual norms was decided to be a limit for exclusion of workers from active work with nerve agents. A further decrease can be considered a significant diagnostic marker for suspect intoxication. According to the decrease, the classification of steps of intoxication can be assumed: a decrease of 30–50% indicates mild poisoning, 50–70% medium poisoning and 70–90% severe intoxication. This decrease is in good agreement with results for humans and animals (Bajgar, 1992). Increased AChE activity was also observed for males (not significant) and is in agreement with other results (Augun *et al.*, 2002). Similar results were obtained by other authors, for example no

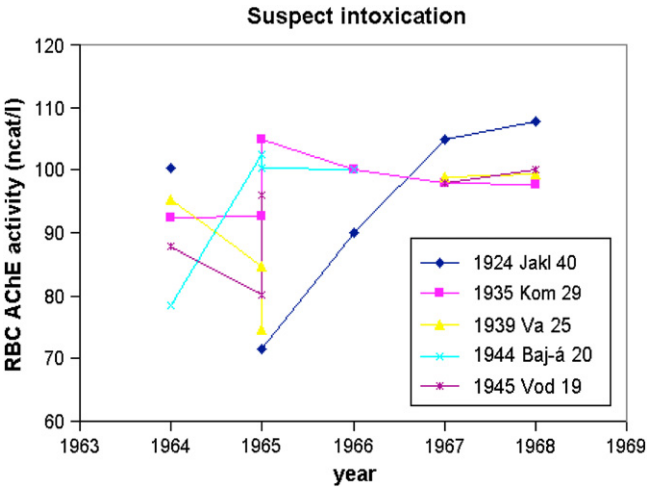

FIGURE 58.4. Suspect OP intoxication.

significant differences in RBC AChE activity between males and females (Rumenjak, 1998), and a tendency to an increase in activity with age (not significant). In general, the values of RBC AChE activity are very good compared with the results of other authors (Augun *et al.*, 2002; Rumenjak, 1998; Zhou *et al.*, 2003).

VI. CONCLUDING REMARKS AND FUTURE DIRECTION

This chapter describes the sensitivity of blood cholinesterase as a diagnostic parameter for monitoring workers exposed to nerve agents. The sensitivity to detect changes in response to nerve agent exposure is ordered as RBC AChE > whole blood cholinesterases > plasma BuChE. Normal cholinesterase activity assayed with different methods is in good correlation. RBC AChE or whole blood cholinesterase can be considered a good marker for the monitoring of nerve agent exposure.

Acknowledgments

This work was supported by the project of the Ministry of Defense (Czech Republic) OPUOFVZ200603 (INTOX – ''A new method of prophylaxis, decontamination, diagnostics and therapy after intoxication with nerve agents and yperits''). Thanks are due to former researchers at the Department of Toxicology, Drs A. Jakl, V. Hrdina, and J. Tulach (in memoriam) for starting this work, and to Mrs M. Zechovska and M. Gregorova (in memoriam) for technical assistance.

CHAPTER 59

Strategies to Enhance Medical Countermeasures After the Use of Chemical Warfare Agents on Civilians

DAVID A. JETT AND DAVID T. YEUNG

The information in this chapter is provided for educational purposes only and does not necessarily represent endorsement by, or an official position of, the National Institute of Neurological Disorders and Stroke or any other Federal agency.

I. INTRODUCTION

The use of chemical warfare agents (CWAs) has historically been a primary concern of military personnel due to their devastating physical and psychological effects when employed on the battlefield. However, largely due to the 2001 terrorist attacks in the USA, there is now a heightened awareness of biological, radiation/nuclear, and chemical threats to the civilian population. As a result of these new threats, agencies within the Department of Health and Human Services (DHHS) and other federal agencies have sustained a highly focused effort to assess and, if necessary, improve upon current emergency response capabilities in the event of an actual terrorist event. These efforts include both nonmedical countermeasures such as personal protective equipment for first responders who must enter a contaminated site, and medical capabilities such as safe and effective antidotes and diagnostic tools to reduce mortality and morbidity after a chemical attack or accident. In 2006, the US Congress appropriated funds to the National Institutes of Health (NIH) to implement the National Strategic Plan and Research Agenda for Medical Chemical Countermeasures (NIAID, 2007). This program, led by the National Institute of Neurological Disorders and Stroke (NINDS) and National Institute of Allergy and Infectious Diseases (NIAID) with participation from five other NIH Institutes and Centers, is called ''Countermeasures Against Chemical Threats (CounterACT)'' (http://www.ninds.nih.gov/counteract). The goal of the CounterACT program is to develop safer and more effective therapeutics to treat victims exposed during a chemical incident. Complementing this goal, the CounterACT program also supports the research and development of novel diagnostic technologies, which could be utilized after a chemical incident to determine the proper course of medical intervention.

II. SCOPE OF RESEARCH

The CounterACT program supports drug development at all stages from target identification to lead optimization to advanced preclinical and clinical trials. The program focuses on basic and translational research that is relevant to the development of novel therapeutic or diagnostic techniques that will enhance our medical response capabilities during a chemical emergency. New medical countermeasures/technologies that have no practical utility during a mass casualty incident are not considered in this program. A high priority of the program is to identify alternative routes of administration for FDA-approved therapeutics that would be safe, effective, and easy to administer during a mass casualty scenario (e.g. intramuscular injection). Similarly, alternative physical and/or chemical formulation of existing therapeutics to prolong their chemical stability is also a program priority. Enhancement of shelf-life would permit these therapeutics to be stockpiled and strategically positioned for rapid deployment in response to a chemical incident.

The CounterACT program also supports mechanistic studies to identify targets for therapeutic/diagnostic development. There are efforts under way to develop standardized *in vitro* and *in vivo* experimental models to determine the efficacy of promising therapeutics. The program also funds initial and advanced efficacy screening studies performed under good laboratory practices (GLP) using either new and/or established experimental models, to include nonhuman primates. Finally, the CounterACT program also supports clinical studies, including clinical trials, of therapeutics that have advanced past the preclinical phase. In the CounterACT program, special consideration is given to research that is relevant to people who are particularly

vulnerable, including the young, the elderly, and individuals with pre-existing medical conditions.

III. COUNTERACT PROGRAM STRUCTURE

From its inception, the CounterACT program has employed a strategy of building partnerships among laboratories within industry and academic sectors (Figure 59.1), and it has relied on the experience and resources within the Department of Defense (DoD). The DoD has been the primary federal agency responsible for research with CWA, including countermeasure development. The DoD has assembled and supported many of the world's experts in the field of CWA research. The NIH also has a vast pool of experts in scientific areas that are very relevant to some of the central questions being posed in this field. For example, the nerve agents cause seizures and the NIH has funded research on seizures caused by epilepsy and other illnesses for decades. The partnership between DHHS and DoD facilitated by CounterACT has led to excellent collaborations among scientists who would otherwise rarely interact. These collaborations have already produced promising novel approaches in the development of medical chemical countermeasures. The CounterACT program is composed of over 30 individual Research Projects, Contracts, and Research Centers of Excellence located in over 20 states within the USA. Most of these have collaborations with other US and foreign laboratories resulting in over 50 funded primary investigators in over 40 different laboratories. This network of researchers maintains collaborative interaction through sharing new and exciting results at annual meetings sponsored by the NIH. Each year, new collaborations among scientists in varied disciplines such as neuroscientists and pulmonary experts with similar interests are formed.

IV. THE CIVILIAN THREAT SPECTRUM AND SPECIAL CONCERNS

Chemical threats can be defined as highly toxic chemicals that could be used in a terrorist attack, or those that could be released from transportation and storage facilities during an accident or after a natural disaster causing mass casualties. The civilian threat spectrum includes not only traditional CWAs, but also thousands of other highly toxic industrial chemicals (TICs). However, based on availability and the feasibility of mass exposures, the number of chemicals that pose a serious threat is probably much smaller. Some TICs are stored in large industrial facilities and transported by rail and other means across the USA. Accidents and fatalities involving human exposures to these TICs are not that uncommon (Broughton, 2005; Varma and Mulay, 2006; Buckley *et al.*, 2007; Wenck *et al.*, 2007) (Figure 59.2),

FIGURE 59.2. Train wreck and chlorine spill in Graniteville, SC, in 2005. (www.cen.online.org June 23, 2008)

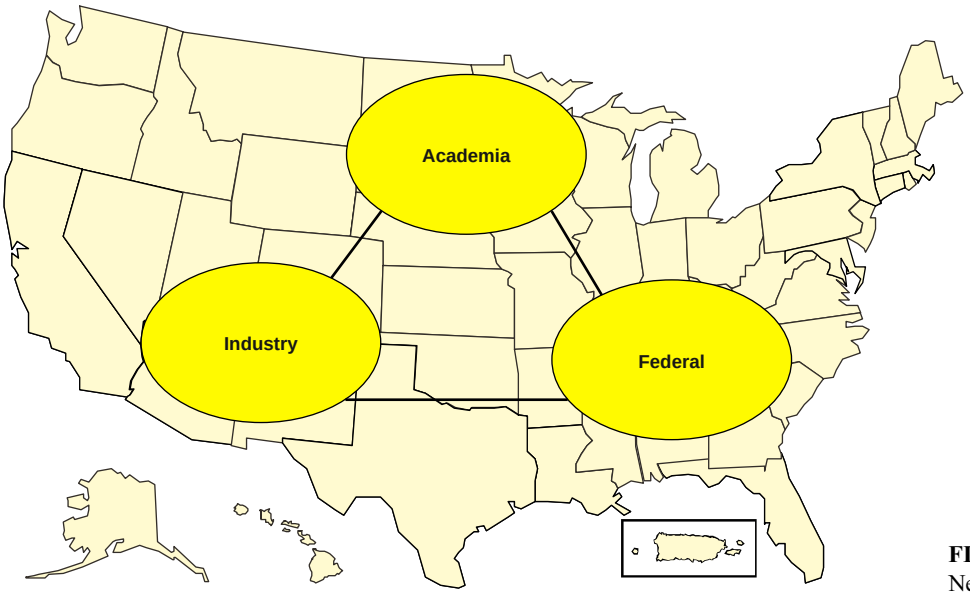

FIGURE 59.1. CounterACT Research Network partnerships.

while CWAs are rarely implicated outside military facilities or off the battlefield. These CWAs can be divided into four general categories: traditional nerve agents such as sarin and VX, vesicating agents such as sulfur mustard, pulmonary agents such as chlorine and phosgene, and metabolic poisons such as cyanide. Detailed descriptions of medical interventions for each of these CWAs can be found elsewhere in this book, and will only be briefly discussed to illustrate the different approaches undertaken by the NIH civilian research community to develop medical countermeasures against threat agents.

Military research on the effects of the organophosphorus (OP) nerve agents and the mustard gases has been ongoing for several decades since their discovery and use in the past world wars. This work along with some efforts in the nonmilitary research community has led to the development of useful therapeutics and diagnostic tools primarily for use to protect those on the battlefield. Of particular note are the developments of more effective personal protective equipment (PPE), prophylactic drugs such as pyridostigmine bromide (PB) that reversibly binds to OP nerve agent (Gordon *et al.*, 2005; Tuovinen *et al.*, 1999), and portable antidote kits like the MARK-1 autoinjector (Rebmann *et al.*, 2008). Differences between the civilian threat and the military threat pose some unique challenges to researchers (Figure 59.3). First, typical military personnel are fit and healthy and between the ages of 18 and 45, whereas the civilian demographic is much broader including pediatric and elderly segments, as well as individuals with preexisting medical conditions such as asthma, heart diseases, or diabetes. These factors will be extremely important when deciding the specific type and dosage of medical countermeasures to be administered during a chemical emergency. Fortunately, some military countermeasures can be adapted to special populations such as children (Baker, 2007; Henretig *et al.*, 2002). However, the development and validation of good animal models to simulate these special segments of the population are still urgently needed.

Another important potential difference between the military and civilian sectors is that military officials may be able to predict with some degree of certainty when CWAs could be used, and thus arm military personnel with pre- and post-exposure countermeasures, such as PB and MARK-1 kits. Since it is impossible to predict when a civilian attack will occur, the NIH has been primarily focused on treating victims after an exposure to CWAs, with the possible exception of some work on prophylactic treatments that could be administered to first responders who must enter a contaminated site.

Military Focus:
- **Warfighter: 18-45 and Healthy**
- **Open air environment**
- **High number of casualties is the goal**
- **Prophylactic measures is focus**

Civilian Focus:
- **Pediatric - Elderly**
- **Pre-existing Medical Conditions**
- **Could happen in closed environment**
- **No need for high casualties**
- **Post-exposure therapies is focus**
- **First responders and DeCon personnel**

FIGURE 59.3. Civilian and military challenges in countermeasure development.

V. PRETREATMENTS

Pretreatments are defined in this chapter as those medical countermeasures to be administered before CWA exposure (see Figure 59.4). Personnel that would be pretreated with medical countermeasures include first responders such as emergency medical technicians (EMTs), other emergency department medical personnel including those that may be exposed within an emergency department, and persons responsible for site decontamination. In theory, prophylactic drugs would be administered in conjunction with proper PPE to first responders before they enter a CWA ''hot zone''. However, depending on possible adverse effects and pharmacokinetics of the proposed drugs, there may be some operational difficulties in the implementation of a prophylaxis program. For example, compliance by otherwise healthy individuals may present an issue if there are potential side effects. Another obstacle to a prophylaxis program is the time needed for the proposed drug(s) to achieve or maintain maximal therapeutic levels when a first responder arrives at the contaminated site. However, if these challenges can be overcome, pretreatments against the toxic effects of chemical agents for emergency first responders would represent a significant advancement in the response capabilities of the nation. In addition to prophylactic drugs, better dermal and ocular medical protectants should also be considered for inclusion as pre-exposure treatments, especially for medical personnel who may have to work in areas where off-gassing may occur by individuals exposed to CWAs.

The only pretreatment currently approved by the FDA for nerve agent is PB, which was first approved for treating myasthenia gravis and is now approved for treating soman

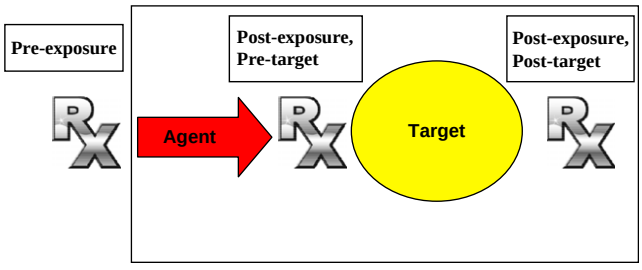

FIGURE 59.4. Different opportunities for medical intervention to reduce mortality and morbidity cause by CWAs.

only. It is to be used by military personnel at high risk of exposure to soman on the battlefield. It is a reversible inhibitor of acetylcholinesterase (AChE) and protects it from permanent inhibition by soman. Because it is itself an inhibitor of the target enzyme in nerve agent toxicity, it is contraindicated after exposure and AChE inhibition has already occurred. The US military has led the effort to explore other potential pretreatments. One effort involves the use of serum-derived or recombinant butyryl-cholinesterase (BuChE) as a stoichiometric scavenger of nerve agent. This could be given as a prophylactic treatment. Previous animal studies have shown that injection of exogenous human BuChE enzyme can protect guinea pigs and Cynomolgus macaques from death against very high doses of soman or VX (Lenz *et al.*, 2006). The challenge with this stoichiometric approach is reaching and maintaining an effective dose when each protein molecule only binds one molecule of nerve agent. The issue of immunogenicity can be a problem with protein and antibody approaches. Alternative approaches with small molecules acting on cholinesterases and related targets are being examined as pre- and post-exposure therapies within the CounterACT program.

VI. POST-EXPOSURE PRE-TARGET PROPHYLACTIC THERAPIES

Most CWAs reach their physiological targets at toxic levels to cause serious illness and even fatality only minutes after exposure. The medical intervention approach in this case is to reverse the toxic action at the target site immediately or treat the physiological response as soon as possible. This latter approach will be further discussed in the section below. Another therapeutic possibility is that some CWAs may exert their toxic effects more slowly and not reach the target site at critical levels until after some period of time. This may be due to the route of exposure such as the relatively slower dermal versus the more rapid inhalation route, or due to slower toxicokinetics and/or toxicodynamics. In this instance, the opportunity for medical intervention may be greater, and a ''post-exposure, pre-target'' approach would be beneficial (Figure 59.4). Under this paradigm, PB (or other reversible cholinesterase inhibitors) may be utilized to protect peripheral AChE before the systemic concentration of irreversibly inhibited OP nerve agent–AChE reaches a critical level. Drugs that act as prophylactic treatments can also act on the agent before it reaches the target. The theoretical post-exposure, pre-target approach is a function of the ratio of bound-to-free agent at the time a therapeutic drug is administered.

Similarly, therapeutics that detoxify the chemical agent from systemic circulation, such as protein scavengers of nerve agent or newer cobalamine-based molecules that bind and scavenge cyanide, could work as well. The Cyanide Antidote Kit has been used for several years to remove cyanide from circulation by forming cyanomethemoglobin (using nitrites) or thiocyanate (using sulfur donors) complexes that are less toxic and more readily excreted. Next generation cyanide antidotes may include drugs that could preserve mitochondrial respiration, sulfur donors with longer half-life, or novel nitric oxide-based approaches.

VII. POST-EXPOSURE POST-TARGET TREATMENT

For many CWAs (e.g. nerve agents, cyanide, etc.), there is little opportunity to medically intervene when the dose is high and/or rapidly delivered to the target site. In these situations, high doses of these CWAs are almost always fatal. If the action at the target site does not cause immediate death, there are several strategies that can be employed to reduce the impending morbidity and fatality. At the molecular level, AChE reactivators such as oximes can be administered during a nerve agent exposure incident to remove nerve agent from the active site of AChE. Administration of oxime therapy will only be successful if irreversible covalent modification of the nerve agent–AChE complex has not occurred (a process called ''aging''). ''Unaged'' AChE enzyme is thus restored to the active state and can continue the hydrolysis of the neurotransmitter acetylcholine (ACh). This intervention approach was developed through an intimate knowledge of the molecular mechanism of nerve agent toxicity.

In cases where less is known about mechanisms at the molecular level, or there are no available drugs that can modify actions at the target site, the intervention approach is to treat the effects of target site activation (or inactivation). For example, at sublethal doses of nerve agents, medical intervention primarily involves combating the effects of nervous system activation and cholinergic crisis. As discussed in other chapters, atropine is used to block overstimulation of cholinergic receptors, and anticonvulsants such as diazepam are used to prevent or treat seizures. Similarly, victims exposed to a sublethal concentration of the fast-acting CWA cyanide are largely treated with ventilation and supportive care to delay mortality and morbidity until transportation to medical facilities. An important area of research in the CounterACT program is to identify new approaches (e.g. better surfactants) to mitigate the pulmonary edemas that typically develop after lung injury caused by agents such as chlorine.

Whether there is sufficient time after an exposure to the CWA for a therapy to be beneficial is dependent on the initial dose. This will depend on the initial level of the agent released and how close a victim is to the point of release, or ground zero. If the dose is low, the risk of an acute life-threatening intoxication will likely not be an issue, but there is evidence that acute sublethal exposures to chemical nerve agent may be associated with long-term neurological sequelae (Hoffman *et al.*, 2007; Yamasue *et al.*, 2007).

Some agents such as sulfur mustard may cause a delayed toxicity after initial exposure or long-term pulmonary effects such as fibrosis years later (Emad and Emad, 2007a, b). Therefore, medical interventions aimed at improving the long-term health outcomes of nonlethal exposures are critical. Since the immune responses observed in the pulmonary system after sulfur mustard or exposure to TICs share similar characteristics, it is likely that therapeutic drugs that prevent, slow, or halt the processes of inflammation and subsequent cellular degeneration will probably have great utility across many different types of chemical agents. The CounterACT program is funding research to determine whether drugs such as anti-inflammatory, anti-oxidant, anti-necrotic/apoptotic compounds, or those that promote cell survival such as growth factors, are effective against CWA threats.

VIII. DIAGNOSTIC TECHNOLOGIES

Proper diagnosis of chemical poisoning can sometimes be an essential part of medical intervention in terms of how to choose the correct treatments and how to monitor effectiveness of a treatment. Because some agents require treatments that may themselves have serious adverse side effects, and some agents may require different kinds of antidotes, technologies that provide medical personnel with information on the chemical or class of chemical agent could significantly improve medical outcomes. Improved rapid diagnostic techniques/technologies for the purpose of differential diagnosis, triage, detection of subclinical exposures, prognosis, and prediction of tissue damage fall into this category. This would include devices for detecting biomarkers (genomic, proteomic, metabonomic) in blood, urine, saliva, lavage fluid, as well as medical diagnosis standards or ''toxidromes'' to help medical personnel identify the best medical interventions. Another example would be when considering the diagnosis of seizure activity and appropriate treatments. The muscular effects of OP nerve agents may mask or mimic signs of seizure activity. A field deployable electroencephalograph (EEG) suitable for use by first responder medical personnel could be used to detect potential nonconvulsive seizures during a chemical event.

IX. BASIC/MECHANISTIC RESEARCH AND TARGET IDENTIFICATION

Support of basic or fundamental research efforts is an important component of the NIH Mission (http://www.nih.gov/about/#mission). Realizing this goal, the NIH CounterACT program supports basic research efforts to identify molecular mechanisms of toxicity exerted by chemical threat agents for the purpose of identifying novel therapeutic targets. For example, the program supports research on understanding the mechanisms of nerve agent-induced seizures with respect to temporal and regional changes, roles of cardiac versus neuronal mitochondria in cyanide toxicity, or the cellular and molecular basis for agent-induced pulmonary edema. Similarly, understanding the toxicokinetics related to the different routes of exposure to chemical agents is also very important for determining therapeutic windows.

X. *IN VITRO* AND ANIMAL MODELS FOR EFFICACY SCREENING

Development and validation of *in vitro* and/or *in vivo* animal models for rapid screening of molecular libraries to identify potential medical countermeasures is another priority of the CounterACT program. These models include seizures in small mammals, models of direct lung injury from an inhaled source, animal models of cyanide intoxication, and medium throughput models of dermal or ocular injuries. It is important that models be amenable to use under GLP methodology so that the data generated are acceptable to the FDA. Since adherence to GLP standards may be expensive, earlier screens to identify potential hits are usually performed under non-GLP conditions.

For efficacy testing, most of these efforts are highly specialized endeavors and are typically performed in-house for each project. However, for some efficacy testing, CounterACT investigators are encouraged to utilize the centralized testing facilities that the NIH has provided. For many years, the NINDS Anticonvulsant Screening Program (ASP) at the University of Utah (http://www.ninds.nih.gov/funding/research/asp/index.htm) has screened compounds for potential therapeutic activity in the treatment of epilepsy. Capitalizing on this considerable experience and the medium-throughput screening infrastructure already in place within the ASP, the CounterACT program created an arm of testing at the ASP. The CounterACT arm specifically tests compounds for potential efficacy in alleviating nerve agent-induced seizures in addition to neuroprotectant screening studies against the neuropathology that results from chemical exposures.

Another key component of the CounterACT program is its collaborative efforts with DoD laboratories. One of the major challenges in developing an NIH program on medical chemical countermeasures is that many of the highest priority chemical threat agents such as the CWAs are highly toxic and can only be used in approved, usually military, research facilities. Consequently, the NIH has partnered with the US Army Medical Research Institute of Chemical Defense (USAMRICD) (http://chemdef.apgea.army.mil/) through the support of four Interagency Agreements and one Research Center of Excellence to conduct chemical countermeasure research against *bona fide* CWAs and other agents.

XI. ADVANCED PRECLINICAL DEVELOPMENT AND CLINICAL STUDIES

Once a lead compound is identified, optimization of that compound into a viable drug is the next crucial step in the development process. Unfortunately, this is the step where many potential therapeutic drugs fail. A very important component of the drug development process is lead optimization using medicinal chemistry to develop the best pharmacokinetic profile for the desired formulation and preferred route of administration. This is an iterative process that is coupled to biological assays of efficacy, safety, and pharmacokinetics. General chemistry and manufacturing support is critical once a lead compound is identified. These studies include current good manufacturing principles (cGMP)-compliant stability studies to support regulatory submission. Manufacturing processes and procedures under cGMP conditions must be developed and reagent-grade and clinical-grade drugs must be synthesized in amounts sufficient for preclinical evaluation and Phase I/II clinical trials. To support these activities, the CounterACT program has utilized several NIH resources, including the CounterACT Preclinical Development Facility at SRI International discussed below, as well as other programs currently in development.

The CounterACT network is supported by several centralized facilities that serve its many investigators. The CounterACT Pre-clinical Development Facility is located at SRI International (http://www.sri.com/) and provides pharmacokinetic, safety, chemistry, and formulation studies under GLP and cGMP conditions. The facility is available to the entire network when a lead compound is ready for investigational new drug (IND)-enabling studies. Alternatively, SRI also provides smaller pilot studies for promising compounds that may require additional characterization before further efficacy testing. This facility and other programs under development also provide regulatory affairs support on an individual basis for the CounterACT investigators. For clinical trials, the CounterACT program leverages itself upon other established resources at the NIH, such as the NINDS Neurological Emergency Treatment Trials Network (NETT) (http://www.nett.umich.edu/nett/welcome). The NETT is currently conducting a Phase II/III clinical trial on a promising anticonvulsant that could potentially be used to treat nerve agent-induced seizures.

XII. CONCLUDING REMARKS AND FUTURE DIRECTION

The NIH CounterACT program employs several strategies for addressing the challenge of developing safer and more effective medical chemical countermeasures. First, the program leverages itself upon the experience and resources of the DoD chemical defense programs which overlap in some areas and differ in others. Second, it engages the NIH research community that otherwise would not be involved in CWA research, but who bring critical expertise in relevant areas of scientific endeavor. The scientific approach is one that looks for opportunities to intervene medically during the course of exposure through acute and long-term responses. Long-term effects are important especially if better acute treatments increase the number of patients surviving an otherwise lethal exposure. This is similar to what could be observed after improved survivability of traumatic injuries, for instance in the military. The CounterACT program is structured with investigator-initiated research projects and facilities to support these efforts. The drug discovery and development process is very expensive and it takes many years to obtain a licensed therapeutic drug ready for market. The future of the CounterACT program will depend on several factors including prior successes of the program and the foresight by leadership to support the program sufficiently through the research and development process in order to obtain the best return on the initial investment.

CHAPTER 60

Medical Countermeasures and Other Therapeutic Strategies for Sulfur Mustard Toxicity

R. VIJAYARAGHAVAN, ANSHOO GAUTAM, AND MANOJ SHARMA

I. INTRODUCTION

Chemically, sulfur mustard (SM) is bis (2-chloroethyl) sulfide and is well known as mustard gas (Table 60.1). There are various mustard agents. However, SM is one of the most important blistering or vesicating agents. It is regarded as the king of chemical warfare agents and is of historical and current interest. Of all the chemical warfare agents, SM is the one which is used the most, for example during the Iran–Iraq War (Sawyer *et al.*, 2002). The easy availability of precursors, the simple method of synthesis and the extremely stable nature of SM make it a chemical weapon of choice by the military and terrorist groups (Table 60.2) (Borak and Sidell, 1992; Balali-Mood and Hefazi, 2005). It is preferred by the military as it can incapacitate rather than kill, and due to its delayed action it produces mass casualties requiring prolonged and intensive care (Graham *et al.*, 2005). The destructive properties of SM on vital organs, and lack of effective and satisfactory antidotes, are additional benefits of SM as a chemical weapon. SM has been used in more than ten conflicts killing and inflicting severe injuries in millions of military personnel and civilians. In the Iran–Iraq War it caused heavy casualties and thousands of victims still suffer due to late effects (Kehe and Szinicz, 2005; Saladi *et al.*, 2006). SM has been stockpiled by several countries but since the Chemical Weapons Convention (CWC) came into force many are in the process of destroying it. However, the complete destruction of all the declared SM may take some time.

SM forms sulfonium ion in the body and alkylates DNA leading to DNA strand breaks and cell death. Due to the high electrophilic property of the sulfonium ion, SM binds to a variety of cellular macromolecules (Somani and Babu, 1989; Dacre and Goldman, 1996). The most common complications of SM occur in lung, skin, and eye which are the principal target organs due to its direct effect. The systemic toxicity leads to several manifestations (Balali-Mood *et al.*, 2005; Dacre and Goldman, 1996).

The first clinical manifestations of SM poisoning in victims occur in the eyes with a sensation of grittiness, lacrimation, photophobia, blepharospasm, and corneal ulceration (Balali-Mood and Hefazi, 2006). If exposure to vapor is prolonged, rhinorhea, laryngitis, bronchitis, necrosis of mucous membranes of the respiratory tract, and bronchopneumonia will occur. Skin lesions include erythema, blisters, and necrosis (Balali-Mood and Hefazi, 2006; Dacre and Goldman, 1996). SM-exposed victims still suffer from delayed effects like chronic obstructive lung disease, lung fibrosis, chronic conjunctivitis, recurrent corneal ulcers, and abnormal pigmentation of the skin (Kehe and Szinicz, 2005).

Despite rigorous research efforts on the development of an antidote to SM, employing a variety of *in vivo* and *in vitro* systems and using various mustard agents, so far no satisfactory and recommended treatment has evolved (Figure 60.1). In general, antidotes to chemical warfare agents are considered as ''orphan drugs'' as they are not a regular phenomenon and the pharmaceutical industry has very little interest in them (Szinicz *et al.*, 2007). In view of the possible threat from various sources against the military and civilian populations, and the risk during the destruction of the stockpiled mustard agents, development of a suitable antidote is a prime requirement. Physicians should also be aware of the likelihood of mass casualties due to SM exposure and should be knowledgeable about the various medical countermeasures.

The current treatment strategy consists of symptomatic management that prevents infections and promotes healing. There are no standardized or optimized methods of casualty management to reduce the suffering and provide speedy wound healing (Graham *et al.*, 2005). At present, no antidote exists for SM poisoning. The best method of minimizing the injury is by immediate decontamination of the exposed individuals, followed by palliative treatment of symptoms (Geraci, 2008; Munro *et al.*, 1990). Antidotes to SM can be sought in four different directions (Figure 60.2): (1) prevention of SM from entering the system (personal

decontamination at the site of contact), (2) prevention of SM from alkylating critical target molecules, mainly DNA, (3) restoration of SM alkylated DNA, and (4) prevention and reversal of the cascade of secondary biochemical reactions following alkylation (Vijayaraghavan *et al.*, 2001a). Of these, most of the research is focused on the decontamination methodologies and prevention or reversal of biochemical complications (Smith and Gross, 2002).

In this chapter the various antidotes and treatment regimes conducted on animal models and the treatment regimens recommended in human casualties are reviewed.

II. SKIN DECONTAMINATION

SM is a lipophillic compound and rapidly penetrates the skin. Hence the decontamination has to be done immediately and should be complete. It is known that decontaminiation done 5 min after SM contact may not be beneficial as a sufficient quantity would have been absorbed by the skin (Vijayaraghavan *et al.*, 2002). A number of proprietary formulations are available that can efficiently decontaminate SM. A useful decontaminant for mustard would be one which is readily available in large quantities, inexpensive, and potentially biodegradable (Table 60.3) (Cerny and Cerny, 1997).

TABLE 60.2. Physicochemical properties of sulfur mustard

Appearance	Yellow, oily liquid
Odor	No odor to garlic, mustard
Molecular weight	159.08
Density	1.27 (specific gravity)
Solubility	Very hydrophobic
Freezing point	14.45°C
Boiling point	215–217°C
Volatility (mg/m^3, 20°C)	610
Persistence	Highly stable

A. Efficacy of Barrier Creams

A number of barrier creams have been developed that prevent the penetration of chemical warfare agents including SM, thereby reducing the morbidity. A barrier cream coded as IB1 (Israel Institute of Biological Research) has been evaluated in pigs and has been found to be safe and effective against SM and VX (Kadar *et al.*, 2003). Barrier creams comprising perfluorinated polymers were effective against SM when evaluated using human skin *in vitro*. Three candidate perfluorinated barrier creams were evaluated in domestic white pigs against SM vapors and found to be very effective. The treated sites looked like the control animals and the untreated animals showed evidence of persistent damage with slow healing (Chilcott *et al.*, 2007). Perfluorinated reactive barrier cream formulations have been developed and evaluated against SM using an *in vitro* diffusion cell system containing human skin. Novel perfluorinated barrier creams were generally more effective under unoccluded conditions. Pretreatment with a proprietary formulation reduced the skin absorption of SM by several fold (Chilcott *et al.*, 2002). The addition of polyoxometalates to perfluoropolyether topical skin protectants enhanced the decontamination efficacy against SM (Johnson and Hill, 1999). Highly reactive nanoparticle-based cream has also been developed that can decontaminate a variety of chemical warfare agents and is safer to use on skin (Koper *et al.*, 1999). Barrier creams known as topical skin protectants have been formulated which can delay the penetration of SM through the skin. One topical skin protectant showed instant decontamination (about 2 s) of SM simulant dibutyl sulfide as studied using the gas chromatographic mass spectrometric technique (Clark *et al.*, 1999). There is a concern that several proprietary formulations may have adverse effects on the effectiveness of the skin decontaminant Fuller's earth (a native form of aluminum silicate) which is generally used as a physical decontaminant (Chilcott *et al.*, 2002). Many countries use approved skin decontaminants for SM such as M291 (US Army), RSDL (Canada), Fuller's earth (UK), and PDK (India). It is also recommended that if the decontaminants are not readily available, talcum powder or flour can be used (Borak and Sidell, 1992). The use of water for decontamination of oily chemical warfare agents is contraindicated, as it may allow the spreading of the agent, facilitating absorption. However, eye contamination can be removed by copious use of water.

B. Efficacy of Fuller's Earth

The decontamination efficiency of Fuller's earth, Ambergard, and BDH spillage granules was tested by measuring the skin absorption rates and the percentage of applied dose of SM that penetrated human and pig ear epidermal membranes *in vitro*. Fuller's earth was found to be better than the other two. This was in agreement with an *in vivo*

test in a rat model and human volunteer study (Chilcott *et al.*, 2001). The Canadian Reactive Skin Decontaminant Lotion has been identified to be better than Fuller's earth when decontaminated 5 min after dermal contact with SM and VX in domestic swine (Taysse *et al.*, 2007). Several proprietary decontaminants are known, such as the Polish formulation ORO and C9 that can react with SM (Popiel *et al.*, 2005).

C. Efficacy of Hypochlorites

The decontamination efficacy of sodium hypochlorite and calcium hypochlorite solutions was found to be similar against low-dose SM in guinea pigs with respect to the wound on the skin. Surprisingly, the skin surrounding nondecontaminated but exposed animals demonstrated less wound showing that the hypochlorite solutions *per se* or the SM–hypochlorite solution interaction might have caused the skin lesions (Gold *et al.*, 1994). The concentration of hypochlorite solution also matters in the efficiency of chemical decontamination. 0.5% is a weak and 4% is a mild decontaminant of SM. If the ratio of hypochlorite to SM was kept at 1,000:1 then 0.5% and 4% effectively decontaminated SM (Wormser *et al.*, 2004). Vaporized hydrogen peroxide is a common gaseous sterilant widely used in industry and it has been found to be an effective chemical

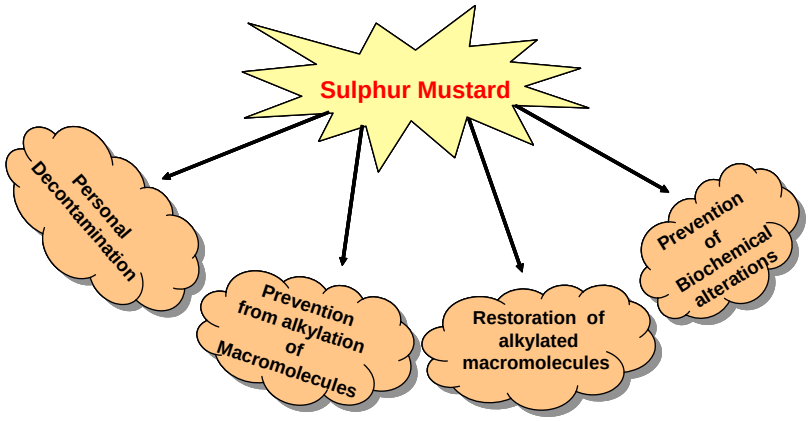

FIGURE 60.2. Possible approaches for antidote development against SM toxicity.

TABLE 60.3. Requirements of a good decontaminant

1. Effective against most of the chemical warfare agents
2. Simple and self-administration without any assistance
3. Safe from any type of toxicity
4. Abundant and easily available
5. Large-scale production possible

warfare agent decontaminant in the presence of ammonia for SM and nerve agents (Wagner *et al.*, 2007).

D. Efficacy of Chloramides

The chloroamide compound 1,3,4,6-tetrachloro-7,8-diphenyl-2,5-diiminoglycoluril (S-330) is a rapid and effective chemical decontaminant of SM, and dermal formulations either in polar media or in perfluoropolyether oil have been developed. A disadvantage of S-330 is that it can tolerate only 5–10% of water. Alcohols and acidic and basic conditions also reduce its efficiency (Shih *et al.*, 1999a, b). A reactive chemical decontaminant, CC2 (*N*,*N*′-dichloro-bis [2,4,6-trichlorophenyl] urea) in various hydrophilic and lipophilic formulations (20%) has been prepared as a personal decontaminant for SM. CC2 reacted with peanut oil and neem oil, and was unstable in povidone iodine and Fuller's earth. Good stability was achieved with petroleum jelly, honey, polyvinyl pyrrolidone, calamine lotion, acacia, and hydroxypropyl cellulose. Though CC2 was stable in lipophilic formulations, it did not protect the animals. The hydrophilic formulations, particularly acacia and hydroxypropyl cellulose, gave very good protection and were highly stable. CC2 is also a very safe compound and compatible with human skin (Kumar *et al.*, 1991; Reddy *et al.*, 1996; Dubey *et al.*, 1999; Vijayaraghavan *et al.*, 2001b, 2002; Lal *et al.*, 2002).

E. Efficacy of Other Decontaminants

The decontamination efficacy of radioprotective agent aminoethylisothiourea and cystamine on rat skin against SM was comparable to standard decontaminants, such as alcoholate, clay, and Fuller's earth (Knezević and Tadić, 1996). A mixture containing bovine hemoglobin, gelatin, and poi (a Hawaiian foodstuff) on the hydrolytic kinetics of the mustard simulants, 2-chloroethyl ethyl sulfide, 2-chloroethyl methyl sulfide and 2-bromoethyl phenyl sulfide, is reported. The kinetic mechanisms and rate constants were dependent upon the mixtures' concentration and viscosity (Cerny and Cerny, 1997).

III. TREATMENT OF SKIN INJURIES

SM is a potent cutaneous vesicant that penetrates rapidly through the skin, causing prolonged injuries and leading to severe incapacitation (Kadar *et al.*, 2000). The metabolically active and proliferating basal cells in the skin are more sensitive to SM (Ray *et al.*, 2000). SM produces blisters with a severe inflammatory reaction in skin of exposed individuals (Casbohm *et al.*, 2004). The development of efficacious countermeasures against SM vesication requires an understanding of the cellular and molecular mechanism of SM-induced tissue injury (Sabourin *et al.*, 2004). Progress towards an effective treatment for SM injuries has been slow due to the lack of a suitable animal model to study the toxicology and pathology.

SM is probably the only chemical showing more toxicity through the percutaneous route compared to subcutaneous route in animal models. For the same dose the percentage body weight loss, hepatic glutathione content, and histopathological lesions were more in the percutaneous route compared to subcutaneous route (Vijayaraghavan *et al.*, 2005). Though 2-chloroethyl ethyl sulfide is used as a simulant for studying the mechanism of toxicity and development of antidotes for SM, the pattern of toxicity of 2-chloroethyl ethyl sulfide is different from SM (Gautam *et al.*, 2006). SM is used in ointment (S-mustard-vaseline), known as Russian ointment, in a concentration of 1:20,000 (0.005%) for the effective treatment of psoriasis (Illig *et al.*, 1979; Janouchek *et al.*, 1987).

A cascade of events follow SM-induced alkylation of macromolecules. SM most likely alkylates purine in deoxyribonucleic acid (DNA). The apurinic endonucleases act at SM–DNA adducted sites to produce backbone breaks in DNA and this activates chromosomal enzyme poly(ADP-ribose)polymerase (PARP). This enzyme utilizes nicotinamide adenine dinucleotide (NAD^+) as a substrate and depletes the NAD^+ content of the cells. The depletion of NAD^+ causes inhibition of glycolysis resulting in the accumulation of intermediates that stimulate the $NADP^+$-dependent hexosemonophosphate shunt. The stimulation of the hexosemonophosphate shunt has been associated with DNA damage and increase in protease synthesis and release. These proteases could be responsible for the development of subepidermal blisters characterized by fluid accumulation in the cavity created by separation of the moribund basal cell layer from the basement membrane (Papirmeister *et al.*, 1985). When a wound was created by scratching human epidermal keratinocytes, the nitric oxide synthase level was increased. SM inhibited the increase in nitric oxide synthase level. Preventing the SM-induced inhibition of inducible nitric oxide synthase may be a prospective strategy to promote wound healing in SM-exposed skin (Ishida *et al.*, 2008).

A. Efficacy of Steroids and Nonsteroidal Anti-Inflammatory Drugs

The mouse ear vesicant model has been used to evaluate pharmacological agents for countering SM dermal injury. The SM-induced skin injury in mouse ear was found to be

very similar to that reported in human skin. The combined topical application of adexone, a steroid, and voltaren, a nonsteroidal anti-inflammatory drug, was found to be effective in reducing the intensity of SM skin injury in the mouse ear vesicant model. But this combination did not protect the cytotoxicity of the epithelial layer (Dachir *et al.*, 2004). The SM-induced inflammation can be reduced only when the treatment is initiated at an early stage (Dachir *et al.*, 2002). The systemic administration of anti-inflammatory drugs, such as hydrocortisone, indomethacin and olvanil, provided a significant reduction of edema induced by SM. They also significantly reduced the subepidermal blisters in the mouse ear vesicant model and olvanil additionally protected the epidermal necrosis (Babin *et al.*, 2000; Casillas *et al.*, 2000).

In the mouse ear model, dimercaprol, octyl homovanillamide, and indomethacin were given 15 min before SM topical application, and ear tissue was harvested for ear weight determination. All three drugs were found to reduce SM damage (Dillman *et al.*, 2006). When SM was applied topically on the inner surface of mouse ear, genes responsible for inflammation, apoptosis, and cell cycle regulation were altered, showing that intervention with these molecular mechanisms could be appropriate targets for developing prophylactic and therapeutic treatments for SM-induced skin injury (Sabourin *et al.*, 2004). The vanilloid olvanil reduced SM-induced edema and also mRNA expression of cytokines and chemokines. This suggests that blocking the inflammatory effects of neuropeptides, such as substance P, may provide protection against SM-induced dermal injury (Casbohm *et al.*, 2004). Exposure to SM on mouse ear edema model showed alteration in interleukin-6 which can be used as an *in vivo* biomarker for evaluating anti-inflammatory drugs (Ricketts *et al.*, 2000). The involvement of tumor necrosis factor-α in SM-induced skin toxicity was confirmed by a reduction in mouse ear edema following administration of anti-tumor necrosis factor-α antibodies. Anti-tumor necrosis factor-α antibodies may be a new approach in the treatment of SM (Wormser *et al.*, 2005).

B. Efficacy of Protease Inhibitors

Anti-inflammatory drugs are effective against SM-induced toxicity, but they are generally evaluated using *in vivo* techniques. Interleukin-8 has been used as a marker for screening SM antidotes in human epidermal keratinocyte cell cultures. A protease inhibitor, ICD 1579 (ethyl *p*-guanidinobenzoate hydrochloride), and an inhibitor of trypsin, *N*-tosyl-L-lysine chloromethyl ketone, were evaluated against SM. ICD and *N*-tosyl-L-lysine chloromethyl ketone dose dependently suppressed SM-induced increase in interleukin-8 (Cowan *et al.*, 2002). Human epidermal keratinocytes exposed to SM were treated with a p38 mitogen activated protein kinase inhibitor, SB203580, and the levels of interleukin-6, interleukin-8, tumor necrosis factor-α and interleukin-1β were significantly decreased, showing that p38 MAP kinase plays a role in SM-induced cytokine production in human epidermal keratinocytes. Inhibition of this may reduce the inflammatory response elicited by SM exposure (Dillman *et al.*, 2004). SM exposure to weanling pigs showed transcriptional activity in the inflammatory response proteins interleukin-6, interleukin-8, interleukin-1β, and matrix metalloproteinase-9 and moderate changes in tumor necrosis factor-α which may contribute to SM dermatotoxicity. Drugs preventing SM-induced inflammation should be one of the medical countermeasures to lessen the toxicity (Sabourin *et al.*, 2002). Pretreatment with caffeic acid phenethyl ester, a known inhibitor of NF-κB signaling, significantly decreased SM and nitrogen mustard (mechlorethamine) induced reporter gene activity in human epidermal keratinocytes (Minsavage and Dillman, 2007).

Epidermal melanocytes have a higher sensitivity to SM compared with other skin cell types, which may be due to the enzymatic production of melanin precursors exerting an additional cytotoxic effect. *In vivo* experiments have shown that melanocytes are more sensitive than keratinocytes for studying the cytotoxic effects of SM. This may be due to the uncoupling of the melanogenic pathway by depletion of cellular glutathione, resulting in the increased production of cytotoxic quinone free-radical species by tyrosinase. Kajoic acid, a depigmenting agent, exerts its effect by acting as a slow-binding, competitive inhibitor of tyrosinase. Kajoic acid can be used as an adjunct for SM skin injuries (Smith and Lindsay, 2001a). Similarly, the control of the cell cycle by protein kinase C modulation and manipulation of melanin synthetic pathways may also have therapeutic benefits (Smith and Lindsay, 2001b). Laminin-5 is a heterotrimer of laminin alpha3, beta3, and gamma2 subunits, and is a component of epithelial cell basement membranes. Studies on human epidermal keratinocytes showed that SM alkylates laminin-5 and degrades it, resulting in basal cell death and separation of the epidermis from the dermis. This information may be useful in developing cutaneous therapies for SM lesions (Jin *et al.*, 2008).

C. Efficacy of PARP Inhibitors

It has been postulated that SM-induced cellular damage may activate PARP, resulting in the depletion of cellular NAD^+ and leading to blister formation. It has been demonstrated that niacinamide, an inhibitor of PARP and a precursor for NAD^+ synthesis, may be useful as a pretreatment compound to reduce SM-induced microvesication in guinea pig skin. When given as a pretreatment and post-treatment it was observed that niacinamide should be repeatedly given to reduce the microblisters induced by SM (Yourick *et al.*, 1992). Pretreatment and post-treatment (4 to 6 h) with a combination of niacinamide, promethazine, and indomethacin reduced the erythema induced by SM in hairless guinea pig skin. But when the combination was applied 24 h

after SM administration no protection was observed (Yourick *et al.*, 1995).

D. Efficacy of Iodine Treatment

Several studies showed that post-exposure treatment with iodine is effective against SM lesions in rodents. SM exposure in guinea pigs showed a marked increase in epithelial nuclear vacuolation, epidermal thickening, and acute inflammation, a few hours after exposure. Topical iodine treatment reduced the severity of these parameters (Brodsky *et al.*, 2006). Povidone–iodine ointment is an efficient protective agent against skin toxicity caused by SM (Wormser *et al.*, 1997). Histopathological examinations in animal models showed that application of povidone–iodine up to 20 min following exposure to the vesicant resulted in marked skin protection. It was also observed that the shorter the interval between exposure and treatment the better the result. Topical iodine preparations have been used as post-exposure treatment against SM-induced skin lesions in fur covered guinea pig skin. Iodine treatment 15 min after SM exposure resulted in statistically significant reductions of dermal inflammation, hemorrhage, and necrosis. It was also observed that SM was not affected chemically by iodine as measured by gas chromatography mass spectrometry analysis (Wormser *et al.*, 2000b). A pig model was used to simulate SM-induced skin lesions and a single dose of iodine formulation was applied. A single application of iodine formulation at 20 min post-SM exhibited no protection as observed by biopsy. This shows that the animal skin may behave differently for SM (Margulis *et al.*, 2007). Apart from being a safe and widely used disinfectant, povidone–iodine ointment is recommended as an efficient protective agent against skin toxicity caused by hazardous chemicals and by heat stimuli (Wormser *et al.*, 2000a).

Topical treatment with iodine or povidone–iodine ointment significantly reduced the skin lesions induced by SM. The combination of anti-inflammatory agents and iodine increased the counterirritating activity. Both human and experimental animal studies demonstrated that the ointment should be applied immediately after SM exposure (Brodsky and Wormser, 2007). Since proteolytic activity is involved in skin damage caused by chemical irritants, the effect of iodine on mechlorethamine-induced skin collagenolytic activity was studied in the guinea pig model. Reduced collagenolytic activity may be one of the mechanisms by which iodine protects the skin against chemical injury (Wormser *et al.*, 2002b). Iodine treatment significantly reduces inflammation and necrosis and increases epidermal hyperplasia. Experiments carried out in animal models show that nitric oxide radicals are involved in SM-induced skin lesions. Reduction of inflammation by iodine ointments may be associated with reduced inducible nitric oxide synthase expression (Nyska *et al.*, 2001). Though some studies showed the effectiveness of topical iodine for 15 to 30 min, in another study the protection was demonstrated for up to 60 min in the mouse ear edema model using an improved topical povidone–iodine preparation termed N66, which contains steroidal and nonsteroidal anti-inflammatory agents. Povidone–iodine preparation combined with anti-inflammatory agent may function as a potent antidote against skin lesions induced by SM at relatively long intervals between exposure and treatment (Wormser *et al.*, 2004).

E. Efficacy of Mechanical Treatments

The SM skin wound is very slow healing. Miniature pig models were used to assess the usefulness of mechanical dermabrasion in hastening the healing of SM vapour-induced skin injuries. Dermabrasion of the SM wound is a valuable procedure in surgical management (Rice *et al.*, 2000). Several treatment modalities for chemical burns, such as surgical excision, laser ablation, and chemical debridement with debridase or trypsin-linked to gauze, were evaluated against SM and nitrogen mustard-induced wounds in the guinea pig model. Debridase was most effective and reduced significantly the burn lesion (Eldad *et al.*, 1998b).

Exposure to SM can produce partial thickness burns which take a long time to cure. To accelerate the rate of healing, laser ablation was given on SM burns on the dorsum of large white pigs, and it was found to be effective (Evison *et al.*, 2006). SM burns were generated on the ventrum of weanling pigs and four treatments were compared: (1) full-thickness CO_2 laser debridement followed by skin grafting, (2) full-thickness sharp surgical tangential excision followed by skin grafting, used in deep thermal burns management, (3) partial-thickness laser ablation with no grafting, and (4) partial-thickness sharp excision with no grafting. It was observed that laser debridement followed by skin grafting was effective in improving the wound healing of deep SM burns (Graham *et al.*, 2002a, b).

When wound healing studies were conducted on SM wounds in weanling pigs, it was observed that re-epithelialization was nearly complete with petrolatum and scarlet red dressings. The use of cultured epithelial allograft material, Xeroform Petrolatum and Scarlet Red Ointment dressings, is an effective and inexpensive treatment for SM injuries (Graham *et al.*, 2006).

An anesthetized domestic swine model was used to investigate whether alteration of skin temperature had any effect either apparently or histopathologically on the development and progression of SM-induced skin lesions. Cooling the SM-exposed skin (15°C) reduced the severity of SM-induced cutaneous lesions (Sawyer *et al.*, 2002). Similarly, the effect of temperature on the development of SM-induced toxicity was investigated in human skin keratinocyte cultures and on hairless guinea pig skin. Moderate cooling (5 to 10°C) of SM exposed sites after 4 to 6 h of treatment significantly reduced the severity of the lesions.

In contrast, *in vitro* cooling only temporarily reduced the toxicity (Mi *et al.*, 2003).

F. Efficacy of Cholinergic Drugs

SM causes blisters because epithelial cells lose their attachments. Since epithelial cell adhesion is under the control of the local cytotransmitter acetylcholine acting through the muscarinic and nicotinic receptor, it is possible that pharmacologic protection from the vesicating action of SM can be achieved by using cholinergic drugs (Grando, 2003). Similar to serine protease inhibitors that can prolong the survival of soman intoxicated animals and also protect against SM toxicity, the PARP inhibitors can reduce both soman-induced neuronal degeneration and SM-induced epidermal necrosis (Cowan *et al.*, 2003).

G. Efficacy of Calmodulin Antagonists

Ointments containing calmodulin antagonists were found to be effective in preventing skin injuries induced by SM. Topically applied pluronic base ointments containing lidocaine or pentamide gave beneficial effects when applied immediately after SM on pig skin (Kadar *et al.*, 2000). Calmodulin antagonists and anesthetics on the skin lesions induced by SM were investigated in hairless mice and it was observed that calmodulin antagonists and anesthetics in water soluble bases may be useful for the treatment of SM-induced skin lesions. The water soluble ointment bases showed some beneficial effects, whereas oily bases made the skin lesions worse. Trifluoperazine (0.5–1%) and thioridazine (2%), potent calmodulin antagonists, in Pluronic F-127 base considerably prevented the development of SM-induced skin lesions. A similar effect was achieved with pentamidine (10%). Anesthetics, such as lidocaine and pentobarbital, showed some protection, although at concentrations above 5% (Kim *et al.*, 1996a). Since *O*-phenanthroline inhibited the ulcerative effect of topically applied meclorethamine in guinea pigs and also protected against meclorethamine-induced toxicity in rat liver slice cultures, it could also be a useful antidote to SM (Wormser and Nyska, 1991).

H. Treatment of Pruritis in Humans

In humans the treatment of skin lesions is mostly symptomatic. Pruritus is a common problem among SM-exposed veterans. A number of treatments like antihistamines, local anesthetics, and corticosteroids are prescribed in order to control pruritus in Iranian patients. When Unna's Boot (a gauze bandage impregnated with glycerine, zinc oxide, and calamine lotion) and betamethasone were compared for the treatment of pruritis, Unna's Boot showed better results (Shohrati *et al.*, 2007a). SM-induced pruritis in chemical warfare-injured veterans was treated with phenol (1%) and menthol (1%), and this combination significantly reduced the pruritis in comparison to placebo (Panahi *et al.*, 2007). A double-blind safety and efficacy study was conducted to compare the safety and efficacy of cetirizine, doxepine, and hydroxyzine as a treatment of chronic pruritus in SM-exposed victims. Though sedation was reported in cetirizine, doxepine, and hydroxyzine groups, hydroxyzine and doxepine gave better results than cetirizine (Shohrati *et al.*, 2007b, c).

IV. TREATMENT OF LUNG LESIONS

Exposure of SM vapors to mice induced sensory irritation during exposure, and there was a concentration-dependent decrease in the respiratory frequency and an increase in tidal volume. The respiratory frequency decreased on subsequent days of exposure depending upon the exposure concentration, and the breathing pattern was characteristic of bronchial obstruction (Vijayaraghavan, 1997; Lakshmana Rao *et al.*, 1999). Administration of aerosolized SM solution through the intratracheal route in guinea pigs induced two main symptoms, asthma-like symptoms reflected by an early bronchoconstriction and late asthmatic responses, and acute respiratory distress syndrome with pulmonary edema and damage to the lung surfactant. Mice exposed to SM vapors showed infiltration of inflammatory cells, swelling and vacuolation of parenchymal cells, and congestion and hemorrhage in the alveoli (Pant and Vijayaraghavan, 1999, 2002).

A. Efficacy of Salbutamol and Curosurf

Intratracheal nebulization of salbutamol solution or bolus administration of curosurf (surfactant) reduced the mortality in guinea pig. Salbutamol appeared to be more effective than curosurf in this respect. Since SM exposure induced damage to the lung surfactant, severe bronchoconstriction, and inflammation of the respiratory tract, a combined treatment consisting of exogenous surfactant, anti-inflammatory drugs, and broncholytics may be a better choice (Van Helden *et al.*, 2004).

B. Efficacy of Corticosteroids

Intratracheal injection of SM in guinea pigs induces airway epithelial damage and the tracheal epithelium appeared disorganized and showed a significant decrease in height and cell density. Corticoids like betamethasone showed significant effects on airway epithelium (Calvet *et al.*, 1996). Intratracheal injection also induces airway muscle hyperresponsiveness to substance P by reducing tracheal epithelial neutral endopeptidase activity. Corticoids like betamethasone inhibit this hyperresponsiveness (Calvet *et al.*, 1994a). Primary alveolar macrophages obtained from guinea pigs were exposed to SM and treated with dexamethasone, and the SM-induced inflammatory effect was reduced. SM intoxication in guinea pigs through intratracheal injection showed severe lesions to the

tracheal epithelium with an increase in respiratory system resistance and microvascular permeability. Pretreatment with capsaicin did not prevent this. Aerosolized substance P and histamine induced airway hyperresponsiveness and pretreatment with phosphoramidon caused a further increase in airway responsiveness to substance P (Calvet *et al.*, 1994b). Accumulation of high levels of TNF-α was observed in guinea pigs exposed to 2-chloroethyl ethyl sulfide, an SM analog, intratracheally. This activates both acid and neutral sphingomyelinases, resulting in the accumulation of ceramides, a second messenger involved in cell apoptosis. Since NF-κB disappears, the cells continue to be damaged owing to accumulation of ceramides and activation of several caspases, leading to apoptosis (Chatterjee *et al.*, 2003).

Chronic bronchitis is the most frequent late respiratory disease among Iranians exposed to SM during the Iran–Iraq War. Oral and intravenous corticosteroid therapy was investigated in improving the lung function in SM-induced chronic bronchitis patients. There was a significant improvement in spirometry indices of oral and intravenous groups (Ghanei *et al.*, 2005). Since short-term corticosteroid therapy has a significant effect on lung function in most of the patients with SM-induced chronic bronchitis, a short-term bolus steroid treatment to triage the patients into responders and nonresponders for subsequent treatment is required (Ghanei *et al.*, 2005). Interferon gamma-1β was administered to patients with bronchiolitis. A 6 month treatment with interferon gamma-1β and a low dose of prednisolone improved the lung function of SM-exposed patients with bronchiolitis (Panahi *et al.*, 2005).

C. Efficacy of Combination of Corticosteroids and β-Agonist

The role of two-combination inhaler therapy was tested in humans exposed to SM. Either fluticasone propionate and salmetrol or beclomethasone and salbutamol were given. Inhaled corticosteroids and long-acting beta 2-agonists are effective in the treatment of patients with chronic bronchiolitis following exposure to SM. However, a medium dose of fluticasone/salmeterol has the same effect on airway reversibility, rather than a very high dose of beclomethasone with the short-acting beta-agonist (Ghanei *et al.*, 2007). Persistent cough is a usual occurrence in SM-exposed victims which is alleviated with an anti-tussive.

D. Efficacy of Doxycycline and Roxithromycin

Respiratory tract lesions induced by SM are characterized by epithelial cell damage associated with inflammatory cell infiltration. SM was injected intratracheally in guinea pigs pretreated with doxycycline. Doxycycline pretreatment resulted in decreased gelatinase activity, decreased inflammation, and protected histological lesions. Doxycycline may be a promising therapeutic agent for SM (Guignabert *et al.*, 2005). Anticytotoxic and anti-inflammatory effects of roxithromycin, a macrolide antibiotic, were tested *in vitro* using normal human small airway epithelial cells and bronchial/tracheal epithelial cells exposed to SM. Roxithromycin has inhibitory effects on the cytotoxicity and inflammation induced by SM. This effect may be due to the down-regulation of proinflammatory cytokines by roxithromycin. Roxithromycin may serve as a potential therapeutics agent for SM toxicity which is independent of its antibacterial activity (Gao *et al.*, 2007).

E. Efficacy of Tetraamines

Hexamethylenetetramine has been shown to protect human lung cells against SM toxicity and has also been shown to be effective *in vivo* against phosgene. The ability of hexamethylenetetramine to protect against the toxicity of SM was investigated in human upper respiratory tract cell lines, BEAS-2B and RPMI 2650. Results demonstrated that it was necessary for hexamethylenetetramine to be available at the time of exposure to SM for effective cytoprotection. No protection was seen when cells were treated with hexamethylenetetramine following exposure to SM, or where hexamethylenetetramine was removed prior to SM exposure. Results suggest that hexamethylenetetramine may be effective as prophylaxis for exposure to SM by inhalation (Andrew and Lindsay, 1998a). The A549 cell line is used as a model to study the toxicity and mechanism of action of SM. The ability of hexamethylenetetramine to protect A549 cells against the toxic effects of SM was studied and it was found that hexamethylenetetramine could protect cells against the effects of SM, though hexamethylenetetramine has to be present at the time of SM challenge (Lindsay and Hambrook, 1997).

F. Efficacy of Methacholine

SM induces asthma in humans. In patients with SM-induced asthma, the airway responsiveness to both methacholine and distilled water depends upon the percentage of bronchoalveolar lavage eosinophils (Emad and Emad, 2007a, b). Hematopoiesis could be affected by SM exposure. The average number of red blood cells and hemoglobin of victims were increased compared with historical data. The mild increase in erythroid cells and hemoglobin concentration may be due to chronic obstructive pulmonary disorder and other respiratory diseases in these patients (Ghanei, 2004).

G. Efficacy of Isopropyl Esters

Human and animal lung cells have been used successfully to model the toxic effects of inhaled SM. The epithelia of the upper respiratory tract are the primary targets of inhaled SM. The potential of monoisopropyl esters and diisopropyl esters of glutathione as cytoprotectants in the human upper respiratory tract cell lines, BEAS-2B and RPMI 2650, was

evaluated against SM. The greatest protection was shown where monoisopropyl esters or diisopropyl esters were present at the time of exposure to SM. The optimum pretreatment times were found to be 1 h for monoisopropyl esters and 2 h for diisopropyl esters. Limited protection of cells treated with monoisopropyl esters or diisopropyl esters immediately following SM exposure was also demonstrated. No protection was observed if monoisopropyl esters or diisopropyl esters were not administered immediately following SM exposure. Results suggest that monoisopropyl esters and diisopropyl esters may be effective treatments for exposure to SM by inhalation (Andrew and Lindsay, 1998b). *N*-acetyl cysteine is also a good antidote for SM lung injury (Mérat *et al.*, 2003).

V. TREATMENT OF EYE LESIONS

The eye is the organ most sensitive to SM vapor. Ocular damage is common in both military and civilian populations exposed to SM in the Iran–Iraq War. Ocular injuries following SM exposure are characterized by an inflammatory response, observed as eyelid swelling, conjunctivitis, corneal edema, cellular infiltration, and photophobia. Patients with significant corneal involvement are at risk for corneal ulceration. Ocular injuries generally heal completely in 1 or 2 weeks. In severe cases, blindness may occur (Safarinejad, 2001). Topically applied steroid treatment and anti-inflammatory drugs are potential therapies, and this can be supplemented with an antibacterial agent if required. The development of SM-induced ocular lesions in rabbits is similar to the lesions described in human casualties (Kadar *et al.*, 2001). Rabbit eyes were exposed to SM vapor and treated with commercial ophthalmic solution of dexamethasone or diclofenac and both treatments gave good protection. Anti-inflammatory agents, though effective, do not have any therapeutic effect on corneal erosions (Amir *et al.*, 2000a, b).

VI. TREATMENT OF SYSTEMIC EFFECTS

A variety of strategies and drugs have been experimented on *in vitro* using a number of cell lines, and *in vivo* using different animal models. None of the agents proved to be effective in all the systems, and hence it could not be recommended as a standard therapy for SM-exposed victims. Moreover, other than SM, its analogs have been used as stimulants without any conclusive evidence of the effectiveness of the therapies (Das *et al.*, 2003; Gautam *et al.*, 2007).

A. Efficacy of Niacinamide, Aminobenzamide, and Cyclohexamide

Human mononuclear leukocytes are a good model for studying SM-induced cytotoxicity. Niacinamide, 3-aminobenzamide, and PARP inhibitors have been shown to be effective in blocking SM-induced cell death when added to the cultures during the first 4 h post-exposure. They offered partial protection when added between 6 and 12 h and were of no benefit when added 12 h post-exposure (Meier, 1996). Upon SM exposure to human lymphocytes the cells lose membrane integrity and viability, the nuclear components get degraded and the cellular function is affected. Treatment of SM-exposed cells with PARP inhibitors prevents or alters the SM-initiated loss of cell viability, membrane integrity, cellular metabolic constituent, and cellular energy, while initiating alterations in nuclear constituents (Meier *et al.*, 2000).

The treatment of human peripheral blood lympocyte cells with selective PARP inhibitors reduced the DNA fragmentation caused by SM. The PARP inhibitors arrested DNA fragmentation at the DNA ladder stage. This effect was observed only when the PARP inhibitors were applied within 8 h of SM exposure (Meier and Millard, 1998). Although endothelial cells and keratinocytes appear to be the primary cellular targets of SM, the role of PARP in SM-induced vesication has not been clearly defined. These observations support the hypothesis that the pathogenic events necessary for SM-induced vesication (i.e. capillary leak and loss of keratinocyte adherence) at higher vesicating doses of SM may depend on NAD^+ loss with PARP activation and subsequent ATP-dependent effects on microfilament architecture (Hinshaw *et al.*, 1999).

SM exposure to normal human epidermal keratinocytes activated the DNA repair enzyme DNA ligase. There is also an active role of PARP in DNA ligase activation and DNA repair in mammalian cells. Concurrent activation of PARP and DNA ligase was also observed when exposed to SM. In human epidermal keratinocytes, when PARP was inhibited by 3-amino benzamide, SM-activated DNA ligase had a half-life that was four-fold higher than that observed in the absence of 3-aminobenzamide. DNA ligase remains activated until DNA damage repair is complete. This suggests that DNA repair requires PARP and PARP is essential for efficient DNA repair. However, PARP participates in DNA repair by altering the chromosomal structure to make the DNA damage sites accessible to the repair enzymes (Bhat *et al.*, 2006). The modulation of a PARP-mediated mechanism may provide a useful approach in preventing SM toxicity (Bhat *et al.*, 2000). Catalytic activation of PARP has been demonstrated to be a major event in response to high levels of DNA damage, and PARP activation may be part of apoptotic signaling (Figure 60.3). In other contexts, overstimulation of PARP triggers necrotic cell death because of rapid consumption of its substrate, NAD^+, and the consequent depletion of ATP. Exposure to SM significantly increased PARP activity in HaCaT cells. The total cell viability was not altered by the administration of 3-aminobenzamide with SM. However, the mode of cell death was influenced by 3-aminobenzamide exhibiting an increase of apoptotic cells and a concomitant decrease in necrotic HaCaT cells (Kehe *et al.*, 2007).

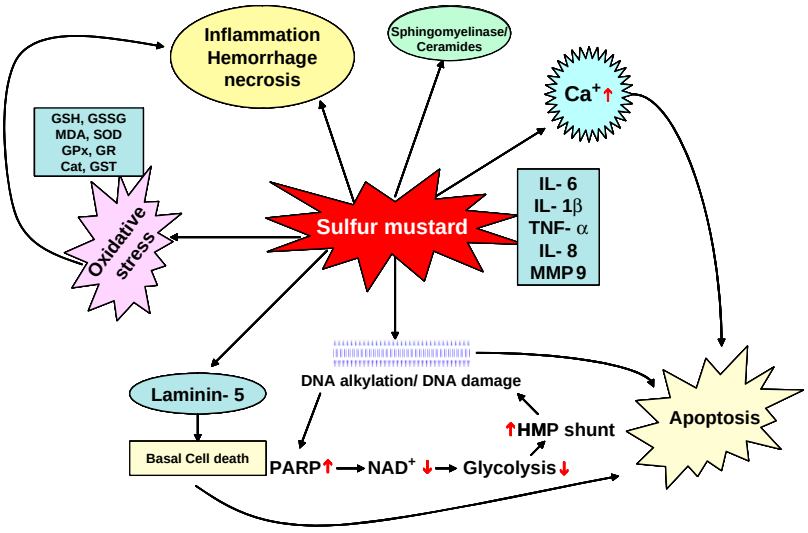

FIGURE 60.3. Possible biochemical alterations after SM toxicity.

When human keratinocytes were exposed to 2-chloroethyl ethyl sulfide, interleukin-1α and related cytokines were depressed, but PGE-2 release was not affected. Histology showed that 2-chloroethyl ethyl sulfide induced the separation of dermal and epidermal regions with severe damage to basal keratinocytes. The adverse changes associated with 2-chloroethyl ethyl sulfide exposure were not ameliorated by niacinamide (PARP inhibitor), CGS9343B (calmodulin antagonist), and leupeptin (cysteine protease inhibitor) (Blaha *et al.*, 2000a, b). Intraperitoneal administration of 2-chloroethyl ethyl sulfide in mice is more potent than its oxidation derivatives 2-chloroethyl ethyl sulfoxide and 2-chloroethyl ethyl sulfone in decreasing organ weight and loss in GAPDH activity, and an increase in GST induction (Kim *et al.*, 1996b). 2-Chloroethyl ethyl sulfide can induce the classical morphological features of apoptosis in the nucleus. Cycloheximide, a protein synthesis inhibitor, does not suppress the 2-chloroethyl ethyl sulfide-induced apoptotic activity, showing that 2-chloroethyl ethyl sulfide-induced apoptosis is a cytotoxic mechanism and is independent of the synthesis of proteins (Hur *et al.*, 1998). Cultured normal human epidermal keratinocytes were used as a model to study and characterize the protease stimulated by the mustards 2-chloroethyl ethyl sulfide, mechlorethamine, and SM. The results suggest that mustard toxicity may involve the stimulation of trypsin/chymotrypsin-like serine protease, dependent on Ca^{2+}. Protease inhibitors may be useful as prospective drugs for SM (Ray *et al.*, 2002).

Inhibitors of mono(ADP-ribose) transferase, lipid peroxidation, and protein synthesis are not effective in reducing SM-induced cell death, while PARP inhibitors are found to be effective in reducing the cytotoxic effects of SM in human lymphocytes. The compound's ability to inhibit PARP has a direct correlation to its ability to reduce SM-induced cell death. PARP plays an important role in SM-induced cell death (Clayson *et al.*, 1993). The effectiveness of various therapeutic agents, namely niacin, niacinamide, and 3-aminobenzamide, was evaluated in human lymphocyte cultures against SM-induced cytotoxicity. Niacinamide and 3-aminobenzamide prevented the cytotoxic effects of SM for up to 2 days (Meier and Johnson, 1992). Lymphocytes exposed to SM show about 30 to 40% of viability, and loss of microvilli, large cytoplasmic vacuoles, extensive blebbing of the perinuclear envelope, loss of cytoplasmic organelles, condensation of nuclear chromatin, and multiple perforations of the plasmalemma. Niacinamide treatment improved the viability to 87% (Petrali *et al.*, 1990). Niacinamide may only be effective as a pretreatment compound to reduce the incidence of SM-induced microvesicle formation (Yourick *et al.*, 1991).

B. Efficacy of BAPTA AM

A Ca^{2+}-dependent mechanism of SM toxicity has been proposed in human epidermal keratinocytes (Figure 60.3). The SM toxicity was inhibited by the Ca^{2+} chelator BAPTA AM [1,2-bis(*O*-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid acetoxymethyl ester]. The mechanism of protection of BAPTA AM against SM may be by decreasing the metabolic derangements produced by SM (Ray *et al.*, 2000). The role of calcium in SM-induced cell death is well known and modulation of intracellular calcium concentrations may assist in providing protection. SM induces an immediate and irreversible increase in internal free calcium level and it is independent of external calcium concentrations. Treatment of neonatal human skin keratinocytes with thapsigargin, an endoplasmic reticulum calcium ATPase inhibitor, or BAPTA-AM, a calcium chelator, did not change SM toxicity. Furthermore, alteration of external calcium concentrations also failed to improve. Treatment of confluent cultures with ionomycin also failed to give protection against SM showing that in neonatal human skin keratinocytes the changes in intracellular calcium induced

by SM do not play a major role in SM cytotoxicity (Sawyer and Hamilton, 2000).

C. Efficacy of Pyrimethamine and Cimetidine

The suppression of the immune system is one of the major causes of infections, septicemia, and death in patients exposed to SM. The effectiveness of two immunomodulating agents, pyrimethamine and cimetidine, was tested in mice exposed to SM. Pyrimethamine and cimetidine enhanced the antibody titers to sheep red blood cells, augmented delayed-type hypersensitivity responses, and restored splenic follicles compared to control exposure. Spleen weight indices were not augmented by either drug. The immunomodulating drugs may prove effective in countering the immunosuppressive effects of SM (Ebtekar and Hassan, 1993).

D. Efficacy of Doxycycline

Doxycycline inhibits the detachment of SM-exposed HaCaT cells in culture from the growth substrate. However, analysis of the metabolic activity of the adherent cells reveals that doxycycline treatment does not maintain cell viability. It is suggested that doxycycline and other matrix metalloprotease inhibitors may have a role to play in therapeutic intervention against SM, only as a combination therapy (Lindsay *et al.*, 2007). Human keratinocyte cell lines were pretreated with mixtures of methenamine and glutathione prior to SM exposure. Though it is possible to protect the cell cultures from the toxic effects of SM, it will be effective only as a pretreatment (Smith *et al.*, 1997).

E. Efficacy of Glutathione Esters

When A549 cell line was used to assess the toxicity of SM it was found that monoisopropylglutathione ester can protect A549 cells against the toxic effects of SM. Though monoisopropylglutathione ester can protect cells against the effects of SM, it can protect only as a pretreatment. The protection may be due to extracellular inactivation of SM by monoisopropylglutathione ester (Lindsay *et al.*, 1997). Similarly, diisopropylglutathione also protects SM-induced cytotoxicity, but it has to be present at the time of SM challenge for protection. The protection may be due to extracellular inactivation of SM by diisopropylglutathione ester (Lindsay and Hambrook, 1998).

F. Efficacy of Anti-Inflammatory Agents

The development of bifunctional drugs with a nonsteriodal anti-inflammatory agent, diclofenac or ibuprofen, and a cholinesterase inhibitor like pyridostigmine may be beneficial for both nerve and alkylating chemical agents (Amitai *et al.*, 2005, 2006). Anti-inflammatory drugs reduce the dermal, respiratory, and ocular damage caused by exposure to SM. It is also possible to design bifunctional molecules based on a CNS-permeable molecular combination of pyridostigmine, a reversible acetylcholinesterase inhibitor with a hydrophobic spacer to a nonsteroidal anti-inflammatory drug such as ibuprofen or diclofenac. This will act for both nerve agents and blistering agents (Martínez-Moreno *et al.*, 2005).

Calmodulin, poly(ADP-ribose)polymerase and p53 are targets for modulating the effects of sulfur mustard (Rosenthal *et al.*, 2000). It was tested whether calmodulin mediates the mitochondrial apoptotic pathway induced by SM in human keratinocytes. Of the three human CaM genes, the predominant form expressed was CaM1. These results indicate that CaM, calcineurin, and Bad also play a role in SM-induced apoptosis, and may therefore be targets for therapeutic intervention to reduce SM injury (Simbulan-Rosenthal *et al.*, 2006).

G. Efficacy of Nitroarginine Methyl Ester, Nitroarginine, and Thiocitrulline

Pretreatment of chick embryo neuron cultures with the nitric oxide synthase inhibitor L-nitroarginine methyl ester was found to confer significant protection against SM-induced cell death. Protection against the toxicity of SM on primary cultures of chick embryo forebrain neurons was dependent on the continued presence of L-nitroarginine methyl ester in the medium and was persistent up to 48 h after SM exposure. It is reported that this compound is one of the most effective drugs yet identified in protecting against the toxicity of SM and is the only one that exerts its effects therapeutically in *in vitro* models (Sawyer, 1998a). However, these protective effects were not mediated through the inhibition of nitric oxide synthase (Sawyer *et al.*, 1996). Another arginine analog and potent nitric oxide synthase inhibitor, L-thiocitrullline, also gave significant protection against SM cytotoxicity. In contrast to the protection conferred by L-nitroarginine methyl ester, L-thiocitrullline gave protection in immature cultures as well as mature cultures of neurons against SM. In addition, L-thiocitrulline was found to give protection prophylactically compared to L-nitroarginine methyl ester's protection which was post-treatment. This shows that these arginine analogs act differently (Sawyer *et al.*, 1998). L-nitroarginine methyl ester pretreatment and L-thiocitrulline simultaneously with SM potentiated the protective effect (Sawyer, 1998b).

The D- and L-nitroarginine methyl ester, L-phosphoarginine, and L-nitroarginine were found to confer concentration-dependent protection against SM in human neonatal foreskin keratinocyte cultures. Protection was prophylactic in nature, with L-thiocitrullline having almost maximal effect when added to the cultures 1 min prior to SM exposure. No protection was evident when L-thiocitruline was added 30 min post-SM (Sawyer and Risk, 2000). D- and L-nitroarginine methyl ester and eight additional arginine analogs

showed significant, concentration-dependent protection against SM toxicity in primary cultures of chick embryo forebrain neurons. Of these, L-nitroarginine was the most potent in increasing the LC_{50} to more than three-fold (Sawyer, 1998b). Surprisingly, L-nitroarginine methyl ester and L-thiocitrulline administered through a variety of routes did not give any significant protection against topical vapor exposure to SM in hairless guinea pigs. However, both compounds were effective in preventing the toxicity of SM in primary cultures of hairless guinea pig skin keratinocytes, indicating that species differences were not likely to be responsible for the poor efficacy of these compounds *in vivo* (Sawyer and Risk, 2000).

H. Other Treatment Strategies

Ebselen (a selenium containing antioxidant), melatonin, and cyclosporine A markedly prevented mustard-induced anoikis, pointing to these drugs as interesting candidates for the treatment of mustard-induced airway epithelial lesions (Sourdeval *et al.*, 2006). It has been previously suggested that acetylcholinesterase is activated during apoptotic processes and may be involved in apoptosis regulation, and acetylcholinesterase activity may be a potential marker of apoptosis in A549 cells after SM injury. If the mechanism of the involvement of acetylcholinesterase in apoptosis regulation during SM poisoning is known, drugs can be targeted (Steinritz *et al.*, 2007). The therapeutic effects of recombinant human erythropoietin (rh-EPO) and recombinant human granulocyte colony stimulating factor (rhG-CSF) on SM-induced toxicity in dogs was evaluated and they stimulate the growth of the erythrocyte, reticulocyte, and leukocyte. The use of rh-EPO and rhG-CSF can be considered as adjuncts to other therapeutic agents (Cai *et al.*, 2004). Though SM is a blistering agent it can also induce neutropenia in exposed individuals, increasing their susceptibility to infection. Granulocyte colony-stimulating factor (G-CSF) and pegylated G-CSF (peg-G-CSF) have been approved by the US Food and Drug Administration as hematopoietic growth factors to treat neutropenia induced by chemotherapeutic agents. African green monkeys untreated but exposed to SM recovered from neutropenia in 28 days, whereas G-CSF or peg-G-CS-treated animals recovered in 8 to 19 days after exposure. G-CSF or peg-G-CSF may reduce the duration of SM-induced neutropenia (Anderson *et al.*, 2006). Improving the fluid balance and electrolyte concentration also has been proved to be very effective in the treatment of SM poisoning in animals (Callaway *et al.*, 1958; Vojvodić *et al.*, 1985; Sugendran *et al.*, 1998).

The toxicity of SM was found to be dependent on extracellular pH. CHO-K1 cell cultures were exposed to SM and the pH was adjusted to between 5 and 10.0. An eight-fold increase in LD_{50} was observed at pH 9.5 compared to pH 5.0. It is possible that SM causes an extracellular acidification through chemical hydrolysis resulting in cytosolic acidification. This decline in pH initiates the cascade of events that results in SM-induced cell death (Sawyer *et al.*, 2007).

VII. SM-INDUCED OXIDATIVE STRESS AND ITS PROTECTION

The cytotoxic mechanism induced by SM is not well understood. Reactive oxygen and nitrogen species may likely be involved leading to lipid peroxidation, protein oxidation, and DNA damage, and trigger many pathophysiological processes resulting in multiorgan toxicity. To be really effective, treatment against SM must take all molecular mechanisms of cytotoxicity into account. A combination of several individual potent agents, each blocking one of the toxic mechanisms induced by SM, would be beneficial (Korkmaz *et al.*, 2006). Intraperitoneal administration of SM in Wistar rats decreased the body weight dose dependently. SM significantly decreased superoxide dismutase, catalase, glutathione peroxidase, and glutathione *S*-transferase activities in liver and brain, and decreased glutathione reductase activity in liver, which was also associated with a depletion of reduced glutathione and increased malondialdehyde level (Figure 60.3) (Jafari, 2007). The effects of SM toxicity may be local, systemic, or both, depending on environmental conditions, exposed organs, and the extent and duration of exposure (Somani and Babu, 1989). There is evidence showing that oxidative stress is an important factor in SM skin toxicity. Oxidative stress results when the production of reactive oxygen or reactive nitrogen oxide species exceeds the capacity of antioxidant defense mechanisms (Paromov *et al.*, 2007). It is important that the reactive oxygen or nitrogen species should be protected to reduce SM toxicity.

A. Effectiveness of *N*-Acetyl Cysteine

The toxicity of 2-chloroethyl ethyl sulfide appears to be mediated by the generation of reactive oxygen species and consequent depletion of reduced glutathione. Exposure of 2-chloroethyl ethyl sulfide to human Jurkat cells or lymphocytes resulted in a marked decrease in the intracellular concentration of reduced glutathione, and this was potentiated by buthionine sulfoximine, an inhibitor of glutathione synthesis. The effects of 2-chloroethyl ethyl sulfide on the accumulation of reactive oxygen species, decrease in glutathione level, decrease in mitochondrial membrane potential, and increase in caspase-3 activity were all inhibited by pretreatment with *N*-acetyl cysteine or with glutathione ethyl ester. They also prevented 2-chloroethyl ethyl sulfide-induced cell death (Han *et al.*, 2004).

Exposure of SM to macrophage monocyte cell line J774 caused an approximately 15% decrease in the cellular glutathione content, 2 h after exposure. Pretreatment with glutathione elevated cellular reduced glutathione. Glutathione pretreatment also increased cell viability. Similar protection

was also observed after glutathione treatment in the human epidermoid carcinoma cell line. But it is necessary that glutathione should be present extracellularly in order to protect cells from SM toxicity (Amir *et al.*, 1998). Compounds that elevate or reduce intracellular levels of glutathione may produce changes in cytotoxicity induced by SM. Pretreatment of human peripheral blood lymphocytes with buthionine sulfoximine, which reduces intracellular glutathione content, sensitizes the cells to the cytotoxic effects of SM. Pretreatment of the cells with *N*-acetyl cysteine, which elevates intracellular glutathione levels, partially protects the cells from the cytotoxic effects of SM. Augmentation of intracellular levels of glutathione may provide partial protection against cytotoxicity of SM (Gross *et al.*, 1993).

Intratracheal infusion of 2-chloroethyl ethyl sulfide in rats induces lung injury characterized by massive localized hemorrhage, edema in the alveolar compartment, accumulation of collagen, and parenchymal collapse. Significant protection was observed when antioxidants such as catalase, dimethyl sulfoxide, dimethyl thiourea, resveratrol and *N*-acetyl cysteine were administered. Among them *N*-acetyl cysteine, a sulfhydryl donor and antioxidant, showed better protection and the protection could be observed even when given up to 90 min after exposure (McClintock *et al.*, 2002). 2-Chloroethyl ethyl sulfide-induced lung injury can be substantially reduced by the presence of reducing agents or antioxidant enzymes delivered via liposomes (McClintock *et al.*, 2006). The SM administered to anesthetized rats intratracheally significantly increased lactate dehydrogenase, gamma-glutamyltransferase, and glutathione peroxidase. Niacinamide treatment did not improve the condition, while *N*-acetyl cysteine treatment to some extent improved the condition showing that *N*-acetyl cysteine may be useful as a potential treatment compound for SM-induced lung injury (Anderson *et al.*, 2000). SM targets eyes, respiratory system, skin, and possibly other organs. Extensive exposure can affect the bone marrow and damage the immune system. Clinical trials have demonstrated that *N*-acetyl cysteine is an effective chemoprotective agent against many toxic chemicals. Several studies have shown that *N*-acetyl cysteine significantly reduces the toxic effects of SM and its simulants. Radiolabeled *N*-acetyl cysteine was administered orally and its distribution was studied. *N*-acetyl cysteine increased the levels of tissue glutathione and the distribution studies indicated that oral administration of *N*-acetyl cysteine can significantly reduce skin, eye, and lung toxicity associated with SM. Maximum tolerable dose of *N*-acetyl cysteine can be recommended for treatment of SM poisoning (Bobb *et al.*, 2005; Arfsten *et al.*, 2007).

Exposure of SM to endothelial cells caused apoptosis and necrosis. Necrosis was accompanied by a significant depletion of intracellular ATP, while in apoptotic cells ATP remained at a level similar to healthy cells. Pretreatment with *N*-acetyl cysteine all but eliminated the apoptotic features of cell death but did not prevent necrosis in response to SM. *N*-acetyl cysteine pretreatment prevented the loss of cell adherence and cell rounding following exposure to SM. The actin filament organization may be an important element in cellular susceptibility to apoptotic stimuli and *N*-acetyl cysteine pretreatment may prevent it (Dabrowska *et al.*, 1996). Buthionine sulfoximine pretreatment increased the sensitivity of G361, SVK14, HaCaT, and NCTC 2544 human skin cells to SM (Simpson and Lindsay, 2005). In the endothelial cells presence of reduced glutathione improved the cell viability when exposed to SM. Pretreatment with buthionine sulfoximine, an inhibitor of glutathione synthesis, alone did not show appreciable toxic effects. However, pretreatment with buthionine sulfoximine potentiated the toxicity of SM. Pretreatment with *N*-acetyl cysteine provided significant protection. Coadminstration of buthionine sulfoximine and *N*-acetyl cysteine eliminated the protective effect of *N*-acetyl cysteine. This shows that the protective effects of *N*-acetyl cysteine may be mediated by enhanced glutathione synthesis. The increased glutathione may act to scavenge SM and also prevent oxidative activation of NF-κB (Atkins *et al.*, 2000).

Following intratracheal infusion of 2-chloroethyl ethyl sulfide in guinea pigs, high levels of tumor necrosis factor-α, ceramides, and nuclear factor NF-κB accumulated in lung and alveolar macrophages. There was an increase in the ^{125}I bovine serum albumin leakage into lung tissue, indicating severe lung injury. A single administration of *N*-acetyl cysteine orally before 2-chloroethyl ethyl sulfide infusion was ineffective to counteract these effects. However, consumption of the antioxidant in drinking water for 3 or 30 days prior to 2-chloroethyl ethyl sulfide exposure significantly inhibited the induction of tumor necrosis factor-α, activation of neutral and acid sphingomyelinases, production of ceramides, activation of caspases, leakage of ^{125}I bovine serum albumin into lung tissue, and histological alterations in lung. Pretreatment with *N*-acetyl cysteine as a daily supplement may be beneficial in reducing the lung injury against SM vapors (Das *et al.*, 2003). The hairs of guinea pigs exposed to 2-chloroethyl ethyl sulfide intratracheally looked rough and dry and lost their shiny glaze. They came out easily though there was no sign of skin lesions or skin damage. The alopecia was more or less permanent or the recovery was very slow. Treatment with *N*-acetyl cysteine prior to 2-chloroethyl ethyl sulfide exposure could prevent the hair loss completely (Chatterjee *et al.*, 2004). Long-term administration of *N*-acetyl cysteine is effective in free radical-related diseases. The effect of 2 and 4 month administration of *N*-acetyl cysteine was evaluated in patients with bronchiolitis obliterans due to SM exposure. Dyspnea and cough were significantly improved after 4 months of treatment (Shohrati *et al.*, 2008).

A number of candidate molecules were evaluated against SM and meclorethamine toxicity using human bronchial–epithelial cell lines. The molecules tested were *N*-acetyl cysteine and WR-1065 (sulfhydryl containing

molecules), hexamethylenetetramine (nucleophile), niacinamide (energy level stabilizer), dimethylthiourea (antioxidant), L-thiocitrulline and L-nitroarginine methyl ester (L-arginine analogs), and doxycycline (anti-gelatinase). Dimethylthiourea and WR-1065 protected meclorethamine toxicity and doxycycline protected against SM toxicity as individual agents, while *N*-acetyl cysteine and L-thiocitrulline were effective against both SM and meclorethamine toxicity. The combination of *N*-acetyl cysteine and doxycycline is also very interesting as these agents are already in human use. It exhibited good efficacy as a cotreatment against SM (Rappeneau *et al.*, 2000).

B. Effectiveness of Bioflavonoids

SM applied on the skin of mice depleted glutathione in blood and liver. Malondialdehyde levels in the liver showed an increase indicating lipid peroxidation. Intraperitoneal administration of vitamin E or two flavonoids, gossypin and hydroxyethyl rutosides, after dermal application of SM, did not alter the depletion of glutathione but did reduce the malondialdehyde level significantly. Survival time of mice was increased by gossypin and hydroxyethyl rutosides to a greater extent than by vitamin E or sodium thiosulfate (Vijayaraghavan *et al.*, 1991). Quercetin, a naturally occurring bioflavonoid, by intraperitoneal injection in mice, also significantly protected the depletion of glutathione and increased the malondialdehyde level by SM. Quercetin was effective only as a pretreatment or simultaneous treatment with percutaneously applied SM (Gautam *et al.*, 2007). Further, it was reported that percutaneous administration of SM induced oxidative stress and intraperitoneal administration of gossypin (3,3′,4′,5,7,8-hexahydroxyflavone 8-glucoside) significantly protected against it. A very good protection was observed when gossypin was administered 30 min prior to or simultaneous to SM exposure, but not as post-treatment. A significant increase in red blood corpuscle count and hemoglobin, and a decrease in total antioxidant status of plasma, reduced and oxidized glutathione of liver, glutathione peroxidase, glutathione reductase, and superoxide dismutase activities were observed in percutaneously administered SM in mice. The biochemical changes were protected only when gossypin was administered as either pretreatment or simultaneous treatment, not as post-treatment (Gautam and Vijayaraghavan, 2007).

Antioxidants could enhance survival time, protect liver and lung from oxidative damage, and reduce accumulation of purine metabolites in blood following SM intoxication. The protective effects of various antioxidants, trolox, a water soluble analog of vitamin E, quercetin, a naturally occurring bioflavonoid, and reduced glutathione were studied following SM vapor inhalation in mice and by the percutaneous route. A significant decrease in reduced glutathione and an increase in the level of malondialdehyde, indicating oxidative damage to liver and lung tissues following SM inhalation and percutaneous exposure, was observed. Blood and urinary uric acid, an endproduct of purine metabolism, showed an increase following both routes of exposure. The antioxidants, trolox and quercetin, protected the liver and lung tissues from oxidative damage caused by SM exposure through inhalation and percutaneous routes (Kumar *et al.*, 2001, 2002). Quercetin, gossypin, *Hippophae rhamnoides* flavone and vitamin E were evaluated against the systemic toxicity of percutaneously administered SM in mice. The study supported the fact that SM induces oxidative stress and flavonoids are promising cytoprotectants against the toxic effects of SM more so than vitamin E, but they all are effective only as a pretreatment (Vijayaraghavan *et al.*, 2008). Reduced glutathione and oxidized glutathione levels were decreased, and the malondialdehyde level was elevated after percutaneous administration of SM in mouse. Oral administration of *Hippophae rhamnoides* leaf extract and the flavone from fruit significantly protected them (Vijayaraghavan *et al.*, 2006). Oral administration of *Aloe vera* gel gave only a partial protection though it also contains antioxidants (Gautam *et al.*, 2005).

C. Efficacy of Amifostine and DRDE-07 Analogs as Promising Cytoprotectants

Although several approaches have been proposed to counteract the toxic effect of SM, no satisfactory treatment regimen has evolved. The synthetic aminothiol, amifostine, originally developed as a radioprotector and earlier known as WR-2721 [*S*-2-(3-aminopropylamino) ethyl phosphorothioate], has been extensively used as a chemical radioprotector for the normal tissues in cancer radiotherapy and chemotherapy. Since SM is known as a radiomimetic agent various analogs of amifostine were evaluated against SM toxicity in rat liver slices. One analog, DRDE-07 [*S*-2 (2-aminoethylamino) ethyl phenyl sulfide] showed excellent protection (Table 60.4). Both amifostine and DRDE-07 protected only when they were administered as pretreatment in rat liver slices. *In vivo* protection was also evaluated in mice with oral treatment of amifostine and DRDE-07 against percutaneously administered SM. The protection was dose dependent and effective only when the agents were administered either as a pretreatment or simultaneously with SM, and DRDE-07 offered better protection. Both *in vitro* and *in vivo* data indicate the

[a]PI (protection index) is the ratio of LD_{50} with treatment to LD_{50} without treatment

promising role of DRDE-07 as a prophylactic agent against SM poisoning (Bhattacharya *et al.*, 2001; Vijayaraghvan *et al.*, 2001a; Kumar *et al.*, 2002).

The protection offered by amifostine and DRDE-07 in mice was better than rat and in a search for more effective antidotes against SM, a series of novel *S*-2(omega-amino-alkylamino)ethyl alkyl/aryl thioethers were synthesized and all are water soluble. A number of compounds demonstrated significant protection (Pathak *et al.*, 2004). Few analogs, such as DRDE-10, DRDE-21, DRDE-30, and DRDE-35 including DRDE-07, gave enormous protection in the mouse skin model (Table 60.5). In the rat skin model, DRDE-07, DRDE-10, and DRDE-21 gave about a two-fold protection. Percutaneously administered SM significantly depleted the hepatic glutathione content and increased the percent DNA fragmentation in mice. Some of the compounds, particularly DRDE-07, DRDE-30, and DRDE-35, significantly protected the mice after SM intoxication. The histopathological lesions in liver and spleen induced by percutaneously administered SM were also reduced by pretreatment with these compounds (Kulkarni *et al.*, 2006). These classes of compounds, though giving very good protection against SM but failing to give appreciable protection against 2-chloroethyl ethyl sulfide and nitrogen mustard, showed the mechanism and toxicity of the mustard agents are different. These compounds may prove effective as prototypes for the designing of more successful prophylactic drugs for SM and nitrogen mustard.

D. Efficacy of Other Antioxidants

The superoxide dismutase activity and the malodialdehyde level in blood platelets were higher in SM exposed cells *in vitro* (Buczynski *et al.*, 1999). SM skin burns in guinea pigs were pretreated with oxygen free radical scavengers, like copper–zinc, and manganese superoxide dismutase. Superoxide dismutase compounds dramatically reduced the burn lesions when administered intraperitoneally before SM exposure as assessed by histopathology. When the superoxide dismutase compounds were administered intraperitoneally 1 h after the burn infliction, and repeated daily for 7 days, no protection was obtained (Eldad *et al.*, 1998a).

Glutathione, a tripeptide that exists in high concentrations in cells, reacts with SM and other electrophilic alkylating agents by forming conjugates and detoxifying them. Compounds that can modulate glutathione levels within the cell may reduce the cytotoxicity of SM when used as a pretreatment. L-oxothiazolidine-4-carboxylate, a cysteine precursor, increased the level of glutathione. Pretreatment of human peripheral blood lymphocytes with L-oxothiazolidine-4-carboxylate resulted in a small decrease in cytotoxicity after SM exposure. Post-treatment with L-oxothiazolidine-4-carboxylate was not beneficial (Gross *et al.*, 1997). SM reacts with glutathione to form a glutathione–SM conjugate by the action of glutathione-*S*-transferase. Ethacrynic acid, an inhibitor, and oltipraz, an inducer, were ineffective in modulating this enzyme in cultured normal human epidermal keratinocytes. However, D,L-sulforaphane, a compound obtained from broccoli extract and a potent inducer of this enzyme, increased the level of this enzyme optimally. When SM was challenged with D,L-sulforphane, there was an improvement in survival compared with unpretreated SM controls (Gross *et al.*, 2006).

The production of reactive oxygen species has been proposed to result from electrophilic or oxidative stress with depletion of cellular detoxifying thiol levels including glutathione. The reactive oxygen species initiates a chain reaction with membrane phospholipids to form lipid peroxides, leading to loss of membrane function, membrane fluidity, and finally membrane integrity. Beneficial effects can be achieved by scavengers of reactive oxygen species

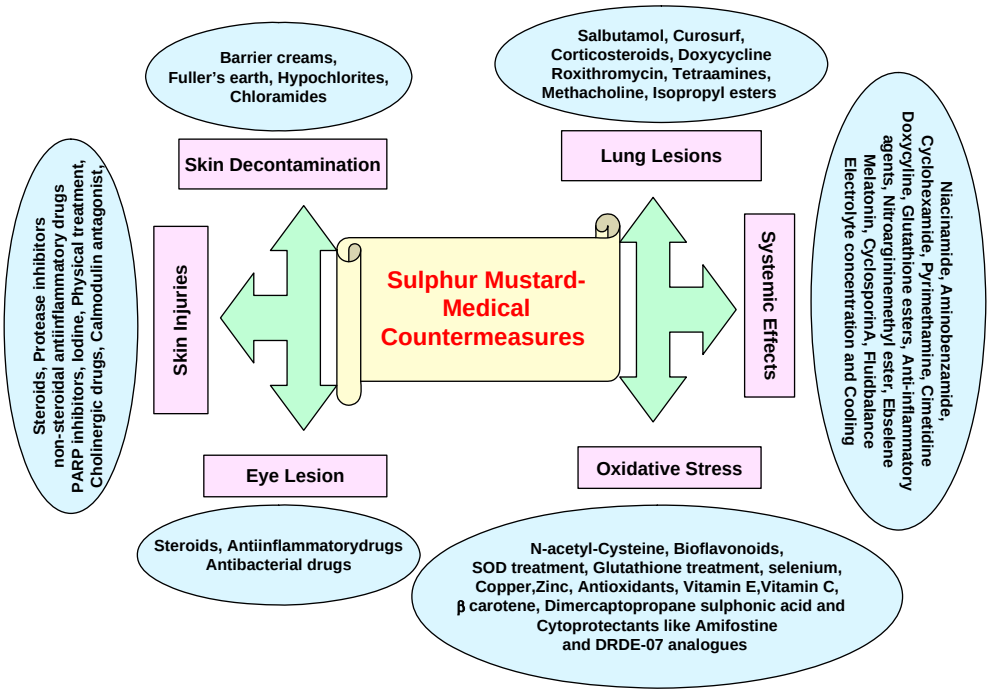

FIGURE 60.4. Schematic presentation of various SM medical countermeasures.

and electrophilic compounds such as glutathione, sulfhydryl compounds, and antioxidants. Substances such as selenium, copper, zinc, and antioxidants including vitamin E, vitamin C, and compounds like beta-carotene may be useful against SM cytotoxicity and lipid peroxidation (Naghi, 2002). Exposure of SM in mice dermally resulted in a significant loss of blood, hepatic, and pulmonary glutathione. These biochemical changes were accompanied by congestion and degeneration in viscera and obliteration of chromatin material in the liver. The biochemical and histopathological changes were less marked in animals pretreated with dimercapto propane sulfonic acid (Pant *et al.*, 2000; Pant and Vijayaraghavan, 2002). SM exposure using the *in vitro* mouse neuroblastoma and rat glioma hybrid cell line model caused a decrease in cellular glutathione level and a time-dependent increase in intracellular-free calcium suggesting a Ca^{2+} mediated toxic mechanism of SM (Ray *et al.*, 1995). Percutaneous administration of SM in mice caused a reduction in glutathione and an increase in malondialdehyde level, and both of them are restored by nifedipine, a calcium channel blocker (Mazumder *et al.*, 1998).

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

A number of animal models and strategies have been used to develop antidotes against the toxicity of SM but none is as successful as decontamination. Decontamination is the best known way to cure or prevent SM-induced toxicity. So far, many decontaminants have been reported but only chloramides and Fuller's earth are to be recommended because of their safety and effectiveness. Various treatment strategies were tried but most of them did not give a satisfactory protection of the *in vivo* system. Povidine iodine, *N*-acetylcysteine and amifostine analogs were found to be effective against SM toxicity *in vivo*. Of these drugs one of the amifostine analogs, DRDE-07, showed maximum protection (Figure 60.4). These types of compounds may prove to be prototypes for the design of more effective antidotes for cytotoxicity of alkylating agents.

CHAPTER 61

Medical Management of Chemical Toxicity in Pediatrics

ELORA HILMAS AND COREY J. HILMAS

Opinions, interpretations, conclusions, and recommendations are those of the author(s) and are not necessarily endorsed by the US Army.

I. INTRODUCTION

There are essentially millions of chemical compounds known to humanity, but only a limited number are weaponized by conventional militaries. The Organization for the Prohibition of Chemical Weapons (OPCW), the 184-member watchdog agency enforcing the guidelines of the Chemical Weapons Convention (CWC), has identified 55 chemical agents and their precursors that can be used as weapons (OPCW, 2005). Although some of the chemicals are well known (e.g. sarin, soman, VX, mustard), other less obvious choices for chemical terrorism include industrial chemicals such as chlorine and toxic precursors, which are considered ''weapons of opportunity''.

In the hands of terrorists, chemical warfare agents (CWAs) and toxic industrial chemicals (TICs) pose significant threats to civilian populations. A 2002 report to Congress by the Central Intelligence Agency reported that terrorist groups ''have expressed interest in many toxic industrial chemicals – most of which are relatively easy to acquire and handle – and traditional chemical agents, including chlorine and phosgene'' (DCI, 2002). While traditional CWAs like nerve agents are attractive to terrorist groups, these agents require a significant degree of financial resources and capital knowledge to manufacture. Furthermore, the USA and remaining signatory members of the CWC have pledged nonproliferation of CWAs (OPCW, 2005). Unfortunately, millions of tons of TICs continue to be manufactured annually in the USA alone. While they support the wide variety of products generated on a daily basis, including dyes, textiles, medicines, solvents, plastics, paints, and insecticides, they are lethal compounds in the hands of terrorists.

Chemical terrorism is the intentional use of toxic chemicals to inflict mass casualties on an unsuspecting military or civilian population, including children. Such an incident could quickly overwhelm local and regional public health resources and emergency medical services. In addition to utilization of CWAs and TICs, an act of chemical terrorism may involve targeting of industrial factories, tanker cars, or vehicles containing toxic substances with conventional explosives near residential communities or schools. Regardless of the methods used, the release of toxic chemicals by terrorists embodies a real and serious threat to our national security and public health. They can quickly incapacitate those who are exposed and can lead to mortality if not recognized and treated promptly. Moreover, the toxicity of these agents can be enhanced in children due to pediatric vulnerabilities. It is imperative to recognize the different ways children may present with toxicity compared to adults.

II. BACKGROUND

Even though many efforts have been made to protect our nation from threats of terror, it is still paramount for our scientific community to continue building our knowledge base regarding CWAs and better understand the toxicities that can occur when children are exposed. Unfortunately, pediatric treatment recommendations are often extrapolated from adult data, even though it is well recognized that pediatric patients should not be regarded as miniature adults. Children present unique vulnerabilities to these chemicals, and special considerations should be taken.

Due to the possibility of pediatric casualties from chemical agent attacks, several pediatric advocacy groups, such as the American Academy of Pediatrics (AAP), have commented on the urgent need for pediatric chemical casualty research (Blaschke and Lynch, 2003). The Committees on Environmental Health and Infectious Diseases have provided the following consensus statement regarding children and chemical–biological threats (CEH/CID, 2000).

> Because children would be disproportionately affected by a chemical or biological weapons release, pediatricians must assist in planning for a domestic chemical–biological

incident. Government agencies should seek input from pediatricians and pediatric subspecialists to ensure that the situations created by multiple pediatric casualties after a chemical–biological incident are considered.

After September 11, the AAP initiated a number of initiatives to try to address the need to prepare for terrorism against children. For example, the AAP created a Task Force on Terrorism, a comprehensive web resource to disseminate information on terrorism and its impact on children. In addition, the AAP has published several reports and policy statements to provide guidance for health care practitioners preparing for a mass chemical casualty event. These efforts were augmented by the passage of several key Federal legislative acts aimed at improving public health emergencies and their response to chemical terrorism. Finally, the Centers for Disease Control and Prevention created the Strategic National Stockpile site (SNS) as a national repository of antibiotics, chemical antidotes, and antitoxins. The SNS contains a pediatric formulary along with compounding materials that would assist clinicians in creating dosage forms appropriate for pediatric administration of chemical antidotes (CEH/CID, 2006) in the event of chemical terrorism.

Indeed, chemical terrorism on US soil is a very sobering possibility in the future. A significant subset of casualties from a mass chemical exposure event will comprise vulnerable populations such as children and the elderly. In the hopes of better understanding the impact of such an event, it is necessary to learn from historical incidents and case studies where children were exposed to toxic chemicals and treated.

In this chapter, the CWAs and ''weapons of opportunity'' most likely to be used by terrorists to inflict casualties will be examined, following a brief historical account and unique challenges of managing pediatric chemical casualties. The sections for each chemical agent will highlight the pediatric-relevant vulnerabilities and guidelines for medical management. The final two sections will discuss decontamination of children and recommendations to help prepare health care managers and providers in the event of a chemical event. It is hoped that this compilation will provide the necessary guidance and treatment recommendations on how best to treat children involved in a chemical attack.

III. HISTORY OF PEDIATRIC CHEMICAL CASUALTIES

Historically, chemical attacks were limited to the battlefield, and casualties were predominantly military personnel. In turn, the majority of our knowledge concerning management of chemical casualties has come from the experiences of treating our military population. Today, the threat of chemical use is extended to civilian populations as state and nonstate sponsored terrorists target innocent civilians. The risk of chemical and biological terrorism is more tangible since the events of September 11, 2001 and the intentional spread of anthrax through the US Postal Service. Terrorists expanded their scope and threat to inflict mass civilian casualties on a scale never before seen. The threat from attack has moved away from the traditional battlefield to the home front. Innocent civilians, including children, are now prime targets for groups to foment terror and destabilize governments. Even before the attack on the World Trade Center towers, the 20th century witnessed numerous instances where civilian populations were exposed to toxic chemicals or targeted on a grand scale.

During the flurry of chemical barrages across trench lines in World War I (WWI), children from bombed towns in France and Belgium were treated at British, French, and American ''gas'' hospitals as a result of CWA exposure. Numerous reports of civilian casualties from mustard, chlorine, and phosgene are well documented in British archives (Thomas, 1985). After the final tally of civilian casualties from ''gas warfare'' was complete, participants saw how ill-prepared their civilians were against such weapons. School-age children learned the importance of protective measures against chemicals through donning of gas masks and evacuating contaminated areas (Figure 61.1).

Civilians have been unintended and, in some cases, intended targets of CWAs since World War I. While cyanide

FIGURE 61.1. School-age girl with US civilian noncombatant gas mask MI-I-I, child size. Photograph: courtesy of the US Army Research Development and Engineering Command, Historical Research and Response Team, Aberdeen Proving Ground, MD.

was used on Jewish prisoners in World War II, chemical weapons would not be used again during combat on civilian populations until the Iran–Iraq War. In the spring of 1987, Saddam Hussein bombed the Iranian city of Sardasht with mustard munitions, resulting in thousands of civilian casualties (Foroutan, 1996a, b, 1998a, b, c).

Following the attack on Sardasht, Iraq attacked Kurd settlements in early 1988, leading to the infamous attack on Kurdish residents of Halabja in March. Thousands of innocent civilian ethnic Kurds perished during the chemical attack, including 75% women and children. Mustard and nerve agents were dropped on civilians from helicopters and planes, and eyewitnesses reported large smoke clouds causing great morbidity and mortality among children (Hay and Roberts, 1990).

Most recently, there have been incidents in the USA where food has been intentionally contaminated with chemical insecticides. Not surprisingly, children were affected in these incidents. One incident occurred in 1998, where a restaurant's salt supply was contaminated with methomyl, a carbamate insecticide. It was reported that five children became ill after eating the insecticide-contaminated food (Buchholz *et al.*, 2002). In another incident that occurred in 2003, approximately 200 pounds of ground beef were contaminated at a grocery store in Michigan with an insecticide called Black Leaf 40. Approximately 90 people (age range 1–76 years) became ill after ingesting the contaminated beef.

These events confirm the devastating reality that chemical threats pose to our unprotected population today. A military and civilian response to the use of chemical weapons on American soil may not be a matter of if but rather a question of when. These events underscore the need for all pediatric-related health care workers to prepare for a mass casualty incident involving CWAs or TICs.

IV. CHALLENGES TO MANAGING PEDIATRIC CHEMICAL CASUALTIES

A. Overview

Managing pediatric victims of chemical terrorism is an especially difficult challenge. In addition to the obvious physiologic and anatomic differences compared to adults (Table 61.1), there are important psychological and behavioral differences that put children at risk (Rotenberg and Newmark, 2003). Anecdotal reports have claimed that children are likely to be the first to manifest symptoms, to develop more severe manifestations, and to be hospitalized for other related illnesses. In fact, it is anticipated that children will be overrepresented among the initial index cases in a mass civilian exposure to toxic chemicals. Children have many characteristics that make them vulnerable to toxic exposures. The smaller mass of a child automatically reduces the dose of toxic agents needed to cause observable or lethal effects. Studies involving organophosphates (OPs), compounds related to nerve agents, have shown greater vulnerability in immature animals. Some OPs produce the same degree of lethality in juveniles at a fraction of the dose producing lethality in the adult (Rotenberg and Newmark, 2003). Children exhibit an exceptional vulnerability to both the acute and chronic effects of chemicals and are disproportionately susceptible in comparison with adults. The increased toxicity seen in children compared to adults from various routes of exposure can be attributable to a wide variety of factors (shown in Exhibit A). These unique anatomical and physiologic considerations described below cause the rates of absorption, distribution, metabolism, and excretion of toxic chemicals/drugs to differ in children with respect to adults.

B. Respiratory Vulnerability

Inhaled doses in young children may be greater than adults. Some studies have demonstrated a two-fold increase in respiratory tract exposure per unit surface area as compared to adults (Bennett and Zeman, 1998). Deposition of fine particles is higher in young children (ages 7 to 14) relative to adults when the data are normalized by lung surface area (Bennett and Zeman, 1998) and an even greater deposition has been modeled for younger age children (Martonen *et al.*, 2000). The higher respiratory rate and minute volumes per respiratory surface area of a child means that they will inhale a greater dose of a toxic chemical vapor (Rotenberg and Newmark, 2003). Also, children can become intoxicated simply through breathing air that is closer to the ground. Many toxic chemicals display a high vapor density, causing them to distribute closer to the ground (CSMC, 2003). This may lead to greater toxicity for a child compared to an adult. In addition, children have less endurance than adults in the use of their respiratory accessory muscles, putting them at risk for respiratory failure.

Children are especially susceptible from toxic chemicals due to their unique airway anatomy (Figure 61.2). These differences include a greater degree of subglottic narrowing, diminished airway diameter, tendency for nose-breathing, and large tongue size relative to the mouth (Rotenberg and Newmark, 2003). OP nerve agents induce bronchospasm and bronchoconstriction during a cholinergic crisis. In comparing the effect of nerve agent on adult and pediatric airways, Figure 61.2 illustrates that a similar change in airway diameter results in a greater percent increase of airway resistance in children. In addition, copious glandular secretions during a cholinergic crisis may further restrict airflow through an already narrow airway. Therefore, children are at higher risk for toxicity from inhalational chemical exposure.

C. Volume Status Vulnerability

The circulatory system of children can be severely affected by chemical attacks (Rotenberg and Newmark, 2003).

TABLE 61.1. Summary chart of pediatric vulnerabilities and implications for clinical management

Unique vulnerability in children	Implications and impact from chemical toxicity
Body composition	
• Larger BSA/body mass • Lower total lipid/fat content	• Greater dermal absorption • Less partitioning of lipid soluble components
Volume status	
• More prone to dehydration • Chemical agents lead to diarrhea and vomiting	• Children can be more symptomatic and show signs of severe dehydration
Respiratory	
• Increased basal metabolic rate/greater minute volume	• Enhanced toxicity via inhalational route
Blood	
• Limited serum protein binding capacity • Greater cutaneous blood flow	• Potential for greater amount of free toxicant and greater distribution • Greater percutaneous absorption
Skin	
• Thinner epidermis in preterm infants • Greater cutaneous blood flow	• Increased toxicity from percutaneous absorption of chemical agents
Organ size/enzymatic function	
• Larger brain/body mass • Immature renal function/lower renal function • Immature hepatic enzymes	• Greater CNS exposure • Slower elimination of renally cleared toxins, chemicals and metabolites • Decreased metabolic clearance by hepatic phase I and II reactions
Anatomical considerations	
• Short stature: breath closer to ground where aerosolized chemical agents settle • Smaller airway • Greater deposition of fine particles in the upper airway • Higher proportion of rapidly growing tissues	• Mustard significantly affects rapidly growing tissues • Exposure to chemicals can have significant impact on bone marrow, developing CNS • Increased airway narrowing from chemical agent-induced secretions
CNS	
• Higher BBB permeability • Rapidly growing CNS	• Increased risk of CNS damage
Miscellaneous	
• Immature cognitive function • Unable to flee emergency • Immature coping mechanisms	• Inability to discern threat, follow directions, and protect themselves • High risk for developing PTSD

EXHIBIT A

Anatomical and Physiological Considerations Unique to Children

- differences in anatomy
- allometric scaling factors (e.g. increased surface area-to-volume ratio)
- cardiovascular status
- permeability of the pediatric blood–brain barrier (BBB)
- dermatologic factors (e.g. increased cutaneous blood flow) (Fluhr *et al.*, 2000; Simonen *et al.*, 1997)
- increased skin pH (Fluhr *et al.*, 2004; Behrendt and Green, 1958)
- plasma protein binding
- volume of distribution (V_d)
- organ size and maturity
- pharmacokinetic maturity (e.g. metabolic differences) (Fairley and Rasmussen, 1983)

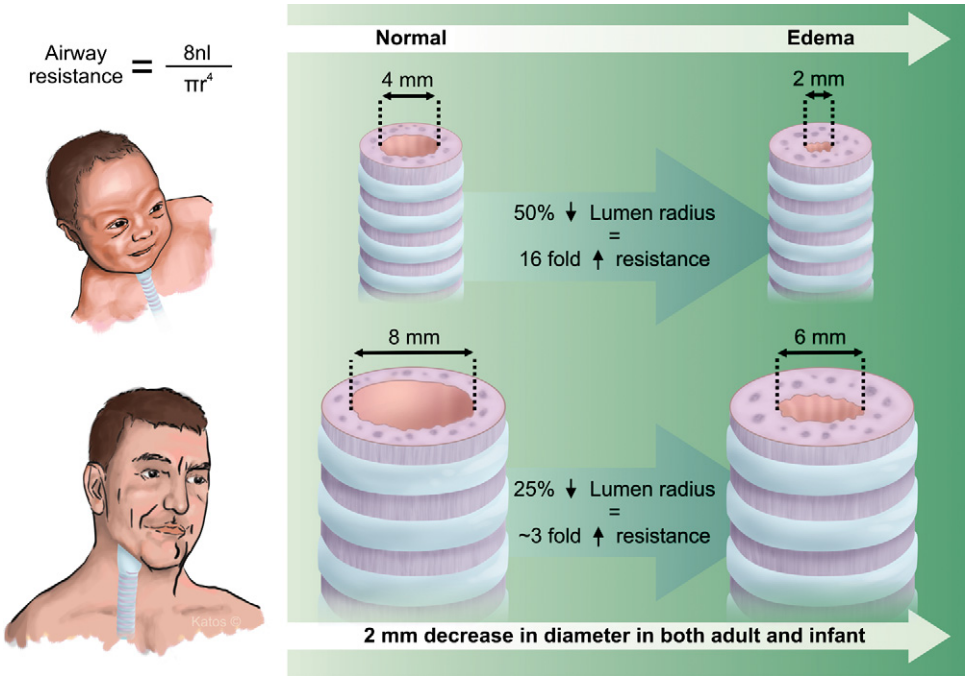

FIGURE 61.2. Comparison of pediatric and adult airways. The most important factor to consider in pulmonary toxicity from cholinesterase inhibition is the airway resistance through the conducting portion of the respiratory system. Airflow from the trachea and mainstem bronchi to the small bronchioles can be characterized as airflow through a series of straight tubes or laminar flow (West, 1995; Guyton and Hall, 2005). Poiseuille's law provides a relationship between flow rate and radius of the tube ($F = P\pi r^4/8nl$), where n is the coefficient of viscosity, P is the pressure difference across the length l of the airway section, r is the radius of the airway, and F is the airway flow rate. Since the resistance to flow R is driving pressure P divided by flow F, using the analogy of Ohm's law, the following relationship for airway resistance R can be derived ($R = 8nl/\pi r^4$). The effect of a 2 mm change in airway diameter on airway resistance is illustrated for both an infant and an adult. *Bottom panel* (adult scenario): a 2 mm reduction in the airway radius as a result of nerve agent-induced bronchoconstriction results in a 25% reduction and a corresponding increase in airway resistance by approximately three-fold. *Top panel* (infant scenario): a similar reduction in a child decreases the airway lumen by 50% and increases airway resistance by 16-fold. Illustrations are copyright protected and printed with permission by Alexandre M. Katos.

Children have lower fluid reserves, and small fluid volume losses can cause significant effects. For example, a 5 kg child, experiencing severe dehydration (15% body weight loss), loses 750 ml of fluid. A significant loss of fluid from the gastrointestinal tract as a result of chemical-induced glandular secretions can affect intravascular volume. Also, children are more prone to vomiting and diarrhea than adults. Therefore, children may dehydrate faster during a chemical event (CSMC, 2003).

D. Neurological Vulnerability

The immature central nervous system (CNS) of children can lead to greater toxicity (Rotenberg and Newmark, 2003). Toxic agents can often transverse the immature blood–brain barrier in children. Infants and children are at greater risk of seizures than adults. This is concerning because seizures are common in cases of moderate to severe nerve agent intoxication. Infants are at the highest risk of toxicity due to their susceptibility to imbalances of neurotransmitter systems. Prolonged seizures, or status epilepticus, can cause neuronal injury and deficits of normal brain development in children.

E. Dermatologic Vulnerabilities

Barrier thickness, cutaneous blood flow, surface to volume ratio, temperature, hydration, and skin pH are important factors to consider in the assessment of pediatric dermatological vulnerabilities. The skin of newborns, while appearing vulnerable, has the same histologic features of adult skin with some differences including immaturity of collagen, hair follicles, and sebaceous glands. While newborns and young children are often described as having thinner skin than adults, the stratum corneum, the most superficial layer of the skin, is thinner in premature infants compared to full-term infants, children or adults (Rutter and Hull, 1979; Harpin and Rutter, 1983; Nopper *et al.*, 1996). The skin of a child, however, does not differ significantly compared to adults as evidenced by similar measurements of skin physiological parameters (e.g. transepidermal water loss, skin pH, and stratum corneum capacitance and conductance) (Fluhr *et al.*, 2000). Children 3 months old have the same abdominal skin stratum corneum thickness as 11 year olds and adults (Fairley and Rasmussen, 1983).

Moreover, children have larger surface area-to-volume (mass) ratios, resulting in greater absorption of chemicals.

The skin surface area of infants and toddlers is very large compared to their body weight. An increase in the surface area-to-body weight ratio increases their potential absorption to dermal exposures of chemicals. For instance, a typical infant weighs a fraction (1/20) of an adult 70 kg male, but an infant's surface area is only 1/8 as great. The total skin surface area that is exposed per kg of body weight is therefore 2.5 times higher for infants than adults (Lynch and Thomas, 2004). Burns with extensive skin loss, as seen with certain chemical exposures, can cause significant water loss and toxicity in children (Lynch and Thomas, 2004). Despite the few prospective scientific studies on skin vulnerability in the pediatric population, it can be summarized that the thin, immature skin of preterm infants and the unique dermatological properties of children put them at higher risk for toxicity from percutaneous chemical exposure (CSMC, 2003).

F. Plasma Protein Binding, Volume of Distribution, and Organ Maturity

Children may be at an increased risk of chemical toxicity due to having lower levels of plasma proteins. One factor affecting the amount of free chemical/drug in the circulation is the fraction bound to plasma protein. Neonates have a low protein binding capacity for albumin and alpha-1-glycoprotein (Besunder *et al.*, 1988; Kearns and Reed, 1989; Clewell *et al.*, 2002) and a decreased ability to conjugate and excrete bilirubin, which binds to plasma proteins. This can lead to a smaller pool of available protein binding sites in plasma (Ginsberg *et al.*, 2004). A lower serum protein binding capacity equates to a greater fraction of free chemical available in the circulation and therefore increased toxicity.

The volume of distribution or V_d (liters per kg body weight) of chemicals/drugs is an important factor to consider in pediatrics. Because of the expanded water content in early life (newborns and infants), water soluble chemicals may tend to have a larger volume of distribution. Toxic lipophilic agents, on the other hand, will be decreased in their partitioning to fat because of the lower body lipid content in young children compared to older children and adults (Kearns and Reed, 1989; Clewell *et al.*, 2002; Morselli, 1989). It can be argued that due to lower fat stores, lipophilic agents such as nerve agents will reach higher concentrations in the plasma, leading to an increased risk of chemical toxicity.

Another factor affecting tissue distribution of chemicals in children is organ size per body weight. The brain is disproportionately large in young children. This fact, combined with an immaturity and permeability of the BBB in young children, leads to higher brain concentrations of some chemicals and the potential for enhanced neurotoxicity (Saunders *et al.*, 2000). Liver mass per body weight is greatest in the early postnatal period and other tissues (liver, kidney, lung, and brain) undergo rapid growth during the first 2 years of life (NRC, 1993). These organs are at increased risk for toxicity in children due to their disproportionately larger size per body weight.

Organ maturity in the pediatric population is another factor affecting clearance of toxic agents and therapeutics. In particular, renal clearance is diminished in children compared to adults. Glomerular filtration rate and transporter (secretory) systems in the proximal convoluted tubule are decreased at birth (Kearns and Reed, 1989; Morselli, 1989). In addition, cardiac output, while higher in children, has a lower percentage reaching the kidneys in early life (Ginsberg *et al.*, 2004). This will tend to decrease renal clearance even more, leading to even greater plasma levels of toxic agent. A consequence of immature kidney function and reduced clearance in children can be seen with nerve agents since the parental forms of nerve agents and their metabolites undergo hydrolysis with predominantly renal elimination.

One might consider that renal clearance is faster due to allometric scaling differences in children compared to adults. According to the rules of allometric scaling, smaller organisms have greater respiratory rates, cardiac output, nutrient and oxygen demands, and basal metabolic rates compared with larger organisms. This appears true for children because respiratory rate, cardiac output, and liver mass are greater per body weight than adults. However, faster metabolic rates are not seen in neonates because of immaturity of hepatic enzymes and reduced hepatic clearance, leading to a prolonged toxic agent/drug half-life and longer duration of action.

G. Metabolic Vulnerability

Children are unable to detoxify toxic agents as efficiently as adults because they have less mature metabolic systems (Rotenberg and Newmark, 2003). In particular, phase I oxidative systems, phase II conjugating systems, and miscellaneous other systems (e.g. serum esterases, hydrolases, dehydrogenases) are all immature in children compared to adults. Neonates and children up to 1 year are most affected in their maturing enzymatic function with the greatest effect seen in the first 2 months of life. This leads to slower metabolic clearance of many drugs, toxic chemicals, and activated metabolites, leading to significant toxicity in this age group (Ginsberg *et al.*, 2004). In addition, several authors have reported a reduced activity of acetylcholinesterases, pseudocholinesterases, and arylesterases (paraoxonase) in premature and full-term newborns (Stead, 1955; Lehmann *et al.*, 1957; Augustinsson and Brody, 1962; Ecobichon and Stephens, 1973). These levels do not reach adult levels until 1 year of age (Morselli, 1976). In addition, newborns possess levels of paraoxonase, the enzyme that detoxifies organophosphate pesticides, that are half of those found in the general adult population (Rotenberg and Newmark, 2003). Other studies suggest that newborns have paraoxonase levels four-fold lower and activities three times lower than in their mothers (Holland *et al.*, 2006).

H. Traumatic Injury Vulnerability

Another special challenge to managing pediatric patients is the fact that trauma and injury often accompany chemical attacks (Abraham *et al.*, 2002). Chemical exposures are often dispersed through explosive devices. Traumatic injury patterns differ in children compared to adults. Due to the smaller size of children, multiple trauma occurs more frequently. Compared to adults, children often sustain more head trauma due to their relatively large head size and weaker supportive musculature. Also, their more compliant skeletal system provides less protection to internal organs, leading to greater internal injuries without overlying fractures.

I. Neurobehavioral Vulnerability

Immature cognitive function can put children at risk during a chemical attack (Rotenberg and Newmark, 2003). Children lack the ability to discern threat, to protect themselves, or to follow directions. Infants, toddlers, and young children do not have the motor skills to flee from the site of an incident (CEH/CID, 2000). This can adversely impact their avoidance of a contaminated area and decontamination in the event of exposure. During decontamination, procedures for children who have been separated from their caregivers must be taken into consideration. Without guidance, children may not be able to follow directions for the decontamination process (Wheeler and Poss, 2003).

J. Psychological Vulnerability

Children have fewer coping skills when sustaining or witnessing injury such as parental or sibling death (Henretig *et al.*, 2002b). These events can produce either short- or long-term psychological trauma. It is not unusual for children involved in attacks to suffer from post-traumatic stress disorder (PTSD) related to what they have experienced (CEH/CID, 2000; ARC, 2002). During the management of a chemical event, there are certain behaviors that make the management of children difficult. Children are often influenced by the emotional state of caregivers, requiring providers to remain calm. Also, fear or discomfort may cause children to disobey or act out against providers of care (see Table 61.1) (Blaschke *et al.*, 2003).

Even beyond the behavior of children, there are other barriers to emergency management. The high pressure hoses and cold water that are used to decontaminate victims can expose children to significant additional risk (CSMC, 2003). Use of these items can result in hypothermia and skin damage. Also, emergency care providers often need to wear bulky full protective suits when treating victims. These suits make it difficult to treat very small children who might need intricate procedures such as blood draws. One constant challenge that is consistent with the management of children is the lack of pediatric formulations of specific therapeutics (e.g. autoinjectors containing oxime). Antidotes for chemical agents are often not available in ready-to-administer pediatric dosages, although some progress has been made. In the event of a true chemical event, there is a risk that pediatric centers would be overwhelmed and the ability to expand the number of pediatric hospital beds may be limited (CEH/CID, 2000). Finally, most health care workers are not fully aware of the management or presentation of toxic signs and symptoms from chemical agents. This problem is exacerbated when children typically present differently than adults.

K. Other Vulnerabilities

In addition to the vulnerabilities listed above, there are other factors that can put children at greater risk for toxicity from chemical agents attacks. For instance, the fluid and food intakes of children differ significantly from adults with greater water and milk consumption per weight. Children ingest about 100 ml/kg per day of water compared to the 40–60 ml/kg per day ingested by adults. If water or milk supplies become contaminated, children would feel a greater impact than adults. Also, the diets of children include greater consumption of foods that can be contaminated such as fruits and vegetables (CEH/CID, 2006).

L. Medical Response Vulnerability

Due to the myriad of factors outlined above that make the management of pediatric chemical exposures challenging, it is not surprising that health care practitioners often do not have the knowledge or are not sufficiently trained to handle a mass influx of pediatric casualties. This deficiency was clearly documented in a recent study done by Schobitz *et al.* (2008), where pediatric and emergency medicine residents were tested on the medical management of pediatric victims of biological and chemical terrorism (Schobitz *et al.*, 2008). A test containing essential content was developed and validated by experts. This test was given to volunteer residents and was readministered 5 months after a lecture on the content. The 34 pediatric residents and 15 emergency medicine residents who took the exam scored a median of 65% and 73%, respectively. The authors investigated the benefit of the lecture and found that the 16 residents who attended the lecture and completed the post-test achieved a median score of 70%. For the 20 residents who did not attend the lecture, but completed the post-test, a median score of 66.6% was recorded. The authors concluded that there are significant knowledge deficits among pediatric and emergency medicine residents in their abilities to handle pediatric victims of biological and chemical terrorism. A suggestion was made to incorporate educational curriculum on preparedness into residency curriculums (Schobitz *et al.*, 2008).

EXHIBIT B (Pediatric Case History) – Nerve Agents

Nerve Agent Exposure in Town of Nazhmar, Iran

One victim of the March 22, 1988 attack on the village of Nazhmar was a young child with unreported age and weight. He presented immediately with marked miosis and was comatose. Breathing was irregular and foamy secretions were evident protruding from his mouth and nose. The patient was working very hard to breathe and noted to be using his accessory muscles of respiration. Wheezing was obvious on auscultation, and he showed obvious difficulty on exhalation. Upon suction removal of oral and nasal secretions, the patient was noted to have progressively rigid extremities such that finding venous access became difficult. The secretions were noted to become bloody. Over a 15 min period, a total of 7.5 mg atropine was administered during three treatments. The patient was noted to improve with eye opening, moaning, and two-word phrases. As his muscle tone decreased, his breathing improved, but wheezing was still evident. The child was decontaminated after treatment and subsequently discharged after an hour. At the time of discharge, secretions were not completely dried up, but his pupils were fully dilated and reactive to light.

V. EFFECTS OF SPECIFIC AGENTS

A. Nerve Agents

1. Introduction

Nerve agents pose a real threat to our unprotected civilian population. They can quickly incapacitate those who are exposed and can lead to mortality if not recognized and treated promptly. The toxicity of these agents can be enhanced in children due to pediatric vulnerabilities. Also, it is important to recognize the different ways children may present with toxicity compared to adults.

The major nerve agents are the G-series (tabun, sarin, cyclosarin, soman) and V-series (VX) compounds. These agents are clear, colorless, tasteless, and in most cases, odorless. They have been demonstrated to penetrate normal clothing and skin. Also, these agents are highly toxic as evidenced by the fact that as little as 10 mg of VX on the skin is considered to be an LD_{50} in adults (Rotenberg and Newmark, 2003). In addition, these agents produce toxicity rapidly compared to biological agents. Most G-series nerve agents are highly volatile, and can be dispersed into aerosols that are inhaled by victims. One of the G-series agents, sarin, is volatile and may sink close to the ground (in undisturbed air) where children breathe. Nerve agents may also be disseminated in liquid form. Treatment for dermal exposure begins with rapid topical decontamination.

Although our military experience managing toxicity from nerve agent exposure is limited, exposures to related chemicals such as the OP class occur commonly each year in the USA. In 2006, there were a total of approximately 5,400 OP exposures across the USA (Bronstein *et al.*, 2007). OPs, such as malathion, are commonly used as pesticides. OP toxicity manifests in a similar fashion as toxicity from nerve agents; however, this chemical class is considerably less toxic. One case series of 16 children who experienced poisonings with OPs confirmed that pediatric patients present with toxicity differently than adults (Lifshitz *et al.*, 1999). These children often did not manifest the classic muscarinic effects (such as salivary secretions and diarrhea) seen in adults.

2. Mechanism of Toxicity

Nerve agents cause toxicity by inhibiting esterase enzymes, especially acetylcholinesterase (AChE) (Rotenberg and Newmark, 2003). When nerve agents bind to AChE, they prevent hydrolysis of acetylcholine (ACh). When ACh accumulates in the synaptic space of neurons, this leads to overstimulation of muscarinic and nicotinic receptors. This overstimulation is often termed ‘‘cholinergic crisis’’. Also, it is important to note that the nerve agent–AChE bond undergoes a reaction called ‘‘aging’’ (Dunn and Sidell, 1989). Once this process is complete, the enzyme becomes irreversibly inactivated. This aging process dictates the need for prompt therapy to prevent irreversible toxicity.

3. Clinical Presentation

The signs and symptoms of a cholinergic crisis can be remembered using the mnemonic BAG the PUDDLES (Figure 61.3); these range in severity from lacrimation and urination to seizure activity (Rotenberg and Newmark, 2003). The manifestations of cholinergic crisis seen in a particular individual depend on the dose and route of exposure, as well as the duration of exposure. If death occurs from nerve agents, it is primarily attributed to respiratory failure. Nerve agents affect the respiratory system by causing central apnea, flaccid neuromuscular paralysis, bronchoconstriction, and profound glandular secretions (Hilmas *et al.*, 2006).

Children present a clinical picture that can be very different to that observed in adults. Children in cholinergic crisis may not necessarily manifest with miosis (constriction of pupils) (Rotenberg and Newmark, 2003). In fact, one case series demonstrated absence of miosis in 43% of pediatric victims. Studies involving pediatric exposure to organophosphates have suggested the appearance of isolated CNS effects (such as stupor, coma) in the absence of peripheral muscarinic effects. Pediatric victims of OP intoxication display significant muscular weakness and hypotonia in the absence of glandular secretions in 70–100% of cases involving moderate to severe levels of exposure (Rotenberg and Newmark, 2003). For adults, a presentation of central

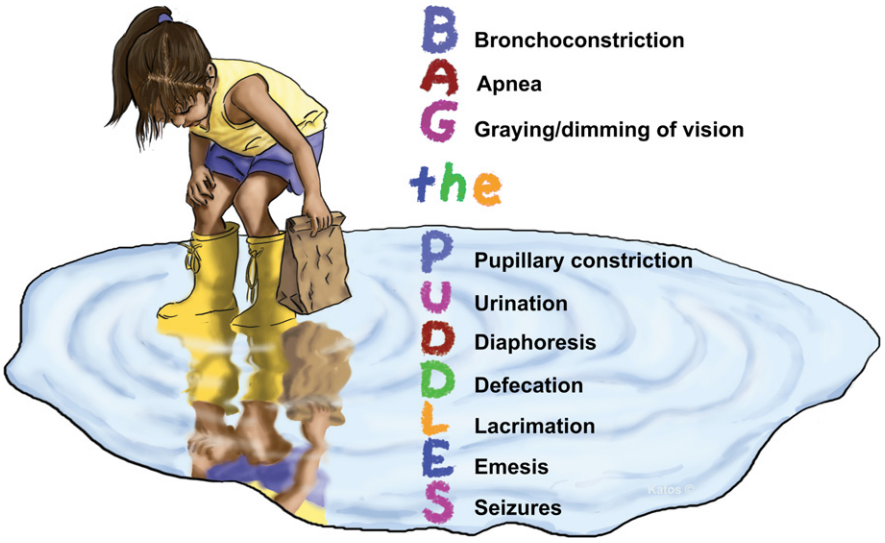

FIGURE 61.3. Helpful mnemonic for cholinergic crisis (BAG the PUDDLES). Illustrations are copyright protected and printed with permission by Alexandre M. Katos (Rotenberg and Newmark, 2003).

intoxication (weakness and hypotonia) from OPs without peripheral muscarinic signs and symptoms would be extremely atypical.

Unfortunately, there are no data on the long-term effects of nerve agent poisoning in children, and the effects must be extrapolated from what has been discovered in the adult population (Rotenberg and Newmark, 2003). Surveillance studies performed on victims of the sarin attacks in Japan revealed a wide range of sequelae, such as continued respiratory problems, vision disturbances, headache, and fatigue. Neuropsychiatric problems were also reported as a delayed effect.

4. Laboratory Findings

Use of cholinesterase levels is limited, especially for confirmation of exposure (Rotenberg and Newmark, 2003). Treatment should not be delayed for these levels to return. Levels should be used after exposure only to confirm diagnosis (after treatment has begun), to monitor recovery, or for forensic investigation.

5. Pediatric Vulnerability

Children have several vulnerabilities, putting them at increased toxicity from this class of chemical agents. A child's smaller mass alone reduces the dose needed to cause symptoms or lethality. For volatile nerve agents, children are especially at risk for respiratory toxicities due to their anatomic differences compared to adults. Their smaller airways can become compromised by the large amount of secretions and the bronchospasm caused by the agents. Also, a greater dose of nerve agent will be inhaled in children due to their higher respiratory rate and minute volumes.

6. Treatment

The overall treatment approach to nerve agent exposure focuses on airway and ventilatory support, aggressive use of antidotes (atropine and pralidoxime), prompt control of seizures, and decontamination as necessary (Henretig, 2002a). Atropine is used for its anti-muscarinic effects, and oxime is used to reactivate AChE. The combination of atropine and pralidoxime chloride (2-PAM Cl) is recommended for the prompt treatment of all serious cases. The timing of atropine and 2-PAM Cl administration is critical. In short, the faster these antidotes are given, the better the outcome. Oxime therapy is rendered ineffective if given after the enzyme aging process has been completed (Dunn and Sidell, 1989). This fact has led to the use of autoinjectors because of their ability to rapidly administer intramuscular doses of these medications. However, there are no currently Food and Drug Administration (FDA)-approved pediatric autoinjectors for 2-PAM Cl. Other administration routes and methods include intravenous (IV) or intraosseous (IO) for atropine and slow IV or continuous infusion for 2-PAM Cl. Data show that peak plasma concentrations of medications administered from autoinjectors are achieved in less than 5 min versus 25 min for intramuscular (IM) administration using a needle and syringe (Rotenberg and Newmark, 2003). The mainstay of adult therapy includes the use of autoinjector technology containing atropine and 2-PAM. Recently, Meridian Medical Technologies™ has developed and received FDA approval for a dual-chambered autoinjector called the ATNAA (Antidote Treatment Nerve Agent Autoinjector) for the military and Duodote™ for civilian emergency medical technicians and first responders (see Figure 61.4). Meridian also produces the older Mark I™ kit (Figure 61.5) which is composed of separate autoinjectors for atropine and 2-PAM.

These products are provided by Meridian Medical Technologies, which has partnered with the US Department of Defense to be the only FDA-approved supplier of nerve agent antidotes. The Mark I™ kit and the single autoinjector devices deliver 600 mg of 2-PAM Cl and 2 mg of atropine (AtroPen®) in seconds. This kit was developed originally

FIGURE 61.4. ATNAA and Duodote™. Photo reproduced with permission from Meridian Medical Technologies™.

FIGURE 61.5. The MARK 1™ kit. Photo reproduced with permission from Meridian Medical Technologies™.

for administration to soldiers, not for children, and with the approval of the Duodote system, the Mark I kit will most likely become antiquated. The autoinjector technology incorporates a spring-loaded needle to disperse medication in an ''all-or-nothing'' fashion. It is impossible to give partial doses of an autoinjector for children. Drug dosing of atropine and 2-PAM Cl in pediatrics is primarily weight based, so a standard dose cannot be used. Pediatric versions of the Mark 1™ kit are available overseas but are not currently available in the USA (PEAP, 2004). In June 2003, the FDA approved pediatric doses of the AtroPen® (atropine autoinjector) to respond to the lack of pediatric specific therapy (Meadows, 2004). Meridian's AtroPen is now available in four dosages, 0.25 mg, 0.5 mg, 1 mg, and 2 mg (Figure 61.6). The 0.25 mg dose should be used for infants weighing less than 7 kg, the 0.5 mg treats patients weighing 7–18 kg, the 1 mg treats patients weighing 18–41 kg, and the 2 mg dose should be used for children/adolescents who weigh more than 41 kg. The needle length for these autoinjectors is 0.8 inches, with a needle gauge of 22. Administration technique of autoinjectors in children is displayed in Figure 61.7. Since the AtroPen® delivers only atropine and not 2-PAM Cl, there continues to be a limitation to the prompt treatment of children. This fact has caused groups such as the pediatric expert advisory panel from the National Center for Disaster Preparedness to recommend the use of the Mark 1™ kit before use of the AtroPen (PEAP, 2004). A table of how to use the Mark

FIGURE 61.6. The Atropen® pediatric autoinjectors. Dose sizes: 0.25 mg – infant, 0.5 mg – child (7–18 kg), 1 mg – child (18–41 kg), 2 mg – adolescent/adults. Photograph reproduced with permission from Meridian Medical Technologies™.

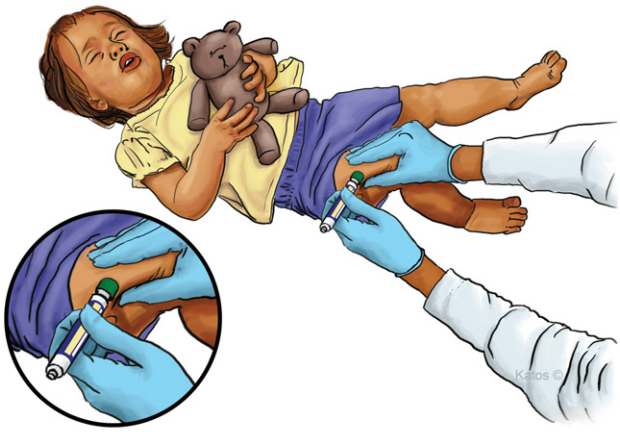

FIGURE 61.7. Technique for using Atropen® pediatric autoinjector.

1 kit for children is displayed in Table 61.2. The use of adult dose-based autoinjectors in children has been addressed. Amitai *et al.* (1992) reviewed 240 instances of accidental pediatric atropine injections using adult dose-based autoinjectors. A low incidence of toxicity was found, with no seizures, arrhythmias, or death. Subsequently, several pediatric guidelines have suggested adult-dose atropine and 2-PAM Cl autoinjectors can be safely used in children larger than 13 kg and inserted to 0.8 inches.

Administration of atropine and 2-PAM Cl must be done cautiously (Rotenberg and Newmark, 2003). Atropine can cause increased heart rate, dry mouth and skin, and near vision can be affected for up to 1 day. Due to the fact that sweating is prevented, elevated temperatures and heat stress may be observed. 2-PAM Cl can cause double or blurred vision and dizziness (Anon, 2002). Doses must be reduced with renal insufficiency. If a medication is given too quickly as an intravenous injection, laryngospasm and rigidity can occur. Higher doses can cause hypertension while lower doses can cause mild electrocardiogram changes (Rotenberg and Newmark, 2003).

Although benzodiazepines are not considered to be an antidote, their use in the treatment of nerve agent exposures is critical (Rotenberg and Newmark, 2003). Status epilepticus can often occur as the nerve agent crosses the blood–brain barrier and causes irritation. Benzodiazepines are the only effective agents that have been proven to treat nerve agent-induced seizures. This group of medications should be used for both prevention and treatment. It is recommended that if more than one organ is impaired, there is impaired consciousness, or muscle twitching, benzodiazepines should be quickly administered. In choosing a specific medication, various agents can be used. Our military department uses the medication diazepam that is administered as an autoinjector (Figure 61.8). In Israel, there is a move towards using midazolam for their population. Some physicians are recommending the use of lorazepam in the pediatric population. Regardless of which medication is used, repeat doses may be needed. For the pediatric population, benzodiazepines should be considered if there is any suspicion of seizure activity. Nonconvulsive status and subtle seizures are common in infants and children, making it difficult for health care providers to recognize nerve agent toxicity.

For each of the medications used to treat nerve agent toxicity, there is weight-based dosing recommendations for pediatric patients. The exact dose to utilize for a specific patient will depend on two critical factors: the severity of the exposure and the weight or age of the patient. Pediatric dosing recommendations for medications used to treat mild to moderate nerve agent exposures are displayed in Table 61.3. Dosing recommendations to treat severe nerve agent exposures are displayed in Table 61.4.

7. Perioperative Care of Children with Nerve Agent Intoxication

As mentioned earlier, it is not uncommon for chemical exposures and trauma to occur at the same time, necessitating the need for surgery. It is important to realize that many drugs used for perioperative management can exacerbate the side effects encountered with nerve agent exposure. Nerve agents can cause drug interactions with medications typically used for resuscitative efforts (Abraham *et al.*, 2001). Anesthetics, such as sodium penthothal and propofol, cause cardiac depression, an effect exacerbated by the excessive muscarinic activity induced by nerve agents. Doses of these drugs may need to be reduced. Use of volatile anesthetics may be preferable because they bronchodilate and reduce the need for nondepolarizing drugs. When nondepolarizing drugs are used, they are often reversed by the use of neostigmine, which affects AChE activity. Halothane should be avoided in infants because the

TABLE 61.2. Dosing of the Mark 1™ kit for children with severe, life-threatening nerve agent toxicity[a] (PEAP, 2004)

Approximate age	Approximate weight	Number of Mark 1™ kit autoinjectors to use	Atropine dosage range (mg/kg)	Pralidoxime dosage range (mg/kg)
3–7 yrs	13–25 kg	1	0.08–0.13	24–46
8–14 yrs	26–50 kg	2	0.08–0.13	24–46
>14 yrs	>51 kg	3	0.11 or less	35 or less

[a]If an adult MARK I kit is the only available source of atropine and pralidoxime, it should not be withheld from even the youngest child (i.e. <3 y.o.)

FIGURE 61.8. The diazepam autoinjector. Photograph reproduced with permission from Meridian Medical Technologies™.

cardiac side effects can be accentuated in the presence of nerve agents. Depression of the cardiovascular system by halothane may cause further bradycardia, hypotension, and reduction in cardiac output. In general, the use of muscle relaxants is not recommended in the setting of nerve agent toxicity. Nerve agents provide a depolarizing block and in the presence of inhibited AChE activity, drugs such as succinylcholine can have longer effects than expected (Rotenberg, 2003b).

Careful use of analgesia is important when caring for victims of nerve agent exposure (Abraham *et al.*, 2001). In general, opioids are considered safe to use because they do not act on the cholinergic system directly. However, some side effects of the drugs, such as histamine release and rare muscle rigidity, can cause difficulty in patient management. Careful dose titration and monitoring for side effects is critical. However, there is one opioid that can have an interaction with nerve agents. Remifentanyl, a potent opioid, contains an ester linkage susceptible to hydrolysis because it is partially metabolized by plasma cholinesterase. This is the same enzyme that is inactivated by nerve agents, resulting in a prolonged duration of action for remifentanyl. Therefore, use of remifentanyl in the post-operative care of nerve agent-exposed victims is not recommended as other analgesics are available (Rotenberg, 2003b). Compared to other chemical warfare agents, patients exposed to nerve agents pose unique challenges for medical and surgical management.

8. Summary

Nerve agent exposures must be handled quickly and efficiently. When children are exposed, it is important to remember that antidote dosing will be determined by the patient's weight and the severity of exposure. Progress has been made to provide pediatric-specific autoinjectors; however, since 2-PAM Cl is not yet available in a pediatric autoinjector form, it is possible to carefully use adult autoinjectors to manage pediatric patients.

B. Carbamates/Organophosphates

1. Introduction

Carbamates and OPs are chemicals that are often used as fungicides, insecticides, or pesticides and possess actions similar to nerve agents. These compounds are considered ''weapons of opportunity'' since their primary use is not by conventional militaries. In the USA, toxicity from these compounds is fairly rare. In 2006, there were approximately 1,200 cases of carbamate exposures and 1,500 organophosphate exposures documented for children 19 years old and younger (Bronstein *et al.*, 2007). Although there were a few fatalities reported in 2006 from these substances, these fatalities occurred only in older individuals.

In general, the toxicity of these compounds resembles that of nerve agents, but is less severe. Pediatric cases of toxicity reported in the literature are often due to accidental poisoning when a young child ingests chemicals placed in unsecured or unlabeled containers. Exposure also can come by consuming foods that have been sprayed with pesticides. Most of the literature on pediatric toxicity from these agents includes retrospective reviews coming out of Israel, where use of these substances as a pesticide for the home and agriculture is common. A retrospective review of 37 cases from the USA has also been published (Zwiener and Ginsburg, 1988).

2. Mechanism of Toxicity

These compounds inhibit the hydrolysis of the neurotransmitter acetylcholine by the enzyme acetylcholinesterase within the mammalian nervous system (Zwiener and Ginsburg, 1988). This inhibition causes acetylcholine levels to rise, thus causing cholinergic hyperstimulation at muscarinic and nicotinic receptors. There are important differences in the way carbamates and OPs bind to acetylcholinesterase as well as their abililty to affect the CNS. Carbamates are reversible inhibitors of cholinesterase enzymes. Carbamates create a reversible bond to the cholinesterase enzyme through carbamylation which can spontaneously hydrolyze, reversing toxicity. Carbamate poisoning produces toxicity similar to that of OPs; however, the toxicity is usually of a shorter duration and less severe in nature (Lifshitz *et al.*, 1994). In contrast, OPs inhibit cholinesterase via an irreversible bond of phosphate radicals

TABLE 61.3. Management of mild/moderate nerve agent exposures (Rotenberg and Newmark, 2003; Anon, 2002)

		Management			
		Antidotes[a]		Benzodiazepines (if neurological signs)	
Nerve agents	Severity of symptoms	Age	Dose	Age	Dose
Tabun, sarin, cyclosarin, soman, VX	**Mild/moderate symptoms** • localized sweating • muscle fasciculations • nausea • vomiting • weakness/floppiness • dyspnea • constricted pupils • blurred vision • rhinorrhea • excessive tears • excessive salivation • chest tightness • stomach cramps • tachycardia or bradycardia	Neonates and infants <6 mo	**Atropine** 0.05 mg/kg IM/IV/IO to max 4 mg or 0.25 mg AtroPen® and **2-PAM** 15 mg/kg IM or IV slowly to max 2 g/h	Neonates	**Diazepam** 0.1–0.3 mg/kg/dose IV to a max dose of 2 mg OR **Lorazepam** 0.05 mg/kg slow IV
		Infants (6 mo–4 yrs)	**Atropine** 0.05 mg/kg IM/IV/IO to max 4 mg or 0.5 mg AtroPen® and **2-PAM** 25 mg/kg IM or IV slowly to max 2 g/h	30 days–5 yrs	**Diazepam** 0.05–0.3 mg/kg IV to a max of 5 mg/dose OR **Lorazepam** 0.1 mg/kg slow IV not to exceed 4 mg
		Children (4–10 yrs)	**Atropine** 0.05 mg/kg IV/IM/IO to max 4 mg or 1 mg AtroPen® and **2-PAM** 25–50 mg/kg IM or IV slowly to max 2 g/h	5 yrs and older	**Diazepam** 0.05–0.3 mg/kg IV to a max of 10 mg/dose OR **Lorazepam** 0.1 mg/kg slow IV not to exceed 4 mg
		Adolescents (>10 yrs) and adults	**Atropine** 0.05 mg/kg IV/IM/IO to max 4 mg or 2 mg AtroPen® & **2-PAM** 25–50 mg/kg IM or IV slowly to max 2 g/h	Adolescents and adults	**Diazepam** 5–10 mg up to 30 mg in 8 h period OR **Lorazepam** 0.07 mg/kg slow IV not to exceed 4 mg

[a]In general, pralidoxime should be administered as soon as possible, no longer than 36 h after the termination of exposure. Pralidoxime can be diluted to 300 mg/ml for ease of IM administration. Maintenance infusion of 2-P at 10–20 mg/kg/h (max 2 g/h) has been described. Repeat atropine as needed every 5–10 min until pulmonary resistance improves, secretions resolve, or dyspnea decreases in a conscious patient. Hypoxia needs to be corrected as soon as possible.

to the active esteratic site of the enzyme (Lifshitz *et al.*, 1999). Thus, the toxicity is more severe.

3. Clinical Presentation

OPs and carbamates have different receptor activities in the mammalian nervous system. OPs have effects on muscarinic and nicotinic receptors and can cause neurological effects in the CNS (Levy-Khademi *et al.*, 2007). Carbamates are thought to cause only parasympathetic muscarinic effects with limited nicotinic and CNS effects (Sofer *et al.*, 1989). However, there are case reports in children that have revealed the presence of CNS effects with carbamate exposures (de Tollenaer *et al.*, 2006). One pediatric case series stated that the signs and symptoms from carbamate poisoning were indistinguishable from OP exposures, with severe CNS depression with stupor and coma occurring in eight cases (Sofer *et al.*, 1989).

Muscarinic hyperstimulation leads to a clinical presentation of miosis, lacrimation, salivation, bradyarrhythmias, urinary incontinence, and intestinal hypermotility (Levy-Khademi *et al.*, 2007). Nicotinic hyperstimulation leads to fasciculations, weakness, and paralysis of skeletal muscles. CNS effects include depression and agitation with coma and seizures occurring in the most severe cases for adults. Generalized tonic–clonic seizures have been seen in several pediatric exposure cases reported in the literature (Zwiener and Ginsburg, 1988).

Additional toxicities that have been reported in the children include diarrhea, pulmonary edema which was associated with OP exposures but not carbamate exposures (Lifshitz *et al.*, 1999), acute pancreatitis, hyperglycemia (Weizman and Sofer, 1992), dyspnea, sweaty cold skin (Sofer *et al.*, 1989), respiratory distress or failure, lethargy, and tachycardia (Zwiener and Ginsburg, 1988).

4. Laboratory Findings

Key findings that have been reported include significant hypoxia, acidosis, and carbon dioxide retention (Sofer *et al.*, 1989). Also hyperglycemia, hypokalemia, and leukocytosis were observed in a case series of organophosphate exposures (Levy-Khademi *et al.*, 2007). A prospective study done on 17 children with typical organophosphate or carbamate poisoning looked at laboratory abnormalities that are associated with acute pancreatitis. Five of the patients (30%) had laboratory values consistent with pancreatitis with elevated immunoreactive trypsin, amylase, and serum

[a]In general, pralidoxime should be administered as soon as possible, no longer than 36 h after the termination of exposure. Pralidoxime can be diluted to 300 mg/ml for ease of IM administration. Maintenance infusion of 2-PAM at 10–20 mg/kg/h (max 2 g/h) has been described. Repeat atropine as needed every 5–10 min until pulmonary resistance improves, secretions resolve, or dyspnea decreases in a conscious patient. Hypoxia needs to be corrected as soon as possible.

glucose. None of the patients had hypocalcemia, renal dysfunction, or acidosis and all had complete recovery of pancreatic function. The authors concluded that acute pancreatitis, due to anticholinesterase intoxication, is not uncommon in the pediatric population (Weizman and Sofer, 1992). Pancreatitis has been described in adult exposures and the association has been investigated in animal studies (Weizman and Sofer, 1992).

EXHIBIT C (Pediatric Case Histories) – Carbamates/ Organophosphates

Carbamate Exposure in a Child

A 7-year-old female, previously healthy, was exposed to an unknown quantity of the fungicide pesticide maneb (manganese ethylene-bis-dithiocarbamate). She was admitted to the pediatric intensive care unit with status epilepticus. She had experienced abdominal pain with nausea, vomiting, and headache for approximately 3 days prior to admission. On the day of admission, she was pale, unconscious, staring, and hypotonic. Upon examination, it was determined that she also had severe hypothermia (32.5°C) and hypoventilation. In addition, she was found to have a combined metabolic and respiratory acidosis and elevated blood glucose levels. Routine diagnostic investigations such as blood counts, electrolytes, liver/renal function, CSF, and blood cultures, were normal. Urine/blood toxicology screens for barbiturates and benzodiazepines were negative. Liquid chromatographic-mass spectrometry confirmed the presence of maneb in her blood. Upon admission, the patient was intubated and her convulsions were treated with benzodiazepines. Within 24 h, there was a complete recovery of all neurological signs. Repeat physical and neurological exams were normal at 48 h. She was discharged 3 days after admission in good condition.

(*ref:* de Tollenaer *et al.*, 2006)

Case History: Organophosphate Exposure in a Child

A 2-year-old, previously healthy male ingested approximately 10 ml of the organophosphate insecticide demeton-*S*-methyl. Upon discovery of the ingestion, the child was disrobed and washed in the bathtub and then taken to the local hospital. Upon admission, which was approximately 30 min following the ingestion, the child was vomiting and salivating. Atropine was administered. He was then transferred to a larger hospital. During transport, he continued to have excessive salivation and experienced bradycardia. These episodes were treated with additional doses of atropine. Upon admission to the larger hospital, he was salivating, vomiting, and experiencing bronchial hypersecretion. At that time, his pupils were dilated with no reaction to light and he was tachycardic with a pulse rate of 150 bpm. At the hospital, gastic lavage was performed and additional doses of atropine administered. He was intubated prior to the completion of gastric lavage and given diazepam for sedation. Bradycardia (<100 bpm) stimulated the physicians to administer additional atropine. Due to the complexity of the case, the patient was transferred again to a hospital better equipped to handle his case. Upon that admission, the patient's blood pressure was 110/60 mm Hg, pulse 100 bpm, temperature 37.6°C, and his pupils were still dilated and unresponsive. Due to continued bronchial hypersecretion, additional atropine was administered. Obidoxime was administered twice, once at 9.5 and 11.5 h after the ingestion. After the oxime therapy, his condition stabilized and he was able to be extubated approximately 13 h after ingestion. Over the next 4 days, atropine was administered periodically to control mild bronchial hypersecretion. Electrolytes and chest X-rays were normal during the entire course of illness. A low hemoglobin and high alkaline phosphatase were the only abnormal labs. The patient was discharged 8 days after the ingestion in good condition. Plasma cholinesterase levels were initially decreased (<400 U/l), but they rose into the normal range by discharge. Twelve-month follow-up revealed that the child had no signs of neurological sequelae.

(*ref:* Rolfsjord *et al.*, 1998)

Another laboratory value that is often obtained in these exposures is serum pseudocholinesterase. Serum pseudocholinesterase activities are often assessed as normal in children because the reference standards may not be reliable when assessing children. To add to the complexity, the normal range of serum cholinesterase activity is wide (Sofer *et al.*, 1989). Authors have described the limitations of this measurement in determining therapy for children. In fact, it is recommended that a therapeutic and diagnostic trial of atropine should be given whenever there is any possibility of intoxication with these chemicals (Sofer *et al.*, 1989).

Additional laboratory abnormalities that have been reported in children are cardiac disturbances. Prolonged QTc intervals were reported in a few children exposed to organophosphates. However, there was spontaneous resolution with no evidence of ventricular dysrhythmia on electrocardiogram (Levy-Khademi *et al.*, 2007).

5. Pediatric Vulnerabilities

The clinical picture of anticholinesterase intoxication in children is very different to that of adults. Often, clinicians have difficulty in diagnosing the exposure in pediatric patients. In fact, in a retrospective review of OP/carbamate toxicity cases that were admitted to a Children's Medical Center in the USA, the transfer diagnosis was incorrect in 80% of the patients (Zwiener and Ginsburg, 1988). Patients were misdiagnosed with a wide variety of disease states that ranged from head trauma to cranial aneurysm to diabetic ketoacidosis. It was noted that the difficulty in identifying nicotinic and muscarinic signs in children may have contributed to the high misdiagnosis rate. For example, it may be difficult to distinguish normal infant crying from excessive lacrimation (Zwiener and Ginsburg, 1988).

The lack of classic muscarinic effects does not exclude the possibility of cholinesterase inhibitor poisoning in young children with central nervous system depression. In one case series, tearing and diaphoresis were not observed in pediatric patients (Lifshitz *et al.*, 1999). Miosis was absent in a number of pediatric patient cases reported in the literature with 27% of children in one case series lacking miosis on admission (Zwiener and Ginsburg, 1988). The percentage was 20% in another case series of pediatric patients (Sofer *et al.*, 1989).

Adult literature states that the most important signs of organophosphate toxicity are fasciculations and miosis. In one published pediatric case series, fasciculations were quite infrequent, occurring in only 16% of cases (Sofer *et al.*, 1989). Another pediatric case series verified this result, with the frequency of fasciculations being 22% (Zwiener and Ginsburg, 1988).

Another difference is the cardiac manifestations that are seen in adults compared to children. In one pediatric case series, cardiopulmonary manifestations were the least common, with tachyarrhythmias being more common than the bradyarrhythmias that are typically seen in adults (11 patients vs one patient) (Levy-Khademi *et al.*, 2007).

Compared to adults, neurological manifestations of toxicity were the most common in children. In one case series, significant hypotonia and muscle weakness were observed in all children (Lifshitz *et al.*, 1999). In addition, severe CNS depression with stupor and coma occurred in all the cases (Lifshitz *et al.*, 1999). In another case series, coma occurred in 54.8% and seizures in 38.7% of children who were accidentally exposed to organophosphates (Levy-Khademi *et al.*, 2007). It can be theorized that the more permeable blood–brain barrier in young children permits penetration of the toxic agents into the brain, thus causing CNS depression. Another theory is that in young children, cholinesterase inhibitors have a stronger affinity to acetylcholinesterase in the CNS and less affinity to cholinergic synapses in the autonomic ganglia (Lifshitz *et al.*, 1999). Accumulation of toxic compounds or their metabolites in the brain could also result in severe CNS dysfunction. Another thought is that the hypoxemia that has been observed in several pediatric cases could contribute to CNS depression (Sofer *et al.*, 1989).

6. Treatment

In all pediatric cases, supportive care was used to balance electrolyte disturbances and oxygen was administered for hypoxic episodes. Often, patients were intubated and given mechanical ventilation due to the excessive salivation and bronchial hypersecretion. Gastric lavage was utilized in one case of organophosphate ingestion (Rolfsjord *et al.*, 1998). The treatment of organophosphate intoxication mimics that of nerve agent exposures. Atropine and an oxime (such as pralidoxime) are the agents of choice for organophosphate exposures. Atropine therapy alone is recommended for carbamate exposure due to the fact that carbamates reversibly inhibit acetylcholinesterase, so there is little need for an agent such as an oxime, which reactivates the enzyme. In cholinesterase inhibitor poisoning, atropine will alleviate most of the muscarinic signs, few of the CNS symptoms, and almost none of the nicotinic symptoms (Lifshitz *et al.*, 1999).

Although atropine use is standard, clinicians are sometimes faced with the dilemma of administering atropine to a pediatric patient with an elevated heart rate. Due to the fact that children may manifest tachycardia with toxic exposures and the fact that the chronotropic effects of atropine may be minimal in infants and small children compared with healthy young adults, one group of authors suggests that atropine should not be withheld or administered in subtherapeutic doses in tachycardic infants and children with organophosphate or carbamate exposures. Their experience with pediatric patients showed that for patients with tachycardia at the time atropine was administered, their heart rate decreased and none of the patients developed cardiac arrhythmias (Zwiener and Ginsburg, 1988).

Use of oximes is well accepted for organophosphate exposures, but their role in carbamate poisoning is controversial. Animal studies have shown oxime use can increase toxicity when treating carbaryl exposures (Lifshitz *et al.*, 1994). Therefore, there is a general guideline that oximes should be avoided if a carbamate exposure is suspected. One case series reported the routine use of oxime therapy for carbamate exposures in children (Lifshitz *et al.*, 1994). Marked clinical improvement was observed in all patients regardless of whether they were exposed to an organophosphate or a carbamate. In addition to the retrospective review of cases, the authors completed an *in vitro* study of oxime use with carbamate toxicity and discovered that oximes play a minor role in direct reactivation of human carbamylated acetylcholinesterase. Due to this result, the authors concluded that the current guideline to avoid oxime use in a carbamate exposure is valid.

Fortunately, in most cases of organophosphate or carbamate toxicity, pediatric patients had a full recovery if they were diagnosed rapidly and appropriate treatments were administered in a timely fashion.

7. Summary

There is a limited amount of literature available describing the toxicities of organophosphate and carbamate exposures in pediatrics. What literature is available describes major differences between the manners children manifest toxicity compared to adults. It is critical to understand these differences so that patients are not misdiagnosed and appropriate therapy is not delayed. In general, the CNS toxicities are greater in children than in adults with coma, stupor, and seizures being common. It is important to recognize that if therapy is given in a timely manner, complete recovery is often the outcome for children exposed to these toxic agents.

C. Vesicants

1. Introduction

Blister agents or vesicants are chemicals that cause blister or vesicle formation upon dermal contact. Agents such as mustards or lewisite have been used as chemical warfare agents in the past (Yu *et al.*, 2003). Although these agents have less toxicity than nerve agents, they cause prolonged morbidity. There are two types of mustard, termed sulfur mustard (HD) and nitrogen mustards (HNs). HD caused

EXHIBIT D (Pediatric Case Histories) – Vesicants

Mustard Gas Exposure in 14 Children/Teenagers from Halabja, Iraq

Mustard gas was used on the civilian population during the Iraq-Iran War (1980–88). A case series of 14 children and teenagers affected by mustard gas was reported by Momeni *et al*. They found that facial involvement was the most frequent disorder (78%), followed by genital (42%), trunkal and axillar lesions (both 14%). The most prominent laboratory abnormality was eosinophilia (12% of patients). As far as the time course of toxicity, skin lesions appeared 4–18 h after exposure and then erythema developed within 20–30 h. After the erythema, blisters would appear. The authors concluded that the time of onset of toxicity was shorter and more severe in children and teenagers compared with adults.

(*ref*: Momeni and Aminjavaheri, 1994)

Clinical Cases from Mofid Medical Center (Mustard Exposure Following the Halabja Attack on March 17, 1988)

A 3-year-old (yo) male presented to Mofid Medical Center 8 days after the Halabja chemical attack with fever (39.5°C), tachycardia (HR 140), and tachypnea (RR 60). Cutaneous skin lesions were mild, but erythema and edema covered 45 % of his skin surface area. Ocular and respiratory findings were as previously described. Laboratory findings were unremarkable except for a mild anemia. Chest roentograms revealed hilar congestion and consolidation bilaterally. The fever continued despite antibiotic therapy. On day 10 of admission (18 days after exposure), the patient developed leukocytosis with 82% PMNs and worsening respiratory distress. The patient finally died 21 days after exposure.

An 8-yo Iranian male presented at 5:30 pm with fever (40°C), severe agitation, delirium and somnolence 24 h after exposure to chemical agents the previous day in Halabja. BP was 110/70 mm Hg and the patient was notably tachycardic (HR 120), and tachypneic (RR 42). The patient was noted to have serious dermatologic, ocular, and respiratory impairment. Erythema, vesicles, erosions, bullae, ulcerations, and edema was present on 35% of the body. Ocular manifestations included conjunctivitis and palpebral edema. At this point, the patient was working hard to breathe as evidenced from accessory muscles of respiration (sternocleidomastoid). On physical examination of the lungs, wheezing and crepitation were noted throughout all lung field. Laboratory findings were the following: Na^+ 139, K^+ 4.1 mEq/l, BUN 25 mg/dl, calcium 7.3 mg/dl, and WBC 9,900/mm^3 with 90% neutrophils. Arterial blood gases: pH 7.30, pCO_2 31, pO_2 65, and HCO_3 15.1. Chest roentograms showed bilateral infiltrates. The patient died 24 h after admission and 48 h after exposure, despite receiving supportive care.

(*ref:* Azizi and Amid, 1990)

more casualties in WWI than any other chemical weapon. It caused a significant number of casualties, both civilian and military, during the Iran–Iraq War of the 1980s. HD vapor is the route most likely to be used by terror groups (Yu *et al.*, 2003). It affects multiple organ systems including skin, eyes, respiratory and gastrointestinal tracts, and bone marrow (Yu *et al.*, 2003). Nitrogen mustards, on the other hand, have never been used on the battlefield and will not be discussed further.

Lewisite, a vesicant with HD-like properties, causes a similar constellation of signs and symptoms involving the skin, eyes, and airways as well as systemic effects (e.g. increased capillary permeability) after absorption. However, it does not produce immunological suppression like mustard. Another difference is that the management of lewisite toxicity includes an antidote, British Anti-Lewisite (BAL) (Yu *et al.*, 2003).

2. Mechanism of Toxicity

HD rapidly penetrates cells and generates a highly toxic reaction that disrupts cell function and eventually causes cell death (Sidell *et al.*, 1997). It is classified as an alkylating agent, targeting poorly differentiated and rapidly reproducing cells (Yu *et al.*, 2003). Death is a result of massive pulmonary damage complicated by infection.

3. Clinical Presentation

Mustard can cause local effects on skin, airways, and eyes; however, large doses can cause fatal systemic effects (Yu *et al.*, 2003). In a study of clinical findings among children exposed to vesicants, ocular, cutaneous, and respiratory signs were the most prevalent (Azizi and Amid, 1990). Ocular findings consisted of the following: conjunctivitis (94%), palpebral edema (81%), eye closure (63%), keratitis (38%), blepharospasm (25%), corneal ulceration (19%), and chemosis (6%). Cutaneous signs included erythema (94%), hyperpigmentation (75%), ulceration (69%), erosion (63%), blister (56%), edema (50%), vesicles (31%), and hypopigmentation (13%). Respiratory signs included dyspnea (63%), crepitation (50%), and wheezing (25%).

Other pediatric signs of mustard exposure were photophobia, lacrimation, ophthalmalgia, and eye burning (94%). Dry cough (81%), dermal pain, and burning (94%) were also frequent complaints. Less frequent complaints were diplopia, itchy eyes, sore throat, sneezing, nasal secretions, dyspnea, burning sensation of the upper respiratory tract, suffocation, and dysphonia (Azizi and Amid, 1990).

Initial dermal signs of toxicity consist of erythema, occurring 4–8 h after exposure. Pruritus can occur with or prior to erythema (Yu *et al.*, 2003; Azizi and Amid, 1990). Over the next 24 h, large yellowish blisters form in areas of

thin skin such as the groin and underarms. Eye damage can occur, ranging in spectrum from pain and irritation to blindness. Mustard also causes clinical effects that can be delayed for hours (Yu *et al.*, 2003; Sidell *et al.*, 1997; Azizi and Amid, 1990). This causes victims not to recognize toxicity until well after exposure. During this time lag, sulfur works to subclinically damage the skin. This latent period is significant because the shorter the latent period, the more severe the exposure, and the worse the outcome.

The CNS and bone marrow can also be affected, as displayed by symptoms of fatigue, headaches, and depression (Sidell *et al.*, 1997). HD can also lead to pneumonia, the cause of death for many HD casualties in WWI due to lack of antibiotics. A leukopenic pneumonia usually occurs between 6 and 10 days after HD exposure. The manifestation of leukopenia (specifically lymphopenia) results from the myelosuppressive effects of mustard agents.

4. Laboratory findings

While there is no diagnostic confirmatory test for mustard exposure, some laboratory tests can prove useful. As described above, inflammation and infection will show up as fever and leukocytosis. Erythrocyte sedimentation rate (ESR) has been shown to be elevated in patients after mustard exposure (Motakallem, 1988). Some of these patients were in the pediatric age range of 0–18 years. CBC determinations may show abnormalities depending on the severity of the vapor inhalation or exposure (Yu *et al.*, 2003; Azizi and Amid, 1990). The CBC may show a low hematocrit and leukopenia if the exposure was severe. There may be only a transient decrease in WBC with subsequent recovery. In pediatric cases of HD vapor exposure, decreases in hematocrit and/or WBC were likely to occur in the first 2 weeks, with the lowest levels of Hb, Hct, WBC, and neutrophil count observed in the 6th to 10th day samples after exposure (Azizi and Amid, 1990).

These pediatric patients also suffered from clear signs of hypoxemia and renal failure (Azizi and Amid, 1990). Unfortunately, serum creatinine and renal function tests (RFTs) were not found in the charts. Arterial blood gases (ABGs) may provide useful information, but they may show a varied picture. In one pediatric study of mustard casualties, most (43%) cases showed a simple metabolic acidosis. The other groups showed showed the following:

- mixed metabolic acidosis and respiratory alkalosis (29%)
- simple respiratory alkalosis (14%)
- mixed metabolic and respiratory acidosis (7%)
- mixed metabolic alkalosis and respiratory acidosis (7%).

Blood urea nitrogen can be elevated with mustard exposure, but it does not necessarily predict outcome or mortality. Blood urea nitrogen was significantly elevated in severe mustard exposure cases in the Azizi study; three of the four pediatric mustard victims that died showed very high blood urea nitrogen (Azizi and Amid, 1990). While elevations in blood urea nitrogen were found in many of the pediatric casualties from mustard exposure, blood urea nitrogen returned to normal levels soon afterwards in survivors.

5. Pediatric Vulnerability

The effects of sulfur mustard on children are more severe than on adults (Yu *et al.*, 2003). Premature infants have thinner skin, and the dermal–epidermal junction is not fully developed in children (Rutter and Hull, 1979; Harpin and Rutter, 1983; Nopper *et al.*, 1996; Seidenari *et al.*, 2000; Mancini, 2004); therefore, the time between exposure and onset of blisters is shortened, and the number and severity of blisters will be more severe (Yu *et al.*, 2003). In fact, lesions in children exposed to mustard have been shown to be more severe. Initial index cases of mass casualties are typically children. Eye findings tend to be greater in children because of their inability to protect themselves and tendency to rub their eyes (Yu *et al.*, 2003; Azizi and Amid, 1990). Children are also shown to be more susceptible to pulmonary injury for reasons previously discussed. One case report looked at the long-term effects of mustard exposure in a child (Dompeling *et al.*, 2004). Acutely, the child suffered a severe chemical pneumonia; the long-term consequence was chronic bronchiolitis. Finally, signs of gastrointestinal toxicity may be greater in children secondary to fluid losses in combination with lower intravascular volume reserves (Yu *et al.*, 2003).

While the decision to evacuate and hospitalize HD casualties is based on the extent [total body surface area (TBSA) $> 5\%$], severity of the skin lesions, and the recognition of multiple organ involvement (Graham *et al.*, 2005), the threshold to hospitalize children with HD injuries should be lower. One reason is that vapor mustard used by terrorists may cause extensive pulmonary involvement while producing mild skin blisters.

6. Treatment

While decontamination and supportive therapy are the mainstays of treatment, antidotes to counteract HD vapor, aerosol, or liquid exposures do not exist (Yu *et al.*, 2003). Adult decontamination may include bleach solutions; however, this method can cause greater toxicity in children. Soap and water are the preferred agents to use for decontamination in children. Supportive care consists of the management of pulmonary and skin manifestations such as the use of cough suppressants and/or topical silver sulfadiazine for burns (Yu *et al.*, 2003; Sidell *et al.*, 1997; Azizi and Amid, 1990). Pediatric dosage and treatment recommendations for vesicant exposures are displayed in Table 61.5.

There are currently no standardized guidelines of casualty management or drugs available to prevent HD effects on skin and mucous membranes (Sidell *et al.*, 1997; Graham *et al.*,

TABLE 61.5. Management of vesicant exposures (Momeni and Aminjavaheri, 1994; Yu *et al.*, 2003)

Vesicant agents	Symptoms	Antidotes/treatment
Mustard	• Skin erythema and pruritis • Development of large yellow blisters leading to ulcers • Eye damage • Inhalational damage: hoarseness and cough, mucosal necrosis, toneless voice, nausea, vomiting	**Decontamination:** soap, water, no bleach Copious water irrigation for eyes **Pulmonary management:** cough suppressants, throat lozenges **Skin management:** topical agents used for burns (1% silver sulfadiazine), antibiotics for secondary infections (Neosporin®), antihistamines for itching (diphenhydramine 1 mg/kg/dose orally q6–8 h max 300 mg/day, hydroxyzine 0.5 mg/kg/dose orally q6–8 h) **Immune system management:** G-CSF (filgrastim) 5–10 micrograms/kg/day subcutaneous for neutropenia
Lewisite	• Shock • Pulmonary injury • Blisters	**Decontamination:** soap, water, no bleach **Antidote:** BAL-dimercaprol may decrease systemic effects of lewisite **Pulmonary management:** BAL 3–5 mg/kg deep IM q4 h × 4 doses (dose depends on severity of exposure and symptoms) **Skin management:** BAL ointment **Eye management:** BAL ophthalmic ointment

2005). The mainstay of treatment is prompt decontamination, blister aspiration or deroofing (epidermal removal), physical debridement, irrigation, topical antibiotics, and sterile dressing application for cutaneous HD injuries. Current treatment strategies rely on symptomatic management to relieve symptoms, prevent infections, and promote healing. The general recommendations are described in the *Medical Management of Chemical Casualties Handbook* (USAMRICD, 2000a), the Field Management of Chemical Casualties Handbook (USAMRICD, 2000b), and other references (Graham *et al.*, 2005). We will discuss the aspects of treatment that relate to the pediatric population. Most pediatric casualties will have involvement of multiple organ systems (skin, ocular, gastrointestinal, bone marrow, respiratory, etc.) as documented by Iranian physicians treating pediatric casualties of HD vapor during the Iran–Iraq War (Azizi and Amid, 1990).

a. Dermatological Management

Managing mustard skin lesions is especially challenging in the pediatric population. The goal of blister management is to keep the patient comfortable, keep the lesions clean, and prevent infection. Children especially will be extremely anxious at the sight of bullae and erythema in addition to the burning, pruritis, and allodynia associated with HD blisters (Sidell *et al.*, 1997). Anxiolytics may be appropriate to calm them down and prevent them from picking at bullae. Burning and itching associated with erythema can be relieved by calamine or soothing lotion/cream such as 0.25% camphor, menthol corticosteroids, antipruritics (i.e. diphenhydramine), and silver sulfadiazine cream (Sidell *et al.*, 1997; Azizi and Amid, 1990). Pain and discomfort can be relieved with systemic analgesics. Systemic analgesics such as morphine should be given liberally before manipulation of the burned area.

Vapor mustard typically causes a first- or second-degree burn, while liquid mustard produces damage similar to a third-degree burn. In either case, tense bullae are the hallmark of HD injuries. Bullae are typically dome shaped, thin walled, 0.5 to 5.0 cm in diameter, superficial, translucent, yellowish, multiloculated, honeycombed (Moradi *et al.*, 1986), and surrounded by erythema (Sidell *et al.*, 1997). Preventing children from breaking the blisters can be a challenge, especially when constant friction from clothing and blankets is irritating to the skin. These areas should be wrapped in protective dressings. Graham *et al.* (2005) have made an important point about the existence of a reservoir of unbound HD in human skin following a vapor (Logan *et al.*, 2000) or liquid exposure, leading to an off-gassing period. They suggested that this off-gassing period can last for 24 to 36 h, whereby application of an occlusive dressing is not beneficial to prevent vapor build-up (Graham *et al.*, 2005).

It is recommended that small blisters (<1 cm) should be left alone on the child, but the immediately surrounding area should be cleaned, irrigated daily, and covered with topical antibiotic (Sidell *et al.*, 1997). Petroleum gauze bandage dressings should be wrapped around these unbroken blisters and changed every few days. Larger blisters (>1 cm) should be unroofed and irrigated several times a day with saline, sterile water, clean soapy water, or Dakin's solution and covered with topical antibiotic cream or ointment. It should be noted that blister fluid does not contain mustard (Buscher and Conway, 1944) and therefore does not represent a hazard to the health care worker. Options for topical

antibiotic creams in children include silver sulfadiazine, and triple combination antibiotic (bacitracin, neomycin sulfate, and polymyxin B sulfate) (Sidell *et al.*, 1997) but not mafenide acetate, which can cause toxicities in children (Geffner *et al.*, 1981; Ohlgisser *et al.*, 1978). These topical antibiotics should be applied to the area of bullae and surrounding areas of erythema. There is no information comparing use of this combination (triple antibiotic topical ointment) in children with use in other age groups.

While skin healing can take months for completion, pigment changes (hyper- or hypopigmentation) can persist (Sidell *et al.*, 1997; Graham *et al.*, 2005). It is also important to note that not all burn injuries require treatment at a burn center. Patients will require aggressive pain management and close observation for the systemic effects of HD exposure. Skin grafting, although rare, has been successfully used for deep burns (Ruhl *et al.*, 1994).

b. Ophthalmology

The objective for any ophthalmology consultation on pediatric HD injuries involving the eye is prevention of scarring and infection (Sidell *et al.*, 1997). Eyes exposed to HD should be irrigated to remove traces of vesicant. Severe ocular involvement requires topical antibiotics (tobramycin OD) applied several times a day. Topical steroids may be useful in the first 48 h after exposure. Temporary loss of vision may also occur after mustard exposure (Sidell *et al.*, 1997; Azizi and Amid, 1990; Motakallem, 1988). The patient should be reassured that vision loss is not permanent and is due to palpebral edema and not corneal damage.

c. Respiratory System

The conducting and ventilation portions of the respiratory tract are affected with HD vapor, necessitating a pulmonary examination (Dompeling *et al.*, 2004; Sidell *et al.*, 1997; Azizi and Amid, 1990). Bronchodilators are useful to diminish hyperreactive airways and should be used if a prior history of asthma or hyperreactive airways is documented. Further support with humidified oxygen may be required. Ventilatory support may be required for severe cases of HD vapor exposure before laryngeal spasm makes intubation difficult. Bronchoscopy is critical for diagnosis, therapeutic dilation against HD-induced tracheobronchial stenosis, and removal of pseudomembranes that cause airway obstruction.

Since the toxic bronchitis produced by HD is nonbacterial, antibiotic therapy should not be given during the first 3 to 4 days (Sidell *et al.*,1997). Continuous monitoring of sputum for Gram's stain and culture growth is necessary to identify the specific organism responsible for the late developing superinfection. The presence of leukopenia in children, a grave sign of HD exposure, will necessitate aggressive support with combination antibiotic treatment.

d. Gastrointestinal Tract

Atropine or common antiemetics can be given to provide relief from nausea and vomiting, early signs of HD intoxication (Yu *et al.*, 2003). Excellent choices for pediatric-specific antiemetics include medications such as promethazine, metoclopramide and ondansetron (Sidell *et al.*, 1997). Persistent vomiting and diarrhea are a later sign of systemic toxicity and require prompt fluid replacement.

e. Bone Marrow Suppression

As a radiomimetic, HD affects rapidly dividing tissues like bone marrow in addition to the gastrointestinal tract (Sidell *et al.*, 1997; Graham *et al.*, 2005). HD destroys hematopoietic precursor cells; WBCs have the shortest life span and decrease in number first, followed by RBCs and thrombocytes. The bone marrow suppression that is sometimes seen can be treated with filgrastim injections. This medication stimulates the bone marrow to create and release white blood cells.

f. Other Treatment Considerations

Fluid status, electrolytes, and urine output should be monitored in the HD-intoxicated patient. Tetanus prophylaxis should also be administered because fatal tetanus may occur even after a small partial-thickness burn (Marshall *et al.*, 1972).

7. Summary

Pediatric exposures to vesicants can be quite toxic; however, in contrast to nerve agent exposures, HD causes significantly greater morbidity than mortality. While mustard did not cause many deaths in WWI, death from HD exposure is usually due to massive pulmonary damage complicated by infection (bronchopneumonia) and sepsis. Children often show a quicker onset and greater severity of toxicity. Skin and eye toxicity occurs in the form of blisters or irritation that can result in blindness for the most severe cases. Except for lewisite, vesicant exposures must be managed with supportive care and rapid decontamination.

D. Pulmonary Agents

1. Introduction

In January 2002, a Central Intelligence Agency (CIA) report stated that terrorist groups may have less interest in biological materials compared to chemicals such as cyanide, chlorine, and phosgene (DCI, 2002) which are able to contaminate food and water supplies (Sidell *et al.*, 1997; Graham *et al.*, 2005). The targeting of children has the potential to destabilize governments and create widespread terror. Industrial chemicals, such as chlorine and phosgene, have advantages that make them potential candidates to be used by terrorists in the future. Both chlorine and phosgene are fairly easy to manufacture and handle, prompting national concern over their future use. In the USA alone, millions of tons of chlorine and phosgene are produced annually toward the manufacture of various products (Burklow *et al.*, 2003). A detailed discussion of the general mechanisms of chlorine and phosgene toxicity can be found

EXHIBIT E (Pediatric Case History) – Pulmonary Agents

Chlorine Gas Exposure in an Adolescent

A 14-year-old male, previously healthy except for a history of asthma, was exposed to chlorine gas when he mixed household bleach with vinegar. Immediately, he began to cough and have difficulty breathing. His symptoms worsened over the next hour, leading to an admission to the local emergency room. Upon admission, the physical exam revealed that the patient was in respiratory distress with bilateral crackles and diffuse wheezing. He also had conjunctival irritation. Vital signs were pulse 100 bpm, blood pressure of 130/80 mm Hg, respiratory rate of 20/min and a temperature of 97°F. His initial oxygen saturation while breathing room air was 92%. A venous blood gas suggested mild CO_2 retention with a pH of 7.35, PCO_2 of 53 mm Hg, and a PO_2 of 33 mm Hg. Chest radiograph showed bilateral alveolar infiltrates with a normal heart size, which is indicative of acute lung injury. Sinus tachycardia was demonstrated on the electrocardiogram. The patient was treated with oxygen, multiple doses of nebulized albuterol and oral prednisone. Despite these measures, his overall respiratory status continued to decline and a repeat pulse oximetry while on 50% oxygen showed a saturation of 85%. Due to his worsening course, he was intubated and transported to another hospital with a pediatric intensive care unit. Upon intubation, it was noted that the patient had copious secretions. After admission to the PICU, the patient developed acute respiratory distress syndromes (ARDS) and needed ventilatory management for 19 days along with additional doses of albuterol and methylprednisolone. After extubation, he was placed on a prednisone taper and discharged with no evidence of residual pulmonary dysfunction.

(*ref:* Traub *et al.*, 2002)

elsewhere in this textbook and will not be explored further here.

2. Clinical Presentation

Pediatric signs and symptoms of chlorine gas exposure include predominantly ocular, nasal, oropharyngeal, and pulmonary irritation of membranes (Burklow *et al.*, 2003). The hallmark of intoxication by these choking agents involves respiratory complaints. Minor chlorine exposures can lead to burning of the eyes and throat, indicative of mucous membrane irritation. More severely exposed patients may complain of cough, choking, sore throat, shortness of breath, chest tightness, difficulty breathing, and other respiratory-related complaints. Clinical findings may also include lacrimation, rhinorrhea, laryngeal edema, hoarseness, aphonia, stridor, expiratory wheezing, tracheitis, and cyanosis (Güloğlu *et al.*, 2002; Traub *et al.*, 2002). Tachypnea may develop as a direct result of pulmonary irritation, and tachycardia has been demonstrated in some studies. Many pediatric patients with a prior history of reactive airway disease are at increased risk of chlorine-induced bronchospasm (Burklow *et al.*, 2003).

Pulse oximetry may indicate low oxygen saturation (Traub *et al.*, 2002). While arterial blood gases usually indicate hypoxemia, carbon dioxide levels have been shown to be decreased, increased, or normal (Güloğlu *et al.*, 2002; Traub *et al.*, 2002). A hyperchloremic metabolic acidosis may show up on blood chemistries due to systemic absorption of hydrochloric acid.

Pulmonary edema, the most significant morbidity from pulmonary agents, can be seen on chest roentograms (Burklow *et al.*, 2003). Pulmonary edema may develop as early as 2 to 4 h after exposure; radiographic evidence typically appears later. Pulmonary edema may progress to the point of producing Kerley B lines on chest x-rays. These lines are often described as rungs of a ladder running perpendicular to the lateral margin of the lungs, beginning at the costophrenic angle. Chest radiographs will often show opacities of acute lung injury. Pneumomediastinum has also been reported in chlorine gas exposure (Traub *et al.*, 2002).

Pulmonary function tests (PFTs) are not helpful (Traub *et al.*, 2002; Pherwani *et al.*, 1989). A study of school children exposed to a chlorine gas leak reported a predominantly obstructive pattern on PFTs. This could be explained by congestion and edema narrowing the central airways rather than smaller airways.

3. Pediatric Vulnerability

Chlorine is a pungent green–yellow gas, twice as heavy as air (Güloğlu *et al.*, 2002) and settles near the ground (Burklow *et al.*, 2003; Traub *et al.*, 2002). This poses a problem for children, leading to increased exposure for this population in the event of accidental release or an act of terror. Children can be exposed as a result of the following activities: inhaling chlorine vapors at swimming pools (Burklow *et al.*, 2003), mixing of household bleach (sodium hypochlorite) with acidic cleaning agents (Traub *et al.*, 2002), and industrial accidents (Pherwani *et al.*, 1989). Phosgene, a dense gas heavier than air, is a more lethal pulmonary agent than chlorine. While the smell of chlorine is associated with swimming pools, phosgene odor is described as freshly mown hay (Burklow *et al.*, 2003).

Initially, both agents cause intense irritation of the mucosal membranes (Burklow *et al.*, 2003) and coughing (Güloğlu *et al.*, 2002; Traub *et al.*, 2002). This is typically followed by a feeling of suffocation (Burklow *et al.*, 2003). Morbidity from pulmonary agents is the direct result of pulmonary edema, appearing 2–4 h after chlorine exposures. Since children have a smaller fluid reserve (Rotenberg and Newmark, 2003), pulmonary edema can cause rapid dehydration or even shock (Burklow *et al.*, 2003). Due to the higher respiratory rates and minute

TABLE 61.6. Management of pulmonary agent exposures (Burklow *et al.*, 2003)

Pulmonary agents	Symptoms	Treatment
Chlorine	• Lacrimation • Rhinorrhea • Conjunctival irritation • Cough • Sore throat • Hoarseness • Laryngeal edema • Dyspnea • Stridor • ARDS • Pulmonary edema	**Decontamination:** Copious water irrigation of the skin, eyes, and mucosal membranes to prevent continued irritation and injury **Symptomatic care (no antidote):** Warm/moist air, supplemental oxygen, positive pressure O_2 for pulmonary edema **Bronchospasm:** Beta-agonists (albuterol) **Severe bronchospasm:** Corticosteroids (prednisone) (also used for PTS with H/O asthma but use unproven) **Analgesia and cough:** Nebulized lidocaine (4% topical solution) or nebulized sodium bicarbonate (use unproven)
Phosgene	• Transient irritation (eyes, nose, throat, and sinus) • Bronchospasm • Pulmonary edema • Apnea • Hypoxia	**Decontamination:** Wash away all residual liquid with copious water, remove clothing **Symptomatic care:** ABCs, hydrate, positive pressure O_2 for pulmonary edema **Bronchospasm:** Beta-agonists (albuterol), corticosteroids INH/IV, furosemide contraindicated **Hypoxia:** Oxygen

volumes of children (Rotenberg and Newmark, 2003), exposure to pulmonary agents will be greater (Burklow *et al.*, 2003). Concerning the effects on children exposed to pulmonary agents and subsequent treatment, there are many documented clinical case studies in the literature as a result of accidental exposures and industrial accidents (Güloğlu *et al.*, 2002; Traub *et al.*, 2002; Pherwani *et al.*, 1989).

4. Treatment

The first line of treatment for children exposed to pulmonary agents is decontamination. Decontamination can be as simple as removing the victim from the source to fresh air, followed by the removal of contaminated clothing (Burklow *et al.*, 2003). Supportive care includes administration of humidified air, supplemental oxygen, water irrigation, and high flow oxygen delivered via positive pressure for pulmonary edema (Burklow *et al.*, 2003; Traub *et al.*, 2002). Further treatment may include surgical debridement, supportive care with medications such as albuterol for bronchospasm, corticosteroids for inflammation, and antibiotics for any secondary bacterial infections. Antidotes or specific post-exposure treatments do not exist for this class of agents. Supportive treatment recommendations are shown in Table 61.6.

5. Summary

Chlorine and phosgene are two chemicals that can cause severe pulmonary toxicity due to pulmonary edema and direct damage to the lungs. Treatment involves decontamination and supportive care. Special care needs to be provided for exposed children because they are at higher risk for toxicity because of their unique vulnerabilities.

E. Cyanide

1. Introduction

Cyanide is used in plastic processing, electroplating of metals, metal tempering, extraction of gold and silver, fumigants, and photographic development (Rotenberg, 2003a; Baskin and Brewer, 1997). It is also found in vehicle exhaust, tobacco smoke, certain fruit pits and bitter almonds. The major cyanide containing compounds used by the military in WWI were hydrogen cyanide, cyanogen chloride, and cyanogen bromide. Cyanide is also liberated during the combustion or metabolism of nitrogen containing polymers of natural and synthetic origin (Riordan *et al.*, 2002). Cyanides can cause lethality through inhalation of cyanide vapor or ingestion (Prajapati *et al.*, 1992). Cyanide poisoning leads to death in minutes but can be effectively treated with antidotes if diagnosed early. Pediatricians, medical first responders, and firefighters need to recognize victims of cyanide poisoning in order to initiate immediate intervention (Rotenberg, 2003a; Baskin and Brewer, 1997). Cyanide is one of the few chemicals for which an effective antidote exists.

2. Mechanism of Toxicity

The cyanide ion kills aerobic organisms by shutting down oxidative phosphorylation in the mitrochondria and therefore the utilization of oxygen in cells (Baskin and Brewer, 1997; Riordan *et al.*, 2002). Cyanide has a propensity to affect certain organs (e.g. brain, heart, and lungs) more than

EXHIBIT F (Pediatric Case History) – Cyanide

Case History: Cyanide Exposure in a Child

A 2-year-old, previously healthy, 12 kg male ingested an unknown quantity of an acetonitrile-containing sculptured nail remover. The product contains an aliphatic nitrile that releases inorganic cyanide upon human metabolization. The child was brought into the emergency room because of lethargy approximately 10 h after the ingestion. Although the child was acting normally at the time of ingestion, 8 h later, he was found to be moaning, poorly responsive, and having just vomited. In the emergency room, he was pale and lethargic, responding only to deep pain. Abdomen and neck exam was normal and the lung exam revealed bilateral coarse breath sounds with a normal chest roentgenogram. Extremities were mottled and cool with a delayed capillary refill time. Vital signs showed a temperature of 36.9°C, pulse of 140 bpm, respiratory rate of 56/min, and blood pressure of 70/30 mm Hg. Arterial blood gas measurements showed a pH of 6.95, PCO_2 of 11 mm Hg, and PO_2 of 114 mm Hg. His electrolytes revealed a sodium of 137 mmol/l, potassium of 5.1 mmol/l, chloride of 114 mmol/l, bicarbonate of 4 mmol/l, serum creatinine of 70.7 µmol/l, glucose of 15.8 mmol/l, and a blood urea nitrogen of 5 mmol/l. The white blood cell count was 9.5×10^9/l and the hematocrit was 31%. Sinus tachycardia, at a rate of 160 bpm, with normal intervals and axis, was observed on the electrocardiogram. Serial whole-blood cyanide levels were obtained with the initial level being 231 µmol/l (600 µg/dl) 12 h after the exposure. The patient was given oxygen, sodium bicarbonate, and fluid resuscitation. Electrolyte and acid–base disturbances were corrected and no antidotal therapy was administered due to prompt response on supportive therapies. The patient was discharged from the hospital 3 days after admission in good condition.

(*ref:* Caravati and Litovitz, 1988)

others (Rotenberg, 2003a; Baskin and Brewer, 1997). Significant exposure can lead to central respiratory arrest and myocardial depression. Cyanide also acts as a direct neurotoxin (Rotenberg, 2003a), disrupting cell membranes and causing excitatory injury in the central nervous system (CNS) (Baskin and Brewer, 1997; Riordan *et al.*, 2002).

3. Clinical Presentation

Cyanide is an uncommon cause of childhood poisoning. In 2006, there were only 12 reported cases of cyanide exposure in the pediatric population (<19 years) (Bronstein *et al.*, 2007). Since signs of toxicity (see Exhibit F) are so similar to carbon monoxide poisoning, which accounts for the largest group of poisoning deaths among children, clinicians must have a high index of suspicion to make the diagnosis (Riordan *et al.*, 2002; Prajapati *et al.*, 1992). Rotenberg describes a typical toxidrome induced by cyanide (Rotenberg, 2003a). This includes a rapid progression from hyperpnea, anxiety, restlessness, unconsciousness, seizures, apnea, and finally death. Skin, blood, and fundi may be cherry red upon physical examination due to the inability of mitochondria to extract oxygen. In reported cases of accidental cyanide ingestion by children, other signs of toxicity included nausea, vomiting, abdominal pain, headache, lethargy, slurred speech, ataxia, stupor, coma, and respiratory depression. In addition, delayed vomiting occurred due to the slow metabolization of the chemical compound acetonitrile to cyanide, a process that can take 6 to 14 h after the ingestion (Geller *et al.*, 2006).

4. Laboratory Findings

Arterial blood gases can provide clues for cyanide exposure. Classic cases are presented with severe metabolic acidosis, elevated anion gap and high lactate concentrations (Rotenberg, 2003a). Impaired cellular respiration will lead to a high oxygen content in venous blood (Rotenberg, 2003a; Riordan *et al.*, 2002). Thus, a reduced arterial-venous oxygen saturation difference suggests this diagnosis. Blood cyanide levels are confirmatory (Rotenberg, 2003a; Baskin and Brewer, 1997; Riordan *et al.*, 2002) but will only delay the diagnosis, which must be based on the initial clinical presentation. Immediate therapeutic intervention with provision of 100% supplemental oxygen and administration of specific antidotes is paramount. An

Soot in nose

almond-like odor on the breath may alert a clinician that a person may have been exposed to cyanide, but up to 40% of the general population is unable to detect this odor.

5. Pediatric Vulnerability

Children are especially vulnerable to cyanide attacks (Rotenberg, 2003a). A larger exposure to cyanide vapor occurs due to the higher respiratory rates and higher surface-to-volume ratios in children. Cyanide liquid causes greater and more rapid absorption when it comes against the immature skin barrier of children. Lower body mass and immature metabolic processes can render children more susceptible than adults to toxicity from cyanide exposure. It has also been noted that children seem more susceptible to ingestion poisoning as demonstrated by various cassava and apricot pit exposures where the severity of toxicity was greater than that seen in adults who were also ingesting these products. In fact, it has been theorized that due to children's higher gastric acidity, leading to greater absorption, they experience more severe toxicity than adults when cassava is ingested (Geller *et al.*, 2006). A case report of potassium cyanide ingestion among ten children reported that the initial symptoms seen included abdominal pain, nausea, restlessness, and giddiness (Prajapati *et al.*, 1992). Cyanosis and drowsiness were also noted, but the signature cherry red skin color was not reported. Post mortem examination from the two children that died showed bright red blood and tissues with congestion. These two children consumed powder packets of potassium cyanide mixed in water, while the other eight children licked the powder, leading to less toxicity. The survivors were managed with aggressive supportive care including gastric lavage, oxygen, and intravenous fluids.

6. Treatment

The mainstay of treatment in cases of cyanide toxicity in the USA consists of supportive treatment and use of a multistage antidote kit (Rotenberg, 2003a; Baskin and Brewer, 1997; Riordan *et al.*, 2002). Table 61.7 details pediatric doses used for the medications in this kit, which contains amyl nitrite, sodium nitrite, and sodium thiosulfate. Antidotes should be provided only for significantly symptomatic patients, such as those with impaired consciousness, seizures, acidosis, hypotension, hyperkalemia, or unstable vital signs (Goldfrank *et al.*, 1998). Even when patients are rendered comatose by the inhalation of hydrogen cyanide gas, antidotes may not be necessary if the exposure is rapidly terminated, the patient has regained consciousness on arrival to the hospital, and there is no acidosis or abnormality of the vital signs (Peden *et al.*, 1986).

7. Supportive Therapy

Irrespective of the antidote treatment available, treatment will always consist of supportive therapy (Rotenberg, 2003a). Supportive therapy alone may reverse the effects of cyanide even in the face of apnea (Rotenberg, 2003a; Baskin and Brewer, 1997; Peden *et al.*, 1986). Supportive therapy includes decontamination, which includes gastric lavage and/or administration of activated charcoal if appropriate, oxygen, hydration, and anticonvulsants. Decontamination measures should take place prior to patient transport to a medical center. First responders and health care professionals should in turn take precautions not to intoxicate themselves through direct mouth-to-mouth resuscitative efforts (Riordan *et al.*, 2002). They must also wear personal protective equipment when transporting the victims to areas with adequate ventilation (Rotenberg, 2003a). Clothes are an obvious source for recontamination of the victim and must be removed. The skin should be subsequently flushed with copious volumes of water. The temperature of the water becomes a major consideration for children who may not tolerate extremes of cold or hot. Depending on the hospital size, antidote kits may or may not be available. Therefore, the time when supportive care is implemented becomes extremely important.

8. Antidotal Therapy

The US standard cyanide antidote kit uses a small inhaled dose of amyl nitrite followed by intravenous sodium nitrite and sodium thiosulfate (Rotenberg, 2003a; Anon, 1998). This antidote converts a portion of the hemoglobin's iron from ferrous iron to ferric iron, converting the hemoglobin into methemoglobin. Cyanide is more strongly drawn to methemoglobin than to the cytochrome oxidase of cells, effectively pulling the cyanide off the cells and onto the methemoglobin (Baskin and Brewer, 1997; Berlin, 1970). Once bound with the cyanide, the methemoglobin becomes cyanmethemoglobin (Anon, 1998). Therapy with nitrites is not innocuous, since methemoglobin cannot transport oxygen in the blood. The doses given to an adult can potentially cause a fatal methemoglobinemia in children or may cause profound hypotension. Treatment of children affected with cyanide intoxication must be individualized and is based upon their body weight and hemoglobin concentration. Once an ampule of amyl nitrite has been broken one at a time into a handkerchief, the contents should be held in front of the patient's mouth for 15 s, followed by 15 s of rest. This should be reapplied using this interrupted schedule until sodium nitrite can be administered. Continuous use of amyl nitrite may prevent adequate oxygenation. Taylor Pharmaceuticals, the manufacturer of the kit, recommends the dose for children of sodium nitrite to be 6 to 8 ml/m^2 (approximately 0.2 ml/kg body weight) but not to exceed an adult dose of 10 ml of a 3% solution (approximately 300 mg). While excessive sodium nitrite can cause methemoglobinemia, it should be noted that in the 70-year history of using the kit, the only reported fatality of such toxicity from using the kit involved a child without serious cyanide poisoning who was given two adult doses of sodium nitrite (Berlin, 1970; Hall and Rumack, 1986). In fact, the scientific literature recommends pediatric dosing based on monitoring hemoglobin levels. The next part of the cyanide

TABLE 61.7. Management of cyanide exposures (Anon, 1998; Berlin, 1970; Hall and Rumack, 1986)

Agent	Severity of symptoms	Antidotes/treatment			
		Multistage antidote kit (for unconscious patients)			
		Age	Amyl nitrite ampules	Sodium nitrite (for Hb = 12)	Sodium thiosulfate (for Hb = 12)
Cyanide	• Tachypnea • Restlessness • Anxiety • Flushing • Tachycardia • Dizziness • Apnea • Respiratory failure • Seizures • Coma	Child <30 kg	1. Crush 1 amp. in gauze close to the mouth and nose of breathing victim 2. Inhale for 15 s, rest for 15 s 3. Replace pearls every 30 s until sodium nitrite can be administered	1. 0.19–0.39 ml/kg not to exceed 10 ml of 3% solution slow IV over less than 5 min or slower if hypotension develops 2. For every 1 g/dl increase or decrease change in Hb, change dose by approximately 0.03 ml/kg accordingly 3. May repeat dose at 1/2 original dose in 30 min if needed	1. 0.95–1.95 ml/kg not to exceed 50 ml of 25% solution IV over 10–20 min 2. For every increase or decrease change in Hb of 1 g/dl, change sodium thiosulfate by 0.15 ml/kg accordingly 3. May repeat dose at 1/2 original dose in 30 min if needed
		Adult	See above	10 ml of 3% solution slow IV over no less than 5 min or slower if hypotension develops	50 ml of 25% solution IV over 10–20 min

Other treatment: evacuation, decontamination, 100% O_2, and correction of acidosis, hypovolemia, and seizures

antidote kit is sodium thiosulfate, which is administered intravenously (Rotenberg, 2003a; Baskin and Brewer, 1997; Anon, 1998; Hall and Rumack, 1986). The sodium thiosulfate and cyanmethemoglobin become thiocyanate, releasing hemoglobin; thiocyanate is excreted by the kidneys. Table 61.8 provides a dosing chart for the safe dosing of sodium nitrite and sodium thiosulfate with continuous monitoring of hemoglobin levels. Before treating pediatric patients with nitrites, it is imperative that prescribers inquire about conditions that may predispose a victim to anemia and, if there are concerns, doses should be decreased. Methemoglobin levels must be monitored sequentially in children and should not exceed 20% (Rotenberg, 2003a). Due to concerns about the excessive methemoglobinemia, along with the complicated administration procedures associated with the cyanide antidote kit, experts have suggested that alternative therapies may be preferable to use in children such as hydroxocobalamin (Geller *et al.*, 2006).

9. Alternative Strategies

Alternative methods of treating cyanide intoxication are used in other countries. For example, the antidote used primarily in France is hydroxocobalamin (a form of vitamin B_{12}), which combines with cyanide to form the harmless vitamin B_{12a} cyanocobalamin (Rotenberg, 2003a; Baskin and Brewer, 1997). In France, this medication is used for children at a dose of 70 mg/kg. A study of 41 French children with fire smoke inhalation showed a prehospital mortality rate of 4% for those given hydroxocobalamin and not found in cardiac arrest (Geller *et al.*, 2006). Authors of the study noted that for those children found in cardiac arrest by paramedics, administration of hydroxocobalmin

TABLE 61.8. Variation of sodium nitrite and sodium thiosulfate dose with hemoglobin concentration (Anon, 1998; Berlin, 1970; Hall and Rumack, 1986)

Hemoglobin (g/dl)	Initial IV dose sodium nitrite 3% (ml/kg) *Do not exceed 10 ml total dose*	Initial IV dose sodium thiosulfate 25% (ml/kg) *Do not exceed 50 ml total dose*
7	0.19	0.95
8	0.22	1.10
9	0.25	1.25
10	0.27	1.35
11	0.3	1.50
12	0.33	1.65
13	0.36	1.80
14	0.39	1.95

did not prevent any mortality. Another case series detailed eight pediatric patients exposed to cassava where four of the most severely affected children were given the cyanide antidote kit, while the four others were given 500 mg of hydroxocobalamin. All children improved regardless of which therapy they were given and were discharged from the hospital with no sequelae. This medication appears to have a good safety profile with adverse effects reported such as transient reddish-brown discoloration of the urine and mucous membranes. Some elevations in blood pressure and rash have also been reported (Geller *et al.*, 2006). The FDA approved hydroxocobalamin for use in the USA in December of 2006 to treat cyanide exposure victims in a product called Cyanokit®, manufactured by EMD Pharmaceuticals, Inc. The package insert for this medication provides adult dosing and a statement that the safety and effectiveness of the Cyanokit has not been established in the pediatric population. However, there is a reference to the 70 mg/kg dose which is used in Europe (Anon, 2006).

10. Summary

Cyanide is found in a wide variety of industrial processes and has been explored by Al Qaeda for use as a weapon of terror (Rotenberg, 2003a). Whether ingested or inhaled, cyanide is very lethal. Cyanide produces toxicity through impairment of mitochondrial enzymes, disrupting the electron transport chain, and preventing their utilization of oxygen. The mainstay of treatment of cyanide toxicity consists of use of a multistage antidote kit. The management of children with cyanide toxicity should include appropriate antidote dose adjustments and proper monitoring to prevent fatal methemoglobinemia. Another antidote, hydroxocobalamin, may gain favor over time as the treatment of choice for pediatric cyanide exposures, due to its preferable safety profile and its ease of administration (Geller *et al.*, 2006).

VI. DECONTAMINATION OF CHILDREN

Decontamination after a chemical terrorist attack needs to be well planned, efficient, and cognizant of the special needs of children. It is well recognized that the unique vulnerabilities of children may lead to a disproportionate number of pediatric victims after a chemical attack. Without proper planning and consideration as to how children will be decontaminated, the potential for preventable pediatric casualties is increased due to time loss and confusion. It is highly recommended for pediatricians to be involved in the development of each hospital's plans for decontamination. Over the last several years, many advances have been made in the management of the critically injured child. In fact, studies have shown that children managed in a pediatric intensive care unit (PICU) have better outcomes than children managed in an adult intensive care unit (Wheeler and Poss, 2003). Not all hospitals have the resources to have their own PICU, but they need to be able to provide the initial resuscitation and stabilization of pediatric victims of a terrorist attack. It is highly recommended that predetermined, written transfer agreements exist between emergency departments in community hospitals and centers that specialize in pediatric care. These agreements will allow the rapid transport of critically injured children to the sites that can ensure the best outcomes.

The first step in the decontamination process is the appropriate triage of patients (Burklow *et al.*, 2003). If this step is done quickly and accurately, patients will be appropriately managed and outcomes will improve. The key to triage is the ability to ration care when resources are limited. Victims are usually classified into tiered categories. Classic categories that have been used on the battlefield include minimal, delayed, immediate, and expectant. Patients in the minimal category have minor injuries that may not require medical care or can be managed with self-care. However, it should be noted that it is difficult for children to manage themselves, in addition to the fact that the category they are placed within can change more rapidly than that seen in adults. The delayed category describes patients who have injuries that will require medical intervention, but the injuries are not immediately life threatening. Logically, the immediate category describes patients who are critically injured and need medical intervention to save life or limb. Finally, the expectant category describes those patients who are so critically injured that they are not expected to survive. The expectant category poses a special challenge to civilian health care workers who are used to expending vast resources and personnel to maximize survival. In a mass casualty event, clinicians need to come to grips with the fact that the most ill may not be treated. Although the classic categories of triage are fairly well known, they are not consistently used among hospitals. Some categories are developed specific to chemical attacks. An example of this are triage categories that separate patients as ''exposed'' or ''not exposed''. At the University of Maryland Medical Center, the biochemical response triage categories differentiate between exposed and not exposed individuals. Furthermore, recognizing that not all exposed individuals will necessarily be symptomatic but may still need to be isolated, the categories differentiate between those who are asymptomatic, exposed and symptomatic, exposed and asymptomatic, and those with unrelated emergent conditions. Regardless of what categories get utilized, triage must focus on the fact that the best outcome is achieved for the greatest number of victims. To achieve this outcome, appropriate identification of the causative agent is critical. This can be a challenge because often full identification is delayed. To protect those involved in triage, full personal protective equipment is highly recommended. Work in full personal equipment can be cumbersome and uncomfortable, but when triage is done correctly, unnecessary decontamination can be avoided.

After triage, the decontamination process should begin (Wheeler and Poss, 2003). All workers who are involved in

this process must be appropriately protected with butyl rubber aprons and gloves, double layers of latex gloves, waterproof aprons, and chemical resistant jumpsuits. Personal protective equipment should also include an appropriately selected air-purifying or atmosphere-supplying respirator, depending upon how well the threat environment has been categorized. It is important to note that this equipment often needs to be changed to prevent health care worker exposure.

The set up and use of the decontamination area must be carefully thought out. Often, the area is split into different zones (Rotenberg *et al.*, 2003). At a minimum, there must be a dirty contaminated zone and a clean decontaminated zone. It is critical to emphasize that traffic must go one-way between zones. This will eliminate the possibility of a cleaned patient becoming cross-contaminated or an exposed patient entering a health care facility before being decontaminated. Security personnel must be utilized to make sure patients do not consciously or unconsciously violate the rules. A secondary triage will be needed as patients enter the clean zone to allow patients to receive antidotes or be referred for further care. Keep in mind that for severely ill patients, antidote administration may precede decontamination.

The selection of the appropriate decontamination agent is important. The gold standard for decontamination is plain water (Rotenberg *et al.*, 2003). Other agents that have been used for decontamination include carbonaceous adsorbent powder, dilute (0.5%) hypochlorite solution, water with soap, and dry decontaminants such as flour or talcum powder. For children, the use or water or water with soap is preferred. In addition to agents used to decontaminate, other cornerstones to management include exposure to fresh air when patients have been exposed to chemicals in the gaseous form, a change of clothing, and showers.

Conducting decontamination in children can be especially difficult. At every step of the process, there are special considerations that need to be addressed (Rotenberg *et al.*, 2003). Starting at triage, clinicians need to understand how chemical toxicities manifest in children; also an understanding of what normal vital signs should be for a child will be critical. Pediatric-specific triage tools often consider different vital signs such as heart rate and respiratory rate parameters and the differing ability of patients to communicate. It is important for the triage to include the examination of the child's mouth and eyes because of frequent hand-to-mouth and hand-to-eye activity. If antidote administration is needed, pediatric references should be readily available, and an understanding of pediatric doses will be needed. When there is a lack of experience with managing children, the otherwise efficient decontamination process can get bogged down. Some hospitals have decided to set up pediatric-specific areas to address the specific needs of children.

Clinicians may need to handle uncooperative or nonverbal children. This becomes especially challenging when an intravenous line needs to be started. Placing a line in a child while in full protective equipment is no small feat. Also, keep in mind that the unfamiliar presence of a clinician in full personal protective equipment can cause fear and distress in a child. Children undergoing decontamination will benefit from a guardian to guide them through and reassure them. For those children who present alone, a guardian will need to be appointed and a system for parental identification will be needed. Hospitals will need to plan for this extra resource. In fact, one Israeli hospital has employed social workers in their disaster preparation to help manage patient/family needs and psychological distress (Rosenbaum, 1993). It is recommended not to separate parents and children during a time of crisis. Plans should be made for the decontamination and treatment of parent–child pairs (Rotenberg *et al.*, 2003).

A range of specially sized supplies is needed to appropriately manage children, which range from pediatric-sized emergency equipment to basic needs such as formula for feeding and diapers for hygiene. Since decontamination often includes disrobing, pediatric-sized clothing would be needed. For children who may need to be observed for hours, toys will be needed.

Also, the agents used to decontaminate children should be carefully selected. Bleach or hypochlorite solutions are not recommended for use with children due to the possibility of skin irritation or damage (Rotenberg *et al.*, 2003). Water is the gold standard for decontamination. When employing water decontamination, the temperature of the water must be addressed. Children, especially newborns and infants, are prone to hypothermia and hemodynamic instability from cold water. Water at a comfortable temperature is recommended along with a good supply of blankets which can be used to quickly warm up pediatric patients after water decontamination. In some situations, indoor sprinkler systems have been used when outdoor conditions were inhospitable.

VII. PREPARATION FOR A CHEMICAL EVENT

Understanding chemical agents used for terrorism and knowing how to manage toxicity is just the first step in preparing for a chemical event. Appropriate training on how to manage pediatric patients in these scenarios is critical. Pediatricians are uniquely trained to participate in the management of pediatric casualties and to advocate for children so that their needs are addressed in emergency planning (Bradley *et al.*, 2003). Many hospitals have held emergency exercises to see how prepared they are for these situations. Beyond this, the assessments should identify deficits and should be used to forge partnerships and relationships and share assets in the community to manage every possible scenario (Blaschke *et al.*, 2003). Health care facilities responsible for treating pediatric victims in

TABLE 61.9. Example pediatric specific hospital emergency drug cache

Drug	Strength	Dosage form	Pediatric dosing	Therapy or prophylaxis	Disease
Albuterol MDI	17 gm	INH	2–4 puffs q4h	Respiratory distress from chemical agents	Chemical exposure
Amoxicillin oral suspension	400 mg/5 ml 100 ml	Oral suspension	15 mg/kg q8h – up to 40 kg, >40 kg 500 mg q8h	Chemoprophylaxis	Anthrax
Atropine	1 mg/ml	Injection	See dosing table	Chemotherapy	Nerve agent exposure
Ciprofloxacin oral suspension	250 mg/5 ml 100 ml	Oral suspension	20–30 mg/kg/day divided q12h for 60 days	Chemoprophylaxis	Anthrax, plaque
Clindamycin	600 mg/NS 50 ml	IVPB	30 mg/kg/day q8h (max 4.8 g/day)	Chemotherapy	Anthrax
Cyanide antidote package	1 kit	Kit	See dosing table	Chemotherapy	Cyanide poisoning
Diazepam IV	5 mg/ml ×2 ml	Injection	See dosing table	Seizures post chemical exposure	SZ post-chemical exposure
Doxycycline oral suspension	25 mg/5 ml 60 ml	Oral suspension	2.5 mg/kg q12h – up to 40 kg, >40 kg 100 mg q12h for 60 days	Chemoprophylaxis	Anthrax, cholera, brucellosis, plague
Oseltamivir suspension	12 mg/ml 25 ml	Suspension	For children ≥1–12 yrs: ≤15 kg: 2 mg/kg/dose (max 30 mg) BID × 5 days, >15–23 kg: 45 mg/dose BID × 5 days, >23–40 kg: 60 mg/dose BID × 5 days, >40 kg 75 mg/dose BID × 5 days	Chemotherapy	Avian influenza
Potassium iodide	65 mg	Tablet	4–18 yrs: 65 mg, 1 mo–3 yrs: 32.5 mg, <1 mo: 16.25 mg	Chemotherapy	Radiation emergency
Pralidoxime	1 gm/20 ml SDV	Powder for injection	See dosing table	Chemotherapy	Nerve agent exposure
Ribavirin solution	40 mg/ml 100 ml	Solution	LD 30 mg/kg followed by 15 mg/kg/day BID × 10 days	Chemotherapy	Viral hemorrhagic fever

a chemical–biological event could be easily strained and overwhelmed. Often large-scale chemical–biological incidents necessitate the use of alternative areas to triage patients such as auditoriums and arenas. These alternative triage areas need to know how to manage pediatric victims (CEH/CID, 2000). Planning for an attack begins with the development of local health resources. Unfortunately, with chemical releases, clinical effects can occur extremely quickly, limiting time to borrow resources from nearby communities. First responders must be educated to recognize pediatric signs and symptoms from each chemical agent, how to wear protective gear in the face of persistent agents, handle pediatric patients, and be able to manage field decontamination. It is critical that adequate supplies of protective gear are available. When planning for decontamination procedures, pediatric vulnerabilities and challenges need to be considered such as the temperature of the water and the ability of children to follow directions.

Since children spend the majority of the day at school, community preparation for a threat must include the local educational system. Development of a rapid evacuation plan and the establishment of in-school shelters are critical. Schools can play a valuable role for the management of pediatric casualties.

Another key element to appropriate preparedness is the development of a pharmaceutical cache of antidotes, antibiotics, and vaccines. This cache will play a key role in the initial management of a chemical attack. Even though the SNS is now in place throughout the USA, it may be several hours before it reaches a hospital and the supply is divided among several sites. The SNS has made efforts to include pediatric-ready medications such as suspensions and solutions. Efforts must be made for local pharmaceutical caches to address pediatric needs. An example of a pediatric pharmaceutical cache is displayed in Table 61.9.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

Much progress has been made in understanding how pediatric patients need to be managed when they are affected by chemical agents. Several pediatric organizations, such as the AAP, have given guidance on how best to handle these situations. It is a special challenge to gather information regarding pediatric chemical casualties because our experience is so limited. Further research and resources are needed to fully understand all the physical and psychological impacts a terror attack has on children. The intention of this work is to provide a framework from which local and national efforts can grow. In the event of a chemical attack, prior preparation and planning will make the difference to whether lives are saved or further lives are lost. Efforts to improve upon current recommendations for managing pediatric chemical casualties must continue in order to better protect this vulnerable population.

CHAPTER 62

Physiologically Based Pharmacokinetic/ Pharmacodynamic Modeling of Countermeasures to Nerve Agents

ELAINE MERRILL, CHRIS RUARK, JEFF GEARHART, AND PETER ROBINSON

I. INTRODUCTION

Physiologically based pharmacokinetic/pharmacodynamic (PBPK/PD) modeling has proven useful in many areas of toxicology and therapeutics. This quantitative, mechanism-based approach has allowed limited experimental *in vivo* and *in vitro* data to be quantitatively integrated with physiological data so as to facilitate predictions of the behavior of organisms under different exposure conditions. Specifically, it has been used for:

- extrapolation across species (particularly experimental animals to humans)
- extrapolation across dosing scenarios (such as high to low doses)
- extrapolation across routes of exposure.

Models have been developed for a number of chemical warfare (CW) agents (Sweeney *et al.*, 2006; Worek *et al.*, 2005; Aurbek *et al.*, 2006; Van der Merwe *et al.*, 2006; see also Chapter 46 by Gearhart in this book) and surrogates, including diisopropyl fluorophosphate (DFP) (Gearhart et al., 1990, 1994), diazinon (Poet *et al.*, 2004), and chlorpyrifos (Timchalk *et al.*, 2002a, b). In the case of agent countermeasures, PBPK/PD modeling also allows the prediction of therapeutic efficacy under varying exposure scenarios. Specifically, it will allow therapeutic regimens to be optimized to particular exposure scenarios (routes, exposure times, concentrations). In order to do so, models of individual agents and countermeasures must be combined to take into account their interactions, whether they be pharmacokinetic or pharmacodynamic. Such modeling of agent/(multiple) counteragent combinations is an example of mixtures modeling (Krishnan *et al.*, 1994).

There is little yet in the literature approaching a complete model of the kinetic and dynamic interaction of a nerve agent and its current (multi-agent) or potential countermeasures. There have been, however, a number of important steps in that direction, both on the level of model development and in the experimental generation of data useful for the development and validation of such models.

We restrict our discussion here to countermeasures of nerve agents (NA), and will not discuss other chemical agents such as mustards and cyanide, and their antidotes. However, the modeling ideas outlined here can also apply to other agents.

II. BACKGROUND

Organophosphate compounds (OPs), such as the NAs – sarin (GB), soman (GD), tabun (GA), and VX – exert their toxicity by rapidly inhibiting serine esterases, the most critical of which is the ubitiquous nervous system enzyme, acetylcholinesterase (AChE). The inhibition of AChE occurs via phosphorylation of the serine hydroxyl group in the enzyme's active site. Many NAs ''age'' the enzyme, in which an R (alkyl) group attached to the oxygen is removed, leaving a phosphonate or phosphate anion irreversibly bound to AChE (Talbot *et al.*, 1988). The aging rate varies with the NA and is an important therapeutic consideration. AChE is involved in the rapid hydrolysis of the neurotransmitter acetylcholine (ACh). Acetylcholine is involved in the numerous cholinergic pathways in the body, i.e. the central nervous system as well as several aspects of the peripheral nervous system: the somatic nervous system innervating skeletal muscles and both the sympathetic and the parasympathetic divisions of the autonomic nervous system. Inhibition of AChE leads to the accumulation of ACh in the synapses and neuromuscular junctions (NMJs) of these cholinergic pathways (Figure 62.1), resulting in hyperstimulation of muscarinic and nicotinic cholinergic receptors. Clinical symptoms include salivation, lacrimation, urination, and defecation arising from impacts on the autonomic nervous system, tremors arising from the impact on the somatic nervous system, potentially convulsions from impacts on the central nervous system, and death (Myhrer *et al.*, 2007). At moderate to high doses, seizures

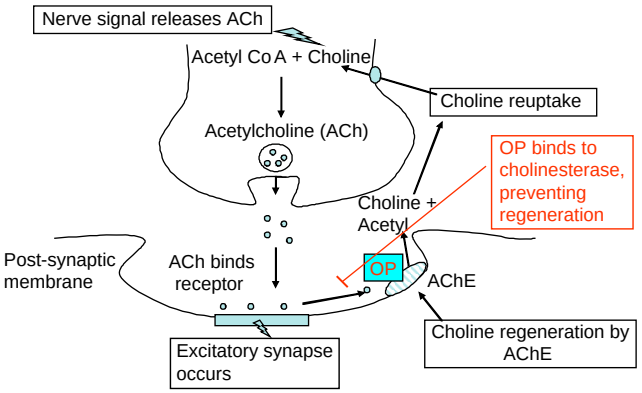

FIGURE 62.1. OPs bind to and inhibit acetylcholinesterase (AChE), the enzyme responsible for degrading the neurotransmitter, acetycholine (ACh), into choline and acetate. When AChE is inhibited by an organophosphate nerve agent, the subsequent reduced hydrolysis of ACh results in an accumulation of ACh within the synaptic cleft and overstimulation of the post-synaptic nerve. Seizures and possibly paralysis and/or death may occur.

rapidly progress to status epilepticus (SE), which can lead to irreversible brain damage (Carpentier *et al.*, 2001; Filliat *et al.*, 1999). Survivors suffer long-lasting cognitive deficits and behavioral changes (McDonough and Shih, 1997) due largely to neuronal degeneration of hippocampal structures. Under acute high-level exposures, the focus of countermeasure treatment is the prevention of seizures, respiratory failure, and bradycardia due to convulsive spasms. For low-level exposures, and for the survivors of high exposures, the concern shifts to minimizing the cognitive impact of the agent which may or may not be related to the degree of seizure activity.

McDonough and Shih (1997) hypothesized that the neurotransmitter systems involved in initiating and maintaining NA-induced seizures follow three main phases. Initially, about 5 min after exposure, hypercholinergic activity triggers the seizure. A transitional phase of cholinergic and glutamatergic hyperactivity follows, as a self-sustaining glutamate–NMDAR-mediated positive feedback loop begins to develop. After approximately 40 min, a predominantly glutamatergic phase sustains seizures, leading to neuronal damage predominantly in the hippocampus, amygdala, piriform cortex, thalamus, and entorhinal cortex across species (Olney *et al.*, 1983; Wade *et al.*, 1987; Fosbraey *et al.*, 1990; Carpentier *et al.*, 1990; Lallement *et al.*, 1992; McDonough and Shih, 1997; Solberg and Belkin, 1997).

High levels of glutamate itself are directly neurotoxic because overstimulation of glutamate ionotropic receptors allows excessive influxes of Na^+ and Ca^{2+}, causing prolonged depolarization of postsynaptic membranes (Bittigau and Ikonomidou, 1997). A cascade of events results from the delayed Ca^{2+} overload, leading to excitotoxic cell necrosis (McDonough and Shih, 1997; Solberg and Belkin, 1997). In addition, as the time lapse before anticonvulsant treatments increases, the Ca^{2+} influx induces transcription factors which mediate significant increases in damaging pro-inflammatory peptides, such as IL-1β, IL-6, and mRNA of TNF-α (Chapman *et al.*, 2006).

The content of this chapter is not inclusive, in the sense of taking one through the complete development and validation of a complex PBPK/PD model, which would describe the kinetics of each component, together with the pharmacodynamic interactions between selected NAs and countermeasures. Rather, this chapter briefly describes some examples of progress made in quantitative modeling and explores how specific countermeasures interfere in this NA-induced cascade of events, and how such quantitative approaches could be used to develop improved treatment regimens.

III. CURRENT COUNTERMEASURES

Conventionally, NA poisoning is treated by a combination of prophylactic and post- exposure therapy, which target the three post-exposure phases of neurotransmitter systems described above. Prophylactic treatments are designed to circumvent aging of the NA–AChE complex and consist of carbamate anticholinesterases, e.g. pyridostigmine, to bind AChE reversibly. Current carbamate pretreatment regimes bind 30–40% of available red blood cell AChE, thereby protecting some of the enzyme from irreversible OP binding (McDonough and Shih, 1997). Carbamates, however, are not without side effects. Partial AChE blockage by pyridostigmine results in a transient overstimulation of the AChR, mimicking mild NA poisoning with nausea, diarrhea, shortness of breath, and dizziness (Abraham *et al.*, 2002). Moreover, repeated prophylactic administration of carbamates is associated with detrimental and debilitating changes in nerve and muscles function (Hudson *et al.*, 1986).

Standard post-exposure treatments include concurrent administration of anticholinergics, such as the muscarinic cholinergic blocker atropine sulfate, and AChE reactivators, such as obidoxime and pyridine-2-aldoxime methochloride (also known as 2-PAM). Oximes cannot reactivate OP-inhibited AChE that has already ‘‘aged’’. Therefore, traditional oxime treatment is considered to be less effective for those agents such as soman, for which aging is rapid (Worek *et al.*, 2005).

If seizures develop, treatments which attempt to attenuate the hyperglutamatergic phase are required. Anticonvulsants, such as benzodiazepine or diazepam, may be used. Diazepam is a lipophilic agonist of the γ-amino butyric acid A ($GABA_A$) receptor, the most important inhibitory receptor of the CNS. The $GABA_A$ receptor is ubiquitously distributed. Therefore, its activation or inactivation affects virtually all brain regions, making dosage critical. Treatments with benzodiazepines depend on

administration within a very narrow time span to be effective because profound neuropathological changes are usually detected within 20 min of the onset of seizures (Lallement *et al.*, 1994; McDonough *et al.*, 1995; Leadbeater *et al.*, 1985; Shih *et al.*, 1999). By themselves, benzodiazepine anticonvulsants provide limited protection, as seizures recur with desensitization of $GABA_A$ receptors (Goodkin *et al.*, 2005). In addition, diazepam has consistently failed to eliminate the neuropathological changes resulting from NA-induced seizures (McDonough and Shih, 1997). Furthermore, in many battlefield and civilian exposure scenarios for NAs, pretreatments are unrealistic, and post-exposure anticonvulsants are likely to be delayed. Epidemiological studies have shown that time to seizure treatment in the USA varies broadly, with only about 41% of all patients receiving their first anti-epileptic drug within 30 min (Pellock *et al.*, 2004).

IV. NOVEL COUNTERMEASURES

Due to the undesirable side effects of the standard treatment regimes, and limitations of $GABA_A$ agonists to adequately control seizures, the need for alternative therapeutics still exists. The focus of OP intoxication treatment is also expanding from immediate survival to include the prevention of long-term cognitive deficits. Other antidotes have been proposed that demonstrate promise in reducing excessive glutamatergic activity and/or prevent destabilization of Ca^{2+} homeostasis, as excitotoxic mechanisms of seizure activity ultimately result in Ca^{2+} overload and activate various enzymes that lead to necrosis of the cell. Attempts have been made by blocking the *N*-methyl-D-aspartate (NMDA) or alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, two subtypes of CNS glutamate receptors (Braitman, 1989; Raveh *et al.*, 2003; Lallement *et al.*, 1994; McDonough and Shih, 1997). NMDA-type glutamate receptors are glutamate-gated cation channels whose permeability to Ca^{2+} underlies aspects of normal synaptic plasticity. Excess Ca^{2+} influx through NMDA receptors (NMDAR) mediates cell death in certain neurodegenerative pathologies. Therefore, neurons must precisely control NMDAR synaptic density, which is negatively regulated by global neuronal activity.

A number of glutamate receptor antagonists have demonstrated neuroprotective and anticonvulsive effects in animals (Urbanska *et al.*, 1998). The high-affinity NMDAR antagonist, ketamine, has shown promise, when administered intramuscularly with atropine sulfate up to 30 min post-poisoning (Dorandeu *et al.*, 2005). Other noncompetitive NMDA antagonists, like dizocilpine (MK-801) and *N*-(1-[2-thienyl]cyclohexyl)3,4-piperidine (TCP), display the ability to terminate seizures when treatment is delayed by 40 min, but seriously depress respiration (Carpentier *et al.*, 1990; McDonough and Shih, 1997; Shih, 1990; Shih *et al.*, 1991).

An unusual NMDAR antagonist that recently demonstrated potent neuroprotection against GD-induced seizure-related brain damage in rats is dexanabinol. Dexanabinol is a nonpsychoactive synthetic cannabinoid, which acts as a highly selective, low-affinity NMDAR antagonist (Eshhar *et al.*, 1993; Feigenbaum *et al.*, 1989). In GD-exposed rats (1.6 LD_{50}, s.c.) dexanabinol, administered interperitoneally (i.p.), at either 5 or 40 min after the onset of seizures, reduced median brain lesion volume 86% and 81%, respectively (as assessed by microtubule-associated protein 2 (MAP2)-negative staining (Filbert *et al.*, 1999). When administered 5 min after seizure onset and repeated every 6 h up to 24 h, 98% reduction was seen. However, it is not known if the same degree of protection would be afforded if measurements were taken later than 24 h post-seizure onset. Dexanabinol did not diminish seizure activity in any of the GD treated rats, suggesting that its neuroprotective effects may be due to its properties as a potent antioxidant and free radical scavenger, as well as its ability to inhibit the production of tumor necrosis factor-alpha (TNF-α) (Shohami *et al.*, 1997), thus also blocking the signal transduction pathway that activates nuclear factor B (NFB).

Impressive data to date also indicate that enzyme-based bioscavengers show tremendous promise for the next generation of pretreatments or antidotes, with potentially no observable side effects. Candidate bioscavenger proteins either bind and sequester toxic OPs (such as serum cholinesterases and carboxylesterases) or catalytically break down the OP into nontoxic products [such as human organophosphorus acid anhydride hydrolases (OPAH) or paraoxonase (HuPON)]. These scavengers as well as carboxylesterase are each capable of providing protection against 2 to 16 LD_{50}s of GD, GB, or VX depending on the scavenger and the test species (rat, mouse, rabbit, guinea pig, or rhesus monkey) with little to no deficits in behavioral testing (Li *et al.*, 2005). Human clinical trials of several bioscavengers are now under way that could lead to FDA licensure.

Human serum paraoxonase (HuPON1) is a Ca^{2+}-dependent enzyme that effectively hydrolyzes many toxic AChE-inhibiting organophosphates (Blum *et al.*, 2008). HuPON1 is present in high-density lipoproteins of human plasma and plays an important role in protecting lipoproteins and cell membranes from oxidative damage. Because it is a human enzyme (Li *et al.*, 2005), it could potentially be used as either a prophylaxis or medical post-treatment for NA exposure, without causing adverse immune reactions (Draganov and LaDu, 2004). Human PON1 has catalytic activity against the pesticide paraoxon and the NAs sarin (GB), soman (GD), and cyclosarin (GF) but shows only minimal activity against the nerve agent VX (Blum *et al.*, 2008). The advantage of catalytic scavengers is the very small amount of the exogenous enzyme needed to hydrolyze and detoxify large amounts of NA.

V. PBPK/PD MODELING

A. Purpose of Mechanism-Based Modeling

For obvious ethical reasons only animal experiments can be used to evaluate new NA antidotes. However, the extrapolation of data from animals to humans is hampered by marked species differences. Currently, quantitative analyses addressing the co-treatment of countermeasures and medicinal treatments, simultaneous with, or immediately preceding or following NA exposures, have been very limited. The current paradigm thus relies on experimentation in various animal models to determine efficacy and then, following the classical model for pharmaceutics, scales the animal results to the human exposure scenario. In the case of NA countermeasures, short of controlled human experimental studies, this leaves a large uncertainty factor as to the protection of military personnel in the face of NA threats, and may severely limit or compromise operational risk management (ORM). One solution to this dilemma is to develop validated mathematical models to predict the biological impact of simultaneous and sequential low-level exposures to specific nerve agents, together with specific countermeasures, countermeasure combinations, and dosing regimens.

Physiologically based pharmacokinetic/pharmacodynamic (PBPK/PD) models can be used to explore the interactions between agents, countermeasures, and the organism with a view to integrate multiple animal and human datasets, and to develop tools for countermeasure design and dosing regimen selection to maximize countermeasure administration efficacy. The result of this approach is the development of an interaction model quantifying competition for AChE binding sites between specific agents and countermeasures, as well as other relevant pharmacodynamic and pharmacokinetic modes of interaction; and the development of methods to optimize countermeasure therapies for specific nerve agent exposure scenarios.

The process of applying mathematical constructs to describe experimental results often reveals patterns in the agent's pharmacokinetics or dynamics that might not otherwise be discernible. Failure of a model's simulations to predict experimental measurements sometimes prompts questioning of the data, such as the reliability of the quantitative methods, or sample collection or exposure techniques. More often, it may indicate that greater complexity in the model's structure is required to capture the data's behavior. This is another primary reason for developing models: to create hypotheses (model structures) that are falsifiable, leading to improved models and improved predictions in an iterative process.

There are currently a number of critical toxicological data gaps related to NA exposure, at both acute high levels and repeated low levels. Many of these gaps are due to the impossibility of conducting controlled human experiments involving nerve agent exposure. Filling these data gaps for exposure to nerve agents is essential for predicting performance degradation of personnel, enhancing risk assessment modeling tools, and defining detection thresholds which are physiologically relevant. The purpose of filling such data gaps is to: (1) develop a valid method for predicting dose–response effects for exposures to low NA agent concentrations/doses over long durations, and (2) identify threshold exposure conditions at which toxicologically significant effects occur. PBPK/PD modeling provides a means to fill these gaps. Due to the physiologically based nature of these models, simulations of experimental data can be performed by one exposure route in a particular species to develop and validate the PBPK model, and then that model can be used to simulate and predict the kinetics and pharmacodynamics in another species such as the human exposed via another exposure route. The power of PBPK/PD models thus lies in aiding the ability of scientists and decision makers to make reliable quantitative predictions concerning the potential health effects of real-life human exposures. In addition, this modeling approach can be useful for the development of meaningful therapeutic animal models. After all, therapeutics that have been successfully tested in animals can ultimately be tested in human clinical trials. However, their therapeutic efficacy against nerve agents can only be tested in animals.

VI. DEVELOPMENT OF PBPK/PD MODELS

Critical components to PBPK models include species-specific physiological parameters, and chemical-specific parameters. Species-specific physiological parameters include the organ weights and blood flow rates for the defined compartments in the PBPK model. These values are most often available in the published literature (Altman and Katz, 1979; Peeters *et al.*, 1980; Brown, 1997) and, when lacking, can be derived by appropriate scaling factors from similar species. The basic structure of the PBPK model used to describe nerve agent pharmacokinetics and pharmacodynamics follows that of the PBPK/PD model for DFP (Gearhart *et al.*, 1990) (see Figure 62.2).

Figure 62.3 shows a schematic representation of the pharmacodynamic processes involved in the interactions between nerve agents such as sarin with the organism (via AChE inhibition), together with interactions with pretreatments [pyridostigmine bromide (PB)] and countermeasures (oxime, atropine, and diazepam). This PD submodel is linked to the PBPK via the simulated concentration of sarin, in the selected target tissue (i.e. RBCs, diaphragm, and brain). It provides a framework for describing these biochemical processes quantitatively. And, when linked with the PBPK model, it puts the biochemical processes into a physiological context. This will allow extrapolation of results to multiple species, and to describe relevant exposure

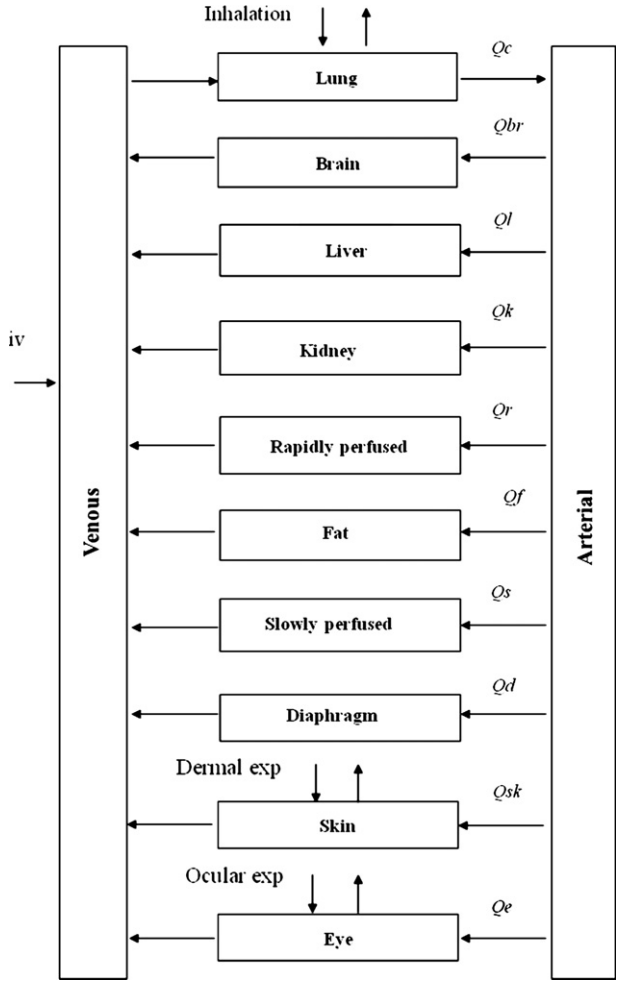

FIGURE 62.2. PBPK model schematic of the distribution of an organophosphate (be it DFP or a NA) in Hartley guinea pig. This model structure allows for the simulation of experimental studies with dosing by intravenous or subcutaneous dosing, and inhalation exposure. This model design was after Gearhart *et al.* (1990) and was also adapted to simulate the pharmacokinetics in the Göttingen minipig.

scenarios so as to address potential health effects and to optimize pretreatment and countermeasure delivery.

VII. EXPERIMENTAL AND QUANTITATIVE STRUCTURE–ACTIVITY RELATIONSHIP (QSAR) METHODOLOGIES TO PREDICT BLOOD AND TISSUE PARTITION COEFFICIENTS

As shown in Figure 62.2, PBPK modeling utilizes mathematical compartments that conceptually represent the physiology of an organism to depict the pharmacokinetics of chemicals exposed to the body. Traditional PBPK models depend on knowing the partitioning of the agent in key tissues of the organism. The distribution of a chemical within a tissue/compartment is most commonly represented by the equation (Krishnan and Andersen, 2001):

$$\frac{dA_t}{dt} = PA(CV_t - \frac{C_t}{P_t}) \tag{62.1}$$

where $A =$ amount of chemical in the tssue, $PA =$ permeation area cross product for the tissue, $CV_t =$ concentration in venous blood emerging from the tissue, $C_t =$ concentration in tissue, and $P_t =$ tissue blood partition coefficient. Note that $A = C_t \times V_t$, where V_t is the volume of the tissue.

PBPK modeling relies heavily on a proper definition of the partition coefficient as this parameter drives chemical uptake into the tissue. It is generally identified for PBPK modeling as the concentration ratio of the free fraction in the tissue to the free fraction in the blood at equilibrium (Schmitt, 2008) as shown in Eq. (62.2).

$$P_t = \frac{C_{Tissue-free}}{C_{Venous-free}} \tag{62.2}$$

The vial equilibration method is the most common *in vitro* method for determining partition coefficients for volatile or semi-volatile materials and has been used most successfully for volatile organic solvents (Gargas *et al.*, 1988). Tissues are harvested from the species of interest, and incubated with the test compound until equilibrium is reached between the tissue and the headspace in the vial. The blood–air or tissue–air partition coefficients are given by the ratio of the concentrations of the chemical in the blood or tissue relative to its concentration in the headspace. Tissue–blood partition coefficients are calculated from the respective tissue–air and blood–air values. A number of operational equations have been derived to calculate these ratios under specific experimental conditions. Time to steady state is critical and should be optimized for the test compound. Metabolism of the compound in exposed tissue samples must be controlled for. Analysis is done by gas chromatography in a verified linear range. Human tissues can be obtained from tissue bank organizations to provide species specificity to models developed with human data. To estimate partitions for compounds of low or nonvolatility, the *in vitro* filtration method of Jepson *et al.* (1994) can be used. Limitations of all such *in vitro* methods include issues of how representative the tissue sample is of the often quite heterogeneous tissue in the animal, and how closely the *in vitro* tissue preparation approximates the *in vivo* state. In addition, for highly lipophilic compounds, issues related to adsorption of the material onto glass and other surfaces need to be addressed.

Identifying the partition coefficient of a chemical for PBPK modeling is difficult due to the fact that most experimental methods fail to address this proper definition. *In vivo* methods most commonly track the kinetics of the chemical (radiolabeled or not). However, if enzymes are not properly inhibited, metabolites can also be tracked instead of the

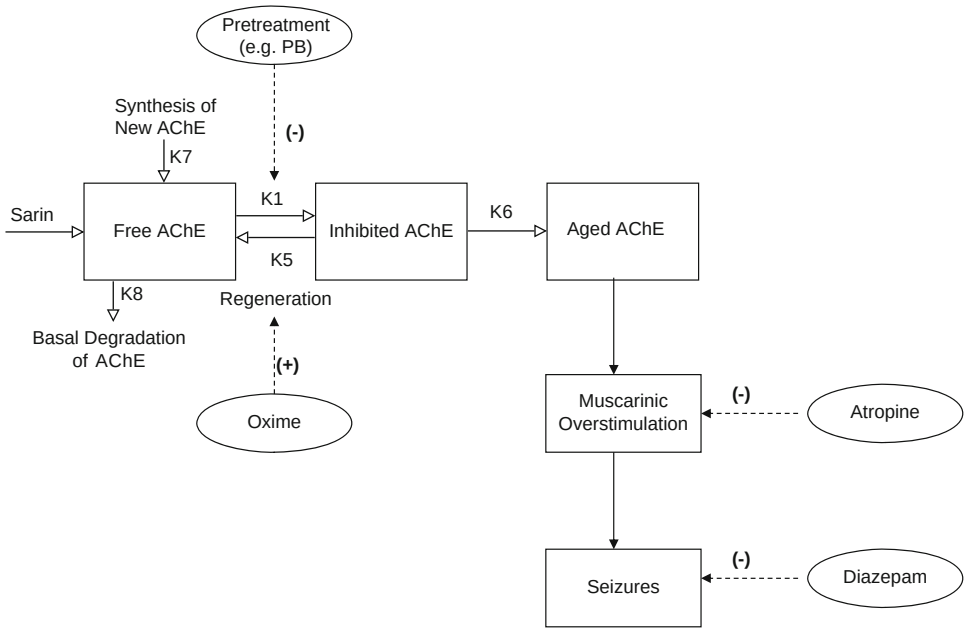

FIGURE 62.3. Schematic for AChE inhibition by nerve agents such as sarin, together with the interaction of pretreatment [pyridostigmine bromide (PB)] and countermeasure treatment (oxime, atropine, and diazepam). Pyridostigmine acts as a reversible cholinesterase inhibitor, oxime acts as an AChE regenerator, atropine acts as a muscarinic receptor antagonist, and diazepam acts as a positive allosteric modulator of GABA.

parent compound leading to contamination of the measured partition coefficient by the more water soluble metabolite. Experiments are most commonly performed via a single dose at different routes of exposure, hardly ever leading to steady state. To reach steady state, a critical point at which measurements should be made, a constant i.v. infusion of a chemical over an extended period of time until the concentration in the blood and tissue becomes constant must be made. Finally, protein binding is most commonly not accounted for, leading to a total concentration measured instead of the available free fraction. Compounds bound to proteins such as albumin, globulin, and lipoproteins reduce a chemical's tendency to partition into or out of tissues. This can be an extremely important issue depending upon the chemical as some are upwards of 90–95% bound in the blood (Poulin and Krishnan, 1996a). These *in vivo* experimental issues are rarely addressed, which leads to utilization of *in vitro* measurements where there is greater control of the system.

Since experimental determinations of partition coefficients are slow and expensive, and are fraught with difficulties, particularly for NAs, an alternative is to predict tissue partitioning from more readily available chemical properties (particularly chemical structure), together with key biological properties of the tissue itself, such as its lipid composition, by means of quantitative structure–activity relationships (QSAR) (Sterner *et al.*, 2008; Ruark *et al.*, 2008). The pharmaceutical industry has utilized QSAR to obtain information on new drug candidates rapidly to help alleviate bottlenecks in the discovery process. A drawback to these models is that they have limited predictive power for scaling across species and to other compounds. However, by utilizing novel mechanistically based methods specifically suited to PBPK modeling, estimations of chemical warfare nerve agent partition coefficient properties can be developed.

Tissue distribution is predicted utilizing a variety of descriptors that range from chemical specific to tissue specific allowing for universal application of the methods across all species, tissues, and chemicals. A compound's structure and its physiochemical properties such as the log of the octanol:water distribution (logP) and the octanol: water distribution mixture of different ionic forms (logD) are commonly utilized in partition coefficient QSAR, or quantitative structure–property relationship (QSPR) models because they describe the relative affinity for a chemical between hydrophilic and hydrophobic phases. Octanol, being amphiphilic, represents the phospholipid bi-layer which provides a barrier for the cell, separating the extracellular from its intracellular components. However, many studies have shown that octanol is not a perfect surrogate for all lipids within organisms and many are beginning to pursue other surrogates such as vegetable oil and specific phospholipid membranes (Schmitt, 2008; Poulin *et al.*, 1999). Other relevant properties include a wide range of descriptors predicted from *ab initio* calculations such as H-bonding acidity and basicity parameters, polarity, polarizability, molar refraction, McGowan volume, energies of the lowest unoccupied molecular orbital (E_{lumo}) and the highest occupied molecular orbit (E_{homo}), the maximum positive and negative atomic charge ($\sum Q$), the solvation of free energy (ΔG), as well as many others (Zhang and Zhang, 2006).

As far as tissue characterization is concerned, the fraction of lipid and water tends to be the dominating factor that influences partitioning into or out of the tissue. Some QSPR studies have included proteins which account for an electrostatic interaction with the amino or carboxyl terminal ends of an ionized chemical at physiological pH as well as some nonspecific binding for neutral compounds. However, a recent QSPR model developed by Schmitt (2008)

identified that nonspecific binding to proteins is approximately 40-fold weaker than to lipids. Therefore, proteins may only become of importance for tissues such as muscle and lung that contain a greater fraction of proteins than that of lipids. There have also been attempts at differentiating between phospholipids and neutral lipids, most notably by Poulin and Krishnan (1995a, b, 1996a, b, c), Poulin and Theil (2000, 2002), and Poulin *et al.* (2001) in the early 1990s. Rodgers and Rowland (2006, 2007) later differentiated between acidic and neutral phospholipids to account for another electrostatic interaction with ionized chemicals within the tissue. There is also a need to distinguish between tissue and interstitial space, as the interstitial space is highly representative of blood plasma. Other tissue components that may be of interest include DNA, RNA, and intracellular organelles. Binding to DNA appears to be highly correlated with β-blockers; however, the fraction of DNA in tissue is too low to make a substantial difference in the current predictions (Rodgers *et al.*, 2005a, b). Some authors have also suggested differences in intracellular organelle pH as another means of accounting for differences in tissue partitioning for ionized chemicals (Daniel and Wojcikowski, 1999; Ishizaki *et al.*, 1996; Siebert *et al.*, 2004; MacIntyre and Cutler, 1988); however, the overall volume of these organelles in relation to the cytoplasm is very low, most likely not resulting in substantial differences.

Optimization of predictions can be made utilizing linear as well as nonlinear relationships by means of statistical methods to correlate chemical and physiological descriptors to experimental datasets. These statistical methods include multilinear partial least square analysis, principal component analysis, and neural networking. Many of these tools are included in QSPR/QSAR packages through companies such as Advanced Chemistry Development, SemiChem, EduSoft, BioByte, TOPKAT, MDL, ChemSilico, Pallas, Pharma Algorithms, and others.

A review of the literature will reveal that several QSPR equations have been developed to predict PCs of drugs for use in PBPK models and many are suitable for a wide variety of chemicals. It appears that the greatest deviations in predicted versus experimental measurements of PCs are largely due to an experimental uncertainty or misinterpretations of the data rather than incorrectness of the models. Strategies still need to be developed for other macromolecular binding (α'-acid glycoprotein) and processes such as blood–brain barrier permeation and active transport but it appears that the methods thus developed are suitable for preliminary PBPK modeling.

VIII. INTERACTION PBPK/PD MODEL FOR NAs AND COUNTERMEASURES

As stated earlier, a number of PBPK/PD models have been developed for individual nerve agents (sarin, VX, soman, cyclosarin) in multiple species. Chapter 51 by Gearhart discusses the development of such models. Standalone PBPK or compartmental models have also been developed that describe the pharmacokinetics of certain countermeasures, such as diazepam (Igari *et al.*, 1983) and oximes (Stemler *et al.*, 1990). However, to date, few models for specific countermeasures (i.e. various oximes, pyridostigmine) have been harmonized and linked to NA PBPK/PD models, so as to be able to quantitatively describe their pharmacokinetic and pharmacodynamic interactions. This is probably due to the fact that most PBPK/PD models developed for NAs and other OPs described the inhibition of ChEs as the critical endpoint. The lack of a mathematical description of the disruption of other complex biochemical pathways, beyond the initial NA-induced ChE inhibition, presents a problem for linking PBPK models of various countermeasure agents to those of NAs. For example, the conventional NA countermeasures, atropine and diazepam, as well as many novel countermeasure agents, do not directly impact ChE kinetics because they act at sites distinct from the esterase's active site. Such agents act at receptor sites such as muscarinic, $GABA_A$, or NMDA receptors (Figure 62.4).

Interactive models, which have been developed and validated, exist for countermeasures which compete with NA inhibition of ChE or the regeneration of the free enzyme from its inhibited state, such as pyridostigmine and oximes, respectively. Numerous data in the literature describe the kinetics of interaction between nerve agents and other OPs and specific countermeasures at active enzyme sites of concern. For example, Davies and Green (1956) have measured the rate of reactivation of inhibited erythrocyte

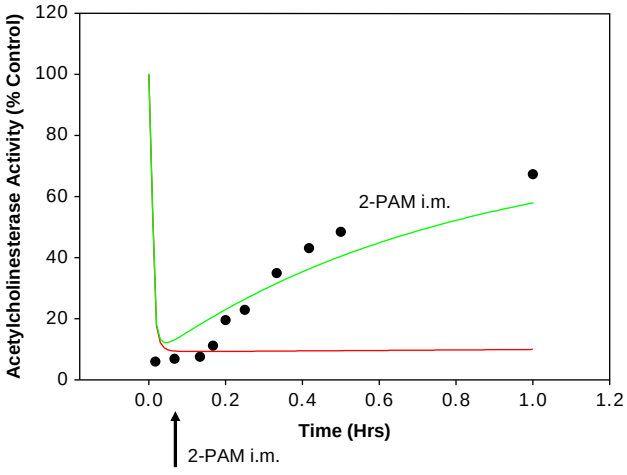

FIGURE 62.4. RBC AChE inhibition in rhesus monkey following administration of sarin [0.75 LD_{50} (15 μg/kg) i.v.] and with 2-PAM (25.8 mg/kg) administered IM at 9 min postsarin i.v. administration. Atropine was administered (0.4 mg/kg) IM 15 min prior to sarin administration. The filled circles indicate experimental data (Woodard *et al.*, 1994); the curves show our PBPK model simulations of AChE activity after sarin, both with (upper curve) and without (lower curve) 2-PAM administration.

TABLE 62.1. Rate of activation of inhibited erythrocyte ChE by various oximes and hydroxamic acids (Davies and Green, 1956)

	Inhibitors		
Compound	**TEPP**	**DFP**	**Sarin**
Diisonitrosoacetone	8.4	0.8	24.3
Monoisonitrosoacetone	6.8	0.7	22.1
*iso*Nitrosoacetophenone	10.7	5.1	4.1′
*iso*Nitrosoacetylacetone	0.7	NA	1.1
Picolinohydroxamic acid	2.9	0.6	0.2
Micotinohydroxamic acid metabolide	0.3	0.05	0.3

Rates of reactivation are given in l/mol/min: temp = 25°C, pH = 7.4
NA–not available

ChE by various oximes (Table 62.1). More recently, Worek *et al.* (2004) determined the kinetic rate constants of inhibition, reactivation, and aging for different NA, pesticides, and oximes with human erythrocyte AChE (see Table 62.2), described by the reactions listed below:

$$[E] + [OP] \xrightarrow{k_1} [EP]$$

$$[EP] + H_2O \xrightarrow{k_2} [EA]$$

$$[EP] + H_2O \xrightarrow{k_3} [E] + [OP]$$

$$[EP] + [OX] \overset{k_D}{\leftrightarrow} [EPOX] \xrightarrow{k_r} [E] + [POX]$$

where [E] is the active enzyme (i.e. AChE), [OP] is the organophosphorus compound, [EP] is the reversibly phosphylated AChE, [EPOX] is the Michaelis–Menten-type phosphyl AChE oxime complex [EPOX], [OX] is the oxime, [POX] is the phosphylated oxime, and [EA] is the dealkylated, ''aged'' AChE. The reaction rates used describe the bimolecular inhibition (k_i), aging (k_a), spontaneous (k_s) and oxime-induced reactivation. The dissociation rate, K_D, is equal to the ratio [EP] × [OX]/[EPOX] and (k_r) represents a first-order rate constant for the displacement of the phosphyl residue from [EPOX], resulting in regenerated enzyme and a phosphorylated oxime.

TABLE 62.2. Rate constants for interactions of AChE, OPs, and oximes (Worek *et al.*, 2004)

		Reactivation constant			
Inhibitor	**Oxime**	k_r (min^{-1})	K_D (μM)	k_{r2} ($mM^{-1}\,min^{-1}$)	**(Oxime) (mM)**
MFPCh	Obidoxime	0.020	1,133	0.018	0.5–4
	2-PAM	0.004	2,949	0.001	1–5
	HI 6	0.076	1,233	0.062	0.3–2
	HLö 7	0.051	606	0.084	0.1–4
MFPβCh	Obidoxime	0.015	1,658	0.009	0.5–4
	2-PAM	0.002	3,131	0.001	0.5–10
	HI 6	0.090	859	0.105	0.5–4
	HLö 7	0.078	458	0.170	0.5–4
MFPhCh	Obidoxime	0.009	3,547	0.003	1–5
	2-PAM	0.003	3,837	0.001	1–5
	HI 6	0.028	1,037	0.027	0.5–4
	HLö 7	0.011	599	0.018	0.3–3

Hence both a high affinity of the oxime to the ''inhibited'' or phosphylated AChE and a high regeneration rate (k_r) are critical for oxime efficacy. Using *in vitro* enzyme kinetic constants and *in vivo* inhibitor and oxime concentrations, Worek *et al.* (2005) were able to extrapolate the percent of AChE inhibition in humans following sarin or cyclosarin (i.v.) and a simultaneous intramuscular injection of various oximes. Similarly, kinetic models have been developed to predict a dose range of human butyrylcholinesterase (HuBChE) required to maintain adequate residual RBC AChE level, following an exposure to sarin, soman, or VX (Ashani and Shlomi, 2004). These and other datasets can readily be integrated into the full PBPK/PD modeling framework, shown previously in Figures 62.2 and 62.3. For example, Figure 62.5 shows a simulation of RBC AChE inhibition and regeneration in the rhesus monkey after exposure to sarin (0.75 LD_{50} i.v.), followed by 2-PAM, administered (i.m.) (25.8 mg/kg) at 9 min post-sarin.

Efforts to develop interactive PBPK models to integrate diverse datasets for both nerve agents and countermeasures continue in order to design an optimized countermeasure delivery program focused on a particular exposure scenario. This involves not just the development of kinetic models for the relevant molecular interactions, but also placing these interactions into an appropriate physiological context wherever possible. It is therefore necessary to take into account the dosimetry of key chemicals at the appropriate site(s) of action. This allows one not only to describe and interpret animal experimental data, but also to extrapolate these kinds of data wherever possible to humans using human physiological parameters and (wherever possible) human *in vitro* data (given the likely absence of human *in vivo* data).

Specific model features relevant to the agent's route of exposure and its biological effect can be incorporated when appropriate, for example quantitative models for ciliary removal of NAs in the upper respiratory tract during inhalation exposure. In addition, it is important to take into account (and incorporate into the model) the limitations of the analytical methods used to quantify circulating and tissue levels of NA, such as the regeneration of NA from its binding sites.

Given that multiple countermeasure agents are currently prescribed for NA treatment, and that future therapeutics will likely also involve multidrug combinations, multiple PBPK models can be used to calculate the co-location of specific compounds at specific sites at specific times, where

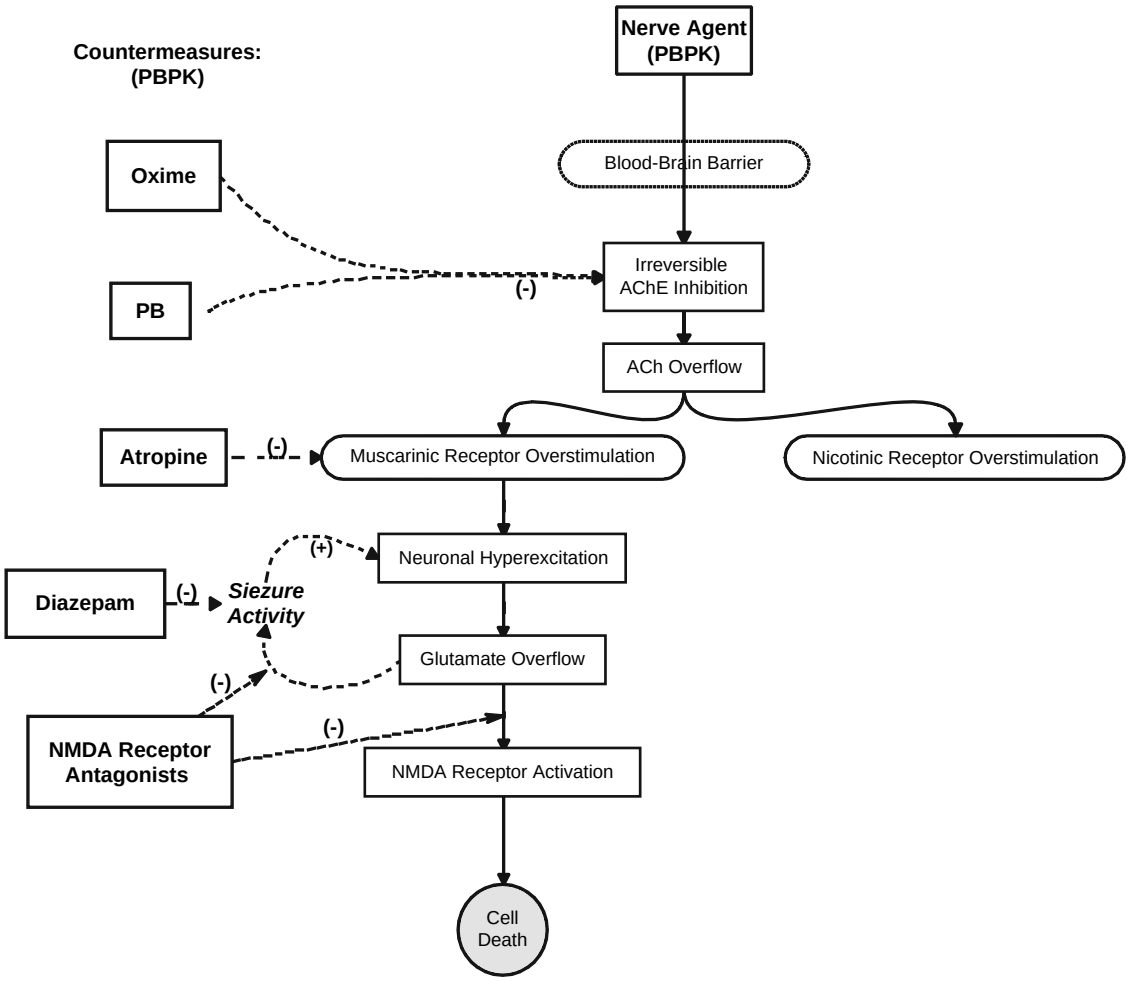

FIGURE 62.5. Schematic showing the progression of biological effects of a nerve agent together with potential points for intervention with countermeasures. It also shows a simplified outline of the scope of a potential set of models, showing the linkage between PBPK models, the nerve agents and countermeasures via their possible interactions.

their pharmacodynamic interactions may then be modeled. For example, it is desirable to model competition for AChE binding sites at erythrocytes and at target sites in the brain; the former since this regenerated NA from red blood cells can be interpreted to calculate a measure NA systemic exposure; and the latter, of course, because of the health impact. In general, the PBPK models can be linked via interaction processes at target sites.

Pharmacokinetic/PD models have been developed and used to predict the pharmacological effect of seizure activity for several anticonvulsants for which drug–receptor kinetics were available from either *in vitro* or *ex vivo* binding studies. Diazepam, an agonist of the γ-aminobutyric acid A ($GABA_A$) receptor, is among the NA antidotes for which the pharmacodynamic impact on electroencephalogram (EEG) activity has been modeled. Danhof and colleagues have developed compartmental kinetic models for various anticonvulsants and modeled their ligand–receptor pharmacodynamics. Electroencephalogram parameters have been used as pharmacodynamic endpoints (Van der Graaf *et al.*, 1999; Bueters *et al.*, 2003; Danhof *et al.*, 2007; Tuk *et al.*, 1999). These receptor binding models (Eq. 62.3) predict changes in receptor binding and pharmacodynamics as a function of changes in the pharmacokinetics of the ligand.

$$E(C) = E_{maxA} \cdot \left(\frac{C_A^N}{K_A + C_A} \right) \tag{62.3}$$

Here $E(C)$ is the observed effect at concentration C, $E_{\max}$ is the maximal effect (based on EEG components), K is the concentration at half-maximal effect, and N is the Hill factor, a constant expressing the sigmoidicity of the concentration–effect relationship. Subscripts A refer to the specific ligand of a ligand-gated ionotropic receptor.

Unfortunately, the impact of anticonvulsants on NA-induced seizures has not been modeled in this way. Given many countermeasures have different ligand–receptor interactions, such an approach would need to be expanded to the other excitatory and inhibitory neurotransmitters and

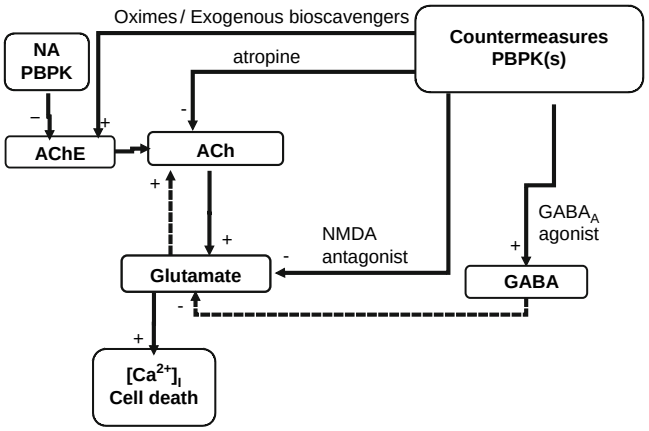

FIGURE 62.6. Simplified PD framework linking NA and various countermeasure PBPK models. Arrows indicate either agonistic (+) or antagonist (−) effect on the cholinergic, glutamatergic, or GABAergic systems. Dashed lines indicate feedback mechanisms. Arrows are synthesis or direct effect.

their respective receptors, which are involved in seizure induction and sustainment. Figure 62.6 suggests such a hypothetical framework that would include modeling of NA-induced increases in ACh and the countermeasures' interactions with associated receptors (esterases, $GABA_A$, mACh, and/or NMDA receptor sites). However, validation of such an approach, using components of gross EEG recordings, may not be plausible, due to the large number of ionotropic channels represented. An endpoint, such as sustained elevated glutamate, may be more appropriate.

While the receptor targets of various NA countermeasures vary distinctly, be they ion channel linked, G-protein linked or enzyme linked, their pharmacodynamic effects often converge upon the final steps leading to the disruption of intracellular Ca^{2+}, beyond which cell death is inevitable. Hence, ultimately a systems biology approach may provide the best predictions of countermeasure efficacy, especially for modeling long-term low-level effects. The Systems Biology Markup Language (SBML) project is an effort to create a machine-readable format for representing computational models in biology. SBML provides an input and output format, so that different software tools can operate on the same representation of a model, removing chances for errors in translation. SBML also provides convenient model databases, such as Biomodels (www.biomodels.net) for sharing these models. Neural Open Markup Language (NeuroML) similarly facilitates building, simulating, testing, and publishing of models, describing channels, neurons, and networks of neurons. Future integration, via a common computational language, of these molecular and cellular level models with PBPK models will permit the development of multiscale models that will link external exposure and tissue dosimetry with NA-induced neurotoxicity. This multiscale approach is necessary for quantitative assessments of the health risks associated with NA exposure.

IX. HEALTH EFFECTS ASSESSMENT AND COUNTERMEASURE OPTIMIZATION

Once validated, these models can be used to predict efficacy of specific countermeasures, countermeasure combinations, and dosing regimens for specific NAs and combinations thereof. In order to do so, appropriate measures of efficacy need to be defined. Perhaps the simplest way to estimate the effectiveness of a particular countermeasure is to determine the degree of a receptor activation at the target site of concern (e.g. brain or brain region) at a certain time or period of time following the administration of the countermeasure(s) compared to the situation in which no countermeasure is administered. Expressed as a simple ratio, countermeasure effectiveness (CE) may be written in terms of the time weighted average concentration (from time $t = T_1$ to $t = T_2$) of receptor occupancy (obtained from the PBPK/PD model):

$$CE = \frac{\int_{T_1}^{T_2} [E]_c dt}{\int_{T_1}^{T_2} [E] dt} \tag{62.4}$$

Here the numerator is calculated by running the model in the presence of the countermeasure, while the numerator is obtained in the absence of countermeasures. The ratio CE can be calculated under a variety of countermeasure dosing regimens to determine an optimum for each specific NA exposure scenario. Clearly, if such an exploration of countermeasure effectiveness were to be conducted experimentally, without the benefit of modeling, it would be prohibitively expensive and time consuming, thus demonstrating the usefulness of the modeling. The information obtained in this way would provide a rational basis for designing countermeasure delivery systems for optimized effectiveness. Ultimately, such an approach would also aid in the design of novel countermeasures, either to be used alone or integrated into an optimized countermeasure delivery ''package''.

A separate though related application of the proposed modeling approach is the development of meaningful therapeutic animal models, based on rational animal to human scale-up. In such an application, dosing regimens for existing countermeasures and countermeasure combinations, and particularly novel countermeasures, can be tested in experimental animals with the knowledge that the results obtained can be extrapolated to humans by taking into account the appropriate species differences incorporated into the models.

X. CONCLUDING REMARKS AND FUTURE DIRECTION

It can be expected that in the near future, PBPK/PD models will be developed that can predict the interaction between mixtures of NAs and countermeasures and their opposing

pharmacodynamic effects. Validation of such complex modeling efforts is data intensive and will rely on compilation of existing *in vitro*, *in vivo,* and *ex vivo* data. Unfortunately, the majority of toxicological studies on NA measure lethality, with little or no additional collection of time-course data of pharmacodynamic endpoints. Similarly, interaction studies between NAs and antidotes often measure only efficacy, in terms of a reduction in cell death. This is understandable due to the difficulty and cost in measuring these NAs in biological matrices and the large number of animals involved in collecting time-course data. Measurements of neurotransmitter changes following OP and countermeasure exposures are very difficult and often there is uncertainty in deciding which biomarker is most predictive of an effect that is not easily quantifiable, such as cognitive deficits. PK/PD analyses may not always be possible if the relationships between the input (the concentrations of the NA and countermeasure) and the output become too indirect. However, it should always be remembered that even without formal concentration–effect analyses, there is always much to be gained if a pharmacological countermeasure test is performed with intensive sampling of PK and PD parameters. Differences in PK/PD parameters give quantitative information about different neurotransmitter systems in the central and peripheral nervous system, which cannot be distinguished by pure statistical group comparisons. PK/PD analyses largely eliminate pharmacokinetic variability, and provide detailed and functional characteristics of pharmacological systems in the brain, or other target organs.

With specific regard to finding novel therapeutics for preventing or ameliorating NA-induced brain damage, PBPK/PD modeling provides a means to extrapolate experimental findings in animals to humans. Differences seen in the efficacy of different therapeutics may sometimes be explained by pharmacokinetics. Perhaps the therapeutic dose reaching a critical tissue, such as the diaphragm, heart or brain stem is too little, too late or not long enough. In addition, many of the animal toxicity studies performed to assess the efficacy of a therapeutic against NA measure a biomarker, such as cell death within 24 h from NA exposure. Biomarkers measured at 24 h may not always be indicative of outcome. Whether or not any protection seen at that point would still have to remain if the biomarker (e.g. cell death) were measured days, weeks or months later then remains unknown. For example, damage seen in thalamus at 24 h might later extend to areas with which it has strong reciprocal connections, such as the cerebral cortex. Lastly, in the quest for antidotes that may rescue one from cognitive deficits down the road, when realistically administered beyond when the glutamatergic phase takes control of seizure activity (i.e. >40 min post-NA exposure), predicting biomarkers that indicate the promotion of physiological balance in the brain, rather than the attenuation of seizure activity, may become the most important endpoints for predicting the efficacy of novel countermeasures.

Given the unsustainable cost and time involved in bringing novel therapeutics to market, quantitative techniques to improve countermeasure development are being used increasingly more. Several opportunities exist in drug development, which could lead us on a more direct path toward finding suitable countermeasures; for example, more complete integration of the available knowledge of therapeutic candidates early in their development, using PBPK/PD model(s) for NAs and countermeasures together. This should be started early, in the preclinical phases of drug development. Extrapolation of animal PBPK/PD models to humans for simulating initial clinical trials should be performed to evaluate the design of proposed clinical trials of a drug development plan and to provide proof of concept. This ability to mathematically explore various exposure–response relationships of NA(s) and countermeasure(s) is useful for designing optimal countermeasure regimens and identifying the limits of its therapeutic window following NA exposure. Uncertainty analysis of the model's parameters may identify biomarkers that may be critical in describing the data. Ways of defining and decreasing the uncertainty in efficacy and safety (risk assessment) in the drug and disease model are needed.

Lastly, the mechanisms (e.g. diffusion-limited transport, receptor binding, protein up-regulation or desensitization) described in a particular NA/countermeasure model should be updated as new information is generated, thereby using the models as knowledge management tools. Thus, modeling the PK/PD of neuroprotectants in the presence of NA may provide direction and guidance early in clinical development when there is opportunity to change direction and plans.

CHAPTER 63

Prophylactic and Therapeutic Measures in Nerve Agent Poisoning

TROND MYHRER

1. INTRODUCTION

Nerve agents are regarded as the most toxic among all chemical weapons. Nerve agents were originally synthesized during the 1930s in Germany in attempts to achieve more efficient pesticides based on organophosphorus compounds. Tabun was the first to be synthesized, followed by sarin and soman. VX is another type of nerve agent which was originally developed in the UK during research for new insecticides. The organophosphorus nerve agents are highly potent irreversible inhibitors of the enzyme acetylcholinesterase (AChE) that hydrolyzes acetylcholine (ACh). Accumulation of ACh in the synaptic cleft results in overstimulation of muscarinic and nicotinic receptors. This cholinergic overactivity can affect all organ systems. The toxic signs in humans include pinpoint pupils (miosis), bronchoconstriction, hypersalivation, increased lung secretions, sweating, diarrhea, loss of consciousness, seizures, and respiratory arrest. Miosis appears to be a very sensitive index of direct exposure, and can be painful for several days. Chest tightness, rhinorrhea, and increased salivation can occur within seconds/minutes of inhalation of nerve agents. If exposure is substantial, death may occur from respiratory arrest within minutes. Individuals moderately exposed usually recover completely, although EEG abnormalities have been reported in those severely exposed to sarin 6–8 months after the terror attack in Japan (Murata *et al.*, 1997). This chapter describes prophylactic and therapeutic measures to combat organophosphate nerve agents.

II. BACKGROUND

Exposure to nerve agents requires immediate medical treatment. For this purpose, military personnel are issued with autoinjectors, or ''buddy aid'', containing countermeasures for self-administration. Antidotes against nerve agents are based on drugs acting at the muscarinic receptors and $GABA_A$ receptors (McDonough and Shih, 1997). In addition, partial protection against nerve agents can be obtained by the use of reversible (carbamate) AChE inhibitors shielding a critical portion of AChE from irreversible inhibition by nerve agents prior to nerve agent exposure. Furthermore, reactivation of any unaged AChE by an oxime is regarded as important immediate treatment after nerve agent exposure.

A number of armed forces have based their therapy against nerve agent intoxication on an oxime (obidoxime, 2-PAM, HI-6), an anticholinergic (atropine), and a $GABA_A$ agent (diazepam, avizafone) combined with carbamate (pyridostigmine) pretreatment (Aas, 2003). However, such treatment regimens can reduce immediate lethality, but they do not attenuate the occurrence of nerve agent-induced seizure activity and concomitant convulsions, unless atropine is given early and at a high dose (McDonough and Shih, 1997). Such seizures rapidly progress to status epilepticus, a condition that is strongly associated with mortality and brain damage in experimental animals (Shih *et al.*, 2003). Thus, there is an urgent need to search for novel strategies able to prevent or terminate nerve agent-induced seizures. For this reason, the present chapter focuses on animal studies (guinea pigs, rats, monkeys) designed to acquire novel insights into the neuropharmacological mechanisms of nerve agent-induced seizures and neuropathology.

III. MECHANISM OF ACTION

It has been hypothesized that several neurotransmitter systems become involved sequentially in the initiation and maintenance of seizures elicited by nerve agents (McDonough and Shih, 1997). The progression of events can conceptually be divided into three phases. An early cholinergic phase lasting from the time of exposure to about 5 min after onset of seizures is dominated by high cholinergic activity followed by a transitional phase of cholinergic and glutamatergic hyperactivity and finally a predominantly glutamatergic phase after about 40 min (McDonough and Shih, 1997). In the latter study, a substantial body of evidence has been provided in support of the above model.

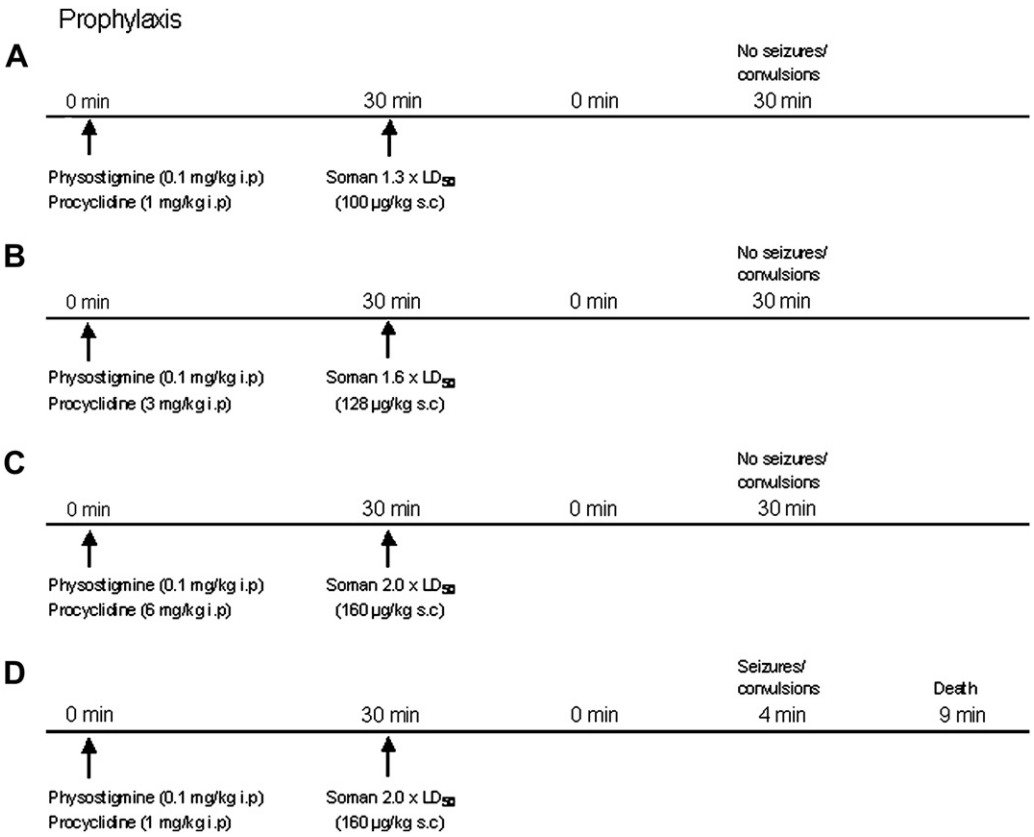

FIGURE 63.1. Experimental design for demonstration of anticonvulsant effects of a fixed dose of physostigmine combined with increasing doses of procyclidine relative to increasing doses of soman (A–C). Insufficient dose of procyclidine compared to soman results in early death (D).

Nerve agent intoxication results in inhibition of AChE and a tremendous buildup of ACh leading to protracted muscarinic receptor activation. This activation seems to happen in a dose-related manner. The higher the soman dose, the shorter the latency to onset of seizures and the greater the likelihood of early death in rats (Myhrer *et al.*, 2006a). The brainstem respiratory drive is vulnerable to increased cholinergic input, because the function of the respiratory center is disrupted. Both muscarinic and nicotinic antagonists can protect the respiratory center against cholinergic overstimulation (Kubin and Fenik, 2004). In compliance with this notion, the nicotinic antagonist mecamylamine in high doses can prolong survival in mice intoxicated by soman (Hassel, 2006). The functional integrity of the diaphragm is not significantly compromised by soman, unless a dose of $14 \times LD_{50}$ is used in cats (Rickett *et al.*, 1986). After a soman dose of $5 \times LD_{50}$ the latency to seizure onset is about 1 min, whereas the latency is about 14 min when the soman dose is $1 \times LD_{50}$ in rats (Myhrer *et al.*, 2003, 2006a). The change in ACh levels throughout the brain has been reported to precede that of any other neurotransmitter (Fosbraey *et al.*, 1990). The increases in glutamate occur in a number of brain regions with different time courses after seizures have started (McDonough and Shih, 1997). According to the three-phase model, efficacious pharmacological countermeasures against nerve agents should preferentially exert cholinergic and glutamatergic antagonism along with GABAergic agonism.

IV. PROPHYLACTIC MEASURES

A. Animal Studies

It takes a higher dose of anticonvulsants to terminate seizures induced by soman than other classical nerve agents such as tabun, sarin, cyclosarin, and VX (Shih and McDonough, 2000). This suggests that a drug capable of stopping soman-generated seizures would be equally effective for the treatment of seizures evoked by other nerve agents. This is the reason why soman is the nerve agent most frequently used in animal models to evaluate potential anticonvulsant drugs.

Pyridostigmine does not penetrate the blood–brain barrier to any extent and therefore provides very limited protection of the brain (Aas, 2003). For this reason, some recent investigations of prophylactic treatment in animals have focused on physostigmine as AChE inhibitor, because this carbamate (in contrast to pyridostigmine) crosses readily the blood–brain barrier (Birtley *et al.*, 1966). Although physostigmine in optimal doses does not protect against a lethal dose of soman, it appears effective when used along with an anticholinergic drug in guinea pigs (Philippens *et al.*, 2000). Physostigmine in combination

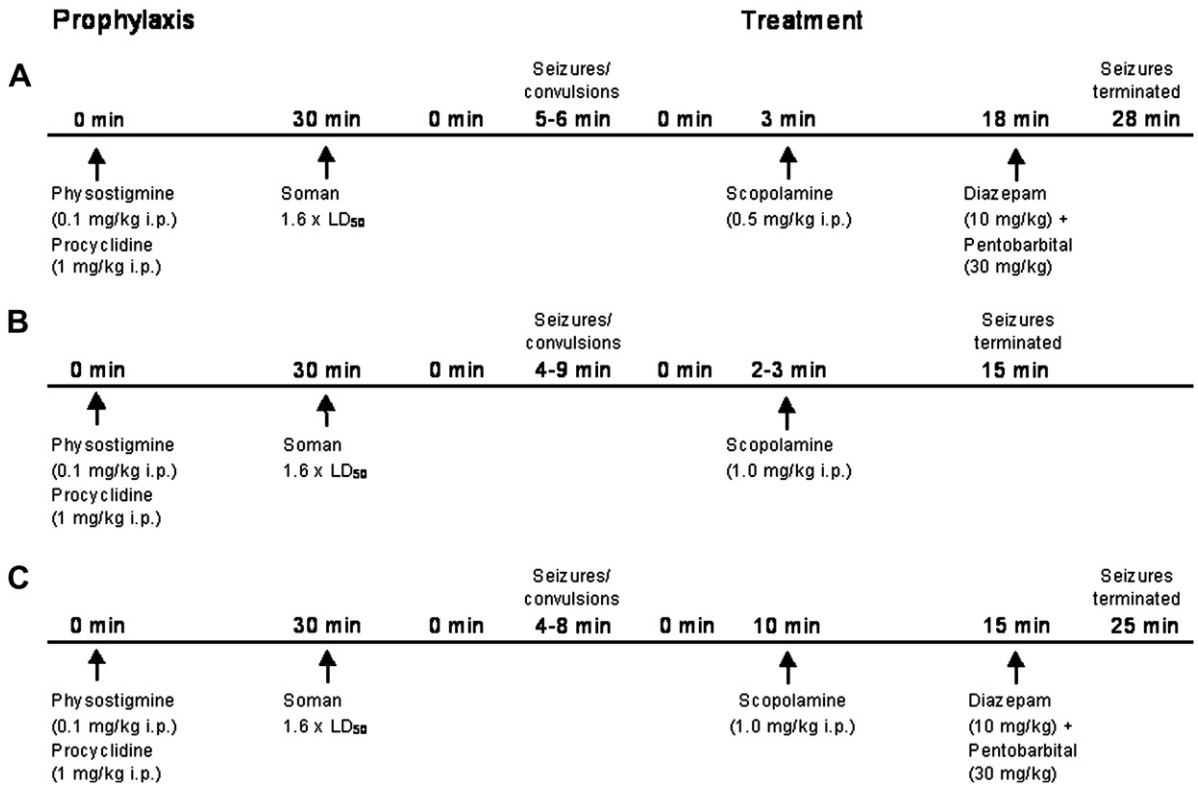

FIGURE 63.2. Experimental design for demonstration of how insufficient prophylactic treatment can be compensated for by adjunct post-exposure treatment. Low dose of scopolamine requires additional treatment (A). High dose of scopolamine is sufficient to terminate seizures (B). High dose of scopolamine given outside the cholinergic window requires additional treatment (C).

with scopolamine has been reported to protect guinea pigs effectively against soman, sarin, and tabun (Philippens *et al.*, 2000; Wetherell *et al.*, 2002). Similar protective effect has also been obtained with monkeys. Pretreatment of rhesus monkeys with physostigmine and scopolamine or physostigmine and trihexyphenidyl 25 min before exposure to $2 \times LD_{50}$ of soman results in survival without convulsions or loss of consciousness (Von Bredow *et al.*, 1991).

The cholinergic and glutamatergic antagonist, procyclidine, has in combination with physostigmine been demonstrated to assure full protective effects against convulsant doses of soman in rats and guinea pigs without any need for post-exposure treatment (Kim *et al.*, 2002). Because physostigmine has a rather short half-life, it will preferably require continuous administration. In a study of rats, osmotic minipumps were implanted subcutaneously affording sustained delivery of physostigmine and procyclidine for 3 days before exposure to a soman dose of $1.3 \times LD_{50}$. This treatment exerted full protective effects against lethality, convulsions, learning and memory impairments, and physical incapacitation (Choi *et al.*, 2004). In a subsequent study in beagle dogs, a matrix-type patch attached to the abdominal side of the animal delivered physostigmine and procyclidine for 2 days before being challenged with various doses of soman ($2–10 \times LD_{50}$). The patch delivery protected against seizures and death up to $4 \times LD_{50}$ of soman. When the patch was combined with HI-6 and atropine injected intramuscularly 1 min after soman exposure, protection was achieved up to a dose of $6 \times LD_{50}$ (Kim *et al.*, 2005).

In a study from our laboratory, the combined effects of physostigmine and procyclidine were tested against various doses of soman. Physostigmine (0.1 mg/kg) in combination with procyclidine at the doses of 1, 3, or 6 mg/kg effectively prevented the development of convulsions and hippocampally monitored seizures when the doses of soman were 1.3, 1.6, or $2 \times LD_{50}$, respectively (Figure 63.1). Results from [^{3}H]MK-801 binding experiments show that procyclidine inhibits the phencyclidine site at the NMDA receptor in a concentration-dependent manner (Myhrer *et al.*, 2004a). Physostigmine (0.1 mg/kg) and procyclidine in a dose of 1 mg/kg do not prevent convulsions/seizures when the soman dose is $1.6 \times LD_{50}$. Subsequent treatment with scopolamine in doses of 0.5 or 1 mg/kg immediately after (3 min) seizure onset shows that only the highest dose produce a reliable termination (Figure 63.2). When scopolamine (1 mg/kg) is given later (10 min) after onset of seizures no effect is obtained. The sustained seizures were subsequently treated with diazepam (10 mg/kg) and pentobarbital (30 mg/kg) and finally terminated 25 min after onset. In rats given inadequate prophylaxis, both modified convulsions and seizures are seen. It is recommended that

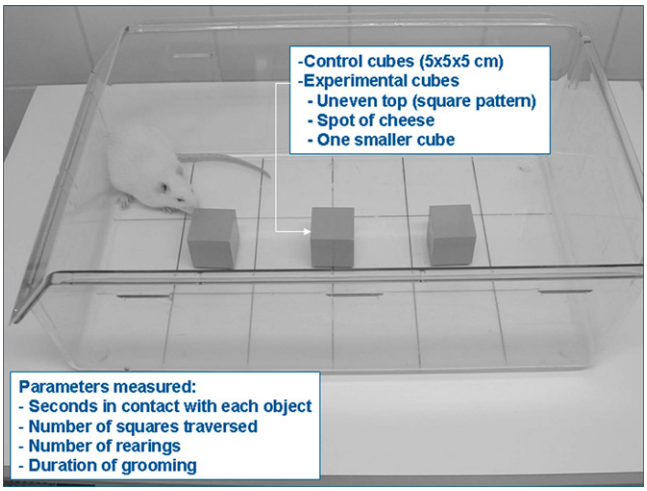

FIGURE 63.3. Novelty test measuring rats' innate preference for novelty, locomotor activity, rearing, and grooming. Testing is carried out in three sessions (one each day). Each session consists of 5 min exploring with neutral cubes present (Phase 1) and Phase 2 (5 min) after 10 min in the home cage during which the central cube has been replaced by a novel one. The novelty is represented by an uneven top (Session I), a spot of cheese on one side (Session II), or a smaller cube (Session III).

moderate doses of prophylactics should be used to avoid adverse effects on cognitive functions, because insufficient prophylaxis can be compensated for by adjunct treatment (Myhrer *et al.*, 2004a).

In order to avoid the problem with a short-lasting prophylactic drug, the AChE inhibitors huperzine, donepezil, and galantamine may offer alternatives with long-lasting efficacy. Both rats and guinea pigs are well protected against soman-induced seizures and neuropathology when pretreated with huperzine, whereas pyridostigmine does not have such effects (Lallement *et al.*, 1997; Tonduli *et al.*, 2001). Donepezil alone does not protect well against seizures evoked by soman, but when donepezil is combined with procyclidine a significant protection is obtained in rats (Haug *et al.*, 2007). Galantamine in combination with atropine administered before a convulsant dose of soman can effectively protect guinea pigs against seizures (Albuquerque *et al.*, 2006).

When pyridostigmine is combined with benactyzine and trihexyphenidyl (exerting both cholinergic and glutamatergic antagonism) in rats, effective protection is obtained against signs of neurotoxicity induced by soman. However, the combination with pyridostigmine and biperiden is reported to be even more efficacious than the former combination against soman poisoning (Kassa *et al.*, 2003).

The results from studies of prophylactic treatment presented so far are in compliance with the notion that seizures are triggered by cholinergic hyperactivity followed by sustained high cholinergic activity for about 5 min after seizure onset. An exception has been seen when MK-801 given before soman can prevent the occurrence of seizures in both guinea pigs and rats (Braitman and Sparenborg, 1989; Shih *et al.*, 1991). In the latter studies, however, MK-801 was combined with other drugs (pyridostigmine, atropine, and pralidoxime or HI-6, respectively). Hence, it is difficult to rule out the possibility that MK-801 interacted with effects of the additional drugs. HI-6 has recently been shown to decrease the release of ACh when hippocampal slices are exposed to soman (Øydvin *et al.*, 2005). Microinfusions of MK-801 or ketamine into the seizure controlling region, area tempestas, do not cause anticonvulsant effects against soman intoxication, whereas microinfusions of atropine or scopolamine do (Myhrer *et al.*, 2008a). Moreover, systemic administration of solely MK-801 or TCP before soman does not prevent the occurrence of seizures (Carpentier *et al.*, 1994; Myhrer *et al.*, 2008a).

It is crucial that prophylactics used to protect military personnel and first responders against lethal doses of nerve agents do not by themselves produce impairment of cognitive capability. This issue appears to be neglected in nerve agent research (Myhrer *et al.*, 2004b). In the latter study, it was examined whether physostigmine, scopolamine, and various doses of procyclidine might reduce rats' innate preference for novelty (Figure 63.3). When these drugs were tested separately, the results show that physostigmine (0.1 mg/kg) and procyclidine (3 mg/kg) do not affect preference for novelty, whereas scopolamine (0.15 mg/kg) and procyclidine in a higher dose (6 mg/kg) result in a preference deficit. The combination of physostigmine and scopolamine or physostigmine and procyclidine (6 mg/kg) causes a marked deficit in preference for novelty. A much milder deficit is observed when physostigmine is combined with lower doses (1 or 3 mg/kg) of procyclidine. The latter combinations also have milder adverse impact on the animals' interest in the test environment and activity measures than the former combinations.

Administration of physostigmine and procyclidine for 3 days by means of minipumps (72 µg/kg/h and 432 µg/kg/h, respectively) in rats does not affect passive avoidance performance (Choi *et al.*, 2004). A similar administration of physostigmine and scopolamine for 2 weeks in marmosets results in normal performance in a two-choice discrimination serial task. However, the concentration of scopolamine used is equivalent to an acute dose of 0.009 mg/kg which is considerably lower than doses which have been shown to affect marmoset cognitive performance (e.g. 0.06 mg/kg) (Muggleton *et al.*, 2003).

In a recent behavioral study of rats, potential cognitive effects of a group of anti-Parkinson drugs (with excellent anticonvulsant properties against nerve agents) were examined in the novelty test (Myhrer *et al.*, 2008b). It was shown that benactyzine (0.3 mg/kg), caramiphen (10 mg/kg), and trihexyphenidyl (0.12 mg/kg) reduce rats' innate preference for novelty, whereas biperiden (0.11 mg/kg) and procyclidine (3 mg/kg) do not. When benactyzine, caramiphen, or trihexyphenidyl is combined with physostigmine, the cognitive impairment disappears. This counteracting effect,

however, produces changes in locomotor and rearing activity not seen by each drug alone. AChE inhibitors and anticholinergics used as prophylactics can offset each other, but exceptions are observed in a previous study (Myhrer *et al.*, 2004b) when a very potent anticholinergic (scopolamine) or a high dose of procyclidine still results in cognitive deficits in spite of coadministration with physostigmine. The half-life of physostigmine is 17 min in plasma and 16 min in the brain of rats (Somani and Khalique, 1986). A crucial issue is how physostigmine is able to antagonize receptor blocking effects of anticholinergics by increasing the level of ACh and thus reduce or prevent cognitive impairment. This apparently subtle balance is probably attained in different ways for other relevant AChE inhibitors used as pretreatment against nerve agents, such as donepezil, huperzine, and galantamine. To equalize cognitive side effects of potent anticonvulsants by use of AChE inhibitors is not recommended, because accurate adjustments for differences in half-life would be required for acute doses. Use of continuous delivery, however, may circumvent the problem with different half-lives of combining drugs.

B. Human Use

Pretreatment with the carbamate pyridostigmine is a well-established method to protect against nerve agent intoxication in the armed forces in a number of nations. A tablet (30 mg) of pyridostigmine bromide is supposed to be taken every 8 h by service personnel. The rationale behind this use is that carbamate occupies a portion of the available AChE (15–40% of the erythrocyte AChE) and renders it inaccessible to nerve agents in the blood, since nerve agents only bind to unprotected enzymes (Leadbeater *et al.*, 1985). The AChE that has been reversibly inhibited by pyridostigmine spontaneously decarbamoylates, and the enzyme is again able to hydrolyze ACh. Because pyridostigmine does not penetrate the blood–brain barrier to any extent under normal circumstances, it only protects the peripheral nervous system. Pyridostigmine has been reported to have negligible physiological and psychological side effects (Leadbeater *et al.*, 1985). However, in a recent meta-analysis, it is stated that carbamate can cause side effects in predisposed individuals (Golomb, 2008).

The carbamate physostigmine, which readily crosses the blood–brain barrier, has been considered a convenient replacement for pyridostigmine. Based on a series of animal studies, the combination of physostigmine and the cholinergic antagonist hyoscine (scopolamine) has been brought to the level of clinical trials in the UK (Scott, 2007). The problem with the relatively narrow therapeutic window and potential side effects of physostigmine has been solved by continuous coadministration with hyoscine in terms of transdermal delivery. The pharmacological antagonism between these two drugs probably alleviates the potentially adverse effects produced by each drug alone. This pretreatment regimen is supposed to be less reliant on supporting therapy than the use of pyridostigmine (Scott, 2007).

The prophylactic combination of pyridostigmine with trihexyphenidyl and benactyzine has been introduced into the Czech Army. The presence of two anticholinergics made it possible to increase the dose of pyridostigmine and thus enhance the prophylactic efficacy (Bajgar, 2004). This combinational regimen (designated PANPAL) has been reported to have no side effects as demonstrated in volunteers: no changes in the psychic state or dysfunctions were observed. Actually, an improvement of tapping test performance was found after administration of PANPAL (Bajgar, 2004).

The use of human plasma-derived butyrylcholinesterase to neutralize the toxic effect of nerve agents *in vivo* has been shown to both increase survival and protect against attenuated cognitive function following nerve agent exposure. No post-exposure autoinjectors are necessary (Lenz *et al.*, 2007). This bioscavenger is currently being produced by using outdated human blood and is ready for clinical trials. Both military personnel and first responders are relevant groups to be protected by biological scavengers.

V. THERAPEUTIC MEASURES

A. Animal Studies

Post-exposure treatment of animals consists of two categories: immediate and subsequent therapies. In the first category, drugs with anticholinergic effects will be of preference, whereas drugs with antiglutamatergic effects will be of preference in the second category according to the three-phase model. Drugs enhancing $GABA_A$ neurotransmission (diazepam and other benzodiazepines) are effective during all phases of nerve agent intoxication (McDonough and Shih, 1997). Immediate therapy also includes an oxime in order to reactivate inhibited AChE.

Reactivation of inhibited acetylcholinesterase is considered to be an important element in post-exposure treatment. Bis-pyridinium oximes can reactivate the phosphorylated enzyme if they are administered prior to the change from the reactivatable to the unreactivatable state, the process referred to as ‘‘aging’’. The aging process is quickest with soman in brain and diaphragm preparation (a few minutes) compared to other nerve agents (Sun *et al.*, 1979). However, administration of oximes after aging has already occurred can enhance survival (McDonough and Shih, 1997). The oximes pralidoxime and obidoxime have been widely used, but HI-6 appears to be a promising substitute in treatment of intoxication with nerve agents. HI-6 has relatively low toxicity and is efficient in the treatment of soman intoxication (Clement, 1982; Hamilton and Lundy, 1989; Kusic *et al.*, 1985; Van Helden *et al.*, 1992; Walday *et al.*, 1993). A disadvantage of HI-6 is its

lack of stability in aqueous solutions that requires storing as powder in a separate chamber in the autoinjector (Thiermann *et al.*, 1996).

Anticholinergic drugs and an oxime are usually applied after prophylactic treatment (pyridostigmine). Anticholinergics have optimal efficacy during the cholinergic phase, i.e. from exposure to about 5 min after onset of seizures. Such drugs are classified as muscarinic receptor antagonists, and they are not able to counteract the nicotinic signs of intoxication like muscle fasciculation, muscle fatigue and weakness (McDonough and Shih, 2007). The rat brain is provided with the muscarinic receptor subtypes M1–M5. However, effective drugs against nerve agents have been shown to be anticholinergics with high specificity toward M1 (McDonough and Shih, 1997). The antinicotinic anticholinergic agent mecamylamine does not have anticonvulsant efficacy in rats poisoned with soman (Shih *et al.*, 1991). The effectiveness of potent centrally active anticholinergics has been shown to be at least as good as diazepam in terminating nerve agent-induced convulsions (McDonough and Shih, 1997). Rats pretreated with HI-6 (to reduce lethality) were given a soman dose of $1.6 \times LD_{50}$ and received anticonvulsants 5 or 40 min after onset of seizures. The results showed that anticholinergics (scopolamine, atropine, benactyzine, trihexyphenidyl) can effectively terminate seizure activity at 5 min, but not at 40 min after onset of seizure (McDonough and Shih, 1993). These anticholinergics were as effective and potent as anticonvulsants as if they had been given as pretreatment.

In our laboratory, we have examined the efficacy of a triple combination of drugs with adequate anticonvulsant effects and a dual combination with inadequate anticonvulsant effects followed by adjunct therapy (Myhrer *et al.*, 2006a). The results show that combined (mixed as a single compound) i.m. injections of HI-6 (42 mg/kg), atropine (14 mg/kg), and avizafone (3 mg/kg) administered 1, 16, and 31 min after exposure to a soman dose of $4 \times LD_{50}$ completely terminate seizures with a moderate mortality rate (25%). When the soman dose is lowered to $3 \times LD_{50}$ the anticonvulsant effect is complete, and no rats die within 24 h. Rats challenged with $5 \times LD_{50}$ of soman all die within 10 min. Without avizafone in the combination, seizures induced by 3 or $4 \times LD_{50}$ of soman cannot be terminated unless an adjunct therapy consisting of procyclidine (6 mg/kg), diazepam (10 mg/kg), and pentobarbital (30 kg/kg) is given, and the mortality rate is comparatively high (78%). Administration of the adjunct therapy alone 6–16 min after $4 \times LD_{50}$ of soman stops the seizure activity, but all the rats die within 24 h (Myhrer *et al.*, 2006a). The latter study shows that administration of countermeasures (mimicking autoinjectors) shortly after exposure to a relatively high dose of nerve agent can prevent death, even without pretreatment of the animals.

The great challenge in treatment of nerve agent poisoned victims seems to be the cases of long delays before treatment can start. Seizures lasting beyond 40 min are increasingly difficult to terminate (Carpentier *et al.*, 2001; Lallement *et al.*, 1999). Even conservative estimates suggest that it will take at least 30 min for emergency personnel to access individuals unprepared for exposure to nerve agent. Even soldiers properly provided with protective mask, gloves, and clothes may need medical help, because bad training, bad discipline, or bad luck can lead to intoxication of nerve agent (Lallement *et al.*, 1999). Hence, there is a pertinent need to search for novel strategies capable of controlling nerve agent-generated seizures well after their onset.

Drugs that enhance $GABA_A$ neurotransmission have been shown to be effective in intoxicated animals during all phases of seizures by counteracting the elevated level of glutamatergic activity (McDonough and Shih, 1997). Seizures induced by kainic acid or lithium/pilocarpine in rats can be terminated 1 h after onset by the administration of diazepam and pentobarbital (Du *et al.*, 1995). This potent combination of two $GABA_A$ agonists may create a promising anticonvulsant therapy, if it is supplied with an anticholinergic agent. Procyclidine was chosen for this purpose, because this drug exerts antagonism on both muscarinic and nicotinic receptors and additionally has antagonistic effect on NMDA receptors (Kim *et al.*, 2002). Procyclidine (6 mg/kg), diazepam (10 mg/kg), or pentobarbital (30 mg/kg) does not stop soman-induced seizures when administered separately, but both convulsions and seizure activity are terminated when these agents are given together. This triple therapy is 100% effective, when administered 30–40 min (5 min between each injection) following onset of convulsions (Figure 63.4) (Myhrer *et al.*, 2003).

In both military and civilian contexts, it would appear somewhat inconvenient for medical personnel to administer three injections of antidotes to achieve termination of seizure activity. It would be more expedient to replace diazepam and pentobarbital by a single $GABA_A$ modulator assuring corresponding anticonvulsant impact. However, systemic administration of $GABA_A$ modulators does not differentiate well between their anticonvulsant properties (Shih *et al.*, 1999). In a recent study based on micro-infusion of GABAergic modulators into seizure controlling areas in the rat brain (area tempestas and substantia nigra), it was found that muscimol, ethanol, and propofol possess the best anticonvulsant potencies against soman seizures among the agents examined (Myhrer *et al.*, 2006b). In a subsequent study, it was shown by systemic administration that procyclidine (10 mg/kg) combined with either muscimol (20 mg/kg), ethanol (3 mg/kg), or propofol (50 mg/kg) can effectively terminate soman-induced seizures when administered 5 min apart 30–35 min after onset. Procyclidine and propofol are considered the most relevant double regimen to replace the previous triple regimen consisting of procyclidin, diazepam, and pentobarbital (Myhrer *et al.*, 2006c).

It has been demonstrated that untreated seizures/convulsions induced by soman result in extensive

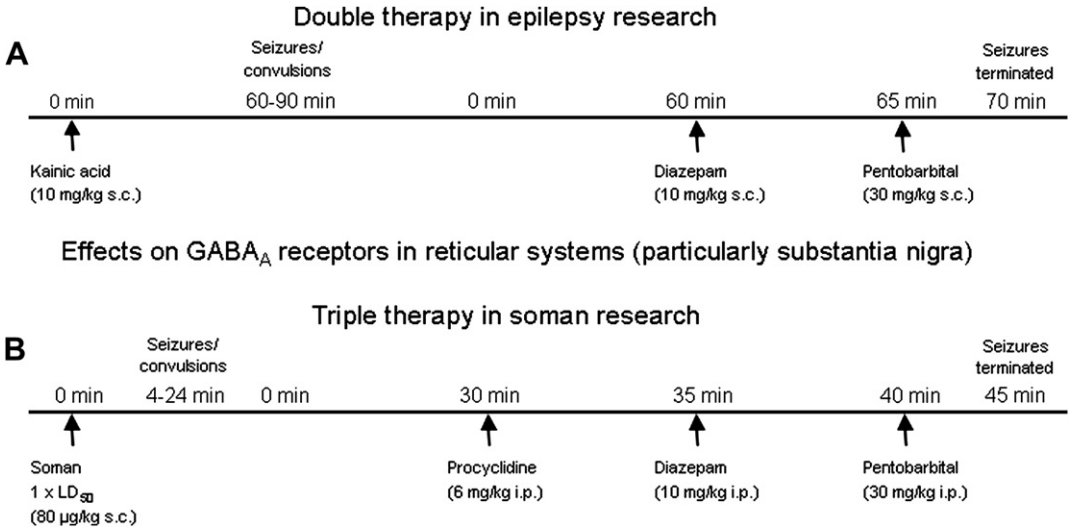

FIGURE 63.4. Experimental design revealing anticonvulsant effects of diazepam and pentobarbital in epilepsy research (A). Anticonvulsant effects achieved by triple regimen when administered 30–40 min after onset of seizures (B).

neuropathology and pronounced cognitive deficits in the Morris water maze (Filliat *et al.*, 1999; Raveh *et al.*, 2002, 2003). In our laboratory, we wanted to investigate whether there is a relationship between the extent of neuronal pathology and degree of dysfunction in the performance of cognitive tasks following soman-induced convulsions that had lasted for 45 min (Myhrer *et al.*, 2005). One behavioral task employed was the novelty test (Figure 63.3) that has proven particularly sensitive in revealing cognitive dysfunctions following selective disruptions of entorhinal projections (Myhrer 1988, 1989). The other behavioral task employed was a simultaneous brightness discrimination test (Figure 63.5) for assessing memory function. A three-choice version of this task has proven sensitive to selective hippocampal or rhinal lesions (Myhrer, 2000). When the convulsions are stopped after 45 min with the triple regimen (procyclidine, diazepam, pentobarbital), the results show that the neuronal pathology (assessed with Fluoro-Jade B staining) varies from none at all to 30% damage in the index areas (hippocampus, amygdala, piriform cortex). Cognitive deficits are seen in the novelty test (11 days post-exposure) (Figure 63.6) and retention of the brightness discrimination task (28 days post-exposure) among the rats with neuropathology (Figure 63.7). Furthermore, significant correlations between neuropathology scores and behavioral measures are found for the animals that convulsed. It is concluded that

FIGURE 63.5. A three-choice simultaneous brightness discrimination test. The rats (deprived of water) learn that they receive water from the well in the positive cylinder (in this case gray, which is used for half of the rats in each group; the other half uses the black cylinder). The criterion (five correct choices in succession) is obtained in 2 days of training. Thirteen days following acquisition the rats are tested for what has been retained of the learning principle (gray or black positive cylinder).

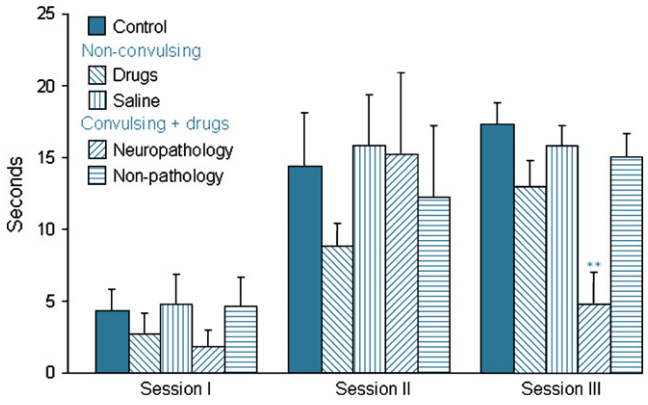

FIGURE 63.6. Mean (SEM) measures of preference for novelty 9–11 days after exposure to soman. Preference for novelty is expressed as the difference in seconds between exploring novel versus neutral objects. Drugs given are procyclidine (6 mg/kg), diazepam (10 mg/kg), and pentobarbital (30 mg/kg). ** Significantly different from all other groups ($p < 0.01$).

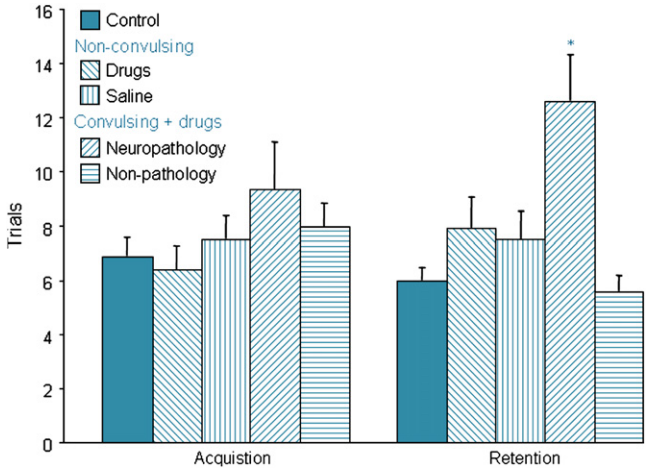

FIGURE 63.7. Mean (SEM) performances (trials to criterion) of acquisition (14–15 days post-soman) in the brightness discrimination task. Drugs are as in Figure 63.6. * Significantly different from all other groups ($p < 0.05$).

early management of soman-induced convulsions is of major importance in preventing neuropathology and accompanying cognitive impairments (Myhrer *et al.*, 2005).

In a number of studies, attempts have been made to terminate soman-triggered seizures/convulsions well after their onset. However, unlike the studies from our laboratory (Myhrer *et al.*, 2003, 2005, 2006c), previous studies have been based on animals also treated before exposure to soman. Marked anticonvulsant effects have been obtained in guinea pigs pretreated with pyridostigmine, given atropine 1 min after a convulsant dose of soman and treated with ketamine 30–120 min post-poisoning (Dorandeu *et al.*, 2005). Treatment with the combination of NBQX and TCP 30 or 50 min after onset of soman-induced seizures has pronounced anticonvulsant impact on rats pretreated with HI-6 and atropine (Lallement *et al.*, 1994b). When pretreated rats (HI-6) are given a single drug of a number of anticholinergics or antiepileptic agents 40 min after onset of soman-evoked seizures the anticonvulsant efficacy is rather modest (McDonough and Shih, 1993; Shih *et al.*, 1999).

Seizures evolving to status epilepticus (seizure activity for 30 min or more) are strongly associated with death or brain damage. The first signs of neuropathology are usually detectable about 20 min after onset of soman-generated seizures in rats (Lallement *et al.*, 1994a; McDonough *et al.*, 1995). The mechanism behind sustained epileptiform activity may be related to increased inactivation of $GABA_A$ receptors along with an up-regulation of NMDA receptors (Chen and Wasterlain, 2006). The net outcome of these changes would require comparatively high doses of anti-glutamatergic drugs to control nerve agent-induced seizures well after onset. This situation appears to make up the biggest challenge within nerve agent research. Animal studies modelling the battlefield/terror situation in which individuals are unprepared to exposure of nerve agent should ideally not include pretreatment. However, in order to assure survival of a reasonable number of animals seizing for 1–3 h, pretreatment appears inevitable.

B. Human Use

Oximes should be used as soon as possible after exposure to nerve agent, because of the short time window of the aging process. The human *in vitro* half-life for soman-inhibited AChE is 1.3 min, for sarin-inhibited AChE 3 h, and for tabun-inhibited AChE 13 h (Vale *et al.*, 2007). When aging has occurred, new AChE has to be synthesized. It is the extremely short aging time of soman that leads to the development of carbamate (pyridostigmine) prophylaxis for nerve agent poisoning. A number of nations use the oxime obidoxime (e.g. Finland, Germany, Norway, the Netherlands), while others use P2S (UK), 2-PAM (USA), or HI-6 (Canada, Sweden) (Aas, 2003). To date, there is no single oxime available that has a high efficiency in reactivating AChE by any known nerve agent. However, HI-6 is considered by most countries to be a very promising oxime following exposure to most nerve agents (Aas, 2003).

Most nations have issued their military personnel with two to three autoinjectors containing atropine and an oxime. Additionally, some nations have provided their soldiers with one autoinjector containing diazepam or avizafone (Aas, 2003). Atropine has to be administered at relatively high dose (2 mg), because of its competitive nature (competes with ACh). The use of autoinjectors speeds up uptake of the drug, due to a spraying effect as the needle plunges into the muscle, resulting in the distribution of drug within a larger muscle area, allowing for more rapid drug uptake than by using conventional needle and syringe (Sidell *et al.*, 1974). However, atropine in too high doses can result in inhibition of sweating and the potential for inducing heat casualties. Even a dose of 2 mg combined with heavy work in a hot environment may induce too high core temperature.

VI. CONCLUDING REMARKS AND FUTURE DIRECTION

This chapter has focused on the development of novel countermeasures against nerve agents in order to improve existing prophylactic and post-exposure treatments. Effective prophylactic treatment can be achieved by using a fixed dose of physostigmine in combination with varying doses of procyclidine. Increased lethal doses of soman can be counteracted by a corresponding increase in the procyclidine dose. However, the higher the doses of procyclidine, the more pronounced the cognitive side effects. Moderate doses of procyclidine should be preferred, because insufficient prophylaxis can be compensated for by adjunct treatment in terms of diazepam and pentobarbital. Since a slight cognitive impairment might be inevitable with effective prophylactics, reduced reliance on pretreatment appears preferable.

Immediate treatment with atropine and an oxime is very efficacious against nerve agent intoxication. However, subsequent treatment well after onset of seizures represents a huge problem in nerve agent research, because of the refractory nature of the epileptiform activity. A triple regimen consisting of procyclidine, diazepam, and pentobarbital has been shown to terminate effectively soman-evoked seizures in rats when administered 30–40 min following onset. A refinement of the triple regimen resulted in a double regimen composed of procyclidine and propofol that can stop seizures 30–35 min after they have been triggered by soman. However, both the triple and double regimens would need monitoring of vital functions, because pentobarbital and propofol can suppress normal function of the respiratory center in the brainstem. Thus, alternative approaches making it possible to design anticonvulsants predominantly affecting the forebrain will be needed. The ultimate aim should be the development of well-tolerated anticonvulsants that can be administered by the soldiers themselves regardless of the point of time after nerve agent intoxication. There are experimental approaches and techniques used in epilepsy research that with great benefit can be adopted in nerve agent studies. A major aim in experimental epilepsy is the identification of seizure controlling brain areas for rational drug designing (Löscher and Ebert, 1996). Microinfusions into area tempestas (AT) or substantia nigra can differentiate more clearly between the anticonvulsant properties of $GABA_A$ modulators against soman-triggered seizures than by systemic administration (Myhrer *et al.*, 2006b). A differentiation between cholinergic and glutamatergic antagonism against soman-induced seizures can be made when anti-Parkinson agents are microinfused into AT (Myhrer *et al.*, 2008a). Thus, it is possible for the microinfusion technique to serve as a tool for screening among drugs with anticonvulsant properties. Furthermore, selective lesions can be used to map potential trigger sites and/or propagation pathways for epileptiform activity induced by nerve agents.

Identification of target areas for nerve agents can allow specification of neurochemical receptors to obtain optimal anticonvulsant effects. Drugs with focal effects may have smaller side effects than drugs acting globally on common denominators for seizure propagation. Simple criteria derived from the three-phase model have been used in the search for effective anticonvulsants against nerve agents. The approach of identifying critical target areas for drug designing used in epilepsy research would probably also become efficient in the search for improved therapies against nerve agents (Myhrer, 2007).

CHAPTER 64

Pharmacological Prophylaxis Against Nerve Agent Poisoning: Experimental Studies and Practical Implications

JIRI BAJGAR, JOSEF FUSEK, JIRI KASSA, KAMIL KUCA, AND DANIEL JUN

I. INTRODUCTION

Inhibitors of cholinesterases are very important chemicals in the group of organophosphates (OPs). These compounds are used in industry, in veterinary and human medicine, and unfortunately in military (chemical warfare agents/nerve agents) and terrorist activities (Japanese incidents in 1994–1995). The bulk of these compounds is used as pesticides (insecticides, acaricides, etc.). According to the World Health Organization, more than one million serious accidental and two million suicidal poisonings with insecticides occur worldwide every year, and of these approximately 200,000 die, mostly in developing countries (Bajgar *et al.*, 2004, 2007a; Eyer, 2003). The mechanism of action, prophylaxis and treatment of intoxications with OP is a very hot topic at present.

The term prophylaxis is sometimes unclear; generally, it is limited to medical countermeasures applied just before penetration of a toxic agent into the organism without further antidotal therapy. It is also described as a pretreatment but usually antidotal treatment is performed. Thus, when treatment is unnecessary, it can be described as prophylaxis. Although successful prophylaxis can be observed for some OPs, full protection of the organism without post-exposure treatment, especially for soman poisoning, remains open. When treatment is given after the exposure, the term post-treatment is used. It is obvious that when the drug is administered prior to nerve agent exposure with the aim of protecting the organism, exposure to these agents is expected, and therefore post-exposure therapy can be used, i.e. pretreatment could be used as the right term. The term prophylaxis used in this chapter is limited to medical countermeasures applied relatively shortly before penetration of a toxic agent into the organism with the aim of protecting the organism against the toxic agent(s).

Prophylaxis against nerve agents has been described and summarized in various publications (Bajgar *et al.*, 2004, 2007a; Layish *et al.*, 2005; Patocka *et al.*, 2006). The basic mechanism of action of OPs is based on their ability to inhibit the enzyme acetylcholinesterase (AChE, EC 3.1.1.7) at cholinergic peripheral and central synapses (Bajgar *et al.*, 2004; Marrs *et al.*, 1996). In general, prophylaxis can be focused on protection of AChE against the inhibition using reversible cholinesterase inhibitors. The level of OP can be diminished by using enzymes hydrolyzing these agents or enzymes binding the agents (to specific proteins or to antibodies) and thereby reducing the OP level and inhibition of cholinesterases – AChE and butyrylcholinesterase (BuChE, EC 3.1.1.8) (scavenger effect) in the organism; this can be described as detoxification. Another approach to prophylaxis is based on using present antidotes and other drugs (Bajgar *et al.*, 2004, 2007a). Different drugs or their combinations can also be used. A simple scheme describing the fate of the agent in the organism and possible target sites for prophylaxis is shown in Figure 64.1.

II. PROTECTION OF AChE AGAINST INHIBITION

Intact AChE is a basic requirement for normal function of the organism and thus for effective prophylaxis. The enzyme is changed in a way that will make it resistant to OP. This can be achieved by using reversible inhibitors (preferably carbamates), which are able to inhibit AChE reversibly, and after spontaneous recovery of the activity (decarbamylation) normal AChE serves as a source of an active enzyme.

The ability of some carbamates to protect an organism poisoned with OP has been known for many years (Koelle, 1946; Koster, 1946). Physostigmine and neostigmine have been used to protect animals against DFP. The number of OPs studied for protection was enlarged, as well as the number of carbamates studied. The results are very dependent on experimental conditions; nevertheless, the protective effects of physostigmine, aminostigmine, pyridostigmine,

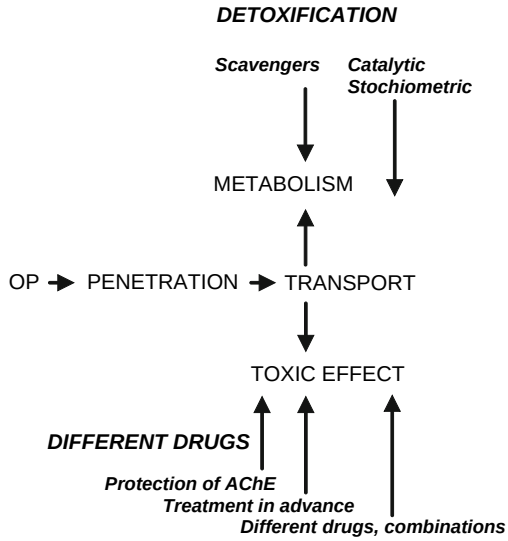

FIGURE 64.1. Four basic reactions of OP in the organism (in capitals) and possible approaches for prophylaxis (in italics)

and others against AChE inhibition caused by different OPs (mostly soman) have been demonstrated (Patocka, 1989; Marrs *et al.*, 1996; Tonkopii, 2003). It has been described that weak inhibitors are able to protect cholinesterases from strong inhibitors (paraoxon) (Petroianu *et al.*, 2005a, 2007). It appeared from the many studies that cholinesterase inhibitor pyridostigmine was the most promising prophylactic drug especially against soman poisoning (Anderson *et al.*, 1992; Bajgar *et al.*, 1994; Gordon *et al.*, 1978, 2005; Kassa and Bajgar, 1996; Kassa and Fusek, 1998, 2000; Kassa *et al.* 2001b, c; Koupilova and Kassa, 1999; Koplowitz *et al.*, 1992; Maxwell *et al.*, 1993; Patocka *et al.*, 1991; Tuovinen, 1998). On the basis of these results, pyridostigmine was introduced into some armies as a prophylactic drug against nerve agents. Its prophylactic effect (like the effects of other carbamates) is increased with its dose; however, with a higher dose, the side effects were more expressed, too. This problem can be solved by adding the pyridostigmine antagonizing drugs – anticholinergics. Many anticholinergics have been tested to protect the organism against intoxication with soman (and other nerve agents) and, on the basis of this research, the prophylactic combination PANPAL composed of pyridostigmine with trihexyphenidyle and benactyzine (Bajgar *et al.*, 1994, 1996; Fusek *et al.*, 2000, 2006; Kassa and Bajgar, 1996; Kassa and Fusek, 1998, 2000; Kassa *et al.*, 2001a) was introduced into the Czech army, and later on into the Slovak army. The presence of anticholinergics allowed us to increase the pyridostigmine dose and, simultaneously, to increase its prophylactic efficacy (Bajgar *et al.*, 2004, 2007a; Fusek *et al.*, 2006; Kassa *et al.*, 1997). Moreover, prophylaxis with PANPAL improves following post-exposure antidotal therapy with anticholinergics and oxime (Bajgar *et al.*, 2004; Kassa, 2006). The prophylactic antidotal combination called PANPAL has no side effects as demonstrated on volunteers: no statistically significant different changes in the actual psychic state as well as no negative changes in the dysfunction time were observed. An improvement of tapping test following PANPAL administration was demonstrated. A decrease in the heart frequency 60 min following PANPAL administration lasting 480 min and returning to normal values within 24 h was demonstrated (Fusek *et al.*, 2006).

Other carbamates also have a good prophylactic efficacy, especially physostigmine and aminostigmine (due to their central effect which is contrary to pyridostigmine) (Kim *et al.*, 2002; Tuovinen and Haninen, 1999; Tonkopii, 2003). Experimental studies with transdermal administration of physostigmine suggest a serious interest in the prophylactic use of this drug (Jenner *et al.*, 1995; Kim *et al.*, 2005; Levy *et al.*, 1992; Walter *et al.*, 1995).

Structurally different inhibitors from the carbamate and OP groups were also studied. From these compounds (preferably binding to the AChE anionic site), tacrine, its 7-methoxyderivative (7-MEOTA) and huperzine A, were considered and experimentally studied with respect to prophylaxis *in vitro* and *in vivo* (Bajgar, 2004). The most interesting results were obtained with huperzine A (Bajgar *et al.*, 2007b; Gordon *et al.*, 2005; Lallement *et al.*, 2002).

III. SCAVENGERS

Keeping AChE intact can be achieved by elimination of the agent before its penetration to the target sites containing the enzyme. In this case, the detoxification principle can be used in two different ways: administration of enzymes splitting the OP or specific enzymes (cholinesterases) which bind the OP. The enzymes hydrolyzing nerve agents are called catalytic scavengers and the enzymes binding nerve agent are described as stoichiometric scavengers. OP is bound to the exogenously administered enzyme or it is decomposed by the enzyme and thus the nerve agent level in the organism is decreased (the action of a ''scavenger''). Enzymes hydrolyzing OPs were thoroughly studied by Li *et al.* (1995) and Raveh *et al.* (1992). Catalytic scavengers are enzymes displaying a turnover with OP/nerve agents as substrates, allowing rapid and efficient protection (Masson *et al.*, 1998). Paraoxonase and similar enzymes are prospective hydrolyzing scavengers (Aharoni *et al.*, 2004; Rochu *et al.*, 2008). On the other hand, many studies have been made with cholinesterases as scavengers. AChE was used as a prophylaxis against organophosphate poisoning and correlation has been found between protection and blood–enzyme level in mice (Raveh *et al.*, 1989; Wolfe *et al.*, 1987). BuChE and AChE were observed to be very effective in protection against OP intoxication (Ashani *et al.*, 1991; Doctor *et al.*, 1991, 1997, 2002; Maxwell *et al.*, 1993, 1998; Moore, 1996, Saxena *et al.*, 1997). The idea to use the plasma as a source of cholinesterase to eliminate nerve agent action after peritoneal dialysis with the human plasma in rats was also described (Bajgar *et al.*, 1982) but without further

development. The administration of enzymes as scavengers seems to be very promising: the enzyme is acting at the very beginning of the toxic action, without interaction with the target tissues and without side effects (Doctor *et al.*, 1997, 2002; Huang *et al.*, 2007; Saxena *et al.*, 2004). All of these features are of great interest and they are yielding practical results – isolation of the enzyme, examination for lack of an autoimmune response, and establishment of pharmacokinetic and pharmacodynamic properties (Saxena *et al.*, 2002). Recombinant human BuChE can be produced from the milk of transgenic goats (Cerasoli *et al.*, 2005). Moreover, BuChE pretreatment also showed protective effects on AChE inhibition in the brain regions following low-level sarin inhalation exposure: the enzyme (BuChE) administered into the blood stream does not influence erythrocyte AChE, plasma BuChE activity is increased, and the brain AChE is not affected. Following intoxication with nerve agent, the agent is bound to plasma BuChE (now existing in excess), and proportionally bound to erythrocyte AChE; both enzymes are inhibited, however, to a lesser extent in comparison with the unpretreated situation. The part of the nerve agent bound to both enzymes represented a loss of the agent and the diminished level of nerve agent is able to penetrate the brain. Therefore, AChE activity in the brain is protected (Bajgar *et al.*, 2007c; Sevelova *et al.*, 2004).

The efficacy of cholinesterases as a bioscavenger of OP can be enhanced by combining enzyme pretreatment with oxime reactivation, since the scavenging capacity extends beyond a stoichiometric ratio of cholinesterases to OP. Human BuChE has previously been shown to protect mice, rats, and monkeys against multiple lethal toxic doses of organophosphorus anticholinesterases (Allon *et al.*, 1998; Maxwell, 1992). An interesting approach can be simultaneous administration of BuChE and reactivators; BuChE acts as a scavenger binding the nerve agents. A reactivator acting as a pseudocatalytic bioscavenger reactivates BuChE simultaneously and reactivated enzyme serves as a new scavenger (Jun *et al.*, 2007).

Given our increasing knowledge of bioengineering and biotechnology, recombinant human BuChE with a good protective effect against nerve agents was obtained from transgenic animals. A connection between these two enzymes (binding and hydrolyzing) is possible with the aim of obtaining a modified enzyme splitting OPs and simultaneously reacting with AChE as a scavenger (Broomfield *et al.*, 1997). Antibodies against OPs are at the research stage and are more focused on the detection of OPs (Lenz *et al.*, 1997; Miller and Lenz, 2001).

IV. PROPHYLAXIS WITH CURRENT ANTIDOTES

The aim of this approach was to achieve a sufficient level of antidotes in the blood circulation before intoxication, so the antidotes can be tested as prophylactics. This can be characterized as ''treatment in advance''. The problem with their use, however, is the timing, duration, and achievement of sufficient levels of these antidotes after administration. The antidotes currently used for the treatment of OP poisoning in this context include anticholinergics, reactivators, anticonvulsants, and others (Bajgar *et al.*, 2004, 2007a). The prophylactic efficacy of antidotes (as demonstrated in treatment studies) is good – administration of the antidotes typically takes place very shortly (minutes) after intoxication. Another study showed good prophylactic efficacy of pyridostigmine or ranitidine with pralidoxime against paraoxon poisoning (Petroianu *et al.*, 2005b, 2006). Extension of the duration of the effects of the antidote by achievement of their sufficient level in the blood by oral administration is not possible (especially reactivators, as they are decomposed in the gastrointestinal tract) and therefore is excluded. Therefore other routes of administration were sought. Transdermal administration of one of the most effective reactivators (HI-6) was shown to be the most realistic approach (Dolezal *et al.*, 1988; Bajgar, 1991). The final result was the new prophylactic transdermal antidote TRANSANT containing the patch impregnated with HI-6. This preparation was clinically tested (including dermal sensitivity) without any harmful effects; field testing was also successful and TRANSANT was introduced into the Czech army and later into the Slovak army (Bajgar *et al.*, 2004; Fusek *et al.*, 2007). If its administration is combined with PANPAL, the two anticholinergics contained in PANPAL are able to prevent and treat symptoms of nerve agent poisoning. Therefore, a combination of TRANSANT and PANPAL administered as a pretreatment provides the best prophylactic efficacy in comparison with pyridostigmine or PANPAL administered alone (Bajgar *et al.*, 2004). The anticonvulsant drugs benzodiazepines (diazepam, midazolam, alprazolam, triazolam, clonazepam) were studied, but isolated prophylactic administration did not offer very good effects (Herink *et al.*, 1990, 1991; Kubova *et al.*, 1990).

V. PROPHYLACTIC USE OF OTHER DRUGS

Prophylactic administration of different drugs (alone or in combination) against intoxication with OPs was studied. Calcium antagonists (nimodipine), neuromuscular blockers (tubocurarine), adamantanes (memantine), and the opiate antagonist meptazinol (Galli and Mazri, 1988; Gupta and Dettbarn, 1992; McLean *et al.*, 1992; Marrs *et al.*, 1996; Karlsson *et al.*, 1998; Stojiljkovic *et al.*, 1998) were also tested, and offered different results with limited practical utility. On the other hand, a positive prophylactic effect has been demonstrated with procyclidine (antimuscarinic, antinicotinic, and the anti-NMDA receptor drug) (Myhrer *et al.*, 2002, 2003), metoclopramide (Hasan *et al.*, 2004), clonidine (Loke *et al.*, 2001), or procyclidine and donepezil (Haug *et al.*, 2007). The prophylactic effect of a group of drugs

TABLE 64.1. Drugs used in the prophylaxis against OP nerve agent poisoning (relatively perspective drugs are in bold)

Principle	Drug group	Drug	Duration	Equipment of the army	Efficacy	Comment
Protection of cholinesterase against inhibition	carbamates	**Pyridostigmine, Aminostigmine, Physostigmine** Syntostigmine, Eptastigmine, Mobam Decarbofuran, Heptylphysostigmine	8 h	PYRIDOSTIGMINE BROMIDE	+++	Dose limited, side effects. Alone is not very effective, following antidotal treatment enhances its effect
	others	**Huperzine A** Tacrine, Methoxytacrine				
	organophosphates					
		TEPP, Paraoxon Ethyl-4-nitrophenylphosphonate				
	aminophenols	Eseroline				
Simulation of treatment	anticholinergics	**Biperidene, Scopolamine, Benactyzine** Atropine, Aprophen, Hyoscine Adiphenine, Caramiphen Pentamethonium, Mecamylamine Trihexyphenidyle				Transdermal administrations of scopolamine, physostigmine and HI-6 were studied
	reactivators	HI-6				
		PAM, Obidoxime, Trimedoxime Methoxime	8 h	TRANSANT (HI-6, transdermal admiministration)	+	Alone is not effective
	others	**Suramine** Benzodiazepines, Tubocurarine Memantine, Procyclidine Nimodipin, Clonidine				
Detoxification	cholinesterases	**Butyrylcholinesterase, Mutants**				
	enzymes hydrolyzing OP	Acetylcholinesterase				Very perspective PROTEXIA®
	monoclonal antibodies against OP	Triesterase Paraoxonase

				PANPAL + TRANSANT	+++++	In combination, the best prophylactic efficacy

with anticholinergic and/or antiglutamatergic properties (benactyzine, biperiden, caramiphen, procyclidine, and trihexyphenidyl) with respect to their anticonvulsant properties was studied to prevent damage of the central nervous system induced by seizures. Only procyclidine and caramiphen antagonized soman-induced seizures (Myhrer *et al.*, 2008a). Among the different drugs tested, procyclidine appears to be an effective anticonvulsant with a few cognitive side effects (Myhrer *et al.*, 2008b). Procyclidine with physostigmine (administered transdermally) showed very good prophylactic efficacy against soman in dogs; moreover, this efficacy was increased using antidotal therapy with HI-6 and atropine (Kim *et al.*, 2005). Special importance can be focused on suramine (a protease inhibitor). Administration of this compound prior to soman intoxication (and followed by administration of atropine) showed good prophylactic effect (Cowan *et al.*, 1996). However, all these studies are experimental ones and they have not reached the practical output stage. The combinations of various drugs as prophylactics can be of very different character. They can be used simultaneously (a combination of different drugs) or as pretreatment and posttreatment with different antidotes. Administration of pyridostigmine (or other AChE inhibitors) prior to intoxication and treatment with different drugs is a typical example (Anderson *et al.*, 1992, 1997; Bajgar *et al.*, 1996; Kassa, 1995; Kassa and Bajgar, 1996; Kim *et al.*, 2002; Tuovinen and Haninen, 1999). There are other combinations such as the administration of triesterase (Tuovinen and Haninen, 1999; Tuovinen *et al.*, 1999), procyclidine (Kim *et al.*, 2002; Myhrer *et al.*, 2002, 2003), clonidine (Loke *et al.*, 2001), or sustained release of physostigmine and scopolamine (Meshulam *et al.*, 2001). The results are dependent on experimental conditions but this approach – administration of different drugs – has yielded some good results though up to now they have been on an experimental level. Only three prophylactics have been introduced into different armies – pyridostigmine alone, PANPAL composed of pyridostigmine, benactyzine, and trihexyphenidyle, and TRANSANT (dermal administration of HI-6).

It appears from these results that simple prophylaxis (without post-exposure treatment) against OP is not sufficient. Therefore, pyridostigmine has importance as a prophylactic drug especially when it is combined with post-exposure antidotal treatment. For further development, it is necessary to search for novel prophylactic drugs and new routes of administration. In this context, preparations of cholinesterases are of special importance for the development of more effective prophylactics.

VI. CONCLUDING REMARKS AND FUTURE DIRECTION

There are many drugs being tested for their prophylactic efficacy against nerve agent intoxication. However, only three prophylactics (pyridostigmine alone, PANPAL, and TRANSANT) have been introduced into military medical practice. The perspective approach seems to be searching for more effective drugs or their combinations, including new routes of administration, and the use of purified enzymes, especially cholinesterases or paraoxonases produced by biotechnology.

CHAPTER 65

Pyridinium Oximes as Cholinesterase Reactivators in the Treatment of OP Poisoning

DEJAN MILATOVIĆ AND MILAN JOKANOVIĆ

I. INTRODUCTION

Organophosphorus compounds (OPs) have been used as pesticides and developed as warfare nerve agents such as tabun, soman, sarin, VX, and others. Exposure to even small amounts of an organophosphorus compound can be fatal; death is usually caused by respiratory failure resulting from paralysis of the diaphragm and intercostal muscles, depression of the brain respiratory center, bronchospasm, and excessive bronchial secretions. The mechanism of OP poisoning involves phosphorylation of the serine hydroxyl group in the active site of acetylcholinesterase (AChE) leading to the inactivation of this essential enzyme which has an important role in neurotransmission. AChE inhibition results in the accumulation of acetylcholine (ACh) at cholinergic receptor sites, producing continuous stimulation of cholinergic nerves throughout the central and peripheral nervous systems. Currently, a combination of an anti-muscarinic agent, e.g. atropine, AChE reactivator such as one of the recommended pyridinium oximes (PAM-2, TMB-4, HI-6, LüH-6), and diazepam are used for the treatment of organophosphate poisoning in humans. This chapter describes the mechanisms of action of OPs and the role of pyridinium oximes used as AChE reactivators in the treatment of OP poisoning.

II. INTERACTION OF CHOLINESTERASES WITH ORGANOPHOSPHATES

There are different types of cholinesterases in the human body, which differ in their location in tissues, substrate affinity, and physiological function. The principal ones are acetylcholinesterase (AchE, EC 3.1.1.7), found in the nervous system and also present in the outer membrane of red blood cells, and plasma cholinesterases (EC 3.1.1.8, ChE), which are a group of enzymes present in plasma, liver, cerebrospinal fluid, and glial cells. Under normal physiological conditions, AChE performs the breakdown of acetylcholine (ACh), which is the chemical mediator responsible for conduction of nerve impulses at the sites of cholinergic transmission. However, its physiological role in blood is not understood. On the other hand, ChE is a circulating plasma glycoprotein synthesized in the liver, which does not serve any known physiological function. Recent evidence indicates that ChE may have roles in cholinergic neurotransmission and involvement in other nervous system functions (cellular proliferation and neurite growth during the development of the nervous system) and in neurodegenerative disorders (Darvesh *et al.*, 2003).

The function of AChE is termination of action of ACh at the junctions of the various cholinergic nerve endings with their effector organs or post-synaptic sites. Organophosphorus compounds and carbamates are the most important AChE inhibitors and are often called anticholinesterases. In the presence of inhibitors, AChE becomes progressively inhibited and is not further capable of hydrolyzing ACh to choline and acetic acid (Jokanović and Maksimović, 1997). ACh accumulates at cholinergic receptor sites and produces effects equivalent to excessive stimulation of cholinergic receptors throughout the central and peripheral nervous systems.

Both substrate and inhibitors react covalently with the esterases in essentially the same manner, because acetylation of the serine residue at AChE catalytic sites is analogous to phosphorylation. In contrast to the acetylated enzyme which rapidly separates acetic acid and restores the catalytic site, the phosphorylated enzyme is stable (Figure 65.1). Inhibited enzyme can be spontaneously reactivated at different rates depending on the inhibitor – for carbamates it occurs very rapidly, while for organophosphates having branched alkyl groups it may occur at a very slow rate. In addition, AChE inhibited with organophosphorus insecticides, having mainly a dimethyl and diethyl phosphate structure, can spontaneously reactivate with half-times for dimethyl phosphates of 1.3 h *in vitro* and 2.1 h *in vivo*. The rate of spontaneous reactivation for diethyl phosphates bound to AChE is much slower (Reiner and Pleština, 1979; Eyer, 2003). As a result, carbamates and dimethyl phosphates are recognized as reversible AChE inhibitors, while other organophosphorus compounds

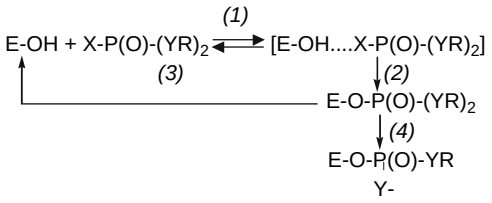

FIGURE 65.1. Interaction of acetylcholinesterase (AChE) and other esterases (E) with organophosphorus esters. Reaction 1 shows interaction of organophosphate molecule with the serine hydroxyl group at the active site of AChE via formation of an intermediate Michaelis–Menten complex leading to phosphorylated enzyme (Reaction 2). Reaction 3 is a spontaneous reactivation of inhibited AChE which occurs very slowly for most OP compounds. Reaction 4, called ''aging'', represents nonenzymatic time-dependent loss of one alkyl group (R) bound to the phosphorus. The aging reaction depends on the chemical structure of the inhibitor and leads to a stable nonreactivatable form of phosphorylated AChE. Y stands for O-, N-, or S-.

having branched alkyl groups are practically irreversible AChE inhibitors.

The variations in the acute toxicity of OPs are the result of their different chemical structures and rates of spontaneous reactivation and aging. The aged form of phosphorylated AChE is resistant to both spontaneous and oxime-induced reactivation. For example, when complexed with VX, AChE in red blood cells spontaneously reactivates at a rate of about 1% per hour for about the first 48 h while the VX–AChE complex ages very little during this period. The soman–AChE complex does not spontaneously reactivate since the half-time for aging is about 2–4 min. The half-time for aging of the sarin–AChE complex is between 5 and 12 h (depending on experimental conditions) and only about 5% of the enzyme undergoes spontaneous reactivation. The half-time for aging of the tabun–AChE complex is about 46 h (Karczmar, 1984; Sidell, 1997; Stojiljković *et al.*, 2001). For OP pesticides containing dimethyl phosphate groups the half-time of spontaneous reactivation of phosphorylated AChE *in vitro* is about 1 h and the half-time of aging is 3.7 h, while these for diethyl phosphates are slower being about 31–57 h and 31 h, respectively (Worek *et al.*, 1999; Mason *et al.*, 2000; Eyer, 2003).

The aging reaction, although appearing with many phosphorylated AChE complexes, has the only major clinical importance and an imperative problem particularly in the treatment of soman poisoning. Aging with soman occurs so fast that no clinically relevant spontaneous reactivation of AChE can occur before aging has taken place. Hence, recovery of function depends on resynthesis of AChE which is a relatively slow process. After soman exposure, it is important to immediately administer atropine and oximes so that some extent of AChE reactivation occurs before all AChE has aged. Even though aging occurs slowly and reactivation relatively rapidly in the case of other nerve agents and OPs, early oxime administration is clinically important particularly in patients poisoned with these agents.

The aging reaction is not the unique property of cholinesterases since it also occurs on other serine esterases such as neuropathy target esterase (NTE) (Johnson, 1982). Although the toxicological consequences of inhibition of AChE and NTE are different, the mechanism of aging on both enzymes is the same as shown in Figure 65.1, and it occurs at a comparable rate for most tested OPs. Earlier studies have shown that atropine can significantly decrease the rate of aging on hen brain NTE inhibited with DFP with a half-time of 7 min (without atropine) and 108 min (with atropine) and this result was confirmed under *in vivo* conditions (Jokanović *et al.*, 1998; Stepanović Petrović *et al.*, 2000). It was also shown that atropine can slow down the aging reaction of soman-inhibited AChE from red blood cells (Schoene and Wulf, 1972; Kuhnen *et al.*, 1985; Van Dongen *et al.*, 1987). Even though no data have been published, it is possible that atropine can show a similar effect on AChE inhibited by other OPs.

III. CLINICAL ASPECTS OF ACUTE OP POISONING

Signs and symptoms of acute poisoning with anticholinesterase agents are predictable from their biochemical mechanism of action and are directly related to the levels of AChE activity (Table 65.1). Three types of effects evident in these poisonings are muscarinic, nicotinic, and central signs and symptoms. The duration of effects is determined mainly by the properties of the compound: its liposolubility, the stability of the OP–AChE complex and whether it is reactivatable after the use of cholinesterase reactivators (such as oximes). It is important to note that only OPs containing the P=O bond (known as direct inhibitors) are potent AChE inhibitors; those having a P=S group (indirect inhibitors) must be metabolically activated to the P=O group (Jokanović, 2001). The signs and symptoms of poisoning with direct inhibitors appear quickly during or after exposure, while those with indirect inhibitors appear slowly and last longer, even up to several days after cessation of exposure.

Clinical diagnosis is relatively simple and is based on medical history, circumstances of exposure, and the presence of clinical symptoms of poisoning. Confirmation of diagnosis can be made by measurement of red blood cell AChE or plasma ChE. Activities of these enzymes are accepted as biomarkers of exposure and/or toxicity of OPs and carbamates. Red blood cell AChE is identical to the enzyme present in the target synapses and its levels are assumed to reflect the effects in target organs. Thus, red blood cell AChE is regarded as a biomarker of toxicity of these compounds. However, it must be kept in mind that the above assumption is only correct when the inhibitor has equal access to blood and synapses. It is difficult to know

TABLE 65.1. Signs and symptoms of poisoning with organophosphorus compounds

Signs and symptoms			Severity of poisoning	Red blood cell AchE (% of control)
Muscarinic	**Nicotinic**	**Central**		
Nausea, vomiting, diarrhea, salivation, lacrimation, bradycardia and arrhythmia, bronchoconstriction, bronchosecretion		Headache, dizziness, drowsiness, anxiety	Mild	>40
As above plus miotic pupils (unreactive to light), involuntary defecation and urination	Twitching of fine muscles, hyperreflexia, fasciculations	As above plus ataxia, psychosis, tremor, dysarthria, slurred speech	Moderate	20–40
	As above plus muscle weakness, reduced tendinous reflexes, paralysis affecting diaphragm and respiratory muscles	As above plus coma, convulsions, respiratory depression	Severe	<20

how closely AChE inhibition in red blood cells reflects this in the nervous system since access to blood is always easier than access to brain. Thus, the inhibition of AChE in red blood cells may be overestimated relative to that in brain (Jokanović and Maksimović, 1997). In addition, AChE in brain is restored by *de novo* synthesis more rapidly than in red blood cells.

The rate of spontaneous reactivation (Figure 65.1, Reaction 3) can be accelerated by pyridinium oximes that have a chemical structure which ''fits'' the structure of the inhibited AChE. The oximes can only be of benefit as long as inhibited AChE is not completely converted to the aged form.

IV. ANTIDOTES IN THE TREATMENT OF OP POISONING

A. Atropine

Atropine acts by blocking the effects of excess concentrations of acetylcholine at muscarinic cholinergic synapses following OP inhibition of AChE. Atropine is the initial drug of choice in acute OP poisoning. Atropine sulfate in combination with an oxime has been used in traditional therapy for intoxication with OP nerve agents as well as with OP insecticides. Atropine can relieve the following symptoms of OP poisoning: sweating, salivation, rhinorrhea, lacrimation, nausea, vomiting and diarrhea, and can help control of bradycardia and circulatory depressions, dilating the bronchi and abolishing bronchorrhea. Atropine does not bind to nicotinic receptors and cannot relieve nicotinic effects of OPCs.

Support for an anticonvulsant property of atropine has been presented by McDonough *et al.* (1987) who found that atropine pretreatment prevents the development of convulsions and brain damage induced by soman and VX. Other authors have stated that atropine can only partly block convulsions after exposure to these agents since other transmitter systems (GABA, glutamate) become involved in cholinergic overstimulation in brain (Zilker, 2005; Antonijević and Stojiljkovic, 2007).

The effects of atropine in OP poisoning are far more complex than muscarinic blockade. In a study in rats, Pazdernik *et al.* (1986) investigated the effect of atropine pretreatment on local cerebral glusose use during seizures induced with soman. Atropine treatment reduced local use of cerebral glucose and brain damage as well. Atropine may be effective in treating acute dystonic reactions and primary position upbeat nystagmus occasionally observed in acute OP poisoning (Heath *et al.*, 1992). Although the clinical efficacy of atropine in OP poisoning is well established, no controlled studies have been published.

The standard dosing of atropine depends on the severity of OP poisoning. The initial dose is usually 2 mg in an adult (0.02 mg/kg in a child) given every 5–10 min until bronchosecretion is cleared and the patient is atropinized (dry skin, sinus tachycardia) which should be maintained during further treatment. The dose may be increased as required. Patients poisoned with OPs appear to be resistant to toxic effects of atropine and may require relatively large doses of atropine administered during prolonged periods. According to IPCS (2002), in severe OP poisoning the total dose of atropine given during 5 weeks of treatment can be as high as 30,000 mg.

B. Diazepam

Benzodiazepines are CNS depressants, anxiolytics, and muscle relaxants. Their main site of action is at the

gamma-aminobutyric acid (GABA) receptor. The $GABA_A$ receptor is a ligand-gated chloride ion channel and part of a superfamily of receptors which also includes the nicotinic acetylcholine receptor and the glycine receptor. GABA is the major inhibitory neurotransmitter in the mammalian central nervous system. Benzodiazepines, including diazepam, alter GABA binding at the $GABA_A$ receptor in an allosteric fashion but these drugs do not directly activate the receptors (Sellström, 1992; Marrs, 2004).

Currently, the most important anticonvulsant is diazepam. The combination of atropine and diazepam is more effective in reducing mortality than atropine or oxime alone. It was also shown that diazepam enhanced the efficacy of low doses of atropine. In the cholinergic nervous system, diazepam appears to decrease the synaptic release of ACh. The main consequence of the action of benzodiazepines in CNS is hyperpolarization of neurons making them significantly less susceptible to cholinergically induced depolarization. The ultimate result is cessation of propagation of convulsions (Sellström, 1992; Marrs, 2004; Antonijević and Stojiljkovic, 2007).

In patients poisoned with OPs, benzodiazepines may have a beneficial effect in reducing anxiety and restlessness, reducing muscle fasciculation, arresting seizures and convulsions, controlling apprehension and agitation, and possibly reducing morbidity and mortality when used in conjunction with atropine and an oxime. Diazepam should be given to patients poisoned with OPs whenever convulsions or pronounced muscle fasciculation are present. In severe poisoning, diazepam administration should be considered even before these complications develop. The recommended dose of diazepam in cases of OPS poisoning is 5–10 mg i.v. in the absence of convulsions and 10–20 mg i.v. in cases with convulsions, which may be repeated as required (Johnson and Vale, 1992; Antonijević and Stojiljkovic, 2007).

C. Oximes

Extensive studies over the past decades have investigated the mechanism of oxime action. There is convincing evidence that the antidotal potency of oximes is primarily attributed to their abilities to reactivate the phosphorylated cholinesterases. Oximes reactivate phosphorylated cholinesterases by displacing the phosphoryl moiety from the enzyme by virtue of their high affinity for the enzyme and their powerful nucleophilicity. Reactivation proceeds as a two-step reaction via formation of an intermediate Michaelis–Menten complex leading to formation of more stable phosphoryl residue bound to the hydroxyl group of serine at the active site of AChE. The rate of reactivation depends on the structure of the phosphoryl moiety bound to the enzyme, the source of the enzyme, the structure and concentration of oxime which is present at the active site, and the rate of post-inhibitory dealkylation known as aging. Phosphorylated oximes are formed during reactivation reaction (Figure 65.2) and some of them appear to be potent inhibitors of AChE (Luo *et al.*, 1999; Ashani *et al.*, 2003; Worek *et al.*, 2007). It was shown that phosphorylated oximes of 2-substituted pyridinium compounds (e.g. 2-PAM, HI-6) are rather unstable while those of 4-pyridinium aldoximes are markedly stable (Ashani *et al.*, 2003; Kiderlen *et al.*, 2005; Worek *et al.*, 2000).

Oximes bind to AChE as reversible inhibitors and form complexes with AChE either at the acylation (catalytic) site, at the allosteric site, or at both sites of the enzyme and protect AChE from phosphorylation. When the reversible inhibitor binds to the catalytic site, the protection is due to direct competition between OP and reversible inhibitor. Binding of a reversible inhibitor to the allosteric site induces indirect protection of the active site. Differences in the mechanisms of enzyme reactivation and protection demonstrate how stereochemical arrangements of oximes can play a role in the potency of their therapeutic efficacy. Direct pharmacological effects, such as direct reaction with OPs (Van Helden *et al.*, 1996), anticholinergic and sympathomimetic effects may also be relevant for the interpretation of antidotal potency of oximes.

In addition to performing AChE reactivation in OPs poisoning, oximes might also show some direct pharmacological effects (Jokanović and Stojiljkovic, 2006). Previous studies supported observations that in some studies the antidotal effects of oximes could be explained only on the basis of AChE reactivation (Schoene *et al.*, 1976; Clement, 1981; Van Helden *et al.*, 1983). Former studies involving adult rhesus macaques (Hamilton and Lundy, 1989) or marmoset monkeys (Van Helden *et al.*, 1992) showed that only limited or no reactivation of soman-inhibited cholinesterase activity occurred when HI-6 was administered in conjunction with atropine and diazepam. These results suggested that some additional mechanism of action of HI-6, other than cholinesterase reactivation, is partly responsible for this enhanced protective activity of HI-6 (Hamilton and Lundy, 1989; Van Helden *et al.*, 1992). HI-6 may have effects on the GABAergic neurotransmission in the CNS (Melchers *et al.*, 1994a).

Furthermore, it was observed that the oxime HI-6 might show direct pharmacological effects in the cholinergic nervous system in skeletal muscles. It has been found that HI-6 reduces the miniature endplate potentials and increases the quantal content by a dose-dependent decrease in the miniature endplate potential amplitude (Melchers *et al.*, 1991). Other possible explanations have been suggested for oximes at other targets in the nervous system, such as

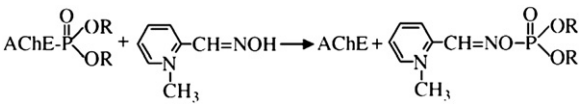

FIGURE 65.2. Reactivation of phosphorylated acetylcholinesterase with pralidoxime and formation of reactivated enzyme and phosphorylated oxime.

alteration of the release of neurotransmitters (Clement, 1979; Kloog *et al.*, 1986), inhibition of acetylcholine release by HI-6 (Van Helden *et al.*, 1998), inhibition of synthesis of neurotransmitters (Clement, 1979), interaction with presynaptic cholinergic nerve terminals (Aas, 1996), and interaction at post-synaptic receptors (Van Helden *et al.*, 1996). It has been shown that both 2-PAM and HI-6 interact with the nicotinic receptor ion complex (Alkondon *et al.*, 1988). The two bispyridinium oximes HI-6 and HLö-7 had significant dose-dependent inhibitory effects on the potassium-evoked release of [^{3}H]acetylcholine from the rat hippocampal slice preparation *in vitro* when the AChE was inhibited with soman. When the AChE was inhibited with soman, two bispyridinium oximes HI-6 and HLö-7 had significant dose-dependent inhibitory effects on the potassium-evoked release of [^{3}H]acetylcholine from the rat hippocampal slice preparation *in vitro*.

Toxic effects of soman and enhanced cholinergic activity might be reduced by suppressing ACh release from cholinergic nerves, thereby reducing the enhanced activation of both muscarinic and nicotinic cholinergic receptors in the brain (Øydvin *et al.*, 2005). It was shown that bispyridinium oximes can slow down the aging reaction of soman-inhibited AChE from red blood cells (Schoene and Wulf, 1972). Oximes may also act as cholinergic blocking drugs at the nicotinic sites (Sidell, 1997). In addition, it has also been proposed that the oximes could participate in hydrolysis of OPs and show direct anticonvulsant effects as well as respiratory stimulation. Patients treated with HI-6 following OP intoxication have shown more rapid improvement than expected on the basis of AChE reactivation. Such effects were attributed to direct pharmacological properties of HI-6 (Kušić *et al.*, 1991).

Mono- and bis-pyridinium oximes are effective against OP-inhibited AChE in the peripheral nervous system, but have a limited penetration across the blood–brain barrier. Limited penetration of HI-6 is due to its pharmacokinetic profile and the two quaternary nitrogen atoms in its structure. However, it appears that oxime penetration through the blood–brain barrier is underestimated since soman can cause seizure-related opening of the blood–brain barrier (Carpentier *et al.*, 1990; Grange-Messent *et al.*, 1999) and thus enable passage of higher oxime concentrations into the brain. Abdel-Rahman *et al.* (2002) have shown that 0.5–1.0 LD_{50} of sarin caused a dose-dependent increase in permeability of the blood–brain barrier in midbrain, brainstem, cerebrum, and cerebellum in rats 24 h after poisoning. Sakurada and coworkers (2003) have determined the amount of 2-PAM passing across the blood–brain barrier at approximately 10% of the given dose which may be effective in reactivation of OP-inhibited AChE in brain. H oximes penetrate the blood–brain barrier at a concentration sufficient to produce biochemical and physiological actions in soman poisoning (Kassa, 2002, 2005). Also, additional data indicate that in OP poisoning, when given with atropine, 2-PAM can pass the blood–brain barrier at higher concentrations.

Possible reasons why oximes may not be effective in OP poisoning were discussed in detail by Johnson *et al.* (2000) and Eyer (2003). Among those reasons the most important are the following:

(a) The oxime dose may be inadequate to produce the optimal concentration required to achieve the desired reactivation and it may not be present at target sites when needed most (i.e. when AChE inhibition reaches its maximum and when OP is present in blood at high concentrations). Proposed minimum-effective plasma levels for oximes of 4 mg/l were also supported by Bokonjić *et al.* (1987), Shiloff and Clement (1987), and Kušić *et al.* (1991). In severe cases of OP pesticide poisoning, higher oxime concentrations may be necessary, especially in the case of pralidoxime. However, Eyer (2003) disagrees with the 4 mg/l concept suggesting necessity of a higher oxime concentration. He proposed that for the most frequently used OPs, pralidoxime plasma concentrations of around 80 µmol/l (13.8 mg/l pralidoxime chloride) or 10 µmol/l of obidoxime (3.6 mg/l obidoxime chloride) should be adequate and maintained for as long as the OP is present in the body. Oxime treatment may be required for up to 10 days.

(b) Besides an inadequate initial dose, subsequent treatment with oxime may not be sufficiently persistent. Oximes are rapidly cleared from the body and although some reactivation may be achieved, another cycle of inhibition and eventually aging of inhibited AChE, due to continuing presence of OPs in blood, may follow. This is particularly possible in the case of massive overdose where residual OP pesticide may persist in the body for several days. In such cases only persistent administration of oximes, by means of continuous infusion or repeated oxime administration, can be expected to result in permanent clinical improvement. Eyer (2003) suggests that the most appropriate dosing regimen consists of a bolus short infusion followed by a maintenance dosage. For pralidoxime chloride a 1 g bolus over 30 min followed by an infusion of 0.5 g/h appears appropriate to maintain the concentration of 13 mg/l. For obidoxime chloride the proposed dosing regimen is a 0.25 g bolus followed by an infusion of 0.75 g/24 h. It is important that the concentrations are well tolerated and effective in keeping the active levels of AChE.

(c) Treatment with oxime may be started too late or terminated too soon. In all cases of poisoning with OPs it would be ideal to start antidotal treatment as soon as possible and to maintain the treatment as long as needed. In cases of poisoning with persistent OP pesticides it is appropriate to start oxime therapy at adequate dose levels up to 10 days after exposure or even later. Eddleston *et al.* (2006) suggest that oximes may be effective if given within about 120 h for diethyl

organophosphorus poisoning and 12 h for dimethyl organophosphorus poisoning. The treatment should be continued until obviously no longer needed and the decission about this can be made on the basis of clinical status of the patient, relatively high AChE activity in red blood cells when compared to control values, and the absence of OPs and/or OP metabolites in urine.

Detailed therapeutic regimens used in the treatment of poisoning with OP compounds are presented in several excellent reviews (WHO, 1986; Lotti, 1991; Johnson and Vale, 1992; Bismuth *et al.*, 1992; Johnson *et al.*, 2000; Eyer, 2003; Marrs and Vale, 2006).

V. PYRIDINIUM OXIMES USED IN THE TREATMENT OF POISONING WITH NERVE AGENTS AND THEIR EFFICACY

Among the many classes of oximes investigated so far, those with clinical application can be divided in two groups – the monopyridinium and bispyridinium oximes. Currently, the only used monopyridinium oxime is pralidoxime (2-PAM), while the most significant bispyridinium oximes comprise trimedoxime (TMB-4), obidoxime (LüH-6, Toxogonin), HI-6 and HLö-7 (Figure 65.3) (Dawson, 1994). There is still no international consensus on the choice of most effective oxime and on dosing regimen.

A. Pralidoxime (PAM-2)

Pralidoxime was synthesized in the USA in 1955 (Wilson and Ginsburg, 1955). Its four salts – chloride (2-PAM Cl), methiodide, methylsulfate, and mesylate (P2S) – were investigated and introduced into practice. 2-PAM is very efficient in reactivating of AChE inhibited with sarin or VX (Johnson and Stewart, 1970; Sidell and Groff, 1974; Harris and Stitcher, 1983; Mesić *et al.*, 1991; Masuda *et al.*, 1995; Nozaki and Aikawa, 1995), but was not successful in reactivation of the tabun- or soman-inhibited enzyme (Inns and Leadbeater, 1983; Koplovitz and Stewart, 1994). Since 2-PAM, as quaternary pyridinium salt, does not readily penetrate across the blood–brain barrier, pro-2-PAM was synthesized as a pro-drug of 2-PAM to gain access to the central nervous system. However, pro-2-PAM was less effective than 2-PAM against experimental poisoning with paraoxon (Bošković *et al.*, 1980). The amount of 2-PAM passing across the blood–brain barrier was quantified as approximately 10% of the given dose, indicating that this level might be effective in reactivation of OP-inhibited AChE in brain (Sakurada *et al.*, 2003). However, in OP poisoning, it appears that 2-PAM, when given with atropine, can pass the blood–brain barrier at higher concentrations.

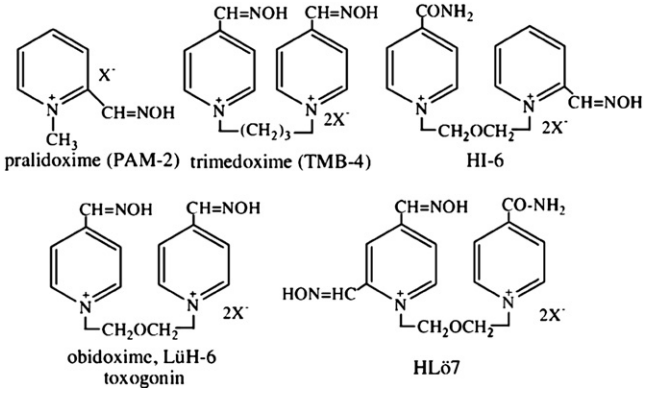

FIGURE 65.3. Chemical structure of pyridinium oximes used in treatment of OP poisoning. X stands for an anion.

Studies with nonhuman primates proved that the combination of atropine and 2-PAM protected against up to five times the LD_{50} of all known nerve agents except soman (Stojiljković *et al.*, 2001).

Pralidoxime administered to human volunteers at a dose of 10 mg/kg by intramuscular route produced a plasma concentration of >4 mg/l within 5–10 min and maintained levels above this threshold for an hour (Sidell and Groff, 1971). Adverse effects of 2-PAM iodide in volunteers include dizziness, blurred vision, occasional diplopia, impaired accommodation, nausea, and headache (Jager and Stagg, 1958; Sidell and Groff, 1971).

Clinical experience with the use of PAM-2 iodide, given with atropine and diazepam, in the treatment of the victims of the Tokyo sarin attack in 1995 was extremely favourable (Stojiljković and Jokanović, 2005). Still, 2-PAM should not be recommended as the drug of choice due to its lack of efficacy against tabun and soman (Kassa, 2005).

B. Trimedoxime (TMB-4)

TMB-4 Cl_2 was synthesized in the USA in 1957 (Poziomek *et al.*, 1958). It is the only one of the major bispyridinium oximes with a propylene bridge between the two pyridinium rings. It was shown that TMB-4 is a more potent reactivator of the DFP-inhibited AChE than 2-PAM (Hobbiger and Sadler, 1958) and better reactivator than LüH-6 in the case of the tabun-inhibited enzyme (Hobbiger and Vojvodić, 1966). TMB-4 was the first oxime to prove its efficiency in the treatment of the animals intoxicated with tabun (Schoene and Oldiges, 1973; Maksimović *et al.*, 1980; Bokonjić *et al.*, 1993). It could also protect the animals poisoned with sarin or VX, but not the ones intoxicated with soman (Maksimović *et al.*, 1980; Inns and Leadbeater, 1983; Binenfeld, 1986). However, TMB-4 was the most toxic oxime among the ''great four'' – it was shown in mice that its LD_{50} is 3, 4 and 8 times less than that for LüH-6, 2-PAM and HI-6, respectively (Clement, 1981).

C. Obidoxime (LüH-6, Toxogonin)

After introduction into medical practice in 1964 obidoxime showed a significant potential as an antidote in poisonings

with OPs (Erdmann and Engelhard, 1964). Given with atropine, obidoxime efficiently protected experimental animals against poisoning with tabun (Inns and Leadbeater, 1983; Maksimović *et al.*, 1989), sarin (Inns and Leadbeater, 1983; Maksimović *et al.*, 1989), and VX (Maksimović *et al.*, 1989). Obidoxime was more effective than TMB-4 as an antidote against intoxication with tabun (Heilbronn and Tolagen, 1965). Similarly to 2-PAM and TMB-4, obidoxime was also inefficient in soman poisoning in mice (Maksimović *et al.*, 1980), guinea pigs (Inns and Leadbeater, 1983), and primates (Hamilton and Lundy, 1989). Obidoxime was more efficient than HI-6 against tabun intoxication. Similarly, obidoxime also was more effective as a medical countermeasure following intoxication with most cholinesterase inhibiting insecticides, while HI-6 is considered to be a better drug against soman inhibited acetylcholinesterase (Aas, 2003). In contrast to TMB-4, obidoxime, when administered with atropine in pyridostigmine-pretreated guinea pigs, could provide some protection against soman as well (Inns and Leadbeater, 1983). Although being less toxic than TMB-4, obidoxime can exert transient hepatotoxic effects (Marrs, 1991), which occur in about 10% of severely poisoned patients (Eyer, 2003).

When administered to human volunteers by the intramuscular route, obidoxime (5 mg/kg) produced a plasma concentration >4 mg/l, from 5 min after injection to 3 h (Sidell and Groff, 1970). Adverse effects of obidoxime in male volunteers were described as pallor, nausea, burning sensation, headache, generalized weakness, sore throat, and paresthesia of the face (Simon and Pickering, 1976; Marrs and Vale, 2006; Eyer, 2003).

D. Asoxime (HI-6)

The first oxime that could reactivate soman-inhibited AChE and provide at least some protection of the animals experimentally poisoned with this nerve agent was synthesized in 1966. It was shown that HI-6 is more potent than LüH-6 and HS-6 in the protection of various rodent species from intoxication with soman (Inns and Leadbeater, 1983; Oldiges and Schoene, 1970; Mesić *et al.*, 1991), as well as sarin and especially VX (Maksimović *et al.*, 1980; Inns and Leadbeater, 1983). HI-6 could not reactivate tabun-inhibited AChE (Clement, 1982; Ćetković, 1984) and it was inefficient, when used as the only oxime, against poisoning with tabun (Maksimović *et al.*, 1980; Inns and Leadbeater, 1983; Mesić *et al.*, 1991). However, other studies found that HI-6 can exert a similar degree of protection against tabun and soman intoxication in primates (Hamilton and Lundy, 1989). It is also suggested that sufficiently high doses of the oxime could even protect rats from the multiple lethal doses of tabun (Lundy *et al.*, 1989). HI-6 given with atropine protected guinea pigs from poisoning against $5 \times LD_{50}$ of soman or cyclosarin (Lundy *et al.*, 2005). The acute toxicity of HI-6 is the lowest among the five oximes (Maksimović *et al.*, 1980; Clement, 1981; Rousseaux and Dua, 1989), with an LD_{50} value after i.m. administration to rats of 781 mg/kg or 2,071 μmol/kg. A clinical study performed on 22 healthy human volunteers did not show any adverse effects when HI-6 was given in doses up to 500 mg by the oral route (Jovanović *et al.*, 1990).

Clinical studies showed that HI-6 dosed at either 250 or 500 mg by the intramuscular route reached plasma concentrations >4 mg/l in 4–6 min. This concentration was maintained for 125 min following the lower dose (250 mg) and 200 min following the higher dose (500 mg) (Kušić *et al.*, 1985, 1991).

HI-6 is considered to be a very promising bispyridinium oxime in medical treatment following exposure to most nerve agents. A disadvantage of HI-6 compared to other available oximes is its lack of stability in aqueous solutions. Both HI-6 and obidoxime are apparently more effective against nerve agents than the monopyridinium oximes P2S or 2-PAM (Aas, 2003).

E. HLö-7

The fourth and the last important ''Hagedorn oxime'' (after LüH-6, HS-6, and HI-6) is HLö-7, which was synthesized in Freiburg, Germany, in 1986 (Löffler, 1986). Only HLö-7 could reactivate AChE inhibited by any of the four major nerve agents *in vitro* and *in vivo* (DeJong *et al.*, 1989; Worek *et al.*, 1994a, b, 1995), as well as AChE inhibited by cyclosarin (Lundy *et al.*, 1992). In addition, HLö-7 more efficiently restored the neuromuscular transmission impaired by *in vitro* superfusion of the neuromuscular preparation with tabun, sarin, soman, or cyclosarin compared to PAM-2, LüH-6, and HI-6 (Alberts, 1990). It was found that HLö-7 induced a significant reactivation of AChE in mice diaphragm inhibited with tabun, sarin, soman, and cyclosarin (Clement *et al.*, 1992). Although both HI-6 and HLö-7 can antagonize sarin-induced hypothermia (proving that, when given with atropine, they can pass the blood–brain barrier and gain access to the CNS) (Clement, 1992; Clement *et al.*, 1992), the toxicity of HLö-7 was 2.5 times higher than that of HI-6 (Clement *et al.*, 1992). The cardiovascular tolerability of HLö-7 was similar, but still not as good as HI-6, at least in anaesthetized guinea pigs (Worek and Szinicz, 1993). HLö-7 appears to be more effective than HI-6 against tabun and VX poisoning and less effective against sarin, soman, and cyclosarin intoxication (Lundy *et al.*, 1992; Eyer *et al.*, 1992). HLö-7-induced protection against tabun poisoning in guinea pigs was significantly better compared to HI-6, while HI-6 was only slightly more efficient than HLö-7 in soman poisoning (Melchers *et al.*, 1994a, b).

The pharmacokinetic profile of HLö-7 was similar to that of HI-6. The mean absorption half-time of HLö-7 was about 14 min after intramuscular administration. Maximum HLö-7 concentration in plasma was reached after 30 min and the half-time of elimination was about 45 min (Eyer *et al.*, 1992).

VI. EFFICACY OF PYRIDINIUM OXIMES IN POISONING WITH OP PESTICIDES

A particular problem in interpreting the beneficial role and efficacy of oximes in clinical practice is a deficiency of published data, especially those evaluated in controlled clinical trials. Studies related to the efficacy of oximes in a clinical setting showed the heterogeneity of therapeutic approaches (i.e. dose regimen, oxime choice, and final outcome of the treatment).

Jokanović and Maksimović (1995) have studied the acute oral toxicity of 25 OP insecticides and one OP fungicide (pyrazophos) in the rat and the efficacy of antidotal treatment involving TMB-4, LüH-6, 2-PAM, and HI-6 (given with atropine and diazepam 1 min after poisining) in animals dosed with $2 \times LD_{50}$ of the OP insecticides. The success of therapy was dependent on the chemical structure of OPs. The oximes were potent antidotes in poisoning with the insecticides having phosphate structure, and provided some extent of antidotal protection in poisoning with phosphonates, phosphorothiolates, phosphorothionates, and phosphorodithioates. However, none of them was an effective antidote against dimethoate and pyridafenthion. The study has shown that TMB-4 was the most effective oxime in the treatment of OP insecticide poisoning.

Kušić *et al.* (1991) have tested the oxime HI-6 in OP pesticide poisoning in 60 patients. HI-6 was administered four times a day as a single i.m. injection of 500 mg with atropine and diazepam treatment. Oxime therapy was started on admission and continued for 2 to 7 days. Most patients were treated with HI-6 and nine patients severely poisoned with quinalphos were treated 2-PAM Cl (1,000 mg four times per day). HI-6 rapidly reactivated human red blood cell AChE inhibited by diethoxy OPs (phorate, pyridaphenthion, quinalphos) as well as that inhibited by dichlorvos (a dimethoxy OP). AChE inhibited with other dimethoxy OPs (dimethoate and phosphamidon) was reported to be resistant to HI-6 treatment, whereas reactivation with malathion was slow (reactivation half-time 10 h). Both HI-6 and 2-PAM successfully reactivated AChE in quinalphos-poisoned patients, with HI-6 acting as a faster AChE reactivator than 2-PAM.

Willems *et al.* (1993) reported that ethyl parathion and methyl parathion could be effectively treated with 2-PAM methylsulfate (plasma concentrations 4 mg/l) and atropine when pesticide concentrations in plasma were relatively low. In severe poisoning with pesticide levels in plasma above 30 µg/l, high 2-PAM concentrations in plasma (14.6 mg/l) did not provide any improvement. In addition, 2-PAM at concentrations of 6.3 mg/l was not effective in AChE reactivation in dimethoate poisoning where AChE was inhibited with its active metabolite omethoate.

Thiermann *et al.* (1997) reported that in parathion poisoning obidoxime (250 mg i.v. administered as a bolus followed by infusion of 750 mg per day) was effective, but AChE reactivation following severe poisoning did not occur until the concentration of paraoxon in plasma was low.

In a clinical study of 63 patients poisoned with organophosphorus insecticides, patients were divided into three groups: one was treated with atropine only, while the other two received atropine and either 2-PAM or obidoxime. Initial and maintenance intravenous doses for 2-PAM were 30 mg/kg and 8 mg/kg/h, respectively, and 8 mg/kg and 2 mg/kg/h, respectively, for obidoxime. The major clinical findings or AChE activities at the time of admission did not show statistically significant differences among the groups. Although the severity of intoxications (based on respiratory complications and duration of hospitalization) was higher in the atropine plus oxime groups, 12% and 50% of patients in the atropine and atropine plus obidoxime groups died, respectively. No mortality was found in the 2-PAM plus atropine group. Incidence of recurrent twitching and convulsions, repeated respiratory arrest, required mechanical respiration, required intensive care unit therapy, and duration of hospitalization were smaller in the atropine plus obidoxime group than in the atropine plus 2-PAM group. Three of the patients who received the obidoxime combination therapy developed hepatitis and two of them died due to hepatic failure, which may indicate overdosage of obidoxime (Balali-Mood and Shariat, 1998).

The only two randomized controlled clinical trials performed so far did not result in a final proof of the efficacy of the oximes in the treatment of poisonings induced by the OP insecticides in humans due to methodological problems (Eddleston *et al.*, 2002). However, experimental and clinical experience suggests that among the pyridinium oximes, obidoxime and trimedoxime, although relatively toxic, could provide reactivation and antidotal protection against most of the OP insecticides. In addition, HI-6 has proved to be effective in the treatment of soman-poisoned animals and safe and effective in patients poisoned with diethoxy OPs.

VII. CONCLUDING REMARKS AND FUTURE DIRECTION

There is no universal, broad-spectrum oxime capable of protecting against all the known OPs. In military toxicology, HI-6 seems to be the best choice for nerve agent poisoning because it was able to protect experimental animals from toxic effects and improve survival of animals poisoned with sublethal doses especially in the cases of soman and cyclosarin. With this exception, available experimental evidence suggests that there are no clinically important differences between pralidoxime, obidoxime, and HI-6 in the treatment of nerve agent poisoning. On the other hand, obidoxime appears to be the best choice for the treatment of poisoning with OP insecticides. The best alternatives for the proposed solutions would be HLö-7 and trimedoxime, respectively. However, it is necessary to rigorously test

these statements in randomized clinical trials conducted according to the latest guidelines. These trials should include objective parameters such as measurement of acetylcholinesterase status, concentration of oximes in blood as well as OPs and their metabolites at different time points in blood and urine. This may be possible in the near future.

CHAPTER 66

Novel Oximes

KAMIL KUCA, KAMIL MUSILEK, DANIEL JUN, JIRI BAJGAR, AND JIRI KASSA

I. INTRODUCTION

Because of the continuous threat of nerve agent misuse, the development of novel antidotes with greater potency is warranted. In this chapter, we would like to turn readers' attention to antidotal therapy with acetylcholinesterase (AChE) reactivators. Although this group of compounds has been known probably for more than half a century, there is no single compound that can counteract every nerve agent's potential to poison. This chapter describes in detail the synthesis of the new AChE reactivators that have been developed within the last few years. During synthesis, special emphasis is given to the structural requirements of these compounds. Finally, several new trends in the development of new reactivators are discussed.

II. ORGANOPHOSPHORUS ACETYLCHOLINESTERASE INHIBITORS

Organophosphorus (OP) compounds are widely used in agriculture as pesticides (DDVP, diazinon, chlorpyrifos, parathion, etc.) and in industry and technology as softening agents and as additives to lubricants. Some OPs are declared as chemical warfare agents or nerve agents. Sarin, cyclosarin, soman, tabun, VX, and Russian VX belong to the well-known members of the OP nerve agent family (Table 66.1; Watson *et al.*, 2006; Bajgar, 2004; Marrs *et al.*, 1996).

The history of nerve agents began prior to World War II in Germany. The first known nerve agent – tabun (*O*-ethyl-*N*,*N*-dimethyl phosphoramidocyanidate) – was synthesized in laboratories of IG Farben by Dr Schrader in 1936 (Germany). Although pesticides were the original aim of Schrader's studies, German authorities identified the deadly potential of organophosphates (OPs), and many other nerve agents such as sarin, cyclosarin, and soman were developed. A few decades later, new nerve agent VX was developed. Other new nerve agents are the intermediate volatile agent (IVA; also named agent GP) and Novichok (Figure 66.1) (Halamek *et al.*, 2007).

During the Cold War, nerve agents were stored and prepared for potential military use but were not used in military conflicts. However, they were misused by Sadam Hussein in Iraq in the Kurdish village of Birjinni (1988) and by the Japanese Aum Shinrikyo sect in Matsumoto (1994) and Tokyo (1995) (Black *et al.*, 1994; Bolz *et al.*, 2002; Tu, 2000).

Nerve agents phosphorylate or phosphonylate the serine hydroxyl group at the esteratic part of the active site of the enzyme acetylcholinesterase (AChE; EC 3.1.1.7) (Figure 66.2). AChE plays a key role in cholinergic transmission in the peripheral and central nervous system and, consequently, its inhibition is life-endangering (Taylor, 1996; Marrs, 1993).

Depending on the particular nerve agent, AChE is irreversibly phosphorylated (a time-dependent process). This process is called aging. Aged enzymes cannot be restored by any nucleophilic agent. Aging is defined as dealkylation of the phosphoryl adduct to give a negatively charged adduct that is stabilized by interaction with the catalytic His 440 (Millard *et al.*, 1999). Because of the irreversible inhibition of AChE, the enzyme is not able to fulfill its physiological role in the organism – splitting the neuromediator acetylcholine (ACh) at the synaptic clefts – and, subsequently, ACh accumulates at the cholinergic synaptic junctions (Taylor, 1996; Patocka *et al.*, 2005).

The acute toxicity of nerve agents is usually attributed to the excessive cholinergic stimulation caused by the above-mentioned excess of ACh, followed by subsequent overstimulation of the cholinergic pathways and desensitization of the cholinergic peripheral and central receptor sites (Dawson, 1994).

Symptoms of intoxication are as follows: when an individual is exposed to low amounts of a nerve agent, the initial symptoms include runny nose, contraction of the pupils, miosis, deterioration of visual accommodation, headache, slurred speech, nausea, hallucination, pronounced chest pain, and an increase in the production of saliva (muscarinic central and peripheral symptoms). At higher doses of a nerve agent the aforementioned symptoms are more pronounced. Coughing and breathing problems also occur. The individual then may begin to experience convulsions (nicotinic symptoms) and a subsequent disturbed ventilation, coma, and death. At even higher doses an exposed individual would almost immediately go into convulsions and die from ventilation and cardiovascular failure because of the

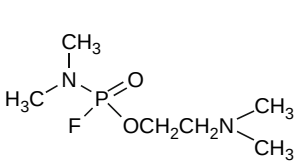
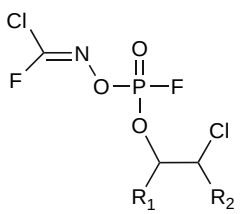
simultaneous shutdown of the nervous and respiratory systems. The initial stages of symptoms of an individual exposed to a nerve agent may vary depending on the particular nerve agent and amount of agent the individual was exposed to (Dawson, 1994; Rotenberg and Newmark, 2003).

III. ACETYLCHOLINESTERASE (AChE; EC 3.1.1.7)

AChE is a serine hydrolase enzyme that belongs to the esterase family within higher eukaryotes. This family acts on different types of carboxylic esters. AChE's biological role is the termination of transmission impulse at cholinergic synapses within the nervous system by rapid hydrolysis of the neurotransmitter ACh (Schumacher *et al.*, 1986). The monomer of AChE with a molecular weight around 60,000 is an ellipsoidal molecule, whose size is approximately $45 \times 60 \times 65$ angstrom (Å), consisting of a 12 stranded central mixed β-sheet surrounded by 14 α-helices (Sussman *et al.*, 1991). Each monomer contains one catalytic center composed from two compartments: the esteratic subsite containing the catalytic triad and the anionic subsite that accommodates the positive quaternary compartment of ACh. The esteratic subsite contains the catalytic machinery of the enzyme: a catalytic triad of Ser 200, His 440, and Glu 327. The anionic subsite is defined by Trp 84, Phe 330, and Phe 331. Its role is to orient the charged part of the substrate that enters the active center. This role is the main function of the Trp residue (Sussman *et al.*, 1991). The recent rendition of the x-ray structure for AChE places the active catalytic site deep within a gorge-like fold of the protein. The aromatic gorge in the protein is approximately 20 Å deep and penetrates halfway into the enzyme. The active site lies at the base of this gorge only 4 Å above the base, leading some to label this the active gorge. The aromatic gorge is a more appropriate term, because 40% of its content is composed of 14 aromatic residues located in the gorge, which is highly conserved from different species of AChE (Harel *et al.*, 1993). The high aromatic content may explain studies that have proposed hydrophobic and anionic binding sites independently on the active site. Only a few acidic residues are present within the gorge. Markedly, the aromatic residues play an important role in the stabilization of the enzyme–substrate complex. Electrostatic as well as hydrophobic effects are of importance here (Berman and Leonard, 1990). The electrostatic potential map of AChE suggests that this enzyme, like the other enzymes with charged substrates, steers its substrate toward its gorge and into the active site.



Agent IVA



Novichok

FIGURE 66.1. Proposed structures of new nerve agents.

The second anionic site of AChE, the so-called peripheral anionic site, is located at the active center gorge entry, and encompasses overlapping binding sites for different

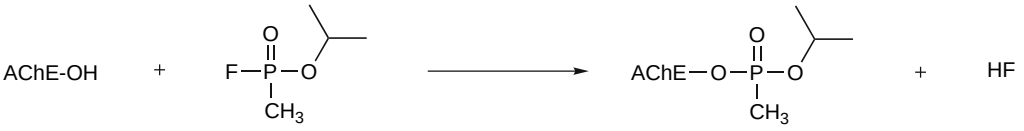


FIGURE 66.2. Inhibition of acetylcholinesterase by sarin.

activators and inhibitors. The peripheral anionic site consists of residues Asp 74 and Trp 286 as a common core. Binding of ligands to these residues may be the key to the allosteric modulation of AChE catalytic activity (Bourne *et al.*, 2003).

IV. ANTIDOTES FOR AChE INHIBITING ORGANOPHOSPHORUS POISONING

Antidotes developed for treatment of nerve agent intoxication could be divided into two parts: prophylaxis as pre-exposure administration of antidotes and post-exposure treatment consisting of anticholinergic drugs, AChE reactivators, and anticonvulsants. Among the most known prophylactic means are carbamates (pyridostigmine and physostigmine), oximes (HI-6; Transant patch – Czech Republic), or scavengers (butyrylcholinesterase, paraoxonase, or phosphotriesterase). The main drugs used for post-exposure treatment are anticholinergics (functional antidotes) that antagonize the effects of accumulated ACh at the cholinergic synapses, and AChE reactivators (called oximes according to the functional oxime group) reactivating AChE inhibited by the organophosphorus inhibitor (causal antidotes). Their effects are synergistic. Central sedative-hypnotics such as benzodiazepines are also used as anticonvulsants (Patocka, 2004).

A. Reactivators of AChE

Pralidoxime (2-PAM; 2-hydroxyiminomethyl-1-methylpyridinium chloride), obidoxime [1,3-bis(4-hydroxyiminomethylpyridinium)-2-oxapropane chloride], methoxime [MMC-4; MMB-4; 1,1-bis(4-hydroxyiminomethylpyridinium)-methane chloride], trimedoxime [TMB-4; 1,3-bis(4-hydroxyiminomethylpyridinium)-propane bromide], and oxime HI-6 [1-(2-hydroxyiminomethylpyridinium)-3-(4-carbamoylpyridinium)-2-oxapropane chloride] are considered to be the most important commercially available AChE reactivators (Figure 66.3a). Other AChE reactivators are currently under development in different countries: HLö-7 (1-[2,4-bis(hydroxyiminomethylpyridinium)]-3-(4-carbamoylpyridinium)–2-oxapropane chloride), and K027

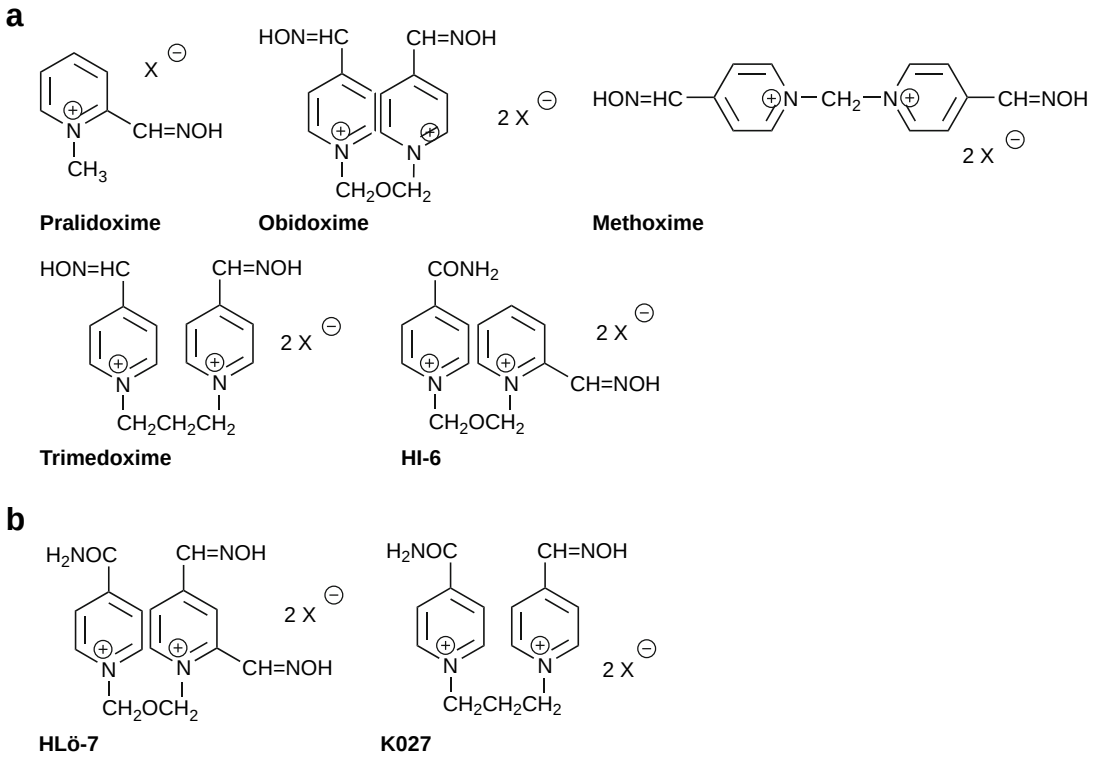

FIGURE 66.3. Selected AChE reactivators.

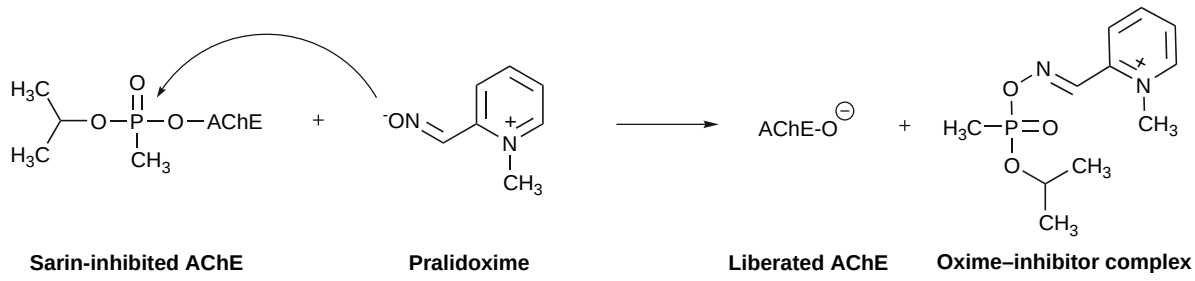

FIGURE 66.4. Reactivation of sarin-inhibited acetylcholinesterase.

[1-(4-hydroxyiminomethylpyridinium)-3-(4-carbamoylpyridinium)–propane bromide] (Figure 66.3b).

From a chemical point of view, AChE reactivators are mono- or bis-quaternary pyridinium salts bearing in their molecule a functional oxime group able to split the bond between the organophosphorus inhibitor and the enzyme, to release free functional enzymes to once again be physiologically active in the organism (Figure 66.4).

Unfortunately, none from the above-mentioned AChE reactivators is sufficiently effective against all known nerve agents and pesticides (Table 66.2; Kuca *et al.*, 2007a).

V. SYNTHESIS OF NEW AChE INHIBITORS

At present, many scientific institutions around the world are interested in the synthesis and improvement of new antidotes against chemical warfare agents, especially nerve agents, because of the continuous threat of the nerve agent misuse by terrorists. Regarding the AChE reactivators, finding a suitable oxime sufficiently effective against inhibited AChE, regardless of the type of OP compounds, is a very important task. There are several reviews dealing with the synthesis of new cholinesterase reactivators (Petrova and Bielavsky, 2001; Primozic *et al.*, 2004). Several studies discussing recent developments in the synthesis of novel reactivators are discussed below.

In 1991, Goff *et al.* reported synthesis and activity testing of monoquaternary imidazole derivatives with various substituents such as ether, silicone, nitrile, ester, halogen, nitro, sulfone or amino group (Goff *et al.*, 1991). Published literature reveals that syntheses started from 1-methylimidazole (Figure 66.5).

Synthesized compounds were tested together with atropine sulfate *in vivo* on mice intoxicated by soman and tabun. Afterwards, they were also tested *in vitro* against ethyl(4-nitrophenyl)methylphosphonate-inhibited human erythrocyte AChE using pralidoxime and HI-6 as reference compounds. The experiments showed that derivatives

FIGURE 66.5. Synthesis of monoquaternary imidazole derivatives (Goff *et al.*, 1991).

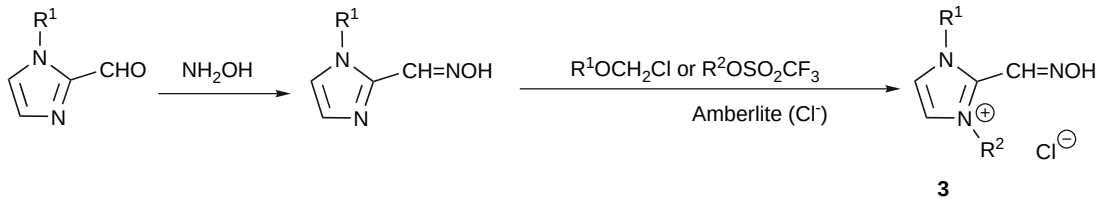

FIGURE 66.6. 2-Hydroxyiminomethylimidazole derivatives (Koolpe *et al.*, 1991).

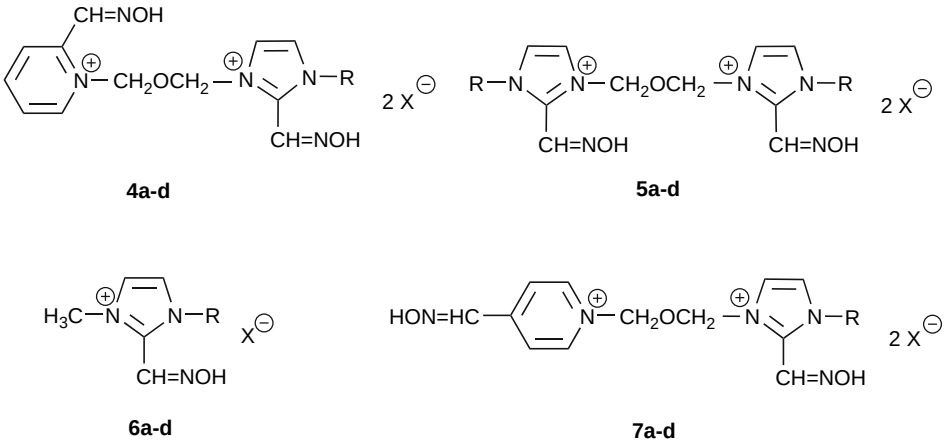

FIGURE 66.7. Mono- and bisquaternary imidazolium or imidazolium–pyridinium compounds (Mesic *et al.*, 1991).

bearing halogen, nitro, sulfone, amine, or aminosulfonyl side-chain functional groups (e.g. **2i–k**, **2n**) greatly improved antidotal protection relative to pralidoxime, whereas those bearing ether, silyl, nitrile, or ester side-chain substituents (e.g. **1a**, **1d**, **2c–d**) were essentially ineffective. Nitro, sulfone, amine, or aminosufonyl functional groups were determined as those which would improve the effectiveness of the quaternary 2-(hydroxyiminomethyl) imidazole. Unfortunately, the ability of tested compounds to reactivate inhibited human AChE was poor and did not correlate with *in vivo* tests on mice.

Koolpe *et al.* (1991) synthesized and studied quaternary salts derived from 2-hydroxyiminomethyl imidazole with various substituents on both nitrogen atoms on the imidazole ring (Figure 66.6), where R^1 is represented by methyl, ethyl, or butyl, and R^2 by a very large spectrum of substituents, e.g. 2-nitropropyl, 2-(ethylsulfonyl)-ethyl, 2-dimethylaminoethyl hydrochloride.

All the synthesized compounds were tested both *in vivo* on mice intoxicated by soman or tabun and *in vitro* on human erythrocyte AChE. In conclusion, nitro, sulfone, amino, and aminosulfonyl side-chain substituents caused high antidotal activity, where the optimum length of side-chain lies between two and four atoms, a cationic quaternary heteroaryl ring is essential for activity, and the presence of an oxime or other nucleophilic moiety is not essential. *In vitro* tests indicated that all these compounds are not particularly effective as AChE reactivators, but they are potent reversible and competitive inhibitors of intact AChE.

Mesic *et al.* (1991) prepared four types of compounds including monoquaternary or bisquaternary imidazolium (imidazolium–pyridinium) salts (Figure 66.7), where R is methyl (**4a**, **5a**, **6a**, **7a**), benzyl (**4b**, **5b**, **6b**, **7b**), phenyl (**4c**, **5c**, **6c**, **7c**) or 4-methoxyphenyl (**4d**, **5d**, **6d**, **7d**), and X is an iodine or a chlorine (only **5a**) anion.

Reactivation activity of the above-mentioned compounds was tested *in vitro* on human erythrocyte AChE and compared to pralidoxime, obidoxime, and HI-6. Some of these (**6b**, **7b**) had better reactivating activity against sarin or tabun than commonly used reference compounds.

Mesic *et al.* (1992) prepared four fluorinated compounds (**8–11**) of mono- and bis-imidazolium type (Figure 66.8).

Reactivation *in vitro* was performed on human erythrocyte AChE inhibited by sarin, VX, tabun, or soman without promising results. Toxicity of all these compounds was tested *in vitro* on human erythrocyte AChE.

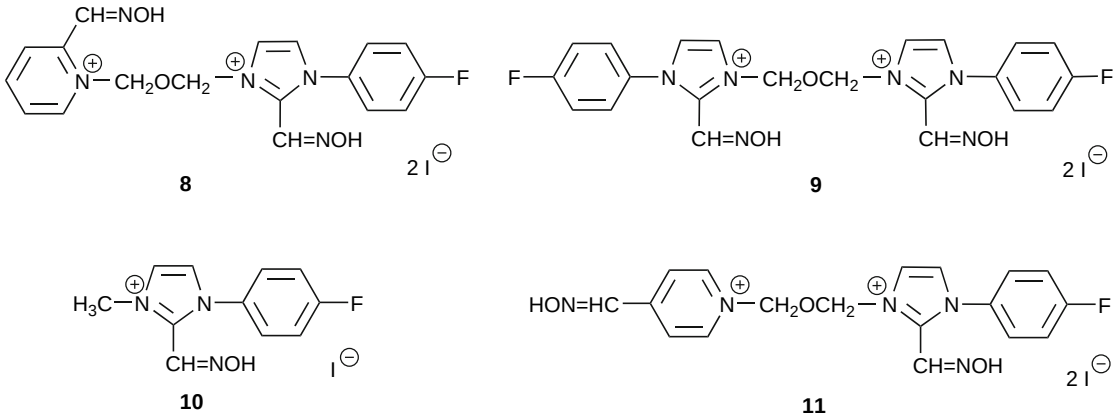

FIGURE 66.8. Fluorinated compounds of mono- and bis-imidazolium type.

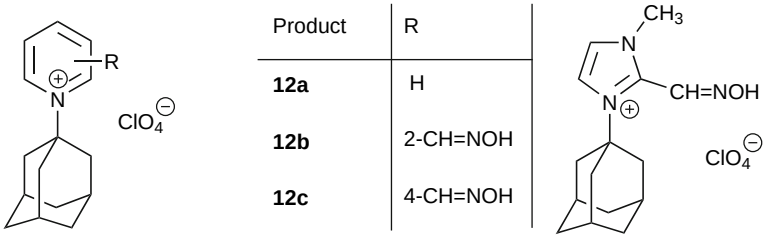

FIGURE 66.9. Monopyridinium and monoimidazolinium adamantane derivatives

Bregovec *et al.* (1992) prepared adamantane derivatives of monopyridinium and monoimidazolinium type (Figure 66.9). In monopyridinium salts, R is hydrogen or hydroxyiminomethyl in position two or four (**12a–c**).

Reactivation *in vitro* was performed on human erythrocyte AChE inhibited by sarin, VX, tabun, or soman compared with HI-6. No newly prepared compound showed reactivation potency stronger than the control substance.

Eyer *et al.* (1992) summarized a study about the methanesulfonate salt of HLö-7 (Figure 66.10). A new synthetic strategy, using bis(methylsulfonoxymethyl)ether linker, was presented.

A broad spectrum of pharmacological data was acquired by *in vivo* experiments on mice, guinea pigs, and dogs. The reactivation experiments were performed *in vitro* on bovine erythrocyte AChE with soman, sarin, or tabun compared to HI-6, and showed that the methanesulfonate salt of HLö-7 is superior to HI-6 in reactivating soman- or sarin-inhibited AChE and exceeds HI-6 in reactivation of tabun-inhibited AChE.

Hsiao *et al.* (1992) patented a preparation of bis-methylene ether-linked bispyridinium compounds (Figure 66.11). Bis(methanesulfonoxymethyl)ether was used to form a linker between pyridine rings, and methanesulfonate anions were replaced by chloride anions.

The patent describes only synthetic pathways and chemical experimental data of prepared compounds (**14**). No biological data were reported. Deljac *et al.* (1992) described compounds of symmetric bisquaternary imidazolium type with a four-carbon linker (Figure 66.12), where R is methyl (**15a**, **16a**), phenyl (**15b**, **16b**), benzyl (**15c**, **16c**), 4-methoxyphenyl (**15d**, **16d**), and 4-fluorophenyl (**15e**, **16e**).

Reactivation *in vitro* was performed on human erythrocyte AChE inhibited by sarin, VX, tabun, or soman. Only one compound, (*E*)-1,4-bis(2-hydroxyiminomethyl-3-methylimidazolinium) but-2-ene dibromide (**16a**), showed promising results in reactivation of AChE inhibited by the above-mentioned inhibitors, except soman (because of aging). In the same publication, two already known AChE reactivators, BDB-108 (**17a**) and BDB-109 (**17b**), and new compounds, BDB-107 (**17c**) and BDB-111 (**17d**), with four carbon linkers and hydroxyiminomethyl in position two or four, are discussed (Figure 66.13) (Deljac *et al.*, 1992).

Reactivation ability and *in vitro* toxicity were performed on human erythrocyte AChE inhibited by sarin, VX, tabun, and soman. All compounds had no reactivation potency against soman-inhibited AChE. Substances with the oxime group in position four on the pyridinium ring (**17a–b**) had high reactivation potency (>70%) against sarin and tabun. Promising potency against VX-inhibited AChE was also achieved. Substances with the oxime group in position two on the pyridinium ring (**17c–d**) had high reactivation potency (>70%) against sarin. However, they were poor reactivators of tabun-inhibited AChE.

Sikder *et al.* (1993) synthesized two new series of 3,3′- and 3,4′-substituted bispyridinium monooximes and two bisoximes bridged by 2-oxapropane (Figure 66.14) and propane (Figure 66.15) connecting chain.

Reactivation potency of the compounds was tested *in vitro* on lyophilized eel AChE inhibited by diisopropylfluorophosphate (DFP). The compounds with a 2-oxapropane linker between both pyridinium rings were weaker reactivators compared to the corresponding propane derivatives.

According to the previous results published in 1992, Mesic *et al.* (1994) synthesized four new *p*-methylphenyl imidazolium derivatives (**20–23**) (Figure 66.16) and compared their biological activity to the corresponding

previously prepared *p*-substituted analogs. *In vitro* tests showed that prepared compounds are poor reactivators of soman-inhibited AChE, except the promising results of compound **22**.

Hampl *et al.* (1995) synthesized some already known and new AChE reactivators derived from pyridinecarbaldoxime (Figure 66.17) and pyridazinecarbaldoxime (Figure 66.18) using it for the purpose of cleavage of mimic nerve agent.

Carvalho and Miller (1995) described derivatives, in which carbon-bonded hydrogen in the 2-hydroxyimino-methyl group of pyridinium monoquaternary salt was replaced by 4-substituted aryl (Figure 66.19). Biological data of the synthesized compounds are not mentioned in the article.

Skrinjaric-Spoljar *et al.* (1999) synthesized some inhibitors and also one reactivator (**27**) of AChE (Figure 66.20), which was found to be weak in reactivation of VX-inhibited human erythrocyte AChE.

Yang *et al.* (2003) used bis(methylsulfonoxy-methyl)ether for synthesis of already known reactivators (obidoxime, HI-6, **14d**) as shown (Figure 66.21). No biological data of synthesized compounds were mentioned in the article.

Pang and Brimijoin (1999) used the method of Poziomek *et al.* (Pang *et al.*, 2003; Poziomek *et al.*, 1958) for synthesis of bispyridinium dicarbaldoximes (**28a–h**, **29a–h**) (Figure 66.22). They found a new efficient method for the synthesis of bis-2-hydroxyiminomethylpyridinium salts using bistriflates as alkylating agents (**30a–h**). This work was previously patented by other authors.

Human erythrocyte AChE inhibited by echothiophate [(2-mercaptoethyl) trimethylammonium-*O*,*O*-diethyl-phosphorothioate iodide] was used for *in vitro* reactivation screening. A compound with three membered carbon linkers (**28b**) was the most effective from the *p*-series and a compound with seven carbon connecting chains (**30f**; Ortho-7) seemed to be the most effective from the *o*-series. These results were explained by the authors using 3D structures.

Kuca *et al.* (2003a) tried to find a reactivator with good efficacy against tabun. The synthesis was made using a subsequent approach under the following scheme (Figure 66.23).

The *in vitro* test on rat brain homogenate showed that oxime K048 has higher efficacy to reactivate tabun-inhibited AChE than pralidoxime or HI-6, which is comparable with obidoxime.

Kuca *et al.* (2003b) prepared a similar potential reactivator of AChE 1-(4-hydroxyiminomethylpyridinium)-3-(carbamoylpyridinium)-propane dibromide (K027) differing from the compound K048 in the length of the connecting chain. Two synthetic pathways were used to reach the proposed structure (Figure 66.24). The activity of new reactivator (K027) was tested *in vitro* on sarin-inhibited AChE with promising results.

Kuca *et al.* (2004a) also synthesized and *in vitro* tested activity of symmetric bispyridinium dicarbaldoximes against cyclosarin-inhibited AChE (Figure 66.25).

Compound 1,4-bis(2-hydroxyiminomethylpyridinium)-butane dibromide (31, K033) gave promising results in *in vitro* reactivation of cyclosarin-inhibited AChE in comparison with commonly used pralidoxime. In the same laboratory, a new series of four monoquaternary compounds using original synthetic strategy was prepared (Figure 66.26) (Kuca *et al.*, 2004b).

The reactivation potency was examined *in vitro* on rat brain AChE. All tested compounds were less effective reactivators of sarin, cyclosarin, VX, or tabun-inhibited AChE compared to pralidoxime.

In India in 2005, Chennamaneni *et al.* (2005) repeated the synthesis of oximes K027 and K048 and moreover they added four more new reactivators (**34**) derived from these compounds (Figure 66.27).

Consequently, they tested their reactivation activity on tetraethylpyrophosphate-inhibited mouse brain cholinesterases. Their activities were compared with pralidoxime. All the compounds (except that with pentylene bridge) were found to be more effective reactivators than pralidoxime. Bispyridinium monooximes with a 3-carbamoyl group were

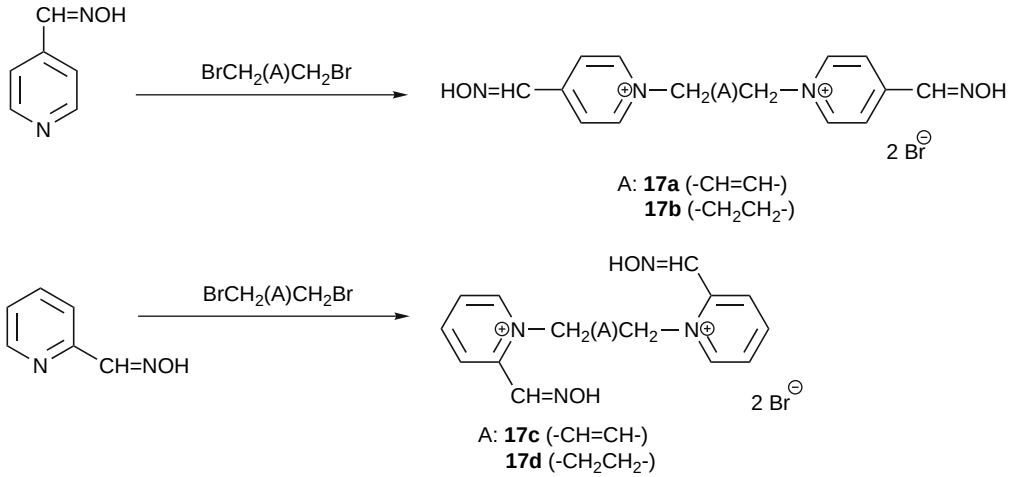

FIGURE 66.13. Bisquaternary pyridinium four carbon-linked compounds (Deljac *et al.*, 1992).

found to be more potent reactivators than the corresponding 4-carbamoyl compounds.

Picha *et al.* (2005) returned to monopyridinium compounds (**35**) with a hydroxyiminomethyl group modified in the side-chain, with the aim of improving the nucleophilicity of this group (Figure 66.28). From the eight oximes prepared and tested, none achieved better reactivation potency if compared with pralidoxime, obidoxime, or HI-6 (Picha *et al.*, 2005; Jun *et al.*, 2008).

In 2006, a new group of 3-oxapentane linker-containing reactivators (**36**) was prepared in Korea (Figure 66.29) (Kim *et al.*, 2005). Among them, several derivatives were found to be promising in case of pesticide and tabun-inhibited cholinesterases reactivation (Kuca *et al.*, 2006; Kim *et al.*, 2006).

Very promising compounds (K074, K075), which are at present being tested in many laboratories throughout the world, were resynthesized in 2005 in the Czech Republic (Figure 66.30) (Kuca *et al.*, 2005a). As mentioned previously, there has been very promising reactivation activity in the case of tabun and pesticides treatment (Kassa *et al.*, 2007; Lorke *et al.*, 2008a). It will be more thoroughly discussed further in this chapter.

A new xylene linker connecting two pyridinium rings was investigated. Within this investigation 18 new oximes (**37**) were prepared and tested for their ability to reactivate

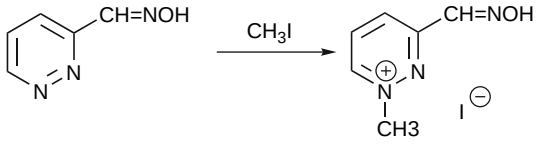
tabun and pesticide-inhibited AChE (Figure 66.31) (Musilek *et al.*, 2005, 2007a; Hrabinova *et al.*, 2006).

Chennamaneni *et al.* (2005) prepared four new series of asymmetrical bisquaternary monooximes (**38**) having the aldoxime group in position four at the pyridinium ring and carbamoyl groups in positions three/four at the second pyridinium ring (Figure 66.32). Similar work was published by this group in 2005. The main difference from their results published earlier was the change in the length of the connection chain between two pyridinium rings. The length was six, seven, eight and nine methylene groups. The ability of tested compound to reactivate tetraethylpyrophosphate-inhibited AChE on mouse brain was compared to pralidoxime. It was found that with the increased chain length (from seven to nine methylene groups) the reactivators potentiated the inhibitory effect of OP (Srinivas Rao *et al.*, 2006).

Musilek and colleagues changed regular connection chains between two pyridinium rings (*n*-methylene or 2-oxapropane) to but-2-ene. When considering the sterical rearrangement of the but-2-ene linker, there could be two possible geometrical isomers (*E* and *Z*). Both groups of bisoxime reactivators were prepared (**39**, **40**) (Figure 66.33). They were tested for their possibility to reactivate tabun and pesticide-inhibited AChE. From the obtained results, several candidates were considered as promising for further evaluation of their reactivation potencies (Musilek *et al.*, 2006a, b, c, 2007d).

Monoquaternary pyridines with an oxime group in positions two (pralidoxime), three, and four (**41**) were prepared together with bisquaternary ones (**42**) connected via



25

FIGURE 66.18. 1-Methyl-3-hydroxyiminomethylpyridazinium iodide.

a propane linker (Figure 66.34). Their reactivation activity was tested on tabun and pesticide-inhibited cholinesterases. As predicted, trimedoxime reached the best activity compared with other oximes synthesized throughout the study (Musilek *et al.*, 2006b, c).

Dr Jung's group prepared new oximes with a novel linker having two oxygen atoms in its structure (**43**) (Figure 66.35). Their reactivation activity was tested on rat brain homogenate inhibited by agent VX. As a result, 1,6-bis(4-hydroxyiminomethylpyridinium)-2,5-dioxahexane dichloride was the most potent and appeared to be the most promising compound as a potential reactivator for AChE inhibited by VX agent. Furthermore, the prepared oximes were tested on housefly AChE and bovine red blood cell AChE inhibited by DFP and paraoxon. Also, in the case of pesticide-induced AChE inhibition, the above-mentioned oxime achieved promising results (Oh *et al.*, 2006; Yang *et al.*, 2007). Acharaya *et al.* (2008a) prepared many other compounds of similar structure in 2008. The whole set consisted of 11 compounds differing in the length of the connection chain and position of the oxime groups. They were tested on the electric eel AChE inhibited by sarin. Two promising oximes were found that should be considered for further investigation.

Musilek *et al.* (2006d) prepared bisquaternary reactivators with a cyano group instead the carbamoyl group (**44**), which is present in the structure of HI-6, K027 or K048 (Figure 66.36). Only one derivative seemed to be promising against paraoxon-inhibited AChE. None of the tested substances was able to satisfactorily reactivate tabun-inhibited AChE.

Owing to the fact that HI-6 is at the present time considered as the reactivator of first choice, there are many efforts to improve its application. One approach is the choice of the right counteranion of the reactivator. The anion could influence the solubility and stability of the reactivator in the solution. In 2007, 12 different salts of HI-6 (sulfate, chloride, acetate, bromide, phosphate, mesylate, tartarate, iodide, malonate, salicylate, maleinate, tosylate) were prepared and tested to discover how the anion can influence the self-reactivation process. It was found that there is no difference in the reactivation of cyclosarin-inhibited AChE (Kuca *et al.*, 2007b).

Because of the presence of promising oximes among those with the but-2-ene linker, this pharmacophor was introduced into several other compounds having an oxime group in position four. At the second pyridinium ring, other functional groups were introduced in position four (**45**) (Figure 66.37). Thanks to this structural combination, many new promising oximes were found (Musilek *et al.*, 2007e).

Among them, oxime K203 seemed to be the best one (Figure 66.38). According to our present knowledge, it is considered to be number one in the case of reactivation of tabun-inhibited AChE (Musilek *et al.*, 2007f).

Because of this promising efficacy, many other derivatives having an oxime group on the first pyridinium ring and

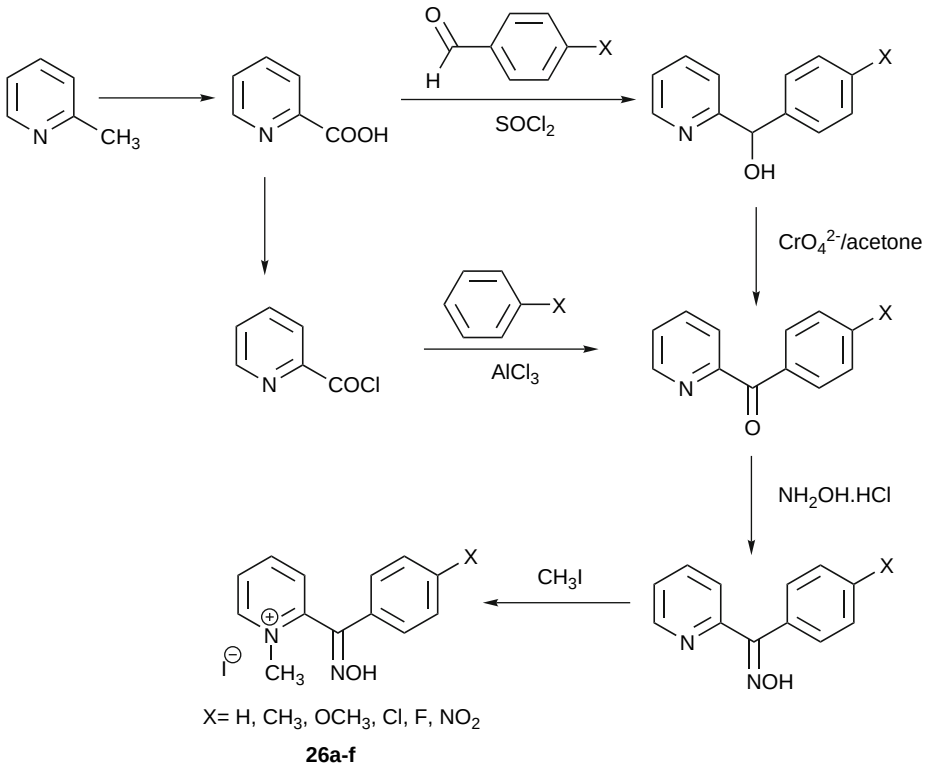


FIGURE 66.19. Preparation of 4-aryl substituted 1-methyl-2-hydroxyiminomethylpyridinium salts.

a carbamoyl group on the other ring were prepared (**46**) (Figure 66.39). Among them, no better reactivator of tabun-inhibited AChE was found. However, many other oximes with promising activity for the treatment of paraoxon-inhibited AChE were found (Musilek *et al.*, 2008).

Another five monoquaternary oximes were prepared and tested in Croatia by Dr Kovarik's group (**47**) (Figure 66.40). All oximes inhibited human AChE reversibly. All prepared oximes reached reactivation of tabun-inhibited AChE within 24 h from 30 to 80% (Odzak *et al.*, 2007).

With the aim of decreasing the size of the reactivator, one oxime group was withdrawn from the trimedoxime structure (**48**) (Figure 66.41). Such modification of the trimedoxime structure decreased its reactivation activity in the case of tabun-inhibited AChE. On the contrary, it increased its reactivation activity in the case of cyclosarin-inhibited AChE (Kuca *et al.*, 2007c).

A Korean group published synthesis and *in vitro* evaluation of several structurally different cholinesterase reactivators (Figures 66.42 and 66.43). Two of them (**28f**, **30f**) were those published already earlier by Pang *et al.* (2003) and Oh *et al.* (2008).

Two other oximes (**49**, **50**) are very interesting when considering blood–brain barrier penetration. They have instead only the quaternary nitrogen, the tertiary nitrogen having no charge. Unfortunately, such structure modification decreased their reactivation potency (Oh *et al.*, 2008).

In 2006 Ohta *et al.* (2006) published a large group of monoquaternary reactivators (**51**) differing in the position of the oxime groups and length and shape of their alkylating chains (Figure 66.44). Subsequently, Okuno *et al.* (2008) examined BBB penetration of selected derivatives using *in vivo* rat brain microdialysis with liquid chromatography–mass spectrometry (LC–MS/MS).

Quite new synthetic results have been achieved in 2008 (Acharaya *et al.*, 2008a, b, c). The findings of Acharya *et al.* (2008b) are focused on the same topic published by other investigators (Musilek *et al.*, 2005, 2007a; Hrabinova *et al.*, 2006; Acharaya, 2008a) – a synthesis of the series of bis-pyridinium oximes connected by xylene linker (**37**). The synthesized compounds were tested for their reactivation of sarin-inhibited electric eel AChE. The other article by Acharya's group describes the synthesis of unique compounds (**52**) having in their structure *para* and

meta-xylene, *cis*-but-2-ene and but-2-ine groups (Acharaya *et al.*, 2008c) (Figure 66.45). All these compounds were tested on electric eel AChE inhibited by DFP. Unfortunately, none of the newly prepared compounds was able to surpass the pralidoxime activity.

VI. *IN VITRO* EVALUATION OF SELECTED AChE REACTIVATORS

There are several techniques to evaluate reactivation activity of structurally different AChE reactivators. Probably the most frequent are Ellmann's method (Ellman *et al.*, 1961; Bajgar, 2005) and the potentiostatic method (Kuca and Kassa, 2003). Each one has its advantages and disadvantages. For example, Ellmann's method does not use real substrate ACh, while the potentiostatic method is very time consuming.

Although the results obtained by both methods are proportionally comparable, to discuss the influence of structural moieties on final reactivator activity only one method should be used. Because of our experiences with the second potentiostatic method, the structure–activity relationship mentioned in this chapter is based on these results.

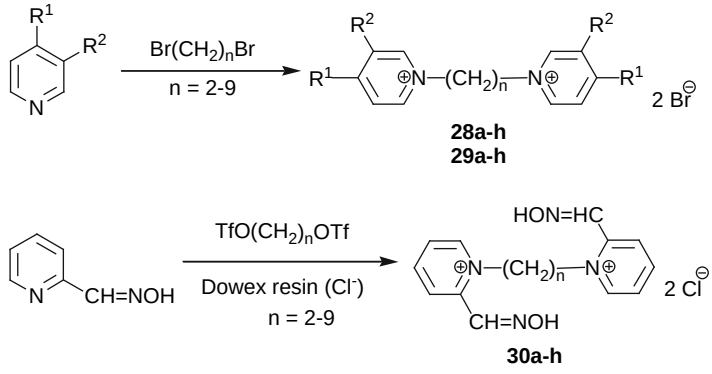
Moreover, species differences in reactivation should be taken into account (Worek *et al.*, 2002; Kuca *et al.*, 2005b). Thus, all results considered in the structure–activity relationship listed below are obtained only with one species (rat).

VII. STRUCTURE–ACTIVITY RELATIONSHIP OF AChE REACTIVATORS

There are five important structural factors which influence the affinity of the AChE reactivators toward inhibited AChE: (1) presence of the quaternary nitrogens in the reactivator's molecule; (2) length and shape of the linker between two pyridinium rings; (3) presence of the oxime group; (4) position of the oxime group at the pyridinium ring; and (5) number of oxime groups in the reactivator structure.

A. Presence of the Quaternary Nitrogen in the Reactivator's Structure

It is generally known that the anionic center of AChE binds the charged quaternary group of the choline moiety of ACh,



Product	R^1	R^2
28a-h	CH=NOH	H
29a-h	H	CH=NOH

FIGURE 66.22. Synthesis of bispyridinium carbaldoximes (Pang and Brimijoin, 1999).

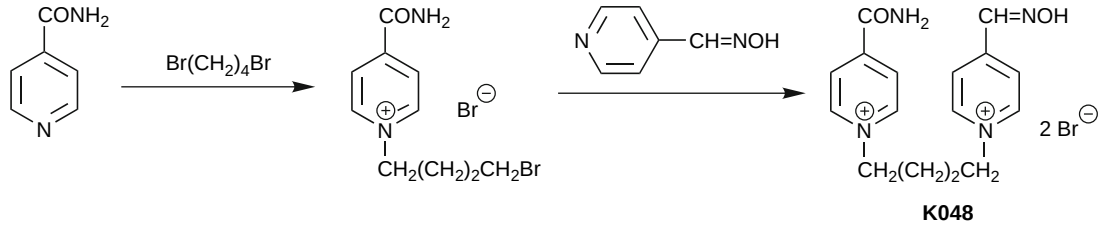


FIGURE 66.23. Synthesis of reactivator K048 for tabun-inhibited AChE.

and also other quaternary ligands including quaternary AChE reactivators (Whiteley and Ngwenya, 1995; Kuca *et al.*, 2004c). Owing to the presence of the quaternary nitrogen in the structure of the AChE reactivator, oximes have increased affinity to both intact and inhibited AChE. In fact, this structural feature allows the entrance of the molecule of the AChE reactivator into the enzyme cavity.

On the other hand, there has been discussion regarding the penetration of the quaternary charged compounds (especially AChE reactivators) through the blood–brain barier (BBB). The partial ability of monoquaternary (Sakurada *et al.*, 2003; Petroianu *et al.*, 2007b) and bisquaternary (Lorke *et al.*, 2007) oximes to penetrate the BBB was published recently. *In vivo* reactivation of nerve agent-inhibited brain AChE was determined many times before and this topic is well described in two recent review articles (Lorke *et al.*, 2008b; Bajgar *et al.*, 2007).

Commonly used AChE reactivators have one (pralidoxime) or two (HI-6) quaternary nitrogens in their molecules. According to our results, affinity of bisquaternary oximes towards intact and inhibited AChE is generally higher in comparison with monoquaternary ones (Kassa and Cabal, 1999; Kuca and Kassa, 2004).

B. Length and Shape of the Connection Chain Between Pyridinium Rings

The length of the connecting chain between both pyridinium rings (for bisquaternary pyridinium reactivators) plays an important role in its potency to reactivate nerve agent-inhibited AChE (Pang *et al.*, 2003; Kuca *et al.*, 2003c). For *n*-methylene linkage chain, there exists dependence between the length of the connection chain and nerve agent used for inhibition. This dependence is shown in Figure 66.46 (Kuca *et al.*, 2003c).

As shown, the ideal length of the reactivator's linker for satisfactory activity of tabun, sarin, or VX-inhibited AChE is three or four methylenes. On the other hand, one methylene group seems to be the most potent reactivator of cyclosarin-inhibited AChE.

Unfortunately, this rule is satisfied just in the case of *n*-methylene linkage chains and oxime groups in position four at the pyridinium ring. Compounds with oxygen, sulfur or other structural fragments differing from the methylene incorporated into the connection chain and with different position of oxime groups do not fulfill the above-mentioned rule (Pang *et al.*, 2003; Musilek *et al.*, 2005, 2006a; Oh *et al.*, 2006; Acharaya *et al.*, 2008c).

These differences could be caused by the presence of the free electrons in the connection chain and subsequent interactions of this part of the reactivator's molecule with the inside of the enzyme cavity.

An important structural factor influencing the reactivation process could also be the ''rigidity'' of the linking chain. Owing to the rigidity of the connection chain, spatial orientation of the pyridinium rings in the enzyme cavity is limited. Compounds with a certain level of rigidity in the connection chain were synthesized with the aim of

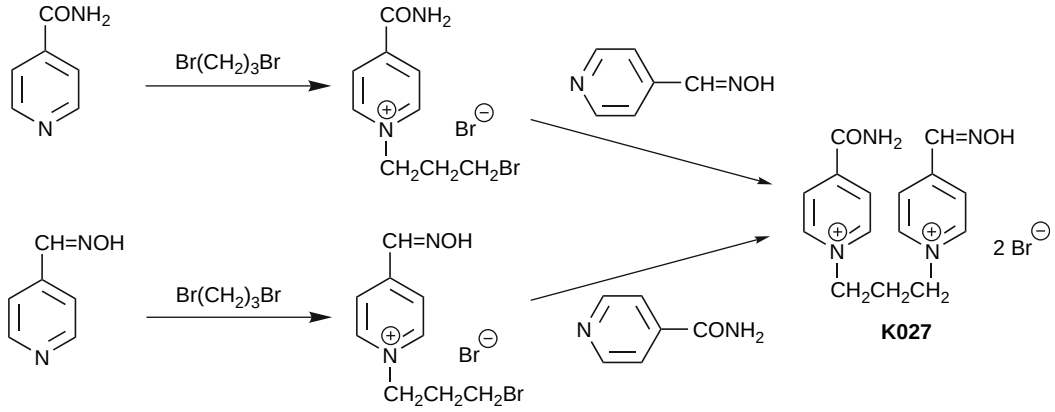

FIGURE 66.24. Synthesis of AChE reactivator K027 (Kuca *et al.*, 2003b).

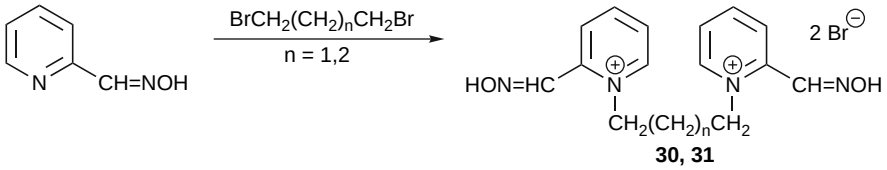

FIGURE 66.25. Synthesis of symmetric bispyridinium dicarbaldoximes (Kuca *et al.*, 2004b).

elucidating the influence of rigidity on reactivation potency. *Z*- and *E*-but-2-ene and *ortho*-, *meta*-, *para*-xylene moieties were inserted into the linkage chain (Musilek *et al.*, 2005, 2006a, 2007c). In Figure 66.47, the angles in the linker caused by incorporation of the rigid moiety are shown.

C. Presence of the Oxime Group in the Oxime Structure

The presence of the oxime group in the structure of the reactivator is another substantial structural factor. Former hydroxyiminoacetone, hydroxamic acids, geminal dioles, and ketoximes were used as potential nucleophilic agents for breaking the bond between inhibitor and enzyme (Picha *et al.*, 2005; Heath, 1961). The aldoxime group currently seems to be used entirely, and therefore it is involved in all newly synthesized AChE reactivators (see Synthesis part of this chapter).

The oxime group (–CH=NOH) in the human body dissociates to the oximate anion (–CH=NO$^-$) which acts as a nucleophile and cleaves the bond between the enzyme and the phosphorus atom of the inhibitor (Patocka *et al.*, 2005; Heath, 1961).

D. Position of the Oxime Group

The other important structural factor is also connected with the oxime group: the position of the oxime group at the quaternary pyridinium ring. As can be seen in Table 66.3, there are significant differences in the reactivation potency of the oximes regarding the oxime group position.

There exists no general rule that all oximes in the given position are able to reactivate all nerve agent-caused inhibitions. However, the general standard is that reactivators containing the oxime group in positions two and four are more effective compared to the oximes in position three. This fact is due to the difference in pKa between oximes in positions two and four versus those in position three.

Although the rule governing the oxime position for all nerve agents is unrealistic, there are some relationships between the position of the oxime group and used nerve agent. This means that the position of the oxime group, as well as the length of connecting chain between quaternary pyridinium rings, are nerve agent dependent. For example, cyclosarin-inhibited AChE is best reactivated by reactivators with an oxime in position two (Kuca and Patocka, 2004). On the other hand, reactivators with an oxime group at the pyridinium ring in position four are currently considered to be the most potent for reactivation of tabun-inhibited AChE (Cabal *et al.*, 2004). Also, pesticide-induced poisonings are best treatable with AChE reactivators with an oxime at position four (Worek *et al.*, 1996; Petroianu and Kalasz, 2007). Very good reactivability of sarin and VX-inhibited AChE has been found with both reactivators (with oxime groups in positions two and four) since they are potent reactivators of inhibited AChE (Kuca *et al.*, 2005c, d).

E. Number of Oxime Groups in the Reactivator's Molecule

The number of oxime groups in the reactivator's molecule is the fifth structural requirement that needs to be discussed in this section. One molecule of the AChE reactivator can contain one, two, three, or four oxime groups with one, two, or three quaternary nitrogens in one structure. Examples of different structures having one, two, three, or four oxime groups are shown in Figure 66.48.

As can be seen, the number of oxime groups does not increase reactivation potency of the potential AChE reactivator. This fact could be connected with increased size of the AChE reactivator's molecule. Owing to the fact that the main role in the reactivation process has just the first oxime group (with the lowest pKa), the presence of the second oxime group is not so strict.

VIII. PROMISING OXIMES

Along with those AChE reactivators which are at the present time commercially available (pralidoxime, trimedoxime, methoxime, obidoxime, and HI-6), there are several oximes which are considered promising.

We can also consider the development of a new reactivator salt as a new compound: HI-6 dimethanesulfonate is probably the number one oxime under development in many countries because of its superior stability and solubility when compared with HI-6 dichloride. It is well known as a broad-spectrum reactivator for nerve agents (except tabun) (Lundy *et al.*, 2006).

In the Czech Republic, great efforts have focused on the development of new reactivators used in the case of tabun poisoning. During the last 5 years, three new generations were prepared. The best reactivators of the first generation (K027, K048) are currently being tested in many countries for their extraordinary potency and low toxicity (Kassa *et al.*, 2006; Calic *et al.*, 2006; Kalasz *et al.*, 2006; Tekes *et al.*, 2006; Gyenge *et al.*, 2007; Benko *et al.*, 2007; da Silva *et al.*, 2008). Subsequently, the second generation was developed. Among the oximes tested, oximes K074 and K075 were recommended as the best ones. However, as they reached the highest reactivation activity, they were too toxic for further thorough investigation (Kassa and Humlicek, 2008; Kuca *et al.*, 2007d). Currently, the best recommended oxime of the third generation for tabun-inibited AChE seems to be oxime K203 (Musilek *et al.*, 2007f; Kassa *et al.*, 2008). Except for the promising results of developed oximes obtained with tabun, these oximes seem to be satisfactory also in case of pesticide poisoning (Petroianu *et al.*, 2006a, b). Among them, oxime K027 was tested in the United Arab Emirates as the best oxime (when compared with obidoxime, trimedoxime, pralidoxime, and HI-6) against pesticides (paraoxon, DFP, methyl paraoxon) both *in vitro* and *in vivo* (Petroianu *et al.*, 2007a, c; Csermely *et al.*, 2007).

There are still efforts being made to compare oxime HLö-7 with HI-6 to see if its activity is comparable or better. Structures of both compounds are almost similar, differing slightly in one added oxime group at position four on the pyridinium ring. However, the reactivation potency of HLö-7 is not much better to perform all the steps, which are needed for introduction to the market.

In USA, oxime MMB-4 (methoxime) will probably replace the currently available pralidoxime, which is already considered an old fashioned antidote. There are many studies focused on this topic (Singh *et al.*, 2007).

According to recent literature, several laboratories are also focusing on Ortho-7, which has been described by many investigators (Pang *et al.*, 2003; Oh *et al.*, 2008; Ekstrom *et al.*, 2006, 2007).

IX. NEW TRENDS IN DEVELOPMENT OF NEW AChE REACTIVATORS

New trends to improve reactivator potency depend on the purpose of their action. There are many directions that should be considered.

FIGURE 66.48. Structurally different compounds having different oxime groups. Source of enzyme – rat brain homogenate; inhibitor – tabun; time of inhibition – 30 min; time of reactivation – 10 min; pH 7.6; 25°C; oxime concentrations – 10^{-5} M and 10^{-3} M (Cabal *et al.*, 2004).

Probably the most discussed factor is the possibility of a broad-spectrum reactivator. Every new oxime could be tested for its broad-spectrum potency. However, the probability of finding such an oxime is low. Alternately, we can use a combination of two oximes. Such an approach was already applied in the former Yugoslavia (Kovacevic *et al.*, 1989a, b) two decades ago. Candidates for this approach should be oxime HI-6 and various other oximes which are applicable in the case of tabun and pesticide poisoning.

Another factor that needs to be discussed is BBB penetration. Such an increase could be solved by chemical modification of the reactivator's structure, for example modifications like withdrawal of the quaternary nitrogen or connection of quaternary moiety with lipophilic compounds, which can serve as carriers into the brain (amino acids, steroids, Alzheimer's disease drugs, sugars, etc.), or the use of special carriers (e.g. nanoparticles, complex systems). However, do we really need to increase the oxime level in the brain? If there are higher concentrations of oximes in the brain, its toxicity could increase. This needs to be taken into account.

A new nucleophilic group instead of the oxime group could also be considered as a promising approach. However, during the last 50 years, no better nucleophilic group has been found.

New techniques used currently for drug design could be used. Among them, molecular docking studies, prediction of new structures using chemometric tools, click chemistry, or random chemistry approaches could be applied to reach the target.

Finally, oximes could be applied not only for the reactivation of AChE as life-endangering enzymes, but their use as BuChE reactivators could contribute to finding the ''pseudocatalytic scavenger''. Such a scavenger could catch the nerve agent (BuChE as stoichiometric scavenger) and then be renewed by oxime to be used once again for nerve agent binding.

X. CONCLUDING REMARKS AND FUTURE DIRECTION

As mentioned above, the threat of the misuse of nerve agents continues. Also, the requirements on agricultural production increase the use of pesticides and, because of this, deaths of agricultural workers increase. Due to the fact that there is no universal oxime that could be applied in every situation of nerve agent or pesticide intoxication, the development of new oximes still continues. We hope that in the near future, new more promising candidates will be found, especially if novel techniques and data from structure–activity studies are used as a starting point for the synthesis of new reactivators.

Acknowledgments

Financial support from the Grant Agency of the Czech Republic, Project No. 305/07/P162, is greatly appreciated.

CHAPTER 67

Paraoxonase (PON1) and Detoxication of Nerve Agents

LUCIO G. COSTA AND CLEMENT E. FURLONG

I. INTRODUCTION

More than half a century ago, certain organophosphorus (OP) insecticides were found to be enzymatically hydrolyzed by plasma, and it was determined that this hydrolysis was catalyzed by enzymes designated A-esterases (Mazur, 1946; Aldridge, 1953). Aldridge's proposal that an A-esterase hydrolyzed both phenylacetate and paraoxon (the active metabolite of the OP insecticide parathion) was conclusively proven several decades later, when it was shown that recombinant paraoxonase/arylesterase catalyzed both activities (Gan *et al.*, 1991). Studies in the late 1970s and early 1980s indicated that the plasma hydrolytic activity toward paraoxon was polymorphically distributed in human populations (Playfer, 1976; Eckerson *et al.*, 1983; Mueller *et al.*, 1983), suggesting a genetically based differential susceptibility to OP toxicity. The molecular basis of the paraoxonase (PON1) activity polymorphisms (Humbert *et al.*, 1993; Adkins *et al.*, 1993) and its role in the toxicity of OP compounds (Costa *et al.*, 2002, 2006) have been elucidated. Furthermore, novel important roles of PON1 in the metabolism of oxidized lipids, of certain drugs and, more recently, of quorum sensing, have also emerged, highlighting the multifaceted roles and importance of this enzyme. These latter aspects of PON1 are not discussed in this chapter but the reader can refer to other recent articles and reviews (Durrington *et al.*, 2001; Costa and Furlong, 2002; Mackness *et al.*, 2002; Costa *et al.*, 2003a; Draganov and LaDu, 2004; Ozer *et al.*, 2005).

II. PON1 POLYMORPHISMS: DEFINING PON1 STATUS

PON1 is a member of a family of proteins that also includes PON2 and PON3, the genes of which are clustered in tandem on the long arms of human chromosome 7 (q21.22). PON1 is synthesized primarily in the liver and a portion is secreted into the plasma, where it is associated with high density lipoproteins (HDL) (Sorenson *et al.*, 1999; Deakin *et al.*, 2002). PON1, which received its name from its ability to hydrolyze paraoxon, its first and most studied OP substrate, hydrolyzes the active metabolites of several other OP insecticides (e.g. chlorpyrifos oxon, diazoxon), as well as nerve agents such as sarin, soman, and VX (see below). The crystal structure for a recombinant PON1 indicates that it is a six-bladed β-propeller, with two calcium ions in the central tunnel, one of which is essential for enzyme activity and the other for enzyme stability (Harel *et al.*, 2004).

Activity of paraoxonase in plasma of human populations exhibits a polymorphic distribution, and individuals with high, intermediate, or low paraoxonase activity can be identified (Eckerson *et al.*, 1983; Mueller *et al.*, 1983; reviewed in Geldmacher von Mallinkrodt and Diepgen, 1988). Studies in the early 1990s led to the purification, cloning, and sequencing of human PON1 (Gan *et al.*, 1991; Furlong *et al.*, 1991; Hassett *et al.*, 1991), and the molecular characterization of its polymorphisms (Humbert *et al.*, 1993; Adkins *et al.*, 1993). Two polymorphisms were observed in the PON1 coding sequence: a Gln(Q)/Arg(R) substitution at position 192, and a Leu(L)/Met(M) substitution at position 55 (Humbert *et al.*, 1993; Adkins *et al.*, 1993). PON1 192 and 55 genotypes have been established in several populations utilizing PCR-based methods. The polymorphism at position 192 has been the most studied, with gene frequencies of $PON1_{Q192}$ ranging from 0.75 for Caucasians of northern European origin, to 0.31 for some Asian populations (Brophy *et al.*, 2002).

In addition to these two polymorphisms in the coding region of PON1, 13 polymorphisms have been found in the noncoding region of the PON1 gene (http://pga.gs.washington.edu) and five of these have been characterized to date (Brophy *et al.*, 2001a; Leviev and James, 2000; Suehiro *et al.*, 2000). The most significant of these promoter region polymorphisms is that at position –108, with the –108C allele providing levels of PON1 about twice as high as those seen with the –108T allele (Leviev and James, 2000; Suehiro *et al.*, 2000; Brophy *et al.*, 2001b).

The coding region polymorphisms of PON1 have been investigated for effects on the catalytic efficiencies of hydrolysis of specific substrates. The L/M polymorphism at position 55 does not affect catalytic activity, but has been

associated with plasma PON1 protein levels, with $PON1_{M55}$ being associated with low plasma PON1 (Blatter Garin *et al.*, 1997; Mackness *et al.*, 1998). However, this appears to primarily result from linkage disequilibrium with the low efficiency of the –108T allele of the –108 promoter region polymorphism (Brophy *et al.*, 2002), although some data indicate that $PON1_{M55}$ may be somewhat less stable than $PON1_{L55}$ (Leviev *et al.*, 2001; Roest *et al.*, 2007). The Q/R polymorphism at position 192 significantly affects the catalytic efficiency of PON1. Initial studies indicated that the $PON1_{R192}$ allozyme hydrolyzed paraoxon more readily than $PON1_{Q192}$ (Humbert *et al.*, 1993; Adkins *et al.*, 1993). Further studies indicated that this polymorphism was substrate dependent, as the $PON1_{Q192}$ alloform was found to hydrolyze diazoxon, sarin, and soman more rapidly than $PON1_{R192}$ *in vitro* (Davies *et al.*, 1996). In the case of diazoxon, however, more recent studies have shown that, under physiological conditions, both PON1 alloforms hydrolyze this compound with the same efficiency (Li *et al.*, 2000).

Complete resequencing of PON1 from 47 individuals, as part of the Environmental Genome Project, has led to the identification of more than 160 new single nucleotide polymorphisms, some in the coding regions and others in introns and regulatory regions of the gene (Jarvik *et al.*, 2003). These polymorphisms have for the most part not yet been characterized, but may affect splicing efficiency, message stability, or efficiency of polyadenylation. A few of them, however, have explained discrepancies found when comparing PON1 status (see below) and PCR analysis of codon 192 (Jarvik *et al.*, 2003).

Most studies investigating the association of PON1 polymorphisms with diseases have examined only the nucleotide polymorphisms (Q192R, L55M, C-108T) with PCR-based assays. A functional genomic analysis, however, provides a much more informative approach, as measurement of an individual's PON1 function (plasma activity) takes into account all polymorphisms that might affect activity. This is accomplished through the use of a high-throughput enzyme assay involving two PON1 substrates (usually diazoxon and paraoxon) (Richter *et al.*, 2004). This approach, in addition to providing a functional assessment of the plasma PON_{192} alloforms, provides the plasma level of PON1 for each individual, thus encompassing the two factors that affect PON1 levels or activity (position 192 amino acid and plasma alloform levels). This approach has been referred to as the determination of PON1 ''status'' for an individual (Richter and Furlong, 1999).

The catalytic efficiency with which PON1 degrades toxic OPs determines the degree of protection provided by PON1. In addition, higher concentrations of PON1 provide better protection. Thus, for adequate risk assessment, it is important to know PON1 levels and activity. In a given population, plasma PON1 activity can vary up to 40-fold (Eckerson *et al.*, 1983; Mueller *et al.*, 1983; Davies *et al.*, 1996; Richter and Furlong, 1999), and differences in PON1 protein levels up to 13-fold are also present within a single $PON1_{192}$ genotype in adults (Davies *et al.*, 1996). Studies investigating the role of PON1 in cardiovascular disease have indeed provided evidence that PON1 status (encompassing genotype and activity levels) is a much better predictor of disease than PON1 genotype alone (Jarvik *et al.*, 2000; Mackness *et al.*, 2001).

III. PON1 AND THE TOXICITY OF OP INSECTICIDES

Evidence that PON1 plays a role in modulating the toxicity of OPs *in vivo* has emerged slowly over the last 30 years. Initial indirect evidence was provided by comparison across animal species which differ in the levels of their plasma PON1 activity. Birds that have very low PON1 activity (Machin, 1976; Brealey *et al.*, 1980; Furlong *et al.*, 2000) display a much higher sensitivity, compared to rats, to the acute toxicity of some OPs (e.g. pirimiphos-ethyl, diazinon) (Brealey *et al.*, 1980). Among mammals, rabbits have a five- to 20-fold higher plasma PON1 activity than rats (Aldridge, 1953; Zech and Zurcher, 1974; Costa *et al.*, 1987), and are four-fold less sensitive to the toxicity of paraoxon (Costa *et al.*, 1987). Though several other factors, such as rates of absorption and distribution of OPs, rates of activation and of detoxication by other metabolic pathways, and intrinsic susceptibility of target enzymes, can affect the overall toxicity outcome, these initial observations provided some supporting, albeit indirect, evidence to the hypothesis that low serum PON1 activity would lead to an increased sensitivity to the acute toxic effects of OPs.

A more direct approach was provided by studies in which exogenous PON1 was injected into rats or mice. Background and impetus for such an approach were provided by an earlier study by Main (1956) who showed that intravenous administration of partially purified PON1 from rabbit serum to rats would protect them from the toxicity of paraoxon. Subsequent experiments in rats and mice utilizing pure rabbit PON1 (Furlong *et al.*, 1991) confirmed and expanded this early observation. Administration (via the tail vein) of the enzyme to rats increased serum PON1 activity toward paraoxon by nine-fold, and that toward chlorpyrifos-oxon by 50-fold (Costa *et al.*, 1990). Thirty minutes after PON1 injection, rats were challenged with an acute dose of paraoxon or chlorpyrifos oxon given by the i.v., dermal, i.p. or oral route, at doses causing similar degrees of AChE inhibition in plasma, red blood cells, brain, and diaphragm. Four hours later, at sacrifice, AChE activity measurements indicated a much lower degree of inhibition in animals that had been pretreated with PON1. Protection was more pronounced in the case of chlorpyrifos-oxon exposure, and was more prominent in two target tissues for OP toxicity, brain, and diaphragm (Costa *et al.*, 1990). Additional experiments were carried out in mice, as much less purified enzyme is required for injection, and since this species was

deemed to be ideal for studies involving genetically modified animals with altered PON1 levels (see below). An initial experiment followed the same protocol previously utilized in rats, and provided evidence that i.v. administration of pure rabbit PON1 increased serum chlorpyrifos-oxonase activity by 30- to 40-fold, and protected animals against AChE inhibition by dermally applied chlorpyrifos oxon (Li *et al.*, 1993). As with i.v. injection of rabbit PON1 the increased serum PON1 activity was short lasting ($t_{½}$ = ~6 h), further experiments were aimed at investigating other routes of administration for PON1. Administration of PON1 by the i.v. + i.p. routes increased plasma enzyme activity toward chlorpyrifos oxon by 35-fold and extended the half-life to 30 h. An even longer half-life, albeit with lower peak activity levels, was found when PON1 was given by the i.v. + i.m. route (Li *et al.*, 1993).

Rabbit PON1 also provided protection against the toxicity of the parent compound, chlorpyrifos, when the OP exposure occurred 30 min after i.v. injection of PON1 (Li *et al.*, 1993), or 24 h after an i.v. + i.p. administration of PON1 (Li *et al.*, 1995). Further experiments also showed that PON1, when given 30 min after dermal administration of chlorpyrifos, prevented the reduction of AChE activity in all tissues; when PON1 was injected 3 h after chlorpyrifos, a protective effect was still seen in brain and diaphragm (Li *et al.*, 1995). Altogether, this series of studies indicated that increasing serum levels of PON1 (by injection of purified rabbit enzyme) decreased the acute toxicity of specific OPs. Also of relevance is the finding that PON1 exerted a protective effect when given after OP exposure, indicating the therapeutic potential for use of recombinant PON1 in cases of OP poisoning, possibly in combination with other conventional treatments.

In the past decade, PON1 knockout and transgenic animals have provided important new tools to investigate the role of PON1 in modulating OP toxicity. PON1 knockout ($PON1^{-/-}$) mice were produced by targeted disruption of exon 1 of the PON1 gene, and have normal appearance and body weights (Shih *et al.*, 1998). Plasma from $PON1^{-/-}$ mice has no detectable hydrolytic activity toward paraoxon and diazoxon, and very limited chlorpyrifos-oxonase activity. A similar pattern of activity is also found in liver, indicating that both plasma and liver PON1 are encoded by the same gene (Li *et al.*, 2000). PON1 homozygous mice ($PON1^{+/-}$) have approximately 40% of plasma and liver PON1 activity compared with wild-type mice ($PON1^{+/+}$). As expected, PON1 knockout mice did not differ from wild-type animals in their sensitivity to demeton-*S*-methyl, an OP insecticide with a structure similar to malathion, and which is not a substrate for PON1 (Li *et al.*, 2000). As also predicted, $PON^{-/-}$ mice showed a dramatically increased sensitivity to chlorpyrifos oxon and diazoxon (Shih *et al.*, 1998; Li *et al.*, 2000). $PON1^{+/-}$ mice showed an intermediate sensitivity to diazoxon toxicity (Li *et al.*, 2000). PON1 null mice showed only a slight increase in sensitivity to the toxicity of chlorpyrifos and diazinon (Shih *et al.*, 1998; Li *et al.*, 2000). The most surprising observation was that PON1 null mice did not show an increased sensitivity to paraoxon, the substrate after which the enzyme was named, in spite of having no paraoxonase activity in plasma and liver (Li *et al.*, 2000).

Additional experiments were designed to determine whether administration of exogenous PON1 to $PON1^{-/-}$ mice, to restore serum PON1, would also restore resistance to OP toxicity. For this purpose, either human pure $PON1_{Q192}$ or $PON1_{R192}$ was injected, by the i.v. route, into PON1 knockout mice; the effects of various OPs on brain and diaphragm AChE activity was then determined. $PON1_{R192}$ provided significantly better protection than $PON1_{Q192}$ toward chlorpyrifos oxon, a finding confirmed by a subsequent study by Cowan *et al.* (2001), who administered recombinant adenoviruses containing PON1-LQ or PON1-LR genes to BALB/c mice before challenge with chlorpyrifos oxon. Both alloforms were equally effective in protecting against the toxicity of diazoxon (Li *et al.*, 2000), while neither $PON1_{R192}$ nor $PON1_{Q192}$ afforded protection against paraoxon toxicity (Li *et al.*, 2000). The results of these experiments in PON1 knockout mice prompted a re-examination of the *in vitro* catalytic efficiencies of the two human PON1 alloforms under more physiological salt concentrations (lower NaCl concentration).

Results from kinetic analysis of substrate hydrolysis by purified human alloforms provided an explanation for the *in vivo* finding. In the case of chlorpyrifos oxon, the catalytic efficiency of both PON1 alloforms was very high, and was higher for the $PON1_{R192}$ alloform. Catalytic efficiency was still high in the case of diazoxon, albeit lower than with chlorpyrifos oxon, but no alloform-specific difference was evident. With paraoxon, the $PON1_{R192}$ alloform was much more efficient than the $PON1_{Q192}$ alloform; however, its overall catalytic efficiency was too low to protect against exposure. This confirms the hypothesis (Chambers *et al.*, 1994; Pond *et al.*, 1995) that PON1 is not efficient at hydrolyzing paraoxon at low concentrations, suggesting that PON1 may not degrade paraoxon efficiently *in vivo,* and that other pathways (e.g. cytochromes P450, carboxylesterase) are primarily responsible for detoxifying paraoxon *in vivo*.

Further experiments carried out in PON1 transgenic mice (mice expressing either human PON_{Q192} or human $PON1_{R192}$ on a knockout background, and mice carrying the human $PON1_{R192}$ on top of mPON1) provided additional evidence for such conclusions. A transgenic mouse line that carries the human $PON1_{R192}$ allele over its mouse PON1 was tested for its sensitivity to paraoxon. These mice, whose serum paraoxonase activity was 3.5-fold higher than wild-type mice, showed similar sensitivity to paraoxon as wild-type mice (Li *et al.*, 2000). On the other hand, $hPON1_{R192}$-TG mice (expressing human $PON1_{R192}$ on a knockout background) were significantly less sensitive to the toxicity of chlorpyrifos oxon than $hPON1_{Q192}$-TG mice, despite having the same level of PON1 protein in liver and plasma (Cole *et al.*, 2005).

Altogether, these animal experiments indicate that the ability of PON1 to modulate the acute toxicity of OPs varies among compounds. In the case of chlorpyrifos oxon, both the level of expression and the Q192R genotype are important determinants of susceptibility, highlighting the importance of assessing PON1 status in potentially exposed individuals. With regard to diazoxon, protection or susceptibility is dictated primarily by the level of expression of PON1, independently of the Q192R genotype, stressing the importance of knowing PON1 levels. Perhaps ironically, PON1 status does not appear to play a role in modulating sensitivity to paraoxon toxicity.

IV. PON1 AND THE TOXICITY OF NERVE AGENTS

A number of nerve agents, such as soman, sarin and VX, are OPs, and have been shown to be metabolized *in vitro* by PON1 (Davies *et al.*, 1996; Rochu *et al.*, 2007). Information is scarce about VX, while more information is available regarding the other two compounds. Both sarin and soman are hydrolyzed to a higher degree by $PON1_{Q192}$ than by $PON1_{R192}$ (Davies *et al.*, 1996). Plasma somanase activity and sarinase activity (both in U/l) were found to be 2143 and 335 for QQ homozygotes, and 992 and 38 for RR homozygotes, respectively (Davies *et al.*, 1996). Thus, homozygotes for the $PON1_{Q192}$ allele hydrolyze sarin approximately ten times better than individuals homozygous for the $PON1_{R192}$ allele, while the ratio is about two for soman (Davies *et al.*, 1996). Results of a kinetic study confirmed these findings; catalytic efficiency for sarin was determined as 0.91 and 0.07 (ratio = 13) for $PON1_{Q192}$ and $PON1_{R192}$ homozygotes, respectively, while values for soman were 2.8 and 2.1 (ratio = 1.3) (Rochu *et al.*, 2007). Soman exists as four stereoisomers (C+P+, C+P−, C−P+, C−P−) (Benschop and de Jong, 1988), with both P- isomers displaying the highest *in vivo* toxicity; wild-type recombinant human PON1 was shown to hydrolyze soman stereoselectively, with a six-fold overall difference in catalytic efficiency (P+ > P−) (Yeung *et al.*, 2007).

In vivo studies in animals have shown that intravenous administration of naked DNA bearing the human $PON1_{Q192}$ cDNA to mice could elevate plasma somanase activity by about two-fold (Fu *et al.*, 2005). The pcDNA/PON1-treated mice survived in greater numbers with a pcDNA/PON1 dose dependence and for a longer period after an acute dose of soman (0.2 mg/kg, s.c.) (Fu *et al.*, 2005).

The 1995 terrorist attack in the Tokyo subway system that left 12 people dead and over 5,000 injured (Suzuki *et al.*, 1995; Nagao *et al.*, 1997) provided the opportunity to investigate the role of PON1 in modulating the toxicity of sarin in humans. The prevalence of the $PON1_{R192}$ genotype in the Japanese population is 0.66, compared with 0.25–0.30 in various Caucasian populations (Brophy *et al.*, 2002; Yamasaki *et al.*, 1997). Thus, Japanese individuals may have been more prone to sarin toxicity because of the low sarin-hydrolyzing ability of the $PON1_{R192}$ allozyme. However, among ten of the victims of the Tokyo attack, seven expressed the $PON1_{192Q}$ genotype, with six Q/R heterozygotes and one Q/Q homozygote (Yamada *et al.*, 2001). Thus, the genotype which confers high hydrolyzing activity toward sarin did not appear to provide protection from acute sarin poisoning. Several issues need, however, to be considered. First, only the Q192R genotype of those ten individuals was analyzed, with no information on their PON1 status. In a Caucasian population, the range of sarinase activity among individuals with the QQ or QR genotype ranged from ~0 to 758 U/l (Davies *et al.*, 1996). Second, exposure to sarin in these seven QQ or QR individuals was indeed massive, as it caused death instantly or, with one exception, in less than 48 h (Yamada *et al.*, 2001). Such high-dose exposure would be expected to overcome any potential protection afforded by the $PON1_{Q192}$ genotype. Third, and most importantly, the catalytic efficiency of sarin hydrolysis by PON1, even in QQ homozygotes, is low; the situation is thus similar (albeit reversed) to that of paraoxon, with one $PON1_{192}$ alloform hydrolyzing sarin with better efficiency, but still not efficiently enough to provide protection.

A few studies have also investigated PON1 polymorphisms in US and UK troops that were deployed in the Persian Gulf area in 1990–1991. Individuals who served in the Gulf War theater were potentially exposed to a wide range of biological and chemical agents, including sand, smoke from oil well fires, solvents, petroleum fuels, depleted uranium, anthrax and botulinum toxoid vaccinations, insecticides, pyridostigimine bromide, and nerve agents (IOM, 2000, 2003). A large number of these veterans have complained of a range of unexplained illnesses including chronic fatigue, muscle and joint pain, loss of concentration, forgetfulness, and headache, symptoms that are often referred to as Gulf War Syndrome (IOM, 2000, 2003). PON1 genotypes and plasma enzyme activity were investigated in a group of 25 ill US Gulf War veterans and 20 controls (Haley *et al.*, 2000). $PON1_{R192}$ homozygotes or $PON1_{Q/R192}$ heterozygotes were more likely to have neurologic symptoms than individuals homozygous for PON_{Q192}. Furthermore, low activity of the plasma $PON1_{Q192}$ isoform appeared to better correlate with illness than the PON1 genotype or the activity levels of the $PON1_{R192}$ genotype (Haley *et al.*, 2000). This study would suggest that low PON1 status may represent a risk factor for illness in Gulf War veterans, though such findings necessitate further confirmation in a larger population (Furlong, 2000).

A similar study in a group of 152 UK Gulf War veterans, who self-reported the presence of symptoms associated with the Gulf War Syndrome, yielded somewhat different results (Mackness *et al.*, 2000). Plasma paraoxonase activity and levels of PON1 protein were lower in veterans than in a control group, and these decreases were independent of the PON1 genotype (Mackness *et al.*, 2000). Thus, while in both

studies a reduced plasma paraoxonase activity was found, in one case it was attributed to an overrepresentation of the low activity PON1 isozyme (Haley *et al.*, 2000), whereas in the other it was common to all PON1 genotypes (Mackness *et al.*, 2000). Though the latter study suggests that this group of veterans may have a decreased capacity to hydrolyze some OP insecticides, such as chlorpyrifos oxon, its significance is hampered by the lack of information on the extent of exposure to such compounds among veterans (Costa *et al.*, 2003b).

A third study compared PON1 genotypes and plasma paraoxonase activity in groups of UK veterans from the Persian Gulf War who were symptomatic by self-reporting ($n = 115$), healthy Persian Gulf War veterans ($n = 95$), symptomatic Bosnia peacekeeping veterans ($n = 52$), and symptomatic nondeployed military controls ($n = 85$) (Hotopf *et al.*, 2003). No differences in genotype distribution or PON1 activity were found between healthy and ill Gulf War veterans. However, individuals who were deployed to the Gulf had 25–35% lower median PON1 values than the other two groups, and these differences were not explained by differences in $PON1_{192}$ genotypes between groups. Thus, $PON1_{192}$ genotype and activity were not associated with Gulf War Syndrome, but appeared to be the results of deployment in the Persian Gulf. Possible explanations suggested for such findings were the potential exposure of those who served in the Gulf to yet unknown agents which led to a long-term decrease in PON1 activity, and/or an overrepresentation in those two groups of individuals with the –108T allele, which is associated with lower PON1 levels (Hotopf *et al.*, 2003).

V. PON1 AS A THERAPEUTIC AGENT

Current therapy for OP poisoning relies on the use of atropine, a cholinergic muscarinic antagonist, and on oximes, such as pralidoxime (2-PAM), to reactivate phosphorylated acetylcholinesterase (Lotti, 2000; Eyer *et al.*, 2007). Anticonvulsant drugs such as diazepam may also be utilized to control OP-induced convulsions (Lotti, 2000). More efficacious pyridinium 4-aldoximes, such as obidoxime and trimedoxime, have also been developed; however, their ability to reactivate phosphorylated acetylcholinesterase is not fully exploited because of the formation of phosphoryloximes, which have themselves very high anticholinesterase activity. Interestingly, phosphoryloximes are rapidly hydrolyzed by PON1, with the $PON1_{Q192}$ allozyme being about 50-fold more active than $PON1_{R192}$ (Stenzel *et al.*, 2007), suggesting that PON1 status would also influence the effectiveness and safety of these oximes (Eyer *et al.*, 2007).

While current therapies are effective in preventing lethality, it has been suggested that they may not prevent behavioral deficits, incapacitation, loss of consciousness, or the potential for permanent brain damage caused in particular by OP nerve agents (Lenz *et al.*, 2007). Complementary approaches have thus focused on the use of human proteins that would act as biological scavengers for OP compounds. Such biological scavengers should have no effects on their own, should not present an antigenic challenge to the immune system, should act rapidly and specifically, and should remain in circulation for a prolonged period of time (Lenz *et al.*, 2007). Out of this general concept, two parallel approaches have emerged, one relying on stoichiometric, the other on catalytic, bioscavengers. Among stoichiometric bioscavengers, B-esterases, such as acetylcholinesterase and butyrylcholinesterase, which react with OPs but do not catalyze their hydrolysis, have been utilized in several studies. Administration of these two proteins to rodents has been shown to afford protection toward two- to five-fold LD_{50} doses of sarin, soman, or VX (Wolfe *et al.*, 1987; Doctor and Saxena, 2005; Lenz *et al.*, 2007). Of particular interest in this regard is human butyrylcholinesterase, either isolated from human plasma, or recombinant (Cerasoli *et al.*, 2005).

While stoichiometric scavengers afford good protection toward OP toxicity, high doses are needed to neutralize an equimolar amount of nerve agent (Ashani and Pistinner, 2004). In contrast, a catalytic scavenger would afford similar or even higher protection at relatively low doses (Sweeney and Maxwell, 2003). For example, it has been estimated that 3 μM sarin would be neutralized by 765 mg of human butyrylcholinesterase, but only 120–550 mg of $huPON1_{Q192}$ (depending on time) (Rochu *et al.*, 2007), or a much lower dose of recombinant, engineered huPON1 with significantly increased catalytic efficiency of agent hydrolysis. A number of arguments would support the use of PON1 as a catalytic bioscavenger. First, PON1 is a human protein, suggesting an expected absence of immunological response. Second, experiments in mice have clearly shown that administration of purified human PON1 protects animals against the toxicity of OP insecticides such as chlorpyrifos oxon and diazoxon (Li *et al.*, 2000). Third, PON1 has been shown to hydrolyze soman, sarin, and VX. Nevertheless, as said, the catalytic efficiency of PON1 (even the more active $PON1_{Q192}$) toward OP nerve agents, in particular sarin, is very low. It has been calculated that to provide a valuable medical countermeasure against intoxication by nerve agents, the catalytic efficiency of PON1 will need to be enhanced by one or two orders of magnitude (Rochu *et al.*, 2007). Some direct evolution variants of a recombinant PON1 were found to exhibit a ten-fold faster detoxication of cyclosarin and soman (Amitai *et al.*, 2006). Other huPON1 mutants with enhanced catalytic activity have also been described, though not in relationship to OP nerve agents (Yeung *et al.*, 2004). Until recently, no one had succeeded in expressing active human PON1 in *E. coli*. However, recently, our research team has produced and purified engineered variants of untagged human PON1 from an *E. coli* expression system. The recombinant PON1 is nontoxic when injected into PON1 null mice, persists in

plasma beyond 2 days, and protects against OP toxicity (Stevens *et al.*, 2008).

An additional approach would be that of stimulating the biosynthesis of natural PON1. A number of compounds have been shown to stimulate the expression of PON1 (Costa *et al.*, 2005), among them, low doses of ethanol, some fibrates, statins, or dietary polyphenols such as quercetin (Gouedard *et al.*, 2004a). The red wine ingredient resveratrol has been shown to increase PON1 activity nearly three-fold *in vivo* (Gouedard *et al.*, 2004b) and less than two-fold in liver cells *in vitro* (Curtin *et al.*, 2007). Interestingly, in the latter study, the increased PON1 afforded protection of cells against the toxicity of soman and sarin (Curtin *et al.*, 2007). Modulation of PON1 activity by drugs or dietary agents is of interest; however, more information of the regulation of the PON1 gene is needed to devise approaches that would offer substantially larger increases in PON1. Further, the low catalytic efficiency of nerve agent hydrolysis by native human PON1 is not adequate to provide efficient protection against nerve agent exposure. The $PON1_{R192}$ alloform, however, does provide good protection against both diazoxon and chlorpyrifos-oxon exposure (Li *et al.*, 2000).

VI. CONCLUDING REMARKS AND FUTURE DIRECTION

Evidence from *in vitro* studies has shown that PON1 can hydrolyze a number of OP compounds, including nerve agents. *In vivo* studies in rodents have also indicated that PON1 status can influence the acute toxicity of certain OPs, and that administration of exogenous PON1 can protect animals from OP toxicity. In the case of nerve agents, the catalytic efficiency of PON1 is relatively low, and PON1 status does not greatly influence an individual's susceptibility to their toxicity. However, as noted above, recombinant variants can be engineered with enhanced catalytic activity toward nerve agents. The nonglycosylated, engineered recombinant PON1s with high catalytic efficiency for OP hydrolysis should be excellent candidates for use as catalytic biological scavengers, with both prophylactic and therapeutic applications.

CHAPTER 68

Role of Carboxylesterases in Therapeutic Intervention of Nerve Gas Poisoning

SIGRUN HANNE STERRI AND FRODE FONNUM

I. INTRODUCTION

Carboxylesterases (CarbEs) constitute an important group of enzymes that plays a major role in the hydrolytic biotransformation of a large number of pro-drugs. In the present context we are, however, more interested in their ability to act as a scavenger towards the highly toxic organophosphorus (OP) compounds. The scavenger function of CarbE in blood plasma is the principal reason for the variation in nerve gas toxicity between the species, in both the presence and absence of carbamate prophylaxis. The scavenger role is primarily a consequence of the different content of CarbE protein in the plasma of different species, and is not necessarily linked to its enzymatic activity. Knowledge of the enzymology of CarbEs is, however, necessary in an attempt to define this scavenger protein, and is also a basis for understanding the role of CarbE in nerve gas poisoning with or without therapeutic intervention. The fact that plasma CarbE in rodents is a natural scavenger towards nerve gases makes it possible for us to handle nerve gas toxicity data in an adequate way. This is of vital importance when comparing and analyzing OP toxicity data for experimental animals such as rodents and species that do not have this specific blood protein such as rhesus monkey and humans. It is apparently a paradox that the plasma CarbE scavenger function in rodents allows us to estimate the protection factor of therapeutic intervention of nerve gas poisoning in humans. This seems to be true for interventions such as carbamate prophylaxis or the use of any artificially supplied scavenger to mimic rodent plasma CarbE. Although experimental protection factors with such interventions in rodents may be relatively low due to their natural scavenger content in plasma, it is worth noting that the estimated factors appear to be high for species including humans that are not supplied with plasma CarbE from nature. Prospective victims of nerve gas poisoning might therefore strongly benefit from further exploitation of any therapeutic intervention which involves the role of CarbE either directly or indirectly.

II. ENZYMOLOGY

A. Classification

Aldridge (1953) separated various esterases into two groups. The first group was A-esterases capable of hydrolyzing OP compounds; the second group was B-esterases, which could bind the OP compounds. CarbE belongs to this B-group of enzymes, which contains the serine molecule in its active site. To this group also belong several other esterases including acetylcholinesterase (AChE), butyrylcholinesterase (BuChE), and chymotrypsin. CarbEs have subsequently been connected to the alpha/beta hydrolase fold – which is common to several hydrolytic enzymes of widely differing phylogenetic origin and catalytic function. The core of each enzyme is similar: an alpha/beta sheet, not barrel, of eight beta-sheets connected by alpha-helices. These enzymes have diverged from a common ancestor and comprise a large family of proteins. They are important as hydrolyzing substrates containing ester or amide groups to free acids and alcohols. They are found in several tissues such as liver, small intestine, kidney, lung, and are also important for the scavenger function in plasma. At present, the database for this family contains over 450 orthologous or homologous members with 44 distinctive functions. Mammalian liver CarbEs belong to a family of proteins encoded by multiple genes. The isoenzymes were initially classified by their substrate specificity and isoelectric point (pI) (Mentlein *et al.*, 1987). However, this classification is now ambiguous because of overlapping substrate specificities, and is imprecise because the CarbEs as glycoproteins exhibit multiple bands with different pI values upon electrophoresis. They are very difficult to classify due to their wide substrate specificity. Satoh and Hosokawa (1998) and Hosokawa and Satoh (2006) have separated all mammalian CarbEs into five main groups based on their molecular properties. The two most important groups are CES1 and CES2. The CES1 group is the largest group and comprises members that have more than 60% homology to human liver CarbE. It contains the liver enzymes of human,

monkey, rat, and mouse. CES1 group enzymes preferentially hydrolyze substrates with a small alcohol group esterified to a large acyl group. Examples of substrates are cocaine, meperidine, methylphenidate, and temocapril (Zhang *et al.*, 1999) all of which contain methanol or ethanol linked to a large acyl group. CES2 includes human, monkey, mouse, rat, and hamster intestinal CarbE. In contrast to CES1 they hydrolyze esters with a large alcohol group and relatively small acyl group. Examples of substrates are heroin, 6-acetylmorphine, and methylprednisolone which contain acetate and succinate as acyl groups. CES3 includes ES male and human hCE3 and is expressed at low level in liver and the gastrointestinal tract. CES4 includes a protein excreted in cat urine with molecular weight 70 kDa (Miyazaki *et al.*, 2003). The CES5 group contains proteins with a much lower molecular weight, namely 46.5 kDa, and with a different structure.

B. Active Site

Through the work of Cohen *et al.* (1955) it was demonstrated that all the esterases in Aldridge group B contain an active serine which binds to the OP group or participates in the ester hydrolysis. Further comparison of the structure of a large number of esterases and lipases confirmed that they all contained a catalytic triad consisting of Ser, His, and Glu (sometimes Asp instead). This catalytic triad was preserved in AChE, BuChE, a series of lipases, and CarbE (Cygler *et al.*, 1993). Two adjacent Gly molecules formed an oxyanion hole. Frey *et al.* (1994) showed for chymotrypsin that the formation of low barrier hydrogen bonds facilitates a nucleophilic attack of the serine–OH group on the acyl carbonyl group of peptides. In the same way these would allow for the reaction between substrate esters or OP esters and the serine–OH of ChEs or CarbEs. CarbEs also contained a catalytic triad consisting of Ser, Glu, and His. When the catalytic triad consisting of Ser203, Glu336, and His450 in CarbE was transferred to The 203, Als 336, and Ala 450, respectively, the mutant had reduced CarbE activity (Satoh and Hosokawa, 1998). The active site gorge of the enzymes has a different size. For torpedo AChE it is 296 D3, for BuChE it is 496 D3, and for CarbE 3,014 D3. This explains why DFP cannot inhibit AChE, only BuChE and CarbE. The steps for interaction of CarbE with substrate or soman (as an example of an OP inhibitor) are the following: the ester bond or the P–F bond is attacked by the serine–OH. The hydrogen bond between the negatively charged oxygen of a tetrahedral complex and the NH groups of glycine stabilizes the charged carbonyl oxygen or phosphate oxygen of the substrate or inhibitor. The ester bond or P–F bond breaks and the leaving group (alcohol or F) diffuses away. A water molecule attacks the serine-*o*-acyl or *o*-phosphoryl group on the enzyme. Then His delivers a hydrogen atom to the serine-*o*-acyl which releases the acyl or phosphoryl group. This reaction is fast for esters but slow in the case of soman.

In the case of AChE there is an intermediate step where serine-*o*-phosphoryl is dealkylated or ''aged''. This is a process where the alkoxy group of the soman residue on the enzyme is hydrolyzed and the soman residue is resistant to the last hydrolysis step. The orientation of the sequence in CarbE allows the alkoxy group in soman residue and other nerve agents to be further away from the His group (7 Å instead of 3.5 in AChE) and therefore it is not dealkylated.

C. Substrate Specificity

Several different carboxylic esters may be hydrolyzed by CarbEs, and among them several may also be hydrolyzed by BuChE and A-esterases. For CarbEs the aromatic butyryl esters are better substrates than the acetyl esters, whereas the opposite holds for A-esterases (Augustinsson, 1961; Aldrige, 1953; Ecobichon, 1970). The hydrolysis of two simple aliphatic and aromatic butyryl esters, namely methyl butyrate and 4-nitrophenyl butyrate, is catalyzed by CarbE with only minimal contribution by ChE and A-esterase in a series of rat tissues, except for duodenum, based on the use of specific inhibitors of the three enzymes (Sterri *et al.*, 1985b). The two substrates are therefore appropriate to use for comparative evaluation of rat tissue CarbEs with respect to both inter- and intra-tissue diversity. Thus, the ratio between activities towards the two substrates in different tissues correlated to the plasma ratio seems to separate CarbEs of rat tissues into two main groups. The CarbEs of cerebrum, kidney, and duodenum display similar relative activity to plasma, whereas liver, lung, heart, and diaphragm constitute the other group with far higher (13–17-fold) relative preference for methyl butyrate than the first group (Sterri *et al.*, 1985b). This may indicate that the two groups are predominantly constituted by CES1 and CES2 CarbEs (see Classification, above) with preference for a substrate with smaller (methanol) and larger (4-nitrophenol) alcohol, respectively, esterified to the butyric acid. Also, the two CarbE isoenzymes of rat plasma seem to differ with respect to their relative specificity for methyl butyrate and 4-nitrophenyl butyrate, as do the three isoenzymes of guinea pig plasma. For each species the ratio between substrate activities of the plasma isoenzymes differs five- to seven-fold in favor of 4-nitrophenyl butyrate, as measured in the top fraction of activity peaks separated by chromatofocusing (Sterri and Fonnum, 1987, 1989).

D. Enzyme Inhibition by OP Compounds

Paraoxon, sarin, and soman inhibit AChE, BuChE, and CarbE almost to the same extent. DFP inhibits BuChE and CarbE to the same extent and 1,000-fold more than AChE. Diphenyl *p*-nitrophenyl phosphinate inhibits CarbEs more than 1,000-fold that of the ChEs. This explains why bis-*p*-nitrophenylphosphate is a specific inhibitor of CarbEs. A problem for CarbE as a scavenger is that VX is a 10,000-fold better inhibitor of the ChEs, and that ecothiophate is

a 10,000-fold better inhibitor of AChE than CarbE. As described under Active site, above, OP-inhibited CarbEs do not age. Instead, they spontaneously reactivate similar to a slow substrate. The half-life for spontaneous reactivation of VX or sarin-inhibited CarbE is 2 h, whereas the half-life for spontaneous reactivation after soman, DFP, or paraoxon inhibition is 20 h (Maxwell and Brecht, 2001). This is in accordance with results from a series of experiments with repetitive injection of $0.5 \times LD_{50}$ of soman in guinea pig at different time intervals. They demonstrated that soman was completely removed within 24 h and at the same time plasma CarbE (tributyrinase) activity was fully recovered (Sterri *et al.*, 1981).

E. Reactivation by Oxime of Nerve Gas-Inhibited CarbE

The original finding by Askew (1956) that diacetylmonoxime (DAM) has an antidotal effect towards sarin poisoning in several species including guinea pig may be due to the reactivation by DAM of sarin-inhibited CarbE in plasma (Myers, 1959; Polak and Cohen, 1970a; Cohen *et al.*, 1971). The authors also reported species differences between rodent plasma CarbEs with respect to reactivation by DAM after sarin poisoning. In addition, they found less effect of DAM reactivation for sarin-inhibited erythrocyte, brain, and lung CarbEs than for plasma CarbE of both rat and mouse (Myers, 1959).

Similar sensitivity to DAM reactivation is reported for various soman-inhibited CarbEs. Following *in vitro* inhibition by soman, the CarbE isoenzymes with low pI in plasma of both rat and guinea pig are partially reactivated (50–60%) by DAM within 5 min and are not further reactivated during the next 30 min (Sterri and Fonnum, 1987; Sterri, 1989). The two isoenzymes in rat plasma cannot be discriminated based on the DAM reactivatability (Sterri, 1989), whereas the one with high pI (6.1) in guinea pig plasma is about half as sensitive to DAM reactivation as the other two (Sterri and Fonnum, 1987). Also, two out of three CarbE isoenzymes in rat small intestine display similar reactivatability as the plasma CarbEs (Sterri, 1989), whereas none of the three CarbE isoenzymes in guinea pig liver can be reactivated by this oxime after soman inhibition (Sterri and Fonnum, 1987). The latter results correspond well with the poor effect by DAM on soman-inhibited commercial CarbEs from porcine liver (Fonnum *et al.*, 1985).

III. ORIGIN OF PLASMA CARBOXYLESTERASE

It follows from their role in nerve gas poisoning that the regulation of plasma CarbEs is of great interest. Possible tissues of their origin may be the liver, according to Yan *et al.* (1995); the intestine as has also been suggested (Sterri, 1989). In contrast to the other rat liver CarbEs, which are microsomal hydrolases A, B, and C with COOH-terminal HXEL consensus sequence for retention in endoplasmic reticulum (Yan *et al.*, 1994), the so-called hydrolase S lacks the COOH-terminal consensus sequence and is therefore presumed to be secreted into the blood (Yan *et al.*, 1995). The authors performed nondenaturing gel electrophoresis of rat serum, followed by staining for esterase activity or immunoblotting with antibody against recombinant hydrolase S. The results were interpreted as evidence that hydrolase S (67 kDa) is synthesized in the liver and undergoes extensive post-translational modification prior to its secretion as a 71 kDa protein in serum. Incomplete processing of hydrolase S was hypothesized to produce the amount of 67 kDa protein in liver microsomes. Results of the same study were taken to support this hypothesis in as much as Western immunoblotting with antibody against recombinant hydrolase S detected a 71 kDa protein in both serum and the medium of cultured hepatocytes. One objection is, however, that since the recombinant hydrolase S antibody also detects hydrolase A and B it may be relatively unspecific and one cannot exclude that other CarbEs may be detected as well. Also, the 71 kDa protein in serum has esterase activity towards 1-naphthylacetate and *para*-nitrophenylacetate, but immunoprecipitation with the hydrolase S antibody led to only a small decrease in the rate of hydrolysis of the two substrates by rat serum. The NH_2-terminal amino acid sequence of the 71 kDa protein is reported to be identical to that deduced from the cDNA encoding hydrolase S beginning with residue 19. Interestingly, based on the results from immunoblots with hydrolase S antibody and mRNA levels detected by Northern blot, the 67 and 71 kDa proteins in liver and serum, respectively, seem to be co-regulated by treatment of rats with various xenobiotics including phenobarbital (approximately 1.7-fold induction) (Yan *et al.*, 1995). Such co-regulation is not supported by the results obtained on plasma and liver CarbE activities with methyl butyrate or 4-nitrophenyl butyrate following phenobarbital treatment of rats by Sterri *et al.* (1985b). In this study the induction was 1.5–1.8-fold in liver and maximally 1.2-fold in plasma. However, phenobarbital induction of CarbE in mice led to similar enhanced activities in both liver and plasma (Clement, 1983).

Some interesting results on soman toxicity, thyroid deficiency, and plasma CarbE were reported by Swisher *et al.* (1986). They observed reduced effect of soman intoxication in hypothyroid rats with respect to both seizure activity and lethality. The resistance to soman was ascribed to increased binding of soman to plasma proteins, since both ChE and CarbE (tributyrinase) of plasma displayed nearly two-fold higher activity in hypothyroid than euthyroid rats. The latter result inspired us to investigate hypothyroid rats with respect to possible parallel coregulation of CarbE and ChE in plasma and liver. Plasma ChE is undoubtedly synthesized in liver (Augustinsson, 1948; Koelle, 1963) and the ChE activity in rat plasma as well as liver is known to differ between males and females (Leeuwin, 1966; Edwards

and Brimijoin, 1983; Andersen *et al.*, 1983; Sterri *et al.*, 1985a) and to respond on thyroidectomy (Leeuwin, 1966). Thus, male and female rats received rat chow supplemented with 0.05% thiouracil for 22, 30, or 38 days, a dosage which led to hypothyroid rats within 3 weeks (Stakkestad and Bremer, 1983). The results on CarbE activities in rat plasma and liver after 38 days were published previously (Sterri and Fonnum, 1989), but the complete set of results including comparison with ChE activities is presented in Figure 68.1. The activities with methyl butyrate increased significantly in liver but did not change in plasma of both male and females after 22 and 38 days of thiouracil feeding, whereas the hydrolysis of 4-nitrophenyl butyrate only varied slightly and inconsistently. The ChE activities of plasma and liver were simultaneously decreased in females and increased in males. The results show that the ChE activities in plasma and liver of both male and female rats are strongly co-regulated, whereas the CarbE activities of the two tissues are definitely not co-regulated (methyl butyrate hydrolysis) or are only marginally influenced by thyroid deficiency (4-nitrophenyl butyrate hydrolysis) (Figure 68.1). This investigation therefore does not indicate that rat plasma CarbE may be synthesized in liver.

Results on the various CarbE isoenzymes with respect to reactivatability by DAM after soman inhibition (see Reactivation by oxime of nerve gas-inhibited CarbE, above) might suggest intestinal origin of plasma CarbE. Two isoenzymes in plasma of both rat and guinea pig are reactivated to a similar degree as the two isoenzymes in the rat small intestine, and are quite different from the three liver isoenzymes of guinea pig which are not sensitive to DAM (Sterri and Fonnum, 1987; Sterri, 1989). Since the results are obtained with the same nerve gas and the same oxime under the same conditions, they may reflect both similarities and differences in enzymatic properties. It is interesting in this context that the DAM-sensitive isoenzymes of rat plasma and small intestine display correspondingly low isoelectric points (4.0–4.8) (Sterri, 1989), whereas higher pI values (5.0–6.4) are reported for six CarbE isoenzymes of rat liver (Mentlein *et al.*, 1987).

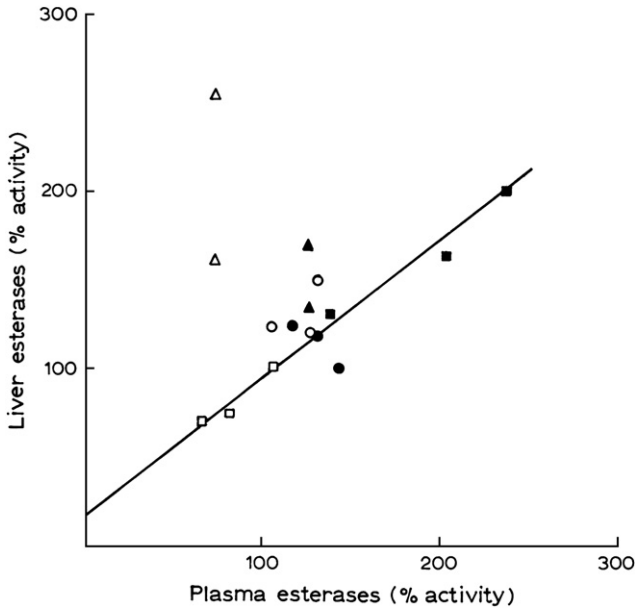

FIGURE 68.1. CarbE and ChE activities in liver versus blood plasma of thiouracil fed rats. The animals received rat chow supplemented with 0.05% thiouracil for 22, 30, or 38 days. Methyl butyrate hydrolysis (▲ △) and 4-nitrophenyl butyrate hydrolysis (● ○) were measured in liver homogenate and plasma in accordance with Sterri *et al.* (1985b), and acetylcholine hydrolysis (■ □) by the method of Sterri and Fonnum (1978). The activities are percent of corresponding control (=100%) in male (closed symbols) and female (open symbols) animals fed standard rat chow.

IV. ROLE OF PLASMA CARBOXYLESTERASE

A. Scavenger Function

The results by Myers (1959) on prophylactic action of DAM against sarin poisoning in rat suggested that most of the sarin required to kill a rat may actually be used up by the inhibition of plasma CarbE, and the sarin may be destroyed in the blood stream before it reaches target AChE in the vital organs of rat. The importance of plasma CarbE for detoxification of sarin in the blood was also suggested by results from the work of Polak and Cohen (1969, 1970a, b) on ^{32}P-sarin injection and its distribution in the rat body. In the case of soman, a completely irreversible AChE inhibitor (Coult *et al.*, 1966), similar conclusions with respect to the function of plasma CarbE were based on results from a series of experiments with acute or repetitive injection of soman in rodents (Sterri *et al.*, 1980, 1981, 1985a; Sterri and Fonnum, 1984; Sterri, 1981; Fonnum and Sterri, 1981). The results showed that the reaction rate between plasma CarbE and soman or sarin may be rapid enough to inactivate a large proportion of the OP-compound before it leaves the blood. Also of special relevance for repetitive exposure, the plasma CarbE seemed to be spontaneously and sufficiently recovered within 24 h, ready to detoxify another dose of soman or sarin.

A scavenger function of plasma CarbE able to prevent the highly toxic OP compounds from reaching AChE in brain and diaphragm requires that an adequate amount of CarbE is present in the plasma. This is fulfilled for rodents, since CarbEs by several authors are reported to be especially abundant in rodent plasma (Myers, 1952; Aldridge, 1953; Goutier, 1956; Augustinsson, 1959; Christen and Cohen, 1969; Polak and Cohen, 1970a; Gupta *et al.*, 1985). In fact, rat and guinea pig plasma may contain as much as 2.8–3.0 μM and 0.5–0.6 μM of CarbE catalytic centers, respectively, as found with ^{32}P-sarin binding to plasma proteins and subsequent polyacrylamide gel electrophoresis or reactivation of CarbE by lowering the pH (Christen and

Cohen, 1969; Christen *et al.*, 1969; Cohen *et al.*, 1971). Interestingly, as this binding capacity has nothing to do with the catalytic enzyme activity, a much higher enzymatic activity was found in guinea pig than in rat with tributyrin as substrate for the plasma CarbE (Christen and Cohen, 1969). However, since CarbE is a B-esterase (Aldridge, 1953; Jansz *et al.*, 1959; Aldridge and Reiner, 1972) it is able to bind and detoxify the highly toxic OP compounds at the active site in equimolar proportions.

The fact that rodent plasma CarbE has a scavenger function against the highly toxic OP compounds is the basis for the CarbE concept, which is an outline of how the toxicity of soman may be influenced by the different content of plasma CarbE in different species in both the absence and presence of therapeutic interventions such as pyridostigmine prophylaxis or any artificially supplied scavenger in the plasma (Sterri and Fonnum, 1989; Sterri, 1989). This is further described below (see Toxicity of nerve gases and Therapeutic interventions).

The various isoenzymes of plasma CarbE might have different importance with respect to their scavenger function. Results show a 2.5-fold higher plasma CarbE activity with methyl butyrate in adult female rats compared to males, whereas the soman toxicity does not differ between them (Sterri *et al.*, 1985a). The same authors also report adult values of soman toxicity in 31 day old rats of both sexes, whereas at that time the methyl butyrate hydolyzing capacity of female plasma is far from fully developed. Thus, the isoenzyme with the highest preference for 4-nitrophenyl butyrate as substrate (Sterri and Fonnum, 1989) may be the most effective soman scavenger of plasma, at least in rats.

B. Toxicity of Nerve Gases

Several investigations have demonstrated that the concentration of CarbE protein in rodent plasma is critical for the tolerance to an acute exposure to highly toxic ChE inhibitors such as soman. For example, a strong correlation exists between the LD_{50} of soman and the plasma CarbE content in developing young rats (Fonnum *et al.*, 1985; Sterri *et al.*, 1985a). In these rats the plasma CarbE activities with 4-nitrophenyl butyrate increased from negligible (5 days old) to adult value (31 days old) and in the same period the acute LD_{50} of soman increased eight- to ten-fold (toxicity decreased) and reached adult value in the 31 day old rats. In addition, young rats (14 days old) with low content of their own plasma CarbE displayed strongly reduced mortality to soman poisoning when a partly purified CarbE protein from rat liver was prophylactically supplied by intravenous injection into their blood before the soman exposure (Fonnum *et al.*, 1985). Also, a linear correlation between soman toxicity and changes in plasma content of CarbE in aging rats is reported by Maxwell *et al.* (1988).

The specific CarbE inhibitors tri-*ortho*-cresyl-phosphate (TOCP) (Mendel and Myers, 1953) and 2-[*o*-cresyl]-4H-1,2,3-benzodioxa-phosphorin-2-oxide (CBDP) (Casida *et al.*, 1961) have been used by several investigators to evaluate the effect on LD_{50} of highly toxic OP compounds. In mice the LD_{50} of soman was reduced to about one-eighteenth by pretreatment with 35–50 mg/kg CBDP (McKay *et al.*, 1971; Boskovic, 1979) whereas pretreatment with 100 mg/kg TOCP reduced LD_{50} of soman to one-third in guinea pig and rat (Sterri, 1981; Fonnum and Sterri 1981; Sterri *et al.*, 1981). In rat the LD_{50} of sarin was reduced to about one-fifth by pretreatment with 40–50 mg/kg TOCP (Myers, 1959; Polak and Cohen, 1969). From studies of the CBDP effect on LD_{50} for several OP compounds by Maxwell (1992) significant protection by plasma CarbE against acute toxicity of the highly toxic soman, sarin, tabun, and paraoxon was reported. Interestingly, for malathion more than a 100-fold increase in acute toxicity by pretreatment with CarbE inhibitor tri-orthotolyl-phosphate is reported by Murphy *et al.* (1976). However, malathion is a less toxic OP compound, which will be hydrolytically detoxified by enzymatic activity of CarbE due to its content of the carboxylic ester group.

Some very interesting results on the prophylaxis of sarin poisoning with DAM in normal and TOCP-pretreated rats are reported by Myers (1959). The author observed that with DAM prophylaxis the LD_{50} of sarin in the atropinized TOCP-pretreated rats was only one-seventeenth of LD_{50} in the atropinized normal rats. This may be regarded as a consequence of sarin binding to plasma CarbE in the normal rats, since any direct reaction between sarin and the prophylactic administered DAM should be similar in the normal and TOCP-pretreated animals.

The scavenger function of plasma CarbE may explain various aspects of soman toxicity and soman inactivation in rodents, but it may also be of value for an adequate understanding of soman toxicity in other species. Rat, guinea pig, and primates including humans are species with respectively high, medium, minor (marmoset), and zero (rhesus monkey and human) concentration of plasma CarbE (Myers, 1952; Aldridge, 1953; Christen *et al.*, 1969; Christen and Cohen, 1969; Cohen *et al.*, 1971). By including these species in an outline describing the influence of plasma CarbE on soman toxicity, Sterri and Fonnum (1989) presented a concept which in principle could explain the differences in LD_{50} of soman between the species. The predicted LD_{50} values of soman for rat, guinea pig, marmoset, and rhesus monkey (or human) agreed well with the experimental values for subcutaneous LD_{50} of soman in rat (Sterri *et al.*, 1980, 1985a), guinea pig (Sterri *et al.*, 1981), marmoset, and rhesus monkey (Dirnhuber *et al.*, 1979). Our general knowledge of experimental LD_{50}s of soman might suggest that rodent plasma CarbE may be a main scavenger for soman by inhalation and intravenous and subcutaneous administration, whereas additional dermal or hepatic factors may influence the LD_{50} of soman by percutaneous or intraperitoneal administration (Sterri, 1989).

The CarbE concept by Sterri and Fonnum (1989) assumes that the concentration of target AChE in the

nervous tissue is small and may therefore be regarded as constant in the different species, whereas the concentration of CarbE in plasma differs. A strongly simplified visual representation of their proportional contribution to LD_{50} of soman in rat is shown in Figure 68.2. The concentrations of target AChE and plasma CarbE in rat are represented by the quadrangles **1** and **2**, respectively, and their proportions are similar to those previously presented in the CarbE concept (Sterri and Fonnum, 1989). At a glance one can see from Figure 68.2 that without therapeutic intervention the LD_{50} of soman is represented by (**1** + **2**) which is strongly influenced by the concentration of plasma CarbE (**2**). Also, it would be reduced in species with lower CarbE concentrations than rat, until it is exclusively represented by the target AChE concentration (**1**) in species such as rhesus monkey and humans which do not have CarbE in the plasma.

C. Therapeutic Intervention

The effect on soman toxicity by pyridostigmine prophylaxis in different species could in principle also be explained by the CarbE concept of Sterri and Fonnum (1989). This means that the protection factors of carbamate prophylaxis as calculated for the different species were similar to the experimental protection factors of pyridostigmine prophylaxis against soman as observed for rat and guinea pig (Gordon *et al.*, 1978) as well as marmoset and rhesus monkey (Dirnhuber *et al.*, 1979). Thus, due to the CarbE concept, we were fairly convinced that the human species would achieve a similar protection by pyridostigmine prophylaxis as rhesus monkey, since both species lack the plasma CarbE. The proportional contribution by pyridostigmine prophylaxis to LD_{50} of soman in rat is visualized in Figure 68.2, as represented by quadrangle **3**. Since this prophylaxis leads to protection of a constant factor, namely target AChE, the contribution to LD_{50} by pyridostigmine is regarded as constant in the species (30 × target AChE concentration) in accordance with the CarbE concept (Sterri and Fonnum, 1989). At a glance one can see from Figure 68.2 that the protection factor of carbamate prophylaxis, which is LD_{50} with prophylaxis (**1** + **2** + **3**) divided by that without prophylaxis (**1** + **2**), is relatively low in rat due to the large concentration of plasma CarbE (**2**), whereas in species such as rhesus monkey and humans the factor would be equal to 30 (Figure 68.2, **1** + **3**) since plasma CarbE is not present.

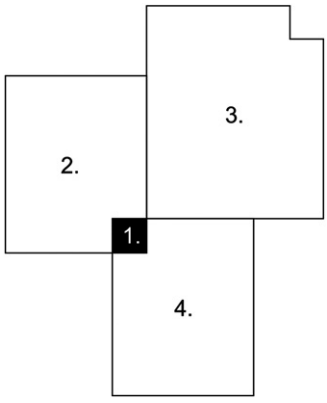

FIGURE 68.2. Visual representation of soman LD_{50} in rat as proportionally influenced by **1.** target AChE, **2.** plasma CarbE, **3.** carbamate prophylaxis, and **4.** artificially supplied scavenger (at rat plasma CarbE concentration). The concentration of target AChE (**1**) or its ''enhancement'' by carbamate prophylaxis (**3**) is constant between the species, whereas the concentration of plasma CarbE (**2**) is varying. The representation is based on the CarbE concept outlined by Sterri and Fonnum (1989) and Sterri (1989). LD_{50} decreases (toxicity increases) when plasma CarbE (**2**) is decreased or absent.

Since plasma CarbE is established as a functional scavenger towards highly toxic OP compounds, this has inspired several experiments on the use of artificially supplied scavengers to improve our protection against the nerve gases. Efficient protection has been observed against OP poisoning by prophylactic injection of either CarbE, AChE, or BuChE into the blood stream of rodent or primate (Fonnum *et al.*, 1985; Wolfe *et al.*, 1987; Raveh *et al.*, 1989, 1997; Broomfield *et al.*, 1991; Maxwell *et al.*, 1991, 1992; Doctor *et al.*, 1993). In the future additional scavengers which could mimic the function of plasma CarbE might hopefully be developed. Based on the CarbE concept (Sterri and Fonnum, 1989) the protection factors of any artificial scavenger added into the plasma of the different species at an adequate concentration could be estimated, and in principle such estimates have been presented by Sterri (1989). The proportional contribution to LD_{50} of soman in rat by an artificially supplied scavenger at a similar concentration as the original plasma CarbE is visualized in Figure 68.2, as represented by quadrangle **4**. At a glance one can see from Figure 68.2 that such a supplement would increase the LD_{50} by a factor of only 2 in rat (**1** + **2** + **4**), but of higher fold in species with a lower concentration of plasma CarbE (reduction in **2**). For rhesus monkey and humans which do not have natural plasma CarbE such a supplement would lead to similar LD_{50}s (**1** + **4**) as for a normal untreated rat (**1** + **2**), which means a protection of about 20-fold in accordance with the CarbE concept (Sterri and Fonnum, 1989; Sterri, 1989). Also, the protection factor in humans would be increased if the concentration of artificially supplied scavenger is enhanced (increase in **4**) (Sterri, 1989).

V. CONCLUDING REMARKS AND FUTURE DIRECTION

Plasma CarbE has proved to have an important role in nerve gas poisoning both with and without therapeutic intervention, and is nature's own example of an effective scavenger of nerve gases being present in the blood. Both CarbE and

other B-esterases have proved to be effective as artificially supplied scavengers, but since they are high molecular weight proteins some practical problems may be difficult to overcome for practical use. It is tempting to speculate, as has been done previously (Sterri, 1989), that a low molecular weight scavenger associated with the large amount of albumin in human plasma would be a better alternative, if possible. Perhaps resources should be utilized so that these possibilities may be worth investigating.

CHAPTER 69

Protection of Acetylcholinesterase from Organophosphates: Kinetic Insight into Bioscavengers

R. J. KERN, M. E. WALES, E. TIFFANY-CASTIGLIONI, AND J. R. WILD

I. INTRODUCTION

Organophosphorus (OP) neurotoxicant-induced inhibition of acetylcholinesterase (AChE, EC 3.1.1.7) results in an accumulation of acetylcholine (ACh) in the neural synaptic junctions. The resulting enhancement of nerve impulses leads to a wide variety of hypercholinergic effects that ultimately result in muscular dysfunction and nerve damage (Qian *et al.*, 2006). Traditional treatment of OP poisoning has utilized three categories of drugs: (1) muscarinic receptor blocking agents, such as atropine, (2) cholinesterase reactivators, such as pralidoxime chloride (2-PAM), and (3) emetics, cathartics, and adsorbents to decrease further absorption. While reversal of the muscarinic manifestation is the objective of atropine therapy, the nicotinic cholinergic effects from OP intoxication, such as muscle fasciculations and muscle paralysis, can still lead to death. In some cases, oximes are employed as cholinesterase reactivators in an attempt to release active cholinesterase from the OP–cholinesterase conjugates. The effectiveness of reactivation decreases with time after exposure, and the rate at which this occurs varies with the strength of the nucleophile, its orientation with respect to the phosphate conjugated to the active center serine, and irreversible aging of the OP conjugate (Wong *et al.*, 2000).

Although successful, the current treatments for acute nerve agent poisoning do nothing to avoid the victim suffering a toxic insult that subsequently requires therapeutic management. In contrast, the mechanism of OP toxicity suggests that an approach based on the reduction of the concentration of OP toxicant in the blood before it can reach its site of action (synaptic endplates) should be particularly effective, and incapacitating or even lethal exposures could be mitigated to comparatively mild symptoms. With this in mind, recent efforts have focused on identifying proteins that can remain stable in the intravascular circulation for extended periods of time and act as biological scavengers of OPs. There are several methods by which this can be accomplished: (1) elevating intravascular levels of the cholinesterases, (2) utilizing endogenous OP-hydrolyzing enzymes, (3) providing exogenous OP bioscavengers, or (4) selecting combinations thereof. This chapter describes a kinetically focused, *in vitro* AChE protection assay that aids in the analysis of bioscavengers' efficacy. This analysis discusses the critical role that binding affinity (K_m) and substrate specificity (k_{cat}/K_m) play in protecting AChE against OP-induced AChE inhibition.

II. PROTECTIVE BIOSCAVENGERS

A. Endogenous Enzymes as Protective Bioscavengers

The sensitivities of various organisms to OP compounds are quite variable and appear to be related to the endogenous OP detoxifying capacity of two families of enzymes which are often categorized as the A- and B-esterases. These include the catalytic, high-density lipoprotein-(HDL) associated PON1 (aryldialkylphosphatase EC 3.1.8.1 or aromatic esterase EC 3.1.1.2), and the B-esterases, where the main mechanism of disposition of OP compounds is inhibitory binding and sequestration. This latter category includes naturally occurring proteins that bind and/or react with nerve agents on a one-to-one basis (stoichiometrically), and includes enzymes such as the cholinesterases (ChEs) and carboxylesterases (CarbEs).

Stoichiometric scavengers have the capacity to bind one molecule of nerve agent per molecule of protein scavenger. Although this approach has been proven to be effective (Table 69.1), it is limited in that the extent of protection is directly proportional to the concentration of unreacted, active scavenger in the blood stream at the time of nerve agent exposure (Cowan *et al.*, 2004; Broomfield *et al.*, 1991). Given that the molecular weights of many proteins that are being considered as stoichiometric scavengers are in

TABLE 69.1. Protection of rhesus monkeys from CWA poisoning by BChE (butyrylcholinesterase) (modified from Broomfield *et al.*, 1991)

OP	BChE (nmol)	OP (nmol)	Challenge[a]	Protection[b]
Soman	460	340	$4 \times LD_{50}$	1/1
Soman	460	253	$3 \times LD_{50}$	1/1
Sarin[c]	460	366	$1 \times LD_{50}$	2/2
Soman	503	220–260	$2 \times LD_{50}$	4/4

the 60–80,000 Da range, and the molecular weights of the nerve agents are about 180 Da, the mass ratio of scavenger to nerve agent is approximately 400:1. Thus, a high concentration of scavenger protein in circulation would be required to achieve the equal or greater molar ratio that would be required for protection.

Alternatively, endogenous scavengers with catalytic activity provide the advantage that small amounts of enzyme could be sufficient to detoxify large amounts of nerve agent. This has been demonstrated by studies in which rats or mice injected with purified rabbit PON1 demonstrated an increased resistance to the OP pesticides, paraoxon, chlorpyrifos, and chlorpyrifos oxon (Li *et al.*, 1995, 2000; Costa *et al.*, 1990; Main, 1956). PON1 is a member of the PON family of proteins, which reside in high-density lipoprotein complexes and appear to prevent lipid oxidation in low-density lipoprotein. Although its natural substrate may be homocysteine thiolactone, it is the only member of the PON family that also hydrolyzes OP compounds. This has been further verified by the creation of PON1 null mice, which were found to have increased sensitivity to chlorpyrifos oxon, chlorpyrifos and diazinon, but, surprisingly, not to paraoxon (Shih *et al.*, 1998).

Studies with human populations have determined that the protection afforded by PON1 is complex, as (1) the intravascular expression varies between individuals, (2) the enzyme has significant sequence polymorphisms, and (3) the resulting allozymes have different substrate specificities. Pedigree analysis has established a polymorphism at position 192 as concordant with the serum paraoxonase phenotypes, with the arginine 192 (192R) allozyme hydrolyzing paraoxon more rapidly than the glutamine 192 (192Q) form (Adkins *et al.*, 1993; Furlong *et al.*, 1993; Humbert *et al.*, 1993; Smolen *et al.*, 1991). This is reversed for the hydrolysis of other OP compounds, and especially sarin as the serum of 192Q homozygotes displayed an almost ten-fold greater activity against sarin than the 192R homozygotes. In studies in which purified human PON1-192Q or PON1-192R was injected into the serum of the PON1 null mice, either alloform protected equally well against diazinon exposure, consistent with their equivalent catalytic efficiency for diazinon hydrolysis. However, the PON1-192R alloform provided significantly better protection against chlorpyrifos exposure, as predicted due to its higher catalytic efficiency with that substrate (Li *et al.*, 2000). These observations have been confirmed in transgenic mice expressing one or the other PON1-192 alloform (Cole *et al.*, 2005).

Similar results have been reported for polymorphisms at amino acid 55, with the PON1 paraoxonase activity in blood serum from 55M (methionine) homozygotes reduced compared to either the 55L (leucine) homozygotes or the LM heterozygotes (Mackness *et al.*, 1997). While it is intuitive that the rate of detoxification of a substrate would be dependent on the expression levels of these endogenous enzymes, the effects of the genetic polymorphisms suggest that catalytic efficiency is an equally important consideration.

B. Exogenous Enzymes as Protective Bioscavengers

In addition to PON1, OP-hydrolyzing enzymes have been identified from a variety of prokaryotic sources, such as the organophosphorus hydrolase (OPH, EC 3.1.8.1) from *Pseudomonas diminuta* (Serdar and Gibson, 1985; Serdar *et al.*, 1982) and the OP acid anhydrolase/prolidase (OPAA) from *Alteromonas* sp. (DeFrank and Cheng, 1991; Cheng *et al.*, 1993, 1996). These enzymes have the potential to compete with physiological targets for OP binding and to catalytically hydrolyze a broad range of OPs (Table 69.2). The hydrolytic capability of the OPAA class of enzymes appears to be limited to the phosphonofluoridates, which includes OP nerve agents of the G series (such as soman and sarin), and warfare agent surrogate DFP. In contrast, the OPHs hydrolyze a broader spectrum of substrates that includes common pesticides (P–O bonds, phosphotriesters), phosphonofluoridates (P–F bonds – type G nerve agents),

phosphonothioates (P–S bonds – type V CW agents), and phosphonocyanidate (P–CN – tabun). A survey of genomic and biological culture libraries, identified on the basis of either sequence homology or activity, has revealed that there is significant variation in the kinetic character of the OPAA family (Wales and Wild, unpublished). Collectively, these families of enzymes provide the opportunity to design a versatile bioscavenger technology based on a consortium of enzymes selected for maximal utility in the detoxification of chemical warfare agents (CWAs).

The kinetic efficiencies of any potential therapeutic enzyme must be considered relative to realistic exposure concentrations and the nature of the neurotoxicants (Table 69.3). Substrate saturating conditions are not likely to occur *in vivo*, and when the concentration of available substrate is at or below the K_M of the enzyme, the catalyzed reaction becomes second order with respect to substrate, and k_{cat}/K_M, the second order rate constant, is indicative of hydrolysis. The high toxicity of OP compounds sets a requirement for protection to be provided at relatively low OP vascular concentrations, well below the K_M of any hydrolyzing enzyme for the OP substrates, especially the CWAs. The half-time for reaction of a catalytic scavenger with a nerve agent can be estimated with some conservative kinetic assumptions. The expected concentration of a nerve agent in the blood at an LD_{50} dose would be approximately 8×10^{-7} M (Lenz *et al.*, 1997). If a scavenger was present in the blood at a concentration of 1 mg/ml (approximately 1×10^{-5} M), then the rate constant for the reaction of a scavenger with a toxicant would be second order with respect to substrate, and the $t_{1/2}$ for the reduction of toxicant would be ~$3–7 \times 10^{-4}$ min, assuming adequate mixing and the retention of the bioscavenger and the toxicant in the bloodstream. Where actual measurements have been made of the rate of reduction in the concentration of soman in guinea pigs in the absence of an exogenous scavenger, the concentration of a $2 \times LD_{50}$ dose of soman in circulation was reduced with a $t_{1/2}$ of 0.15 min (Langenberg *et al.*, 1997). These results support the contention that the presence of a bioscavenger in circulation at the time of exposure could provide significant prophylactic protection. The need to administer, repetitively, a host of pharmacologically active drugs with a short duration of action at a precise time following exposure would be all but eliminated if a scavenger with the appropriate kinetic characteristics were used. In order to address these issues, an *in vitro* protocol for rapidly evaluating the efficacy of enzymes and drugs to protect AChE was developed.

C. Encapsulated Enzymes as Protective Bioscavengers

Logically, since bacterially derived enzymes have no known mammalian homologs, they are likely be potent initiators of immune responses and so are deemed unlikely to be appropriate for use as a bioscavenger in humans. An enzyme

carrier or encapsulation method can be employed to present the bacterial enzymes in a manner which protects against any potential for adverse disposition and rapid clearing from the circulation. The medical value of encapsulation was first reported for enzymes and drugs successfully entrapped within resealed and annealed erythrocytes (CRBCs) (Ihler *et al.*, 1973). Since that first report, CRBs have demonstrated efficacy in both cyanide antagonism (Leung *et al.*, 1991a, b; Petrikovics *et al.*, 1994, 1995) and OP antagonism (Pei *et al.*, 1994, 1995; Petrikovics *et al.*, 2007).

In spite of their long circulation time, CRBCs are not considered a practical carrier system, as their use requires prior blood typing, and they are relatively fragile cells requiring a sophisticated encapsulation technique. Research over the years has refined the list of parameters which should be considered when selecting an encapsulation method to include: (1) circulation half-life, (2) RES (reticuloendothelial system) resistance, (3) permeability by the target toxin, (4) intrinsic toxicity, (5) encapsulation efficiency, (6) biocompatibility, (7) pharmacokinetic profile, and (8) activity of encapsulated enzyme. Most of these parameters have to be evaluated on a case-by-case basis, but liposomes are often considered the ''workhorse'' of the drug delivery industry, and dendrimers are a relative new approach.

Petrikovics *et al.* (1999a, b, 2000a, b) employed sterically stabilized liposomes (SL) as the encapsulation system to deliver OPH (SL-OPH) or OPAA (SL-OPAA) as the antagonist of the model OP compounds, paraoxon ($LD_{50} = 0.85$ mg/kg) or DFP ($LD_{50} = 4.55$ mg/kg). Liposomes are small spherical systems that are synthesized from cholesterol and nontoxic phospholipids. They can be engineered to possess different characteristics depending upon the lipid of choice in the production process. Recent studies with small, low-clearance liposomes have shown that more specialized formulations may provide benefits over simpler ''first generation'' liposomes, including prolonged residence in plasma, and increased tissue exposure. Other characteristics, such as their relatively easy preparation method, high encapsulation efficiency, favorable biodistribution/pharmacokinetic properties, and good *in vivo* tolerance, make them an attractive choice. One of the ''second generation'' systems is the ''stealth'' liposome, designed to circumvent the body's immune defenses, thereby avoiding rapid uptake by the macrophage cells of the reticuloendothelial system (Woodle and Lasic, 1992; Papahadjopoulos *et al.*, 1991). In these studies, the APRs were calculated using the mean of the LD_{50} values determined from three or more experiments, and demonstrated that while SL-OPAA was more effective than either 2-PAM or atropine, it was less effective than the combination. [The *in vivo* efficacies of the antidotal systems are expressed here as the antidotal potency ratio, or APR, which represents the ratio of the LD_{50} (mean) of the OP with antagonists and LD_{50} (mean) of OP without antagonists.] OPH, however, demonstrated not only a $33 \times LD_{50}$ protection against paraoxon poisoning when delivered as the free enzyme, but protection against 125 LD_{50} when the SL is encapsulated. This was twice the protection afforded by the 2-PAM + atropine combination (Table 69.4).

Alternatively, the *in vivo* efficacy of the nanostructures, DP-OPH and DP-OPAA, was evaluated for each encapsulated enzyme. The *in vivo* application of dendritic polymers (DP), a nanocapsule, polyoxazoline-based hyperbranched polymer (HBP) with a C18 surface modifier, was first reported in the mid-1980s (Tomalia *et al.*, 1985). The application of these dendritic polymers as drug carriers has rapidly gained favor, primarily due to their inertness relative to temperature, solvent, and pH. These polymers have attracted an interest as drug carriers which can be loaded with drugs, nucleic acid, or protein either in the interior of the dendrimers or attached to the surface groups. Due to their relatively recent appearance on the scene, the toxicity, biodegradability, and biocompatibility of dendrimers have to be explored for each system and each application. In the studies reported by Petrikovics *et al.* (2007), DP-OPH alone provides a $95.5 \times LD_{50}$ protection against paraoxon, while DP-OPAA demonstrates a more modest $2.7 \times LD_{50}$ protection against DFP (Table 69.4). The DP-OPH alone provides better protection against paraoxon than the traditional therapies of 2-PAM

TABLE 69.4. OP antidotal protection of the OPH and OPAA dendritic polymer (DP) and the sterically stabilized liposome (SL) systems

OP compound	Antidotal system	APR

[d]Petrikovics *et al.* (2007)

(20×) and atropine (40×). Similarly, the DP-OPAA was slightly more effective than 2-PAM (2.3×) and atropine (1.5×). DP-OPH alone was slightly better (1.5×) than the 2-PAM + atropine combination.

It is interesting to note that the co-administration of the three therapies (encapsulated enzyme, 2-PAM, and atropine) provided the most effective antidotal system. The DP-OPAA nanocapsule system enhanced the protection of the 2-PAM + atropine combination by 3.2× in DFP antagonism, while the DP-OPH nanocapsule provided a more substantial (12.8×) increase in protection with 2-PAM + atropine against paraoxon. Although the *in vivo* efficacy of the DP-OPH system was approximately 30 times greater than that of the DP-OPAA (alone or in combination with 2-PAM + atropine), both DP-enzymatic systems synergistically enhanced the traditional 2-PAM + atropine combination therapy. This was even more dramatic when SL-OPH was employed in combination with 2-PAM and/or atropine: the magnitude of prophylactic antidotal protection was an astounding 920 × LD_{50} and the therapeutic antidotal protection was 156 × LD_{50}.

III. DEVELOPMENT OF A TOXICOKINETIC PROTECTION ASSAY

A. Determining Bioscavenger Efficacy

The *in vitro* protection assay focused on the extent to which two OP hydrolyzing enzymes (OPAA and OPH) and an oxime (2-PAM), alone or in combinations, could prophylactically prevent AChE inhibition. The catalytic bioscavengers were the native forms of OPH (EC 3.1.8.1) and OPAA (EC 3.1.8.2). The effects of the regenerative oxime 2-PAM were included because its site of action is the inhibited AChE which would be expected to have an *in vitro* effect, whereas atropine, with an alternative muscarinic receptor site of action, was excluded from *in vitro* consideration (Figure 69.1). The addition of an OP hydrolyzing enzyme and the reaction of oximes with acetylthiocholine (ASCh) effected a complex, multiphasic set of reaction equations related to the analytical measurement of the activity and inhibition of AChE (Figure 69.2). The products of various interrelated reaction activities of AChE were monitored spectrophotometrically through the hydrolysis of thiocholine, the hydrolytic product of the substrate ASCh, with 5,5′-dithio-bis-2-nitrobenzoic acid, leaving a compound that absorbed at 405 nm (reactions I and VII, sequentially). Depending on the OP neurotoxin and/or the oxime, the potential existed for other reaction products to contribute to the spectrophotometric signal, thus complicating the analysis. For example, 2-PAM reacts with ASCh to produce thiocholine (reaction IV), and the enzymatic hydrolysis of paraoxon, the neurotoxic inhibitor of AChE (reaction V) or demeton-*S* produced *p*-nitrophenol, and a free thiol, respectively, both of which are typically monitored at 405 nm. In

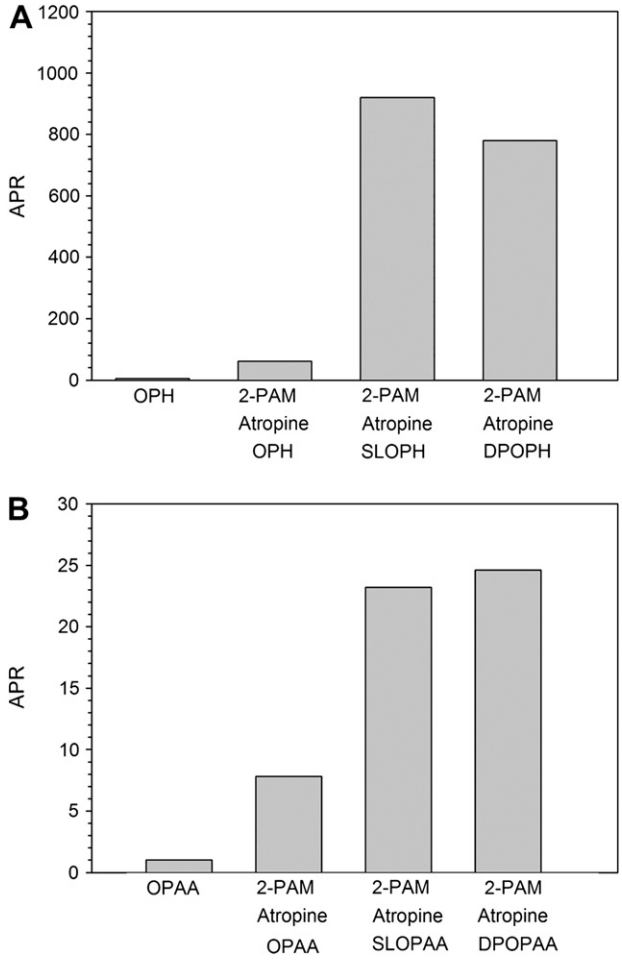

FIGURE 69.1. Bioscavenger enhancement of the protection of mice by the traditional 2-PAM + atropine therapy in mice. The *in vivo* efficacy of two different enzyme-based bioscavengers was determined by Petrokovics *et al.* (2007). Panel A summarizes the effect of OPH (EC 3.1.8.1) on paraoxon neurotoxicity, while panel B summarizes the effect of OPAA (EC 3.1.8.2) against DFP. The antidotal potency ratio, APR, is the average LD_{50} of paraoxon with and without antagonists.

order to ensure that only the catalytic AChE activity was being monitored, it was necessary to remove the remaining OP or oxime prior to spectrophotometric analysis. By working at low levels of OP neurotoxins that were just sufficient for complete AChE inhibition, the effectiveness of any added protectant could be directly evaluated by the amount of AChE activity that was protected. The potential to protect AChE with OP hydrolyzing enzymes is significant, and this would add a direct route for the elimination of the neurotoxins, complementing any regeneration of inhibited AChE that might be achieved by 2-PAM.

B. Kinetic Evaluation of the Inhibition of AChE by OP Neurotoxicants

The potential AChE activity and inhibition levels for each new preparation of AChE had to be determined empirically

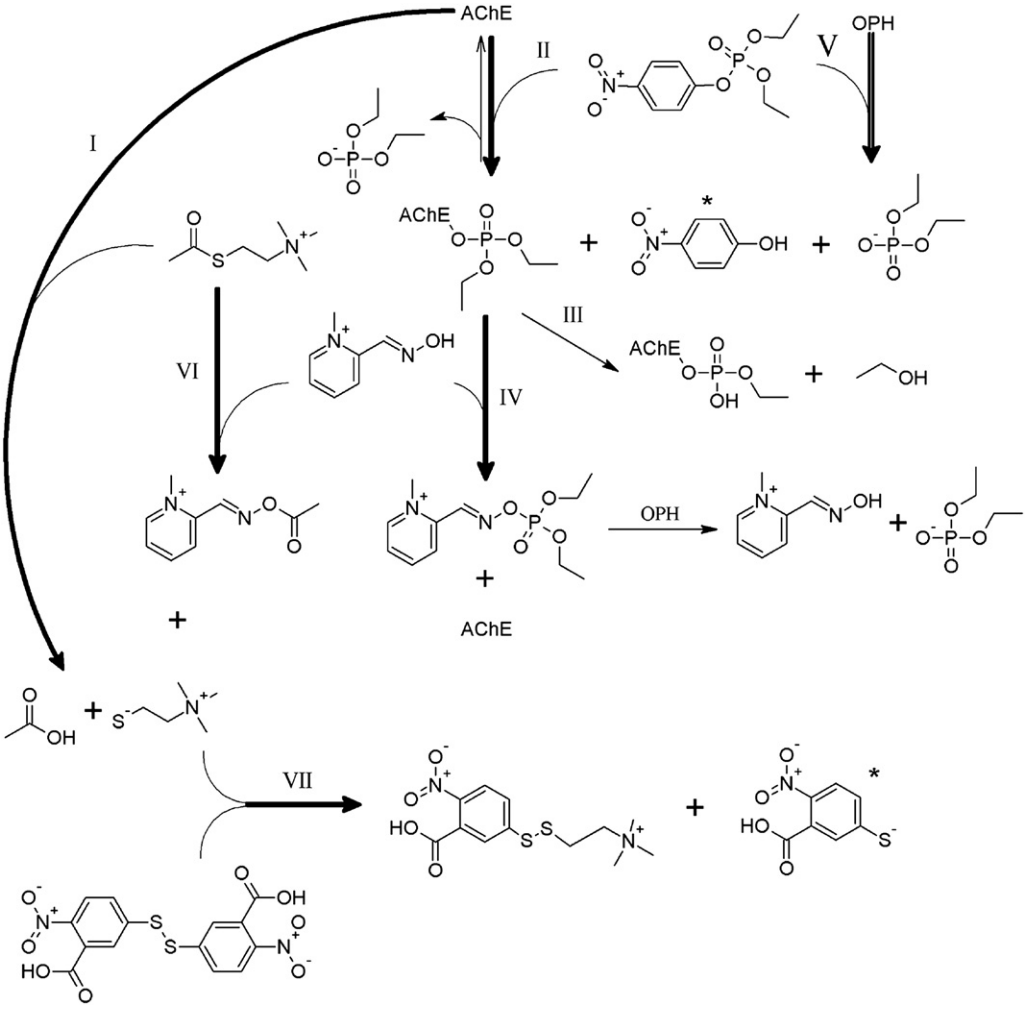

FIGURE 69.2. Reaction scheme of acetylcholinesterase inhibition, reactivation, and protection activities. OPH, 2-PAM, and paraoxon are used in the example. Reaction (I) – cholinesterase AChE reaction with ASCh; Reaction (II) – inhibition of AChE inhibition by paraoxon; Reaction (III) – aging of AChE associated with OP exposure; Reaction (IV) – reactivation of AChE by 2-PAM; Reaction (V) – hydrolysis of paraoxon by OPH; Reaction (VI) – reaction of 2-PAM oxime with ASCh; and Reaction (VII) – DTNB reaction with SCh. The * indicates a photometrically detectable metabolite.

for each of the OP compounds of interest. The AChE was resuspended to a protein concentration of 1 mg/ml (~1,000 units) and incubated for 24 h at a protein concentration of 0.1 mg/ml over a suitable concentration range determined for each neurotoxin. Following the inhibition period, a P-6 microspin column (Biorad) was used to separate the AChE and excess inhibitor. The remaining, uninhibited AChE activity was determined by measuring the rate of acetylthiocholine (ASCh) conversion by monitoring the increase in free thiol concentration at 405 nm with 1 mM 5,5′-dithiobis-2-nitrobenzoic acid (DTNB). The concentration of each of the OP neurotoxicants selected for use in the protection studies corresponded to the concentration which resulted in ~95% inhibition of AChE activity. This concentration had to be empirically determined for each preparation of AChE in order to accommodate variations in the commercial enzyme activities. The concentration ranges for the OP compounds which inhibited 95% of the AChE and the protectant concentration ranges were determined empirically (Table 69.5). The P_{50} is defined as the [protectant]/[inhibitor] molar ratio at which AChE has 50% of the activity of the no inhibitor control. As a stoichiometric protectant, one molecule of 2-PAM can reactivate one molecule of AChE and so is expected to have a relatively high P_{50} of one or greater. The P_{50}s of 2-PAM with paraoxon and DFP were 1 and 10, respectively (Figure 69.3). In the context of this protection assay, these results can be interpreted to mean that it takes one mole of 2-PAM for every mole of paraoxon to effectively protect 50% of the AChE from the inhibiting effects of paraoxon. Similarly, it requires 10 moles of 2-PAM to protect AChE from 50% inhibition by DFP. Although enzymatic bioscavengers have the potential for a much lower P_{50} due to their catalytic nature, in practice this will be related to the catalytic efficiency and binding affinity of the enzyme for the specific OP inhibitor.

The P_{50} values of OPH with paraoxon and DFP were determined to be 0.0002 and 0.0005, respectively, four and five logs more effective than the protection by 2-PAM alone. The P_{50} values of OPAA with paraoxon and DFP were 15 and 0.3, respectively. The P_{50} values for the enzymes are correlated with their catalytic efficiencies (Figure 69.4A and D). Even though the k_{cat}s of OPH and OPAA with DFP were virtually identical, $3784 \pm 370\ s^{-1}$ and $3780 \pm 560\ s^{-1}$, respectively (Figure 69.4B), the P_{50} of OPH indicated it was approximately 600 times more effective at protecting AChE

TABLE 69.5. Concentration of protectants (μM) and inhibitors (μM)

Protectant	Paraoxon (0.2–0.4)	DFP (0.6–0.8)	Demeton-S (2.0)
2-PAM	0.02–8.0	0.3–160	0.1–80.0
OPH	3.5×10^{-10}– 7.0×10^{-3}	5.3×10^{-5}– 7.0×10^{-2}	nd
OPAA	8.2×10^{-3}– 1.6×10^{1}	6.0×10^{-5}– 5.0×10^{0}	3.4×10^{-1}– 7.0×10^{-0}
H254R/H257L	nd	nd	2.0×10^{-4}– 2.0×10^{-1}

H254R/H257F	nd	nd	2.4×10^{-4}– 2.4×10^{-1}

nd – No activity was detected

against the inhibitory effects of DFP. Thus, there appears to be a good correlation between the P_{50} (Figure 69.4A) and enzyme specificity (Figure 69.4D), but when the enzyme's binding affinity for substrate is considered a very specific aspect of AChE protection is noticed: at substrate concentrations well below the K_Ms of the bioscavenger enzymes the second order rate kinetics become an important, if not the most important, predictor of efficacy. This can be seen in the comparison of Figure 69.4A and D, where the profile of the k_{cat}/K_M values of the enzymes is inversely correlated with the P_{50} values.

IV. KINETIC RELEVENCE – EFFICACY IN PROTECTION

A. Kinetic Description of Potential Candidate Bioscavengers

Based on the concentration of an OP cholinergic neurotoxicant which is required to provide 95% inhibition of AChE, the inhibitors can be ordered by their relative toxicity, from most toxic to least toxic, as follows: paraoxon (P–O bond) > DFP (P–F bond) > demeton-S (P–S bond). The protection ratio (P_{50}) values generally correlate with the k_{cat}/K_m values of each enzyme indicating the more catalytically efficient the enzyme, the better the protection ratio. With paraoxon and DFP, both 2-PAM and OPAA require an amount approaching or above stoichiometric levels to obtain an appreciable amount of AChE protection, with P_{50} ratios from 0.3 to 15. This finding is particularly noteworthy because OPAA has significant catalytic activity with DFP ($k_{cat} = 3780\ s^{-1}$) yet its protective value ($P_{50} = 0.3$) seems to be most strongly influenced by the relatively high K_m. In contrast, OPH has a similar catalytic activity ($k_{cat} = 3784\ s^{-1}$) with a protective ratio of 5×10^{-4}, which is 600-fold more efficient. A notable characteristic which might contribute to this dissimilarity is that the K_Ms of OPAA and OPH for DFP in this study are quite different (K_M-OPAA = 15.3 mM; K_M-OPH = 2.8 mM). This observation suggests that the substrate binding affinity plays a critical role in defining the protective capacity of a bioscavenger, particularly in those cases of similar catalytic rates. In this scenario, 2-PAM and OPAA both function as a reactant. Each 2-PAM molecule reacts with a single inhibited AChE and is thus removed from further consideration as it decomposes to free AChE and phosphorylated oxime, which is no longer reactive with additional inhibited AChE. OPAA is behaving in a similarly stoichiometric fashion, with the P_{50} values suggesting that OPAA binds the OP, sequestering it and preventing AChE inhibition without evidence of catalysis. This suggests that catalytic bioscavengers with high K_m values will tend to function as stoichiometric scavengers, requiring as least one high molecular concentration to drive the second order protection reaction. This perspective provides a cautionary note with *in vivo* exposures where the LD_{50}s of the agents are so low that the apparent binding affinities of the selected bioscavenger will likely need to be in the submicromolar range to be effective.

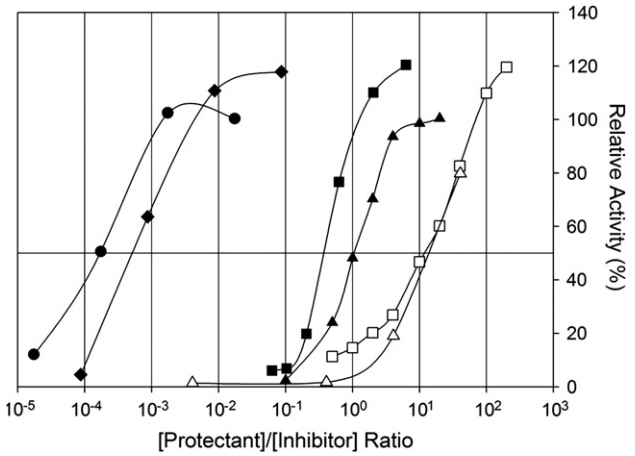

FIGURE 69.3. *In vitro* protection of AChE from inhibition by paraoxon or DFP by enzymatic bioscavengers (OPH or OPAA) and 2-PAM. The P_{50} value is the ratio at which 50% of a fixed concentration of AChE is protected from neurotoxic poisoning. From left to right, the kinetic curves are: (1) OPH and paraoxon; (2) OPH and DFP; (3) OPAA and DFP; (4) 2-PAM and paraoxon; (5) 2-PAM and DFP; (6) OPAA and paraoxon.

The broad-spectrum OP phosphonothioate (P–S bond) hydrolyzing enzyme OPH has been modified to enhance its catalytic specificity, with some of the most important modifications targeting their capability to hydrolyze

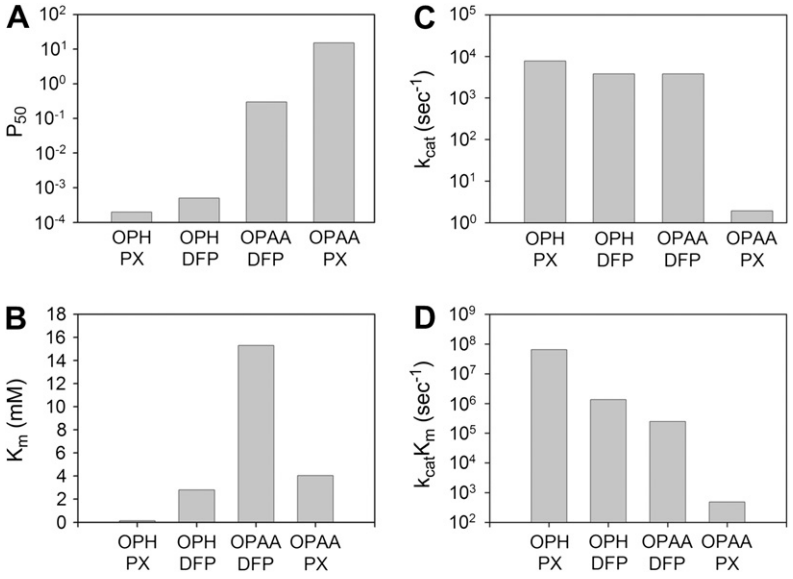

FIGURE 69.4. Comparison of the protection potential (P_{50}) and kinetic characteristics of OPH and OPAA. The P_{50}, [protectant]/[inhibitor] ratios of the enzymes are compared (Panel A), the K_Ms (mM) (Panel B), the k_{cat}s (s^{-1}) (Panel C), and the k_{cat}/K_Ms ($M^{-1}\,s^{-1}$) (Panel D) for each enzyme with both paraoxon (PX) and diisopropyl fluorophosphonate (DFP).

phosphorothioates (P–S bonds, particularly the chemical warfare V-agents). Several genetically engineered variants of OPH have been created to improve the catalytic efficiency for the VX surrogate substrate demeton-S (Reeves *et al.*, 2008). These variants have mutations near the active site that have improved k_{cat} and K_m values for the P–S bond substrates. Selected variant enzymes, including H254R/H257L (RL), H254R/H257F (RF), and H254S/H257L (SL), were evaluated to determine if the catalytic improvements were sufficient to improve protection of AChE against demeton-S over the protection provided by the native form of the bioscavenger (''WT OPH''). This was indeed the case, as the P_{50} values for the wild-type, RL, RF, and SL are 0.2, 0.015, 0.006, and 0.010, respectively. The variant enzymes demonstrated decreased P_{50} values (higher levels of protection) with demeton-S by factors of 13-, 20-, and 33-fold for RL, SL, and RF, respectively (Figure 69.5). The RF enzyme appears to be an outlier in that its K_M is higher than that of the wild-type enzyme while the other two variants selected for this study had lower apparent binding affinities. Furthermore, the enzyme specificity value (k_{cat}/K_M) is significantly lower for RL than the others. Nonetheless, its P_{50} index was virtually identical. This suggests that a larger than two-fold difference in enzyme k_{cat}s is required to observe a change in P_{50} as evidenced by the variants' k_{cat} values and their respective indistinguishable P_{50}s.

B. Enzyme Engineering for Enhanced VX Bioscavenger Protection

The protection of AChE from demeton-S inhibition by wild-type OPH was initially very poor and approached stoichiometric levels ($P_{50} = 0.2$) with the phosphorothioate inhibitor (P–S bond; the V-agent surrogate). This can be

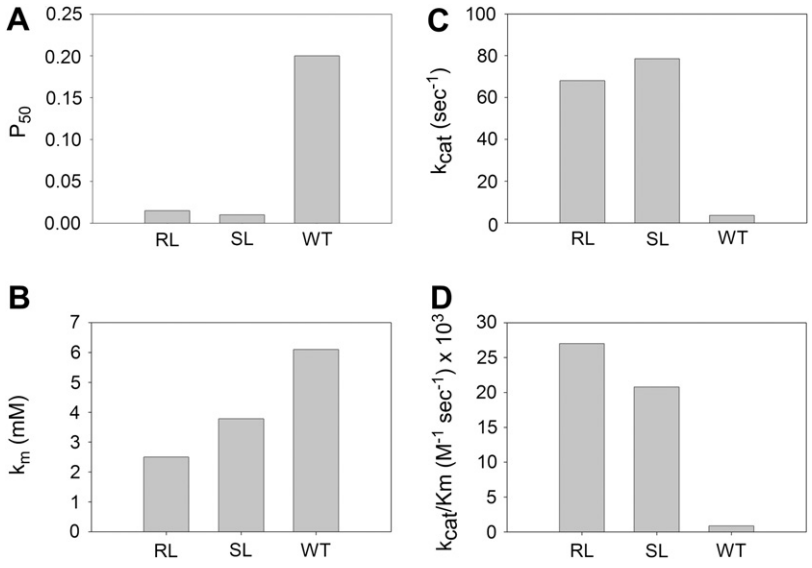

FIGURE 69.5. Comparison of the protection potential (P_{50}) and kinetic character of OPH variants with demeton-S (V-agent surrogate). The P_{50} [protectant]/[inhibitor] ratios of each enzyme are compared (Panel A), the K_M (mM) (Panel B), the k_{cat} (s^{-1}) (Panel C), and the k_{cat}/K_M ($M^{-1}\,s^{-1}$) (Panel D).

explained by the low catalytic efficiency rate ($k_{cat}/K_M = 759\ M^{-1}\ s^{-1}$) of the native enzyme toward demeton-S. Improvement in this protective ability is quite important, as there are few alternative enzymes for P–S bond hydrolysis. To address this need, OPH variants were evaluated as protectants against the inhibitory effects of demeton-S, demonstrating that stoichiometric, catalytic protectants can be designed to provide enhanced protection from OP-induced inhibition of AChE. The variant enzymes decreased the P_{50}s with demeton-S by as much as 33-fold. This finding demonstrates that enzymes with poor protection abilities can be altered to make their *in vitro* protection catalytically efficient instead of stoichiometric in nature and that the overall protection trends inversely with the catalytic efficiency. This becomes even more important when the CWAs are considered. For example, the reported LCt_{50}s of racemic sarin and soman are 70 and 100 mg/min/m^3, respectively, and the LD_{50} of VX is 0.04 mg/kg (Munro *et al.*, 1994). With the following assumptions, (1) respiration of 15 l/min, (2) a 70 kg body weight, (3) 5 liter vascular blood volume, (4) these values represent the effective dose of nerve agent, and (5) that all OP appears in the blood stream, the intravascular concentration of a lethal dose of sarin, soman, and VX can be estimated at 0.0015, 0.0016, and 0.0020 mM, respectively. Thus, the substrate binding affinity (K_M) may be the most critically important consideration for developing an intravascular treatment.

V. CONCLUDING REMARKS AND FUTURE DIRECTION

The conventional treatment for exposure to G- and V-agents involves the intramuscular injection of 2-PAM and atropine upon suspicion of neurotoxicant exposure. While this combined treatment is useful in nerve agent poisoning mitigation, it can have toxic effects of its own and is not always successful in treating extreme OP poisonings. The addition of catalytic bioscavengers to the exposure treatment procedures has proven effective at mitigating and even preventing the cholinergic effects of toxic OP exposures in mice (Petrikovics *et al*, 2007). In those studies, OPAA was able to protect mice against DFP concentrations (P–F bonds) that were 40-fold higher than the unprotected LD_{50}s, and OPH in the presence of 2-PAM and atropine. Similarly, it was possible to raise the LD_{50} for paraoxon from 400–800 LD_{50}. Furthermore, both of the OP hydrolytic enzymes demonstrated significant protective effects as determined by the AChE-protector/inhibitor:protection ratio *in vitro*. The protective effects of the enzymes as bioscavengers can be attributed to their catalytic capability, with the k_{cat}/K_Ms of the enzymes for given substrates indicative of their protective potential for those substrates. However, the K_M for a substrate becomes increasingly more important as the reaction becomes second order with low substrate concentration. It should be noted that the chemical warfare agents are chiral in nature, adding another degree of complexity in those instances in which the more toxic stereoisomers (i.e. more potent inhibitors of AChE) are poorer substrates for the hydrolytic enzymes (Hill *et al.*, 2000). While the substrates used in this study are achiral, the AChE-inhibition protection methodology described here could be easily applied to the evaluation of enzymes with the chemical warfare agents. This screening method cannot predict the bioscavenger immunogenicity or clearance rates of the therapeutics, which are important considerations with *in vivo* exposures. Enzymes can have various biodistribution and pharmacokinetic characteristics which cannot be challenged in this *in vitro* assay, yet they will be important in determining efficacy. The screening method developed here can be used as an important precursor to the costly and time-intensive *in vivo* pharmacokinetic and animal protection studies.

CHAPTER 70

Catalytic Bioscavengers: The Next Generation of Bioscavenger-Based Medical Countermeasures

PATRICK MASSON AND DANIEL ROCHU

I. INTRODUCTION

Organophosphate esters (OPs) were discovered in the middle of the 19th century by French chemists. They are mostly pesticides (parathion, malathion, chlorpyriphos, dichlorvos); some of them have been used as drugs (echothiophate, metrifonate, cyclophosphamide); and other OPs are potent chemical warfare agents (G agents: tabun, sarin, soman, cyclohexyl-sarin, and V agents: VX, VR, VS). These compounds are irreversible inhibitors of cholinesterases (ChEs) (Figure 70.1) (Costa, 2006). There are two types of ChEs, acetylcholinesterase (AChE; EC 3.1.1.7) and butyrylcholinesterase (BChE; EC 3.1.1.8). AChE plays a major role in the cholinergic system terminating the action of acetylcholine. Inhibition of AChE leads to accumulation of acetylcholine (ACh) in synapses, and blockade of cholinergic transmissions in peripheral and central nervous systems. Inhibition of AChE is the main cause of acute toxicity of OPs (Maxwell *et al.*, 2006).

Significant progress has been made in the past 20 years in emergency treatments of acute poisoning and management of poisoned casualties (Aas, 2003; Albuquerque *et al.*, 2006; Eddelston *et al.*, 2008; Wetherell *et al.*, 2007; Eyer *et al.*, 2007; Thiermann *et al.*, 2007). However, classical pharmacological approaches are reaching their optimum limits. In addition, due to accumulation of OP in depot sites and subsequent slow release from these stocks, blood and tissue cholinesterases may remain inhibited for long periods of time. Therefore, persistence of certain OPs in the body after initial exposure complicates treatments. This is particularly well documented for severe intoxications by parathion (Willems and de Bisschop, 1993).

Endogenous enzymes are involved in natural defenses against OP toxicity. The presence of detoxifying enzymes in skin contributes to reduce the OP dose that penetrates into the body (Schallreuter *et al.*, 2007). Numerous secondary targets of OPs found in various tissues are detoxifying enzymes and they certainly play a role in the natural defenses against OPs (Wang *et al.*, 1998; Nomura *et al.*, 2005, 2008). Natural blood bioscavengers significantly contribute to reduce the amount of OP molecules reaching physiological targets. It has been shown that animal species in which the concentration of paraoxonase-1 (PON1; EC 3.1.8.1) or carboxylesterase (CaE; EC 3.1.1.1) is high are relatively resistant to OPs (Kaliste-Korhonen *et al.*, 1996). Conversely, *knockout* mice for PON1 are very sensitive to OPs (Shih *et al.*, 1998). Albumin displays a low esterase activity, and slowly reacts with carbamyl- and phosphoryl-esters. However, its concentration in blood and lymph is so high ($\approx$0.6 mM) that it likely plays a role in detoxification of carbaryl at toxicologically relevant concentrations (Sogorb *et al.*, 2007). Thus, plasma albumin could also play a role in detoxification of certain OPs (Li *et al.*, 2008; Tarhoni *et al.*, 2007).

Toxicity of OPs can be countered by reducing skin absorption and lowering OP concentration in the blood compartment, thus preventing the transfer of OP molecules towards cholinergic synapses and other biological targets (Figure 70.2). Neutralization of toxicant can be achieved by using stoichiometric traps or catalysts acting on exposed surfaces (e.g. active topical skin protectants) or in the blood stream (bioscavengers).

II. STOICHIOMETRIC SCAVENGERS

The first molecules to be studied for the purpose of making stoichiometric scavengers were cyclodextrins (Désiré and Saint-André, 1986), neutralizing antibodies (Glikson *et al.*, 1992), and activated charcoal. Though the interest of charcoal is much debated, hemodialysis on a charcoal cartridge was successfully used on a Tokyo casualty who was resistant to the classical treatment of sarin poisoning (Yokoyama *et al.*, 1995). Transfusion of human plasma has been used for treating OP poisoning. The effects of fresh frozen plasma on cholinesterase levels, and outcomes in patients

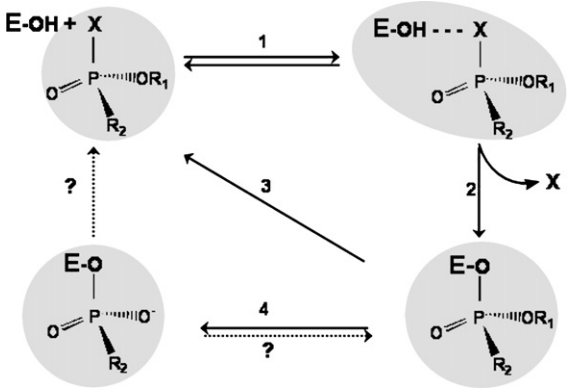

FIGURE 70.1. Mechanism of inhibition of cholinesterases by OPs. After formation of the reversible complex between ChE and OP (step 1), the active serine (esteratic site, E-OH) is phosphylated; the reaction leads to release of the leaving group X (step 2). The phosphylated enzyme can be reactivated by nucleophilic agents, such as oximes (contrathion or pralidoxime, MMB4, obidoxime, HI-6, etc.) used as antidotes in emergency treatment of OP poisoning (Lundy *et al.*, 2006; Worek *et al.*, 2007) (reaction 3); water is too weak a nucleophile for fast spontaneous reactivation of phosphylated ChE. The phosphyl–ChE conjugate may undergo a spontaneous dealkylation through alkyl–oxygen bond scission (''aging'') (Shafferman *et al.*, 1996; Viragh *et al.*, 1997; Masson *et al.*, 1999), resulting in irreversibly inactivated (''aged'') enzyme (step 4). The dealkylation reaction can be very fast ($t_{1/2} = 3$ min at 37°C for human AChE phosphonylated by soman). At the moment, drug-mediated reactivation of aged ChE is not possible.

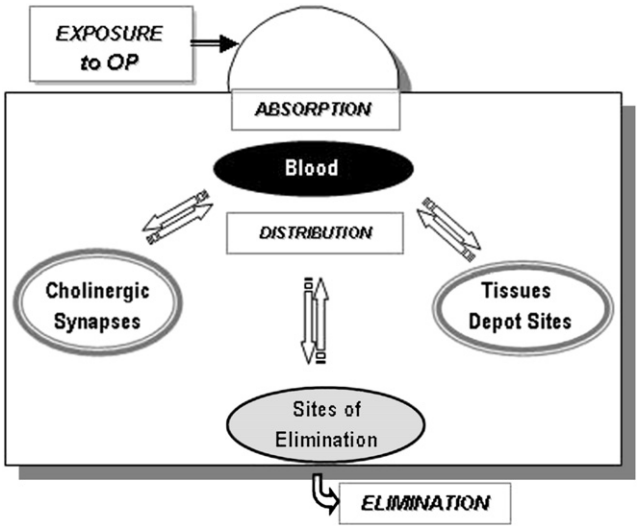

FIGURE 70.2. Biological fate of organophosphorus compounds in humans. Routes of penetration of OPs are absorption through the skin, eyes, and/or respiratory tract (nerve agents, pesticides), or ingestion (self-poisoning). OP molecules distribute from the blood compartment into tissues, including depot sites, biophase (cholinergic synapses and secondary targets) and sites of elimination (liver and kidneys). Cholinesterases are the main biological targets (acute toxicity); reaction with secondary targets (carboxylesterases, serine-amidases, peptidases, and other proteins) may be responsible for noncholinergic sublethal effects of OPs and chronic toxicity at low-dose exposure (Casida and Quistad, 2004; Costa, 2006).

with OP poisoning were evaluated (Güven *et al.*, 2004). Results suggest that plasma (fresh or freshly prepared) therapy may be an effective alternative or adjunctive treatment method. Plasma BChE, and possibly other abundant OP scavenging proteins in plasma (e.g. albumin, PON1), may have contributed to this result.

At the end of the 1980s, research on scavengers mostly focused on enzymes that specifically react with OPs. Cholinesterases (Wolfe *et al.*, 1987) and carboxylesterases (Redindo and Potter, 2005; Fleming *et al.*, 2007) have been proposed as stoichiometric scavengers. However, enzymatic stoichiometric neutralization of OP needs administration of a huge amount of enzyme, e.g. about 3 mg/kg of highly purified plasma BChE (Ashani and Pistinner, 2004). Large-scale production of enzymes under GMP conditions at a reasonable cost has been the subject of intense research over the past 10 years. However, although several thousand tons of outdated human plasma are available in the USA for preparing the enzyme, a liter of human plasma provides less than 1 mg of GMP BChE.

Today, two industrial GMP processes exist for mass production of human BChE. The first one is purification of the natural enzyme from human plasma (Cohn Fraction IV). This process has been developed by Baxter Healthcare Corporation (www.baxter.com). Human plasma derived BChE was granted Investigational New Drug (IND) status by the FDA in 2006 for protection against nerve agents (Lenz *et al.*, 2007). Clinical trials on volunteers (Phase I) started in October 2006. The second method has been developed by Nexia (www.nexiabiotech.com); it uses the recombinant human enzyme produced in milk of transgenic goats. Several grams of enzyme can be secreted in 1 liter of milk. This enzyme has been named Protexia™. Since 2005, Pharmatheme (www.pharmatheme.com) has been developing Protexia, PEGylated derivatives of this enzyme (Huang *et al.*, 2007), and fusion proteins (Huang *et al.*, 2008).

Certain secondary targets of OPs are potential bioscavengers. In particular, owing to the high number of amino acid residues in albumin that covalently bind OP molecules (5 tyrosines and 2 serines) (Ding *et al.*, 2008), it may be hypothesized that reactivity of these residues could be enhanced upon specific chemical modification. Modified albumins could lead to a new generation of stoichiometric bioscavengers. Finally, low molecular weight stoichiometric scavengers could be an economic alternative to enzyme-based stoichiometric scavengers. Several serine- and tyrosine-containing hexapeptides from a random library of peptides have been selected because they form a phosphoester bond with a fluoresent analog of sarin (Landry and Deng, 2006).

III. CATALYTIC SCAVENGERS

Catalytic scavengers are enzymes or artificial catalysts capable of degrading OPs. These catalysts detoxify OPs by hydrolyzing the phosphoester (organophosphorus acid anhydride hydrolase activity, also called phosphotriesterase activity) or lead to less toxic compounds by degrading their alkyl/aryl chains through oxidation.

The catalytic bioscavenger concept, second generation bioscavengers, is based on the idea of continuously trapping and degrading OPs in the blood stream before OP molecules reach their central and peripheral neuronal and neuromuscular targets. Then, prophylactic injection of enzymes capable of hydrolyzing OP quickly (alone or in association with current prophylactic countermeasures, i.e. pyridostigmine bromide) would allow first responders, firefighters, explosive ordnance disposal technicians, and medical personnel to operate safely in contaminated environments or with contaminated casualties. Intravenous or intramuscular administration of bioscavengers to chemical casualties is expected to greatly improve the efficacy of implemented pharmacological countermeasures (Ashani *et al.*, 1998; Saxena *et al.*, 2006).

These enzymes could be used also for protection of skin (Fisher *et al.*, 2005) and decontamination of skin, mucosa, and open wounds (Lejeune and Russell, 1999; Gill and Ballesteros, 2000). Genetically engineered bacteria producing OP hydrolases could be introduced into water effluents of decontamination units to purify contaminated water before recycling or washing up (Chen and Mulchandani, 1998).

Though research on catalytic antibodies (Amital *et al.*, 1996; Vayron *et al.*, 2000; Kolesnikov *et al.*, 2000; Jovic *et al.*, 2005) and functionalized β-cyclodextrins (Masurier *et al.*, 2005; Ramaseshan *et al.*, 2006) has made progress, engineering of enzymes capable of degrading OPs is the most promising short-term research field.

IV. REQUIREMENTS

The general requirements for the use of enzyme degrading OPs as medical countermeasures against OP poisoning are as follows.

These enzymes must have a large activity spectrum, and ideally enantioselectivity for toxic stereoisomers. Their mass production under GMP conditions must be realizable at a reasonable cost. Long-term storage without activity loss (in solution, lyophilized, or adsorbed/bound on a matrix) must be possible under field conditions. Conformational stability can be optimized by chemical modification or addition of stabilizers such as polyols. Thermostable enzymes from thermophilic bacteria (Merone *et al.*, 2005) or mutated/evolved highly stable enzymes from mesophilic bacteria (Elias *et al.*, 2008) are promising alternatives.

Other conditions depend on the method of administration, delivery system, or galenic formulation of these enzymes. For parenteral administration, the toxicant concentration in blood has to be considered. Even in the most severe case of poisoning, this concentration [OP] is always very low. For example, the sarin concentration in the serum of casualties after the Matsumoto and Tokyo chemical attacks has been estimated between 1.5 and 30 nM, 14 h post-exposure (Polhuijs *et al.*, 1997). Therefore, the [OP] in plasma is always well below the K_m of the enzyme for OP substrates. This determines first order kinetics for hydrolysis of OP in blood (Masson *et al.*, 1998) as described by Eq. (70.1):

$$v = k_{cat}/k_m \cdot [E] \cdot [OP] \tag{70.1}$$

In Eq. (70.1), the product of the bimolecular rate constant (k_{cat}/K_m) and the enzyme active site concentration ([E]) is the first order rate constant. The amount of enzyme to be injected for degradation of toxic molecules in a very short time depends on the enzyme efficiency, i.e. k_{cat}/K_m. The higher the efficiency, the lower the dose of enzyme to be administered. The enzyme concentration that reduces the OP concentration to a nontoxic concentration in time t is:

$$[E] = \frac{X}{k_{cat}/K_m.t} \tag{70.2}$$

where X is the factor by which [OP] is reduced ($X = \ln[OP]_0/[OP]_t$) (Masson *et al.*, 2008). The efficiency of a given enzyme can be increased by several orders of magnitude by mutagenesis or chemical engineering (Griffiths and Tawfik, 2003; Hill *et al.*, 2003).

The second constraint is to maintain the bioscavenger concentration, [E], in the blood as high as possible for a long time. [E] is controlled by the enzyme pharmacokinetics and/or the frequency of repeated injections. Increasing the size of the enzyme by polymerization, decreasing glycosylation microheterogeneity, and chemical modifications of the solvent-exposed surface (''capping'') improve the biological life of injected enzymes (Cohen *et al.*, 2006). Fast clearance of glycoproteins is often due to glycosylation defects. These can be corrected by chemical modifications or selection of an appropriate expression system (Chitlaru *et al.*, 1998). Immunotolerance of injected enzymes is a major issue. For instance, bacterial enzymes are not suitable for use in humans, but conjugation to dextran or polyethylene glycol is often sufficient to reduce antigenicity and slow down clearance.

Extracorporeal dialysis can be implemented for blood decontamination. Enzymes can be immobilized on dialysis cartridges (Klein and Langer, 1986). In that case, k_{cat}/K_m has to be as high as possible and the flow rate reduced to increase the efficiency of the reactor. Moreover, accessibility of OP molecules to the enzyme active center must not be altered by the immobilization method or by matrix effects. The enzyme concentration per surface unit has to be maximized to reduce diffusion constraints. First order

degradation kinetics takes place under the particular conditions of immobilized enzymes in a continuous-flow system. Immunocompatibility problems are theoretically suppressed, thus permitting the use of nonhuman enzymes.

Lastly, *in situ* transient production of enzymes, if the need arises, will be possible by gene therapy in the future. Promising results have been published with human paraoxonase (Conwan *et al.*, 2001; Fu *et al.*, 2005; Bradshaw *et al.*, 2005; Miyoshi *et al.*, 2007; Guns *et al.*, 2008) and human AChE (Li *et al.*, 2006).

Enzymes in skin and eye lotions, immobilized in foams and on tissues for skin and eye decontamination (Gordon *et al.*, 2003), or in topical skin protectants (Braue *et al.*, 2002), act under conditions where local OP concentrations can be very high. In these cases, enzyme reaction order in [OP] tends to zero, so that reaction rate is close to maximum velocity:

$$v \rightarrow V_{\max} = k_{\text{cat}} \cdot [\text{E}] \qquad (70.3)$$

The enzyme efficiency depends on its concentration and its catalytic constant k_{cat}. Thus, for external use, enzyme preparations have to be highly concentrated with high molecular catalytic activity. Co-immobilization of different enzymes could be an easy way to extend the spectra of agents to be degraded. This should allow simultaneous detoxification of G and V agents, as well as other potential chemical warfare agents. Indeed, exposure to multiple agents has to be considered. In this view, it should be remembered that during the war between Iran and Iraq, tabun and other OPs were combined to mustard gas in some attacks (UN Reports, 1984, 1987). In asymmetric conflicts, eschatological and Mafia-like terrorist activities, the most extreme scenarios have to be taken into account.

V. POTENTIAL ENZYMES

A. Cholinesterases

As seen in Figure 70.1, OPs may be regarded as pseudo-substrates of cholinesterases. When ChEs react with carboxyl-ester substrates, the acyl-enzyme intermediate is a transient, the acyl group being rapidly displaced by a water molecule. On the contrary, in the case of phosphyl-esters, the stereochemistry of the phosphyl-enzyme intermediate restricts the accessibility of water to the phosphorus atom. Thus, hydrolysis of phosphylated intermediate is very slow, and the enzyme remains inhibited (Järv, 1989). It was postulated that introduction of a second nucleophile pole in the active center could activate a water molecule. This water molecule could subsequently attack the phosphorus atom on the back face, leading to breakage of the P-serine bond.

The determination of the three-dimensional structure of AChE from *Torpedo californica* (Sussman *et al.*, 1991) opened the way to rational redesign of cholinesterases. The possibility of converting a ChE into an OP hydrolase (OPH) was demonstrated a few years later by Millard *et al.* (1995). Human BChE was chosen as the model enzyme because its active center is larger (500 $Å^3$) and less stereospecific than that of AChE (300 $Å^3$). Molecular modeling based on the structure of the *Torpedo* AChE model was used for making the first mutants of human BChE. The second nucleophile pole was created in the oxyanion hole of the active center; a glycine residue was replaced by a histidine. The first mutant, G117H, was capable of hydrolyzing paraoxon, sarin, echothiophate, and VX (Millard *et al.*, 1995; Lockridge *et al.*, 1997) (Figure 70.3). However, this mutant was irreversibly inhibited by soman because the ''aging'' process of the conjugate was faster than the dephosphorylation reaction (Figure 70.1, reaction 4). The mechanism of aging, i.e. dealkylation of an akyl chain on the adduct, is almost completely elucidated. The dealkylation reaction involves a carbocationic transient that is stabilized by active site residues E197 and W82 and water molecules (Shafferman *et al.*, 1996; Viragh *et al.*, 1997; Masson *et al.*, 1999; Li *et al.* 2007). Mutation of E197 into D, Q, or G considerably reduced the rate of aging. As expected, the double mutant G117H/E197Q was capable of hydrolyzing soman (Millard

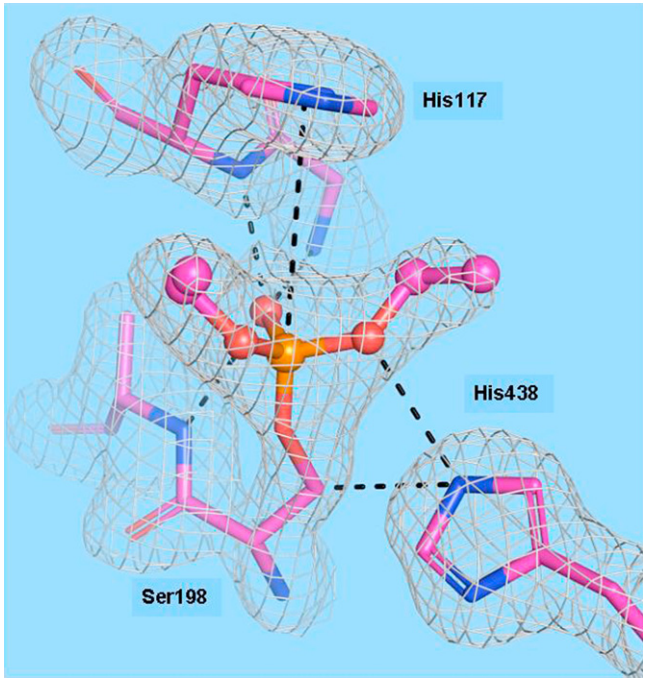

FIGURE 70.3. X-ray structure of the active center of diethylphosphorylated G117H mutant of human butyrylcholinesterase at 2.1 Å resolution (Nachon *et al.*, 2007). The enzyme was phosphorylated by soaking the crystal in 10 mM echothiophate for 5 min. X-ray data were collected at the European Synchrotron Research Facility (ESRF, Grenoble, France). Active serine (Ser198), catalytic histidine (His438), and the mutated residue (His117) in the oxyanion hole are shown as sticks. His117 is mobile enough to both activate a vicinal water molecule and stabilize the trigonal bipyramidal dephosphorylation transition state.

et al., 1999). However, the catalytic activity of this mutant was too slow to be of pharmacological interest.

The discovery of a blowfly (*Lucilia cuprina*) that is resistant to OPs because it carries a mutated carboxylesterase (CaE), G137D, at a position homologous to G117, stimulated research on G117H-based mutants of BChE. Though the OPH activity of the G137D is low, it is balanced by the abundance of the enzyme in the insect organs (Newcomb *et al.*, 1997). Transgenic mice *knockout* for AChE and carrying the G117H mutant of human BChE were found to be less sensitive to OP than wild-type animals (Wang *et al.*, 2004). Though transgenic mice expressed the G117H mutant in all organs, unlike resistance of the blowfly, their resistance to OP cannot be explained by OP hydrolysis that was too slow, but rather by hydrolysis of excess acetylcholine in cholinergic synapses.

More than 60 double or triple mutants based on G117H were made (Schopfer *et al.*, 2004), and certain mutants were eventually designed using the x-ray structure of human BChE (Nicolet *et al.*, 2003). At the same time, mutants of human AChE and *Bungarus fasciatus* AChE were made on the same principle (Poyot *et al.*, 2006). Unfortunately, none of these muteins was more active than the G117H mutants. Actually, there is evidence that mutations at position G117 cause dislocation and loss of functionality of the oxyanion hole (Masson *et al.*, 2007). For a historical review of this quest, see Masson *et al.* (2008).

Computer-assisted design of new OPH mutants of BChE is conceivable. This new approach, called ''intelligent'' directed mutagenesis design, is based on simulation of transition states. Thus, simulation of dephosphylation transition states is expected to indicate how to optimize interactions favoring productive crossing of the energetic barrier for dephosphylation. Simulation of activation transition state approach was already successfully applied to the design of BChE mutants. Using the three-dimensional structure of human BChE, molecular dynamic simulations of deacylation transition state allowed highly active mutants to be made against (−)-cocaine (Pan *et al.*, 2005; Zheng and Zhan, 2008).

Directed evolution of cholinesterases could be an alternative to computer-based methods. However, so far, functional expression of cholinesterases is difficult in yeast and has failed in bacteria.

Certain ChE mutants sensitive to OPs do not ''age'' after phosphylation; they are fully reactivatable (cf. Figure 70.1, reaction 3). Such ChE mutants when associated with oximes (e.g. 2-PAM, HI-6) act as pseudocatalysts in displacing the OP moiety bound to the enzyme. These enzyme–reactivator coupled systems could lead to a new family of pseudocatalytic bioscavengers (Kovarik *et al.*, 2007; Taylor *et al.*, 2007).

Bioavailability and biological stability of mutated ChEs for injection is an important issue. First, pharmacokinetic studies of highly purified human BChE injected into the rat showed that the half-time ($t_{1/2}$) of enzyme in the blood stream depends on sialylation of enzyme carbohydrate chains (Douchet *et al.*, 1982). It is well known that rapid elimination of asialoglycoprotein from the circulation is due to their capture by specific receptors located on the surface of hepatocytes. These receptors recognize galactosyl residue, the carbohydrate that precedes sialic acid at the terminus of complex glycans. Studies with other natural and recombinant ChEs confirmed the importance of sialic acid (*N*-acetylneuraminic acid) residues ending glycans (Kronman *et al.*, 1995, 2007; Saxena *et al.*, 1998; Cohen *et al.*, 2007). It was found that $t_{1/2}$ is inversely proportional to the number of unoccupied attachment sites of sialic acid (Kronman *et al.*, 2000). To increase $t_{1/2}$ of administered recombinant ChEs, all galactosyl residues have to sialylated. Full sialylation of recombinant enzymes can be achieved using an expression system capable of synthesizing glycans similar to natural human glycoprotein glycans and adding inhibitors of sialidase in the cell culture medium. Co-expression of the enzyme of interest and sialyltransferase in HEK 293 cells was found to lead to fully sialylated recombinant human AChE (Kronman *et al.*, 2000). Alternatively, *in vitro* sialylation of purified enzymes is possible with a sialyltransferase or using a chemical method (Gregoriadis *et al.*, 1999). PEGylation has also been proven to be an effective chemical modification for increasing circulatory half-life of administered recombinant ChE (Huang *et al.*, 2007; Cohen *et al.*, 2007; Kronman *et al.*, 2007). Recently, a 150 kDa recombinant fusion protein human albumin–human BChE showed a substantially improved pharmacokinetics when administered to juvenile pigs, $t_{1/2} \approx 32$ h against ≈ 3 h for recombinant 70% tetrameric BChE (Huang *et al.*, 2008).

B. Phosphotriesterases

1. Bacterial Phosphotriesterases

The bacterial phosphotriesterases (PTEs; EC 3.1.8.1) are encoded by the organophosphate degradation (*opd*) gene found in species of *Pseudomonas diminuta*, *Flavobacterium* sp., and *Agrobacterium radiobacter*, and genes similar to *opd* were also located in Archaea (Merone *et al.*, 2005). PTEs belong to a superfamily of amidohydrolases (Holm and Sander, 1997).

Pseudomonas diminuta PTE is a 72 kDa dimeric bimetallic enzyme with Zn^{2+} involved in the catalytic process (Carletti *et al.*, 2009, in press). Substitution of the native Zn^{2+} ions in the active site with Mn, Co, Ni, or Cd ions results in the almost full retention of catalytic activity. Following the first determination of the three-dimensional structure of *P. diminuta* PTE (Benning *et al.*, 1994), a series of crystal structures, kinetic, and spectroscopic experiments were described. Nevertheless, the enzyme mechanism is still debated and the functional roles of divalent metal cations and amino acids in the active centre are not yet fully understood (Aubert *et al.*, 2004; Samples *et al.*, 2007; Chen *et al.*, 2007; Wong and Gao, 2007; Jackson *et al.*, 2008). No natural substrate has yet been identified (Ghanem and

Raushel, 2005) and PTE is suspected to have evolved from a bacterial lactonase (Afriat *et al.*, 2006), the phosphotriesterase activity being a promiscuous activity (Elias *et al.*, 2008). Whereas the catalytic efficiency of PTE for paraoxon, the best substrate identified so far, is approaching the diffusion-controlled limit, it is slowest against OP nerve agents (Table 70.1). Meanwhile, directed evolution of PTE showed that only three amino acid changes dramatically enhanced the catalytic efficiency for an analog of soman by ~3 orders of magnitude (Hill *et al.*, 2003).

There have been numerous studies highlighting the potential of this enzyme for decontamination or skin protection in addition to OP detection (Lejeune and Russell, 1999; Gill and Ballesteros, 2000; Létant *et al.*, 2005; Ghanem and Raushel, 2005; Karnati *et al.*, 2007). Administration of PTE before or after OP exposure was shown to improve pretreatment and current treatment of OP intoxication (Doctor and Saxena, 2005). However, in order to prevent abnormally fast pharmacokinetics and/or immunological response due to injection of a bacterial enzyme, PTE could be PEGylated (Jun *et al.*, 2007) or encapsulated. First attempts at using PTE encapsulated within sterically stabilized liposomes were promising, providing protection of rats from multiple LD_{50}s of OP pesticides (Petrikovics *et al.*, 2004). An alternative route could be the blood detoxification by extracorporeal circulation through a cartridge containing PTE immobilized in hollow fibers (unpublished results). PTEs could possibly also be used for skin protection as active components of topical skin protectants (TSPs) or covalently coupled to the cornified layer of the epidermis (Parsa and Green, 2001).

PTE was also entrapped in additives for latex coating of biodefensive surfaces. Such PTE-based additives for paints and coatings were shown to retain catalytic parameters and stability of the enzyme (McDaniel *et al.*, 2006). For decontamination of OPs in the environment and remediation, an alternative approach, phytodegradation by transgenic plants (e.g. tobacco) expressing a bacterial PTE, has been considered as a potentially low-cost, effective, and environmentally friendly method (Wang *et al.*, 2008).

2. Human Paraoxonase (PON1)

The human paraoxonase-1 (PON1) is a 45 kDa calcium-dependent enzyme bound to high-density lipoprotein (HDL) particles, in association with other apolipoproteins. PON1 shows a genetic polymorphism; the most prominent determines the Q192R allozyme, which can have a substantial impact on PON1 activity against OPs and arylesters (Smolen *et al.*, 1991) (Table 70.1). The enzyme was shown to be involved in the protection against atherosclerosis (Shih

TABLE 70.1. Catalytic efficiency (k_{cat}/K_m $10^6 \cdot M^{-1}$ min^{-1}) of different natural and engineered OP hydrolases towards different OPs

et al., 1998; Watson *et al.*, 1995) and thus became a player in vascular physiology. Although its primary function is likely to be a lipophilic lactonase (Khersonsky and Tawfik, 2005), PON1 displays promiscuous enzyme activities.

Abundant biochemical, biological, and toxicological information has been collected for a decade, leading to partial characterization of the enzyme function (Costa and Furlong, 2002; Mackness *et al.*, 2008), but recurrent attempts at solving the structure of human PON1 failed. Through chemical modification and site-directed mutagenesis studies, some amino acid residues have been identified as essential for activity (Josse *et al.*, 1999). Finally, molecular modeling (Fokine *et al.*, 2003; Yeung *et al.*, 2004) and crystal structure of a hybrid rPON1 (a synthetic construct issued from shuffling of rabbit, mouse, rat, and human PON1 genes expressed in *E. coli*) (Harel *et al.*, 2004) showed that human PON1 is a six-bladed β-propeller protein with a structure very similar to that of *Loligo vulgaris* DFPase (Katsemi *et al.*, 2005). The phosphotriesterase mechanism of this eukaryotic calcium-dependent enzyme was recently described (Blum *et al.*, 2006). Confirmation of a similar mechanism for human PON1 activity would considerably help in designing more active PON1 mutants.

As a naturally occurring enzyme present in plasma, human PON1 is the most promising catalytic scavenger candidate for pretreatment and therapy of poisoning by OP (La Du, 1996; Rochu *et al.*, 2007a). Thus, the enzyme is the focus of intensive research to improve its efficacy and functionalization. To provide a valuable medical countermeasure against intoxication by nerve agents, the catalytic efficiency of PON1 has to be enhanced by only one or two orders of magnitude. New rPON1 mutants obtained by directed evolution and exhibiting enhanced OP-hydrolase activity (Amitai *et al.*, 2006) suggest this goal could be achieved reasonably soon. However, instability of the mutants of interest could impinge on their biotechnological development. Indeed, as an HDL-bound protein, PON1 requires association to apolipoprotein partners to retain its stable active conformation (James and Deakin, 2004; Gaidukov and Tawfik, 2005).

Human phosphate binding protein (HPBP), an apolipoprotein that binds inorganic phosphate in blood, was serendipitously discovered. Its three-dimensional structure and complete amino acid sequence were solved (Morales *et al.*, 2006; Diemer *et al.*, 2008). The conditions found to separate HPBP and PON1 *in vitro* indicated that HPBP is strongly associated with PON1 (Renault *et al.*, 2006). Moreover, the stabilization of the active form(s) of human PON1 by HPBP suggests that HPBP could be a functional chaperone for PON1 (Rochu *et al.*, 2007b, c).

Our strategy is now to attempt co-crystallization of the PON1/HPBP complex. For this, the first step will be to construct a hybrid gene allowing co-expression of HPBP and PON1 in *E. coli*. This approach needs to have the gene coding for HPBP, up to now not found in the human genome. To overcome the difficulty of this absence, we made a synthetic gene issued from amino acid sequence data (Diemer *et al.*, 2008). Afterwards, co-expression of the PON1/HPBP complex will be attempted. Co-expression, aimed to favor correct folding of active PON1 and stabilization of the active functional conformation of the enzyme, is expected to provide crystallizable PON1/HPBP complex. Finally, diffractable crystals of the complex are assumed to provide the three-dimensional structure of natural human PON1. This crucial phase will be the first step on the staircase leading to the development of stable human PON1 mutants with enhanced catalytic efficiency against OPs.

Gene therapy could also be considered to challenge OPs by using a mutated PON1 gene coding for an enzyme with high OPH activity against nerve agents. Several approaches with different gene delivery vectors in mice showed increased PON1 level serum that reduced or even prevented the entry of OP into the brain, and reduced atherosclerosis signs (Conwan *et al.*, 2001; Fu *et al.*, 2005; Bradshaw *et al.*, 2005; Guns *et al.*, 2008). Local delivery of PON1 gene using Sendai virus vector inhibited neonatal hyperplasia after arterial balloon injury in rabbits fed a high-fat diet (Miyoshi *et al.*, 2007). Thus, enhanced expression of PON1 by gene therapy could be beneficial for the different functions of the enzyme. Meanwhile, the complex and defectively identified PON1 activities make it apparent that strategies for repetitive administration of high concentrations in humans must be undertaken cautiously.

C. Other Enzymes

Other enzymes are involved in biodegradation of OPs, e.g. hydrolases such as prolidases; others are oxidases such as cytochrome P450s, glutathione *S*-transferases, laccases, and peroxidases. Prolidases (EC 3.4.13.9) were first isolated from halophilic bacteria (*Alteromonas haloplanktis* and *Alteromonas* sp. JD6.5). Prolidase from *Alteromonas* sp. JD6.5 is an OPAA that displays the highest known activity against soman ($k_{cat} = 3{,}100\ s^{-1}$), but it is inactive against VX (Cheng *et al.*, 1999). Prolidase was also isolated from human liver. This enzyme displays a catalytic activity against soman (Wang *et al.*, 1998) and exhibits sequence homology with the *A. haloplanktis* prolidase (Wang *et al.*, 2006). Glutathione *S*-transferases (GST; EC 2.5.1.18) are 20–30 kDa enzymes that catalyze glutathione conjugation (nucleophilic attack of the thiol group) to electrophilic substrates. They are involved in cellular detoxification processes of endogenous compounds and of numerous xenobiotics, and their role in resistance to insecticide of insects is well established. OP detoxification by GSTs results from a regioselective dealkylation of alkyl or aryl side chain (Maturano *et al.*, 1997). These enzymes exhibit wide genetic polymorphism. Some GST allelozymes from the flies *Drosophila melanogaste*r and *Musca domestica*, highly active against OP insecticides, have been cloned and expressed in *E. coli* (Fournier *et al.*, 1992). There is evidence that GSTs contribute to OP detoxification in

humans (Fujioka and Casida, 2007). Laccases (EC 1.10.3.2) are fungal phenol oxidoreductases that have been used for detoxification of numerous xenobiotics, including dyes and pesticides (Richardt and Blum, 2008). The laccases from *Pleurotus ostreatus* and *Chaetomium thermophilium* were found to rapidly degrade VX and VR in the presence of 2,2′-azinobis(3-ethylbenzthiazoline-6-sulfonate) (ABTS) as a mediator (Amitai *et al.*, 1998). In our laboratory, we found that laccases from *Trametes versicolor* and *Coriolopsis polyzona* with ABTS display similar properties against V agents (Trovaslet *et al.*, unpublished results). The heme-containing chloroperoxidase (EC 1.11.1.X) from *Caldaromyces fumago*, with peroxide as co-substrate, is another efficient VX-degrading enzyme (Amitai *et al.*, 2003).

These enzymes are promising for destruction of chemical weapons stockpiles, soil remediation, decontamination of materials, protective equipment, and water polluted by pesticides and nerve agents (Russel *et al.*, 2003). In particular, phosphorothiolates such as VX are relatively resistant to PTE. Thus, oxidative cleavage of the P–S bond could be achieved by oxidases like laccases. These enzymes could be used in association with other OP-degrading enzymes for skin decontamination or in topical skin protection formulations. Though no work has been performed on combined action of oxidases and hydrolases, oxidation of P-bonded alkyl/aryl chains by oxidases is expected to alter enantioselectivity of PTE for parent OPs, and therefore to improve the efficiency of catalytic bioscavengers.

VI. CONCLUDING REMARKS AND FUTURE DIRECTION

Enzymes that neutralize or degrade OPs can be purified from natural sources, e.g. human plasma. Recombinant enzymes can be produced using procaryotic expression systems (*E. coli*) or eucaryotic expression systems (yeast, insect, mammalian cell cultures), or transgenic animals (worm, rabbit, goat), or transgenic plants (tomato, potato, tobacco), and also acellular biosynthetic systems. The goal of current research in protein engineering is to improve mass production of stable muteins at low cost. OP hydrolases improvement of *in vitro* and *in vivo* catalytic properties toward nerve agents and pesticides is still the main issue. In addition, improvement of thermodynamic stability (storage stability in solution or in dry forms) and *in vivo* operational stability, improvement of immunotolerance and biodisponibility are other goals. For this purpose, the different strategies of enzyme engineering have been implemented. They consist of research into new natural enzymes, in particular in extreme environments (Feerer *et al.*, 2007) – potential extremozymes have been discovered in halophilic, thermophilic, and piezophilic bacteria – in insects resistant to OP pesticides, and among secondary targets of OPs in humans. Molecular modeling and transition state simulations, site-directed mutagenesis and directed evolution approaches in combination with chemical modifications and medium manipulations have been used with success to improve the desired properties of selected enzymes (Bershtein and Tawfik, 2008). Lastly, pharmacokinetic, toxicokinetic, and immunological studies on animal models allow the validation of enzymes of interest.

Catalytic bioscavengers will be part of the arsenal of medical countermeasures for prophylaxis and treatments of OP poisoning in the very near future. Next, gene therapy will offer the possibility of transitory production of humanized OP-degrading enzymes in the body. Multiple enzyme associations will be part of active topical skin protectants and decontamination tools.

CHAPTER 71

Rapid Decontamination of Chemical Warfare Agents

RICHARD K. GORDON AND EDWARD D. CLARKSON

I. INTRODUCTION

Chemical warfare agents are some of the most lethal and sinister substances manufactured (organophosphates) and the most psychologically threatening (vesicants). Organophosphate nerve agents include tabun (GA), sarin (GB), and soman (GD) and the low volatile compound VX, some of which were incorporated into munitions during World War II. Sarin was used by terrorists in the mid-1990s in Japan. The chemical nerve agents irreversibly inhibit the enzyme acetylcholinesterase (AChE) in both the central nervous system (CNS) and peripheral nervous system (PNS). When AChE is inhibited, it cannot hydrolyze the neurotransmitter acetylcholine (ACh). Excess endogenous ACh produces characteristic signs of nerve agent poisoning and cholinergic overload, such as hypersecretion and respiratory distress. When the nerve agent accesses the CNS, symptoms such as convulsions appear and lead to coma and death. In contrast, vesicants, such as sulfur mustard used in World War I and the Iran–Iraq War in the 1980s, are known not for lethality, but for the resulting burns and blisters that incapacitate military personnel. In contrast to nerve agents, where symptoms are observed in minutes, sulfur mustard presents clinical symptoms hours after exposure, although tissue damage by alkylation is rapid. Sulfur mustard alkylates peptides, proteins, and nucleic acids, and perturbs other cellular components. It is documented that to reduce the effects of chemical warfare agents, decontamination of the skin soon after exposure is the best post-medical countermeasure against chemical warfare agents. Thus, the decontamination product should be lightweight for incorporation into the limited space in a soldier's pack and easily used in the field under harsh and likely confusing conditions. Personal wipes, pads, and sponges have been developed to facilitate this goal. These products should exhibit long-term stability and be nontoxic and environmentally friendly. In addition to removing these toxic agents from skin, increased effectiveness can be obtained by detoxification of the chemical agents both on and in the skin and upon removal to protect the environment. Detoxification of the agent will also prevent secondary contamination of medical personnel or a soldier's buddy. The different approaches to solving field decontamination and detoxification are explored in this chapter. The importance of continued improvement of personal decontamination products cannot be underestimated when one considers today's constant threat of chemical warfare, terrorist acts, and pesticide spills.

II. THE NATURE OF HUMAN SKIN

Human skin, the largest human organ, developed as a physical barrier to the environment (to keep things out) but also maintains the aqueous nature of the human body (to keep things in). Mammalian skin consists of three major layers: stratum corneum, epidermis, and dermis. The stratum corneum, the thin outer layer of keratin-filled dead cells (corneocytes) bounded by densely crosslinked protein and embedded in crystalline lamellar lipids, represents the major barrier protecting the body from loss of internal components and entry of undesirable external materials. The layer underneath the stratum corneum, the epidermis, contains cells that differentiate from viable keratinocytes to corneocytes during their migration from the dermis to the stratum corneum. It also contains a large number of specialized dendritic cells. Smaller amounts of specialized cells are integral to the epidermis, including the pigmentation melanocytes, the immunological Langerhans cells, and the sensory Merkel cells. Throughout the epidermis sebaceous glands, sweat glands, and hair can be found. The next inward layer, the dermis, contains hair follicles with associated sebaceous glands, ecrine sweat glands and ducts, dendritic cells, and a vascular network including subepidermal capillaries, vascular plexi associated with the sweat glands, and dermal papillae associated with the hair follicles. Capillaries are responsible for transporting any chemicals that enter the skin systemically. Recent reviews of the skin structure and permeation are available for further reading (Menon, 2002; Hadgraft and Lane, 2005; Godin and Touitou, 2007; Wester and Maibach, 2000).

The stratum corneum, composed of keratinized dead cells that are continually being replaced, is the first major barrier to chemical agents. The barrier qualities of the stratum corneum depend on a number of factors, including its location on the body, which affects thickness, and how much hair is present. Thus, hair follicles and sweat glands can either provide channels through the stratum corneum, and thereby bypass its barrier attributes, or at least provide increased surface area for penetration of compounds, since a number of compounds were shown to penetrate faster in hair follicle-rich areas (Illel *et al.*, 1991). Maibach studied three radiolabeled pesticides – parathion, malathion, and carbaryl – for their permeability at 13 different anatomical sites in humans (Maibach *et al.*, 1971). Variations in percutaneous penetration were observed; higher penetration of the pesticides occurred at the abdomen and dorsum of the hand.

The lipid matrix is another feature important for barrier function in the epidermis. The arrangement of lamellar-like sheets yields a barrier to hydrophilic compounds and transcutaneous water transport. Extraction of those lipids from skin with organic solvents reduces barrier function (Hadgraft, 2001). The lamellae, which have few phospholipids as they are catabolized, ultimately contain mainly ceramides, cholesterol, and fatty acids (Wertz and Downing, 1989; Bouwstra and Ponec, 2006). The resulting matrix is composed of nonpolar compounds enriched in cholesterol that are adapted to protect from water loss. While extraction of these lipids may increase the penetration of aqueous moieties, in the case of organophosphates (note the organic-like nature of the chemical warfare agents, as described below), the hydrophobic nature of skin likely facilitates partition of these chemical agents through the lipid matrix, which then enter the subepidermal capillaries for dissemination throughout the body. Further insight into the barrier properties of skin can be observed in disease states including psoriasis, where there is an increase in epidermal cell replication yielding an irregularly stacked stratum corneum and abnormal capillaries in the dermis. This leads to an increase in drug penetration such as hydrocortisone (Kranz *et al.*, 1977). No studies have evaluated pesticide or chemical warfare agent penetration in psoriasis.

Aging contributes to decreased lipid barrier protection, decreased intercellular cohesion and increased absorption of toxic material. This barrier is also complicated by environmental effects such as exposure to sun, disease, and other aging processes that include many changes to the structure of the skin. Examples of such changes are decreased amounts of collagen, loss of melanocytes, decreased number of glands and hair follicles, reduced blood flow (Yates and Hiley, 1979), and the loss of lipid content in the stratum corneum (Elias and Ghadially, 2002). Another study found that 11 of 14 pesticides showed different rates of skin penetration in aged rats compared to young rats (Shah *et al.*, 1987). Generally, decreased absorption occurred in studies of aged skin (Fisher *et al.*, 1992; Farage *et al.*, 2007).

Percutaneous absorption *in vivo* leads to the occurrence of chemical or drug delivery to the microcirculation in the dermis. The period of time that it takes for entrance to the blood supply and circulation throughout the body depends on the diffusion parameters and the interaction with the lipid matrix (Roberts, 1997). Thus, chemicals exhibiting a longer lag time through the skin should be less toxic if quickly removed compared to rapidly penetrating compounds. Another aspect of percutaneous absorption is whether there are single or multiple exposures to the chemical. Some chemicals, such as azone (1-dodecylazacylohepan-2-one), alter the organization of the skin so that there is an increase of absorption or synergistic effect observed with each exposure (Ademola *et al.*, 1993). Chemicals that do not alter the skin's structure would not be likely to increase their bioavailability and absorption, but rather provide an additive response (Bucks *et al.*, 1985).

III. ORGANOPHOSPHATE NERVE AGENTS

Nerve agents are among the most toxic of the known chemical agents. Nerve agents are organophosphates (OPs) that bind irreversibly to acetylcholinesterase (AChE) (Taylor *et al.*, 1999), and to the bioscavenger butyrylcholinesterase (BChE) (Wolfe *et al.*, 1992) in both the peripheral and central nervous system. AChE is responsible for terminating the action of the neurotransmitter acetylcholine by hydrolysis. OP-inhibited AChE results in an excess of acetylcholine and the overstimulation of muscarinic and nicotinic receptors. Characteristic signs of nerve agent poisoning and cholinergic overload include hypersecretion and respiratory distress. When the nerve agent is transported past the blood–brain barrier, convulsions can lead to coma and death. OPs pose a hazard in both their vapor and liquid states. Notably, AChE inhibitors are used as both a therapy for treating glaucoma, myasthenia gravis, Alzheimer's disease or atropine poisoning and for more sinister reasons, e.g. as pesticides to kill insects and as chemical warfare agents by terrorists and in warfare to kill humans (Sidell, 1977; Leikin *et al.*, 2002; Martin and Lobert, 2003).

The G-nerve agents include GA (tabun, ethyl *N*,*N*-dimethyl-phosphoramidocyanidate), GB (sarin, isopropyl-methylphosphonofluoridate), GD (soman, 1,2,2-trimethylpropyl methylphosphonofluoridate), and VX (*o*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothiolate). The V-type nerve agents are several orders of magnitude less volatile than the G-type agents and act primarily as a liquid via the percutaneous route; for example, VX is several orders of magnitude more lethal percutaneously than sarin (Reutter, 1999).

Log P data (octanol:water partition coefficients and a reflection of lipid solubility) of nerve agents were used to both predict absorption through the skin and determine the distribution of OP compounds in tissues, and then correlated with toxicity as measured by the onset of fasciculation in

guinea pigs. An excellent correlation ($r = 0.95$) was established between the measured log P value and the rate of onset of local fasciculations, reflecting absorption in the skin and penetration to blood and dissemination to muscle tissue throughout the animal (Czerwinski *et al.*, 2006).

Maxwell and Lenz (1992) reported that, in general, AChE and BChE are more reactive with cationic nerve agents such as VX, while neutral agents that contain less than two bulky groups (e.g. GA, GB, and GD) were equally reactive with the cholinesterase enzymes. Since AChE has a smaller active site than BChE, the size and ionic character of the active sites determine the specificity of these esterases for the agents. The estimated ranked percutaneous nerve agent LD_{50}s are VX > GD > GA > GB, which reflect their volatility. The ranked volatility for these agents is VX < GA < GD < GB.

Using parathion as a model simulant for the nerve agent VX, the *in vitro* percutaneous absorption through unprotected human skin and clothed and uniformed skin was determined. The percent parathion dose absorbed through the unprotected skin was significantly greater than that observed through dry uniformed skin, while absorption was higher through the wet (sweat) uniform. These results suggested that military uniforms and public clothing provide protection to this stimulant and by analogy to VX; but absorption through cloth and skin quantitatively occurred more readily with wet clothing than dry. Thus, even with clothing, immediate responses and decontamination of skin and clothing are required (Wester *et al.*, 2000).

In conclusion, due to the extreme toxicity of nerve agents, the search for medical decontamination countermeasures to OPs is of paramount importance. Rapid removal from the skin would prevent penetration to the general circulation and the resulting decrements of cholinergic toxicity, which ultimately leads to seizure and/or death in untreated individuals. In the development of medical decontamination countermeasures to nerve agent poisoning, it is acknowledged that different nerve agent administration routes are likely to have different requirements for effective treatment. There is a limited window of opportunity for decontamination treatment following agent exposure. The signs of poisoning develop within minutes, and if decontamination is delayed, it is likely that toxic levels of the nerve agents will be disseminated via the blood stream after the agent has been absorbed. Decontamination will prevent continued absorption of the agent, reducing the need for further medical management (Table 71.1) (Hamilton *et al.*, 2004; Clarkson *et al.*, 2004).

Hamilton *et al.* (2004)

IV. VESICATING AGENTS (DISTILLED SULFUR MUSTARD, HD; IMPURE SULFUR MUSTARD, H; LEWISITE, L)

Sulfur mustard (HD), a synthetic vesicating agent, was a major chemical warfare agent during World War I and continues to be a modern-day threat (Reutter, 1999; Ghanei and Harandi, 2007; Bismuth *et al.*, 2004). Sulfur mustard's simple and cheap chemical synthesis makes it readily accessible to terrorists and use by the military. Sulfur mustard is an alkylating agent that causes its damage by disrupting nucleic acids and proteins, impairing cell homeostasis and eventually causing cell death, although the significance of the multiple pathways is unclear (Smith *et al.*, 1995). Whole-body exposure results in cutaneous (liquefaction necrosis of the epidermis), respiratory (injures the laryngeal and tracheobronchial mucosa), and ocular effects (severe conjunctivitis). In contrast to H agents, there is no delay with lewisite, which produces immediate burning of the skin and eyes. Compared with the G-nerve agents, sulfur mustard has a relatively low acute lethal toxicity, that is, its toxicity as an incapacitating agent is of much greater concern than its capacity to kill. Furthermore, mustard is persistent in the soil and other materials for hours to weeks (Devereaux *et al.*, 2002).

The skin is an important port of entry for vesicating agents. The agent's lipophilic nature, and the propensity of skin to exclude aqueous compounds but not lipophilic substances, make the skin an unwitting transport system. An increase in ambient temperature causes increased penetration (which was used effectively in World War I, where it was disseminated at night and warmed in the early morning sun). It has been estimated that 80% of liquid mustard evaporates, and 20% penetrates the skin. Of the 20%, 12% is retained in the skin matrix, while 8% is absorbed systemically, so only large dosages of mustard will produce significant systemic toxicities (Cullumbine, 1947; Dacre and Goldman, 1996).

Mustard skin lesions first present erythema followed by blisters (Somani and Babu, 1989). Erythema usually begins 2–24 h after contact, followed by acute itching, which diminishes as the characteristic blisters appear. Blisters initially appear 18 h after contamination as small vesicles within the area of erythema, which then coalesce to form the characteristic pendulous blisters containing large volumes of clear but yellow fluid. Blisters are not painful *per se* but they may be uncomfortable and may feel tense. Warm, moist areas such as genitalia and axilla are more likely to exhibit bullous lesions. By 48 h post-exposure, blistering is clearly evident and a new round of blisters appears. Due to the disruption of the skin layer, the large blisters break leading to erosions and full thickness skin loss and

ulceration, necrosis, and 72 h post-exposure, formation of an eschar. The eschar sloughs in a 4–6 day time period, finally leaving a pigmented scar (Reid *et al.*, 2000, 2007). The burn caused by blister agents is much slower to heal in comparison with a thermal burn, likely due to the multiple mechanisms by which the agent affects biological tissue, as known from World War I and reestablished in Iranian casualties. The site of healed mustard burns is hypersensitive to mechanical trauma. In a comparison of cutaneous lesions in 500 mustard-exposed Iranian veterans and 500 unexposed veterans, a correlation was observed between exposure and skin lesions such as severe dry skin, hyper- and hypopigmentation, local hair loss, eczema, and chronic urticaria. Histopathological examination of skin biopsies has revealed nonspecific findings including epidermal atrophy, keratosis, and basal membrane hyperpigmentation (Balali-Mood and Hefanzi, 2006).

V. MODEL SYSTEMS TO MEASURE ABSORPTION, REMOVAL, AND DECONTAMINATION

A. Rats

There are many different animal models that have been used to assess the percutaneous absorption of toxic chemicals. There is little question that while *in vivo* human studies are best for predicting the absorption of percutaneous applied chemical warfare agents, ethics preclude conducting such studies. Rats have been widely used in the study of skin contamination, wounds, and healing and the efficacy of different decontamination modalities (Wester and Maibach, 2000; Shah *et al.*, 1987; Baynes *et al.*, 1997).

B. Guinea Pigs

While rats are often selected for their availability, low cost, small size, and thorough biological characterization, they are not the ideal chemical warfare agent model because they contain a high amount of carboxylesterase, a potential hydrolytic enzyme for OPs (Sweeney and Maxwell, 2003). Unlike rats, humans have small amounts of this enzyme relative to acetylcholinesterase and butyrylcholinesterase. To overcome this limitation, the guinea pig, which exhibits low carboxylesterase, has been developed as a model for chemical warfare agent exposure (Fonnum *et al.*, 1985). Guinea pigs have been evaluated for skin damage due to burns, often used as a wound healing model for sulfur mustard (Ramos *et al.*, 2008), and for skin irritation to toxic industrial chemicals (Kennedy, 2007; Weaver *et al.*, 2003). Guinea pigs have also been used to study absorption of chemical warfare agents through the skin (Dalton *et al.*, 2006; Wormser *et al.*, 2002), uptake of radioactive sulfur mustard through guinea pig skin (Logan *et al.*, 1999), as animal models for pretreatment regimens to protect against chemical warfare agents (Wetherell *et al.*, 2006), and as a model of cholinesterase activity assessments (Haigh *et al.*, 2005) to GD exposure and OP-induced seizure (Harrison *et al.*, 2004).

For evaluating the decontamination of guinea pig skin, typically, sedated and shaved guinea pigs were cutaneously exposed to neat soman on their sides. One minute after exposure, a sponge wrapped around a pair of forceps was moved across the guinea pig's side; then the forceps were rotated 180 degrees, so that the clean surface of the sponge was pointed at the animal. Three more passes were taken from the rear towards the front. An identical procedure was used when the protocol required an additional second sponge to decontaminate the animal. Similarly, guinea pigs were used for decontamination of sulfur mustard. In this case, 24 h post-neat HD exposure and decontamination, animals were injected with trypan blue and then euthanized. The skin covering the backs of the animals was removed. In addition, skin punches were taken from each of the exposure sites (control, exposed, and decontaminated sites) (Gordon *et al.*, 1999; Gordon and Doctor, 2003).

C. Swine

Pig skin has long been a valuable model for human skin (Meyer *et al.*, 1978; Riviere and Monteiro-Riviere, 1991) since pig skin expresses a sparse hair covering, epidermis, and a similar arrangement of dermal collagen and elastic fibers to human skin. Again, many investigations have used the porcine skin model to study cutaneous toxicology of sulfur mustard (Gold *et al.*, 1994). Pig skin, because of its similarity to human skin with respect to hair covering, apocrine sweat glands, and other morphological similarities (Reifenrath *et al.*, 1991), is an attractive model for cutaneous absorption and toxicology studies of OP nerve agents (Hamilton *et al.*, 2004). Cutaneous absorption studies show that pig skin permeability, compared to rat and rabbit, most closely resembles that of human skin (Bartek *et al.*, 1972) with a variety of test agents. Therefore the pig represents a good model to assess the effects of introduction of extraneous material or chemicals on the early events of exposure. The downside is that pigs are large animals, difficult to house, are more costly, and require special cages to maintain them in comparison to rodents.

VI. DECONTAMINATION REQUIREMENTS

Medical decontamination executes removal and/or neutralization of chemical warfare agents, which, upon penetration of the skin, produces vesication, or for OPs, penetrates to the systemic circulation and inactivates ChEs. The most important process for the exposed soldier or civilian is to remove the chemical agent from the skin as quickly as possible. The soldier, under harsh conditions, must use the

product quickly to minimize transdermal penetration. A decontaminant that inactivates the chemical agent prevents its penetration through the skin and potentially protects a medical worker or buddy from suffering a second hand exposure.

Other criteria for the decontaminating system and reagents are that they are as universal as possible and protect against the various classes of chemical agents (as well as radiochemicals and biological agents, although the latter compounds will not be discussed). In other words, the soldier has a limited amount of space and weight to carry, and cannot carry multiple decontamination schemes. Furthermore, it is unlikely that a soldier would be able to determine the type of agent with which he is contaminated in the absence of symptoms.

In addition, proven efficacy of a decontamination product would have to meet Federal Drug Administration (FDA) guidelines and approval, assuring safety of the product for the soldier. The product should be environmentally safe to use by itself and render the chemical/biological agent environmentally safe, to prevent cross-contamination. Logistics would preclude decontamination products that require freezing or refrigeration, since they would not be available in the field. Lastly, the product needs to be simple and easy to use by the soldier under stressful conditions. Complicated decontamination procedures are unacceptable, since they increase the probability of failure during the stressful decontamination procedure. Products like the M291 kit (see below) are used by simply wiping the contaminated skin, and do not require significant training. However, the M291 kit has some drawbacks, such as a black offensive dust that is precluded from the eye. Thus, a decontaminating product should not have offensive odor (as some potential mercapto compounds exhibit) (Shi *et al.*, 2008) and be nonirritating and nonallergenic, or the product will be hesitantly used.

Methods for decontamination, neutralization, and removal of chemicals, such as OP and organosulfur compounds, herbicides and insecticides, are known in the literature (Hurst, 1977; Houston and Hendrickson, 2005; Rosenberg, 2005; Baker, 2004). The compositions and devices utilized for medical purposes are markedly different from nonmedical devices; the latter are not compatible with the skin or other sensitive tissues, having undesirable properties such as corrosiveness, flammability, toxicity, difficulty in making and storing, two component system composition, and limited shelf-life. For example, DS2, a standard decontamination agent, is comprised of 70% diethylenetriamine, 28% ethylene glycol monomethyl ether, and 2% NaOH by weight (Modec, 2003). Although DS2 is effective, it is corrosive upon exposure to air. DS2 and any matter resulting from its use are classified and regulated as hazardous material. After an application, the DS2 must stand for 30 min before rinsing the treated area with water. Additionally, DS2 comprises a teratogen. Clearly, this is not a better method for neutralizing, detoxifying, decontaminating, and cleaning personnel exposed to chemical warfare compounds.

VII. DECONTAMINATION SCHEMES

OP nerve agents are a serious threat to military and civilian personnel. Another serious problem that may be encountered while caring for personnel contaminated with OP nerve agents is the possibility that there will be cross-contamination to the medical personnel treating affected personnel. During combat or terrorist acts, individuals might be exposed to chemical toxins before they don their protective gear. Several schemes, each exhibiting their own advantages and disadvantages as medical decontaminants, are described below. While the ideal candidate does not exist, the final product must be fieldable for the individual – that is, for personal use in a rapid, deployable manner. Simple materials such as bleach and complex products such as OP-degrading immobilized enzymes sponges are described. Inexpensive and readily available household materials were tested for pesticide decontamination of fabric materials over 20 years ago (Easter and De Jonge, 1985). The household products provided only marginal decontamination efficacy.

A. Classical Liquid–Sodium Hypochlorite (Bleach)

Decontamination methods employing hypochlorite formulations have some corrosive and toxic side effects. A Chlorox® (hypochlorite) solution is composed of household bleach, which is about 5% sodium hypochlorite. Thus, for a 0.5% solution, bleach is mixed with 9 parts water, although even this diluted solution is contraindicated for use in or on a number of anatomical areas including the eye.

Undiluted bleach is not used because it is toxic to the skin and may create more damage than no decontaminant. Hairless guinea pigs were exposed to sulfur mustard in wounds and the surrounding intact skin, and then decontaminated with water, 0.5 or 2.5% bleach. No significant differences were observed among wounds decontaminated with the three solutions. Unexpectedly, the skin surrounding nondecontaminated (but exposed) control animals showed the least visual pathology. The lesions observed after decontamination might be due to the mechanical flushing of sulfur mustard onto the perilesional skin, by chemical damage of the skin induced by the solution, enhanced penetration of the agent, or interaction of sulfur mustard with the decontaminating solutions (Gold *et al.*, 1994). In a study evaluating decontamination of GB from skin, it was observed that rabbits receiving GB had no convulsions or deaths without decontamination. In contrast, when decontaminated with 5% bleach, there were increased symptoms and death, suggesting that 5% bleach perturbed the protective barrier of the skin or facilitated GB transport through the skin (Kondritzer *et al.*, 1959). Since diluted bleach

(0.5%) is a nonirritant to human skin, it is preferred (Racioppi *et al.*, 1994).

In contrast, the effectiveness of diluted bleach has been demonstrated. This study measured the rate of sulfur mustard disappearance from the skin after topical application of the vesicant, which rapidly penetrates the skin due to its hydrophobicity. Three swabbing treatments of undiluted HD-exposed skin with gauze pads soaked in 0.5% hypochlorite caused 68% reduction in skin HD content and a 64% reduction when hypochlorite was replaced by water (Wormser *et al.*, 2002). The effectiveness of 0.5% hypochlorite with water for decontaminating sulfur mustard on guinea pigs was also evaluated. However, the gauze pads soaked with the bleach contained microgram quantities of HD when water was used but no detectable HD levels when 0.5% bleach was used. Thus, the neutralizing effect of 0.5% bleach occurred after the agent was removed from the skin and away from the lipophilic structures of the skin where the 0.5% hypochlorite could react with and reduce levels of the agent.

Similar to bleach's oxidative iodine properties, topical povidone–iodine at 15 and 30 min post-exposure to sulfur mustard exhibited protective effects. Severity of the dermal parameters, acute inflammation and dermal necrosis was significantly reduced, and reduced skin damage was observed in areas adjacent to treated sites (Brodsky and Wormser, 2007).

B. Powder Decontamination Material: M291 Skin Decontamination Kit

The current individual product provided to the US soldier for use in the field is the M291 personal skin decontamination kit (Figure 71.1). There are three main components incorporated into individual pouches: a fiber pad (six to a pouch), an absorbent activated charcoal, and a reactive resin (Ambergard XE-555). Each component serves a unique purpose. First, the cotton pad provides structural integrity for use on a finger. Second, the carbon incorporated into the pad absorbs organic material such as OPs and HD. Third, the ion-exchange resin binds chemical agents and very slowly detoxifies them. The soldier takes the M291 pad and rubs the area that needs to be decontaminated. The goal is to rapidly bind chemical agents still on the surface of the skin and prevent their penetration through the stratum corneum. The M291 kit is precluded from use in the eye because its particulate nature is irritating; but can otherwise be used on the face and around wounds. Much of the black powder from the M291 kit remains on the skin, and has been a deterrent to its use. However, the black powder provides the soldier with an indication that the material still remains and should be brushed off for maximum effectiveness.

Efficacy of the M291 kit has been evaluated in a number of animal models for OP poisoning (DO49 Technical Report, 1987). In an early report, rabbit skin was shaved (to mimic human skin without fur) and then the skin exposed to

FIGURE 71.1. M291 kit (www.defenselink.mil).

GD and VX for 2 min. Decontamination with the M291 kit yielded higher LD_{50}s (of more than ten- and 20-fold, respectively) (Hobson *et al.*, 1985), in comparison to control (not decontaminated) animals. In another study, with rabbits under similar conditions, the penetration of the organophosphate VX was measured by red blood cell AChE inhibition. The M291 kit increased the amount of VX required to inhibit AChE by 50% (Joiner *et al.*, 1988). Thus, the M291 kit neutralized and/or removed VX so that less penetrated through the skin to be systemically delivered as indicated by RBC AChE inhibition. In another animal model, the guinea pig, decontamination with the M291 kit after 1 min of neat exposure to GD increased the LD_{50} from 9.9 to 17.7 mg/kg, yielding a protective ratio of 1.8. Some of the differences in protection can be related to the animal model (rabbit in comparison to the guinea pig as described above) and likely methods of decontamination (number of wipes with the M291 pad). The M291 kit is also efficacious in rabbits against the vesicating agents HD and L. Shaved dorsal skin of rabbits was exposed to neat HD and then decontaminated after 1 min. Vesicant-induced histopathology determined after tissue staining was reduced over 20-fold compared to nondecontaminated control rabbits.

C. Liquid Decontamination Material – Sandia Foam

Sandia National Laboratories decontaminating foam (licensed to Modec Inc., Denver, Colorado) is a solution (MDF-100) composed of two parts: part a: a solution of 6.6% *N*,*N*,*N*,*N*′′,*N*′-penta-methyl,-*N*′-tallow alkyl 1,3-propanamine diammonium; 2.6% tallow pentamethyl propane quaternary ammonium compounds; benzyl-C12-18 alkyl dimethyl; 1% isopropyl alcohol, and part b: a solution of 8% hydrogen peroxide. Mixing the two parts results in a foam-like product which lasts for up to 30 min (Figure 71.2).

The mixture was tested in the guinea pig model, where fur was shaved on the side of the animal one day before exposing the skin of the anesthetized animals to neat GD or VX (Lukey *et al.*, 2004). The animals were decontaminated 1 min later with sterile gauze soaked in the combined solution in a defined manner: the contaminated side was wiped across the exposure site in the direction of the shaved fur once and then rotated so that a clean surface of the gauze could be used to wipe the skin for three additional passes. Next, the OP-exposed area was similarly dried with a second piece of gauze. The exposed area was wiped a total of eight times. Twenty-four hours later, survival was determined. Control non-decontaminated animals yielded an LD_{50} of 11.3 mg/kg for the OP GD, while animals decontaminated with the mixture yielded an LD_{50} of 400 mg/kg, a 35-fold protective ratio. For the OP VX, cutaneous neat exposure and decontamination with Sandia foam yielded an LD_{50} of 10.1 mg/kg compared to the control animals' LD_{50} of 0.14 mg/kg, a 72-fold protective ratio.

FIGURE 71.2. Sandia foam.

Despite its efficacy, Sandia foam has a number of drawbacks for field use by the soldier. First, it must be stored as separate components, which would require a rapid, personal, on-site mixing chamber for combining the two solutions. Second, the presence of hydrogen peroxide, a strong oxidizing agent, precludes its use near the eye, and would create much discomfort if used in a wound (Watt *et al.*, 2004). To partially address these concerns, Sandia developed the formulation DF-200, which in part contains less hydrogen peroxide and surfactant.

D. Liquid Decontamination Material – Diphotérine®

Diphotérine is a product for chemical spatters on the eye and skin. Prevor Laboratory in France manufactures this odorless, colorless liquid dispensed as an eye wash or skin decontamination spray. It is composed of an aqueous solution to wash many chemical families and pull hydrophilic chemical agents away from the surface of tissues, an amphoteric solution that acts on acids and bases and restores the tissue physiological pH, and a hypertonic solution that stops penetration of corrosive chemicals into tissues. The pH is slightly alkaline (pH 7.2–7.7) and is sterile. Although not classified as such in the USA, it is classified as a medical device in Europe, Canada, Australia, and Brazil (www.prevor.com).

Diphotérine's action on more than 600 chemical compounds was reviewed (Hall *et al.*, 2002). These chemicals included acids, alkalis, oxidizing and reducing agents, irritants, lacrimators, solvents, alkylating agents, and radionuclides. In the literature, there is one abstract describing the decontamination of sulfur mustard (Gerasimo *et al.*, 2000). In this report, radiolabeled sulfur mustard was placed on human skin for 5 min *in vitro*. The skin was then treated with Diphotérine, water and soap, or saline at different time periods after sulfur mustard exposure and Diphotérine was reported to be significantly better at removing sulfur mustard. No reports could be found in the literature for organophosphate decontamination, although Hall *et al.* (2002) also state that Diphotérine is suitable for decontamination of OP pesticides.

The bulk of evaluation of Diphotérine has occurred in the European workplace. There, it has been reported not to be irritating to normal human eyes or skin, and is essentially

nontoxic in guinea pigs and does not sensitize their skin (Mathieu *et al.*, 2007). The product has prevented or decreased severity of chemical eye/skin burns with 96% sulfuric acid, 100% acrylic acid, 50% acrylamide, solid sodium hydroxide flakes, and dimethylethylamine; no eye/skin burns developed and there was no necessity for further medical or surgical burn treatment in a German metallurgy facility where 24 workers were exposed to weak or strong acids and bases and obtained immediate Diphotérine decontamination (Nehles *et al.*, 2006). Clearly, Diphotérine's potential is intriguing and needs to be critically evaluated for decontamination and detoxification of chemical warfare agents.

E. Liquid and Sponges: Reactive Skin Decontamination Lotion

Reactive skin decontamination lotion (RSDL) was developed for cutaneous decontamination of chemical warfare agents after exposure to a chemical warfare agent (Figure 71.3). It was developed for topical use by the Defense Research Establishment in Suffield, Canada, with broad spectrum decontamination properties for chemical agent cutaneous threats. The RSDL solution is composed of 1.25 M potassium 2,3-butanedione monoximate in polyethylene glycol monoethyl ethers of average molecular weight 550 daltons ($MPEG_{550}$) with 10% w/w water (pH 10.6). The pads consist of a sponge-like plastic foam, Opcell®, which is lightweight and easy to store. It is used instead of a cotton pad, and the Opcell holds more of the decontaminating solution for spreading on the skin.

The toxicological profile of this formulation was determined prior to FDA (Food and Drug Administration) clearance by the US military (Tonucci *et al.*, 2004). The Army tested the product's safety by conducting skin irritation, sensitization, and photoirritation studies in more than 300 people. It also tested its effectiveness by treating animals that had been exposed to chemical agents. On March 28, 2003, the product was approved by the FDA to remove or neutralize chemical warfare agents and T-2 fungal toxin from the skin (but not other biological threat agents or radiological contaminants).

The efficacy of reactive skin decontamination lotion has been demonstrated. The high efficacy of this lotion in inactivating OPs was measured in rats. In addition, primary cultures of chick embryo neurons were used to test the efficacy of the RSDL. By relating the anticholinesterase activity in these cultures of the OP/RSDL mixture to that of pure OP standards, a sensitive measure of the value of the RSD in inactivating tabun, sarin, soman, and VX was obtained. Experiments with all four nerve agents in this *in vitro* system provided a good correlation with the *in vivo* data, and also indicated that the inactivation process was time and agent dependent and also related to the ratio of OP to RSDL. RSDL is also effective in decontaminating GD and VX cutaneously in exposed guinea pigs (Table 2, Gordon, unpublished observations).

FIGURE 71.3. RSDL reactive skin decontamination lotion (www.nbcdefence.net).

The product was also compared to Fuller's earth in a pig model. The potency of the RSDL/sponge was statistically better than Fuller's earth against skin injury induced by sulfur mustard, observed 3 days post-exposure. RSDL was more efficient than Fuller's earth in reducing the formation of perinuclear vacuoles and inflammation processes in the epidermis and dermis. The potencies of the RSDL/sponge and Fuller's earth were similar to severe inhibition of plasma cholinesterases induced by VX poisoning. Both systems completely prevented cholinesterase inhibition, which indirectly indicates a prevention of toxic absorption through the skin (Taysse *et al.*, 2007).

However, there are some caveats for the use of RSDL. The application of RSDL directly to open wounds impaired wound strength and decreased collagen content in the early phases of wound healing. This may have clinical implications for the treatment and outcomes of chemical casualty combat trauma (Walters *et al.*, 2007). RSDL is also reported to be flammable.

F. Polyurethane Sponge

At the Walter Reed Army Institute of Research, an enzyme immobilized polyurethane foam sponge to decontaminate the skin of chemical warfare agents in a wide variety of

environmental conditions is being developed (Munnecke, 1979; Wood *et al*., 1982; Havens and Rase, 1993) (Figure 71.4). A porous polyurethane foam formed *in situ* from water-miscible hydrophilic urethane prepolymers has been combined with enzymes such as ChEs, producing immobilized enzyme sponges (Gordon *et al.*, 1999; Gordon and Doctor, 2003; Ember, 1997; Medlin, 1998). In this method, the enzyme becomes an integral part of the solid support. Some of the advantages of this technique include retention of similar kinetic characteristics as the soluble form of the enzyme. Most important, the immobilized enzyme retains high activity after prolonged storage, and it is resistant to the detrimental effects of low and high temperatures and long exposure to the environment. In addition, the enzymes are covalently attached to the polyurethane so they will not leach from this polymer support.

In order to increase the OP/enzyme stoichiometry, polyurethane immobilized enzymes were combined with oximes (enzyme reactivators such as HI-6; Peter *et al.*, 2007) so that the catalytic activity of OP-inhibited AChE (or BChE) is rapidly and continuously restored before irreversible aging of the enzyme–OP complex can occur. The OP is continuously detoxified. Thus, a reusable immobilized enzyme sponge of ChEs and oximes for OP decontamination is the envisioned product. Next, it was demonstrated that the OPs diisopropyl fluorophosphate (DPF) or 7-(methyl-ethoxyphosphinyloxy)-1-methylquinolinium iodide (MEPQ) inhibited the activity of ChE sponges, as was observed for non-immobilized ChE in solution. The oxime HI-6 restored activity of the AChE sponge until the molar concentration of MEPQ reached approximately 1,000 times that of the cholinesterase active site. However, the AChE sponge could be recycled many times by rinsing the sponge with HI-6 in the absence of OP. In this case, most of the original ChE activity could then be restored to the sponge. Therefore, the bioscavenger approach can be used externally: the sponge would soak up OP decontaminating the OP contaminated skin (Caranto *et al.*, 1994). Then the ChE sponge and oxime would detoxify the OP in the sponge. We have found that the ability of the immobilized enzymes and HI-6 to detoxify the OP MEPQ was dependent upon the efficiency of the sponge in decontaminating particular surfaces including plastic or guinea pig skin.

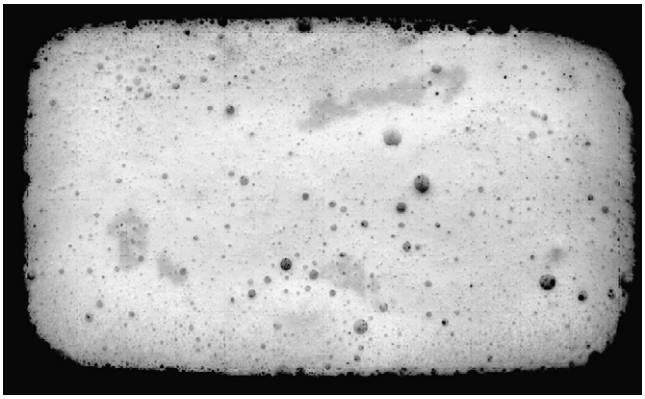

FIGURE 71.4. Polyurethane sponge.

Characteristics of polyurethane immobilized enzymes are as follows. The longevity of sponges composed of immobilized ChEs is greater than 5 years at room temperature (not shown). The immobilized enzymes are also very stable in aqueous environments. One significant difference and advantage the immobilized enzymes have compared to the soluble ChEs is that immobilized enzymes do not dissociate (leach) from the sponge. Therefore, the immobilized enzymes can be left in the liquid or other environments. For instance, the AChE activity in the immobilized sponge was stable for more than 60 days in continuous immersion in aqueous samples including Allegheny River fresh water or brackish water (Gordon *et al.*, 2002). Since the results were identical for autoclaved and untreated water, the immobilized enzymes were also resistant to microbial-induced proteolytic degradation. Also note that the same sponge was assayed multiple times over many days, so it is evident that the immobilization process confers dramatic stability to covalently coupled ChEs.

OP removal by the sponge and formulation is as follows. The capacity of sponges to remove GD or other OPs from guinea pig skin was determined using a back-titration method, where removed OP in the sponge was added to a known amount of ChE. Inhibition of the exogenously added ChE permits quantitation of the OP concentration. From these studies, it was determined that additional components when added to the sponge improved the sponge's efficacy by leaching out the chemical warfare agents. In this case, we settled on tetraglyme, which has a propensity to dissolve organic-like materials, including OPs and sulfur mustard (see below). In part, the inability of sponge–tetraglyme to remove all the GD likely reflects the rapid penetration of GD through skin and that tetraglyme cannot extract this fraction. It also points to the requirement for as rapid decontamination as possible. These results clearly demonstrate that the sponge not only removed OP from the skin of the guinea pigs, but in the presence of oxime effectively and completely detoxified the OPs within hours. Thus, these sponges would not pose any additional cross-contamination hazard.

The protective ratios of the sponge are as follows. It proved to be impossible to modify the prepolymer since currently there is no formulation with an increased hydrophobic nature that might be expected to absorb the OP more effectively. Instead, we utilized additives described above to provide the additional ability to remove soman from the skin, protecting guinea pigs significantly better than the M291 kit (Table 71.2). A comparison with RSDL is also shown. Compared to LD_{50} values of 9.9 and 17.7 mg/kg for untreated animals (not decontaminated) and the M291 kit, respectively, the sponge provided an LD_{50} of 290. This combination is also effective against VX contaminated guinea pigs: the sponge increased the LD_{50} from 0.14 mg/kg to 21, yielding a protective ratio of 150. RSDL provided a protective ratio of 137.

TABLE 71.2. Decontamination of OP-exposed guinea pigs

OP/treatment	LD_{50} (mg/kg)	PR
Soman		
M291 kit	17.7	1.8
RSDL	240	24
Sponge	290	29
None	9.9	n/a
VX		
M291 kit	0.14	n/a
RSDL	19.1	137
Sponge	21.0	150
None	0.14	n/a

PR – protective ratio

Sulfur mustard decontamination and formulation are as follows. The sponge was used to wipe guinea pig skin contaminated with neat sulfur mustard. The following day, the animals were injected with trypan blue. Those areas representing vesicant injury take up the dye. It was observed that the neat HD-exposed tissue (positive control) has a significant dye uptake, while the area decontaminated by the sponge has only a slight uptake of the dye. The control has no dye uptake. In addition, the amount of HD taken up and removed by the sponge was measured over time. While neat mustard remained after 15 min in water, the corresponding amounts are destroyed in the matrix of the sponge and additives. Histopathology of the HD-exposed skin specimens after 24 h demonstrated microvesicles, coagulation at the dermal interface, and in the most severe cases, dermal coagulation. Overall, sponge decontamination of the HD-exposed area exhibited characteristics associated with reduced exposure (microvesicles). Thus, these sponges could reduce the damage that HD produced. ChEs may provide sinks as alkylation sites for the sulfur mustard, and account for some of the reduced toxicity of the agent upon sponge decontamination. Another feature demonstrated was that the tetraglyme leaches from skin not only OPs, but also the organic-like sulfur mustard, thereby reducing its ability to alkylate skin proteins. Finally, the formulation of the sponge was modified to include nucleophilic additives to act as a reactive moiety for the sulfur mustard in place of skin proteins. Taken together, the polyurethane sponge was shown to decontaminate and detoxify guinea pig skin exposed to two classes of chemical warfare agents: OPs such as GD and alkylating compounds such as HD.

G. Immobilized Enzyme Badges

The sponge can incorporate a detection system for OPs and alkylating agents – a unique attribute not present in current decontamination methods (Gordon *et al.*, 2002). The immobilized enzymes provide a detector and a rapid field system capable of identifying the type of OP. In addition to OP detection, a coupled enzyme reaction provides a rapid colorimetric or electrochemical indication of mustard. With the constant threat of chemical warfare or terrorist acts, the development of alternative means of protecting and decontaminating individuals from exposure to CWA agents is critical.

Like Diphotérine, which has been evaluated only for sulfur mustard decontamination, the polyurethane enzyme immobilized sponge is a novel technology that has demonstrated efficacy for OP and sulfur mustard cutaneous poisoning, but is only now undergoing evaluation for decontamination of biological warfare agents (T-2 mycotoxin, botulinum toxin) and radionucleotides (Gordon *et al.*, 2006). Another advantage of ChEs over general reacting additives is that the ChEs are the direct target for current or future warfare agents, and therefore should not require major reformulation. These new technologies likely will provide more efficacious solutions for the soldier in the future.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

OP nerve agents are a serious threat to military and civilian personnel. These agents are some of the most potent toxic agents and are specific inhibitors of ChEs. OP nerve agents can exist as a vapor and be inhaled; as a liquid they can contaminate skin, or can be ingested if food or water is contaminated. Vesicating agents such as sulfur mustard cause irreversible cell damage as a result of rapid alkylation, and were an agent of terror during World War I and more recently in Iran and Iraq. Another serious problem that may be encountered while caring for personnel contaminated with chemical warfare agents is the possibility that there will be cross-contamination to the medical personnel. In addition, during combat or terrorist acts, individuals might be exposed to chemical toxins before they don their protective gear. Decontamination post-exposure has the potential to be an important, integral, and therefore necessary step for medical countermeasures against chemical warfare agents. The products described here must meet several criteria to be effective personal decontaminants and detoxifiers of chemical warfare agents for the soldier, although there is room for improvement, thus novel technologies have been discussed. However, any product must be lightweight for individual use, yet be shelf-stable under environmental conditions found in the field. The importance for readily available and rapid use of a decontamination and detoxification product is due to the rapid damage caused by CWAs – OPs penetrate skin in less than 5 min and mustard produces irreversible cell damage as a result of alkylation equally rapidly. The product should also be environmentally friendly. In the future, one product should incorporate chemical, biological, and radiological decontamination and,

when possible, detoxification. With the constant threat of chemical warfare, terrorist acts, or spillage of pesticides, the development of alternative means of protecting and decontaminating individuals from exposure is critical.

CHAPTER 72

Detoxification of Arsenic

KIRAN KALIA AND DHAVAL N. JOSHI

I. INTRODUCTION

Arsenic, which is ubiquitous in the environment, has become a worldwide public health problem. Every organism, from bacteria to mammals, has a mechanism for transport and detoxification of arsenicals (Rosen, 2002a). It has become evident that increasing use of arsenic-containing insecticides, herbicides, fungicides, pesticides and wood preservatives, and through the mining and burning of coal, have modified the global cycle of arsenic (Luo *et al.*, 2007; Smedley and Kinniburgh, 2002). Arsenic (As) ranks first on the US government's Priority List of Hazardous Substances, because of both its toxicity and its prevalence in the environment (Chou and De Rosa, 2003). The health of millions of people worldwide is at risk from drinking arsenic-contaminated well water (Milton and Rahman, 2002). Increased arsenic mobility in natural environments is a major concern in the creation of new wells and water supply systems in areas that are rich in arsenic. A large-scale shift in water resource allocation from surface water to groundwater in West Bengal, India, and Bangladesh has resulted in very extreme environmental health effects (Mukherjee *et al.*, 2006). The toxic effects of arsenic are related to its oxidation state (Thomas *et al.*, 2007), therefore, the examination of factors affecting the speciation of arsenic has become an important issue.

The threat of environmental pollution from the release and dispersal of naturally occurring and anthropogenic arsenic has stimulated extensive research on the properties of the metalloid and its interaction with biological systems. Arsenic is lethal to most microorganisms, yet certain bacteria and phytoplankton are known to survive arsenic exposure. Microorganisms have evolved a number of mechanisms to tolerate high levels of arsenic in their environment, including transformation of arsenic species by oxidation (Fisher *et al.*, 2008), reduction (Mukhopadhyay *et al.*, 2002), and methylation (Bentley and Chasteen, 2002). Arsenic detoxification has been reported in a number of bacterial species such as *Escherichia coli*, *Bacillus* sp., *Staphylococcus aureus*, *Staphylococcus xylosis, Chromobacterium violaceum* and *Pseudomonas* sp. (Patel *et al.*, 2007; Mateos *et al.*, 2006; Rosen, 2002a) which select variants possessing genetic resistance determinants which confer the ability to tolerate the higher levels of arsenic in their environment. It has been well documented that bacteria can use arsenic as electron donors, electron acceptors, or possess arsenic detoxification mechanisms to confer resistance against arsenic toxicity. In general, metals in contaminated water are removed by methods such as chemical precipitation, ion exchange, or adsorption (Schmidt *et al.*, 2008). However, these methods have disadvantages such as high cost and the generation of secondary contaminants. Recent recognition of the need to develop low-cost environmentally friendly technologies for water treatment has stimulated interest in studies in the bioremediation of metals (Mondal *et al.*, 2008; Patel *et al.*, 2007; Mateos *et al.*, 2006). The bacterial cells capable of removing arsenic from their surroundings could be ideal candidates for bioremediation, and could be used as an alternative or to supplement existing physicochemical methods of arsenic removal. Although some genetically engineered microorganisms have been developed (Kostal *et al.*, 2004) their potential use for the removal of arsenic is not yet established (Takeuchi *et al.*, 2007).

II. ARSENIC IN THE ENVIRONMENT

Arsenic enters to biosphere primarily by leaching from geological formations. Its ubiquity in the environment has led to the evolution of arsenic defense mechanisms in every organism studied, from *Escherichia coli* to humans. Arsenic ranks 20th in natural abundance, consisting about 0.00005% of the earth's crust, 14th in seawater, and 12th in the human body (Mandal and Suzuki, 2002). Arsenic is positioned in Group 15 in the Periodic Table below phosphorus, and is a silver–gray crystalline metallic material that melts at 817°C, sublimates at 613°C, and has a density of 5.72 g/cm^3 (Eisler, 1994). Due to its complex chemistry and ability to form many different compounds arsenic is an intricate element to understand. Arsenic is most commonly found in two valence states, As(III) and As(V). The most common inorganic As(III) compounds found are arsenic trioxide, sodium arsenate, and arsenic trichloride. As(V) compounds such as arsenic pentoxide, arsenic acid, and arsenates are also quite common. Arsenic is methylated by microorganisms,

but neither group is considered as toxic as inorganic As(III) and As(V) compounds (Islam *et al.*, 2005).

Arsenic in the atmosphere comes from various natural sources such as volcanoes (gas fumes), microorganisms, and human release (mainly by burning fossil fuels) (Figure 72.1). Under anoxic conditions, arsenite can be reduced by microorganisms in soil to the volatile compounds arsine (AsH_3) and methyl arsines, these compounds being the most toxic form of arsenic. In addition, the anthropogenic sources have broadened the arsenic cycle and large amounts of arsenic are found in the environment and in living organisms. About 90% of arsenic compounds are used as wood preservatives and the remaining 10% as insecticides, anthropogenic fertilizers, weedkillers, fungicides, semiconductors, and in the production of glass and metal alloys. In most cases, arsenic occurs naturally within subsurface aquifers. This mobilization of arsenic into the aqueous phase serves as the first crucial step in eventual human arsenicosis (Oremland and Stolz, 2005). Worldwide, arsenic in soil ranges from 0.1 to 40 mg/kg[1] with a median concentration of 5–6 mg/kg[1] (Smedley and Kinniburgh, 2002). Arsenic in seawater averages 1.7 µg/l with a relatively homogeneous range from 1.5 to 5 µg/l. In contrast, freshwater from lakes and rivers varies widely in arsenic concentration and is dependent upon the minerals subject to transport. Arsenate is more predominant in oxygenated water while arsenite is more common under reduced anaerobic conditions. The total arsenic influx into oceans is estimated at 246,110 metric tons/year. Of this total 62,900 metric tons is dissolved arsenic, 178,900 metric tons is sediment suspended arsenic, and 4,310 metric tons is from the atmosphere per year (Smedley and Kinniburgh, 2002).

Arsenic has been detected in groundwater in several countries of the world, with concentration levels exceeding the World Health Organization (WHO) drinking water guideline value of 10 µg/l as well as the national regulatory standards of 50 µg/l in India and Bangladesh (Mukherjee *et al.*, 2006). In groundwater it is often associated with geological sources, but in some locations anthropogenic inputs can be extremely important. Arsenic in groundwater has emerged as the largest environmental health disaster putting at least 100 million people at risk of cancer and other arsenic-related diseases. In Asia, the impact of arsenic toxicity is particularly alarming predominantly in the Bengal Basin of Bangladesh and West Bengal, India. Recent studies indicate the occurrence of geogenic arsenic in the Central Gangatic Plains of Uttar Pradesh, Bihar, Jharkhand and the Brahmaputra valley in Assam, and several regions of Madhya Pradesh and Chattisgarh, India (Mukherjee *et al.*, 2006).

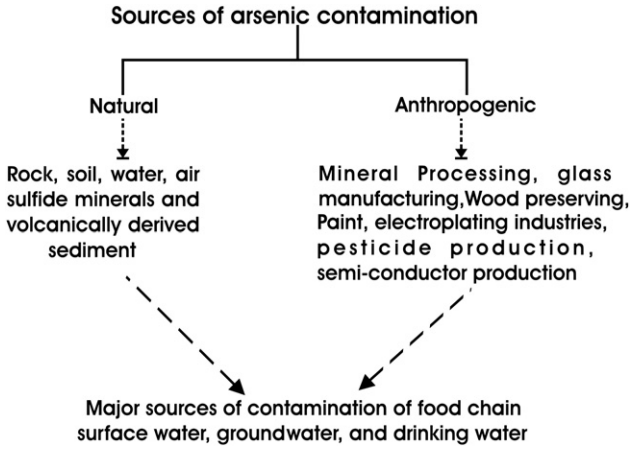

FIGURE 72.1. Arsenic contamination in the environment through natural and anthropogenic sources.

III. BIOLOGICAL PROPERTIES OF ARSENIC

Arsenic occurs in four oxidation states: As^{5+}, As^{3+}, As^{0}, and As^{3-}. The two highest oxidation states are the most common biologically important redox states, which are arsenite [As (III)], the reduced form and the oxidized form, arsenate [As (V)], whereas the other two are rare. The ionic forms, arsenate and arsenite, are interconvertible and pH dependent, hence at physiological pH, As(V) is dominant as $H_2AsO_4^{-1}$ $(2.5 < pH < 7)$ and $HAsO_4^{-2}$ $(7 < pH < 12)$, while As(III) is dominant as H_3AsO_3 $(pH < 9.3)$ (Inskeep *et al.*, 2002). Arsenic also exists in organic forms, which are often found in association with biological systems. These include the methylated arsenicals such as monomethylarsonate (MMA) and dimethylarsonate (DMA), which are common arsenic metabolites found in most environmental compartments, and other arsenicals such as arsenobetaine, arsenocholine, and tetramethylarsonium ion, which are common species in marine animals (Geiszinger *et al.*, 2002). In the natural environment, both arsenate and arsenite are subjected to chemically and microbiologically mediate oxidation, reduction, and methylation reactions. The oxyanion form as pentavalent arsenate (As^{5+}) is an analog of phosphate and is a potent inhibitor of oxidative phosphorylation, the key reaction of energy metabolism in metazoans, including humans, the most toxic form to algae (Knauer *et al.*, 1999). The arsenite has strong affinity to form bonds with functional groups such as the thiolates of cysteine residues and the imidazolium nitrogens of histidine, thus it binds readily to many enzymes, including those involved in respiration (Knauer *et al.*, 1999). In solution at neutral pH, arsenic acid exists as the arsenate anion. The pKa of arsenous acid is 9.2, so that, at neutral pH, arsenic would be present in solution as neutral $As(OH)_3$ (Rosen, 2002a). In natural waters, arsenic is mostly found in inorganic form as oxyanions of trivalent arsenite (As^{3+}), which is the most toxic form to humans and other vertebrates. In soils, the most often encountered arsenic forms are inorganic As(III) and As(V) (Cullen and Reimer, 1989).

IV. MICROBIAL TRANSFORMATIONS OF ARSENIC

The ecology of arsenic is strongly dependent on microbial transformations which affect the mobility and bioavailability as well as the toxicity of arsenic in the environment. Bacteria implicated in the processes of biotransformation readily metabolize arsenic, participating in various metabolic functions including detoxification, anaerobic respiration, assimilation, and methylation (Figure 72.2). Arsenic speciation and mobility are affected by microbes through oxidation/reduction reactions as part of resistance and respiratory processes. The *arr* and *ars* encode two different arsenate reductases associated with cellular respiration and the detoxification mechanism, respectively, whereas *aox* and *aso* coding for arsenite oxidase is responsible for its oxidation to gain energy. Respiratory arsenate reductases encoded by *arr*, arsenic methyltransferases encoded by *arsM* and some new components in arsenic resistance have been recently described. To date, the best studied mechanism of transformation is the reduction of arsenate As(V) to arsenite As(III) mediated by *ars* operon. On the other hand, the physiology, enzymology, and genetics of the oxidation of arsenite as well as the underlying regulatory processes remain largely unknown at present.

A. Dissimilatory Reduction of Arsenate

Microbial arsenate respiration contributes to the mobilization of arsenic from the solid to the soluble phase in various locales worldwide. In particular, microbial respiratory reduction of arsenate, As(V), to arsenite, As(III), is thought to prevent the readsorption of arsenic onto sediment surfaces once it is transported away from iron-rich environments (Ahmann *et al.*, 1994). Dissimilatory arsenate-respiring prokaryotes including archea and bacteria capable of using arsenate as the terminal electron acceptor in anaerobic respiration of arsenate could provide enough energy for microbial growth (Ahmann *et al.*, 1994; Laverman *et al.*, 1995). Arsenate reduction may be an important process in an environment where arsenic concentrations are too high. Arsenate reduction by bacteria can significantly enhance the arsenic mobility in the environment. Two different arsenate reduction pathways exist in microorganisms encoded by the *ars* and *arr* systems, known to specifically reduce As(V) (Figure 72.3). The arsenate reductase encoded by the *arr* genes is associated with cellular respiration, whereas *ars* genes encode arsenate reductase associated with detoxification mechanisms (Saltikov *et al.*, 2005). The *arr* system is required for As(V) reduction under environmentally relevant conditions and is highly conserved among diverse bacterial species. Respiratory arsenate reductase (Arr) has been purified from anaerobic organism *Chrysiogenes arsenatis* (Krafft and Macy, 1998) and *Bacillus selenitireducens* strain MLS10 (Afkar *et al.*, 2003). It has been reported that an enzyme from *Bacillus selenitireducens* (Afkar *et al.*, 2003) was membrane associated, whereas an enzyme from *Chrysiogenes arsenatis* was found in periplasm and is different from the nonrespiratory arsenate reductases of *Escherichia coli* and *Staphylococcus aureus* (Krafft and Macy, 1998).

Recently, the respiratory arsenate reductase was characterized from *Shewanella* sp. strain ANA-3 (Malasarn *et al.*, 2008), which was initially identified in the same strain

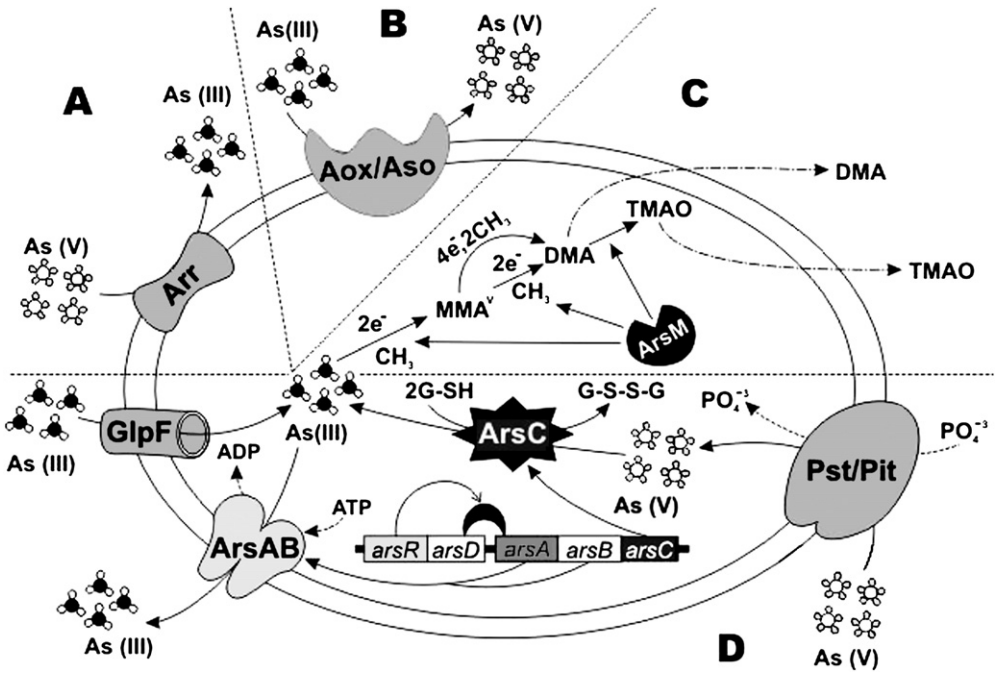

FIGURE 72.2. Arsenic detoxification mechanisms (reduction, oxidation, methylation, and resistance) in prokaryotes. (A) Respiratory arsenate reductase (Arr) is involved in the reduction of As(V) by the dissimilatory arsenate respiring organisms. (B) Arsenite oxidase (Aox/Aso) is responsible for oxidation of As(III) by chemoautotrophic or heterotrophic arsenite oxidizers. (C) *S*-adenosylmethyltransferase (ArsM) is responsible for methylation of As(III) to produce trimethylarsine as the end product. (D) Genes (*arsRDABC*) and proteins involved in the uptake of As(III) and As(V) (GlpF and Pst/Pit transporter), reduction of As(V) (ArsC), extrusion of As(III) (ArsAB), and regulation (ArsRD) by arsenic resistant organisms.

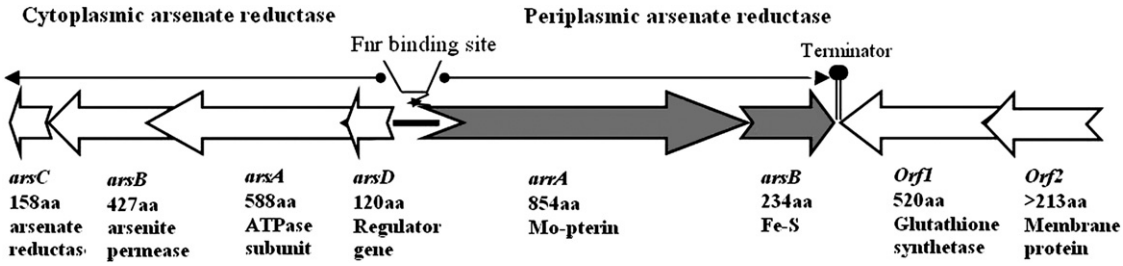

FIGURE 72.3. Molecular organization of *arrAB* (periplasmic arsenate reductase) and *arsDABC* (cytoplasmic arsenate reductase) of *Shewanella* strain ANA-3 (from GenBank Accession no. AY271310). *arrAB* gene cluster is located upstream in the opposite orientation to an *arsDABC*. aa–amino acid (modified from Saltikov and Newman, 2003; Silver and Phung, 2005).

through mutagenesis studies (Saltikov and Newman, 2003). The *Shewanella* sp. contains two systems for reducing As(V), one is similar to the well-conserved *ars* detoxification system of *Escherichia coli* plasmid R773, which is advantageous, but not required for respiratory As(V) reduction mediated by *arr* operon. The *arr* operon in *Shewanella* sp. lies immediately downstream of the *ars* operon and contains only two genes, *arrA* and *arrB*. Sequence analysis and biochemical studies of respiratory arsenate reductase from various sources revealed that it is a heterodimer $\alpha_1\beta_1$ with a native molecular mass of ≈123–131 kDa and consists of larger subunits with molecular masses of ArrA ≈ 87–95 kDa, molybdenum-containing enzyme and smaller subunit ArsB ≈ 27–26 kDa, containing several Fe–S clusters (Krafft and Macy, 1998, Malasarn *et al.*, 2008 Afkar *et al.*, 2003; Sargent *et al.*, 2002). The N-terminus of ArrA was similar to a number of prokaryotic molybdenum-containing polypeptides (e.g. the formate dehydrogenases H and N of *Escherichia coli*) and the N-terminus of ArrB is similar to iron–sulfur proteins (Krafft and Macy, 1998). Both the proteins belong to the enzymes of the dimethyl sulfoxide reductase family (Krafft and Macy, 1998; Afkar *et al.*, 2003). It has been reported that ArrA could be the subunit that binds As(V) and reduces it to As(III), whereas ArrB serves as a channel for electrons stemming from c-type cytochromes in the respiratory chain (Macy *et al.*, 2000). Because the *arrA* is well conserved among almost all of the isolated bacterial As(V) respires, several research groups have used a set of degenerate PCR primers to amplify and sequence a major portion of *arrA* from other bacterial species including *Bacillus arseniciselenatis*, *Chrysiogenes arsenatis*, and the *Desulfoporosinus* sp. strain Y5 (Malasarn *et al.*, 2004; Perez-Jimenez *et al.*, 2005). The expression dynamics of As(V) respiration and detoxification showed that at very low concentrations of arsenate and under anaerobic conditions the *Shweanella* sp. strain ANA-3 was primed to activate *arr* transcription and during the early phases of growth couples the reduction of As(V) to growth instead of detoxification by *arsC*, whereas increased intracellular As(III) concentration initiates production of its detoxification machinery by turning on the transcription of *ars* operon (Saltikov *et al.*, 2005). Recently, respiratory arsenate reductase has been identified from *Alkaliphilus oremlandii* through biochemical and Western blot analysis and confirmed by cloning and sequencing of the gene encoded for the structural subunit ArrA (Fisher *et al.*, 2008). It has been suggested through genomic analysis and growth experiments that *Alkaliphilus oremlandii* couples the reduction of the nitro group of the organoarsenical to the oxidation of either lactate or fructose in a dissimilatory manner, generating ATP via a sodium-dependent ATP synthase (Fisher *et al.*, 2008).

Gram-negative bacterial strains MIT-13 and SES-3 were capable of obtaining energy from arsenate respiration (Ahmann *et al.*, 1994; Laverman *et al.*, 1995) and classified as two species of *Sufurospirillum* based on 16S rRNA sequence analysis and DNA–DNA hybridization, designated as *Sufurospirillum arsenophilum* and *Sufurospirillum barnesii* with 97% sequence homology with each other and differing slightly in metabolism (Stolz *et al.*, 1999). Both the strains were able to grow using arsenate, nitrate, thiosulfate, or sulfur as the terminal electron acceptor in anaerobic respiration and micro-aerobically with low levels of oxygen (Stolz *et al.*, 1999; Laverman *et al.*, 1995). The *Desulfomaculum auripigmentum*, a sulfate-reducing organism capable of respiring lactate when using either arsenate or sulfate as the terminal electron acceptor, was isolated and characterized, which was phylogenetically affiliated to MIT-13 and SES-3 (Newman *et al.*, 1997). Gram-positive *Bacillus arsenicoselenatis* and *Bacillus selenitireducens*, with the low G + C content isolated from an alkaline, arsenic-rich, saline lake, which can specifically recognize arsenate as electron acceptor, showed a novel mechanism of arsenate reduction (Switzer Blum *et al.*, 1998). Dissimilatory arsenate-respiring prokaryotes characterized at the molecular level are shown in Table 72.1. *Pyrobaculum arsenaticum* is capable of respiratory growth using arsenate, sulfur, or selenate (Huber *et al.*, 2000). 16S rRNA gene sequence analysis showed that this organism belongs to the *Thermoproteales* order of archea, which can also grow anaerobically in the presence of arsenate or selenate (Huber *et al.*, 2000). The strain GBFH of *Desulfitobacterium* and strain HR13 of *Deincoccus* have been isolated from arsenic-contaminated sites (Niggemyer *et al.*, 2001; Gihring and

Banfield, 2001), having the ability to grow through dissimilatory reduction. Indeed, evidence is mounting that dissimilatory arsenate reduction may be an important process in an environment where arsenic concentrations are too high. It is suggested that arsenic may inhibit a variety of ecologically important anaerobic respiratory processes as arsenic was shown to inhibit denitrification in subsurface aquifer sediments. It is possible that the overall toxicity of arsenic has limited the distribution of this process among bacteria. However, very little information is available about regulatory genes and details of the mechanisms involved in the dissimilatory process.

B. Oxidation of Arsenite

Microbial As(III) oxidation is considered to be the mechanism of detoxification because the toxicity of arsenic is dependent on its oxidation state; As(III) is 100 times more toxic than the As(V) for most biological systems (Cervantes *et al.*, 1994). In contrast to the dissimilatory arsenate reducers, which use arsenate as the terminal electron acceptor in anaerobic respiration, some bacteria are capable of using arsenite as the electron donor and hence gain energy for growth by oxidizing As(III) to As(V). This was first reported in 1918 and since then organisms representing over 30 strains of at least nine genera including α, β and γ proteobacteria, *Deinocci* (*Thermus*) and *Crenarcheota* have been shown to oxidize As(III) to As(V). These include *Thermus aquaticus* and *Thermus thermophilus*, which have been found to rapidly oxidize As(III) to As(V) (Gihring *et al.*, 2001). The investigation into structural genes coding for arsenite oxidase in various organisms indicates that *aox* and *aso* genes are responsible for the activity of arsenite oxidase in *Cenibacterium arsenoxidans* and *Alcaligens faecalis*, respectively (Rhine *et al.*, 2007; Muller *et al.*, 2003).

Alcaligenes faecalis and five members of the β *Proteobacteria* are heterotrophic arsenite oxidizers, whereas *Pseudomonas arsenitoxidans* and ''NT-26'' grew anaerobically through chemoautotrophic oxidation (Oremland and Stolz, 2005; Santini *et al.*, 2000). However, six members of α *Proteobacteria* (Ben-5, NT-3, NT-4, NT-2, NT-26, and NT-25) and one member of γ *Proteobacteria* (MLHE-1) were known chemolithoautotrophic arsenite oxidizers (Oremland *et al.*, 2002). The best characterized and probably most studied of all arsenite oxidizers is *Alcaligenes faecalis*, a heterotrophic arsenite oxidizer (Osborne and Enrlich, 1976). The arsenite oxidase from *Alcaligenes faecalis* has been purified and structurally characterized (Ellis *et al.*, 2001). A similar enzyme has also been purified from the heterotrophic arsenite oxidizers *Hydrogenophaga* sp. strain NT-14 (Vanden Hoven and Santini, 2004) and the chemolithoautotrophic *Rhizobium* sp. strain NT-26 (Santini and Vanden Hoven, 2004), which indicate that the arsenite oxidase enzyme is also a member of the DMSO reductase family of molybdenum enzymes, similar to the respiratory arsenate reductases (Arr). The arsenite oxidase heterodimer comprises an 88 kDa catalytic subunit encoded by the *aoxB* gene that contains a [3Fe–4S] cluster and molybdenum bound to the pyranopterin cofactor and a 14 kDa subunit

encoded by the *aoxA* gene with a Rieske 2Fe–2S cluster motif (Ellis *et al.*, 2001) which is a unique feature among all arsenite oxidizers. The genes encoding the two subunits have been cloned and sequenced by different groups and unfortunately were given different names; the gene designation *aox* is synonymous with *aro* and *aso* (Stolz *et al.*, 2006). It has been reported that Na^+:H^+ antiporter and a molybdate transporter play an important role in arsenite oxidation in *Agrobacterium tumafaciens* (Kashyap *et al.*, 2006). Recently, over 160 diverse *aroA*-like sequences from arsenic-contaminated sites and from 13 different arsenite-oxidizing organisms have been characterized by using degenerate primers suggesting that genes for aerobic arsenite oxidation are widely distributed in the bacterial domain. These bacteria are widespread in soil–water systems containing arsenic and play a critical role in the biogeochemical cycling of arsenic (Inskeep *et al.*, 2007). However, despite progress characterizing the metabolism of arsenic in various pure cultures, no functional gene approaches have been developed to determine the importance and distribution of arsenite-oxidizing genes in soil–water–sediment systems (Table 72.2).

C. Methylation of Arsenic

In the 19th century, the inhabitants of many houses who had wallpaper decorated with green arsenical pigments suffered illness and sometimes death caused by certain fungi that grew on the wallpapers – these fungi formed a toxic, garlic-odor gas which was actually used to develop a delicate microbiological test for arsenic. Microbial methylation plays important roles in the biogeochemical cycling of arsenic and possibly in their detoxification. Although biomethylation of arsenic is very widespread, occurring not only in microorganisms but also in algae, plants, animals, and humans, it is not universal. The mechanism for trimethylarsine formation was originally described on the basis of work done with the fungus *Scopulariopsis brevicaulis* (Challenger, 1945), which involves a series of steps, in which the reduction of arsenate was followed by oxidative addition of a methyl group by *S*-adenosylmethionine as the usual methyl donor. Thiol groups have important roles in the reductions. In anaerobic bacteria, methylcobalamin may be the donor. A similar pathway has also been suggested for prokaryotes, although the formation of arsine is a feature more common in bacteria (Bentley and Chasteen, 2002).

The widely used wood preservative chromated copper arsenate is converted to trimethylarsine by the yeast *Candida humiculus* (Cullen *et al.*, 1984). Chromated copper arsenate is quite similar to the arsenical wallpaper pigments that had triggered Gosio's work.

The methylation of As(III) has been observed in a number of organisms, including humans. For example, higher eukaryotes and bacteria have been reported to produce monomethylarsine or dimethylarsine, fungi which produce trimethylarsine (Bentley and Chasteen, 2002; Dombrowski *et al.*, 2005), and methanogens and aerobic eubacteria which produce methylated arsines (Honschopp *et al.*, 1996).

Cornybacterium sp., *Escherichia coli*, *Flavobacterium* sp., *Proteus* sp., and *Pseudomonas* sp. transform arsenate to arsenite, and they all produce dimethylarsine, whereas *Pseudomonas* sp. forms all three of the methylated arsines from arsenic-containing pesticides (Shariatpanahi *et al.*, 1981). Six bacterial species (*Achromobacter* sp., *Aeromonas* sp., *Alcaligenes* sp., *Flavobacterium* sp., *Nocardia* sp., and *Pseudomonas* sp.) produce both mono and dimethylarsine from methylarsonate and only two of them produce trimethylarsine, whereas *Nocardia* sp. was the only organism to produce all of the methylarsines from arsenical herbicides (Shariatpanahi *et al.*, 1983).

It has been reported that soil bacteria *Pseudomonas* sp. and *Alcaligenes* sp. incubate under anaerobic conditions, producing arsine, but only in the presence of nitrate and nitrite. In order to explore the formation of trimethylarsine by the bacteria, human skin anaerobic and aerobic cultures were isolated, which showed a reduction of trimethylarsine oxide to trimethylarsine with the production rate of 3–10 nmol/min/g of cells (wet weight) (Cullen and Reimer, 1989). Three bacterial spp., *Veillonella alcalescus*, *Streptococcus sanguis* and *Fusobacterium nucleatum*, which were isolated from dental plaque also showed transformation of trimethylarsine oxide to trimethylarsine (Cullen and Reimer, 1989). *Staphylococcus aureus* has shown transformation of trimethylarsine oxide to trimethylarsine with a very high production rate, i.e. 208 nmol/min/g of cells (wet weight), which was almost 20–60 times higher than the value reported in anaerobic bacteria (Cullen and Reimer, 1989). *Pseudomons* sp., isolated from the marine environment, has shown a production rate of 585 nmol/min/g of cells (wet weight) which was the highest production rate for the formation of trimethylarsine in aerobic bacteria (Bentley and Chasteen, 2002).

The enzymology of arsenic biomethylation is complicated because of its many oxidation states, its propensity to react with sulfur compounds, and low concentrations of arsenic compounds in biological specimens. The chemical intermediates and reactions in the metabolism of arsenate are similar in microorganisms and animals. However, in microorganisms, the reactions tend to proceed to methylarsines, whereas in mammalian species the major urinary metabolite is generally dimethylarsinate and only a very small amount of it is reduced further. The arsenate reductase and methylarsonate reductase were thought to play an important role in arsenic biomethylation; however, with the exception of arsenate reductase most of the enzymatic experiments involved mammalian systems.

Arsenate reductase can reduce arsenate to arsenite, and is involved in bacterial resistance to arsenic; however, the reduction can also be mediated nonezymatically by reduced glutathione. The arsenate reductase utilizes thioredoxin and glutaredoxin rather than glutathione which is usually postulated to play a role in biomethylation. The cytosolic and periplasmic, two different arsenate reductases, exist in microorganisms encoded by *ars* and *arr* systems. *Escherichia coli* converts dimethylarsinate to trimethylarsine oxide, however, both *Staphylococcus aureus* and *Escherichia coli* has shown biotransformation of trimethylarsine oxide to trimethylarsine (Bentley and Chasteen, 2002).

Monomethylarsonate reductase was expressed in *Escherichia coli* and purified by Ni–agarose affinity chromatography (Schmuck *et al.*, 2005). The same reductase was also identified in human liver, indicating that this enzyme is a member of the glutathione-*S*-transferase superfamily (Zakharyan *et al.*, 2001). Methylarsonate reductase purified from rabbit liver required GSH. The dithiothreotol did not substitute glutathione; however, dithiothreotol almost doubled the formation of methylarsonite in the presence of glutathione (Zakharyan and Aposhian, 1999). This enzyme was rate-limiting in arsenic biotransformation; however, no bacterial methylarsonate reductase has been reported to date.

In general, methylation of inorganic arsenic has been regarded as a detoxification mechanism as monomethylarsonic acid and dimethylarsinic acid are less toxic forms than inorganic As(V) and As(III) because of their low solubility and reduced affinity. In recent years, however, this interpretation has been questioned and it has become evident that methylation increases the arsenic toxicity, because the trivalent species are more toxic than inorganic As(III) (Suwalsky *et al.*, 2008; Styblo *et al.*, 2000). It has been reported that *arsM* [As(III) *S*-adenosylmethyltransferase] contributes to global cycling of arsenic through methylation of As(III) (Qin *et al.*, 2006; Wang *et al.*, 2004). The *arsM* was found to be adjacent to *arsR* (transacting repressor) for *ars* operon, suggesting that *arsM* plays an important role in arsenic detoxification. The mammalian Cyt19 catalyzes the arsenic *S*-adenosylmethyltransferase activity and has shown homology with *arsM* found in bacteria and archea, suggesting that this enzyme may evolve for arsenic detoxification. In bacteria and fungi, *arsM* homologs catalyze the formation of a number of methylated intermediates from As(III), with trimethylarsine as the end product (Bentley and Chasteen, 2002). This biogenic source of gaseous arsenic has been estimated to produce eight-fold more atmospheric arsenic than does continental dust (Tamaki and Frankenberger, 1992). Because *arsM* homologs are widespread in nature, this microbial-mediated transformation is proposed to have an important impact on the global arsenic cycle (Qin *et al.*, 2006). The *arsM* [As(III) *S*-adenosylmethyltransferase] from arsenite methylating prokaryotes is characterized at molecular level as shown in Table 72.3.

D. Resistance Mechanisms for Arsenic

Cellular arsenic uptake in the form of As(V) is mediated via phosphate transporters and in the form of As(III) via glyceroporin membrane proteins (Mukhopadhyay *et al.*, 2003) or hexose transporters (Liu *et al.*, 2004) or glucose permease GLUT1 (Liu *et al.*, 2006). The best characterized arsenic

Symbiobacterium thermophilum is an uncultivable bacterium isolated from compost that depends on microbial commensalism. The 16S ribosomal DNA-based phylogeny suggests that this bacterium belongs to an unknown taxon in the Gram-positive bacterial cluster (Ueda *et al.*, 2004), low G + C Gram-positive bacteria

resistance mechanisms in bacteria involve reduction of As(V) to As(III), which is either extruded from the cells or sequestered in intracellular compartments.

The transport of arsenate into bacterial cells comparable to those of phosphate is carried out by phosphate transport membrane systems because of the structural similarity of phosphate and arsenate ions; for example, the arsenate oxyanions in water show three pKa values, 2.2, 7.0, and 11.5 (Ni Dhubhghaill and Sadler, 1991), comparable to 2.1, 7.2, and 12.7 for phosphate. In bacteria, arsenate As(V) enters the periplasmic space through the outer membrane porin, the PhoE protein, and is transported into the cytoplasm via two phosphate uptake systems, inorganic Pi transport (Pit) and phosphate-specific transport (Pst). The constitutive Pit system does not discriminate between phosphate and arsenate, having a K_m value for phosphate equal to the K_i for arsenate (25 μM). Under phosphate abundant conditions, the V_{max} is high, but the less specific Pit system fulfills the phosphate's need for the cell and leads also to arsenate accumulation (Elvin *et al.*, 1987), whereas under phosphate starvation conditions, the more specific Pst system is induced (Surin *et al.*, 1987). Eukaryotic microbes *Saccharomyces cerevisae* express a phosphate transporter similar to the low-affinity transporter of the prokaryotes. Their expression is regulated via a feedback mechanism. Members of the low-affinity Pit family are expressed predominantly during high phosphate concentration in the environment. These transporters belong to the permease transporter channels. Pst is the transporter which discriminates between phosphate and arsenate 100-fold better than Pit (Rosenberg *et al.*, 1987). Thus, one way for the cell to adapt to arsenate stress is to inactivate the Pit system by a pit mutation, which leads to moderate arsenate tolerance due to the discrimination between arsenate and phosphate by the Pst system. During periods of phosphate starvation or arsenate toxicity the Pst system is activated and despite having an identical K_i for arsenate, the higher affinity for phosphate leads to the reduction in cellular arsenic. The K_m of the Pst system for phosphate is 0.25 pM showing 100 times higher affinity than the Pit system (Rosenberg *et al.*, 1987). Thus the activation of the Pst system during the arsenic stress confers higher levels of arsenate resistance by virtue of reduced uptake of arsenate (Silver and Nakahara, 1983). Arsenite, in contrast, appears mostly unionized as $As(OH)_3$ at neutral pH, with a pKa of 9.3 for dissociation to $H_2AsO_3^{3-}$ (Ni Dhubhghaill and Sadler, 1991).

$As(OH)_3$ is transported into cells at neutral pH by aqua-glyceroporins (AQP) (Stahlberg *et al.*, 2000) in bacteria (Meng *et al.*, 2004), yeast (Liu *et al.*, 2006; Wysocki *et al.*, 2001), and mammals (Liu *et al.*, 2002). $As(OH)_3$ resembles the inorganic equivalent of a polyol, GlpF, which was originally identified as the glycerol facilitator in *Escherichia coli*, and is a member of the aqua-glyceroporin family. Transporters of this kind are involved in the osmoregulation of every cell. The ability of glycerol transporters to transport arsenite is probably a result of the similarity of arsenite to other polyols. It seems that $As(OH)_3$ is also a GlpF substrate. The structure of the *Escherichia coli* GlpF protein has been solved at 6.9 Å resolution (Stahlberg *et al.*, 2000) and showed a tetrameric assembly of subunits, comparable to aquaporins, but with a larger central channel in each subunit. Deletion of the gene for yeast aqua-glyceroporin Fps1p confers resistance to As(III) (Wysocki *et al.*, 2001). However, the Fps1v strain is still relatively sensitive to As(III), suggesting that the yeast cell also has an additional As(III) uptake pathway (Mukhopadhyay *et al.*, 2002). High osmolarity, which closes the Fps1p aqua-glyceroporin channel, provides resistance to As(III) and mutants with a constitutively open glycerol channel protein, hypersensitive to As(III). It was reported that the mammalian homologs of Fps1p, AQP7 and AQP9, functionally substitute for Fps1p in yeast strain Fps1v (Liu *et al.*, 2002). Thus, it is probable that As(III) also enters mammalian cells via aqua-glyceroporins. In order to understand the role of AQP in arsenic resistance, the *aqpS* gene of *Sinorhizobium meliloti* was disrupted resulting in increased tolerance to arsenite and indicating that AqpS facilitates transport of arsenite in *Sinorhizobium meliloti* (Yang *et al.*, 2005).

Once inside the cell, there is a problem involving arsenate detoxification due to the structural similarity with

phosphate; it would be difficult to export arsenate effectively in the presence of a higher intracellular phosphate concentration (Rosen, 1999). Thus, arsenate detoxification has to follow arsenate transformation mechanisms by discriminating it with phosphate, which is mainly by the reduction of arsenate to arsenite using arsenate reductase and/or other detoxification mechanisms such as methylation and sequestration (Patel *et al.*, 2007; Mateos *et al.*, 2006; Ji and Silver, 1992).

The arsenate reductase (ArsC) was found to have unrelated sequences and structural folds, divided into three different families based upon their structure, reduction mechanism, and location of catalytic cysteine residues. The first type, based on the product of the *arsC* gene from the *Escherichia coli* plasmid R773, uses glutaredoxin as a source of reducing equivalents, and was present in several Gram-negative bacteria (Jackson and Dugas, 2003). The second type of arsenate reductase from *Staphylococcus aureus* pI258 and *Bacillus subtilis* was related to low molecular weight tyrosine phosphatase and uses thioredoxin as the source of reducing equivalent, which did not show significant sequence similarity with the R773-encoded enzyme. The third type of arsenate reductase represented by the Acr2p enzyme from *Saccharomyces cerevisiae*, which was a homolog of CDC25 phosphatase, uses glutaredoxin as the source of reducing equivalents (Mukhopadhyay *et al.*, 2003).

The structure of the bacterial ArsC from *Escherichia coli* plasmid R773 has been solved at 1.65 Å resolution, and revealed that arsenate reductase (ArsC) has only one cysteine residue (Cys-12) in the active site, surrounded by an arginine triad composed of Arg-60, Arg-94, and Arg-107 (Mukhopadhyay *et al.*, 2002). However, the arsenate reductase from *Staphylococcus aureus* has three cysteine residues (Cys-10, Cys-82, and Cys-89). The biochemical and mutational studies established that the arsenate binds to the triad of arginine (Arg-60, Arg-94, and Arg-107) residues and forms a covalent bond with the cysteine (Cys-12) residue near the N-terminus at the active site of arsenate reductase and/or participates in catalysis (Rosen, 2002a; Silver and Phung, 2005; Shi *et al.*, 2003; Martin *et al.*, 2001).

V. GENES ASSOCIATED WITH ARSENIC RESISTANCE MECHANISM

The arsenic resistance mechanism conferred by *ars* operon, which is located on plasmid or chromosome, has been extensively studied in various microorganisms (Silver and Phung, 2005; Stolz *et al.*, 2006; Mukhopadhyay *et al.*, 2002; Rosen, 2002a). As more and more bacterial genomes are sequenced, it has become clear that arsenic resistance operon is a very ancient system (Qin *et al.*, 2007; Mukhopadhyay *et al.*, 2002) which must have evolved early after the origin of life because of the wide range of toxic inorganic chemicals that were likely present at that time. The gene organization of the *ars* operons from Gram-negative and Gram-positive bacteria is shown in Figure 72.4. The observed different but comparable arsenic operons have evolved through convergent evolution (Silver and Phung, 2005). These arsenic resistance determinants, isolated from both Gram-positive and Gram-negative bacterial species, have been found to be very homologous and each system has essential components, the arsenate reductase (*arsC*, *acr2*), an arsenic-specific efflux pump (*arsB*, *acr3*), and the trans-acting repressor (*arsR*, *acr1)* which senses environmental arsenic trioxide and controls the expression of *arsB* and *ars C* (Stolz *et al.*, 2006; Silver and Walderhaug, 1992). The *arsC* encoded small molecular weight protein (13–15 kDa) related to the class of tyrosine phophatase mediates the reduction of As(V) to As(III) in the cytoplasm (Rosen, 2002a), while *arsB* encoded arsenite permease extrudes As(III) out of the cells by functioning as an $As(OH)_3/H^+$ antiporter (Meng *et al.*, 2004), therefore expression of both *arsB* and *arsC* provides resistance to both As(III) and As(V), which are controlled by *arsR*. The appearance of arsenate-resistance microorganisms, however, is surely more recent, and probably evolved after the appearance of atmospheric oxygen, which created pressure for the evolution of arsenate reductase (*arsC*) from the protein tyrosine phosphatase (Mukhopadhyay *et al.*, 2003).

In some of the organisms, the *ars* operon (*arsRDABC*) consists of five genes with two additional components *arsA* and *arsD* which code for two additional proteins. *arsD* exhibits weak As(III)-responsive transcriptional repressor activity (Lin *et al.*, 2007; Chen and Rosen, 1997). The *arsA* codes for intracellular ATPase proteins which bind as a dimer to the arsenic membrane efflux pump coded by *arsB* to provide the higher levels of As(III) resistance (Rosen, 2002b). The arsenite membrane efflux pump is unique in that it can function either chemiosmotically (alone) or as an ATPase (dimer complexes).

The chromosomal locus of *Escherichia coli* contains only *arsRBC* (Martin *et al.*, 2001), whereas *ars* operon in *Escherichia coli* plasmid R733 (Accession no. J02591), R46 (Accession no. U38947), and *Acidiphilium multivorum* plasmid KW301 (Accession no.AB004659) comprises five mentioned genes, *arsRDABC*. The *Staphylococcus* plasmid pI258 (Accession no. M86824), pSX267 (Accession no. M80565), chromosome of *Pseudomonas stutzeri* (Accession no. AY702476), and chromosome of *Pseudomonas aeruginosa* (Accession no. X80057) contains only three genes, *arsRBC*. The *ars* operon in the skin element of *Bacillus subtilis* contains *arsR*, *orf2*, *arsB*, and *arsC*; however, *orf2* homologs are not established enough to play an essential role in the resistance mechanism (Sato and Kobayashi, 1998). The multiple *arsC* genes were found in the plasmid YS314 *Cornybacterium efficiens* (Accession no. NC_004369). Arsenite and arsenate resistance has been identified in *Cornybacterium glutamicum* resulting in the finding that resistance is mediated by two operons *ars1* and *ars2* located some distance from each other in the bacterial chromosome. Although both the operon *ars1* and *ars2* contain *arsR*, *arsB*,

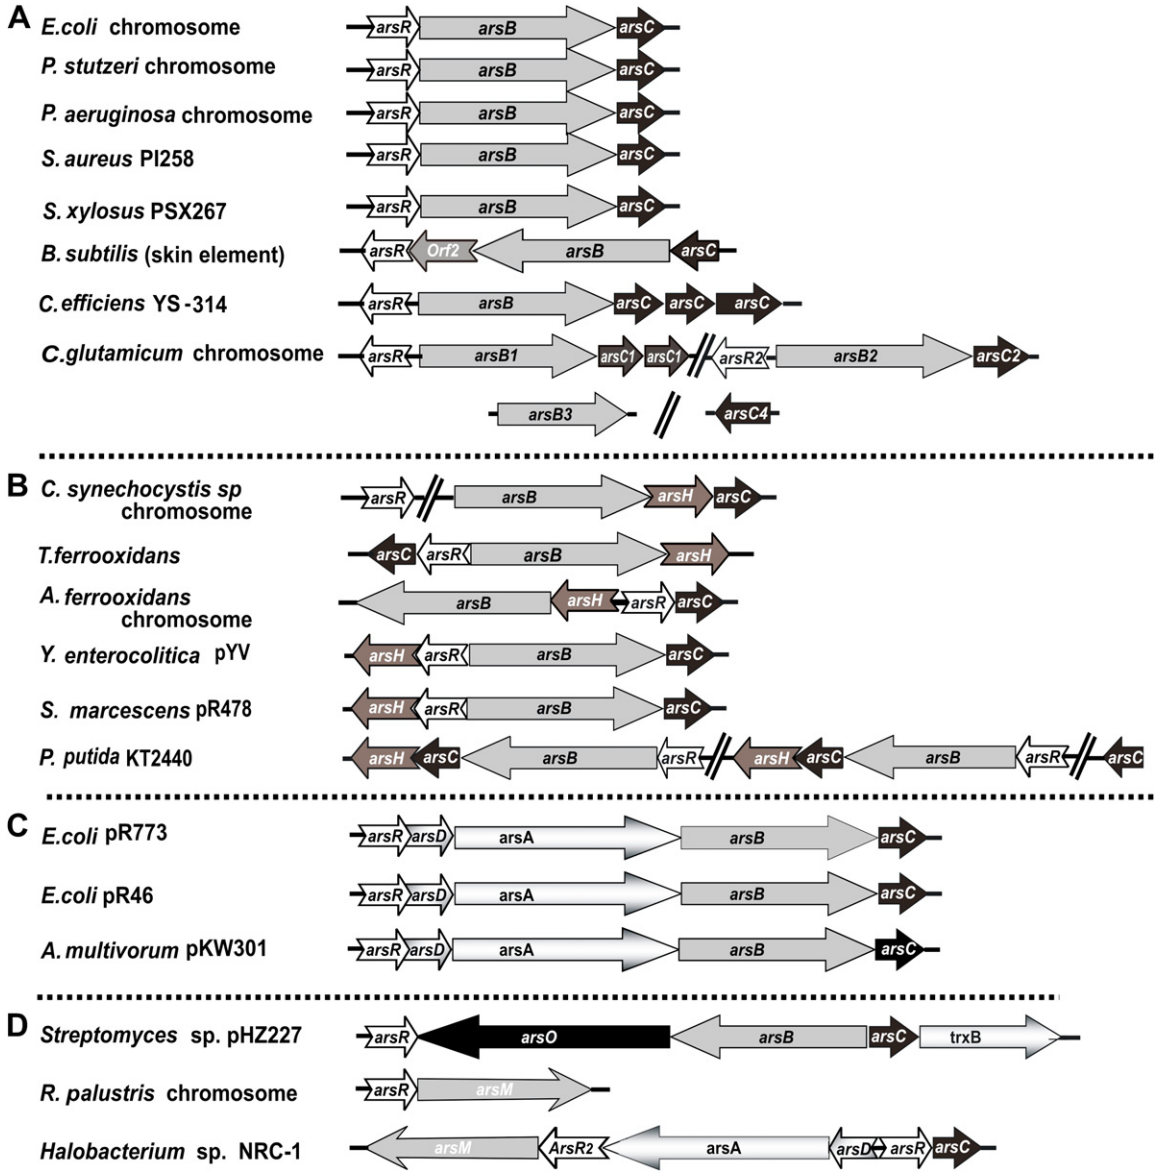

FIGURE 72.4. Schematic representation of genes involved in arsenic resistance/detoxification. Arrows represent open reading frames. Dashed boxes indicate the internal fragments of desired genes. (A) Three gene operon (*arsRBC*) encoding transcriptional repressor (*arsR*), an arsenite permease (*arsB*), and arsenate reductase (*arsC*) present in the *E. coli* chromosome (Accession number X80057), *P. stutzeri* chromosome (Accession number AY702476), *P. aeruginosa* chromosome (Accession number AF010234), *Staphylococcus* plasmid I258 (Accession number M86824), and SX267 (Accession number M80565), *Bacillus subtilis* skin element (Accession number D84432), *C. efficiens* plasmid YS314 (Accession number NC_004369), *C. gutamicum* chromosome (Accession number NC_003450). (B) The four gene operon (*arsRBHC*) has an additional protein of unknown function (*arsH*) in chromosome C, S*ynechocystis* sp. (Lopez-Maury *et al.*, 2003), in chromosome from *T. ferooxidans* (Butcher *et al.*, 2000), in chromosome from *A. ferooxidans* (Accession number AF173880), plasmid R478 from *S. marcescens* (Accession number AJ288983), plasmid YV from *Yerisiniae enterocolitica* (Accession number U58366), and plasmid *P. putida* (Accession number NC_002947). (C) The five gene operon (*arsRDABC*) encoding arsenite inducible repressor (*arsR*), negative regulatory protein (*arsD*), an oxyanion-protruding ATPase, an arsenite efflux pump (arsA and *arsB*, respectively), and arsenate reductase (*arsC*) present in *E. coli* plasmid R773 (Accession number J02591) and R46 (Accession number U38947) and in plasmid KW301 from *A. multivorum* (Accession number AB004659). (D) The five gene operon (*arsROBCT*) encoding arsenite inducible repressor (*arsR*), putative monoxygease (*arsO*), an arsenite permease (*arsB*), arsenate reductase (*arsC*), and putative thioredoxin reductases (*arsT*) present in plasmid HZ227 of *Streptomyces* sp. (Accession number DQ231520). Additional arsM [putative arsenite (III)] methyl transferase regulated by arsR type repressor from *R. palustris* (Qin *et al.*, 2006) and the arsADRC-R2M-type arsenic gene cluster from *Halobacterium* sp. strain NRC-1 (Wang *et al.*, 2004) (modified from Ordonez *et al.*, 2005, Mateos *et al.*, 2006).

and *arsC* genes, the operon *ars1* contains an additional arsenate reductase gene (*arsC1*), located immediately downstream from *arsC1*, arsenite permease (*arsB3*) and arsenate reductase gene (*arsC4*), scattered on the bacterial chromosome (Ordonez *et al.*, 2005).

In addition to the above-mentioned arsenic resistance operons, a broad diversity of four gene *ars* operons has been described in different species. An additional regulatory gene *arsH* has been identified which regulates the arsenic resistance operon. The *arsH* was originally identified in the *ars* cluster of a Tn2502 transposon of *Yersinia enterocolitica*, and appears to be necessary for arsenic resistance (Neyt *et al.*, 1997). The chromosomal arsenic resistance genes, including *arsH* of the acidophilic, chemolithoautotrophic, biomining bacterium *Thiobacillus ferrooxidans*, were cloned and sequenced and showed an unusual arrangement of *ars* genes where the putative *arsR* and *arsC* genes and the *arsBH* genes were translated in opposite directions (Butcher *et al.*, 2000). The complete genome sequence and comparative analysis of *Pseudomonas putida* KT2440 revealed the presence of additional regulatory genes *arsH1* and *arsH2* (Canovas *et al.*, 2003). In *Pseudomonas putida* both *arsH1* and *arsH2* were very similar to their counterparts in *Yersinia enterocolitica* and *Thiobacillus ferrooxidans* (over 74%). The genetic organization of the *ars* operon in *Pseudomonas putida*, *Yersinia enterocolitica*, and *Thiobacillus ferrooxidans* is different. In *Pseudomonas putida arsH* is placed downstream of *arsC* and transcribed in the same orientation, whereas *Yersinia arsH* is located upstream of *arsR* and transcribed divergently. The *arsBHC* operon in the *Cyanobacterium synechocystis* strain PCC 6803 was elucidated where the *arsH* gene was required for arsenic resistance, although the function of the *arsH* product was not explained (Lopez-Marury *et al.*, 2003). The *arsH* protein was annotated as a member of the NADPH-dependent FMN reductase family. Recently, the crystal structure of an *arsH* protein from *Shigella flexneri* refined at 1.7 Å resolution revealed that the *arsH* protein has an alpha/beta/alpha-fold typical for FMN binding proteins (Vorontsov *et al.*, 2007).

The arsenic resistance systems are found in many prokaryotes and there can be many variations in gene number and order (Butcher *et al.*, 2000). Some species have multiple *ars* operon and tandem *arsC* genes (Qin *et al.*, 2006). The legume symbiont *Sinorhizobium meliloti* possesses a unique *aqpS–arsC* detoxification system, the AqpS is the primary transport system associated with arsenite import, which was found in place of ArsB and functioned in arsenite efflux (Yang *et al.*, 2005). The *ars* operons have also been found in arsenate-respiring bacteria though arsenic resistance is not directly involved in arsenic respiration (Saltikov *et al.*, 2005). Many arsenite-oxidizing bacteria also have an *ars* operon, providing them with the ability to both oxidize and reduce arsenic (Macur *et al.*, 2004). Other genes that have also been found in *ars* operons are rhodanese (Bordo and Bork, 2002) and *arsO* and *arsT* (Wang *et al.*, 2006) but their functions have not been established in the arsenic resistance mechanism. New arsenic resistance gene clusters continue to emerge, and varied mechanisms seem to occur in diverse biological systems. The *ars* operon in the *Rhodopseudomonas palustris* contains *arsM* [As(III) *S*-adenosylmethyltransferase] to confer the arsenic resistance (Qin *et al.*, 2006). The *Halobacterium* sp. strain NRC-1 possesses an *arsADRC-R2M*-type arsenic resistance gene cluster involving a putative arsenite (III)-methyl-transferase (Wang *et al.*, 2004). The circular plasmid pWCFS103 in *Lactobacillus plantarum* carries a uniquely organized *arsRDDB*-type arsenic resistance gene cluster (Kleerebezem *et al.*, 2003) that lacks the arsenate reductase gene *arsC* and contains two copies of the *arsD* regulatory gene. In the arsenic resistance gene cluster from the large linear plasmid pHZ227 in *Streptomyces* sp. strain FR-008, two novel genes, *arsO* (putative flavin-binding monooxygenase) and *arsT* (putative thioredoxin reductase), were coactivated and cotranscribed with *arsR1–arsB* and *arsC*, respectively (Wang *et al.*, 2006). The *arsO* was homologous to flavin-binding monooxygenases, as it was 57% identical to putative monooxygenase (ZP_00420634) from *Burkholderia vitenaminesis* G4 and 48% identical to putative monooxygenase (NP_744078) from *Pseudomonas putida* KT2440. The *arsT* showed extensive homology to numerous thioredoxin reductases, such as thioredoxin reductases from *Streptomyces coelicolor* A3 (71% amino acid identity to CAA63076) and *Streptomyces clavuligerus* (73% amino acid identity to CAA79940).

VI. ENHANCED ARSENIC ACCUMULATION IN BACTERIAL CELLS

Biological methods are gaining momentum because of their potential in providing a cost-effective technology for heavy metal remediation. One more emerging technology that has received more attention in recent years is the development of biosorbents with high affinity and specificity. Unfortunately, very few reports for arsenic removal have been demonstrated except for nonspecific binding to the cell walls. These biosorbents, however, generally lack the high affinity and specificity. Although arsenic hyperresistant and hypertolerant organisms have been isolated from arsenic-contaminated sites (Joshi *et al.*, 2008; Canovas *et al.*, 2003), their use for arsenic bioremediation has not been reported. The selective removal of arsenic and mercury was reported by generating microbial biosorbence with surface exposed *arsR* and *merR*. The phytochelatins play a central role in heavy metal tolerance and detoxification in plants. The phytochelatins (PC), with good binding affinities for a wide range of heavy metals (Schmoger *et al.*, 2000), were exploited to develop microbial sorbents for removal of cadmium and arsenic by cloning PC synthase genes from *Arabdiposis thalina* in *Escherichia coli* and resulted in increased cellular content of copper and arsenic (Li *et al.*,

2004; Sauge-Merle *et al.*, 2003). The transgenic plant *Brassica juncea* expressing an *Arabidopsis* PC synthase exhibited enhanced arsenic tolerance without increasing arsenic accumulation (Gasic and Korban, 2007). Recently, PCs were introduced by expressing *Arabidopsis thaliana* PC synthase in the yeast *Saccharomyces cerevisiae* for enhanced arsenic accumulation and removal, resulting in six times higher arsenic accumulation as compared to the control strain under a wide range of arsenic concentrations (Singh *et al.*, 2008).

The metalloregulatory protein *arsR* was overexpressed in *Escherichia coli* and resulted in both elevated levels of arsenite bioaccumulation leading to severe reduction in cellular growth (Kostal *et al.*, 2004), and the efficacy of this strain at low arsenic levels. Equivalent strains overexpressing PC synthase genes and *arsR* could be developed to have arsenic hypertolerant strains with higher bioaccumulation, valuable for the bioremediation of arsenic.

VII. PROTEINS INVOLVED IN ARSENIC RESISTANCE

Arsenite exposure affects the transcription of gene-encoding functions related to protein biosynthesis, arsenic detoxification, oxidative stress defense, redox maintenance, and proteolytic activity. Importantly, it was observed that nearly all the components of the sulfate assimilation and glutathione biosynthesis pathways were induced at both gene and protein levels in *Saccharomyces cerevisiae*. The arsenite-exposed cells channel a large part of assimilated sulfur into glutathione biosynthesis, controlled by the transcriptional regulators Yap1p and Met4p (Thorsen *et al.*, 2007).

One of the most striking mechanisms by which bacteria combat arsenic stress is through internal metal sequestration. However, it can be assumed that proteins within the cells may provide a mechanism for sequestering metal ions and conferring a degree of resistance. In the prokaryotes, metal ion sequestration within the cell is performed by a well-characterized family of metal binding proteins called metallothioneins. Arsenic binding to *Fucus vesiculosus* metallothionein has been reported; however, the mechanism and character of metallothionein induction by arsenicals is unknown (Merrifield *et al.*, 2004). Exposure to arsenicals either *in vitro* or *in vivo* in a variety of model systems has been shown to cause the induction of a number of major stress protein families such as heat shock proteins. Among them are members with low molecular weight, such as metallothionein and ubiquitin, with masses of 27, 32, 60, 70, 90, and 110 kDa. It has been reported that a 72 kDa stress protein (Hsp72) was induced in cultured human pulmonary (L-132) cells by exposure to dimethylarsinic acid (DMA) and was accumulated specifically in the cell nuclei (Kato *et al.*, 2000). One of the most important heat shock proteins, GroEL, has been shown to be an essential component for maintaining viability with changes in temperature (Susin *et al.*, 2006; Fayet *et al.*, 1989). Recently, it has been reported that arsenate stress leads to induction of 18 unique proteins belonging to a group of phosphate transporters, heat-shock proteins involved in protein refolding, and enzymes participating in carbon and energy metabolism in the *Comamonas* sp. strain CNB-1 (Zhang *et al.*, 2007). Although very little information is available regarding arsenic stress proteins, detailed studies would enable researchers to explore the role of these proteins in arsenic resistance mechanisms, which will further open up a new avenue in the rapidly growing field of environmental bioremediation.

VIII. POTENTIAL APPLICATION FOR BIOREMEDIATION OF CONTAMINATED SITES

The discharge of heavy metals due to industrial, agricultural, and military operations has serious adverse effects on the environment (Ji and Silver, 1995). In recent years, there has been dynamic growth in the understanding of arsenic as a result of teamwork by a worldwide community of researchers working on arsenic speciation, transformations, transport kinetics, seasonal cycling, accumulation, biochemistry, molecular biology, geochemistry, and toxicology. New developments in arsenic biological and geochemical behavior will engender a better understanding of the development of new, safer, and cheaper technology to clean up the arsenic contaminated sites and polluted drinking water.

A wide variety of fungi, algae, and bacteria are now under study or are already in use as biosorbents for arsenic remediation (Deng and Ting, 2007; Macaskie and Dean, 1990). Metal binding by biomolecules of structural components or excreted polymers is fortuitous, and relative efficiencies depend on attributes of the metal ion, as well as on the reactivity of the provided ligands. The macromolecular composition of a biosorbent could be manipulated by cultivation conditions, e.g. stress-inducible fungal melanins (Macaskie and Dean, 1990) to improve its metal binding properties.

During the last few decades extensive attention has been paid to the hazards arising from contamination of the environment by arsenic. Decontamination of heavy metals in the soil and water around industrial plants has been a challenge for a long time. The use of microorganisms for the recovery of metals from waste streams (Joshi *et al.*, 2008; Patel *et al.*, 2006, 2007; Macaskie and Dean, 1990), as well as the employment of plants for landfill application (Tripathi *et al.*, 2007), has received increasing attention. Recent developments and improvements have resulted in the construction of bioreactors (Oehmen *et al.*, 2006) that have a smaller footprint, and treat the metals more effectively. Many studies have demonstrated primary removal mechanisms for the metals by arsenate-reducing bacteria, which transform arsenate to arsenite (Cohen, 2006; Afkar *et al.*, 2003; Mukhopadhyay *et al.*, 2002). Plants have been

shown to remove metals by uptake or oxidative precipitation near the roots (Shi *et al.*, 2008; Tripathi *et al.*, 2007). Plants seem to account for only a small percentage of the metal removal capacity of the wetland treatment systems. Moreover, the possibility of altering the properties of living species used in heavy metal remediation or constructing chimeric organisms possessing desirable features using genetic engineering is now under study in many laboratories. Many scientists have sought microbial community members responsible for arsenate reduction. It was found that, in the anoxic water of Mono Lake (California), two subgroups of the proteobacteria lineage *Sulfurospirillium* and *Desulfovibrio* were present and most likely using arsenate as an electron acceptor for growth (Hoeft *et al.*, 2002). They have found an interesting cycling of arsenic by rapid reoxidation of arsenate in the presence of nitrate. Thus, in some environments, both oxidation and reduction of arsenic may occur. In another study of aerobic contaminated mine tailings, it was found that members of the *Caulobacter*, *Sphingomonas*, and *Rhizobium* families may be responsible for the reduction and mobilization of arsenic (Macur *et al.*, 2001). These studies provide encouraging information on the interaction of living organisms and their constituents with arsenic, which will be useful for the bioremediation of polluted sites.

When organisms are confronted with sudden changes such as exposure to potentially toxic substances (heavy metal ions) or the onset of starvation, these stimulations induce the production of the so-called stress responsive proteins. The most thoroughly studied stress proteins include the heat-shock proteins (HSP), the induction of which is a highly conserved response across genera.

Naturally occurring microbial consortia have been utilized in a variety of bioremediation processes. Recent developments in molecular microbial ecology offer new tools that facilitate molecular analyses of microbial populations at contaminated and bioremediated sites. Information provided by such analyses aids in the evaluation of the effectiveness of bioremediation and the formulation of strategies that might accelerate bioremediation.

IX. CONCLUDING REMARKS AND FUTURE DIRECTION

The relative ubiquity of arsenic operon and the processes involved in arsenic detoxification and resistance indicate that there have been important selective factors in microbial evolution. These taxonomically diverse and metabolically versatile microorganisms have evolved a number of mechanisms to gain energy for their growth from this toxic element in their environment, and developed detoxification mechanisms including oxidation, reduction, and methylation for increased tolerance and resistance to high levels of arsenic in their environment. Through a variety of detoxification and respiratory mechanisms, microorganisms have the ability to greatly influence the speciation of arsenic within the environment and thus play a significant role in the arsenic cycle and impact of arsenic toxicity. The extensive database for arsenic resistance genes in bacterial genomes indicates that arsenic resistance operon must have evolved due to the presence of arsenic in the natural environment. New arsenic resistance gene clusters continue to emerge, and varied mechanisms seem to occur in diverse biological systems. The increasing availability of genome data and proteome analysis will help researchers to explore metabolic diversity, which may possibly lead to the discovery of new pathways and regulatory elements. Additional key areas for further investigation are regulatory genes and mechanisms involved in the dissimilatory process and the processes and enzymes involved in methylation and demethylation of arsenic which are the main processes to regulate gaseous forms of this toxic metalloid. With a better understanding of the biochemical processes involved in bacterial arsenic uptake, transport, accumulation and resistance, systematic improvements in bioremediation using molecular genetic approaches are suggested which can develop arsenic hyperaccumulating microorganisms for developing the environmental cleanup processes However, long-term efforts should be directed towards the development of a ‘‘molecular toolbox’’ composed of genes valuable for bioremediation and the systematic screening of bacterial species, and genotypes for arsenic accumulation and resistance which will broaden the spectrum of genetic material available for optimization and transfer. Mutagenesis of selected bacterial genes may also produce improved strains for the potent bioremediation processes.

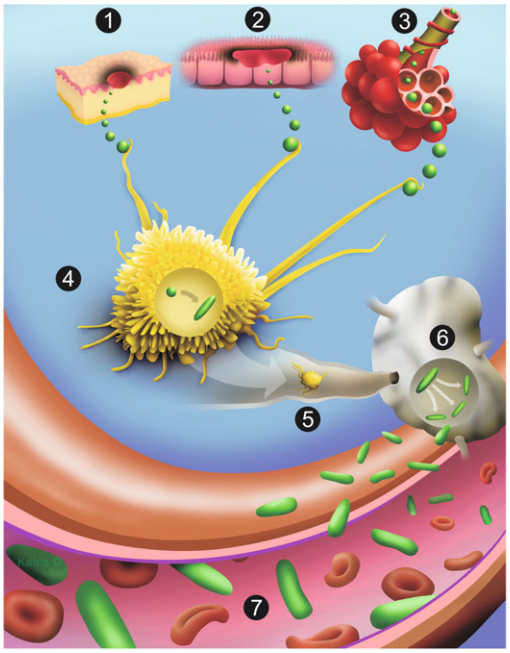
Summary of Anthrax Pathogenesis

Cutaneous 1
Spores gain access to subepidermal structures in the host through an abrasion of the skin, followed by uptake via resident macrophages.

Gastrointestinal 2
Spore uptake by phagocytes occurs after ingestion of contaminated food. Germination follows soon after entry in host immune cells.

Inhalational 3
Alveolar macrophages take up inhaled spores from the alveoli and repiratory tract. A small fraction of spores will evade destruction in the phagolysosome. Lung lesions are not found after inhalational anthrax.



4 In each case, spore germination into mature *B. anthracis* bacilli takes place in the macrophages at the primary site of infection. In the case of inhalational anthrax, germination occurs later upon arrival at the local lymph node.

5 After spore uptake into phagolysosomes by tissue macrophages, the bacilli are transported via lymphatic channels to local and regional lymph nodes.

6 Final germination takes place in the lymph nodes draining the primary site of infection. Through an unclear mechanism, mature bacilli escape from macrophages and multiply systemically.

7 Bacilli spread through the circulatory system, causing septicemia and infection of other target organs.

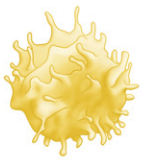
Effects of Anthrax Bacilli and Toxins on Various Cell Types

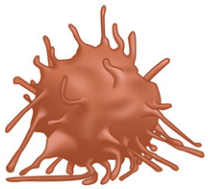
Macrophage



Suppresses cytokine production (LT)
Cell death (ET)
Increased apoptosis
Inhibits:
- Proliferation (LT)
- Differentiation (LT)

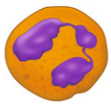
Decreases:
- ROS
- NF-κB
- IRF-3
- TNF-α
- IL-1β

Dendritic Cell



Causes cell death(Immature Dendritic) (LT)
Suppresses cytokine production (LT, ET)
Co-stimulatory molecule expression (LT)
Co-stimulatory T cell stimulation (LT)
Decreases:
- TNF-α
- IL-1β
- IL-12
- IL-10
- CD40
- Cd80
- Cd86

Neutrophil



Inhibits:
- Mobility (LT)
- Phagocytosis (ET)

T Cell

Inhibits:
- Activation (LT, ET)
- Proliferation (LT, ET)
- Surface-molecule expression (LT, ET)
- Cytokine expression (LT, ET)

Erythrocyte

Cell death

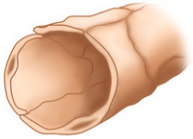
Platelet

Coagulopathy (LT, ET)

B Cell

Lowers:
- Proliferation
- IgM production
- IgG production

Endothelial Cells



Apoptosis
Leaky blood vessels
Hemorrhages

Melanocyte

Increased melanin production (LT, ET)
