While there are currently seven known antigenic serotypes of BoNT, only serotypes A, B, and E are predominantly associated with human intoxication. Intoxication by BoNTs leads to bilateral flaccid paralysis, involving skeletal muscle and structures innervated by autonomic fibers (Habermann and Dreyer, 1986; Simpson, 1986; Shapiro *et al.*, 1998). Death is inevitable if left untreated. The toxicity of BoNTs leading to flaccid paralysis of skeletal muscle is due to their ability to block acetylcholine (ACh) release from peripheral cholinergic nerve endings. Paralysis could persist for weeks to months depending on the serotype, and the available treatment consists of supportive care including fluids, total parenteral nutrition (TPN), and mechanical ventilation. Death occurs when the diaphragm and intercostal muscles become sufficiently compromised to impair ventilation or when patients succumb to secondary infections following long periods of intensive care (Hatheway *et al.*, 1984; Shapiro *et al.*, 1998; Robinson and Nahata, 2003).

BoNTs pose a serious concern to our national security. The toxins are highly lethal, easy to isolate, and easy to deliver by terrorists. Activities of hostile nations, international terrorists, and antigovernment groups make the threat of BoNTs a serious problem for both our military and civilian populations. Development of BoNTs as weapons of mass destruction began over 50 years ago. Nonstate-sponsored terrorists have an interest in BoNTs; members from the Aum Shinrikyo cult attempted to disperse BoNT in Tokyo and at US military installations throughout Japan on at least three occasions in the 1990s (Brackett, 1996). Furthermore, in the years following Operation Desert Storm (1990–1991), it was discovered that Iraq produced thousands of liters of concentrated BoNT in their weapons program. Moreover, approximately half of that volume was already loaded into military weapons. The BoNT generated by Iraq has yet to be fully accounted for. An act by terrorists to release BoNT into a civilian population through contamination of products of consumption or inhalation would pose a serious threat to national security and public safety. Wein and Liu (2005) modeled the threat of deliberate BoNT release into a milk-processing facility. The actions by such a terrorist group could lead to massive casualties. Another study estimated that dispersal of BoNT via inhalation could kill 10% of an exposed population within 0.5 km downwind of the incident.

II. BACKGROUND

A. Toxin Structure and Molecular Function

1. Background

The highly potent neurotoxins synthesized by the *Clostridium botulinum* microorganism and several related clostridial species (*C. baratii*, *C. butyricum*, and *C. argentinense*) are the causative agents of botulism, a potentially lethal disease historically associated with the ingestion of contaminated food products. Seven different BoNTs, designated A through G, are currently known to be produced by various strains of clostridial bacteria; these neurotoxins are antigenically distinct but comparable in basic structure. The BoNTs are members of a superfamily of homologous proteins that also include tetanus neurotoxin. BoNTs are generated as single-chain polypeptides which are then post-translationally modified (proteolytically nicked) to yield a disulfide bond-linked dichain structure composed of a heavy chain (H-chain or HC) and a light chain (L-chain or LC). Enzymes synthesized by these microorganisms themselves often mediate this cleavage although the gastrointestinal enzymes of the host can also generate the dichain structure from the ingested toxin. The three-dimensional dichain protein structure of the purified toxin is provided (see Figure 30.1).

2. Function of Heavy and Light Chains

The HC and LC of BoNTs each play critical roles in toxicity. HC is thought to mediate binding and internalization of the toxin at peripheral nerve synapses. LC, the toxic moiety, inhibits neurotransmitter exocytosis through its zinc-dependent endoproteolytic activity. The LCs of the various BoNT serotypes differ in their distinct molecular targets within the peripheral cholinergic nerve terminals (Schiavo *et al.*, 1992, 1993a, b, 1994; Blasi *et al.*, 1993; Yamasaki *et al.*, 1994). The endoproteolytic activities of the different toxin LCs produce similar flaccid paralytic effects, despite their distinct targets.

BoNT serotype A is the most well characterized of the different serotypes in terms of both structure and function.

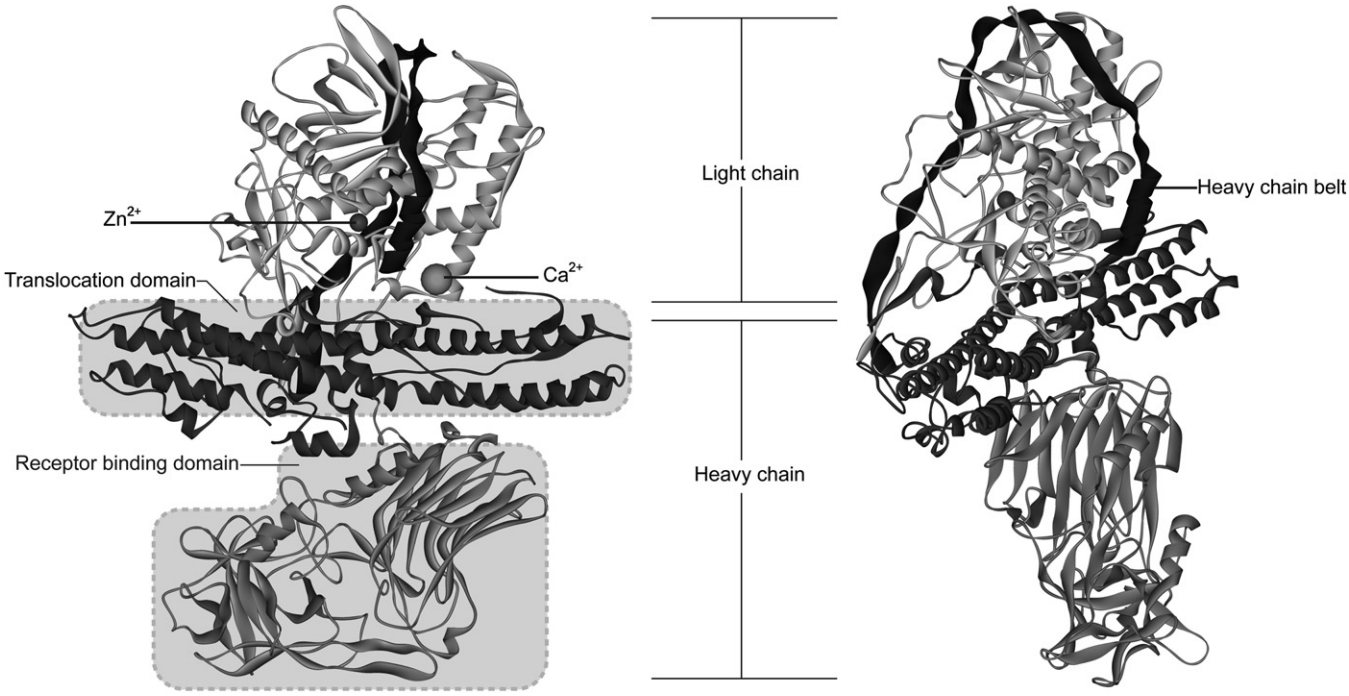

FIGURE 30.1. Three-dimensional structure of botulinum toxin serotype A (BoNT/A). BoNT/A (1,296 amino acids), rendered as a ribbon structure, is depicted in two views. BoNTs are synthesized as a single polypeptide and nicked by bacterial proteases to form a dichain molecule. The 50 kDa light chain (LC), 448 residues, and the 100 kDa heavy chain (HC), 848 residues, are linked by a dilsulfide bond. All BoNTs comprise three major domains: a receptor binding domain (C-terminal end of HC), a translocation domain (N-terminal end of HC), and a zinc-binding metalloprotease domain on LC. All seven BoNTs exhibit conserved sequence, but are also antigenically distinct at the same time. The LC seems to be held in place by the translocation belt of HC (Brunger *et al.*, 2007). The belt spans residues 492–545 in BoNT/A and 481–532 for BoNT/B and wraps around the catalytic domain of LC. Brunger *et al.* (2007) suggest that the belt acts as a surrogate pseudosubstrate inhibitor of the LC protease and acts as a chaperone during translocation across the endosome membrane into the cytosol. The belt occludes access to the active site of LC, thereby holding the unreduced holotoxin in its catalytically inactive state. The sphere represents the bound Zn^{2+} at the LC active site. The structure of BoNT/A holotoxin was provided free of copyright restrictions from the Research Collaboratory for Structural Bioinformatics (RCSB) Protein Data Bank (PDB) (Berman *et al.*, 2000; PDB ID: 2nz9; Garcia-Rodriguez *et al.*, 2007) and rendered using Accelrys DS Visualizer 2.0 software.

Early biochemical efforts led to its crystallization, and this crystalline form was used in numerous animal studies on the pathogenesis of botulism. Crystalline type A toxin has a sedimentation constant of 19S (around 900 kDa), which is far larger than the combined size of the HC and LC components (Simpson, 1981). This large ''progenitor toxin'' form was shown to dissociate under moderately alkaline conditions, releasing the ''derivative'' (7S) or neurotoxin component (Heckly *et al.*, 1960; Sugii *et al.*, 1977a, b; Chen *et al.*, 1998). The derivative neurotoxin has a molecular weight of 150 to 160 kDa, representing the combined size of the heavy and light chains. Additional work led to the finding that the dichain molecules comprising the various neurotoxins are often released as higher-order polypeptide complexes. The crystalline type A progenitor toxin consists of the 7S neurotoxin and one or more noncovalently linked accessory proteins. These nontoxic components of the progenitor toxin complex were later identified as three different hemagglutinins (HAs) and a nontoxic nonhemagglutinin (NTNH) protein.

3. Accessory Proteins of the Progenitor Toxin Complex

The accessory proteins of the progenitor toxin serve to enhance the stability of the toxin to ensure uptake from the gut. The NTNH component of the multimeric type A toxin complex is encoded by a single gene upstream of the neurotoxin locus while three different HA proteins have been characterized in association with BoNTs. All *C. botulinum* serotypes have been shown to produce neurotoxin complexes with the NTNH and HA proteins.

B. Overview of BoNT Action

After gaining entry to the lymphatics and circulation via the gastrointestinal tract, BoNTs function as potent neuromuscular blockers. The cellular and molecular mechanisms involved in toxin absorption, transit to specific target tissues, escape from the vasculature, and uptake within peripheral cholinergic nerve terminals have yet to be fully characterized. However, each of the neurotoxins has been shown to block vesicular neurotransmitter release at peripheral cholinergic synapse through the endoproteolytic cleaveage of proteins associated with the exocytosis machinery (Schiavo *et al.*, 1995, 1993a, b; Blasi *et al.*, 1993). At peripheral cholinergic nerve endings, BoNT binding to high-affinity receptor(s) leads to acceptor-mediated endocytosis and low pH-induced translocation across the endosomal membrane into the cytosol. The carboxy-terminal region of the toxin heavy chain appears to mediate binding at the nerve synapse while the amino-terminal domain controls translocation. The LC is held in close association with the HC by an amino acid belt. The LC of each toxin functions as a zinc-dependent endoprotease, cleaving at least one of three soluble *N*-ethylmaleimide-sensitive fusion (NSF) protein attachment receptor (SNARE) proteins involved in neurotransmitter release.

Stimulus-evoked, calcium-dependent release of acetylcholine (ACh) from the cholinergic synapse normally occurs through the formation of a fusion complex between ACh-containing vesicles and the intracellular leaflet of the nerve terminal membrane (Arnon *et al.*, 2001). This synaptic vesicle fusion complex consists of several proteins of the SNARE family, including a 25 kDa synaptosomal associated protein (SNAP-25), vesicle-associated membrane protein (VAMP, or synaptobrevin), and the synaptic membrane protein syntaxin. Other SNARE proteins have been identified as components of membrane transport systems in yeast and mammals but have not been implicated as targets for BoNTs. Meanwhile, type A and E neurotoxins cleave SNAP-25 while types B, D, F, and G act on VAMP and type C1 toxin cleaves both syntaxin and SNAP-25. Neurotoxin-mediated cleavage of any of these substrates disrupts the processes involved in the exocytotic release of ACh and leads to flaccid paralysis of the affected skeletal muscles.

C. Clinical Forms of Botulism in Humans and Animals

Exposure to BoNTs can produce lethal disease in humans and other animal species. Six different clinical forms of human botulism have been described in the literature (see Table 30.1). These include: (1) foodborne botulism, (2) infant botulism, (3) wound botulism, (4) an adult form of infant botulism, (5) inadvertent systemic botulism, and (6) inhalation botulism (reviewed by Cherington, 1998; Middlebrook and Franz, 2000; Arnon *et al.*, 2001). Botulism is the result of either an infectious process, involving elaboration of toxin from the colonizing clostridial organism, or a noninfectious process. Infant and wound botulism are the most prevalent infectious forms of botulism. Although rare, an adult form of infant botulism has been documented; gastrointestinal colonization in adults may be enabled by alterations in normal gastrointestinal flora resulting from antibiotic treatment (Cherington, 1998). Foodborne and inhalational have noninfectious etiologies and are the result of ingesting or inhaling preformed toxin. Although only one inhalational botulism incident has been reported in humans, this incident demonstrates that humans are susceptible to respiratory intoxication similar to that which has been experimentally produced in many laboratory species (Holzer, 1962; reviewed by Middlebrook and Franz, 2000). Finally, the emergence of a multitude of therapeutic applications for BoNTs has led to infrequent cases of inadvertent systemic botulism resulting from local toxin injection (reviewed by Arnon *et al.*, 2001).

D. Infectious Forms of Botulism

1. Infant Botulism

Infectious botulism is a consequence of ingesting or inhaling clostridial spores which colonize the large intestines,

TABLE 30.1. Clinical forms of botulism

	Infectious			Noninfectious		
	Infant	**Wound**	**Adult colonization**	**Foodborne**	**Inhalational**	**Inadvertent systemic**
Cause	Colonization of immature intestinal tract	Wound colonization resulting from contact with contaminated material	Intestinal colonization secondary to disruption of normal intestinal flora	Ingestion of preformed toxin in contaminated food products	Respiratory exposure to toxin aerosols or droplets	Systemic toxin uptake after therapeutic toxin administration
Susceptibility	Young infants (2 to 4 months of age) prior to establishment of normal intestinal flora	Self-administering users of intravenous drugs (often black tar heroin)	Antibiotic-treated patients	All exposed individuals	All exposed individuals	Patients treated with local toxin injections

germinate, and elaborate toxin into the bloodstream. Infant and wound botulism are the most prevalent infectious forms of botulism. Infant botulism comprises the majority (72%) of reported human botulism cases in the USA, while most of the remaining cases involve foodborne and wound botulism (Mackle *et al.*, 2001). Young infants are especially susceptible to infant botulism. Infants were found to be uniquely susceptible to gastrointestinal colonization due to a lack of well-established competing gut flora (Arnon, 1995). While infant botulism can be acquired by inhalation of spores, this differs markedly from inhalational botulism, which results from inhaling preformed aerosolized toxin and not spores. Clostridial spores do not pose a threat in older infants or most adults (Arnon, 1995, 1998; Cox and Hinkle, 2002).

2. Wound Botulism

Wound botulism involves growth of *C. botulinum* spores in a contaminated wound with *in vivo* toxin production (Weber *et al.*, 1993). It accounts for less than 25% of all botulism cases (Sandrock and Murin, 2001). The majority of wound botulism cases are caused by serotype A and the remainder by serotype B (Shapiro *et al.*, 1998). The neurological symptoms of wound botulism differ little from those of foodborne botulism except for the general absence of gastrointestinal symptoms. From its discovery in 1943 until 1996, only 111 incidents of wound botulism were documented (CDC, 1998; Merson and Dowell, 1973; Shapiro *et al.*, 1998); among the 100 laboratory confirmed cases, 83 cases were type A, 16 cases type B, and one a mixture of type A- and B-producing organisms (Hatheway, 1988; CDC, 1998). Risk factors for wound botulism include deep wounds, avascular areas, compound fractures, and crush injuries of the hand. Although a rare form of naturally occurring BoNT intoxication, it most recently occurred in Maryland as a result of a construction worker receiving a contaminated, compound fracture of the femur after falling into an excavated pit (Hilmas, personal observation). Wound botulism also occurs in intravenous drug users as a result of bacterial colonization at needle puncture sites or nasal/sinus lesions secondary to cocaine snorting (MacDonald *et al.*, 1985). From 1986 through 1996, 78 cases of wound botulism were reported, and the majority of cases were linked to black tar heroin, introduced intravenously.

3. Child or Adult Botulism from Intestinal Colonization

Gastrointestinal colonization in adults or children by clostridial bacteria does not typically take place except under circumstances where the normal flora has been altered by antibiotic treatment (Cherington, 1998). Botulism results from *in vivo* production of toxin, analogous to the pathogenesis of infant botulism (McCroskey and Hatheway, 1988; Chia *et al.*, 1986). Support for this form of botulism is provided by demonstration of prolonged excretion of toxin and *C. botulinum* in stool and/or by the demonstration of *C. botulinum* spores but not preformed toxin in suspected foods.

E. Noninfectious Forms of Botulism

1. Foodborne Botulism

Worldwide, BoNT intoxication is most commonly associated with food poisoning. In the early 19th century, the effects of botulism were observed to be associated with the consumption and handling of meat products. Thus German physician Justinus Kerner described what he termed ''sausage poisoning'' (Erbguth, 2004). It was later in the 19th century that the term ''botulism'' was used, from the Latin *botulus* for ''sausage''. Foodborne botulism results from ingesting preformed toxin in food contaminated with toxin spores. Inadvertent and inhalational botulism, two other noninfectious forms of botulism, also involve

exposure to preformed toxin. Outbreaks of foodborne botulism in the USA result from eating improperly preserved home-canned foods (CDC, 1995). The majority of cases of foodborne botulism are due to serotypes A, B, and E. From 1990 through 1996, type A accounted for 44.6% of foodborne outbreaks in the USA, followed by type E (35.7%) and type B (12.5%) (CDC, 1998). The prompt recognition of such outbreaks in the USA and early treatment with serotype-specific botulinum antitoxin has limited the number of casualties, severity of the disease, and the case-to-fatality ratio. Mortality from foodborne botulism has declined from 60% (CDC, 1998) in 1950 to less than 10% of clinical cases (Shapiro *et al.*, 1998).

2. Inhalational

Because humans are relatively resistant to gut colonization by the *C. botulinum* microorganism, oral and inhalational exposures to preformed neurotoxin are likely to present the greatest threats with respect to intentional dissemination. The ability for inhaled botulinum neurotoxins to produce illness has been documented in humans and in several experimental species. Only one incident involving inhalational intoxication in humans has been reported. Three laboratory workers presented with physical and neurological symptoms after accidental respiratory exposure to aerosolized type A toxin (Holzer, 1962; Middlebrook and Franz, 2000; Arnon *et al.*, 2001). These patients were all successfully treated with antiserum, gradually recovering from their weakness and visual disturbances over the next several days. After inhalational exposure, the neurotoxins are absorbed from the respiratory tract into the lymphatics and circulation for transport to peripheral cholinergic synapses (reviewed by Simpson, 2004). The pathogenesis following neurotoxin absorption is thought to be similar for both the respiratory and gastrointestinal exposure routes. Thus, the primary neurophysiological signs and symptoms associated with respiratory exposure parallel those observed in cases of foodborne botulism.

3. Inadvertent Systemic Botulism

The therapeutic indications for BoNTs are numerous. They are used in the treatment of ophthalmological disorders (strabismus, Duane's syndrome, esotropia/exotropia), movement disorders (focal dystonias, blepharospasm), spasticity, neuromuscular disorders, pain (headache, myofacial pain), disorders of the pelvic floor (anal fissures), ear/nose/throat disorders, cosmetic applications (wrinkles), and hyperhidrosis. The recent explosion in new indications for BoNTs in the treatment of a wide range of medical conditions also brings the possibility for medical errors in BoNT dosing. Systemic botulism may result from injection of excessive doses of the potent neurotoxin. The most infamous case of systemic botulism involved the paralysis of four Florida patients, including the doctor, treated with BoNTs for wrinkles. The physician used non-FDA approved formulations of type A from Toxin Research International, Inc. The research grade type A neurotoxin was apparently sold to the doctor and reconstituted to be thousands of times more potent than the typical dose used in BOTOX® for paralyzing facial muscles. Later testing estimated that the raw bulk toxin used contained between 20,000 and 10 million units of botulinum toxin. In comparison, a typical vial of BOTOX from Allergan, Inc. contains only 100 units (CIDRAP, 2004). All three patients and the physician were injected with the toxin preparation; they developed severe systemic botulism requiring mechanical ventilation. While all four survived the super-lethal dose of type A toxin, several of the patients have experienced a syndrome involving chronic gastrointestinal symptoms and discomfort months after exposure.

F. Human Intoxication

The basic syndrome of BoNT intoxication is similar for all naturally occurring forms, as well as for inhalation exposure and does not vary appreciably among serotypes (Simpson, 1986; Habermann and Dreyer, 1986; Hatheway *et al.*, 1984; Jankovic and Brin, 1997). Based upon documented laboratory evidence, human BoNT intoxication is caused by exposure primarily to serotypes A, B, E, and to a much lesser extent to serotype F; disease manifests mostly as a result of foodborne, infant, and wound botulism (Habermann and Dreyer, 1986; Simpson, 1986). BoNTs are also lethal from inhalation of aerosolized toxin, although this form is not generally observed in nature.

The various toxin serotypes are usually associated with analogous clinical presentations. Paralysis proceeds in a descending fashion after an initial bulbar involvement. The earliest symptoms of botulism typically include visual disturbances, followed by dysphagia, dysphonia, and dysarthria, reflecting an especially high susceptibility of cranial efferent terminals to BoNT action (Habermann and Dreyer, 1986; Jankovic and Brin, 1997). A descending generalized skeletal muscle weakness may then develop, progressing from the upper to lower extremities. Involvement of the diaphragm and intercostal muscles can lead to ventilatory failure and death unless appropriate supportive care is provided (Shapiro *et al.*, 1998; Robinson and Nahata, 2003).

III. EPIDEMIOLOGY

A. Foodborne Botulism

Human foodborne botulism outbreaks have typically been linked to the consumption of toxin-contaminated home-prepared or home-preserved foods (Maselli, 1998). The vast majority of foodborne botulism cases are attributed to toxin types A, B, or E. Maselli (1998) reports that type B is the most prevalent (52%) in the USA, followed by type A (34%) and type E (12%), while the CDC (1998) suggests 37.6% of all foodborne botulism outbreaks since 1950 were caused by

type A, 13.7% by type B, 15.1% by type E, 0.7% by type F, and 32.9% were unidentified with respect to toxin type. Outbreaks of type F and G botulism are rare (Sonnabend *et al.*, 1981; Maselli, 1998; Richardson *et al.*, 2004), and only anecdotal reports of isolated type C1 and D botulism cases can be found in the published literature (Lamanna, 1959).

The natural epidemiology of foodborne botulism provides additional insight into the similarities and discrepancies between the human disease and that represented in various animal models. In the USA, around 25% of reported human botulism cases are classified as foodborne and 72% are infant (Mackle *et al.*, 2001). Human type A and B foodborne botulism cases occur worldwide and constitute the vast majority of reported human intoxications (Maselli, 1998). The majority of other botulism cases are attributed to serotype E and are typically associated with the consumption of contaminated seafood. Generalizations have been made regarding the geographic distribution of the most common *C. botulinum* strains within the USA. Most human foodborne botulism outbreaks occurring west of the Mississippi are due to type A toxin; type B strains are more prevalent east of the Mississippi while type E strains are typically isolated to Alaska and the Pacific Northwest (Arnon *et al.*, 2001; Richardson *et al.*, 2004).

Several clinical and epidemiological reports have evaluated the worldwide geographic distributions of human foodborne botulism cases. A review of 13 outbreaks between 1970 and 1984 identified geographic differences in the toxin serotypes associated with human foodborne botulism cases. Type B botulism was predominant in Portugal, Spain, France, and several other European countries (Lecour *et al.*, 1988). Interestingly, the low mortality rate associated with human type B foodborne botulism (8.8% versus 24.3% for type A and 30.8% for type E in the USA from 1950 to 1979) did not correlate with the high oral toxicity for type B toxin in mice (Ohishi *et al.*, 1977; Sugii *et al.*, 1977a, b, c; Ohishi, 1984). Serotype E was linked to botulism outbreaks in select regions such as the Baltic countries (Lecour *et al.*, 1988) and typically resulted from the consumption of contaminated fish (Maselli, 1998).

Type F toxin was only associated with two reported outbreaks of human foodborne botulism prior to 1998 (Maselli, 1998). The first of these outbreaks occurred in Denmark (on the Island of Langeland) and was attributed to a contaminated liver paste product (Muller and Scheibel, 1960; Richardson *et al.*, 2004). The second outbreak, in 1966, affected three individuals in California and was associated with home-made venison jerky (Midura *et al.*, 1972; Richardson *et al.*, 2004). While a few other type F botulism cases have been reported, they are generally thought to have resulted from intestinal colonization and type F toxin production by another related species, *C. baratii* (Hall *et al.*, 1985; Richardson *et al.*, 2004). A recent report of a type F botulism case in California provided some additional insight into this uncommon toxin serotype and the associated clinical disease (Richardson *et al.*, 2004). The patient described in this report presented with typical signs and symptoms including ptosis, dysphagia, and weak extremities. Although the source of the ingested toxin was not conclusively determined, the exposure was tentatively linked to shellfish consumption, and type F toxin was subsequently detected in the patient's stool (Richardson *et al.*, 2004). Human type F botulism cases may have been underreported in the past since some laboratories did not test culture isolates for the presence of *C. baratii*, which also produces type F toxin.

Type G toxin-producing clostridial organisms (*C. argentinense*) have been detected in several soil samples from a South American cornfield (Gimenez and Cicarelli, 1970; Maselli, 1998), but only one reported outbreak of type G botulism (in Switzerland) has been identified in the published literature (Sonnabend *et al.*, 1981). Certain aspects of this outbreak draw questions as to whether it was truly associated with type G intoxication. Type G organisms were isolated from all four affected adults and an 18-week-old infant, suggesting that the intoxications were due to ingestion and subsequent colonization by type G spores (Sonnabend *et al.*, 1981). Type G toxin was detected at low levels of 2–7 mouse intraperitoneal lethal dose 50 ($MIPLD_{50}$)/ml in the serum of three out of the four lethally intoxicated adults, all of whom died suddenly sometime after the presumed foodborne intoxication. Type A toxin was also detected in two of these individuals, suggesting that the intoxications may have involved colonization either by a mixed set of clostridia or by a unique strain producing multiple toxins (Sonnabend *et al.*, 1981). Alternatively, detection of dual serotypes could have been an artifact of the culture or testing methods. Soil samples taken from the area indicated the presence of only type A clostridial organisms (Sonnabend *et al.*, 1981). Regardless, the occurrence of human type G botulism is rare, and the relative susceptibility of humans to colonization and intoxication from this serotype is not clear.

Species-specific patterns of susceptibility to different toxin types are common in both naturally occurring and experimental foodborne botulism. These differences do not necessarily facilitate identification of the most appropriate animal models from the human condition, but they may help to eliminate highly variant species. For example, mink were reported to be relatively resistant to toxin types A, B, and E (Yndestad and Loftsgard, 1970), which are responsible for the vast majority of human botulism outbreaks (Maselli, 1998; Arnon *et al.*, 2001). Weanling pigs, on the other hand, were shown to be moderately resistant to types A, C1, E, and F and highly resistant to type D toxin (Smith *et al.*, 1971). Experimental and epidemiological studies have identified one persistent difference in the epidemiology of botulism in humans compared to many other animal species. Few reports citing human outbreaks of type C and D are available. One of these reports mentions two human type C outbreaks and one type D outbreak but provides no

reference for these cases (Lamanna, 1959). More recent reports of human type C or D botulism have not been found in the literature, and it is widely assumed that human foodborne intoxications are rarely, if ever, associated with these toxin types. In contrast, naturally occurring botulism of both types is quite common among domestic and wild animal species, and several studies have established the susceptibility of various laboratory species to experimental type C and D botulism.

The authors of this chapter have studied the effect of C and D toxin serotypes, as well as A, B, and E, on human intercostal muscle (Hilmas, unpublished data). All serotypes showed a similar ability to produce complete muscular paralysis in *ex vivo* human intercostal muscle. Intercostal muscle was excised from patients receiving a thoracotomy and intercostal muscle flap procedure. The muscle was removed tendon to tendon by surgical excision without electrocautery and dissected into multiple bundles with their associated intercostal nerves. The nerve–muscle units were placed in a vertical twitch bath and stimulated at 0.03 Hz (0.2 ms pulses of supramaximal strength) using a novel nerve clamp electrode to illicit an indirect muscle twitch. Potent toxins (1 nM) from various serotypes were added to the bath after confirming the stability of control muscle responses. In each case, twitch tensions declined to negligible amplitudes by 1 h after direct toxin application to the tissue bath.

Several nonhuman primate species are known to be susceptible to type C1 and D toxins both in nature and as experimental models. A large natural outbreak of type C botulism was reported in a troop of captive *hamadryas* baboons in 1989 (Lewis *et al.*, 1990). The outbreak resulted in the deaths of 36 animals, including 3 adult males, 6 sub-adult males, 17 adult females, and 10 sub-adult females. Additional animals displayed mild to moderate symptoms that resolved over a period of several days (Lewis *et al.*, 1990). As with human foodborne botulism, various age groups and both sexes were affected, and no macroscopic lesions were apparent. Serum samples and gastric contents taken from ill animals contained type C1 toxin, although the source of the toxin was not identified (Lewis *et al.*, 1990). The authors speculated that man is probably also susceptible to type C1 toxin. The reason for the relative lack of human type C botulism cases remains unknown. It has been suggested that serotype C is often associated with carrion, providing a possible explanation for the absence of reported human cases. At least two other outbreaks of naturally occurring type C botulism in nonhuman primates were previously reported, one in squirrel monkeys (*Saimiri sciureus*) and capuchin monkeys (*Cebus capucinus* and *Cebus olivaceus*) (Smart *et al.*, 1980) and the other in gibbons (*Hylobates lar*) (Smith *et al.*, 1985).

In addition to nonhuman primates, most other animal species that show some sensitivity to botulinum intoxication are in fact susceptible to toxin serotypes C1 and D. Several rodent species are susceptible to oral intoxication with most botulinum toxins, including types C1 and D (Matveev, 1959; Jemski, 1961a, b; Cardella *et al.*, 1963; Sergeyeva, 1966; Sugiyama *et al.*, 1974; Smith, 1986; Fujinaga *et al.*, 1997; Gelzleichter *et al.* 1999; Middlebrook and Franz, 2000). The majority of botulism outbreaks in cattle have also been attributed to toxins C1 and D (Schocken-Iturrino *et al.*, 1990). Cattle intoxication is typically associated with the ingestion of contaminated bones and other carcass remains; their apparent susceptibility to type C and D botulism might simply be due to frequent ingestion of decaying material that is primarily contaminated with these toxin types. A recent study indicated that cows are also uniquely sensitive to intravenous injection of type C1 toxin (Moeller *et al.*, 2003). The high susceptibility of cattle to type C botulism is not dependent on exposure route although the specific factors contributing to their sensitivity are not known.

A recent outbreak of type C botulism among farmed mink and foxes in Finland underscores the need to consider not only the quantitative susceptibility of various species to the toxins but also the potential epidemiological significance of interspecies differences in dietary patterns. Lindstrom *et al.* (2004) reviewed the Finland incident, which was the largest documented type C botulism outbreak in fur production animals. Over 52,000 animals developed illness after consumption of feed product that was contaminated with over 600 MLD of type C1 toxin per gram. This feed consisted of acidified slaughter by-products from poultry, beef, and fish (Lindstrom *et al.*, 2004). According to national regulations, these by-products were acidified with an organic acid to yield a final pH of 4.0 or lower. Such processing would inhibit the growth of many microorganisms but would not necessarily result in significant toxin inactivation. Over 44,000 of the 52,000 affected animals died, and the death rate among all potentially exposed animals was almost 22% (Lindstrom *et al.*, 2004).

The large number of animals affected and the high lethality associated with the outbreak could be considered indicative of the high susceptibility of the affected species to foodborne type C botulism. This high susceptibility might appear to be in stark contrast to that of man due to the scarcity of human type C cases. However, the Finland outbreak provides a clear indication that dietary differences between species may play a significant role in these epidemiological patterns. Humans would be far less likely to consume slaughter by-products (including intestinal tissues) as opposed to the higher quality beef, poultry, and fish products. Moreover, preparation of such products for human consumption would generally involve cooking rather than acidification. Thus, the influence of dietary habits must be taken into consideration when evaluating interspecies differences in epidemiological patterns for the various toxin serotypes.

It remains possible that humans generally do not consume the types of foods that are typically subject to contamination with type C1 and D toxins. Some researchers continue to speculate that humans are likely to be susceptible to both serotypes because they lead to botulism in monkeys both in nature and after experimental oral

exposure. Alternatively, humans might display a unique pattern of physiological susceptibility to the different toxin types. Lack of human susceptibility to type C1 and D intoxication could be attributed either to poor absorption of these specific toxins from the human gastrointestinal tract or to resistance of human cholinergic nerve terminals to the activity of these toxins. One cell culture study provided some support for the latter explanation. Type C1 neurotoxin was shown to bind with high efficiency to mouse neuroblastoma cells and to hybridomas of mouse neuroblastomas and rat gliomas, but not to human neuroblastoma cell lines (Yokosawa *et al.*, 1989). Yokosawa *et al.* (1989) suggested that reduced binding of type C1 toxin to human versus mouse neuroblastoma cells could provide one explanation for the lack of human type C botulism cases.

Another potential explanation for the unique epidemiology of human botulism was provided in a study of botulinum toxin binding and transcytosis across polarized monolayers of two human colon carcinoma cell lines (T-84 and Caco-2). Substantial binding of iodinated BoNT/A and BoNT/B to human colon carcinoma cells was observed while minimal binding of type C1 neurotoxin was detected (Maksymowych and Simpson, 1998). Both type A and B neurotoxins were also efficiently taken up, transcytosed, and released, by the polarized human carcinoma cells, whereas minimal transcytosis of type C1 neurotoxin was observed. The patterns of neurotoxin transcytosis (A and B but not C1) observed in these human gut epithelial cell lines correlate with human susceptibility to foodborne botulism (Maksymowych and Simpson, 1998). The authors speculated that since human tissues are fully sensitive to the neuromuscular blocking properties of C1 neurotoxin (Coffield *et al.*, 1997; Eleopra *et al.*, 2004), the relative absence of human foodborne type C botulism could be due to the inability of this toxin to penetrate from the gut to the general circulation. Human susceptibility to type C1 and D neurotoxins remains unclear; however, clarification of this issue will be important in interpreting data derived both from *in vitro* studies on toxin transcytosis and from animal models for oral intoxication.

IV. PATHOGENESIS

A. Overview of Pathogenesis

BoNTs are a group of immunologically distinct but closely related bacterial proteins that act as potent inhibitors of synaptic transmission in skeletal muscle. Inhibition of ACh release from the presynaptic terminal of the neuromuscular junction (NMJ) is thought to be the sole mechanism involved in the toxins' lethal action (Sellin, 1985; Simpson, 1986) and therefore the cause of botulism. The pathogenesis of intoxication is not completely understood but is generally thought to involve a multistep process to interrupt normal vesicular release of ACh from the presynaptic motor nerve terminal. In a process of transcytosis, ingested or inhaled BoNT must first cross a barrier (either intestinal or pulmonary epithelial cells) to gain access to the circulation (see intestinal absorption of BoNT, Figure 30.2). Once in the circulation, BoNT travels to its major target, located on presynaptic membranes of alpha motor neurons at NMJs and neuroeffector junctions. Toxin binding through its heavy chain to a cell surface receptor on the presynaptic motor nerve ending is followed by internalization via an endocytotic vesicle, acidification of the endosome, conformational change allowing cleavage of the enzymatically active light chain (LC) from bound heavy chain (HC), and release of light chain toxin into the cytoplasm. Here the light chain cleaves one of the integral members of the SNARE complex (SNAP-25, VAMP, or syntaxin), proteins involved in exocytosis of ACh (Simpson, 1986, 2004; Black and Dolly, 1986; Blasi *et al.*, 1993; Montecucco *et al.*, 1994; Schiavo *et al.*, 1995). BoNT thereby prevents docking of synaptic vesicles with presynaptic plasma membrane by selective proteolysis of synaptic proteins. Each stage in BoNT action provides a potential point for pharmacological intervention.

B. Toxin Stability

1. Biological Stability of the Toxins in the Gastrointestinal Tract

A major factor to consider in botulism is the stability of both the organism and the toxin. A variety of factors can affect the stability of ingested BoNTs within the gastrointestinal tract. The oral potency of the toxins is closely related to their ability to withstand the conditions found in these biological compartments prior to absorption into the lymphatics and general circulation. The stability of BoNT preparations has therefore been examined in the gastrointestinal compartments of intoxicated animals, as well as under different enzymatic and acidic conditions *in vitro*. Some of the earliest work on BoNT intoxication indicated that the stability and resulting potency of type A toxin vary both qualitatively and quantitatively in different rodent species (Minervin and Morgunov, 1941).

Several groups have evaluated the influence of ingested foods on the gastrointestinal stability and potency of BoNTs. Lamanna and Meyers (1959) reported that the ingestion of protein- or fat-containing foods prior to oral type A exposure in mice resulted in moderate increase in toxicity. The mechanisms by which food intake enhanced toxin potency were not clarified; however, the relatively small observed increases (two-fold) could have been to normal experimental variation in determining oral toxicity values. The same study demonstrated that fluorescein-labeled type A toxin was quickly destroyed in the stomach of mice. Crystalline and purified toxins form stable complexes with albumin and other proteins found in food and serum (Lamanna and Meyers, 1959). Albumin was later shown to prevent loss of potency when type A toxin was

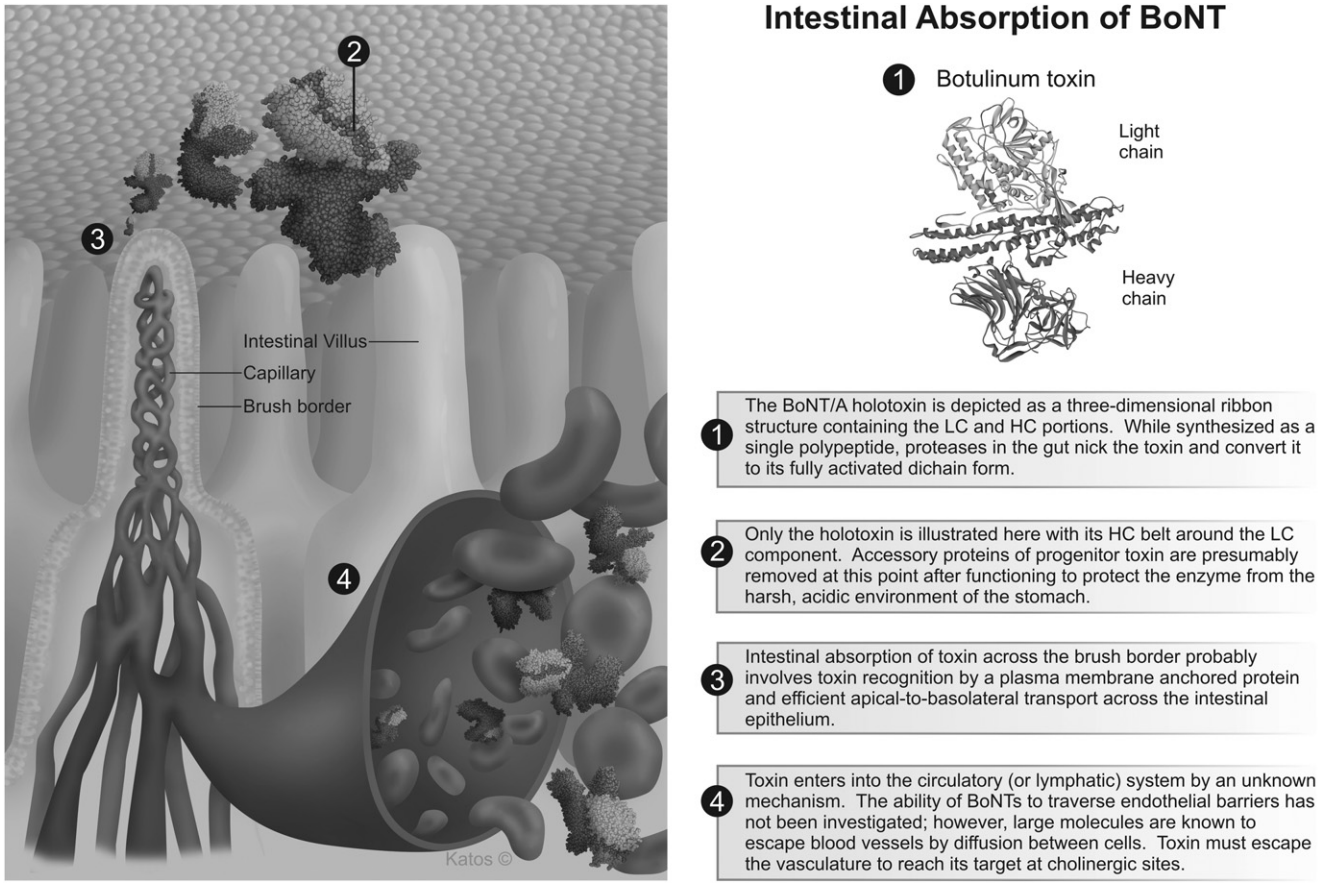

FIGURE 30.2. Intestinal absorption of botulinum neurotoxin. Neurotoxin present in the gut lumen as a result of foodborne (ingested toxin) or infant botulism (toxin synthesized by clostridial spores) must cross the epithelial membrane to reach the circulatory and lymphatic systems. The toxin presumably binds to an as yet unidentified receptor on the intestinal villus epithethium that is linked to an efficient transport process. Progenitor toxin contains nontoxic HA and NTNH accessory proteins which are probably shed from the protein prior to entry across the intestine brush border. Progenitor toxin is thought to be too large for any significant rate of paracellular diffusion (Simpson, 2004). The ability of botulinum holotoxins without accessory proteins to traverse endothelial barriers has not been investigated; however, large molecules are known to escape blood vessels by diffusion between cells. Toxin escapes the circulatory system and reaches peripheral (and possibly central) cholinergic sites. These include neuromuscular junctions, ganglia of the sympathetic and parasympathetic nervous system, postganglionic parasympathetic sites, and postganglionic sympathetic sites that release ACh. Illustrations are copyright protected and printed with permission by Alexandre M. Katos.

exposed to a wide range of pH values (Zacks and Scheff, 1967). This observation was consistent with the more recent finding that the enzymatic activity of BoNT A was enhanced in the presence of albumin (Schmidt and Bostian, 1997).

Subsequent studies expanded upon this early work by investigating the stability of other toxin types and preparations in solutions having different pH values and other conditions similar to those encountered in the gastrointestinal tract. Type C1 toxin was stable in most acidic and basic environments, as significant inactivation (as indicated by loss of toxicity in a mouse lethality assay) was only observed following exposure to extreme pH values (pH 1.8 and pH 12) (Halouzka and Hubalek, 1992). Progenitor type E toxin was more stable than its derivative (purified) form, which was subject to rapid inactivation when exposed to pH values less than 4.0 (Sakaguchi and Sakaguchi, 1974). This study demonstrated that type E progenitor toxin dissociated either during or after gastrointestinal absorption in mice, as only the derivative component could be detected in the blood and lymph following oral administration of the progenitor form.

Similar findings on the relatively high stability of progenitor versus derivative forms of the other toxin serotypes have been reported in other studies. Types A, B, and F progenitor toxins were more stable under conditions of low pH, as well as more resistant to digestion by pepsin and papain, than their corresponding derivative toxins (Sugii *et al.*, 1977a, b).

The derivative forms of toxins A and B were almost completely inactivated after 10 min of peptic digestion at pH 2.0, while the progenitor forms retained over 60% toxicity after an 80 min treatment (Sugii *et al.*, 1977a). Crystalline type A toxin was shown to be partially resistant to proteolysis by trypsin, retaining 25% of the potency of

control-treated toxin even after a 72 h trypsin digestion at 37°C (Coleman, 1954). The crystalline toxin was more readily inactivated by digestion with pepsin at pH 1.4 and chymotrypsin at pH 6.5. Interestingly, another group reported that the potency of type A toxin was weakened by 80% after a 5 h incubation in phosphate buffer (pH 7.5), while toxins C1 and D maintained 100% toxicity under the same conditions (Miyazaki and Sakaguchi, 1978). These findings demonstrate both serotype- and enzyme-dependent effects on the *in vitro* stability of the BoNTs that are also likely to impact their persistence in the gastrointestinal tract. A similar pattern of stability among the various BoNT forms in gastrointestinal juices isolated from different animal species has been demonstrated (Sugii *et al.*, 1977a). The progenitor forms for all toxin serotypes retained significant toxicity in comparison to their derived holotoxin counterparts.

Epitope mapping experiments suggested that the nontoxic component of the intact progenitor toxin complex covers a large portion of the binding domain of the neurotoxin (Chen *et al.*, 1998). Toxin interaction studies also revealed that the purified neurotoxin adheres to lipid monolayers while the progenitor complex is not subject to significant adsorption to the same monolayers. This observation led to speculation that the protective nontoxic components (HA and NTNH) may also facilitate progenitor toxin transit through the gastrointestinal tract by minimizing neurotoxin adherence to lipid membranes (Chen *et al.*, 1998). On the other hand, toxicity studies suggest that adherence to lipid membranes is not critical for neurotoxin absorption since the intact progenitor complex is generally much more potent by the oral route than the purified neurotoxin. Moreover, the neurotoxin has been shown to protect the agglutination capacity of the associated nontoxic HA components within the progenitor toxin complex (Chen *et al.*, 1998).

Importantly, the nontoxic HA components of the progenitor complex appear to protect the neurotoxin from proteolysis and degradation under pH extremes while the agglutinating activity of the nontoxic component is maintained by the presence of the neurotoxin. The type A progenitor toxin complex contains several HA components that might contribute to protecting the neurotoxin from degradation. One of these HA components, referred to here as HA-33 (or HA1 in some studies), was shown to interact directly with type A neurotoxin and to significantly increase its resistance to enzymatic proteolysis *in vitro* (Sharma and Singh, 2004). The authors of this work hypothesized that HA-33 provides protection against enzymatic degradation either by blocking the accessibility of protease-sensitive sites on BoNTs or by inducing structural changes within the neurotoxin itself.

Collectively, these studies offer important insight into the relative stability of the BoNTs within the gastrointestinal tract based upon their resistance to inactivation under various enzymatic conditions. In general, toxin stability directly correlates with the presence of the accessory HA and NTNH components of the multimeric progenitor toxin complex. These proteins appear to function in protecting the neurotoxin from degradation or inactivation. The various toxin serotypes also display unique resistances to enzymatic digestion although the basis for these differences is not known.

C. Oral Intoxication: Toxin Absorption from the Gastrointestinal Tract

1. Role of Progenitor Toxin Accessory Proteins

The role of the nontoxic accessory proteins within the progenitor toxin complexes is not fully understood. They appear to function in protecting the ingested toxins from degradation and in facilitating absorption from the gastrointestinal tract. Functional characterization of the HA and NTNH proteins has been advanced by biochemical techniques for generating toxin preparations containing only select components of the progenitor complex. These 7S toxins are relatively sensitive to proteolytic degradation and denaturation in the stomach (Schiavo *et al.*, 1992). The auxiliary HA and NTNH proteins within the multimeric complex have been shown to dramatically increase the stability of the associated neurotoxin during transit through the gastrointestinal tract (Ohishi *et al.*, 1977; Fujinaga *et al.*, 1997; Sugii *et al.*, 1977a, b, c). The multimeric complex is then thought to readily dissociate either in the intestine or after absorption into the circulation. Most studies suggest that the accessory proteins do not appear to have any involvement in the activity of the toxins at peripheral nerve terminals. Thus, the HA and NTNH components are likely to be dispensable in disease pathogenesis after parenteral or respiratory exposure, where the toxins bypass the harsh conditions of the gastrointestinal tract.

2. Role of Enterocytes

Both absorptive enterocytes and Peyer's patch-associated M cells have been implicated in toxin transcytosis from the gastrointestinal tract after oral exposure. Peyer's patches are collections of lymphoid tissue that are part of the gut-associated lymphoid tissue. M cells are found not only in the intestinal tract, but also in the respiratory epithelium overlying bronchus-associated lymphoid tissue. Unpublished work by Park and Simpson (2003) indicates that knockout mice deficient in Peyer's patch M cell complexes are still susceptible to both oral and respiratory botulinum intoxication and the development of HC-specific antibody responses. Based upon these results, the authors suggest that M cells are not likely to be involved in toxin uptake and processing from the respiratory tract. In addition, both cell types have comparable transcytosis rates (M cells are five times as efficient in transcytosis than intestinal enterocytes), but enterocytes greatly outnumber M cells; therefore, gastrointestinal enterocytes are the predominant cell types involved in toxin uptake and processing from the gastrointestinal tract.

Maksymowych and Simpson (1998) used transwell culture systems with various transformed epithelial cell lines to evaluate the fate of the HA components of type A progenitor toxin complex. Radiolabeled preparations of both BoNT/A and HA were taken up by cultured T-84 human colon carcinoma cells by bulk endocytosis. However, efficient delivery across the T-84 cells was only observed for the neurotoxin.

D. Respiratory Intoxication

The potential threat posed by aerosolized botulinum toxins is emphasized by their ease of production, their extremely high potency relative to other biological toxins, and their use in various weaponization programs over the past several decades (Arnon *et al.*, 2001). This threat, along with the relative lack of information on respiratory toxicity and pathogenesis in humans, has fueled research on inhalational botulism in several animal models including mice, rabbits, guinea pigs, mongrel dogs, and rhesus monkeys.

1. Toxin Absorption from Respiratory Tract

The relative persistence and absorption of the toxins following experimental respiratory exposure have been investigated in a few animal species. An early literature review suggests that type A toxin is more potent in mice by the respiratory route than by subcutaneous (SC) administration but less potent by the intraperitoneal (IP) route (Morton, 1961).

Guinea pigs were shown to be highly sensitive to inhaled botulinum toxins when compared to other rodent species. Respiratory penetration and retention of inhaled toxin are higher in guinea pigs than mice (Lamanna, 1961). Toxin could be detected in the lungs of guinea pigs after intranasal (IN) administration of only 2 mouse lethal doses of type E toxin although detection in the blood or liver required higher doses (Sergeyeva, 1962, 1966). Guinea pigs were also reportedly more susceptible to type A toxin by inhalation than mice because shorter incubation periods were observed in guinea pigs prior to the onset of acute disease (Iakovlev, 1958).

Although inhalational botulinum intoxication was investigated in other animal species, these studies have not provided specific data on toxin absorption. The behavior of BoNTs in the respiratory tract was only recently investigated. Park and Simpson (2003) studied the properties of pure BoNT/A neurotoxin both *in vivo* and *in vitro* using mice and pulmonary cell culture models, respectively. Mean survival times were compared in mice receiving various doses of pure BoNT/A either IN or IP. Pure BoNT/A was found to be a potent intranasal poison, although the toxicity (as determined by mean survival time) associated with IP administration was somewhat higher. Mean survival times in mice were less than 100 (IP) or 600 min (IN) after administration of 0.1 μg pure toxin; 75 (IP) or 400 min (IN) for 1 μg toxin; and 120 min (IN) for 10 μg toxin (Park and Simpson, 2003). As seen with oral and parenteral routes, a linear relationship existed between the log of the intranasal dose administered and the geometric mean survival time. The HA and NTNH component of the progenitor toxin did not enhance toxicity, establishing different requirements for the stability and absorption of inhaled versus ingested toxin (Park and Simpson, 2003).

Transwell experiments were also performed to investigate BoNT/A transcytosis across a human pulmonary adenocarcinoma cell line (Calu-3), the MDCK cell line, and a primary rat alveolar epithelial cell line (Park and Simpson, 2003). Efficient BoNT/A transcytosis in both directions across polarized Calu-3 monolayers was observed, while toxin transcytosis occurred at a much lower rate across MDCK cells. These findings were in agreement with previous work demonstrating that the efficiency of BoNT/A transcytosis across MDCK monolayers was much lower than that observed across gut epithelial cells (Maksymowych and Simpson, 1998). BoNT/A transcytosis was also observed across primary rat alveolar cells, although at a slightly slower rate than that seen for the human adenocarcinoma cells (Park and Simpson, 2003). While the light chain of BoNT/A was not essential for transcytosis, heavy chain apical–basolateral (A-B) and basolateral–apical (B-A) transcytosis rates were somewhat lower than those of intact BoNT/A for both Calu-3 cells (HC 53% lower than BoNT/A for A→B; 45% lower for B→A) and rat alveolar cells (HC 62% lower for A→B; 17% lower for B→A). The transcytosis process was shown to involve an active-energy-dependent mechanism and was significantly inhibited by toxin preincubation with immune serum (Park and Simpson, 2003).

An important caveat to consider when evaluating the relevance of these *in vitro* studies is the use of pulmonary adenocarcinoma and alveolar epithelial cell lines in modeling respiratory absorption. It is generally believed that systemic absorption of inhaled particles is more likely to occur within the distal regions of the respiratory tract; therefore, particles must pass through thinner membranes in the deep lung and are less susceptible to nonabsorptive particle clearance (Palm *et al.*, 1956; Lamanna, 1961; Schlesinger, 1989). Some potential also exists for significant particle absorption from the nasopharyngeal and tracheobronchial regions of the respiratory tract; the cell lines utilized in these *in vitro* studies clearly do not account for this absorption potential. Importantly, investigators in the field have recently sought to characterize the specific cell types involved in toxin absorption from the respiratory tract.

M cells are found not only in the intestinal tract, but also in the respiratory epithelium overlying bronchus-associated lymphoid tissue. The studies of Park and Simpson (2003) indicate that M cells are not the major players in transepithelial transport of toxin across the respiratory epithelium. Additional studies directly investigating the absorption of inhaled BoNTs do not exist.

E. Toxin Binding and Uptake into Target Tissues

The remaining steps of BoNT pathogenesis following neurotoxin absorption are thought to be similar for both the respiratory and gastrointestinal exposure routes. After oral or inhalational exposure, the neurotoxins are absorbed from the gut or respiratory tract, respectively, into the lymphatics and circulation for transport to peripheral cholinergic synapses (Simpson, 2004). Figure 30.3 illustrates the neuromuscular junction, a major target for the actions of BoNTs. BoNTs are taken up presynaptically at the endplate region of neuromuscular junctions (Verderio *et al.*, 1999) and at other cholinergic synapses. Toxin binding involves high-affinity presynaptic receptors. These receptors have recently been identified as a combination of poly-sialogangliosides, synaptic vesicle (SV) protein 2 (SV2), and synaptotagmin (Verderio *et al.*, 2006). Each serotype displays an affinity for a unique combination of receptors. For example, BoNT/B recognizes synaptotagmin II (and I) and ganglioside lipids (Jin *et al.*, 2006; Nishiki *et al.*, 1996; Dong *et al.*, 2003) (see Figure 30.3). BoNT/A involves recognition of SV2C, SV2A, and SV2B (Dong et al., 2003); binding to SV2C also involves a lipid. After toxin binding,

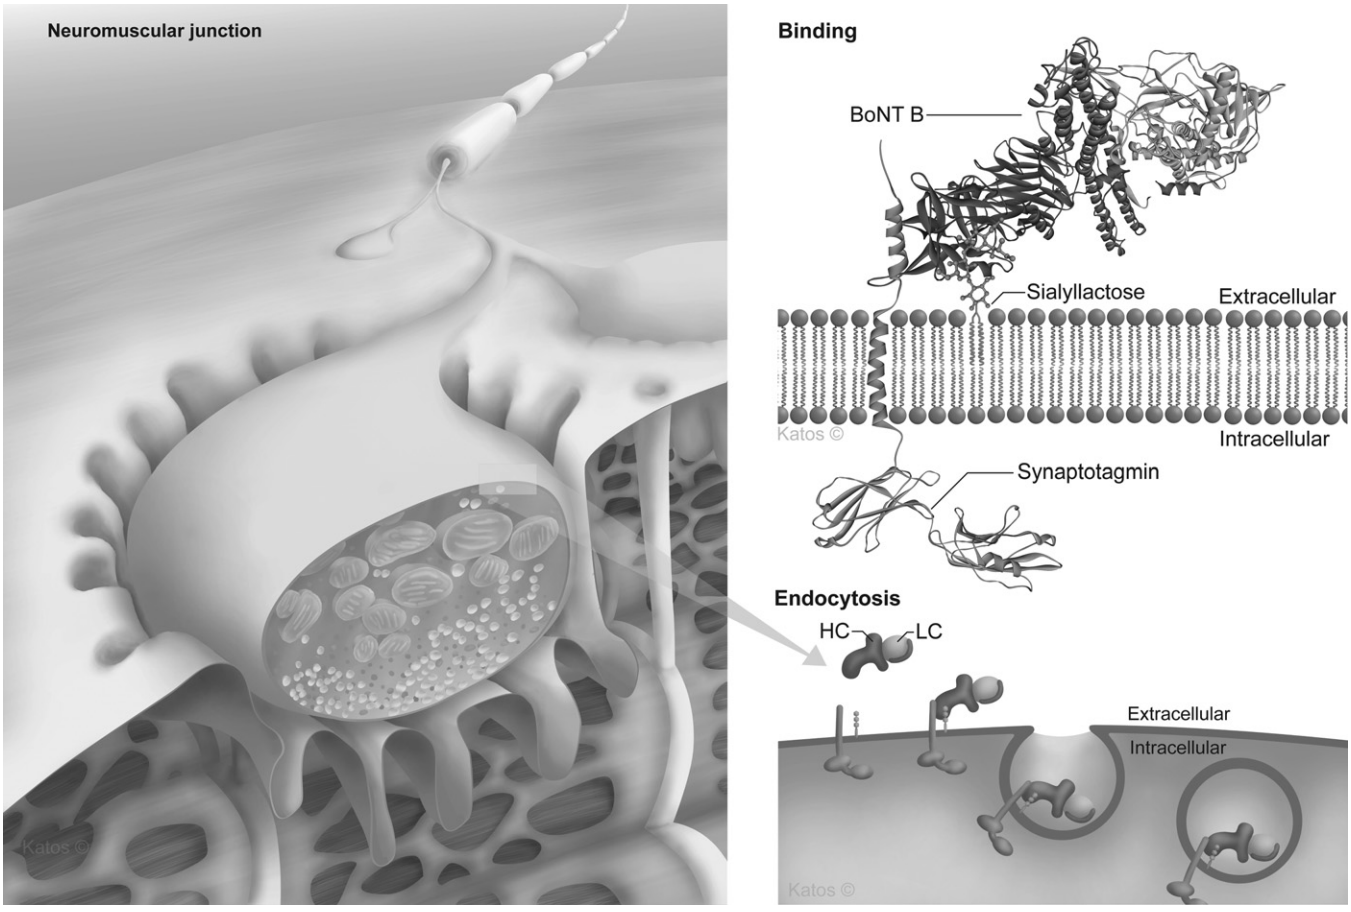

FIGURE 30.3. Toxin binding and internalization at the neuromuscular junction. Left panel: A mammalian neuromuscular junction is illustrated with the alpha motor neuron innervating skeletal muscle at specialized junctional folds in the membrane (Couteaux, 1973). Invaginations of the T system are also illustrated at the level of transition between the A and I bands. The axon loses its myelin sheath and dilates to establish an irregular contact with the muscle fiber. Muscle contraction begins with the release of ACh from synaptic vesicles (tiny spheres) at the motor endplate region. ACh binds to post-synaptic muscle-type nicotinic ACh receptors and causes an increase in the permeability of the sarcolemma. This process is propagated to the rest of the sarcomlemma and ultimately to the sarcoplasmic reticulum (SR) by the T system. An increase in SR permeability liberates calcium ion (Ca^{2+}) stores, resulting in sliding of illustrated muscle filaments and muscle contraction. BoNTs bind and internalize at the presynaptic side of the neuromuscular junction (Verderio *et al.*, 1999). Release of BoNTs into the cytosol results in inhibition of ACh release and flaccid paralysis of innervated muscle. Top right panel (Toxin binding): A three-dimensional ribbon structure of BoNT/B is illustrated. The receptor binding domain of BoNT/B HC binds to synaptotagmin (Syt-II) and ganglioside (sialyllactose) receptors of the presynaptic motor endplate. Each BoNT serotype binds to a different set of receptors in the membrane (Verderio *et al.*, 2006). Bottom right panel (endocytosis): Receptor-mediated endocytosis of BoNT/B holotoxin is illustrated in this panel. The remaining steps in BoNT toxicity involve acidification of the endosome, pH-induced conformational change in the toxin, translocation of BoNT LC across the endosomal membrane with the aid of BoNT HC, and proteolytic degradation of target SNARE proteins by LC. Illustrations are copyright protected and printed with permission by Alexandre M. Katos.

the complex is internalized by what is believed to be a clathrin-mediated endocytotic process.

V. TOXICOKINETICS

The onset of symptoms in botulism depends upon the amount of toxin ingested or inhaled and the related kinetics of absorption. Time to onset can range from as early as 2 h to as long as 8 days, although symptoms typically appear between 12 and 72 h after consumption of toxin-contaminated food (Lecour *et al.*, 1988; Arnon *et al.*, 2001). In a review of 13 foodborne botulism outbreaks involving 50 patients from 1970 to 1984, the incubation period ranged from 10 h to 6 days (Lecour *et al.*, 1988).

A. Foodborne Toxicity

1. Toxin Persistence in Circulation and Transit to Target Tissues

Case reports of human foodborne botulism incidents offer some information on toxin persistence and transit after oral exposure in humans. Koenig *et al.* (1964) reported that circulating toxin was detected in five out of six patients suffering from type E botulism after consuming contaminated fish by the mouse lethality assay on serum samples collected from the patients from 1 to 10 days after foodborne exposure. Serum from one of the patients who rapidly succumbed to disease contained approximately 8 MIPLD$_{50}$/ml; extrapolation of this value yields an estimate that 20,000 to 24,000 human LD$_{50}$s were in this individual's circulation (Koenig *et al.*, 1964). The toxin isolated from the serum of these clinically ill patients was not further activated *in vitro* by trypsin treatment. This observation was in agreement with other studies demonstrating cleavage of the single-chain prototoxin to the active dichain form within the gastrointestinal tract. Importantly, circulating toxin was not detected in a patient with minimal disease 11 days after ingestion of contaminated food (Koenig *et al.*, 1964). Six out of seven individuals who had consumed the contaminated fish but did not develop clinical illness also lacked circulating toxin. Circulating toxin was therefore detected much more consistently in symptomatic patients associated with this outbreak than in subjects who were unaffected after toxin ingestion (Koenig *et al.*, 1964).

Koenig *et al.* (1964) also reviewed previously published literature on the detection of circulating toxin in botulism patients. Circulating toxin (primarily serotype B) had been detected in select patients from 2 to 25 days after consumption of contaminated food, and was rarely detected in type A botulism patients (Koenig *et al.*, 1964). The authors suggested that serotype-specific differences in the persistence of circulating toxin might be attributed to their unique avidities to target tissues. Circulating toxin is generally detected only at very low levels at or immediately prior to death in lethally intoxicated patients (Ono *et al.*, 1970).

Efforts have been made to determine the kinetics of the accessory components of the progenitor toxin complexes after systemic absorption of BoNTs. Iida *et al.* (1970) found that circulating type E toxin was shown to exist in the 7S form after oral administration of the progenitor toxin to rabbits, suggesting that the larger toxin complex dissociated at some point during or after absorption from the gastrointestinal tract. Similar findings were reported on the absorption and persistence of progenitor type A toxin in the rat; the mean sedimentation value of toxin in the lymph after intraduodenal instillation was 7.9S, significantly lower than that of the crystalline toxin (Heckly *et al.*, 1960).

B. Inhalation Toxicity

1. Toxin Persistence in Circulation and Transit to Target Tissues

Very limited data are available on the persistence of BoNTs in circulation following inhalation exposure in any animal species. These data indicate that circulating toxin can be detected soon after exposure but is subsequently cleared rapidly from the circulation. Park and Simpson (2003) reported on the time course for appearance (and amount) of either purified BoNT/A or type A HC in the circulation of mice after intranasal exposure. Maximum serum levels were observed at 2 h post-exposure for both proteins although the peak values were higher for BoNT/A than for HC. Rapid clearance was observed over the next few hours.

An earlier study showed that type A toxin could be detected primarily in the lungs and liver rather than the serum of guinea pigs after intranasal exposure (Sergeyeva, 1962). The same group reported on the correlation between administered toxin dose and detection of toxin in the blood, lungs, and liver of guinea pigs intoxicated via the IN route (Sergeyeva, 1966). Type E toxin was detected in the lungs of guinea pigs after IN administration of two lethal doses, while toxin only appeared in the blood or liver following IN administration of at least five lethal doses. The organ distribution patterns were similar in guinea pigs after inhalation exposure to types A, B, or C toxins (Sergeyeva, 1966). These studies did not address the potential for persistent toxin detection in the lymph after inhalational intoxication, despite the fact that other routes of exposure result in significant absorption into the lymphatics.

While scant literature is available on persistence and distribution after inhalation exposure, several studies have evaluated the systemic behavior of parenterally administered toxins. One group investigated toxin persistence in serum and tissue distribution in white mice following intravenous (IV) administration of 1,000 lethal doses of ^{35}S-labeled type B toxin (Pak and Bulatova, 1962). Mice were sacrificed at 20, 60, and 150 min after toxin administration, and blood and tissues were harvested for toxin distribution analysis. These mice showed symptoms of severe intoxication, including atypical breathing patterns and paralysis, at 150 min post-exposure. Toxin levels (as determined by

radioactivity) were highest in the lung 20 min after toxin injection, followed by the liver, heart, kidneys, intestines, and brain (Pak and Bulatova, 1962). Radioactivity levels in the blood, as well as the liver, heart, intestines, and brain, were further reduced after 60 min post-toxin injection. Serum toxin concentrations were lower than those detected in any other tissue at all time points (Pak and Bulatova, 1962). The authors concluded that the toxin rapidly escaped from blood to various other tissues, suggesting the capacity for unimpeded passage of the toxin through the vasculature and cellular membranes.

Somewhat slower kinetics for toxin clearance from the circulation were observed in dogs following parenteral [IV, IP, or intramuscular (IM)] exposure to type A toxin (House *et al.*, 1964). Serum toxin persistence was evaluated in mongrel dogs receiving 8,000 to 10,000 mouse units/kg of type A toxin. Peak serum toxin levels were detected 5 h after IP administration (13% of injected dose), 12 h after IM administration (9% of injected dose), and within only 3 min after IV administration (79% of injected dose) (House *et al.*, 1964). The relative clearance kinetics were slower after IM and IP exposure than for IV administration, as serum toxin levels were identical 22 h after injection via all three rounds (approximately 6% of injected dose). Some serum toxin activity could be detected by the mouse lethality assay for 2 to 4 days after parenteral administration. Serum toxin patterns were also evaluated in rhesus monkeys following IV administration of type A toxin (Stookey *et al.*, 1965). Serum toxin levels dropped by about 50% of maximum within 16 to 24 h after IV injection, and previous exposure did not affect toxin clearance rates after the administration of subsequent doses.

Another study investigated circulating toxin levels in weanling pigs (5 to 12 weeks old) following parenteral administration of toxin types A, B, C1, and D (Smith *et al.*, 1971). Toxin was cleared from circulation less than 24 h after IV injection of type B (560 $MIPLD_{50}$/kg), type C1 (5,000 $MIPLD_{50}$/kg), or type D (60,000 $MIPLD_{50}$/kg) toxin. In contrast, toxin could consistently be detected in the serum over the entire 4 day period prior to death in pigs injected with serotype A (21,400 $MIPLD_{50}$/kg) (Smith *et al.*, 1971). Serum toxin levels were 100 MIP_{50}/ml at 24 and 48 h after injection of type A toxin, 30 $MIPLD_{50}$/ml after 3 days, and 10 $MIPLD_{50}$/ml after 4 days. These findings indicated serotype-specific differences in the persistence of circulating BoNTs, at least in systemically intoxicated pigs.

Although these studies provide some insight into the persistence of circulating toxin after parenteral administration, they do not necessarily reflect the behavior of absorbed toxin after respiratory exposure. The route of administration may not have a significant impact on the behavior of toxin once absorbed into the serum and lymph, but the patterns and kinetics of absorption into the circulation might be quite different after inhalational versus parenteral exposure. Respiratory exposure could lead to a different proportion of toxin taken up into the circulation and/or lymphatics over a given time period than that seen after systemic injection. Such discrepancies might impact both the quantitative persistence of circulating toxin and its transit to peripheral target tissues. At this point, information is not yet available on the homing and distribution of toxins to target nerve tissues. The available literature also provides no insight on the mechanisms by which toxin is removed from the circulation, either through extravasation and uptake in target tissues or by metabolic processes. In the future, such data will be important in characterizing the pathogenesis of botulism after respiratory intoxication and other routes of exposure.

VI. MECHANISM OF ACTION

ACh release from presynaptic vesicles is dependent upon a propagated action potential, localized depolarization at the presynaptic motor endplate, proper SNARE complex formation (i.e. SNAP-25, syntaxin, and synaptobrevin), and synaptic vesicle docking with the presynaptic membrane (see neuromuscular transmission in absence of BoNT; Figure 30.4). Regardless of the exposure route, BoNTs lead to inhibition in the release of ACh from peripheral cholinergic nerve terminals resulting in flaccid paralysis (Habermann and Dreyer, 1986; Simpson, 1986; see Figure 30.5). The specific target for BoNT/A and/E is the 25 kDa vesicle docking protein SNAP-25; BoNT/A cleaves the last nine residues, whereas BoNT/E cleaves a larger 26 residue fragment from the C-terminus of this protein (Blasi *et al.*, 1993; Montecucco *et al.*, 1994). The target of BoNT/B is the small transmembrane protein synaptobrevin/VAMP located on the surface of small synaptic vesicles (Schiavo *et al.*, 1995). The enzymatically active portion of the 150 kDa BoNT is the 50 kDa light chain; the role of the 100 kDa heavy chain involves binding to cholinergic nerve endings and intracellular penetration via receptor mediated endocytosis (Simpson, 1986, 2004; Monteccuco *et al.*, 1994).

A. Heavy Chain (HC)

The heavy chain of the botulinum neurotoxins has been shown to mediate toxin binding and internalization at cholinergic nerve terminals (Daniels-Holgate and Dolly, 1996; Lalli *et al.*, 1999; Maruta *et al.*, 2004; Simpson, 2004). The mostly β-strand-containing carboxy-terminus of the heavy chain (Hc) appears to be directly involved in toxin binding while the mostly α-helical amino-terminal region (Hn) mediates translocation across the endosomal membrane (Lalli *et al.*, 1999; Simpson, 2004). Through mechanisms that have yet to be fully characterized, the toxins gain entry into the nerve terminal through receptor-mediated endocytosis followed by pH-induced translocation from the endosome to the cytosol. The ability of the Hn region to form transmembrane ion channels raises the possibility that they are intimately involved in translocating the toxic moiety into the cytoplasm (Koriazova and Montal,

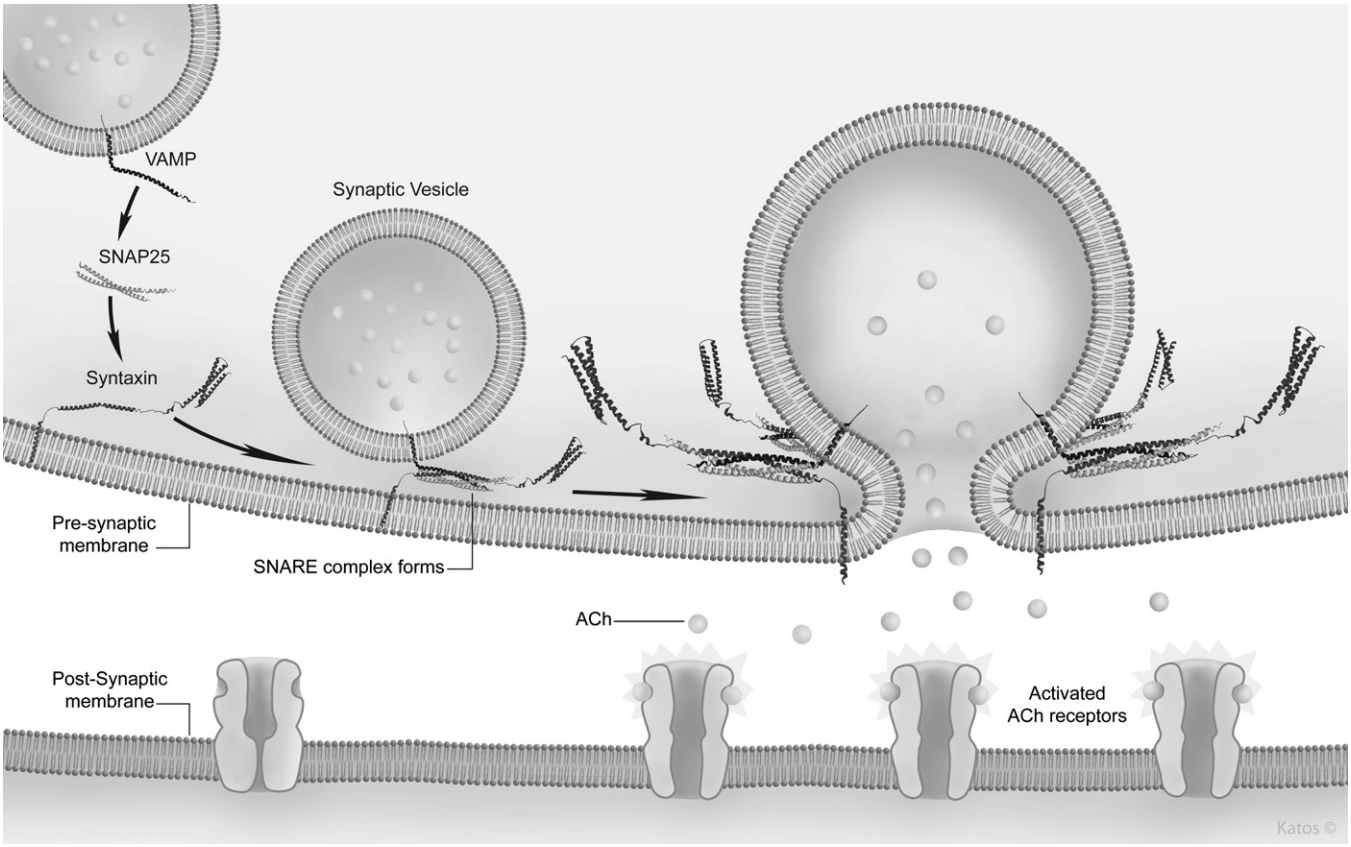

FIGURE 30.4. Neuromuscular transmission in the absence of BoNT. A nerve impulse is transmitted to the effector (muscle) cell by neurotransmitter liberated at the synapse. When the action potential arrives at the axonal terminus to depolarize the presynaptic membrane, Ca^{2+} ions enter through voltage-dependent Ca^{2+} channels. Ca^{2+} ions facilitate the fusion of synaptic vesicles, containing the neurotransmitter ACh, with the presynaptic membrane. Three SNARE proteins (syntaxin, synaptobrevin, and SNAP-25) are critical for synaptic vesicle fusion. As long as the SNARE complex is intact, ACh releases by exocytosis, diffuses across the synaptic cleft, and binds to postsynaptic muscle-type nicotinic ACh receptors. Binding of ACh makes the sarcolemma of the muscle cell more permeable to sodium, which results in membrane depolarization. Excess ACh is hydrolyzed by the enzyme cholinesterase bound to the synaptic cleft basal lamina. ACh breakdown is necessary to avoid prolonged activation of ACh receptors. Illustrations are copyright protected and printed with permission by Alexandre M. Katos.

2003). Once translocated into the cytosol, the toxic fragments exert their paralytic effects by inhibiting ACh release from neuromuscular junctions as well as other peripheral cholinergic sites, including sympathetic and parasympathetic ganglia and post-ganglionic parasympathetic synapses (Lamanna, 1959; Vincenzi, 1967; Simpson, 2004).

B. Light Chain (LC)

These paralytic effects have been attributed to the proteolytic activity of BoNT light chain (LC) on protein substrates required for vesicular exocytosis. BoNT LC inhibits neurotransmitter exocytosis through its zinc-dependent endoproteolytic activity. The LCs of the various neurotoxin serotypes possess distinct molecular targets within the peripheral cholinergic nerve termainals (Schiavo *et al.*, 1992, 1993a, b, 1994, 1995; Yamasaki *et al.*, 1994). The endoproteolytic activities of the different toxin LCs produce similar flaccid paralytic effects.

The intracellular proteins SNAP-25, syntaxin, and synaptobrevin (or vesicle-associated membrane protein, VAMP) normally interact with each other in mediating neurotransmitter release from cholinergic and other nerve terminals (see Figure 30.4). Toxin types B, D, F, and G cleave the VAMP proteins while types A, C1, and E act on SNAP-25; type C1 toxin also cleaves syntaxin (Dong *et al.*, 2003). The functions of the various neurotoxins are even more specialized in that one toxin type can cleave its substrate at a different site than that targeted by other toxin serotypes. For example, BoNT/A cleaves SNAP-25 between residues 197 and 198 (resulting in the loss of nine amino acids), while BoNT/E cleaves the same protein between residues 180 and 181 (thereby removing 26 amino acids) (Schiavo *et al.*, 1993a).

Although the LCs of both BoNT/A and/E target SNAP-25, these two serotypes exert significantly different potencies and paralytic profiles in cultured neurons and *in vivo*. A potential molecular basis for this discrepancy was

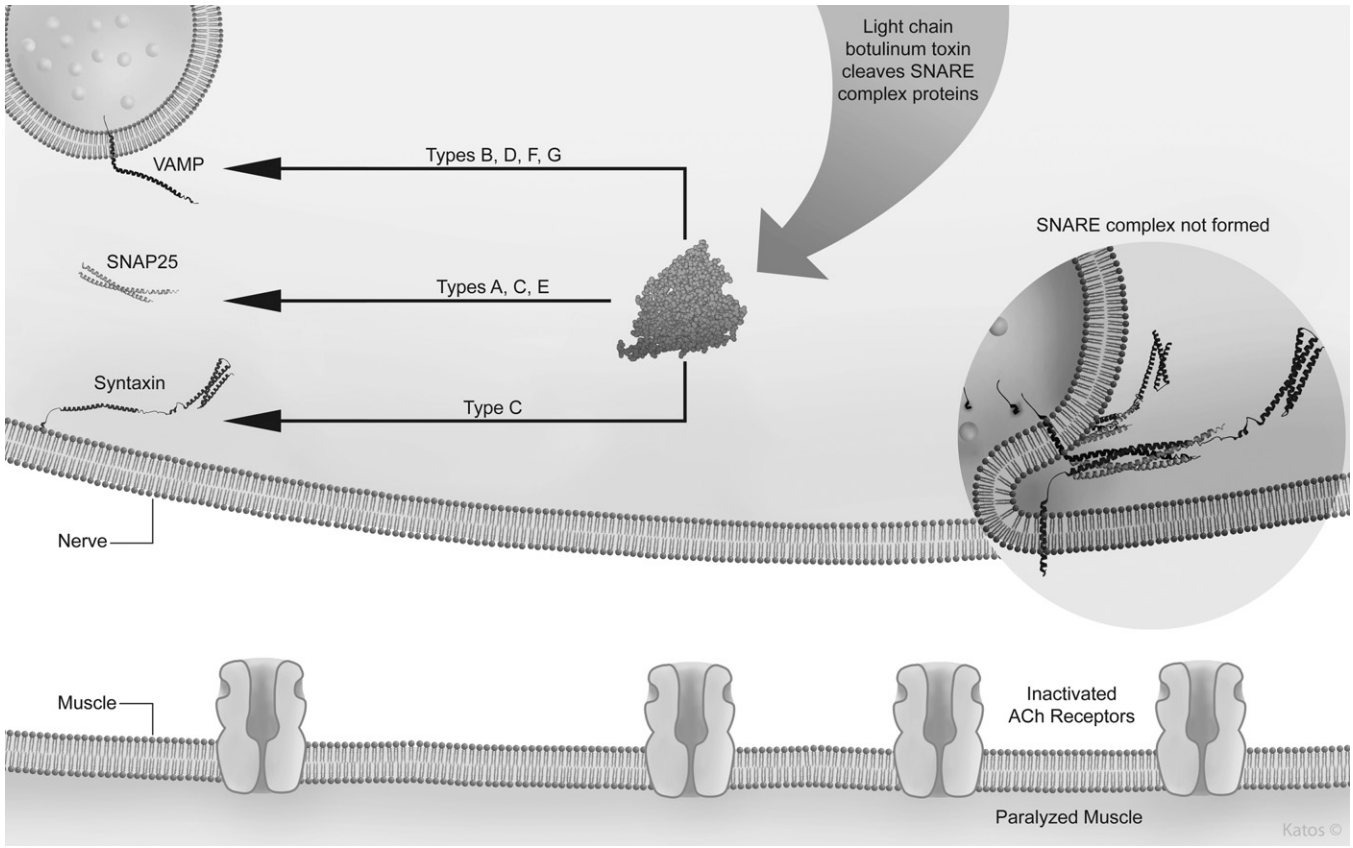

FIGURE 30.5. Neuromuscular transmission in the presence of BoNT. The catalytic LCs of the various serotypes cleave specific SNARE proteins. The SNARE complex does not form if any of the proteins are cleaved. In the presence of BoNT LC inside the axonal terminus, synaptic vesicles will not fuse with the presynaptic membrane, ACh will not be released, and the muscle will not contract, resulting in paralysis at the neuromuscular junction. Illustrations are copyright protected and printed with permission by Alexandre M. Katos.

established by the finding that these neurotoxins target different cleavage sites within the SNAP-25 protein. BoNT/A cleavage generates a 197-residue truncated protein (P197) by cleaving the last nine amino acids from the C-terminus of SNAP-25 while BoNT/E cleavage produces a 180-residue species (P180) by removing the final 26 residues (Schiavo *et al.*, 1993a). A series of studies by Keller *et al.* (1999) and Keller and Neale (2001) provided additional insight into the molecular mechanisms associated with the potent and persistent action of type A neurotoxin relative to type E.

Serotype-specific cleavage events provide insights into the differential activities of the toxins at nerve terminals. In some cases, substrate cleavage studies also revealed important information regarding interspecies differences in the activity of certain toxins. BoNT/B was shown to block neuromuscular transmission by cleaving VAMP proteins between residues Q76 and F77 (in humans and mice) (Bakry *et al.*, 1997). However, the rat VAMP1 (synaptobrevin) protein sequence differs at this critical cleavage site in that the glutamine at position 76 is replaced by a valine, rendering the region more resistant to proteolysis by BoNT/B (Bakry *et al.*, 1997; Verderio *et al.*, 2006; Callaway, 2004). On the other hand, rats and mice were shown to have similar susceptibilities (body weight adjusted) to IM injection of type A toxin; rats have also been shown to be much more resistant than mice to type F toxin (Kauffman *et al.*, 1985).

The specific paralytic profiles associated with each of the BoNTs are typically attributed to their unique proteolytic activities within the nerve terminal. These activities are known to be mediated by the LC components of the various neurotoxins. The various nontoxic components within the multimeric progenitor toxin complexes have traditionally been considered accessory proteins that primarily function to increase neurotoxin stability and, in some cases, to facilitate absorption. Yet studies over the past few years have suggested a potential role for the HA constituents in enhancing the endopeptidase activity of the LC (Cai *et al.*, 1999; Sharma and Singh, 2004). It is widely believed that pure BoNT/A requires either proteolytic ‘‘nicking’’ or chemical reduction for significant SNAP-25 cleavage activity. However, new evidence suggests that the type A progenitor toxin complex is apparently highly active even in nonreduced form (Cai *et al.*, 1999). Further research is needed to substantiate this preliminary work and to establish a more detailed understanding of the prerequisites for LC proteolytic activity.

A recent study by Sharma and Singh (2004) provided additional support for the expanded roles of at least one

neurotoxin-associated protein within the type A progenitor complex. The HA-33 component, representing 25% of the accessory protein content of progenitor neurotoxin, significantly increases the proteolytic activity of both BoNT/A and/E *in vitro* and in rat synaptosome preparations. The addition of HA-33 to nonreduced BoNT/A leads to a 21-fold increase in GST-SNAP25 fusion protein cleavage activity *in vitro* and a 13-fold enhancement of endopeptidase activity in rat synaptosomes (Sharma and Singh, 2004). Similar enhancement of proteolytic activity was seen when HA-33 was added to BoNT/E both *in vitro* and in rat brain synaptosomes.

The enhancement of SNAP-25 cleavage activity by HA-33 in rat brain synaptosomes was taken as evidence that the neurotoxin and the accessory protein both gain entry to the nerve terminal (Sharma and Singh, 2004). The possibility that an accessory component of the progenitor toxin complex could exert direct effects on LC endopeptidase activity within the nerve terminal could have important implications with respect to neurotoxin function *in vivo*.

Two recent reports revealed additional layers of complexity regarding the mechanisms involved in the distinct durations of action associated with the different toxin serotypes. Fernández-Salas *et al.* (2004) investigated the subcellular localization of BoNT/A, /B, and /E LC-GFP fusion proteins following overexpression in several different mammalian cell lines. The LC/A fusion protein was shown to localize within discrete plasma membrane compartments in both neuronal (PC12) and nonneuronal (HEK293, HeLa, HIT-T15) cell lines, while LC/B was detected throughout the cell and LC/E was primarily found within the cytosol.

VII. TOXICITY

A. Lethality

BoNTs are the most potent substances known to man. A comparison of the lethal nature of BoNTs in relation to other toxic chemicals and substances discussed throughout this textbook is provided in Table 30.2. The toxicity associated with oral exposure of a given species to BoNTs is significantly lower than that resulting from parenteral administration (see Table 30.3). The susceptibility of various animal species to parenteral intoxication does not provide adequate indication of their sensitivity to gastrointestinal exposure (Lamanna, 1961). The estimated human LD_{50} of approximately 1 ng/kg for parenteral botulinum intoxication is similar to that reported for most laboratory animals (Arnon, 1995; Middlebrook and Franz, 2000). In contrast, the relative susceptibilities of humans and other animal species to oral intoxication vary significantly (Morton, 1961). A recent clinical review of human botulism reported that the ingestion of as little as 0.05 to 0.1 μg of BoNT A may be sufficient to cause death in humans (Cherington, 1998). Human lethal

TABLE 30.2. Comparison of toxic chemicals and substances

Chemical or toxin	Mouse IV LD_{50}* (mg/kg)	Chemical or toxin	Mouse IV LD_{50}* (mg/kg)

doses have also been extrapolated from primate studies, yielding an oral lethal dose of approximately 70 µg for crystalline type A toxin for a 70 kg human (Arnon *et al.*, 2001). The lethal human respiratory dose is estimated to be 0.7–0.9 µg and the intravenous or intramuscular dose is 0.05–0.15 µg (Middlebrook and Franz, 2000; Arnon *et al.*, 2001).

B. Oral Toxicity

An earlier report suggested that humans are more susceptible than monkeys to type A toxin by the oral route based on toxin dose estimates in foodborne botulism case studies (Morton, 1961). Morton (1961) also summarized the susceptibility of numerous other animal species to oral botulinum intoxication. Mice, monkeys, and guinea pigs were considered highly susceptible while chickens, rabbits, horses, dogs, rats, and cattle were classified as more resistant, and ferrets, minks, and hogs were deemed resistant. The oral lethal doses of type A toxin in guinea pigs (1,000–3,000 MIPMLD) and monkeys (2,000 MIPMLD) (Morton, 1961) are similar to the estimated oral lethal dose for humans (7,000 MIPMLD).

Morton (1961) provided evidence for an estimated human oral lethal dose of much less than 3,500 MIPMLD for type B toxin. This estimate was based upon an earlier report describing a fatal type B human botulism case resulting from the ingestion of 3,500 MIPMLD in toxin-contaminated cheese (Meyer and Eddie, 1951). A man weighing 104 kg consumed approximately 70 g of contaminated cheese; repeated tests of the cheese indicated that it contained only 50 MLD/g of type B toxin. The patient first developed somewhat atypical disease symptoms of nausea, vomiting, diplopia, dysphagia, phagodynia, and instability within 7 h of exposure (Meyer and Eddie, 1951). The man was later hospitalized and developed symptoms more characteristic of foodborne botulism within 18 to 20 h. He died 57 h after toxin ingestion, despite receiving 35,000 units each of both type A and B antitoxins (Meyer and Eddie, 1951). Therefore, it was determined that 3,500 MIPMLD is in great excess of one minimum lethal dose of type B toxin for humans due to the rapid onset of illness and severity of disease (Morton, 1961). The same study reported a woman who died from botulism 42 h after consuming a small piece of toxin-contaminated pear.

C. Inhalation Toxicity

Naturally occurring botulism cases in humans and other animal species are almost exclusively associated with the ingestion of toxin- or spore-contaminated foods. The level of knowledge in the published literature on toxin absorption following inhalational exposure is therefore much more limited than that associated with gastrointestinal intoxication. The potencies of inhaled BoNTs have been investigated in several experimental animal species. In an early literature review, Morton (1961) reported comparatively similar ratios (5.9:1) of oral to respiratory toxicity (the comparative lethal doses for toxin administered via the oral versus the respiratory route) for type A toxin in guinea pigs and mice. Iakovlev (1958) concluded that guinea pigs were more susceptible than mice to type A toxin by inhalation because they succumbed to intoxication after a shorter incubation period (1–2 days versus 3–4 days for mice). Several technical reports established more specific guinea pig inhalation toxicity data for serotypes A through E (Jemski, 1960, 1961b).

D. Clinical Toxicity

The natural occurrence of human foodborne and infant botulism translates into a wealth of information on the clinical signs and symptoms of disease. This information can be compared to the array of physiological and pathological findings in various species of experimental animals after oral administration of BoNTs. The ability for inhaled BoNTs to produce illness has also been documented in

humans and in several experimental species. The primary neurophysiological signs and symptoms associated with respiratory exposure parallel those observed in cases of foodborne botulism; however, infants display a unique clinical picture of botulism. In addition, the various toxin serotypes are usually associated with analogous clinical presentations, with the most severe cases of foodborne botulism being caused by the ingestion of type A toxin.

Exposure to BoNT via oral or inhalational routes results in symptoms indicative of an inactive peripheral cholinergic system due to inhibition of ACh release from the nerve terminal. The time to onset of disease is dependent on the amount of toxin ingested and ranges from several hours to a few days after oral exposure (Lecour *et al.*, 1988; Arnon *et al.*, 2001). Prominent signs and symptoms of intoxication common to all serotypes and various routes of exposure include, in order of descending frequency: dysphagia, xerostomia, diplopia, dysarthria, fatigue, ptosis of the eyelids, constipation, arm weakness, leg weakness, gaze paralysis, blurred vision, diminished gag reflex, nausea, facial palsy, dyspnea, emesis, tongue weakness, sore throat, dizziness, dilated or fixed pupils, abdominal cramps, reduced or failed reflexes, nystagmus or involuntary rapid eye movement, diarrhea, ataxia, and paresthesia (reviewed by Arnon *et al.*, 2001).

1. Foodborne Botulism

Human foodborne botulism presents as an acute, symmetric, flaccid paralysis that generally involves multiple cranial nerve (CN) palsies initially, termed bulbar involvement. Early symptoms involve paralysis of the motor components of the CNs. The motor components are derived from cell bodies located in the brain with axons that exit the cranium to control muscles, glandular tissue, or specialized muscle in the heart and gastrointestinal tract. Paralysis by BoNTs lead to ptosis and dilated pupils (CN III), disconjugate gaze and blurred vision (CN III, IV, VI), facial droop or palsy (CN VII), dysphagia, dysarthria, and absence of gag reflex (CN IX, X), tongue weakness (CN XII), and weakness of neck strap muscles (CN XI). Botulism patients typically develop difficulty in seeing, speaking, or swallowing in the early phases of intoxication. As paralysis extends caudally, toxic signs and symptoms include loss of head control, hypotonia, generalized weakness, and flaccid paralysis or floppy appearance (infants and children). In infants and young children exposed to BoNT, floppy appearance and constipation may be the only presenting signs to warrant a diagnosis of BoNT exposure, since obtaining a reliable history may not be possible in this population.

Loss of the gag reflex and dysphagia may require intubation and mechanical ventilation. Deep tendon reflexes are often lost during later stages of intoxication, and death in untreated patients results from airway obstruction or inadequate tidal volume (Arnon *et al.*, 2001). Respiratory failure is the most serious clinical manifestation of botulism, and the decline in mortality associated with foodborne botulism is primarily due to improvements in ventilatory support (Lecour *et al.*, 1988). Around 60% of botulism patients in the USA require mechanical ventilation at some point during their hospitalization and treatment (Varma *et al.*, 2004). In severe botulism cases, as in the Florida physician case involving research grade type A toxin instead of BOTOX® for facial muscle paralysis, respiratory support may be required for prolonged periods of time and autonomic dysfunction may persist for months to years (Mackle *et al.*, 2001).

Other clinical forms of the disease share many of these signs and symptoms. The presentation and duration of disease are coupled to the relative persistence of the toxin in blocking the release of ACh at peripheral nerve synapses. Although untreated botulism is potentially deadly, the availability of antiserum has dramatically reduced the mortality rates for the common clinical manifestations of the disease. Severe cases of foodborne botulism may still require ventilatory support for over a month, and neurological symptoms can sometimes persist for more than a year (Mackle *et al.*, 2001).

2. Infant Botulism

The characteristic symptoms of infant botulism are poor sucking, constipation, generalized weakness, floppy appearance, and respiratory insufficiency (Cox and Hinkle, 2002). Infant botulism may quickly progress to respiratory failure if not treated. The development of the intestinal flora has been demonstrated to suppress germination and growth of *Clostridium botulinum* spores in mice (Sugiyama and Mills, 1978). Ingestion of honey by infants is the classic scenario cited in infant botulism; honey is therefore not recommended in this susceptible population (Spika *et al.*, 1989; Arnon, 1998).

VIII. RISK ASSESSMENT

BoNTs present a very real threat to the public health and are the most toxic substances known to humankind. In a military or bioterrorist incident, intoxication by BoNT is likely to occur by inhalation of aerosolized toxin or by ingestion of contaminated food or beverages (Franz, 1997; Sobel *et al.*, 2004). Although the municipal water systems are considered to be safe from BoNT attacks, due to chlorination and dilution, it is not known whether current water treatments adequately decontaminate the toxin. Furthermore, bottled mineral water and milk (Sobel *et al.*, 2004; Kalb *et al.*, 2005) are obvious targets for terrorist groups. The vulnerability of the nation's milk supply was highlighted in a recent modeling study, where its complex distribution system would magnify the consequences of poisoning by BoNT (Wein and Liu, 2005; Kalb *et al.*, 2005). BoNTs are a serious threat to our national security due to their potency, remarkable stability, and persistence in the body.

Wein and Liu (2005) modeled a bioterror attack using BoNTs on the nation's milk supply. Modeling of toxin for dispersal in a liquid medium has been previously computed in a terrorist scenario (Dembek, 2005) involving a water fountain and contamination at a recreational center (CDC, 1999). Wein and Liu's assessment estimates the amount of toxin required, critically evaluates entry points into the milk supply industry, and details deficiencies in our current detection capabilities required to thwart such an attack (Wein and Liu, 2005).

The most prevalent BoNTs isolated in human botulism are serotypes A, B, and E. The ability of serotypes C and D, in addition to F, to paralyze human skeletal muscle should also be noted (Hilmas, unpublished). Complicating matters is the fact that all BoNTs remain stable in common beverages and retain significant potency for prolonged periods of time (>90 days) at room temperature and in biological fluids (human whole blood and serum) at physiological temperatures (Hilmas *et al.*, 2006b; Williams *et al.*, 2007). In addition, BoNTs possess a remarkable ability to remain within the nerve terminal for extended periods. Keller *et al.* (1999) showed BoNT protein detectable by western blot for 90 days in rat spinal cord cultures.

Stability of the BoNT protein should be considered in an assessment of the threat posed by intentional release of the toxins. In addition to the remarkable persistence of the toxin in biological fluids and beverages described above, BoNT remains a potent environmental threat. BoNT/A was subjected to desiccation to simulate the residue of an intentional release. Following 28 days of drying, the toxin still possessed remarkable paralytic properties (Williams *et al.*, 2007).

The duration of muscle paralysis following intoxication by BoNT/A exceeds that resulting from exposure to other BoNT serotypes (Keller *et al.*, 1999; Robinson and Nahata, 2003; Fernández-Salas *et al.*, 2004). The remarkable persistence of BoNT/A action has led to its widespread use in the treatment of disorders of muscle tone and movement (Jankovic and Brin, 1997). Although a long duration is desirable in clinical use, the prolonged action of BoNT/A would also make intoxication by this serotype difficult to treat, particularly if used as a bioweapon (Franz, 1997). The duration of intoxication by BoNT/E is relatively brief (several weeks), whereas BoNT/B is of intermediate duration (Keller *et al.*, 1999; Blanes-Mira *et al.*, 2004). The basis for the differences in serotype persistence is currently unknown. In any case, a bioterrorist attack, involving the most lethal substance known to humankind, would overwhelm the limited resources (i.e. mechanical ventilators) available to treat botulism patients.

IX. TREATMENT

There are currently seven known antigenic serotypes of botulinum toxin, designated with the letters A through G, whereby antitoxin to one type does not cross-neutralize any of the others. Only early administration of antitoxin antibody in cases of suspected botulism will minimize the neurologic damage but will not reverse any existing paralysis. Paralysis could persist for weeks to months, and the available treatment consists of supportive care including fluids, total parenteral nutrition (TPN), and mechanical ventilation.

A. Antitoxin

The administration of heterologous antitoxin was one of the first therapeutic approaches developed for botulism patients and remains the most effective when initiated in the early stages of intoxication. The primary limitation of antitoxin treatment was established in some of the earliest published reports on experimental botulism. One of these reports evaluated the pathogenesis of oral intoxication and the efficacy of antitoxin therapy in monkeys (Dack and Wood, 1928). Antitoxin treatment was not effective when administered after symptoms of botulism were already apparent, despite the fact that circulating toxin could still be detected in many of the animals.

Oberst *et al.* (1967) investigated the effectiveness of antitoxin therapy, artificial respiration, and supportive treatment in rhesus monkeys after IV type A toxin injection. These treatments were administered to the animals either alone or in combination after signs of intoxication were observed. Only one in six monkeys survived after receiving antitoxin injections alone as treatment for overt intoxication with 2.5 LD_{50} of type A toxin (Oberst *et al.*, 1967). A combination of antitoxin therapy and supportive treatment initiated soon after the development of toxic signs protected eight of ten animals from death after IV injection of 4 to 5 LD_{50}. Artificial respiration prolonged survival in monkeys with respiratory paralysis but was not effective as a primary treatment after lethal intoxication; no animals receiving only artificial respiration survived intoxication with 5 to 24 LD_{50} (Oberst *et al.*, 1967). Untreated animals developed overt signs of intoxication within 20 to 38 h and died 32 to 135 h after toxin injection.

While antitoxin treatment was generally ineffective in experimental animals displaying significant clinical signs, several case studies of foodborne botulism indicated that antitoxin therapy remained potentially beneficial in humans even after the onset of illness. Iida (1963) reviewed the high efficacy of antitoxin therapy in type E botulism outbreaks associated with contaminated fish consumption in Japan. A mortality rate of only 3.5% was observed among 85 antitoxin-treated patients in nine recent foodborne botulism outbreaks, while a rate of 28.9% was reported among 135 untreated patients in 19 previous outbreaks. Iida noted that all moderately and seriously ill patients in a 1962 foodborne type E botulism outbreak survived after antitoxin treatment. Hatheway *et al.* (1984) reported on the effectiveness of trivalent (ABE) antitoxin therapy during a 1978 outbreak of type A botulism. Four of seven patients with confirmed

disease from type A toxin ingestion were treated with two to four vials of trivalent antitoxin (Hatheway *et al.*, 1984). All four treated patients survived, although one of these individuals continued to suffer from severe paralysis and required ventilatory assistance for several months.

The current Centers for Disease Control and Prevention (CDC) therapy for the public is an FDA-approved, bivalent, botulinum equine antitoxin against serotypes A and B. The trivalent antitoxin against types A, B, and E is no longer available. In cases of exposure to any of the other botulinum toxin serotypes, the US Army can provide an investigational heptavalent (ABCDEFG) equine antitoxin, but the time required for typing a toxin subtype would limit its effectiveness in such cases as an outbreak. A parenteral vaccine against the toxin is currently available, but the need exists for newer nonparenteral vaccines that could be administered orally or via inhalation.

B. Treatment for Infant Botulism

Administration of equine antitoxin is not recommended for preexposure prophylaxis. The heterologous serum of antitoxin therapy can lead to a high frequency of adverse reactions. The equine antitoxin available for use in humans has been reported to cause adverse reactions such as anaphylaxis in over 20% of treated patients (Lewis and Metzger, 1980). This problem has been circumvented in the development of a safer approach to the treatment of infant botulism using plasma isolated from human subjects repeatedly immunized with pentavalent toxoid. Equine antitoxin is not used as a treatment for infant botulism due to the high risk of serious adverse reactions and the possibility of long-term sensitization to horse serum-based therapeutics (Arnon, 1998). An antiserum product termed BabyBIG (botulism immune globulin), derived from human volunteers immunized with pentavalent toxoid, is available for infant botulism patients. Intravenous BabyBIG therapy has proven extremely effective in counteracting the toxic effects of *C. botulinum* colonization in infants and in avoiding the risk of adverse reactions to equine antitoxin. It is also most effective when administered within 24 h of a high-dose aerosol exposure to the toxin (Gelzleichter *et al.*, 1998a, b, 1999).

C. Vaccines

There are as yet no FDA-approved vaccines to prevent botulism. An investigational pentavalent botulinum toxoid (PBT) product, developed at Fort Detrick, is available for persons at risk for botulism (i.e. laboratory workers, warfighters). While determined to be safe and immunogenic, PBT is not useful or recommended for post-exposure prophylaxis. Antitoxin titers do not develop until a month after the third dose in the vaccine schedule. PBT is reserved for employees at high risk for BoNT exposure but not the general population. Several factors limit the usefulness of PBT as a vaccine for inoculating the general population. These include a declining potency and immunogenicity in recent years, the need to take multiple doses to maintain titers, and the limited supply of the vaccine.

X. CONCLUDING REMARKS AND FUTURE DIRECTION

The toxicity of botulinum toxins leading to paralysis is due to their ability to block ACh release from peripheral cholinergic nerve endings (Simpson, 2004). Once ingested or inhaled, the toxin binds to epithelial cells, transports to target tissues via the circulatory system, targets the NMJ, and penetrates cellular and intracellular membranes. BoNTs bind to the lipid bilayer of the neuronal cell surface, gain access by receptor-mediated endocytosis, and cleave polypeptides involved in exocytosis of ACh. As a result, botulism leads to a descending flaccid paralysis, starting usually in the bulbar musculature to involve deficits in sight, speech, and swallowing. Paralysis eventually progresses beyond cranial nerve (CN) palsies to include generalized muscle weakness and loss of critical accessory muscles of respiration. If untreated, death is inevitable from airway obstruction secondary to paralysis of pharyngeal, diaphragm, and accessory respiratory muscles, as well as loss of the protective gag reflex.

The CDC recommended therapy for the public is a trivalent equine antitoxin against types A, B, and E. In cases of exposure to other BoNT serotypes, the US Army can provide an investigational heptavalent (ABCDEFG) antitoxin. However, the antitoxins are in limited supply and would need to be retrieved from stockpiles. Therefore, the development of safe and effective post-exposure therapeutic compounds for BoNT intoxication is of paramount importance to serve the requirements of the military and civilian populations. In conjunction with drug discovery efforts, there is a parallel exigency to develop appropriate animal models to test the usefulness of various strategies for protection against BoNT intoxication.

A. Development of Animal Model Test Systems

1. Inadequacies of Current Animal Model Test Systems

Currently, a large number of animal models (mice, rats, guinea pigs, rabbits, and nonhuman primates) have been used for BoNT research, and it is not clear which species is the most appropriate. This is especially problematic since there are marked species differences in the relative potencies of the different serotypes and in their latency of action (effect of BoNT/B in mice, rabbits, guinea pigs vs rats; Erdal *et al.*, 1995; McLellan *et al.*, 1996; Hilmas *et al.*, 2006a). Mice, in particular, are desirable in BoNT research because they offer the most favorable balance between the scientific needs of the experiment and consistency with the

existing literature. A variety of mouse strains and sexes have been used for other BoNT studies. The mouse LD_{50} is still used to quantitate the purity of BoNT batches and is the basis of the international standard used in serum neutralization assays of BoNT antitoxin. The mouse phrenic nerve–hemidiaphragm assay has been used to measure the effect of BoNTs on skeletal muscle contraction and the doses necessary for inhibition are well characterized. The mouse has further advantages over other rodent species like rats.

Rats are not a valuable test system for BoNTs as they are widely recognized as being insensitive to serotype B (Verderio *et al.*, 2006). On the other hand, skeletal muscles of CD-1 mice, Hartley guinea pigs, and New Zealand white rabbits have similarities to humans in that their muscles are sensitive to serotypes A, B, C, D, and E (Hilmas *et al.*, 2006b). *In vivo* and *in vitro* physiological assessments of BoNT action in rat have also proved to show inconsistent and erroneous results. *In vivo* experiments using the rat extensor digitorum longus (EDL) muscle assay showed sensitivities of rat muscle to the B serotype at low doses (10 MU, corresponding to approximately 1–10 pM) (Adler *et al.*, 1996), despite the wide body of literature on the rat to the contrary. In addition, *ex vivo* rat phrenic nerve–hemidiaphragm preparations are insensitive to BoNT/B at even very high concentrations in the nanomolar range (Williams *et al.*, 2007).

Another physiological model to evaluate therapeutic candidates against BoNT intoxication is the rat toe spread assay. The rat toe spread assay is problematic as a model test system. First, it will not allow for the evaluation of therapeutic candidates against the B serotype since rats are insensitve to BoNT/B. Second, the rat toe spread assay does not involve focal application of BoNT; neighboring muscles are paralyzed due to local diffusion of toxin from the site of intramuscular injection. Toe spread in the rat is mediated predominantly by digiti minimi abductor muscles and to a lesser extent by the EDL, the actual muscle injected in the assay. Intramuscular injection of rat EDLs with BoNT will primarily paralyze the EDL and to a lesser extent the digiti mini muscles, the true abductors of toe spread, by local diffusion. Therefore, EDL muscles injected with BoNTs would tend to show an erroneously early recovery of toe spread as the primary effectors of toe spread recover sooner compared to injected EDL muscles. To date, there is no acceptable *in vivo* model to test the efficacy of inhibitory compounds.

2. Advantages of the Mouse Hemidiaphragm Assay

Current approaches to the inhibition of BoNT activity involve a number of strategies, each with potential advantages and disadvantages. Ultimately, model test systems that can incorporate each of these potential approaches are needed to evaluate the relative merit of potential therapeutic compounds. Since the presynaptic terminal is the primary target for BoNTs, a test system based on toxin action at presynaptic terminals is indicated. Such systems should permit testing of all relevant aspects of toxin (internalization, activity, overcoming inhibition of transmitter release), should be simple and reliable, and should permit rapid evaluation of novel therapeutics or their precursor compounds.

Due to the high sensitivity of mammalian synapses to the actions of BoNTs, due in part to the presence of high-affinity binding sites for toxin on the cell surface and to the intracellular presence of the appropriate enzymatic substrates, the test model systems should be of mammalian origin. Muscle is the ideal test system for BoNT since it is the most sensitive *in vivo* target for neurotoxin action. In addition, inhibition of the diaphragm muscle is the proximal cause of death in botulism (Habermann and Dreyer, 1986; Simpson, 1986). Furthermore, a positive result with BoNT on muscle implies that the toxin is correctly folded and the binding, catalytic, and translocation domains are all intact. Enzyme linked immunosorbent assays (ELISAs), on the other hand, detect only components of the toxin and may provide positive results when the toxin has in fact lost its ability to intoxicate (Kalb *et al.*, 2005). The mouse phrenic nerve–hemidiaphragm assay is a favorable model test system to evaluate therapeutics against BoNT-induced paralysis.

CHAPTER 31

Anthrax

COREY J. HILMAS, ALEXANDRE M. KATOS, PATRICK T. WILLIAMS, AND JAIME ANDERSON

Opinions, interpretations, conclusions, and recommendations are those of the author(s) and are not necessarily endorsed by the US Army.

I. INTRODUCTION

Anthrax is a virulent, contagious, and potentially fatal disease. The first accounts of anthrax infection were written by the Roman poet Vergil in early antiquity. While its lethal effects were ascribed to the actions of an exotoxin over a half century ago, the pathogenesis and mechanism of anthrax toxicity continue to be refined. Depending on the route of exposure, anthrax can cause a different disease, including inhalational, cutaneous, and oral/ingestional forms. Anthrax infection involves a complex set of steps in its pathogenesis from spore uptake by immune cells, germination, transport to local lymph nodes, production of deadly toxins, systemic spread, and ultimately death of the host. The details of each step are continually being debated. Even today debate ensues regarding the mechanisms of macrophage killing by the toxins and the importance of other cell types involved in toxin-induced fatality.

While anthrax infection causes high numbers of bacilli and overt septicemia, it is the exotoxins which are responsible for the intoxicating symptoms and death. Birth of the molecular age in modern research led to the identification and enzymatic characterization of three proteins that constitute two anthrax exotoxins. These are the protective antigen (PA), edema factor (EF), and lethal factor (LF). A better understanding of the precise mechanisms of toxicity initiated by anthrax toxins will uncover many of the unsolved mysteries surrounding *Bacillus anthracis* infection. Moreover, nature's clever engineering will be evident from the sometimes contradictory actions of the spore form, vegetative bacilli, and bacterial toxins.

II. HISTORY

Anthrax has plagued man and beast since early recorded history. Scholars have attributed several plagues in antiquity to anthrax. The Plague of Athens (430–427 BC) and two of the plagues of Egypt (the fifth – death of livestock – and sixth plagues – boils), during the time of the Israelites' captivity have both been ascribed to outbreaks of anthrax (McSherry and Kilpatrick, 1992). Publius Vergilius Maro or Vergil (70–19 BC) provided the earliest, definitive, and detailed descriptions of an anthrax epidemic in his four-volume *Georgics*, a narrative on agriculture and animal husbandry (Sternbach, 2003). Vergil described the same disease ravaging sheep, horses, cattle, dogs, and various other animals. In addition to signs of toxicity, he provided insight into knowledge of how the disease was transmitted, namely wool. He even noted the virulent and contagious nature of anthrax, as well as its ability to spread to humans (Dirckx, 1981).

> The pelts of diseased animals were useless, and neither water nor fire could cleanse the taint from their flesh. The sheepmen could not shear the fleece, which was riddled with disease and corruption, nor did they dare even to touch the rotting strands. If anyone wore garments made from tained wool, his limbs were soon attacked by inflamed papules and foul exudates. (Dirckx, 1981)

During the course of the next 1,500 years, Europe witnessed sporadic outbreaks of anthrax as they occurred in 14th century Germany and 17th century central Europe and Russia. The disease was classified as anthrax or charbon malin (Morens, 2003) in 1769 by the French physician Nicholas Fournier (Fournier, 1769; Morens, 2003). The name is derived from the black eschar lesions, the hallmark of cutaneous infection. Fournier also noted a link between those who worked with raw animal hair or wool and an increased susceptibility to disease. In the 18th century, an epidemic destroyed half of the sheep in Europe, possible evidence that anthrax was a major problem. Inhalation anthrax became known in the Victorian era as woolsorters' disease; however, infection was more often the result of contact with goat hair or alpaca than wool.

In 1850, Pierre-Francoise Olive Rayer (Rayer, 1850) and Casimir-Joseph Davaine (Davaine, 1863) reported the presence of ''small filiform bodies'' in the blood of anthrax-infected sheep (Carter, 1988). By 1855, Franz Aloys Antoine Pollender confirmed this discovery and implicated their role in producing anthrax disease (Pollender, 1855). In 1858, Freidrich August Brauell noted the ''bodies'' to be absent from healthy animals or animals infected with diseases other than anthrax. Brauell also noted their inability to be transmitted from pregnant sheep to fetus (Brauell, 1857).

In the 1870s, Robert Koch, a Prussian physician, isolated the anthrax bacillus and traced the complete life cycle using suspended-drop culture methods. Koch determined the bacillus could form spores which remained viable, even in hostile environments (Koch, 1876). Louis Pasteur provided demonstration of infectious disease transmission. He inoculated one cohort of cattle with live attenuated vaccine and a control cohort without vaccine. When all animals were injected with virulent anthrax, only the control cattle died.

A. Modern History: Weaponizing Anthrax and Terrorism

Research into the utilization of anthrax spores as a biological weapon began in the early 20th century. During World War I, German development of *B. anthracis* and other disease-causing organisms gave rise to covert programs intended to infect livestock and animal feed to be exported to the Allies. These plans included contaminating feed for horses and cattle to be exported from the USA to England, infecting sheep from Romania to be exported to Russia, and exporting contaminated livestock from Argentina to various Allied nations (Hugh-Jones, 1992; Merck, 1946).

During World War II, the pace of anthrax and biological weapons research in general accelerated. Imperial Japan had a large, active bioweapons program that included a substantial anthrax component. The central Japanese research facility was located in Manchuria, known as Unit 731. It is believed that in excess of 10,000 prisoners of war died either by direct experimental exposure to *B. anthracis*, among other pathogens, or by execution following exposure (Harris, 1992, 1994). Much of the Japanese bioweapons research transitioned to the battlefield. Operations such as Nomonhan in 1939, where Japanese troops entered the Soviet Union to infect Russian herds, met with only partial success. As it turned out, Japanese troops were unprepared to operate in a biological weapons environment. Their actions resulted in many inadvertent friendly casualties (Harris, 1992).

The Allies were pursuing biological weapons programs at the same time as the Axis powers. In 1942, the United Kingdom conducted anthrax experiments off the coast of Scotland at Gruinard Island. British scientists working at the biological weapons laboratory at Porton Down had demonstrated the lethality and military utility of the bacillus. Spores persisted and remained theoretically capable of infection for decades afterwards. A subsequent decontamination effort took nearly 10 years to clean up the island (Carter, 1992). The USA began developing anthrax as a biological weapon in 1943. A civilian agency, the War Reserve Service, constructed a research facility at Camp Detrick (later Fort Detrick in 1956), and conducted research into a number of pathogens, including *B. anthracis*.

In April and May of 1979 an anthrax epidemic occurred in Sverdlovsk, a city of then 1.2 million people, 1400 km east of Moscow. The Soviet medical community reported an outbreak in livestock south of the city, and human exposures by ingestion of infected meat and contact with diseased animals led to cases of gastrointestinal and cutaneous anthrax. According to Soviet medical reports, 96 cases of human anthrax were identified, of these 79 were said to be gastrointestional and 17 cutaneous. These cases resulted in 64 deaths, all reported to be gastrointestional exposures (Meselson *et al.*, 1994). In 1986, the Soviet Union invited a group of American scientists to visit Russia and investigate the outbreak. In collaboration with the Russian clinicians who treated the victims, the panel concluded that the outbreak was the result of inhalation exposure due to the accidental release of an estimated 10 kg of military-grade anthrax from the Soviet military microbiological facility in Sverdlovsk. This event remains the largest documented outbreak of inhalation anthrax (Sternbach, 2003).

In 2001, the first case of intentional anthrax release in the USA occurred. In October and November of that year, 11 confirmed cases of inhalation anthrax and 11 confirmed or suspected cases of cutaneous anthrax were reported in postal workers and others who handled mail that had been deliberately contaminated with anthrax spores (Abalakin *et al.*, 1990). These contaminated letters were mailed anonymously to several news media and Federal government offices. The letters contained handwritten threats as well as cryptic references to the terrorist attacks on September 11 of that year. The anthrax spores were analyzed and determined to be of the ''Ames'' variety, the strain which originated in the USA and had been acquired by Army research institutes for vaccine development.

Anthrax remains both a serious public health hazard and a very real biological weapon threat. A deliberate release of an anthrax weapon in a populated area could have catastrophic implications. An economic model developed by the Centers for Disease Control and Prevention (CDC) suggested a cost of $26.2 billion to treat 100,000 people exposed to anthrax (Kaufmann *et al.*, 1997). A risk assessment, provided at the end of this chapter, will serve to highlight the dangers of a realistic scenario involving anthrax spores.

III. EPIDEMIOLOGY

A. Persistence

Bacillus anthracis can remain for extended periods of time in soil. The mechanism responsible for its persistence is unclear. Therefore, persistence may involve multiplication cycles and sporulation. It may involve multiplication of the organism in the soil or bacterial amplification in infected animals prior to soil contamination by the carcass. Spores may germinate simply upon application of water to soil (Hanna and Ireland, 1999; Oncul *et al.*, 2002).

B. Infection

Infection typically results from herbivores grazing on soil or feed contaminated with spores. Oral consumption may

produce oropharyngeal or gastrointestinal infection, an invariably fatal condition. Terminally ill herbivores generally bleed from the nose, mouth, and bowel, resulting in further contamination of the soil or drinking source (Shafazand *et al.*, 1999). While the actual number of cells or spores shed by an infected animal is unknown, studies have shown that counts of 10^4 to 10^6 spores/g of soil can be found near infected carcasses (Turnbull *et al.*, 1998).

C. Dissemination

Dissemination of anthrax spores may result from biting flies or vultures (de Vos, 1990; Hugh-Jones and De Vos, 2002; Davies, 1983; Turell and Knudson, 1987). Flies and mosquitoes contaminated with the vegetative cells, as a result of feeding on blood, can remain infectious for hours. The infectious material is deposited onto leaves through defecation, leading to contamination of herbivore species such as cattle, sheep, horses, and goats. Vultures often feed on contaminated carcasses and disseminate the organism to other birds or common drinking sources shared by various animals.

D. Forms of Anthrax Disease

Anthrax in humans is associated with agricultural, horticultural, or industrial exposure to infected animals or animal products. Three forms of anthrax can be diagnosed in humans: cutaneous, gastrointestinal, and inhalational. Cutaneous anthrax infection can occur through handling of contaminated hides, wool, bones, and carcasses. Cutaneous anthrax is the most common form of natural human infection, consisting of >95% of anthrax cases, and is treatable if recognized early. Infection occurs as a result of direct contact with infected animals or animal products. The skin is typically damaged or abraded prior to establishment of successful skin lesions by the bacteria. The persons most at risk of a natural cutaneous exposure are industrial or agricultural workers, such as herders, butchers, slaughterhouse workers, or processing mill workers (Pile *et al.*, 1998). Infection can also occur through an insect bite (Spencer, 2003). While cutaneous anthrax is rarely fatal (mortality <1% in treated cases; Anon, 2000), it can progress to a systemic infection with a mortality rate of 5–20% in untreated cases (Pile *et al.*, 1998). In general, cutaneous anthrax is not as life threatening as the inhalational form, which results in much higher mortality. However, it is still important to study dermal pathogenesis models, particularly because cutaneous anthrax cases may result from an aerosol release (Inglesby *et al.*, 1999), a method most likely to be used by bioterrorists.

Inhalational anthrax may occur after inhaling aerosols of spores, formed from processing contaminated animal products (wool) or as the result of direct bioweaponization. Inhalational anthrax contributes to only 5% of all reported cases but is by far the most lethal form. The estimated mortality is approximately 90% in untreated patients (Atlas, 2002; Bales *et al.*, 2002; Dixon *et al.*, 1999; Friedlander, 1999, 2000; Meselson *et al.*, 1994; Oncu *et al.*, 2003). Inhalational anthrax is typically reported in industrial settings where animal products are handled in enclosed spaces, allowing for exposure to aerosolized spores. Individuals passing by these industrial facilities have been stricken with inhalational anthrax. In one study of 27 anthrax cases involving textile mills, 21 cases were cutaneous and six were inhalational. All but one of the inhalational cases was fatal. One case of inhalational anthrax occurred in a secretary at a goat hair-processing facility.

Gastrointestinal anthrax is far less common than inhalational anthrax, but the mortality rate is extremely high, from 50 to 75%, even with early treatment (Mansour-Ghanaei *et al.*, 2002). Oropharyngeal or gastrointestinal forms of anthrax can result from ingestion of contaminated meat (Atlas, 2002; Bales *et al.*, 2002; Dixon *et al.*, 1999; Friedlander, 1999). Gastrointestinal anthrax has never been confirmed in the USA, but this may be the result of cases being unreported in rural communities, where physicians may not be aware of this form (Atlas, 2002; Bales *et al.*, 2002; Dixon *et al.*, 1999; Friedlander, 1999; Oncu *et al.*, 2003; Pile *et al.*, 1998; Shafazand *et al.*, 1999). Two out of 53 persons in a 1998 Kazakhstan outbreak developed the gastrointestinal form, resulting from the consumption of contaminated raw meat. In Minnesota, several family members consumed steer meat and fell ill with gastrointestinal symptoms (Bales *et al.*, 2002). The meat was later confirmed to contain *B. anthracis*, but the bacteria could not be cultured to confirm the presence of the gastrointestinal pathogen. According to one case of a 15-year-old male who was infected after ingesting half-cooked sheep meat, the incubation period for gastrointestinal anthrax varies from 2 to 5 days (Mansour-Ghanaei *et al.*, 2002).

Worldwide, the annual incidence of human anthrax infection is estimated between 20,000 and 100,000 (Oncu *et al.*, 2003; Pile *et al.*, 1998). The vast majority are cutaneous anthrax. In the USA, less than one case is diagnosed per year, as compared to 127 cases/year diagnosed in the early 20th century (Oncu *et al.*, 2003; Pile *et al.*, 1998; Shafazand *et al.*, 1999). Occasionally, outbreaks of anthrax will occur as a result of breakdown in public health standards and practices or lack of public health services.

IV. PATHOGENESIS

A. Overview

Themes common among all anthrax infections are the following: (1) uptake by macrophages and other immune cells, (2) germination to the vegetative form at or near the site of inoculation prior to transit to target tissues, (3) time course of transport to target organs, (4) organs targeted for toxicity, (5) overwhelming septicemia, and (6) release of

soluble factors responsible for death. Two types of *B. anthracis* have been identified: a spore form and a vegetative form. Unless stated otherwise, the vegetative bacillus will be referred to as *B. anthracis* because this is the form that produces the deadly toxins; however, both forms will be discussed at length. The spore form is essential for uptake by host cells.

B. Uptake of Spores

Anthrax infection typically results from entry of *B. anthracis* spores into the host through a minor abrasion, insect bite, ingestion of contaminated meat, or inhalation of airborne spores. These routes of exposure lead to cutaneous, intestinal/oropharyngeal, and inhalational anthrax diseases (Figure 31.1). While *B. anthracis* is not categorized as an intracellular pathogen, it uses tissue macrophages as a sanctuary where the engulfed spores can germinate during the early phase of infection (Guidi-Rontani and Mock, 2002). Successful infection and eventual disease requires uptake of spores. While spores are resistant to phagosomal superoxide (Baillie *et al.*, 2005), they have evolved to recognize receptors contained on host phagocytic cells through their pathogen-associated molecular patterns (PAMPs). While most studies have shown uptake of the bacterium by macrophages, one study showed that human dendritic cells can be triggered to internalize *B. anthracis* spores (Brittingham *et al.*, 2005). This led to the hypothesis that these cells may take part in bacterial transport to the lymph nodes, similar to macrophages. Spore PAMPs are antigenic determinants containing highly conserved molecules which interact with cell-surface Toll-like receptors (TLRs) on tissue macrophages, dendritic cells, polymorphonuclear leukocytes (PMNs), and other cell types (Janeway and Medzhitov, 2002). PAMPs typically include lipopolysaccaride (LPS) from Gram-negative bacteria and lipoteichoic acid and peptidoglycan from the cell wall of Gram-positive bacteria such as *B. anthracis*. Anthrax spores can trigger a strong inflammatory response by activating TLR4 on antigen presenting cells of the immune system at the entry site into the host (Hsu *et al.*, 2004). In addition, anthrolysin O, a protein secreted by *B. anthracis*, is a potent agonist for TLR4 (Park *et al.*, 2004).

C. Uptake Via Lungs

Anthrax spores are approximately 1 to 2 μm in diameter, optimal for inhalation and deposition in the alveolar spaces (Brachman *et al.*, 1966; Penn and Klotz, 1997; Brachman, 1970, 1980). In the case of inhalational anthrax, inhaled spores reach the respiratory bronchioles and alveoli (Figure 31.2). While most spores are internalized rapidly into phagolysosomes by resident macrophages in the alveolar space (Guidi-Rontani *et al.*, 1999b; Ross, 1957), the exosporium layer of anthrax, discovered by Flügge (1886) prevents its degradation. It should be noted that the exosporium is not present on vegetative forms of anthrax bacteria and therefore only spores contain the antigenic

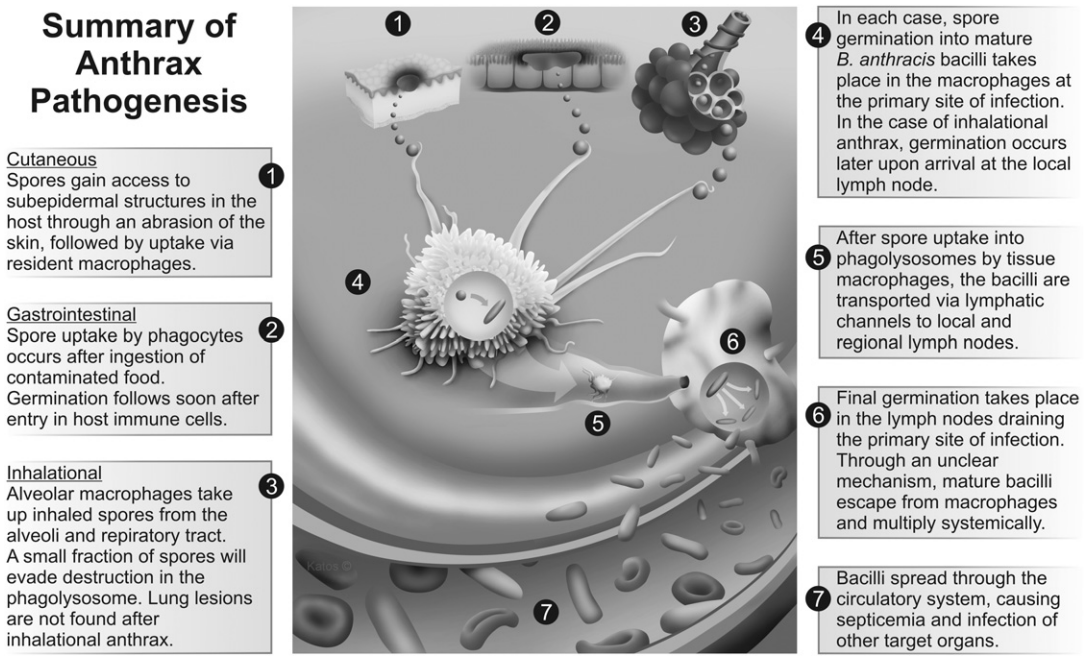

FIGURE 31.1. Overview of anthrax disease and pathogenesis. The steps of anthrax intoxication including spore uptake by macrophages, germination to the vegetative form, migration to lymph nodes, bacillus multiplication, release into the circulatory system, and septicemia are illustrated. Illustrations are copyright protected and printed with permission by Alexandre M. Katos.

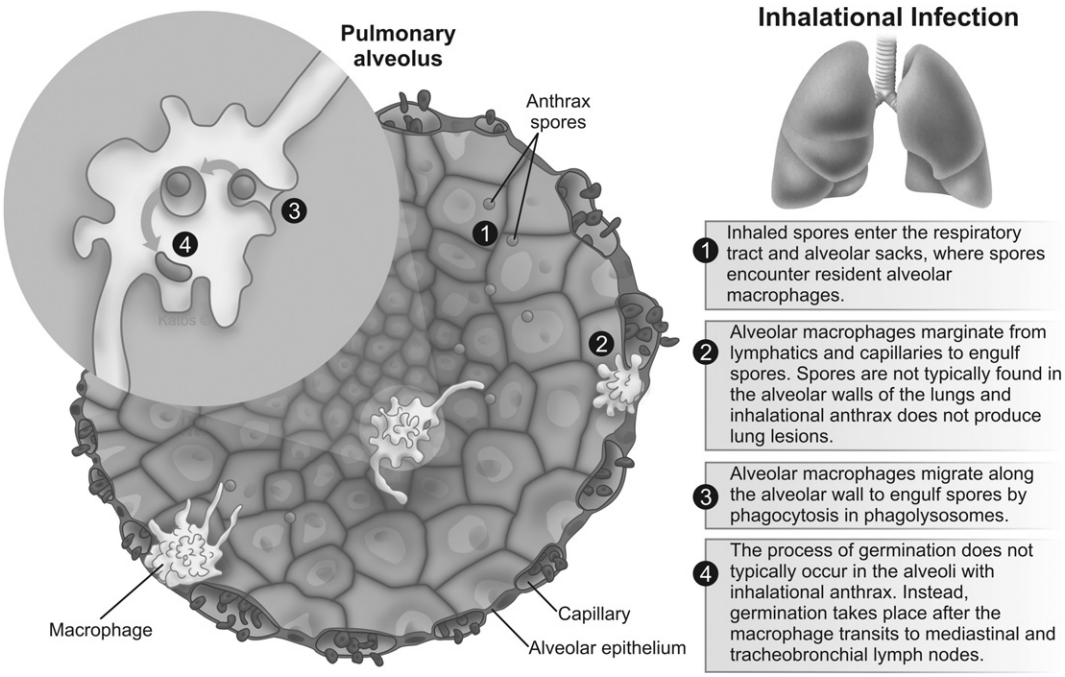

FIGURE 31.2. Spore uptake in inhalational anthrax disease. The steps involving spore deposition into a pulmonary alveolus, margination of alveolar macrophages out of capillaries into the alveolar space, spore uptake, and entry into lymphatic channels are illustrated. Illustrations are copyright protected and printed with permission by Alexandre M. Katos.

determinants recognized by TLR4 receptors of immune cells. In any case, spores will escape destruction due to their resistance to superoxide and enzymes of the phagolysosome. Spore-bearing alveolar macrophages migrate along lymphatic channels to mediastinal, peribronchial, and tracheobronchial lymph nodes (Ross, 1957; Lincoln *et al.*, 1965), while germinating en route.

D. Uptake Via Skin

The cutaneous infection process initiates as a result of anthrax spores colonizing an abrasion in the skin (Figure 31.3). A small eruption or lesion develops into a painless, black eschar. Eschars usually develop within 2–5 days following exposure. During this stage of infection, low-level spore germination can occur at the primary site of infection, leading to localized edema and necrosis. While this infection often remains localized, some patients experience systemic symptoms.

Systemic disease, a rare secondary occurrence of cutaneous anthrax, is likely due to phagocytosis by macrophages in the dermis that marginate out of lymphatic channels and blood capillaries (Figure 31.3). In cutaneous anthrax, germination typically occurs immediately inside the host macrophage. Macrophages carrying *B. anthracis* cells migrate back into lymphatic ducts *en route* to regional lymph nodes draining the primary site of infection (Dixon *et al.*, 1999). The anthrax bacilli spread through the blood and lymph and proliferate to high concentrations, creating acute septicemia.

E. Uptake Via Gastrointestinal Route

The infection process of gastrointestinal anthrax starts with ingestion of spore-contaminated food/drink or ingestion of inhaled spores. In general, gastrointestinal anthrax is similar to cutaneous anthrax, but gastrointestinal anthrax occurs in the intestinal mucosa. As in cutaneous anthrax, the organisms probably invade the mucosa through a preexisting wound or lesion or possibly through interaction with a cell-surface receptor on epithelial cells. Presumably, the mucosal lining is the entry point for the endospores (Figure 31.4), but the exact germination location is yet unknown in cases of gastrointestinal anthrax infection. The bacteria may spread from the mucosal lesion to the lymphatic system by way of macrophages migrating to the primary site of infection. Germination can occur inside host macrophages after uptake prior to macrophage migration back to lymphatic channels draining to lymph nodes (Figure 31.4). Ulcer formation is a typical symptom during gastrointestinal anthrax, and ulcers may be present at various locations along the gastrointestinal tract from the oral cavity to the cecum. However, it is not known whether ulceration occurs only at sites of bacterial infection, or if it is caused by the anthrax toxins and therefore has a less restricted occurrence (Dixon *et al.*, 1999).

F. Spore Function

Several studies have examined the molecular mechanisms by which *B. anthracis* spores undergo phagocytosis,

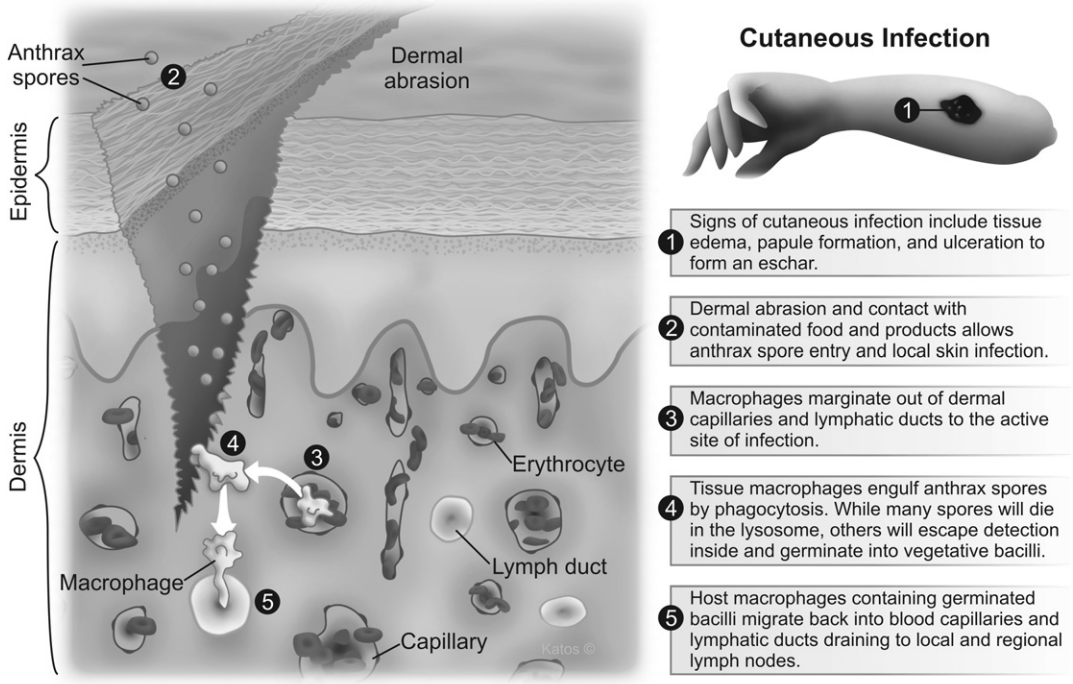

FIGURE 31.3. Spore uptake in cutaneous anthrax disease. The steps involving spore uptake at the primary site of local infection on the skin, germination inside the macrophage, and migration back into lymphatic ducts are illustrated. Illustrations are copyright protected and printed with permission by Alexandre M. Katos.

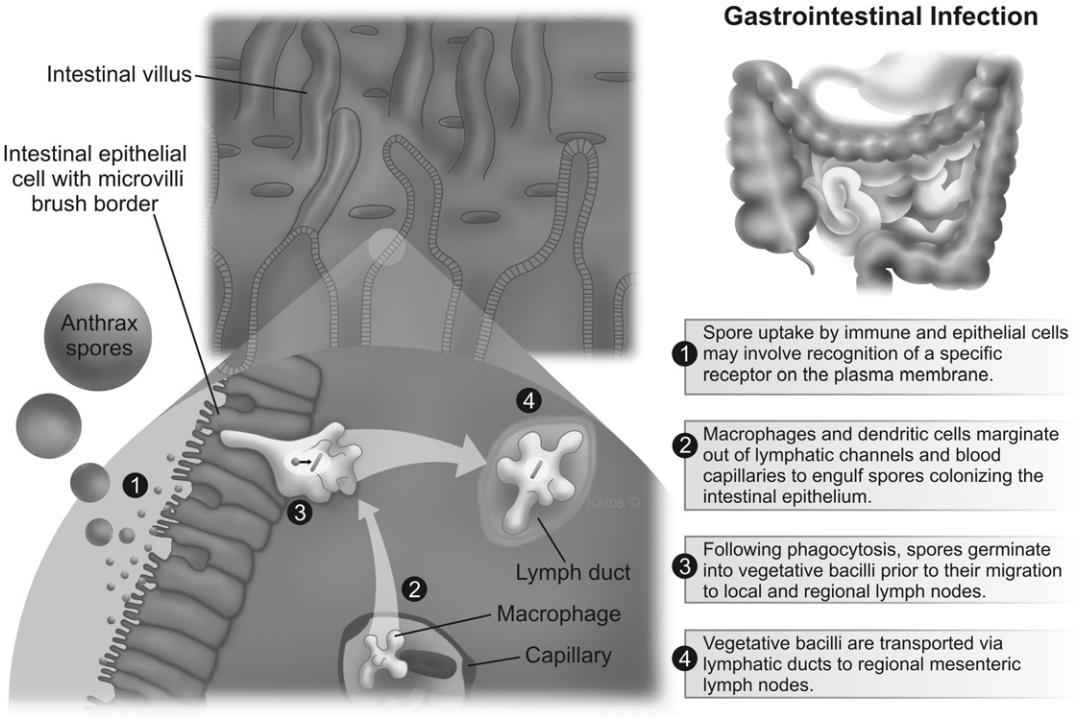

FIGURE 31.4. Spore uptake in gastrointestinal anthrax disease. The steps involving spore colonization of the gastrointestinal mucosa, uptake by phagocytes, germination, and lymphatic spread are illustrated. Illustrations are copyright protected and printed with permission by Alexandre M. Katos.

germination, and subsequent escape to mediate systemic infection. Time-lapse microscopy suggested that the number of spores per macrophage can affect whether any spores are able to outlast the macrophage's inhibitory action of the bacteria. Macrophages that have engulfed a larger number of spores are more likely to have a few that survive to germinate and become vegetative bacilli (Ruthel *et al.*, 2004). Inside the macrophage, the spores must first avoid cellular nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase activation. This enzyme, which is present in the phagosomal membrane, initiates the reduction of oxygen to superoxide anion through NADPH oxidation. The superoxide anion is further converted to other reactive oxygen species (ROS), including hydrogen peroxide. To date, no *B. anthracis* enzymes have been discovered that are involved in the removal of ROS (Guidi-Rontani and Mock, 2002). After surviving the initial membrane oxidative burst, the anthrax spores must contend with the acid environment of the phagolysosome to further germinate and multiply. Several pathogens have shown an ability to evade phagolysosomal activity; however, the mechanism by which anthrax spores avoid hydrolysis in the phagolysosome is unclear (Guidi-Rontani and Mock, 2002).

Anthrax spores promote expression of interleukins (ILs) and other pro-inflammatory cytokines in macrophages and dendritic cells (Pickering and Merkel, 2004; Pickering *et al.*, 2004). Macrophages are important mediators of the inflammatory response, and produce tumor necrosis factor alpha (TNFα), interleukin-1β, and IL-6 in response to infection. While some spores will be killed by immune cells, many will evade the host cell detection only to initiate germination. The purpose of promoting inflammation here by anthrax spores is to increase their chance for internalization by tissue macrophages and dendritic cells, in order to germinate into the vegetative form of the bacteria (Welkos *et al.*, 1989).

An intact mitogen-activated protein kinase (MAPK) cascade and pro-inflammatory response by macrophages is also necessary for host cell migration to regional lymph nodes and recruitment of additional macrophages to the primary site of infection. Without functional immune cells, the toxin would not be able to enter lymphatics or the general circulation. In fact, dendritic cells which engulf *B. anthracis* spores change their pattern of chemokine-receptor expression. Specifically, they lose tissue-retaining receptors (CCR2 and CCR5) and up-regulate lymph node homing receptors (CCR7 and CD11c) (Brittingham *et al.*, 2005).

G. Time Course of Spore Germination

In cutaneous and gastrointestinal anthrax, spore germination takes place at or near the inoculation site following uptake by the macrophage or dendritic cell. It is the vegetative form, not the spore, which produces the deadly factors. After transformation to the vegetative bacilli, these bacteria are free to mediate toxicity at the inoculation site in skin and gastrointestinal tract (Beatty *et al.*, 2003). In inhalational anthrax, germination does not occur until the spores have been transported to the local lymphatics and mediastinal lymph nodes (Riedel, 2005). In the case of inhalational anthrax, spores are not believed to germinate at the site of infection in the alveoli or bronchioles. Instead, they germinate en route or after migrating to local nodes of the lymphatic system.

H. Spore Germination

While the anthrax endospore has no measurable metabolism, spore germination is a predictor of productive anthrax infection. Similar to endospores from other species, anthrax spores seem to represent a biologically inert organism with the ability to transform into one of the most lethal organisms on earth. Germination inside the host immune cell is the key step toward this transformation from benign bystander to active infection. The spores have little or no water, no ATP production, no macromolecular synthesis, and no active enzymes. Thus, endospores can remain stable in the environment under adverse conditions for decades. Once inside a host cell, spores start to germinate and initiate early synchronous *de novo* expression of genes vital for infection, as well as expression of genes necessary for vegetative growth (Hanna and Ireland, 1999; Oncul *et al.*, 2002).

Several putative germination proteins have been identified (Guidi-Rontani *et al.*, 1999a, b; Huang *et al.*, 2004), but their roles in spore germination have yet to be clarified. L-alanine appears to be essential in initiating germination (Foster and Johnstone, 1990), but the mechanism that leads to spore germination is unclear. A germinant receptor locus (*ger S*) essential to *B. anthracis* germination has been identified; without it, the organism could not germinate in macrophages (Ireland and Hanna, 2002). Once the spore has germinated, the vegetative bacilli are free to synthesize deadly bacterial toxins; however, the precise manner in which vegetative bacilli or spores break free from immune cells is still poorly understood. A recently proposed model suggests that an interaction between anthrax toxin from newly germinated spores inside the phagolysosome of macrophages and anthrax toxin receptor 2 promotes escape of the bacilli from the cells (Banks *et al.*, 2005).

I. Vegetative Anthrax and its Capsule

The role of the vegetative bacillus is in stark contrast to that of the spore form (Table 31.1). The vegetative form functions mainly to produce the deadly toxins lethal toxin (LT) and edema toxin (ET). Germination of *B. anthracis* within macrophages is closely followed by expression of the toxin genes (Guidi-Rontani *et al.*, 1999a). *Bacillus anthracis* contains no capsule *in vitro*, but capsule synthesis begins upon host infection (Preisz, 1909). Host signals, including carbon dioxide concentrations above 5%, are thought to induce transcription of capsule and toxin genes (Uchida *et al.*, 1997; Koehler *et al.*, 1994; Sirard *et al.*, 1994).

TABLE 31.1. Differences between spore and vegetative forms of *Bacillus anthracis*

Spore form	Vegetative form
• Contains an exosporium which promotes immune host detection and uptake	• Contains poly-D-glutamic acid capsule, essential for virulence and avoidance of immune detection
• Exosporium promotes internalization by macrophages	• Capsule avoids phagocytosis by macrophages
• Requires phagocytosis, internalization by macrophages, and germination to become pathogenic	• Survives as extracellular pathogen within the body of the host
• Does not produce anthrax toxins	• Produces lethal and edema toxins to kill the target host cell
• Requires target host cells to remain intact so they can circulate to local lymph nodes	• Kills the host cell
• Promotes TNF-α and cytokine production	• Inhibits TNF-α and cytokines
• Requires target host cells to remain intact so they can circulate to local lymph nodes	• Kills the host cell
• Enhances host inflammatory response	• Suppresses the immune system
• Can remain dormant for months	• Unable to survive outside the host for any appreciable length of time

In vitro studies by Ezzell and Abshire (1995) suggest that encapsulated vegetative cells appear within 30 min after germination *in vitro*. The capsule enables vegetative forms to survive as extracellular pathogens and avoid phagocytosis by macrophages (Guidi-Rontani and Mock, 2002). Indeed, *B. anthracis* isolates lacking capsules are significantly less virulent. Vegetative cells move through the bloodstream and lymphatics to cause systemic infection.

J. Systemic Infection and Septicemia

Significant numbers of bacilli in the blood are characteristic of the late stages of infection (Atlas, 2002; Shafazand *et al.*, 1999; Oncu *et al.*, 2003; Riedel, 2005). Without an activated immune response due to the release of soluble anthrax toxins which suppress immune function, *B. anthracis* is free to multiply to high concentrations. It is currently unclear whether *B. anthracis* multiplies within the macrophage as some studies suggest (Shafa *et al.*, 1966) or the bloodstream. Cultured blood from infected rabbits and guinea pigs suggest a continuous rise in bacterial counts until the final hours of life; numbers increase sharply to 10^7 and 10^9 organisms per milliliter of blood for rabbits (Bloom *et al.*, 1947) and guinea pigs (Smith and Keppie, 1954; Keppie *et al.*, 1955), respectively. Death was shown to be dependent on bacteremia, but death was not shown to be a consequence of mechanical obstruction by large bacterial counts. Regardless of the route of infection, systemic spread results in similar colonization. The lungs and gastrointestinal tract are particular targets of system infection by mature bacilli, with the spleen, brain, liver, and almost any other organ being colonized within hours or days (Riedel, 2005). *Bacillus anthracis* has been isolated from stool specimens of both animals and humans, reflecting its presence in the bowel (Beatty *et al.*, 2003). While septicemia is important, death is the direct result of soluble factors (discussed below) secreted by the vegetative bacilli which weaken the immune response and initiate cell death.

K. Anthrax Infection Cycle

An infection cycle for *B. anthracis* has been proposed by Hanna and colleagues (Hanna and Ireland, 1999). Phagocytosis of spores by macrophages, germination, vegetative cell proliferation, and toxin release occur within hours after exposure to *B. anthracis* in a productive infection. During the middle stages of infection, the bacilli grow extracellularly and express toxins and other virulence factors. During the final stages of infection, the bacilli, having depleted nutrients from the host, form endospores, which return to the environment for the next cycle of infection (Hanna and Ireland, 1999; Oncul *et al.*, 2002). The precise sequence of events leading to successful establishment of infection is not completely understood. After germination, anthrax bacilli multiply in the lymph nodes, causing an immediate lymphadenitis, hemorrhagic mediastinitis, and spread throughout the body via the circulatory system (Dutz and Kohout, 1971; Albrink, 1961).

L. Release of Soluble Factors

Bacillus anthracis possesses four known virulence factors, including an antiphagocytic capsule of the vegetative form, lethal factor (LF, 90 kDa), edema factor (EF, 89 kDa), and a protective antigen (PA, 83 kDa). These virulence factors acting together play a key role in pathogenesis but are not toxic when present individually. In combination, PA, LF, and EF induce a dangerous cascade of events upon cell entry. As early as 1953, Smith and colleagues implicated toxic factors as the cause of death from anthrax infection (Smith *et al.*, 1953, 1955; Keppie *et al.*, 1953, 1955). It has since been shown that these three factors combine to form the two protein exotoxins of anthrax LT and ET.

PA binds to an as yet ill-defined cell receptor/lipid raft, mediating the entry of the other two components inside the cytoplasm via the endosomal pathway. Edema factor is a Ca^{2+}/calmodulin-dependent adenylate cyclase involved in producing a generalized accumulation of fluid into the interstitium, characteristic of anthrax. Lethal factor is a proteolytic enzyme involved in the inactivation of MAPK kinases (MAPKK), key players in secondary messenger signal transduction cascades. Both toxins are translocated into the cytosol of target cells by way of endosomes through a pore formed from a heptamer of PA molecules. They interfere with vital cellular responses to bacterial infection, disabling host immunity and promoting bacterial dissemination. As the disease progresses, the toxins accumulate to higher levels, causing respiratory distress, shock, widespread hemorrhage, and death.

V. TOXICOKINETICS

A. Inhalational Anthrax

To date, mice, rats, guinea pigs, rabbits, nonhuman primates, dogs, swine, and sheep have been used in inhalational animal model studies for *B. anthracis*. Routes of administration have included aerosol, intranasal, and intratracheal methods. In addition, various animal species differ in their natural resistance to infection (Welkos and Friedlander, 1988). Some of the most common findings in human inhalational anthrax concern the respiratory tract. A majority of patients experience mediastinal widening (70%), pulmonary infiltrates (70%), and pleural effusion (80%). These signs demarcate inhalational anthrax cases from influenza-like illnesses (Oncu *et al.*, 2003). Pathological findings from inhalational anthrax patients in a bioterrorism-related outbreak cited hemorrhage and necrosis in mediastinal lymph nodes, hemorrhage or inflammation of the pleurae and interhilar septae, and prominent intra-alveolar macrophages or inflammation in the lung parenchyma. There were no skin lesions. Bacilli were located in the lung, mediastinal tissues, and thoracic tissues, as identified by staining (Guarner *et al.*, 2003).

Early studies with mice were unable to identify the vegetative form of *B. anthracis* in the alveolar walls of the lungs. Aerosol exposure was achieved by exposing mice (mouse strain unreported) to clouds of spores (Albrink, 1961). Other aerosol studies involving mouse models indicated evidence of the spore form in lung sections but not the vegetative form (Young *et al.*, 1946; Barnes, 1947). The Barnes study highlighted the fact that not all of an aerosolized dose ends up in the lungs; spores can be swallowed to pass through or infect the alimentary tract.

Intratracheal administration of anthrax has demonstrated a respiratory lesion in mice (Lyons *et al.*, 2004). Inoculation of the Ames strain (5,000 vs 10,000 vs 50,000 spores) in BALB/c mice does not produce signs of early pulmonary lesions. Significant numbers of anthrax colony forming units were found in lung-associated lymph nodes harvested 5 h post-inoculation in a dose-dependent manner (Lyons *et al*, 2004). Airway damage did occur after 24 h post-inoculation with all anthrax doses; signs of toxicity include widespread edema vacuole formation, degeneration, airway epithelial cell sloughing, and necrosis. After 48 h, bacterial rods (vegetative form) were located within alveolar capillaries, suggesting active bacterial uptake from the respiratory tract.

Drysdale *et al.* (2005) investigated the role of *B. anthracis* capsule in uptake from the respiratory tract. These investigators deleted the capsule operon *capBCAD* in mutant strains of *B. anthracis* and inoculated female BALB/c mice intratracheally with ~4×10^4 mutant spores. All capsule-deficient strains germinated in the lungs (Drysdale *et al.*, 2005), indicating no role for the capsule at this particular stage in pathogenesis. This contradicts the accepted hypothesis that germination takes place in the lymph nodes for inhalational anthrax exposure.

In the only intranasal mouse model, Guidi-Rontani *et al.* (1999b) demonstrated uptake of *B. anthracis* by alveolar macrophages. A dose of 2.5×10^7 Sterne strain spores was given to Balb/c mice. Bronchial alveolar lavage (BAL) fluids were subsequently collected at 1, 3, and 24 h post-inoculation. Germination of spores in the fluid was assessed by exposing the material to heat (65°C) for 30 min. Ungerminated spores are resistant to this treatment. Germination was significantly evident in the alveolar macrophage fraction of BAL fluid by 24 h post-inoculation. Therefore, the uptake of bacteria by alveolar macrophages occurs rapidly in this system (Guidi-Rontani *et al.*, 1999b).

To date, evidence of respiratory lesions in humans does not exist. Spore cloud exposure studies by Ross (1957) determined the pathogenicity of anthrax in guinea pigs. Guinea pigs were exposed to high numbers of M.36 strain spores for 20 min and sacrificed at various time points to assess spore location. After 1 h, spores were indeed found in alveolar macrophages. Free spores were not, however, isolated from surrounding lymph nodes at this early time point. However, after 18–24 h, bacilli were observed throughout the lymphatic system. The results of these studies led to the idea that spore germination takes place in regional lymphatic nodes (i.e. tracheobronchial nodes) before spreading to the rest of the body via the blood circulatory system (Ross, 1957).

In a guinea pig/aerosol model, 6×10^5 spores of the vaccine anthrax strain STI were detected in the lungs 1 h after infection from a dose of 2.43×10^6 spores. *Bacillus anthracis* was not detectable in the tracheobronchial lymph nodes until 2 days post-infection. On day 36 post-infection, lung levels were down to 10^3 spores and tracheobronchial lymph nodes were again negative.

B. Cutaneous Anthrax

Dermal *B. anthracis* pathogenesis has been studied in mice, rats, hamsters, rabbits, guinea pigs, nonhuman primates, and

dogs. Several methods of inoculation have been tested, including subcutaneous, intradermal, epicutaneous, footpad, and scarification. Data on uptake/absorption from the skin, persistence in the circulation, transit to target tissues, and lethality will be discussed. The only animal models that have been used in bacterial uptake studies following dermal inoculation to date are the mouse and rabbit.

An extensive study on the interaction of *B. anthracis* with mouse skin following epicutaneous inoculation was conducted by Hahn *et al.* (2005). C57BL/6 and DBA/2 mice were inoculated with the Sterne strain. Epicutaneous inoculations were performed by applying an inoculum of 10^7 spores onto the shaved, tape-stripped, or abraded area of the mouse. A difference in foci development was observed, according to skin treatment prior to inoculation. Shaved-only inoculation sites did not have foci of vegetative bacilli. In contrast, abraded inoculation sites had readily apparent foci. Germination and proliferation occurred at the skin surface and in the epidermis and hair follicles. Hair follicles had deeper foci of infection, $>200\,\mu m$ below the skin surface. In animals inoculated with 2×10^8 spores onto unshaved skin, foci appeared only in the hair follicles and not in the epidermis or dermis (Hahn *et al.*, 2005). According to reviews of human infection, germination and proliferation also occur, to some degree, at the site of inoculation (Cranmer and Martinez, 2001). Proliferation also occurs in the draining lymph nodes near the site of inoculation (Anon, 2000). Zaucha *et al.* (1998) subcutaneously inoculated New Zealand white rabbits with 43 to 1.56×10^5 CFU of the Ames strain of *B. anthracis*. At the inoculation site, the main sign of bacterial uptake involved dermal and subcutaneous edema, signs observed in human cutaneous anthrax.

C. Gastrointestinal Anthrax

Despite the rarity in documented human cases of gastrointestinal anthrax (Beatty *et al.*, 2003), this form is common in underdeveloped areas of the world where infected carcasses are consumed (Sirisanthana and Brown, 2002). Gastrointestinal anthrax infection carries a 25–60% mortality rate (Mansour-Ghansei *et al.*, 2002). Gastrointestinal anthrax can be divided into intestinal and oropharyngeal forms. In the intestinal form, following an incubation period of 1–7 days, there is severe abdominal pain, hematemesis, melena and/or hematochezia, ascites and watery diarrhea. Intestinal anthrax carries a greater risk of mortality. In contrast, the milder, oropharyngeal form can be contracted following consumption of infected cattle and water buffalo. In this form, there is marked neck edema and ulcerative lesions in the oropharynx. Clinical signs include nausea, loss of appetite, emesis, and fever. In one natural outbreak of oropharyngeal anthrax, only three out of 24 patients died (Anon, 2000; Pile *et al.*, 1998).

Limited data regarding the pathogenesis of gastrointestinal *B. antracis* infection in any animal model system are available. Barnes (1947) observed that 1 h following inhalational exposure to anthrax spores, the majority of spores were found in the stomach. Therefore, regardless of the route of exposure, there is a high risk of spores transiting to the gastrointestinal tract. Unfortunately, further pathophysiology was absent from the study.

The guinea pig is the only animal model to date for which there are data following oral exposure. There is a need for more oral animal models of *B. anthracis* infection. Gastrointestinal anthrax is perhaps far underdiagnosed in humans; however, it remains an important disease due to the significant risk of ingesting spores after exposure to inhalation anthrax. Since there are limited data regarding pathogenesis of gastrointestinal anthrax in humans, evaluation of future animal models will be difficult. Stability of the organism as a function of pH in the various compartments of the gastrointestinal tract, method of inoculation, presence of stabilizers, and gastrointestinal physiology will become important factors to analyze for oral anthrax.

Aloni-Grinstein *et al.* (2005) assessed the stability of spores and vegetative cells in the gastric fluid and gastrointestinal tract. Female Hartley guinea pigs were given 5×10^9 spores or 5×10^8 vegetative cells of the anthrax MASC-13 variety *per os*. This vaccine strain is nontoxigenic, devoid of capsule, and lacking a nonfunctional form of PA. Bacteria in feces and gastric fluid were charted according to days post-ingestion. Gastric fluid incubations were conducted at 37°C with fluid taken from the guinea pig stomach. Anthrax spores exhibited much greater stability to the harsh environment created by the gastric mucosa than their alternate form. Vegetative cells were barely detectable on day 1 post-ingestion in feces and gastric fluid. There are no animal models or human studies that have examined bacterial persistence in circulation and transit to target tissues following oral exposure to *B. anthracis*. Similarly, there are no animal models that examine oral lethality, clinical signs, or epidemiology following oral exposure.

VI. MECHANISM OF TOXICITY

The significance of the capsule in virulence was demonstrated early last century when anthrax strains lacking a capsule were shown to be avirulent (Bail and Weil, 1911; Bail, cited by Sterne, 1959). The genes encoding synthesis of the capsule were found to be encoded on a 110-kilobase (kb) plasmid. Anthrax strains lacking the plasmid no longer produced the capsule and were attenuated (Ivins *et al.*, 1986), confirming the role of the capsule in pathogenesis.

The capsule contains a polymer of poly-D-glutamic acid, conferring resistance to phagocytosis by macrophages (Keppie *et al.*, 1963). This linear polymer of the capsule is weakly immunogenic (Goodman and Nitecki, 1967). The negatively charged capsule enables the bacterium to inhibit phagocytosis of bacilli by macrophages (Tomcsik and Szongott, 1933; Sterne, 1937; Keppie *et al.*, 1963; Ezzell

and Welkos, 1999). In conjunction with LF and EF, whose target cells include macrophages, dendritic cells, and other immune cells, the capsule allows *B. anthracis* to grow virtually unimpeded in the infected host. The capsule functions as a ''one-way'' filter, allowing bacilli to diffuse the other three virulence factors through the capsule, resulting in host cell intoxication without causing self-harm.

A. Protective Antigen

Bacillus anthracis secretes three plasmid-encoded soluble toxin proteins collectively referred to as anthrax toxin; these are PA, LF, and EF. LF and EF function individually and in combination as catalytic enzymes in susceptible host cells. In an unusual twist of nature, they both have evolved to share PA as a common receptor binding moiety for translocation into the cytosol of the host. PA is a dominant component of the three-part protein toxin secreted by *B. anthracis* (Liddington *et al.*, 1999; Petosa *et al.*, 1997). The mature form of PA, a secreted 735 amino acid protein, has a molecular weight of 83 kDa. The ribbon structure is illustrated in Figure 31.5 along with a detailed description of its functional domains. PA forms a membrane-insertion heptamer that translocates other toxic enzymes (EF and LF) into the cytosol of host cells.

The mechanisms by which *B. anthracis* toxins work at the cellular level are illustrated in Figure 31.6 and are described elsewhere in great detail (Mock and Fouet, 2001; Duesbery and Vande Woude, 1999). In this model, PA released from the vegetative form of the bacilli binds to cell surface receptors, namely tumor endothelium marker (TEM) 8 and capillary morphogenesis protein (CMG) 2, which are expressed as different isoforms by many cell types, including immune cells (Collier and Young, 2003; Bradley *et al.*, 2001; Liu and Leppla, 2003; Scobie *et al.*, 2003; Baldari *et al.*, 2006). Upon binding to the receptor, PA is cleaved into a 20 kDa C-terminal domain (PA_{20}) and a 63 kDa fragment (PA_{63}) by furin or similar host cell surface-associated protease (Klimpel *et al.*, 1992; Molloy *et al.*, 1992). The PA_{20} fragment is released, resulting in spontaneous oligomerization of truncated PA (PA_{63}) into heptamers that bind to EF and LF. It was once thought that a PA heptamer complex may bind up to seven molecules of LF and/or EF (Beauregard *et al.*, 2000; Duesbery *et al.*,

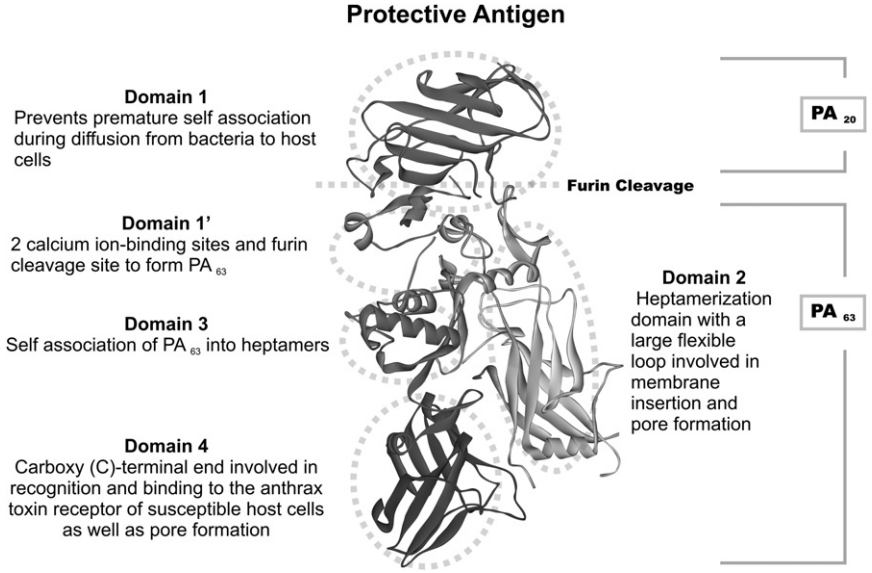

FIGURE 31.5. Three-dimensional ribbon structure of protective antigen (PA). PA, an 83 kDa protein with 735 residues, is organized into antiparallel β-sheets comprising four major domains (Petosa *et al.*, 1997). Domain 1 contains the first 258 residues and the furin enzyme cleavage site between residues 164 and 167. Prior to translocation of soluble factors into the host cell, PA is cleaved by a cell-surface protease (furin enzyme) into PA20 (20 kDa portion containing residues 1–167) and PA63. PA20 is responsible for maintaining PA as a soluble monomer and preventing premature self-association (Collier and Young, 2003). Domain 1′ (residues 168–258) designates the N-terminal end of PA63. This domain contains two charged calcium (Ca^{2+}) atoms which function to maintain PA63 in a conformation capable of self-association into heptamers and binding to the host ligand anthrax toxin receptor (Gao-Sheridan *et al.*, 2003, Petosa *et al.*, 1997; Collier and Young, 2003. Domain 2, comprising residues 259–487, is illustrated with a β-barrel core structure and large flexible loops. This structure enables membrane insertion and pore formation (Petosa *et al.*, 1997; Benson *et al.*, 1998). Domain 3, comprising residues 488–595, is involved in self-association of PA63 into heptamers. Domain 4 contains the remaining C-terminal end of PA63 (residues 596–735) and binds to the anthrax toxin receptor on the host cell membrane (Singh *et al.*, 1991; Collier and Young, 2003). The various domains of PA63 enable the protein anchor to the plasma membrane of the host, form heptamers, bind EF or LF, and translocate these soluble factors into the cytosol through a pore. The structure of PA was provided free of copyright restrictions from the Research Collaboratory for Structural Bioinformatics (RCSB) Protein Data Bank (PDB) (Berman *et al.*, 2000; PDB ID: 1acc; Petosa *et al.*, 1997) and rendered using Accelrys DS Visualizer 2.0 software.

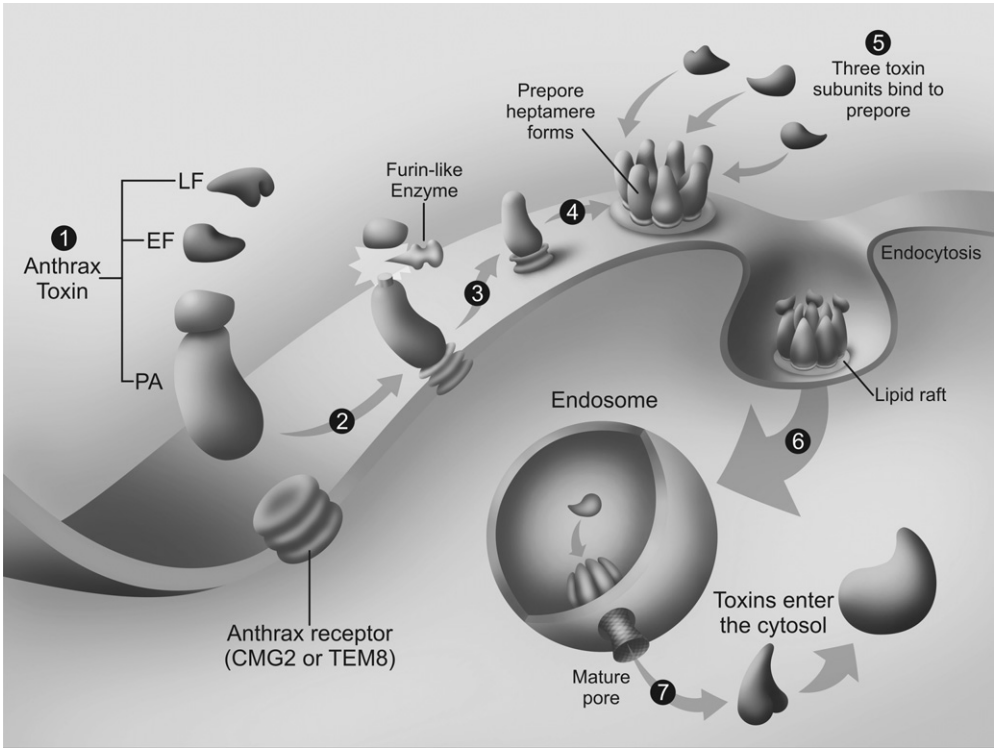

FIGURE 31.6. Anthrax toxin entry. Cellular entry of LF and EF into susceptible host cells involves an unusual mechanism for sharing PA. Binding of PA to the host cell, cleavage to form PA63, heptamerization of PA in the plasma membrane, organization into lipid rafts, binding of EF and LF to PA, internalization, PA pore formation, and translocation of anthrax soluble factors across the vesicle membrane are illustrated. Illustrations are copyright protected and printed with permission by Alexandre M. Katos.

1998; Mock and Fuet, 2001); however, evidence suggests that LF or EF binding sites on the PA_{63} heptamer span the interface between adjacent PA_{67} subunits. Therefore, it is believed that a single heptamer can interact with a maximum of three EF or LF molecules (Baldari *et al.*, 2006). The heptamer PA-LF and PA-EF complexes enter lipid rafts, illustrated as a shaded disc in Figure 31.6, in the membrane. Binding and oligomerization trigger a receptor-mediated endocytotic event followed by internalization of the hetero-oligomeric toxin complex in a membrane-bound vesicle (Beauregard *et al.*, 2000) via clathrin-dependent, receptor-mediated endocytosis. The internalized vesicle becomes an acidic endosome. The acidic pH of the endosome triggers a conformational change in the complex, leading to insertion of a flexible loop of each PA molecule into the lipid bilayer to form a pore. Formation of the pore allows for translocation of LF and EF out of the late endosome and into the cytoplasm of the host cell. Once inside the cytoplasm, LF and EF reach their respective targets.

B. Structure and Activity: Edema Factor

EF (89 kDa) is a calmodulin (CaM)-dependent adenylate cyclase, increasing intracellular cyclic adenosine monophosphate (cAMP) levels in the infected host cell cytosol. The first 261 N-terminal residues of EF are responsible for CaM binding (Duesbery and Vande Woude, 1999; Labruyere, 1990). The catalytic domain resides in amino acids 265–570 of the EF peptide sequence (Betsou *et al.*, 1995; Escuyer *et al.*, 1988). The ribbon structure of EF is illustrated in Figure 31.7. The N-terminal sequence of EF is highly conserved to a similar region in LF; this domain is essential for binding to PA. Fusion of this highly conserved N-terminal sequence to other toxins, such as Shiga and diphtheria, can cause toxic effects in mammalian cells (Arora and Leppla, 1994). Edema toxin (ET), the combination of PA and EF, causes edema when injected into the skin of experimental animals (Stanley and Smith, 1961; Beall *et al.*, 1962). Injection of EF alone, in contrast, has no toxic activity.

C. Structure and Activity: Lethal Factor

LF has a molecular weight of 90 kDA and is one of the key agents of anthrax disease. The structure of LF is illustrated in Figure 31.8. LF consists of several domains, including a PA-binding domain, a Zn^{2+}-binding domain, an imperfect repeat region, and a catalytic domain. LF functions as a highly specific Zn^{2+}-binding metalloprotease that can cleave MAPKKs near their amino (N)-termini. This cleavage reaction can potentially inactivate one or more host cellular signaling pathways (Pannifer *et al.*, 2001). Similar to EF, the LF N-terminal residues (1–254) serve as the binding domain for PA (Arora and Leppla, 1994). Adjacent to the PA-binding domain is a region of imperfect repeats containing 19 amino acids each. This region was demonstrated to be essential for toxic activity (Arora and Leppla, 1993). Deletion of the first of the four imperfect repeats of residues 308–383 eliminated LF toxicity. The LF catalytic domain resides in the C-terminus where a zinc-metalloprotease consensus sequence has been identified

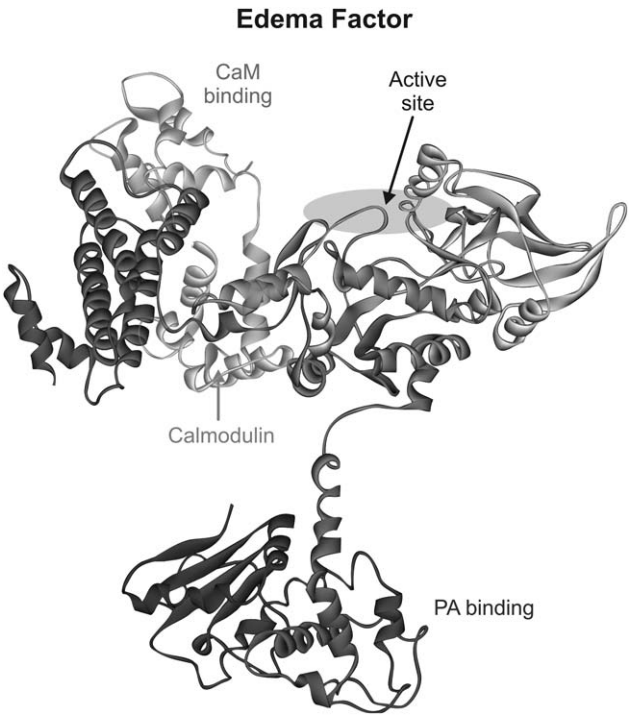

FIGURE 31.7. Three-dimensional ribbon structure of edema factor (EF). The purified and crystallized structure of EF has been previously reported (Shen *et al.*, 2005). EF is a calmodulin (CaM)-activated adenylyl cyclase and is another key factor in anthrax pathogenesis. EF contains a finger-like projection comprising a CaM-binding region, an active site to bind Mg^{2+} and 3′ deoxy-ATP, and a separate PA63 binding region. The structure of EF with bound CaM is illustrated. CaM binding causes a conformational change and activation of EF. The PA63 binding region of EF is separate from the remainder of the protein. It is shown in the same approximate position as the homologous PA-binding domain of LF in Figure 31.8 for comparison. The structure of EF was provided free of copyright restrictions from the RCSB PDB (Berman *et al.*, 2000; PDB ID: 1xfv; Shen *et al.*, 2005) and rendered using Accelrys DS Visualizer 2.0 software.

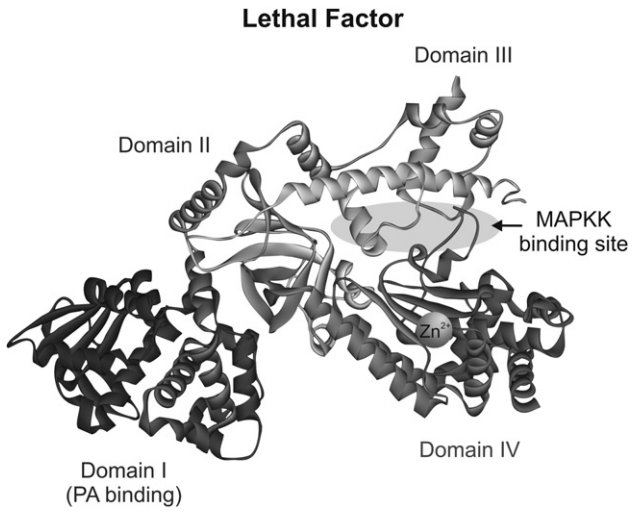

FIGURE 31.8. Three-dimensional ribbon structure of lethal factor (LF). The purified and crystallized LF has been reported (Bernardi *et al.*, 2000; Pannifer *et al.*, 2001). LF contains four recognized regions, termed domains I–IV. Residues 28–263 comprising domain I are illustrated as being entirely separate from the rest of the protein. Domain I binds the membrane-translocation component of PA63 (Lacy *et al.*, 2002). It is homologous to the same PA binding domain of edema factor (EF). Domains II–IV function together to create a long, deep pocket that holds the 16-residue N-terminal tail of MAPKK before the cleavage reaction takes place. Members of the MAPKK proteins are the only known cellular substrates of LF. The cleavage reaction removes the docking sequence for the downstream mitogen-activated protein kinase (MAPK) and therefore blocks cellular signaling via the MAPK pathway. Domain II has an ADP-ribosyltransferase active site. Domain III contains an α-helical bundle, and domain IV contains both a Zn^{2+}-binding motif and a catalytic center of the protease. The structure of LF was provided free of copyright restrictions from the RCSB PDB (Berman *et al.*, 2000; PDB ID: 1jky; Pannifer *et al.*, 2001) and rendered using Accelrys DS Visualizer 2.0 software.

within residues 686–692 (Klimpel *et al.*, 1994). The zinc metalloprotease activity is responsible for the cytotoxicity of LF. LF binds Zn^{2+} (Klimpel *et al.*, 1994; Kochi *et al.*, 1994), and mutations in LF which decrease zinc binding are poorly cytotoxic to cultured cells (Brossier *et al.*, 2000; Klimpel *et al.*, 1994).

LF interferes in the MAPK pathway which relays environmental signals to the machinery required for transcription in the nucleus and therefore modulates gene expression and protein synthesis. Specifically, LF inhibits MAPKKs; the identified substrates for LF enzymatic activity are MAPKK1, MAPKK2, MAPKK3 (Duesbery *et al.*, 1998; Pellizzari *et al.*, 1999; Vitale *et al.*, 1998), MAPKK4, MAPKK6, and MAPKK7 (Vitale *et al.*, 2000); MAPKK5 has never been demonstrated to be cleaved by LF. MAPKK cleavage occurs within the N-terminal proline-rich region preceding the kinase domain, subsequently inhibiting protein–protein interactions essential for assembly of host cell signaling complexes (Hammond and Hanna, 1998).

D. Mechanism of Toxicity: Edema Toxin

Edema toxin does not produce major tissue damage. In fact, its major role is to impair phagocyte function (Leppla, 2000). This is consistent with other toxins which function to elevate cAMP concentrations. Edema toxin inhibits phagocytosis of spores by human PMNs (O'Brien *et al.*, 1985) similar to LF; this is in contrast to spores which promote immune cell uptake (see Table 31.1). Increased intracellular cAMP induced by EF inhibits neutrophil chemotaxis, phagocytosis, superoxide production, and microbicidal activity (Crawford *et al.*, 2006; Turk, 2007; O'Brien *et al.*, 1985; Friedman *et al.*, 1987; O'Dowd *et al.*, 2004; Ahmed *et al.*, 1995). EF has been shown to inhibit TNFα and increase IL-6 production (Hoover *et al.*, 1994). Increased cAMP levels also block LPS-induced activation

of extracellular signal regulated kinase (ERK) and c-Jun N-terminal kinase (JNK) MAPK pathways in monocytes through protein kinase A (PKA) activation. This might explain suppression of cytokine production by EF (Willis and Nisen, 1996; Dziarski *et al.*, 1996; Delgado and Ganea, 2000). EF also activates guanine nucleotide-exchange proteins directly activated by cAMP 1, known as Epac1, through elevated cAMP levels. Epac1 inhibits phagocytosis by both alveolar macrophages and monocyte-derived macrophages (Aronoff *et al.*, 2005; Bryn *et al.*, 2006). EF also inhibits T-cell proliferation and subsequent cytokine production through inhibition of ERK and JNK MAPK pathways (Comer *et al.*, 2005). Therefore, EF impairs the adaptive immune response as well. EF affects other cell types; it causes endothelial cell barrier dysregulation, coagulopathy, and RBC death (Banks *et al.*, 2006).

E. Mechanism of Toxicity: Lethal Toxin

The mechanism of death accredited to lethal toxin is unclear. A summary of the cellular targets and effects of lethal and edema toxins is provided in Table 31.2. LF has similar actions on phagocytes; it disables phagocytosis by macrophages and dendritic cells. Once internalized, LF cleaves the N-termini of MAPKKs, kinases for MAPKs and ERKs, and MEKs (MAPKs and ERKs) (Turk, 2007; Collier and Young, 2003). As a result, LF blocks three critical cell signaling pathways downstream of MAPKKs and MEKs. These include the ERK1/2, JNK, and p38 MAPK pathways. In addition, LF has additional targets within host cells.

There is evidence that LT suppresses pro-inflammatory cytokine production in macrophages (Erwin *et al.*, 2001) and decreases TNFα (Pellizzari *et al.*, 1999). These reports, which suggest impairment of innate immunity in the host cell, are in contrast to those which suggest LT functions to increase cytokines by macrophages (Hanna *et al.*, 1993). LT has also been shown to cause an increase in ion permeability and rapid depletion of ATP in J774 macrophage-like cells, leading to cell lysis by osmotic mechanisms (Hanna *et al.*, 1992). Inhibition of MAPKKs may block induction of NF-κB target genes, causing apoptosis of activated macrophages (Park *et al.*, 2002).

LF effects on monocytes and macrophages are multiple. LF seems to decrease innate immune responses by blocking maturation of monocytes, which differentiate into both macrophages and dendritic cells, and promote death of activated macrophages (Banks *et al.*, 2006). LF causes reductions in pro-inflammatory cytokines and inhibits the ability of dendritic cells to activate T cells *in vivo* (Agrawal *et al.*, 2003). This negates an important mechanism of inducing adaptive immunity. Alileche *et al.* (2005) demonstrated that LF can be cytotoxic to human and murine dendritic cells. Cytotoxicity was demonstrated to be through either a caspase-dependent apoptotic mechanism in the case of human dendritic cells or a necrotic pathway. LF alters PMNs, important mediators of the adaptive and innate immune response. LT also slows neutrophil mobility (During *et al.*, 2005).

LF promotes lysis of red blood cells (RBCs) when PMNs are present (Banks *et al.*, 2006). It is believed that LT induces these immune cells to release toxic factors that are hemolytic, causing RBC lysis (Wu *et al.*, 2003). Vascular damage is pathognomonic of anthrax disease. Signs of endothelial damage include hemorrhages and leaky blood vessels, leading to vascular collapse, shock, and death. LF appears to induce a caspase-dependent apoptotic pathway in endothelial cells derived from large vessels or so-called human umbilical vein endothelial cells; LF has been shown to cause similar apoptosis in small vessels, namely neonatal dermal vascular endothelial cells (Kirby, 2004).

F. Interactions Between Lethal and Edema Toxins

Since their expression is coordinately regulated, both anthrax toxins circulate together during infection (Turk, 2007). These toxins have distinct mechanisms of toxicity, yet they target similar cell types. Both LF and EF cause endothelial cell barrier dysregulation, coagulopathy, RBC death, inhibition of neutrophil mobility and phagocytosis, and alterations in cytokine modulation. Acting together, EF and LF inhibit superoxide production by neutrophils and cytokine production by dendritic cells (Crawford *et al.*, 2006; Tournier *et al.*, 2005). EF up-regulates PA receptors, TEM 8 and CMG 2, in macrophages and increases their sensitivity to LF cytotoxicity (Comer *et al.*, 2005; Maldonado-Arocho *et al.*, 2006). Finally, the appearance of black pigmentation characteristic of anthrax disease might be explained by the combined effects of LF and EF on melanocytes. LF has been shown to produce melanin in melanoma cell lines, an effect enhanced by the addition of EF (Koo *et al.*, 2002).

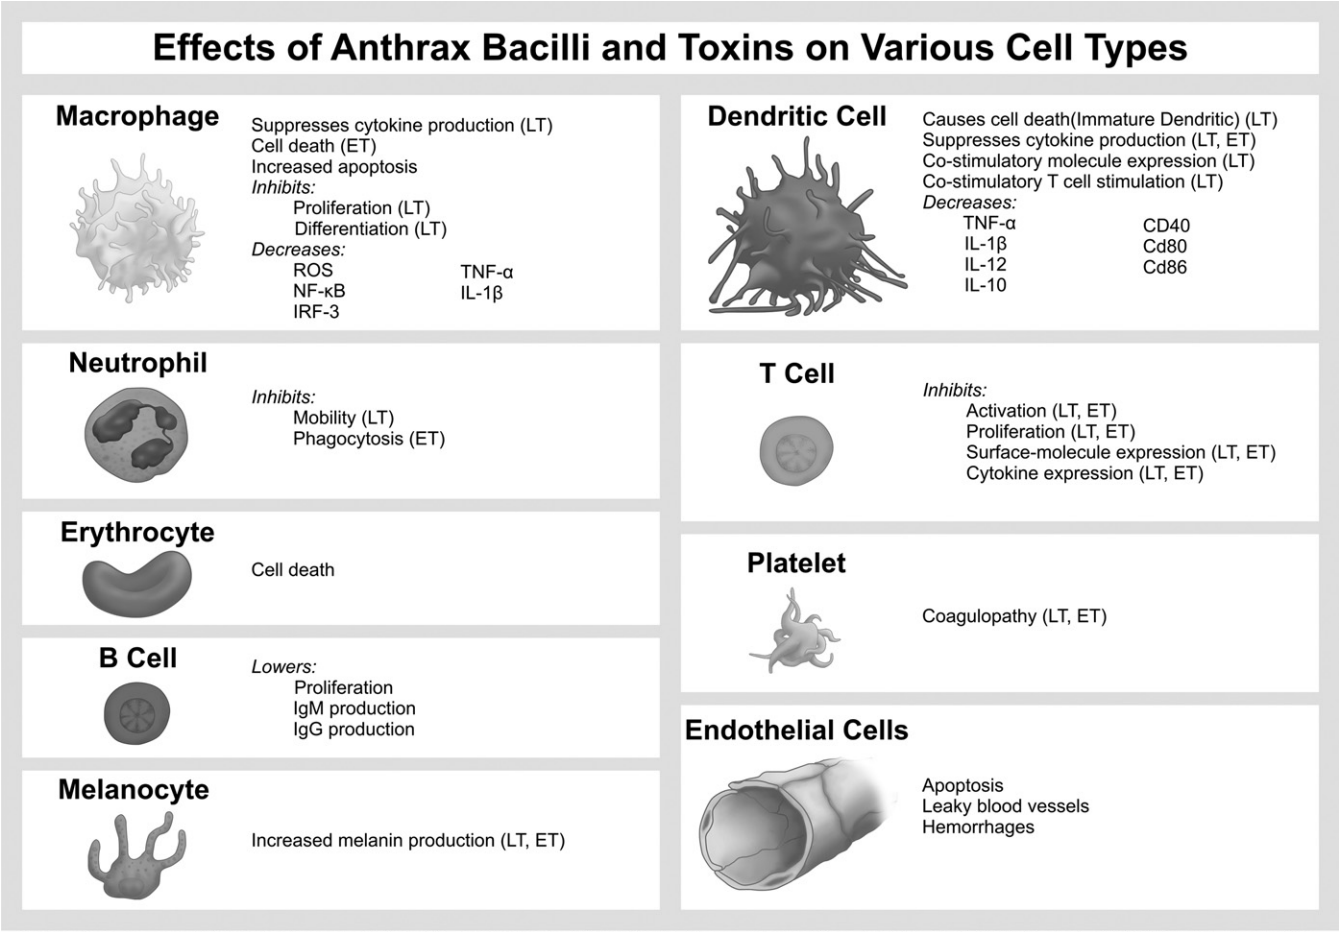
VII. TOXICITY

A. Cutaneous Anthrax

Cutaneous anthrax is the most common form of anthrax encountered worldwide, consisting of >95% of anthrax cases. The most obvious sign of bacterial uptake/absorption from the skin in human anthrax cases is the developing papule. This papule progresses to become vesicular in nature and then ulcerative. Finally, a black eschar forms, which is the hallmark of human cutaneous anthrax infection (Bell *et al.*, 2002). A more detailed look at the lesion discloses subepidermal edema, vessel thrombosis, tissue destruction, and hemorrhagic interstitium (Oncu *et al.*, 2003).

Symptoms of cutaneous anthrax infection begin with a painless papule at the site of infection 3–5 days after exposure. After 24–36 h, the papule progresses to a vesicle 1–2 cm in diameter. Once the lesion ruptures, it slowly

TABLE 31.2. Effects of anthrax bacilli and toxins on various cell types



Illustrations are copyright protected and printed with permission by Alexandre M. Katos. Adapted from (Baldari *et al.* 2006; Turk *et al.* 2007; Banks *et al.* 2006; Koo *et al.* 2002).

erodes, leaving a necrotic ulcer with a black central scab, termed an eschar. Eschar lesions typically form at exposed areas of the body (arms, hands, neck, and face). The formation of edema around the eschar lesion is also characteristic of cutaneous anthrax. Two to three weeks later, the eschar sloughs off the skin. Other signs and symptoms of cutaneous disease in humans include fever, headache, malaise, toxemia, and regional lymphadenopathy. Painful swelling of regional adrenal glands can occur.

B. Inhalational Anthrax

Signs and symptoms of inhalational anthrax follow a biphasic course. The initial phase is characterized by fever, malaise, and unproductive cough characteristic of an upper respiratory infection. Following this flu-like phase, the patient will typically recover after 2–4 days. The second phase proceeds rapidly with the following constellation of signs and symptoms: acute dyspnea, pleural effusion, fever, progressively worsening respiratory failure, cyanosis, circulatory collapse, shock, and death, if left untreated. Death occurs 24 h after the onset of this second phase secondary to toxemia and suffocation (Atlas, 2002; Bales, 2002; Dixon *et al.*, 1999; Friedlander, 1999). Although the lung is the primary site of infection here, inhalational anthrax is not considered a true pneumonia. In most, but not all cases, there is no infection in the lungs (Abramova *et al.*, 1993; Albrink, 1961). An infectious dose is estimated at 8,000 to 50,000 spores via aerosol (Franz *et al.*, 1997).

C. Gastrointestinal and Oropharyngeal Anthrax

Although extremely rare, gastrointestinal anthrax has a high estimated mortality rate (25–60%). Symptoms occur 1–7 days post-ingestion, presenting as either oropharyngeal or intestinal anthrax. Oropharyngeal anthrax presents as tongue lesions, lymphadenopathy, fever, and dysphagia. Intestinal anthrax presents 2–5 days after infection with abdominal pain, fever, nausea, emesis, and diarrhea. Abdominal pain and diarrhea are a direct result of ulceration, edema, and hemorrhaging of the gastrointestinal tract

due to edema and lethal factors (Friedlander, 1997). Therefore, diarrhea may be bloody with extensive fluid loss and circulatory collapse. If treatment is not started early, toxemia and shock may develop, resulting in death. Oropharyngeal anthrax produces a milder infection than the intestinal form and leads to a better outcome. Treatment for either form reduces symptoms and typically leads to full recovery 10–14 days after infection.

D. Meningitis

Meningitis is a complication of all anthrax infections and is associated with high mortality. Anthrax meningitis occurs through either a hematogenous or lymphatic spread from the infection site to the central nervous system (CNS) (Sejvar, 2005). High bacterial counts from anthrax bacteremia allow for *B. anthracis* to cross the blood–brain barrier into the CNS to infect the meninges and cerebrospinal fluid. Anthrax meningitis is most common with inhalational anthrax and seen in ~50% of those cases. Development of anthrax-associated meningitis is a very grave sign and invariably fatal. Even with antibiotic treatment, death occurs approximately 1–6 days after signs and symptoms of meningitis appear (Dixon *et al.*, 1999), and the mortality rate is estimated to be 94% (Sejvar, 2005).

Symptoms at the onset of anthrax meningitis include fever, headaches, nausea, vomiting, chills, malaise, agitation, and nuchal rigidity (Sejvar, 2005). Delirium, coma, refractory seizures, and neurological degeneration occur within 2–4 days (Kim *et al.*, 2001; Sejvar, 2005). Neurological degeneration can be seen, with signs that include cranial nerve palsies, myoclonus, fasciculations, decerebrate posturing, and papilloedema (Sejvar, 2005). A notable feature of anthrax meningitis infection includes subarachnoid and intraparenchymal hemorrhages. Hemorrhage can be observed in the cerebrospinal fluid, as well as polymorphonuclear pleocytosis, an increase in protein concentration, and a decrease in glucose concentration. *Bacillus anthracis* can be observed in the cerebrospinal fluid (CSF), meninges, subarachnoid space, and brain parenchyma.

VIII. DETECTION AND DIAGNOSIS

A. Detection

Detection and diagnosis of anthrax infection can be difficult. Diagnosis is made predominantly on a positive history of exposure to contaminated animal products and a physical exam of the presenting signs and symptoms. Tests to detect *B. anthracis* are typically never ordered unless there is evidence of exposure. The disease typically progresses to an advanced stage prior to initiating appropriate treatment. The formation of a black eschar with hyperemic and edematous borders is a hallmark of cutaneous anthrax infection. Unfortunately, the black eschar occurs in the later stages of infection. The appearance of painless, pruritic papules with edematous borders is suggestive of possible cutaneous anthrax infection. Further tests to identify *B. anthracis* as the infectious agent should be attempted but should not delay initiation of antibiotic treatment. Evidence of pulmonary involvement on chest x-ray can provide suspicion of inhalational anthrax. The common triad of findings is mediastinal widening, pulmonary infiltrates, and/or pleural effusions (Friedlander, 1997; Dixon *et al.*, 1999). Without a proper diagnosis, progression of some forms (i.e. inhalational anthrax) to the second stage of infection is nearly 100% fatal.

Depending on the form of disease suspected, certain specimens should be collected. If cutaneous anthrax is suspected, swabs of the lesion are warranted. A sterile, dry swab should be used to collect vesicular fluid if the lesion is in the vesicular stage. If the lesion is in the eschar stage, the edge of the eschar should be lifted and the swab should rotate underneath for 2 to 3 seconds. However, if the lesion is not in either the vesicular or eschar stage, the base of the ulcer can be swabbed with a sterile swab moistened with saline. Blood cultures should be collected regardless of the route of exposure or signs of disease (Beatty *et al.*, 2003). If gastrointestinal anthrax is suspected, ascitic fluid should be taken, and if oropharyngeal anthrax is suspected, swabs from oropharyngeal lesions should be taken (Beatty *et al.*, 2003). If pleural effusions are seen, pleural fluid should be collected, and if meningeal signs/symptoms are present, CSF should be collected.

B. Diagnostics

Laboratory tests for anthrax can include Gram staining, differential plating, γ-bacteriophage plaque assay, blood cultures, motility tests, enzyme-linked immunosorbent assays (ELISA), and fluorescent covalent microsphere immunoassay (FCMIA). Although microbial tests take 24 h to perform, often delaying the diagnosis, these tests may be necessary to confirm a diagnosis of anthrax. If there is a high index of suspicion for anthrax, initiation of therapy should not be delayed for results of these confirmatory tests.

1. Microbiological Tests

Simple tests to rule out anthrax infection are Gram staining of cultured bacteria, differential plating, and a γ-bacteriophage plaque assay. Gram staining is nearly always used in the identification of bacteria (CDC, ASM, APHL, 2002). *Bacillus anthracis* will appear as large, Gram-positive rods in short chains. The size of the bacterium is approximately 1–1.5 by 3–5 μm. *Bacillus anthracis* capsules will not take up India ink stain and will cause the bacilli to appear as clear zones on a black, stained background. *Bacillus anthracis* can be distinguished from other *Bacillus* species by culturing the organism on blood agar plates. It is the only *Bacillus* species that does not cause hemolysis. In addition,

B. anthracis cells are lysed by the bacterial virus γ-bacteriophage to form small plaques on nutrient agar plates.

Blood cultures should follow normal laboratory protocol. Specimens collected for cutaneous anthrax can be plated on 5% sheep blood agar (SBA), MacConkey agar (MAC), or any media normally used for surface wounds (CDC, ASM, APHL, 2002). Stool specimens from gastrointestinal anthrax cases should be plated on phenylethyl alcohol agar (PEA), MAC, and SBA. Sputum specimens from inhalational anthrax patients should be plated on chocolate agar, SBA, and MAC. Cultures will show isolated *B. anthracis* colonies 2–5 mm in diameter, flat or slightly curved, with a wavy border after 15–24 h. *Bacillus anthracis* shows growth on SBA and not on MAC. Colonies of *B. anthracis* plated on SBA will appear as a ''beaten egg white'' when teased with a loop (basic diagnostic testing). These blood cultures are useful, especially in the differential diagnosis of anthrax, and should be completed before antibiotic treatment is given.

A motility test is useful because *B. anthracis* is a nonmotile bacterium. Two motility tests available are the wet mount and motility medium variety. In a wet-mount preparation, organisms with Brownian movement or no movement will support the presence of *B. anthracis*. The presence of *B. anthracis* in a motility medium preparation would be a single line of growth along the original inoculum stab (CDC, ASM, APHL, 2002).

2. Molecular Tests

Acute and convalescent serum samples for serological ELISA testing should be collected for diagnosis. The CDC developed an ELISA for the detection of *B. anthracis* protective antigen (PA) using immunoglobulin G (IgG) antibodies in response to the bioterrorist anthrax plot in 2001. ELISA proved extremely useful in the detection of cutaneous and inhalational anthrax (Quinn *et al.*, 2002). The diagnostic sensitivity and diagnostic specificity for this test are 97.6% and 94.2%, respectively.

A more recent study reports another tool that detects anthrax better than ELISA detection of PA (Biagini *et al.*, 2004). The FCMIA can be multiplexed, meaning that numerous analytes can be measured simultaneously. In anthrax cases, anti-PA and anti-LF can be examined in serum samples at the same time. FCMIA is more sensitive, rapid, and reliable than ELISA.

3. Histopathology

Punch biopsies can confirm cutaneous anthrax if Gram stain and culture results are negative, due to antibiotic treatment (Godyn *et al.*, 2005), and a suspicion of cutaneous anthrax remains (Celia, 2002). The center of the eschar, the erythematous region, and the skin margin should all be included in the biopsy when an eschar is present (Godyn *et al.*, 2005).

4. Radiology

Radiological tests are available to narrow the differential diagnosis for anthrax. A chest radiograph will almost always exhibit a widened mediastinal contour that includes unilateral or bilateral hilar enlargement, as well as prominent periobronchovascular markings and pleural effusions (Frazier *et al.*, 2006). The size of the widened mediastinum contours and pleural effusion can increase rapidly over hours/days. However, findings from the radiograph might be subtle and even appear normal in the early stages of infection (Frazier *et al.*, 2006). Noncontrast CT will exhibit high-density mediastinal and hilar lymphadenopathy, which can rapidly increase in size over days (Friedlander, 1997; Frazier *et al.*, 2006). This indicates both hemorrhage and edema in the mediastinal lymph nodes. In addition, contrast-enhanced CT on mediastinal nodes can display rim enhancement and central hypodensity (Frazier *et al.*, 2006). The role of radiological tests has not been identified in the diagnosis of gastrointestinal/oropharyngeal anthrax (Beatty *et al.*, 2003). Radiographs of patients with gastrointestinal anthrax displayed findings indicative of obstruction; however, further studies need to be completed to determine if radiology can be used to help diagnose gastrointestinal anthrax (Beatty *et al.*, 2003). Patients with anthrax disease can also acquire complications of anthrax meningitis. CT or magnetic resonance imaging (MRI) shows hemorrhages in the deep gray matter, subarachnoid space, and ventricles (Sejvar *et al.*, 2005).

IX. RISK ASSESSMENT

The risks posed by an intentional outbreak of anthrax cannot be minimized, as the potential effects go beyond merely the medical. The primary costs of a biological terrorism-related anthrax event in terms of lives lost, medical resources required to treat affected individuals, and economic burden to decontaminate spores are significant. Certainly, the subsequent psychological and societal costs could be as high or higher, based on the US Federal government experience with the 2001 anthrax letters. ''On a collective level, a major epidemic of anthrax can destroy the social order'' (Guillemin, 1999).

The distribution of *B. anthracis* endospores in mailings through the US Postal Service in the fall of 2001 served to ignite public awareness concerning anthrax as a weapon of mass destruction. Deliberate contamination of the mail resulted in 22 cases of anthrax (11 inhalational and 11 cutaneous). These mailings led to five deaths among the inhalational anthrax cases and an enormous economic burden associated with decontamination. The media coverage and public fallout unveiled the deficiencies in our current risk assessment of anthrax.

The effects on public order, as well as economic and social effects, should be considered in an assessment of weaponized anthrax risk. Decontamination of the Hart

Senate Office Building in Washington, DC required 7 months at a cost of $23 million. Decontaminaton of the postal facilities that processed the ''anthrax letters'' in Brentwood, DC and Hamilton Township, NJ required more than a year at a cost in excess of $100 million (Fernandez, 2002). The psychological effects of an anthrax attack could exceed the medical or economic effects, especially in the short term. Panic caused by seemingly random outbreaks of symptoms in apparently unrelated persons or events ''could degenerate into panic, flight, communications breakdown, general societal dysfunction'' (Wein *et al.*, 2003).

A comprehensive risk assessment is dependent in part on determining the health risk posed to the individual by this biological agent. Animal models play a critical role by providing key sources of information for predicting consequences of human exposure since comparable naturally occurring human indices are rare. These animal models have been reviewed in previous sections throughout this chapter. Another method to assess risk is to use an anthrax stimulant. The Defense Research Establishment Suffield (DRES) in Canada undertook a series of experiments to assess the risk of envelopes filled with anthrax spores (Kournikakis *et al.*, 2001). In their experiments, envelopes containing spores of the nonpathogenic *Bacillus globigii* were opened in a mock mail room inside an aerosol test chamber to estimate aersol release from the envelopes. Investigators showed that dispersal by passive letter opening was far more effective than initially thought. A lethal dose could be inhaled within seconds of opening the content (Kournikakis *et al.*, 2001). Not only would the mail handler opening the envelope receive a lethal dose (LD) of between 500 and 3,000 LD_{50}s, but other workers in the room would inhale lethal numbers of spores.

In silico models of anthrax release can be used to bridge the gap to help predict consequences of human exposure in the event of an outbreak or biological attack scenario. Several modeling studies have been published (Wein *et al.*, 2003) in attempts to assess anthrax risk. The model of Wein *et al.* (2003) assumes a point-release of 1 kg of spores at a height of 100 m over a city of 10 million inhabitants. The effects on mortality of different antibiotic treatment strategies in an urbanized anthrax release are examined. This *in silico* biological weapon attack results in >100,000 deaths, given both symptomatic and asymptomatic persons receive antibiotics and the model incorporates availability and distribution parameters. In the base case, an approximation of current treatment and distribution strategies, deaths are estimated at >1% (Wein *et al.*, 2003). The model predicts significantly higher death rates (≥7 times) in cases where less aggressive distribution or administration is modeled (Webb, 2003).

One of the greatest fears of a scenario involving anthrax is the application of genetic engineering to enhance its pathogenicity. Several studies have demonstrated the ability to generate antibiotic-resistant anthrax (Pomerantsev *et al.*, 1992, 1993). In addition to developing multiple antibiotic-resistant strains of *B. anthracis*, biotechnology offers a highly likely scenario that the very nature of *B. anthracis* could be altered. It is possible that *B. anthracis* can be engineered to produce novel toxin activity (Mesnage *et al.*, 1999; Sirard *et al.*, 1997a, b). Other approaches may focus on the modification of PA such that it remains functional but immunologically distinct from the PA used in current vaccines.

X. TREATMENT

A. Overview

Treatment of any form of anthrax infection is generally the same: aggressive antibiotics and supportive care. Rapid definitive diagnosis of anthrax is critical for effective treatment, though in cases where anthrax is suspected prior to confirmation antibiotic therapy should not be withheld pending test results. Post-exposure treatment should be given in cases of putative exposure to anthrax spores to prevent systemic disease. Antibiotics and supportive management are the mainstays of treatment to prevent septic shock, fluid and electrolyte imbalance, and dyspnea associated with systemic anthrax disease. Initial administration of ciprofloxacin or doxycyclin is recommended (USFDA, 2001; CDC, 2001a, b, c). A duration of 60 days has been recommended for prophylaxis, though the most efficacious duration has not been determined (Brook, 2002).

Intravenous ciprofloxacin or doxycycline are recommended for treatment of anthrax, usually as part of a cocktail of antibiotics (CDC, 2001a, b). Multiple antibiotics are usually indicated in anthrax cases with signs of septicemia, extensive edema, or for cases with cutaneous lesions in the head and neck (Brook, 2002). Penicillin may be included in the antibiotic cocktail, but is not recommended as a standalone therapy due to *B. anthracis* β-lactamase production. *Bacillus anthracis* can express β-lactamase variants, penicillinases and cephalosporinases, which would undermine a lone-penicillin therapy (Lightfoot *et al.*, 1990). *Bacillus anthracis* has shown *in vitro* resistance to cephaloporins and trimethoprim-sulfamethoxazole (Inglesby *et al.*, 2002). Corticosteroid therapy may help treat edema from head and neck lesions or prevent airway obstruction. Table 31.3 contains therapeutic guidelines, based on CDC recommendations (CDC, 2001a, b, c), for pharmacologic management of *B. anthracis* infection.

B. Inhalational, Oral, and Gastrointestinal Anthrax

At the time of writing, the recommended initial therapy for inhalational, oral, and gastrointestinal anthrax in adults is 400 mg of ciprofloxacin every 12 h or 100 mg of doxycycline every 12 h, administered intravenously (Inglesby *et al.*, 2002). In addition to these treatments, one or two

TABLE 31.3. Anthrax therapeutic guidelines[a]

Therapy		Adults		Children		Pregnant women	
		Initial therapy[e] (intravenous dosing)	**Oral dosing**	**Initial therapy (intravenous)**	**Oral dosing**	**Initial therapy**	**Duration**
Recommended first line treatment – inhalational, GI, and oropharyngeal anthrax[b]	Ciprofloxacin (use in combination with one or two additional antimicrobials listed below)	IV treatment initially (400 mg q 12 h) in combination with one or two additional antimicrobials[f]	Switch to oral dosing when appropriate (500 mg PO BID)	IV treatment initially (10–15 mg/kg q 12 h)[h] in combination with one or two additional antimicrobials	Switch to oral when appropriate (500 mg PO BID)	Same for adults	
		Duration: Continue for 60 days total (IV and PO combined)[i]					
	Doxycycline[d] (use in combination with one or two additional antimicrobials listed below)	IV treatment initially (100 mg q 12 h) in combination with one or two additional antimicrobials[f]	Switch to oral when appropriate (100 mg PO BID)	IV treatment initially >8 yrs & >45 kg (100 mg q 12 h) >8 yrs & <45 kg (2.2 mg/kg q 12 h) <8 yrs (2.2 mg/kg q 12 h)	Switch to oral therapy when appropriate >8 yrs & >45 kg (100 mg PO BID) >8 yrs & <45 kg (2.2 mg/kg PO BID) <8 yrs (2.2 mg/kg PO BID)		
		Duration: Continue for 60 days total (IV and PO combined)[i]					

Therapy		Adults		Children		Pregnant women	
		Initial therapy (oral)[g]	**Duration**	**Initial therapy (oral)**	**Duration**	**Initial therapy**	**Duration**
Recommended first line treatment – cutaneous anthrax[b]	Ciprofloxacin	500 mg BID	60 days[i]	10–15 mg/kg q 12 h (not to exceed 1 g/day)	60 days[i]	500 mg BID	60 days[i]
	Doxycycline [d]	100 mg BID		>8 yrs & >45 kg (100 mg q 12 h) >8 yrs & <45 kg (2.2 mg/kg q 12 h) <8 yrs (2.2 mg/kg q 12 h)		100 mg BID	
Alternative option in cutaneous anthrax[c]	Amoxicillin		500 mg PO TID		80 mg/kg/day divided every 8 h		

[a]Therapeutic treatment protocol for immunocompromised persons is the same for immunocompromised adults and children
[b]Ciprofloxacin or doxycycline are first line therapeutics for all forms of anthrax
[c]Amoxicillin is an alternative option in adults and children for completion of therapy only after clinical improvement
[d]If meningitis is suspected, doxycycline may be less optimal due to poor central nervous system penetration
[e]Steroids may be considered in as adjunct therapy for patients with severe edema and for meningitis. [Dexamethosone: Adults (0.75–0.90 mg/kg/day orally, i.v., or i.m. in divided doses every 6 h); Children (0.25–0.50 mg/kg every 6 h)] [Prednisone: Adults (1–2 mg/kg or 5–60 mg orally/day); Children (0.5–2 mg/kg/day)]
[f]Other agents with *in vitro* activity include rifampin, vamcomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, and clarithromycin. Because of concerns for beta-lactamases in *Bacillus anthracis*, penicillin and ampicillin should not be used alone. Consultation with an infectious disease specialist is advised
[g]Cutaneous anthrax with signs of systemic involvement, extensive edema, or lesions of the head or neck require intravenous therapy, and a multidrug therapeutic approach
[h]In children, ciprofloxacin dosage should not exceed 1 g/day
[i]Due to the potential for spores to persist after an aerosol exposure, antimicrobial therapy should be continued for 60 days

additional antimicrobials should be administered (list mentioned above) (Inglesby *et al.*, 2002). These guidelines should be followed until the condition of the patient improves. The treatment should then be switched to either 500 mg of ciprofloxacin twice a day or 100 mg of doxycycline twice a day (Inglesby *et al.*, 2002). This stage of treatment should begin intravenously and switch to oral dosing when appropriate (Inglesby *et al.*, 2002). Treatment should continue for 60 days (Inglesby *et al.*, 2002). Oral amoxicillin can be used as an alternative in adults and children for completion of therapy only after clinical improvement (Inglesby *et al.*, 2002; CDC, 2001a, b). Pediatric guidelines for medical management of anthrax are provided in Table 31.3, in addition to recommendations for pregnant women and immunocompromised patients.

C. Cutaneous Anthrax

The recommended initial therapy for adults with cutaneous anthrax is either 500 mg of ciprofloxacin orally administered twice a day or 100 mg of doxycycline orally administrated twice a day (Inglesby *et al.*, 2002). The duration of therapy is suggested to be 60 days (CDC, 2001a, b), although previous guidelines recommend 7 to 10 days (Inglesby *et al.*, 2002). Intravenous therapy and a multidrug regimen approach are recommended for patients with signs of extensive edema, or head/neck lesions (CDC, 2001c). The guidelines for pharmacologic management of cutaneous anthrax in pediatric patients and pregnant women are also provided (Table 31.3). With early treatment, systemic disease does not occur, and laboratory cultures will yield negative results for *B. anthracis*; however, treatment will not curtail formation of the black eschar and progression of the edematous skin ulcer (CDC, 2001c).

D. Bacteremia

Bacteremia often occurs with anthrax infection, especially with gastrointestinal/oropharyngeal and inhalational anthrax. A multidrug approach consisting of ciprofloxacin or doxycycline, along with one or two other antimicrobials, is suggested when bacteremia is suspected (CDC, 2001c). Other drugs that are recommended for use with ciprofloxacin or doxycycline include rifampin, vancomycin, imipenem, chloramphenicol, penicillin/ampicillin, clindamycin, and clarithromycin (CDC, 2001c).

E. Anthrax Meningitis

There is limited clinical experience for treating patients with anthrax meningitis (Sejvar *et al.*, 2005). However, the recommended therapy is also a multidrug treatment, including the use of a fluoroquinolone and two additional drugs with excellent CNS penetration. The fluoroquinolone that is recommended for use is ciprofloxacin. The ciprofloxacin level in CSF is 26–50% of serum levels. Other fluoroquinolones include levofloxacin, gatifloxacin, moxfloxacin, and ofloxacin. Doxycycline is not recommended as a first-line agent for anthrax meningitis. Although doxycycline has a low MIC (0.03 mg/l), it has low CNS penetration and a lower percentage in the CSF of serum levels than ciprofloxacin (10–26%). These drugs have been shown to work against *B. anthracis*; however, these drugs have not been observed in humans and have not been tested in animal models. Drugs with significant CNS penetration include ampicillin, meropenem, rifampicin, or vancomycin. Although penicillin is a beta-lactam, like ampicilin and meropenem, it is not suggested for use against anthrax meningitis for reasons stated above. Similar to the treatment suggestions above, the recommended duration of therapy is 60 days. Even with the effectiveness of antibiotic treatment, there is no guarantee that anthrax will be diagnosed in time to initiate therapy. Therefore, anthrax represents a significant risk to the public because it is lethal, potent, and induces public anxiety.

F. Vaccines

While vaccines are promising, further research needs to be conducted with the goal of updating vaccine technology. Conclusive demonstration of seroconversion against an anthrax infection was demonstrated in animals previously immunized with an active anti-PA vaccine and later given post-exposure antibiotic therapy (Friedlander *et al.*, 1993). Therefore, other therapies, such as injection of anthrax-specific monoclonal antibodies (Maynard *et al.*, 2002), may lead to a promising treatment following exposure to *B. anthracis*. Both of the current anthrax vaccines, *anthrax vaccine adsorbed* (AVA) and a newer one based on recombinant PA (rPA), offer long-lasting protection against an aerosol challenge of *B. anthracis* in rhesus macaques. Efficacy of both vaccines is due primarily to the PA. The AVA vaccine offers similar protection from challenge in rabbits; however, the duration of immunity is unknown (Phipps *et al.*, 2004). Various negative side effects have been reported after administration of the current anthrax vaccine to humans, and it would be beneficial to develop a vaccine that has fewer side effects before instituting a massive vaccination plan. Recent reports suggest that the addition of CpG oligonucleotides may offer an improved response. These CpG motifs interact with various receptors on B cells and dendritic cells, which improve antigen presentation and up-regulate pro-inflammatory cytokine expression. After co-administration of CpG oligonucleotides with the AVA vaccine, this combination triggered a fast and higher-titer immune response in comparison with the vaccine alone (Klinman *et al.*, 2004). These findings suggest a potential for using oligonucleotides as an adjuvant in a post-exposure vaccine.

Other studies have used an adenoviral delivery system to invoke a protective immune response in mice (Tan *et al.*,

2003). Immunization with this form of vaccine demonstrated a rapid anti-PA antibody response at a higher level than that of the current vaccine. Further, this method of delivery offered a longer protection time in comparison to that of the rPA vaccine. However, current public fears of using a virus as an immunization vector coupled with the lack of similar findings with other model systems make it imperative to further research this potential area of vaccine technology.

XI. CONCLUDING REMARKS AND FUTURE DIRECTION

The fear of *B. anthracis* has only been heightened in recent years as a result of the terrorist events in 2001 and the increase in acts of terrorism worldwide. There are few infectious agents that are more feared or notorious than *B. anthracis*, the causative agent of the zoonotic disease anthrax. *Bacillus anthracis* would be an ideal weapon for a terrorist attack not only because of the disease pathology but also because this organism can sustain desiccation and survive long term outside of its host as a dormant spore. Moreover, infection of humans by inhalation of spores has been reported. Thus, *B. anthracis* disseminated in an aerosol could be a feasible means by which to target and infect a large population.

The processes of *B. anthracis* infection and pathogenesis have been studied in various animal models. During the initial phases of infection, regardless of the route of infection (i.e. inhalational, dermal, or oral), the host animal may display general symptoms that are characteristic of numerous infections or disease states, making a positive diagnosis difficult. Pathogenesis involves initial uptake of dormant spores by phagocytes. Germination takes place soon afterwards either at the site of inoculation or later after transport to the lymph nodes. It is the vegetative cell that moves through the circulatory system and lymphatics to infect other target organs. Lungs and gastrointestinal tract are major targets for vegetative bacilli. Later the spleen, brain, liver, and almost every other organ in the body can be colonized. In systemic anthrax, there is overwhelming septicemia. While septicemia is important, lethality from *B. anthracis* is believed to be mediated by the actions of anthrax toxins (LT and ET). The toxins are thought to be primarily responsible for causing immune system suppression, necrosis of critical cells, vascular leakage, hemorrhage, shock, and death.

There are numerous gaps in our understanding of anthrax. While the general pathogenesis of *B. anthracis* has been studied in a variety of animals, a number of important questions still remain unanswered. Although spore uptake has been demonstrated in macrophages and dendritic cells, the molecular interactions involving uptake, spore germination, and escape require additional research. Further *in vitro* and *in vivo* studies will help to elucidate these mechanisms. Understanding of the molecular mechanisms of TLR signaling and its relationship to LT-mediated apoptosis may lead to new therapies. The inhibition of TLR-mediated signaling of apoptosis may inhibit macrophage cell death and assist in controlling the pathogen.

Several studies have shown bacilli in many organs of the body following various routes of exposure. However, the time course of transit to target organs and the targeting order of these organs may be helpful in further defining therapeutic windows of opportunity. Lastly, the molecular mechanisms of toxicity and death caused by LT and ET remain unclear. There is no direct evidence that proves the importance of macrophage apoptosis in the course of disease progression. Recent reports suggest that LT may induce apoptosis of endothelial cells, which suggest that macrophages are not the sole cell type affected by LT (Kirby, 2004). In addition, reports which demonstrate LT reduces cytokine expression (Erwin *et al.*, 2001; Moayeri and Leppla, 2004; Pellizzari *et al.*, 1999) suggest that death may not be due to an inflammatory reaction.

Several animal model studies have focused on the immune response to infection and also to vaccination. Most studies identify antibody titer, but some also show cytokine production or possible mechanisms of bacterial evasion. A focus on immune response studies will help to further define *B. anthracis* pathogenesis and provide insight into the design of future vaccines and therapeutics. Most countermeasure studies have been conducted on vaccines, as antibiotic studies have typically been performed *in vitro*. Primary concerns are the length of required treatment, efficient prophylaxis methods, and less complicated dosing regimens for vaccines. In a theoretical bioterrorist attack scenario, it will be essential to distribute effective treatment and prophylaxis to infected or potentially exposed persons in an expedient manner.

The choice of an appropriate animal model system that most closely mimics the human response to *B. anthracis* infection is crucial to the development of improved treatments and more effective vaccines. Such development relies on testing in appropriate animal models in which disease, infection, and progression mimic that seen in humans. The importance of selecting an appropriate animal model for human anthrax is magnified by the potential of a genetically engineered *B. anthracis* bacterium made more virulent than its predecessor. The addition of antibiotic resistance genes would render prophylactic treatment against infection by modified organisms difficult, if not futile. Further, the inclusion of genes that encode toxins not naturally found in *B. anthracis* may assist the bacterium in escaping host immunosurveillance. Therefore, defining the pathogenesis of *B. anthracis* and designing appropriate countermeasures is a critical necessity for treatment of those exposed in occupational settings, national security, and the global community. Whether medical systems would be able to provide treatment early enough to prevent widespread disease in the event of a bioterrorist attack involving anthrax remains questionable.

CHAPTER 32

The Nervous System as a Target for Chemical Warfare Agents

LINNZI WRIGHT, CAREY POPE, AND JING LIU

I. INTRODUCTION

Chemical warfare agents (CWAs) comprise a widely diverse group of chemicals. As outlined in this and the following chapters, multiple organ systems can be targeted by CWAs, and some types of CWAs can affect one or more of the major organ systems. One of the earliest forms of CWA was possibly natural toxins placed on the tips of arrows. Indeed, the importance of arrow poisons (the Greek word *toxikos* roughly means ''pertaining to the bow'') had a prominent influence on the early development of the field of toxicology. Evidence suggests that some types of CWAs have been used for centuries. Their use in ''modern'' warfare, however, dates back only to World War I (WWI, 1914–1919). The prominent CWAs used during WWI (i.e. chlorine gas, mustard gas, and phosgene) were primarily dermal and/or pulmonary toxicants. Mustard gas was again used during WWII. During the 1930s and 1940s, a number of organophosphorus (OP) chemicals, which primarily act on the nervous system, were synthesized as potential CWAs. There remains widespread public recognition of the neurotoxic potential of the OP ''nerve agents'', reinforced by their military use in the Iran–Iraq War of 1980–1988 and their use by terrorists in Japan in 1994 and 1995. Other CWAs also have prominent effects on nervous system function. This chapter will provide a brief overview of the nervous system, highlighting some of the factors contributing to its often unique sensitivity to CWAs. This sensitivity can be due to both direct interactions with elements of the nervous system and indirect actions on other organ systems. Specific information on the effects of selected CWAs on the nervous system is provided for illustration.

II. OVERVIEW OF THE NERVOUS SYSTEM

The nervous system can be divided into two major structural divisions: the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain and spinal cord, whereas the PNS consists of the autonomic and somatic systems. Communication within and among these various systems is absolutely essential for physiological coordination.

There are two basic types of cells in the nervous system: neurons and glia (Vander *et al.*, 2001). Neurons are highly specialized cells designed for the conduction of electrical impulses to other nerve cells and to innervated tissues such as glands and muscles. There are several types of neurons in the nervous system, but in all types there exists a cell body (soma), smaller branching structures (dendrites), and an electricity-conducting fiber (axon), which gives rise to specialized areas of intracellular communication (synapses). Afferent neurons conduct electrical impulses from innervated tissues into the CNS; efferent neurons conduct electrical impulses from the CNS to innervated tissues while interneurons transmit information between neurons. Despite outnumbering neurons in the nervous system (Jehee and Murre, 2008), the primary functions of glia (i.e. astrocytes, microglia, and oligodendrocytes) have historically been considered to be the metabolic and physical support of neurons. Astrocytes are thought to aid in the maintenance of homeostatic conditions in the extracellular fluid surrounding neurons by removing excess potassium ions (K^+) from the synapse (Leis *et al.*, 2005). Microglia participate in the phagocytosis of foreign materials following neuronal damage/degeneration (Jordan and Thomas, 1988). Oligodendrocytes (CNS) and Schwann cells (PNS) sheath axons with a lipid-rich material (myelin) (Bunge *et al.*, 1978), which increases the speed of electrical signals down the axon and impairs the spread of electrical impulses between juxtaposed axons. While the covering of neurons with myelin increases conduction velocity, the rate of conduction also depends on the diameter of the axon, i.e. large axons conduct impulses faster than smaller axons (Govind and Lang, 1976).

Neurons (as all cells) maintain a resting potential across their plasma membranes, typically −60 to −75 mV relative to the extracellular fluid. This resting potential is generated by the active and passive diffusion of ions across the plasma membrane. In the resting state, the sodium ion (Na^+) concentration is higher in the extracellular fluid than in the intracellular fluid. In contrast, the K^+ concentration is higher

on the inside of the cell. If the membrane potential of a neuron exceeds a certain voltage (the threshold potential), a series of events are triggered that result in the transmission of an impulse (the action potential) along the length of an axon. Each action potential begins with a rapid reversal of voltage from the negative resting potential to a positive potential (depolarization phase) and then ends with an almost equally rapid change to a negative potential (repolarization phase). The depolarization phase of an action potential is due to the opening of voltage-gated Na^+ channels, which dramatically increases the membrane permeability to Na^+. Na^+ then passively moves into the neuron down the steep concentration gradient. The repolarization phase of an action potential is due to the inactivation (closure) of voltage-gated Na^+ channels and the subsequent opening of voltage-gated K^+ channels. K^+ moves out of the neuron, also down the concentration gradient, and contributes to the restoration of resting voltage conditions.

Conduction is the movement of an impulse down an axon within a single neuron. Once initiated, the action potential is self-propagated to the end of the neuron in an ''all-or-none'' fashion, i.e. either there is an action potential generated or there is not, and one action potential has the same characteristic as another action potential within that particular neuron. When an action potential reaches the distal terminal region of the axon, voltage-gated Na^+ channels become less involved while voltage-gated calcium ion (Ca^{2+}) channels assume prominent importance. Impulses are conducted from one neuron (presynaptic neuron) to another (postsynaptic neuron) by the release of a neurotransmitter into the synaptic cleft. When an action potential in the presynaptic neuron reaches the synapse, Ca^{2+} channels open. Due to the extensive concentration difference within and outside the terminal, Ca^{2+} then moves into the neuron and triggers a cascade of biochemical reactions (exocytosis), in which vesicles containing neurotransmitter molecules fuse with the plasma membrane and release their contents into the synaptic cleft. The neurotransmitter molecules diffuse within the synaptic cleft and interact with specific membrane receptors on the postsynaptic neuron. This neurotransmitter–receptor interaction typically either alters ion conductance in the plasma membrane influencing the postsynaptic cell's membrane polarity (either depolarizing or hyperpolarizing) or affects the synthesis of intracellular signaling molecules (second messengers), which can alter a host of intracellular signaling pathways and functions.

III. SPECIAL FEATURES OF THE NERVOUS SYSTEM

Table 32.1 lists special features of the nervous system that may contribute to its sensitivity to CWAs. For example, the nervous system is comprised of different cell types interconnected by a complex communication mechanism dependent upon chemical transmission. Each of these special features often carries with it metabolic requirements and unique vulnerabilities to toxic agents. Given that the nervous system has only a modest capacity for repair/regeneration (Freed *et al.*, 1985), subtle damage may have long-lasting effects.

A. Architecture

The cell body (soma) of neurons is responsible for supplying the metabolic needs of the elongated processes (axons and dendrites). Two interrelated demands placed on the neuron are the maintenance of a much larger cellular volume than most cells and the transport of intracellular materials over great distances (Cavanagh, 1984). Nissl substance, found exclusively in cell body of neurons (Liu and Bahu, 1975), is formed by clusters of ribosomal complexes and is involved in the synthesis of large amounts of protein necessary to maintain the neuron. The process of transporting materials from the soma to the distal aspect of the axon (anterograde axonal transport) can be an important site of toxic action.

B. Blood–Brain Barrier

The mature brain is functionally separated from the circulation by a continuous lining of endothelial cells whose apposed surfaces contain specialized tight junctions (Reese and Karnovsky, 1967) that, along with associated glial cells (Tao-Cheng and Brightman, 1988), constitute a barrier to

TABLE 32.1. Special features of the nervous system that contribute to sensitivity to CWAs

Feature	Description
Architecture	The soma of a neuron is responsible for supplying the metabolic needs of axons and dendrites, which can extend great distances
Blood–brain barrier	The brain is separated from the circulation by a lining of endothelial cells whose apposed surfaces contain specialized tight junctions
Electrochemical communication	The arrival of an action potential at the synapse activates a cascade of events that culminates in the release of neurotransmitters into the synaptic cleft
Energy requirement	Neurons require the continuous supply of glucose and oxygen in order to generate the large amount of ATP needed to support various cellular processes

the free passage of molecules. In humans, this blood–brain barrier is incompletely developed at birth (Saunders *et al.*, 1999) and even less so in premature infants (Graziani *et al.*, 1992). It also does not cover the choroid plexus and certain regions of the brain that typically have neurosecretory functions, i.e. the area postrema, hypophysis, hypothalamic regions, pineal body, and the supraoptic crest (Duvernoy and Risold, 2007). Because of the presence of these endothelial cell tight junctions, the entry of most exogenous molecules into the brain is largely limited by their lipid solubility and thus their ability to diffuse through the plasma membrane (Oldendorf, 1974). Therefore, the blood–brain barrier plays a major role in maintaining the microenvironment of the brain both by excluding hydrophilic molecules (e.g. dopamine) and by participating in the specific transport of required molecules (e.g. glucose). Certain abnormal states, whether induced (e.g. anesthesia), metabolic (e.g. adrenocorticoid hypertension), pathological (e.g. meningitis) or stress related, lead to loss of blood–brain barrier integrity and can thereby promote the leakage of molecules into the brain (Pollay and Roberts, 1980).

C. Electrochemical Communication

As noted above, the arrival of an impulse at the synapse activates a cascade of events that culminates in the release of neurotransmitters into the synaptic cleft, the diffusion of neurotransmitters to membrane-bound receptors on a neighboring neuron or cell, and the removal of neurotransmitter molecules from the synaptic cleft. These events are readily disrupted by a number of toxicants and can lead to both subtle and severe functional deficits.

D. Energy Requirements

Neurons have an absolute requirement for the continuous supply of glucose and oxygen in order to generate aerobically the large amount of ATP needed to support ionic membrane pumps, intracellular transport mechanisms, and energy-requiring signaling processes (Magistretti and Pellerin, 1999). The high oxygen requirement of the human brain takes about 20% of the total cardiac output (Hoyer, 1982). Toxic agents that interrupt the supply of oxygen [e.g. carbon monoxide (Penney, 1990)] or the utilization of oxygen by neurons [e.g. cyanide (Brierley *et al.*, 1976)] can produce catastrophic cellular damage in susceptible brain regions. Neuronal damage under these conditions can thus be a combination of direct effects on the nervous tissue and secondary damage from hypoxia/ischemia (Kristian, 2004).

IV. TYPES OF NEUROTOXICANTS

Neurotoxicants are any chemical agents that disrupt the normal function of the nervous system, in the presence or absence of visible structural damage. Hundreds of agents are recognized as having neurotoxic potential including animal venoms [e.g. green mamba snake venom (Dajas *et al.*, 1987)], drugs of abuse [e.g. cocaine (Rowbotham and Lowenstein, 1990)], industrial solvents [e.g. toluene (Filley *et al.*, 2004)], gases [e.g. carbon monoxide (Penney, 1990)], metals [e.g. arsenic (Vahidnia *et al.*, 2007)], nerve agents [e.g. soman, sarin, tabun, VX (Fernando *et al.*, 1985; Gupta *et al.*, 1987, 1991)], pesticides [e.g. parathion (Liu *et al.*, 2005)], and pharmaceutical drugs [e.g. doxorubicin (Lopes *et al.*, 2008)]. Some of these agents act directly on the nervous system, whereas others interfere with metabolic processes on which the nervous system is dependent. Table 32.2 lists four cellular mechanisms of neurotoxicity for direct acting toxicants, i.e. chemicals that cause neuronopathies, axonopathies, or myelinopathies, or that affect synaptic neurotransmission (Anthony *et al.*, 2001).

The first category of neurotoxicants [e.g. doxorubicin (England *et al.*, 1988), MPTP (Langston and Irwin, 1986), and trimethyltin (Bouldin *et al.*, 1981)] results in a neuronopathy or death of a neuron, with subsequent degeneration of its associated axon, dendrites, and myelin sheath when present.

TABLE 32.2. Cellular mechanisms of neurotoxicity

Mechanism	Description	Example
Neuronopathy	Loss of neurons with subsequent degeneration of axons, dendrites, and myelin sheath	Doxorubicin MPTP Trimethyltin
Axonopathy	Loss of axons with subsequent degeneration of myelin sheath	Acrylamide Some organophosphates Pyridinethione
Myelinopathy	Loss of myelin sheath or separation of myelin lamellae	Hexachlorophene Lead Tellurium
Disruption of neurotransmission	Alteration of synthesis, transport, storage, release, metabolism, reuptake, signaling of neurotransmitters	Cocaine Nicotine Cholinesterase inhibitors

Such neuronal degeneration is irreversible and can result in an encephalopathy with global dysfunction or, if only certain neuronal populations are affected, the interruption of particular functionalities. The second category of neurotoxicants [e.g. acrylamide (LoPachin *et al.*, 2003), organophosphorus esters (Lotti and Moretto, 2005) and pyridinethione (Ross and Lawhorn, 1990)] results in the loss of axons that later can include the degeneration of all associated myelin sheaths. Cell bodies, however, remain intact. Such axonal degeneration is reversible in the PNS and results in a clinical condition known as peripheral neuropathy in which sensations and motor strength are first impaired in the hands and feet, later progressing to other areas of the body. However, axonal degeneration is irreversible in the CNS (Richardson *et al.*, 1980). The third category of neurotoxicants [e.g. hexachlorophene (Powell *et al.*, 1973), lead (Dyck *et al.*, 1977), and tellurium (Said and Duckett, 1981)] results in the loss of myelin (i.e. demyelination) or the separation of the myelin lamellae (i.e. intramyelinic edema). While neurons are structurally unaffected by such myelin degeneration, their functions may be altered. Remyelination of axons occurs in the PNS, but only to a limited extent in the CNS (Ludwin, 1988). The fourth category of neurotoxicants [e.g. cocaine (Rowbotham and Lowenstein, 1990) and nicotine (Benowitz, 1986)] interferes with neurotransmission. These neurotoxicants can inhibit or increase the release of neurotransmitters, alter the removal of neurotransmitters from the synaptic cleft, or act as agonists or antagonists at specific receptors. Their effects are usually reversible, but nevertheless of toxicological relevance as they may result in severe acute toxicity or even death.

V. CELLULAR MAINTENANCE

All cells must assemble macromolecular complexes, maintain the intracellular environment, produce energy, and synthesize endogenous molecules in order to survive. Xenobiotics with neurotoxic potential can interfere with key aspects of cellular maintenance including adenosine triphosphate (ATP) synthesis and Ca^{2+} homeostasis.

A. ATP Synthesis

ATP plays a central role in cellular maintenance both as a chemical for biosynthesis of macromolecules and as the major source of energy for all cellular metabolism. ATP is utilized in numerous biochemical reactions including the citric acid cycle, fatty acid oxidation, gluconeogenesis, glycolysis, and pyruvate dehydrogenase. ATP also drives ion transporters such as Ca^{2+}-ATPase in the endoplasmic reticulum and plasma membranes, H^{+}-ATPase in the lysosomal membrane, and Na^{+}/K^{+}-ATPase in the plasma membrane. Chemical energy (30.5 kJ/mol) is released by the hydrolysis of ATP to adenosine diphosphate (ADP).

Oxidative phosphorylation is the process by which ATP is formed as electrons are transferred from the reduced forms of nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$) to molecular oxygen (O_2) by a series of electron transporters (i.e. the electron transport chain). ATP is required for cell division, fueling cellular motility, the maintenance of cell morphology, muscle contraction, the polymerization of the cytoskeleton and vesicular transport, and other vital functions. Impairment of oxidative phosphorylation results in the depletion of ATP and compromises these cellular processes. ATP depletion decreases neuronal membrane potential and thereby enhances the activation of glutamate receptors (Wang *et al.*, 1994). Oxidative phosphorylation can be affected by various neurotoxic agents, which are divided into four classifications (Gregus and Klaassen, 2001). Class I agents [e.g. ethanol (Li *et al.*, 1995) and fluoroacetate (Saito, 1990)] interfere with the delivery of hydrogen to the electron transport chain. Class II agents [e.g. cyanide (Piantadosi *et al.*, 1983)] inhibit the transfer of electrons along the electron transport chain to O_2. Class III agents [e.g. carbon monoxide (Piantadosi *et al.*, 1988) and cocaine (Yuan and Acosta, 2000)] interfere with the delivery of O_2 to the electron transport chain. Class IV agents [e.g. chlordecone (Jinna *et al.*, 1989)] inhibit ADP phosphorylation. These agents have a propensity to induce striatal damage, which results in large part from the supraphysiological excitation of neurons equipped with glutamate receptors (i.e. excitotoxicity) and the failure of energy-dependent homeostatic mechanisms (Del Rio *et al.*, 2007).

B. Calcium Homeostasis

Intracellular Ca^{2+} levels are highly regulated by the impermeability of the plasma membrane to Ca^{2+} and by efflux pumps that transport Ca^{2+} from the cytoplasm. Ca^{2+} is actively pumped from the cytosol both to the extracellular fluid and into storage vesicles in the endoplasmic reticulum and mitochondria. Ca^{2+} homeostasis can be affected by various neurotoxic agents, which are divided into four classifications (Gregus and Klaassen, 2001). Class I agents [e.g. glutamate (Choi, 1987)] induce Ca^{2+} influx into the cytoplasm. Class II agents [e.g. chloroform (Levitt, 1975)] inhibit Ca^{2+} export from the cytoplasm. Class III agents [e.g. carbon monoxide (Piantadosi *et al.*, 1988) and cyanide (Piantadosi *et al.*, 1983)] impair ATP synthesis. Class IV agents [e.g. MPTP (Singer *et al.*, 1988)] induce the hydrolysis of $NADP^{+}$. Sustained elevations in intracellular Ca^{2+} levels trigger a series of potentially neurotoxic events including mitochondrial dysfunction, oxidative stress and mitogen-activated protein kinase (MAPK) pathway activation.

There are three types of MAPKs: extracellular signal-related kinase (ERK), c-Jun N-terminal kinase (JNK) and p38. Sustained elevations in intracellular Ca^{2+} levels stimulate p38 activation, which inactivates B-cell leukemia 2 (BCL-2) and decreases its antiapoptotic potential

(De Chiara *et al.*, 2006). The inactivation of BCL-2 triggers cytochrome c release and activation of the caspase cascade. Caspase-3 also cleaves transcription factors associated with myocyte enhancer factor-2 (MEF2) contributing to neuronal injury (Okamoto *et al.*, 2002).

Sustained elevations in intracellular Ca^{2+} levels promote mitochondrial Ca^{2+} uptake, which decreases the mitochondrial membrane potential and blocks the electron transport chain leading to ATP depletion. Large increases in mitochondrial Ca^{2+} uptake also increase mitochondrial membrane permeability (Dubinsky and Levi, 1998) resulting in the release of proapoptotic factors such as cytochrome c and apoptosis inducing factor (AIF) (Luetjens *et al.*, 2000). Cytochrome c binds to apoptotic protease-activation factor 1 (APAF1) and procaspase-9, forming a multiprotein complex known as the apoptosome that activates the caspase cascade. The apoptosome activates caspase-9, which in turn activates caspase-3. Caspase-3 activates caspase-activated DNase (CAD), resulting in DNA fragmentation, characteristic of apoptosis.

Prolonged elevation of intracellular Ca^{2+} levels also interrupts the electron transport chain, leading to accumulation of hydrogen peroxide and superoxide, which further react to form hydroxyl radicals. Superoxide also reacts with nitric oxide to form peroxynitrite, contributing to excitotoxicity associated with ischemia (Dawson and Dawson, 1998) and leading to lipid peroxidation and protein nitration.

VI. VOLTAGE-GATED ION CHANNELS

Voltage-gated ion channels are formed by integral membrane proteins that belong to a superfamily of proteins necessary for the formation of channels that are ''gated'' (i.e. opened or closed) by changes in membrane potential (Conley and Brammar, 1999). Many xenobiotics with neurotoxic potential interfere with ion channel functions, and they tend to have rapid and sometimes dramatic effects on sensory and neuromuscular functions.

A. Calcium Ion (Ca^{2+}) Channels

Ca^{2+} channels play a critical role in the release of neurotransmitters from the presynaptic neuron into the synaptic cleft. Four types of Ca^{2+} channels (L, N, P, and T) have been identified based on biophysical and pharmacological criteria. L-type Ca^{2+} channels function in the excitation–secretion coupling of endocrine cells and some neurons. N-type Ca^{2+} channels are restricted to neurons where they function in neurotransmitter release. P-type Ca^{2+} channels are restricted to Purkinje cells where they mediate depolarization-induced repetitive spikes. T-type Ca^{2+} channels, which deactivate more slowly than any other Ca^{2+} channel, mediate depolarization-induced repetitive spikes in endocrine cells and neurons. L-type Ca^{2+} channels are pharmacologically blocked by diltiazem, nifedipine, and verapamil (Triggle, 2006), N-type Ca^{2+} channels are blocked by ω-conotoxin (Nielsen *et al.*, 2000), and P-type Ca^{2+} channels are blocked by ω-agatoxin (Adams *et al.*, 1993).

B. Chloride Ion (Cl^-) Channels

Cl^- channels underlie a wide range of physiological processes including cell volume regulation, intravesicular acidification and the maintenance of electrical excitability in muscle and nerve membranes. Nine types of Cl^- channels have been identified, and common pharmacological blockers include 4,4′-diisothiocyano-2,2′-stilbenedisulfonate (DIDS), 9-anthracene-carboxylic acid (9-AC) and p-chlorophenoxy-propionic acid (CPP) (Pusch *et al.*, 2006).

C. Potassium Ion (K^+) Channels

K^+ channels are responsible for maintaining the resting potential of a neuron as well as its repolarization following an action potential. Six types of K^+ channels have been identified including delayed rectifier (K_V) channels, which are activated with some delay following membrane depolarization; rapid-delayed rectifier (K_{VR}) channels, which are activated rapidly following membrane depolarization; slow-delayed rectifier (K_{VS}) channels, which are activated after a long delay following membrane depolarization; A (K_A) channels, which are activated by membrane depolarization after a period of hyperpolarization; inward rectifier (K_{IR}) channels, which are activated at resting potential; and sarcoplasmic reticulum (K_{SR}) channels, which are located in the sarcoplasmic reticulum and have a low selectivity for K^+. Dendrotoxin, a toxin found in the venom of green mamba snakes, blocks K^+ channels (Harvey and Anderson, 1985). Other classical K^+ channel blockers include the bee toxin apamin and 4-aminopyridine.

D. Sodium Ion (Na^+) Channels

Na^+ channels are responsible for the generation of the rising phase of an action potential, which is the result of a rapid diffusion of Na^+ across the axonal membrane. Na^+ channels also influence the threshold for action potential generation and the frequency of neuronal firing. Two types of Na^+ channels have been identified based on their sensitivity to tetrodotoxin (TTX). TTX-resistant Na^+ channels are predominantly expressed in the neonatal brain, whereas TTX-sensitive Na^+ channels are predominantly expressed in the adult brain (Novakovic *et al.*, 2001). Tetrodotoxin is the classical sodium channel blocker, while saxitoxin, a cyanobacterial toxin that contaminates shellfish, also blocks Na^+ channels (Llewellyn, 2006).

VII. NEUROTRANSMITTER SYSTEMS

Many xenobiotics with neurotoxic potential target macromolecules/processes involved in the metabolism, release, reuptake, signaling, storage, synthesis, and transport of neurotransmitters (Cooper *et al.*, 2003). The major neurotransmitter systems are briefly described below.

A. Acetylcholine (ACh)

ACh is synthesized in cholinergic nerve terminals from acetyl CoA and choline in a reaction catalyzed by choline acetyltransferase (ChAT). Acetyl CoA is synthesized from acetate, citrate, or glucose in the mitochondria of the presynaptic cell. The transport of choline from the extracellular fluid into the presynaptic neuron is the rate-limiting step in the synthesis of ACh. Once synthesized, ACh molecules are packaged in synaptic vesicles by the vesicular ACh transporter along with ATP and proteoglycan. This transport of ACh into the synaptic vesicles can be pharmacologically blocked by vesamicol (Prior *et al.*, 1992). Upon terminal depolarization, vesicles fuse with the plasma membrane of the presynaptic cell and release their contents into the synaptic cleft. Black widow spider venom (Hurlbut and Ceccarelli, 1979) and β-bungarotoxin (Spokes and Dolly, 1980) promote the release of ACh molecules from vesicles, whereas botulinum toxin inhibits the release of ACh molecules from vesicles (Sellin and Thesleff, 1981). In the synapse, ACh molecules interact specifically with postsynaptic cholinergic (muscarinic and nicotinic) receptors on the postsynaptic cell membrane to modulate the function of that cell. Muscarinic receptors are G protein-coupled receptors that affect the formation of second messengers [e.g. cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), diacylglycerol (DAG), and inositol triphosphate (IP3)]. To date, five muscarinic receptors (M1–M5) have been cloned. M1, M3, and M5 receptors are coupled to phospholipase C (PLC) via G_q and increase the formation of DAG and IP3, whereas M2 and M4 receptors are coupled to adenylyl cyclase via G_i and decrease the formation of cAMP. Nicotinic receptors are ligand-gated ion channels that increase Na^+ influx. ACh molecules can also interact with presynaptic receptors that modulate the function of the presynaptic cell (i.e. release of ACh molecules) in a ''feedback'' manner. AChE is located within the synaptic cleft where it hydrolyzes ACh to choline and acetic acid. Nerve agents and other OP esters inhibit AChE to elicit cholinergic toxicity (Taylor, 2001). Because AChE is one of the most efficient enzymes in the body [each molecule of enzyme can hydrolyze approximately 5,000 molecules of ACh per second (Cooper, 1994)], ACh molecules have a very short half-life in the synaptic cleft and only a transient ability to activate cholinergic receptors. Choline is transported back into the presynaptic cell by a high-affinity choline uptake process, which can be pharmacologically blocked by hemicholinium-3 (Freeman *et al.*, 1979).

B. Dopamine (DA)

DA is synthesized in dopaminergic nerve terminals from tyrosine in a series of reactions catalyzed by tyrosine hydroxylase (TH) and L-aromatic acid decarboxylase, respectively. The rate-limiting step in the synthesis of DA is the conversion of tyrosine to 3,4-dihydroxy-L-phenylalanine (L-DOPA) by TH. L-DOPA is subsequently converted to DA by L-aromatic acid decarboxylase. DA molecules are packaged along with ATP into synaptic vesicles by the vesicular monoamine transporter. The transport of DA molecules into synaptic vesicles is pharmacologically blocked by reserpine (Henry *et al.*, 1998). Upon terminal depolarization, vesicles fuse with the plasma membrane of the presynaptic cell and release their contents into the synaptic cleft. γ-Hydroxybutyrate (GHB) inhibits the release of DA molecules from the vesicles (Feigenbaum and Howard, 1996). In the synapse, DA molecules interact with postsynaptic receptors to modulate the function of the postsynaptic cell. Dopamine D1 receptors are coupled to adenylyl cyclase via Gs and increase the formation of cAMP. Dopamine D2 receptors are coupled to adenylyl cyclase via G_i/G_o and decrease the formation of cAMP, decrease Ca^{2+} influx, and increase K^+ efflux. DA molecules can also interact with presynaptic receptors to modulate the function of the presynaptic cell. Dopamine D2 receptors on the postsynaptic cell have a micromolar affinity for DA, whereas dopamine D2 receptors on the presynaptic cell have a nanomolar affinity for DA molecules (Creese *et al.*, 1984). Catechol-O-methyl transferase (COMT) is located within the synaptic cleft where it converts DA to 3-methoxytryptamine, which is then converted to homovanillic acid (HVA) by monoamine oxidase (MAO). Tropolone is an inhibitor of COMT (Broch, 1972), whereas pargyline is an inhibitor of MAO (Finberg and Youdim, 1983). DA molecules may also be taken back into the presynaptic cell by a high-affinity DA transporter. Amphetamine blocks the reuptake of DA into the presynaptic cell (Heikkila *et al.*, 1975). In the presynaptic cell, MAO converts DA to dihydroxyphenyl acetaldehyde, which is subsequently converted to dihydroxyphenyl acetic acid (DOPAC) by aldehyde dehydrogenase. DOPAC is converted to HVA by COMT. DOPAC is the major metabolite in rats (Wilk *et al.*, 1975), whereas HVA is the major metabolite in humans (Wilk and Stanley, 1978).

C. γ-Aminobutyric Acid (GABA)

GABA is synthesized in GABAergic nerve terminals from glutamic acid in an irreversible reaction catalyzed by glutamic acid decarboxylase (GAD) using pyridoxine as a cofactor. GABA is also synthesized from α-ketoglutarate in a reversible reaction catalyzed by GABA transaminase (GABA-T). GABA molecules are packaged into synaptic

vesicles by a vesicular transporter. Upon terminal depolarization, vesicles fuse with the plasma membrane of the presynaptic cell and release their contents into the synaptic cleft. In the synapse, GABA molecules interact with postsynaptic receptors ($GABA_A$ or $GABA_B$ receptors) in order to modulate the function of the postsynaptic cell. $GABA_A$ receptors are ligand-gated ion channels that increase Cl^- influx. $GABA_B$ receptors, which can be distinguished pharmacologically from $GABA_A$ receptors by their selective affinity for baclofen, are coupled to adenylyl cyclase via G_i/G_o and decrease the formation of cAMP, decrease Ca^{2+} influx and increase K^+ efflux. GABA molecules can also interact with presynaptic receptors to modulate the function of the presynaptic cell. GABA-T and succinic semialdehyde dehydrogenase (SSADH) are located within the synaptic cleft. GABA-T converts GABA to succinic semialdehyde, which is then converted to succinic acid by SSADH. Aminooxyacetic acid is an inhibitor of GABA-T (Stoof and Mulder, 1977). GABA molecules may also be taken back into the presynaptic cell by a high-affinity GABA transporter.

D. Glutamate (Glu)

Glu is synthesized in glutamatergic nerve terminals from α-ketoglutarate in a reaction catalyzed by GABA-T and from glutamine that is synthesized in glial cells, transported into nerve terminals and locally converted by glutaminase. Glu molecules are packaged into synaptic vesicles by a vesicular transporter. Upon terminal depolarization, vesicles fuse with the plasma membrane of the presynaptic cell and release their contents into the synaptic cleft. In the synaptic cleft, Glu molecules interact with postsynaptic receptors [α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), kainic acid (KA) and *N*-methyl-D-aspartate (NMDA) receptors] to modulate the function of the postsynaptic cell. Both AMPA and KA receptors are ligand-gated ion channels that increase Na^+ influx to mediate fast excitatory neurotransmission. Metabotropic glutamate (mGlu) receptors are coupled to PLC via G_q and increase the formation of DAG and IP3. NMDA receptors are ligand-gated ion channels that increase Ca^{2+} influx in order to mediate slow excitatory neurotransmission. As with other transmitters, Glu can also interact with presynaptic receptors to modulate the function of the presynaptic cell. Glu molecules are taken back into either glial or presynaptic cells by a number of high-affinity Glu transporters (EAAT1–EAAT5). Glu molecules that are transported into glial cells are converted by glutamine synthase into glutamine, which can then be transported into neighboring nerve terminals to act as a precursor for the synthesis of Glu.

E. Glycine (Gly)

Gly is synthesized in glycinergic nerve terminals from serine in a reaction catalyzed by serine hydroxymethyl transferase. Gly molecules are packaged into synaptic vesicles by a vesicular transporter. Upon terminal depolarization, vesicles fuse with the plasma membrane of the presynaptic cell and release their contents into the synaptic cleft. In the synapse, Gly molecules interact with postsynaptic receptors to modulate the function of the postsynaptic cell. Gly receptors are ligand-gated ion channels that increase Cl^- influx. Gly molecules may be taken back into the presynaptic cell by two high-affinity Gly transporters (GLYT-1 and GLYT-2). GLYT-1 is found primarily in glial cells, whereas GLTY-2 is found primarily in neuronal cells (Zafra *et al.*, 1995).

F. Norepinephrine (NE)

NE is synthesized in adrenergic nerve terminals from tyrosine in a series of reactions catalyzed by tyrosine hydroxylase (TH), L-aromatic acid decarboxylase, and dopamine-β-hydroxylase, respectively. As with DA, the rate-limiting step in the synthesis of NE is the conversion of tyrosine to 3,4-dihydroxy-L-phenylalanine (L-DOPA) by TH. L-DOPA is subsequently converted to DA by L-aromatic acid decarboxylase. DA molecules are packaged into synaptic vesicles by a vesicular monoamine transporter and rapidly converted into NE by dopamine-β-hydroxylase with ascorbic acid and molecular oxygen as cofactors. Upon terminal depolarization, vesicles fuse with the plasma membrane of the presynaptic cell and release their contents into the synaptic cleft. In the synapse, NE molecules interact with postsynaptic receptors (various subtypes of α- and β-adrenergic receptors) to modulate the function of the postsynaptic cell. α_1-Adrenergic receptors are coupled to PLC via G_q and increase the formation of DAG and IP3, whereas α_2-adrenergic receptors are coupled to adenylyl cyclase via G_i and decrease the formation of cAMP. Both β_1- and β_2-adrenergic receptors are coupled to adenylyl cyclase via G_s and increase the formation of cAMP. Other subtypes exist. NE molecules can also interact with presynaptic receptors to modulate the function of the presynaptic cell. COMT is located within the synaptic cleft, and converts NE to normetanephrine, which is then converted to 3-methoxy-4-dehydroxyphenylglycolaldehyde by MAO. 3-Methoxy-4-dehydroxyphenylglycoaldehyde is subsequently converted to 3-methoxy-4-hydroxymandelic acid (VMA) by aldehyde dehydrogenase. NE molecules may also be taken back into the presynaptic cell by a high-affinity NE transporter. In the presynaptic cell, MAO converts NE to 3,4-dihydroxyphenylglyceraldehyde, which is then converted to 3,4-dihydroxymandelic acid (DOMA) by aldehyde dehydrogenase. DOMA is subsequently converted to VMA by COMT.

G. Serotonin (5-HT)

5-HT is synthesized in serotonergic nerve terminals from tryptophan in a series of reactions catalyzed by tryptophan hydroxylase and L-aromatic acid decarboxylase,

respectively. Tryptophan, which is the rate-limiting factor in the synthesis of 5-HT, is transported from the extracellular compartment into the presynaptic cell by a neutral amino acid transporter and converted into 5-hydroxytryptophan (5-HTP) by tryptophan hydroxylase. 5-HTP is subsequently converted to 5-HT by L-aromatic acid decarboxylase. 5-HT molecules are packaged into synaptic vesicles by a vesicular monoamine transporter. Upon terminal depolarization, vesicles fuse with the plasma membrane of the presynaptic cell and release their contents into the synaptic cleft. In the synapse, 5-HT molecules interact with postsynaptic receptors (5-HT_1, 5-HT_2, 5-HT_3, 5-HT_4, 5-HT_5, 5-HT_6, and 5-HT_7 receptors) to modulate the function of the postsynaptic cell. 5-HT_1 receptors are coupled to adenylyl cyclase via G_i/G_o and decrease the formation of cAMP, open K^+ channels, and close Ca^{2+} channels. 5-HT_2 receptors are coupled to PLC via G_q and increase the formation of DAG and IP3. 5-HT_3 receptors are ligand-gated ion channels that increase Na^+ influx. 5-HT_4, 5-HT_6, and 5-HT_7 receptors are coupled to adenylyl cyclase via G_s and increase the formation of cAMP. 5-HT_5 receptors are G protein-coupled receptors with an unknown second messenger system. 5-HT molecules may be taken back into the presynaptic cell by a 5-HT membrane transporter, which is inhibited by fluoxetine and sertraline (Rickels and Schweizer, 1990). In the presynaptic cell, MAO converts 5-HT to 5-hydroxyindole acetaldehyde, which is subsequently converted to 5-hydroxyindole acetic acid (5-HIAA) by aldehyde dehydrogenase.

VIII. SELECTED CWAs THAT AFFECT NERVOUS SYSTEM FUNCTION

As briefly described above, the nervous system has some unique biochemical and physical characteristics that can contribute to its relative sensitivity to xenobiotics including CWAs. Many CWAs adversely affect the nervous system, and some of these have been covered in detail in subsequent chapters. This chapter provides a discussion to illustrate how some CWAs may directly or indirectly target nervous system functions.

A. Cyanides

Cyanogen chloride (CK) and hydrogen cyanide (AC) are the only cyanide-containing compounds designated as CWAs. Due to their high volatility, these two compounds rarely achieve lethal atmospheric concentrations except in enclosed spaces (Lee, 1997). When the Nazis used hydrogen cyanide in concentration camps during WWII, it was used in enclosed chambers and not on the battlefield. Although they are not CWAs, potassium and sodium cyanide salts have been used for equally malicious purposes. In the fall of 1982, seven people in the Chicago area of the USA died after ingesting Extra Strength Tylenol capsules that had been adulterated with potassium cyanide (Dunea, 1983).

Signs of cyanide exposure include agitation, dizziness, headache, and mental confusion followed by cardiac disturbances, loss of consciousness, respiratory distress and seizures. While cyanide exposure is often fatal, there are reports in the literature on its long-term effects. Finelli (1981) described a 30-year-old male who attempted suicide with cyanide. Over a year after intoxication, the patient developed choreiform movements of his extremities and an impairment in the movement of his left hand. Similarly, Carella *et al.* (1988) described a 46-year-old woman who drank a beverage poisoned with cyanide and later developed a dystonic posture of the mouth and tongue, which was deviated to the right and twisted. Computed tomography scans showed that both individuals had lesions in the basal ganglia.

Although there are a number of reports in the literature on the neuropathological consequences of cyanide exposure including necrotic lesions in the cerebellar gray matter of dogs (Haymaker *et al.*, 1952) and demyelinative lesions in the corpus callosum and optic nerves of rats (Lessell, 1971), its neurobehavioral consequences have received little attention. D'Mello (1986) reported that a single exposure to sodium cyanide (4 mg/kg, s.c.) impaired swimming ability in guinea pigs. Mathangi and Namasivayam (2000) reported that repeated exposure to sodium cyanide (2 mg/kg, i.p.) impaired the memory aspects of T-maze performance in rats.

The main mechanism of action underlying cyanide-induced toxicity is inhibition of cytochrome c oxidase, the terminal enzyme of the electron transport chain, resulting in a cytotoxic hypoxia with a shift from aerobic to anaerobic metabolism, a decrease in ATP production and an increase in lactic acid production (Way, 1984). The CNS is particularly sensitive to the toxic effects of cyanide due to its limited anaerobic metabolic capacity and high energy dependence. Ikegaya *et al.* (2001) showed that the inhibition of cytochrome c oxidase activity following the oral administration of potassium cyanide (10 mg/kg) was highest in rat brain compared to other organs. Thus, not only is the CNS particularly sensitive to the action of cyanide, but the target enzyme itself may be more sensitive to inhibition compared to other tissues.

Oxidative stress may also play a critical role in cyanide-induced toxicity. Potassium cyanide (7 mg/kg, s.c.) decreased the activities of catalase, glutathione peroxidase, and superoxide dismutase in mouse brain (Ardelt *et al.*, 1989). Potassium cyanide also stimulated the formation of reactive oxygen species (ROS) and increased levels of malondialdehyde in a number of neuronal cell lines including cerebellar granule cells (Gunasekar *et al.*, 1996), primary cortical cells (Li *et al.*, 2002), and rat pheochromocytoma (PC-12) cells (Kanthasamy *et al.*, 1997). Johnson and colleagues (1986) proposed that a rise in intracellular Ca^{2+} levels following potassium cyanide exposure is

responsible for the formation of ROS. In support of this proposal, Gunasekar and colleagues (1996) showed that the removal of Ca^{2+} from the culture medium blocked the formation of ROS in cerebellar granule cells exposed to potassium cyanide (100 μM). Antioxidants (Muller and Krieglstein, 1995), Ca^{2+} channel blockers (Johnson *et al.*, 1987), cyclooxygenase-2 (COX-2) inhibitors (Li *et al.*, 2002), NMDA receptor antagonists (Gunasekar *et al.*, 1996), and phospholipase A2 inhibitors (Kanthasamy *et al.*, 1997) all blocked the formation of ROS in neuronal cell lines exposed to potassium cyanide.

Cyanide-induced cell death involves the selective activation of apoptosis or necrosis in different neuronal populations. Mills *et al.* (1999) reported that cyanide-induced cell death occurred via apoptosis in the cortical region of a mouse brain and via necrosis in the substantia nigra. Similarly, Prabhakaran *et al.* (2002) reported that cyanide-induced cell death occurred via apoptosis in primary cortical cells and via necrosis in primary mesencephalic cells. While exposure to potassium cyanide (400 μM) increased the formation of ROS in both cell types, the rates of formation and the nature of ROS varied. For example, catalase and superoxide dismutase decreased the formation of ROS in cortical cells but not in mesencephalic cells. These findings suggest that the selective vulnerability of these neuronal populations to cyanide may be related to differences in their susceptibility to oxidative stress.

Dopaminergic neurons have an enhanced sensitivity to oxidative stress possibly due to the autoxidation of DA to quinones and ROS (Basma *et al.*, 1995; Ben-Shachar *et al.*, 1995). Kanthasamy *et al.* (1994) reported that mice repeatedly exposed to potassium cyanide (6 mg/kg, s.c.) had a reduced number of TH-positive cells indicating a loss of dopaminergic neurons in the substantia nigra. Approximately 30% of the cyanide-treated mice exhibited decreased locomotor activity and akinesia, which were suppressed by the administration of L-DOPA (100 mg/kg, i.p.). Cassel and Persson (1992) reported that striatal DA and HVA levels were rapidly decreased in rats exposed to sodium cyanide (20 mg/kg, i.p.). However, the *in vivo* synthesis of DA, measured as the rate of L-DOPA accumulation after neuronal decarboxylase inhibition, was increased in these rats suggesting an increase in striatal DA release. In support of this hypothesis, Kiuchi *et al.* (1992) reported that perfusion of sodium cyanide (2 mM) into rat striatum produced a transient but marked increase in DA release. In addition, Cassel *et al.* (1993) reported that the administration of sodium cyanide (2 mg/kg, i.p.) to rats decreased dopamine D1 and D2 receptor binding in the striatum. Given that Parkinson's disease is a condition characterized by the selective loss of dopaminergic neurons in the substantia nigra and the depletion of striatal DA levels (German *et al.*, 1989), these findings suggest that decreased dopaminergic activity may play an important role in the development of Parkinsonian-like signs following cyanide exposure.

Glutamatergic neurons also have an enhanced susceptibility to excitotoxicity and oxidative stress (Coyle and Puttfarcken, 1993). Excitotoxicity is the pathological process by which high concentrations of Glu overexcite and damage neurons through excessive activation of ionotropic Glu receptors (Olney, 1969). At NMDA receptors, high concentrations of Glu cause excitotoxicity by allowing an excessive amount of Ca^{2+} to enter into the neuron (Choi, 1987). Patel *et al.* (1992) demonstrated that NMDA receptor activation was responsible for the rise in intracellular Ca^{2+} levels contributing to cyanide-induced toxicity in cultured hippocampal neurons. Yamamoto and Tang (1998) showed that the morphological changes observed in cerebrocortical neurons exposed to potassium cyanide (1 mM) were blocked by 2-amino-7-phosphonoheptanoic acid (AP7; 1 mM), a selective NMDA receptor antagonist. Given that there is a strong correlation between whole-brain Ca^{2+} levels and cyanide-induced seizures in mice (Johnson *et al.*, 1986), increased glutamatergic activity may contribute to the development of seizures following cyanide exposure. Furthermore, Yamamoto and Tang (1996) showed that cyanide-induced seizures in mice were blocked by MK-801 (2 mg/kg, s.c.), a selective NMDA receptor antagonist.

Decreased GABAergic activity may also contribute to the development of seizures following cyanide exposure. Persson *et al.* (1985) reported that striatal GABA, Glu, and glutamine levels were decreased in rats exposed to sodium cyanide (20 mg/kg, i.p.), and Cassel *et al.* (1991) showed that these decrements were associated with an increased susceptibility to seizures. Similarly, Yamamoto (1990) reported that whole-brain GABA levels were markedly decreased in cyanide-treated mice exhibiting seizures. The decrease in GABA and the associated seizures were blocked by α-ketoglutarate (500 mg/kg, i.p.).

B. Sulfur Mustard

Sulfur mustard (2,2′-dichlorethyl sulfide; HD) was first used as a CWA in WWI during a German attack on British troops at Ypres, Belgium, in 1915. Subsequently, it has been used in a number of military conflicts including the Iran–Iraq War of 1980–1988 (Marshall, 1984). During this conflict, Iraqi troops employed sulfur mustard against both military personnel and civilians. Approximately 40,000 victims of sulfur mustard have been documented among Iranian and Kurdish populations (Hay, 2000; Khateri *et al.*, 2003), and a majority of those victims sent to European hospitals for medical treatment had mild CNS complaints including anxiety, confusion, headache, and lethargy (Balali-Mood and Hefazi, 2006).

Sulfur mustard exerts a local action on the eyes, respiratory tract, and skin followed by a systemic action on the central nervous, gastrointestinal and hematopoietic systems (Dacre and Goldman, 1996). A moderate exposure to sulfur mustard can cause blisters, conjunctivitis, erythema, lacrimation, nausea, and respiratory inflammation; whereas

a more severe exposure can cause blindness, bronchitis, bronchopneumonia, corneal damage, leucopenia, seizures, and vesication. The most accepted theory as to the basis of these clinical signs of exposure is alkylation of DNA, which activates chromosomal poly(ADP-ribose) polymerase (PARP), reducing the intracellular supply of NAD^+ and thus inhibiting glycolysis and causing cell death (Papirmeister *et al.*, 1985). However, more recent hypotheses suggest that oxidative stress, via the formation of ROS, plays a critical role in sulfur mustard-induced toxicity (Naghii, 2002). In support of this proposal, Jafari (2007) demonstrated that high doses of sulfur mustard (>10 mg/kg, i.p.) decreased the activities of catalase, glutathione peroxidase, glutathione *S*-transferase, and superoxide dismutase in rat brain leading to impairment of the antioxidant defense system.

While the literature on the effects of sulfur mustard on the central nervous system is sparse, Lynch *et al.* (1918) reported that lethal doses of sulfur mustard (>10 mg/kg, s.c.) caused hyperexcitability followed by unsteadiness of gait, muscular weakness and seizures in dogs. Philips and Thiersch (1950) reported that lethal doses of 2,4,6-tris (ethylenimino)-*S*-triazine (>125 mg/kg, i.p.), which has an ethylenimine moiety analogous to sulfur mustard, caused similar effects in mice. Although the mechanism responsible for these effects is entirely unknown, it is interesting to note that sulfur mustard (3.15 μM) induced acetylcholinesterase activity in neuroblastoma cell cultures suggesting that cholinergic activity may play a role in the central nervous system effects of sulfur mustard (Lanks *et al.*, 1975). Thus, while sulfur mustard is typically thought of as a dermal toxicant, clinical and experimental data suggest it has the potential to cause neurotoxicity possibly mediated by direct action in the nervous system elicited by oxidative stress.

C. Botulinum Toxins

The bacterial group *Clostridium botulinum* produces seven immunologically distinct toxins (types A–G) that are the most potent neurotoxins known to humankind (Gill, 1982). These toxins inhibit spontaneous and impulse-dependent ACh release (Kao *et al.*, 1976) resulting in a potentially fatal neuroparalytic illness (i.e. botulism). The typical manifestation of botulism is a flaccid paralysis involving skeletal muscle and structures innervated by autonomic ganglia (Habermann and Dreyer, 1986; Merz *et al.*, 2003). Other clinical features include a decrease in intestinal motility and tone, the inhibition of bronchial and salivary secretions and sweating, mydriasis, and respiratory collapse. Human intoxication is caused by botulinum toxin types A, B, and E and is generally manifested as foodborne, intestinal (infant), and wound botulism (Simpson, 1981).

Botulinum toxins are synthesized as 150 kDa single-chain, inactive progenitors that undergo proteolytic cleavage to form two chains coupled by a disulfide bond (de Paiva *et al.*, 1993). The heavy chain (100 kDa) is responsible for the binding and translocation of the light chain (50 kDa) into the neuronal cell; whereas the light chain is responsible for the inhibition of one of three proteins in the soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) complex that are required for neurotransmitter exocytosis (Rizo and Sudhof, 1998; Simpson *et al.*, 2004). Botulinum toxin types B, D, F, and G cleave synaptobrevin (Sollner *et al.*, 1993), botulinum toxin types A and E cleave synaptosomal-associated proteins of 25 kDa (SNAP-25) (Otto *et al.*, 1995), and botulinum toxin type C cleaves SNAP-25 and syntaxin (Schiavo *et al.*, 1995). Botulinum toxin thus acts directly and specifically in the nervous system, disrupting the fusion of synaptic vesicles and blocking cholinergic neurotransmission.

D. Organophosphorus Anticholinesterases

As noted above, the organophosphorus (OP) nerve agents are widely recognized as CWAs. Cyclosarin (*o*-cyclohexylmethyl phosphonofluoridate; GF), sarin (isopropyl methyl phosphonofluoridate; GB), soman (pinacolyl methyl phosphonofluoridate; GD), tabun (ethyl *N,N*-dimethylphosphoramidocyanidate; GA), and VX (*o*-ethyl *S*-2-diisopropylaminoethyl methylphosphonothioate), commonly referred to as nerve agents, were originally synthesized between 1936 and 1958 in various attempts to create more effective pesticides. Nerve agents are among the most lethal CWAs ever developed, and tons of these agents were previously stockpiled for military use by the USA and the Soviet Union during the Cold War. However, the first documented use of nerve agents was not until the Iran–Iraq War of 1980–1988 (Newmark, 2004). During this conflict, Iraqi troops employed sarin against both military personnel and civilians, confirmed by detection of trace amounts of a breakdown product, isopropyl methylphosphonic acid, in soil samples taken from a Kurdish village in northern Iraq (Macilwain, 1993).

More than 100,000 US military personnel participating in the Gulf War were potentially exposed to low levels of cyclosarin and sarin following the destruction of a munitions storage facility at Khamisiyah, Iraq, in March 1991 (Smith *et al.*, 2003). Reviews of medical records for these veterans and of published field accounts revealed no clinical indications of cyclosarin or sarin acute intoxication at this time (Riddle *et al.*, 2003). However, deficits in motor dexterity and visuospatial abilities (Proctor *et al.*, 2006) and a two-fold increase in the incidence of brain cancer deaths (Bullman *et al.*, 2005) were reported in these veterans 4 years after possible exposure. In addition, Heaton *et al.* (2007) reported a reduction in the overall volume of white matter and an enlargement of the lateral ventricles in Gulf War veterans. A number of persistent neurological symptoms are still expressed in many Gulf War veterans, and

substantial evidence suggests exposure to AChE-inhibiting neurotoxicants may have played a role (Binns *et al.*, 2004).

A Japanese cult named Aum Shinrikyo (Divine Truth) employed sarin in two separate terrorist attacks in the mid-1990s. The first attack, which occurred on June 27, 1994 in a residential neighborhood in Matsumoto, Japan, resulted in 56 hospitalizations and seven deaths, whereas the second attack, which occurred on March 20, 1995 in several subway cars in Tokyo, Japan, resulted in 796 hospitalizations and 12 deaths (Yanagisawa *et al.*, 2006). Although few abnormalities were observed in survivors 3 months after the attacks (Okumura *et al.*, 1996), changes in psychomotor functioning (Yokoyama *et al.*, 1998b), impairments in postural sway of low frequency (Yokoyama *et al.*, 1998a), and neurophysiological alterations as measured by visual evoked potentials (Murata *et al.*, 1997) were observed in survivors 6–8 months after the attacks. Yamasue *et al.* (2007) observed smaller regional white matter volumes and diffuse bilateral disruption of white matter integrity in survivors 5–6 years after the attacks, and Miyaki *et al.* (2005) observed deficits in attention and gross motor speed in survivors 7 years after the attacks.

Nerve agents exert their toxicological effects by inhibiting AChE in the central and peripheral nervous systems. Changes in other cholinergic neurochemical signaling components may be directly or indirectly elicited. Fosbraey *et al.* (1990) reported that AChE levels were maximally inhibited by 90% in guinea pigs treated with soman (31.2 μg/kg, s.c.), and Whalley and Shih (1989) reported a 30–40% decrease in high-affinity choline uptake in the cortex and hippocampus of rats treated with sarin (135 μg/kg, s.c.) or soman (120 μg/kg, s.c.). The accumulation of ACh within the synaptic cleft following AChE inhibition causes the prolonged activation of muscarinic and nicotinic receptors on postsynaptic cells. Shih (1982) reported a 320% increase in ACh levels in the cortex of rats treated with soman (120 μg/kg, s.c.), and Khan and colleagues (2000) reported a 10% increase in muscarinic receptor binding and a 132% increase in nicotinic receptor binding in the cortex of rats treated with sarin (100 μg/kg, i.m.). In the PNS, the prolonged activation of cholinergic receptors results in hypersecretions (e.g. defecation, lacrimation, rhinorrhea, salivation, and urination), miosis, muscle fasciculations, and tremors (Ecobichon, 2001). In the CNS, the prolonged activation of cholinergic receptors can lead to loss of consciousness, respiratory distress, and seizures/convulsions.

Respiratory distress was observed in approximately 63% of the casualties from the terrorist attack in Tokyo, Japan (Okumura *et al.*, 1996). Rickett *et al.* (1986) demonstrated that one of the first signs of nerve agent-induced respiratory distress in cats was disruption of the normal firing of respiratory-related neurons in the pons medulla followed by changes in airflow, diaphragm contraction, diaphragm electromyogram (EMG), and phrenic nerve activity. Spectral analysis of diaphragm EMG activities showed that the functional integrity of the diaphragm in guinea pigs following soman exposure (15 μg/kg, s.c.) was not sufficiently compromised to produce respiratory distress despite signs of fatigue (Chang *et al.*, 1990). These studies suggest that respiratory depression following nerve agent exposure is affected through disruption of central cholinergic signaling. Bajgar *et al.* (2007) showed that the pons medulla was particularly sensitive to AChE inhibition by nerve agents.

Seizures were observed in approximately 3% of the casualties from the terrorist attack in Tokyo, Japan (Okumura *et al.*, 1996). Shih and McDonough (1999) demonstrated that all five of the classic nerve agents (i.e. cyclosarin, sarin, soman, tabun, and VX) were capable of inducing seizures at lethal doses ($2.0 \times LD_{50}$ in guinea pigs and $1.6 \times LD_{50}$ in rats). In the case of VX exposure, however, the latency of seizure development was 3–5 times longer than with the other nerve agents. Tonduli *et al.* (2001) reported that soman-induced seizures occurred in rats only when the cortical AChE inhibition was over 65%, and Churchill *et al.* (1985) showed that early body weight loss was a nonlethal indicator of the severity of soman-induced seizures in rats. Both anticholinergics (atropine sulfate, biperiden HCl, and trihexyphenidyl HCl) and benzodiazepines (diazepam and midazolam) were able to terminate nerve agent-induced seizures in guinea pigs when administered within 5 min of seizure onset, but a higher dose of each was typically required to terminate seizures induced by soman than by other nerve agents (Shih *et al.*, 2003).

Prolonged seizure activity (i.e. *status epilepticus*), following nerve agent exposure, has been shown in several animal models to cause neuropathological lesions that are associated with long-term deficits in cognitive function and other behaviors (Geller *et al.*, 1985; Raffaele *et al.*, 1987; Rylands, 1982). Shih *et al.* (2003) demonstrated that all five of the classic nerve agents were capable of inducing neuropathology when they were administered to guinea pigs at doses that produced seizures. Moderate to severe neuropathological lesions were reported in 70% of sarin- (Kadar *et al.*, 1995) and 98% of soman-treated (McDonough *et al.*, 1995) rats exhibiting seizures for 20 min or longer. Lesions were primarily noted in the hippocampus, piriform cortex, and thalamus, but pathology later progressed to other brain regions. Filliat *et al.* (1999) reported that spatial memory performance in the Morris water maze was directly related to the severity of hippocampal lesions in soman-treated rats. Interestingly, no memory impairment was observed below a threshold of 15% neuronal loss. Soman-induced deficits were also reported in active (Romano *et al.*, 1985) and passive (Buccafusco *et al.*, 1990) avoidance, brightness discrimination (Myhrer *et al.*, 2005), differential reinforcement of low rate (DRL) acquisition (McDonough *et al.*, 1986), match-to-sample discrimination (Gause *et al.*, 1985), maze learning (Raffaele *et al.*, 1987), and various schedule-controlled behaviors (Brezenoff *et al.*, 1985; Hymowitz *et al.*, 1985).

Seizures followed by the cessation of respiration are important components of severe nerve agent intoxication. Neuropathological lesions are proposed to occur via ''recruitment'' of a glutamate-mediated excitotoxic mechanism; nerve cells targeted by glutamatergic neurons experience an unrelenting stimulation (excitotoxicity) that results in a failure of their homeostatic mechanisms, cytoplasmic changes and cell death (Solberg and Belkin, 1997). Lallement *et al.* (1991) observed a 78% increase in extracellular Glu levels in the CA3 region of the hippocampus within 30 min of seizure onset in soman-treated rats. In the hippocampal CA1 region, they observed a 180% increase in extracellular Glu levels within 50 min of seizure onset. Sparenborg *et al.* (1992) found that post-treatment with MK-801 (30, 100, or 300 μg/kg, i.m.) following soman administration arrested seizure activity in a dose-dependent manner suggesting that NMDA receptor activation may play a critical role in the spread and maintenance of nerve agent-induced seizures. Given that excitotoxicity is also induced by decreasing the amount of oxygen-derived energy available to sustain cellular maintenance, it seems likely that the glutamatergic effects of nerve agents are exacerbated by their indirect actions on the respiratory control center and on peripheral neuromuscular sites involved in ventilation. Oxidative phosphorylation would also be interrupted by anoxia and hypoxia associated with nerve agent-induced seizures, and excessive bronchial secretions may interrupt airflow and contribute to cyanosis.

Thus, the OP nerve agents illustrate an example of neurotoxicity in which a specific (cholinergic) neurotransmitter system is initially affected to disrupt neuronal function. As opposed to botulinum toxins that block cholinergic neurotransmission, the OP nerve agents enhance cholinergic signaling by disrupting ACh degradation. These actions can be life-threatening and can involve disruption in the cholinergic regulation of higher functions (e.g. cognition), ventilation, cardiac function, and somatic motor and autonomic functions. Persistent neurological sequelae may result from acute intoxications. While generally thought to be at least initially selective for cholinergic neurotransmission, noncholinesterase actions and other neurotransmitter systems may be involved, and oxidative stress may play a role in both acute and persistent toxic consequences.

E. 3-Quinuclidinyl Benzilate (QNB)

QNB (1-azabicyclo[2.2.2]oct-3-yl hydroxy(diphenyl)acetate; BZ) is a potent, atropine-like glycolic acid ester that blocks muscarinic receptors in the CNS and PNS (Spencer, 2000). During the 1950s QNB was explored by both the USA and the Soviet Union as a potential antidote for OP anti-ChEs. However, the marked hallucinogenic actions of QNB led to its potential use as a CWA (Marshall, 1979). In July 1995 the Yugoslav People's Army allegedly used an incapacitating agent that caused hallucinations and irrational behavior against Bosnian refugees fleeing from the town of Srebrenica (Hay, 1998). While many believe that this incapacitating agent was QNB, there is no hard evidence to support this allegation.

QNB acts as a potent, competitive inhibitor of ACh at muscarinic receptor sites located in brain, autonomic ganglia, exocrine glands, and smooth muscles, resulting in a confusional state with delusions, a decrease in intestinal motility and tone, inhibition of bronchial and salivary secretions and sweating, erratic behavior, hallucinations, mental slowing, mydriasis, and tachycardia (Ketchum, 1963). Early studies demonstrated that QNB was a potent and selective ligand for muscarinic receptors. Yamamura and Snyder (1974) showed that the inhibition of [^{3}H]-QNB binding to homogenates of rat brain by muscarinic drugs correlated with their pharmacological potencies, whereas nicotinic and noncholinergic drugs had negligible affinity. Kuhar and Yamamura (1976) reported that the injection of [^{3}H-]QNB into rat brain led to its localization to muscarinic receptors in the cerebral cortex, hippocampus, nucleus accumbens, and striatum. In addition, Jovic and Zupanc (1973) reported that the subcutaneous administration of QNB (5–20 mg/kg) to rats decreased oxygen consumption in the cerebral cortex and medulla oblongata. Interestingly, while QNB as a radioligand appears to bind to all known subtypes of muscarinic receptors, some evidence suggests that it has selectivity for the M2 subtype of muscarinic receptors when administered *in vivo* (McRee *et al.*, 1995). QNB thus can produce a variety of neurological effects presumably through the antagonism of cholinergic muscarinic receptor signaling in the CNS and PNS.

IX. CONCLUDING REMARKS AND FUTURE DIRECTION

The nervous system has a number of biochemical and structural characteristics that can make it particularly sensitive to CWAs. Indeed, many of the different types of CWAs can elicit neurotoxic responses. In some cases, these neurotoxic effects are elicited by direct interaction with specific target molecules within the nervous system, while in other cases the target is less specific but the tissue itself is more sensitive, and in yet other cases actions on other organ systems can lead to indirect impairment of neurologic function. The global importance of the continuous neuronal regulation of vital processes throughout the body makes the nervous system an effective target for disruption by CWAs. Thus, knowledge of mechanisms of neurotoxicity for CWAs can aid in understanding how to counteract such adverse neurological effects.

CHAPTER 33

Behavioral Toxicity of Nerve Agents

JIRI KASSA, JIRI BAJGAR, KAMIL KUCA, AND DANIEL JUN

I. INTRODUCTION

Behavioral changes in humans exposed to highly toxic organophosphorus compounds, called nerve agents, have been discussed in numerous reports. The incidence of behavioral effects is higher in individuals who have been severely exposed to nerve agents, but they may occur in individuals who have received a small exposure and have no or minimal physical signs and symptoms. The behavioral effects usually start within a few hours and last from several days to several weeks or months. The most frequent symptoms include feelings of uneasiness, tenseness, and fatigue. Exposed individuals may be forgetful and generally display impaired memory and learning, poor comprehension, decreased ability to communicate, or occasional mild confusion.

There are a few reports describing behavioral changes in subjects accidentally exposed to nerve agents. They reported sleep disturbance, mood changes, fatigue, jitteriness or tenseness, an inability to read with comprehension, difficulties with thinking and expression, forgetfulness, a feeling of being mentally slowed, depression, irritability, giddiness, poor performance in arithmetic tests, minor difficulties in orientation, and frightening dreams. It was observed that the complex of central nervous system (CNS) symptoms may not fully develop until 24 h after exposure. In addition, no correlations between the presence or severity of symptoms and the degree of acetylcholinesterase inhibition were seen. Most of the effects of exposure disappear within 3 days. It was concluded that not only severe but also mild intoxication of nerve agents may cause behavioral and psychological disturbances. In general, the behavioral effects have not been permanent but have lasted from weeks to several months, or possibly several years. Long-term behavioral effects after poisoning with nerve agents or organophosphorus insecticides have been reported (Karczmar, 1984; Levin and Rodnitzki, 1976; Sidell, 1974). These reports are based on clinical observations, which are occasionally supported by psychological studies.

II. THE METHODS USED TO EVALUATE BEHAVIORAL EFFECTS OF NERVE AGENTS

A. Functional Observatory Battery

The functional observatory battery (FOB) is a noninvasive and relatively sensitive type of neurobehavioral examination of 40 sensory, motor, and automatic nervous functions. Some of them are scored (Table 33.1), and the others are measured in absolute units (Frantik and Hornychova, 1995; Slechta, 1989). The first evaluation is made when nerve agent-exposed or control rats are in the home cage. The observer evaluates each animal's posture, palpebral closure and gait, and the presence or absence of convulsions is noted. Each rat is then removed from the home cage and briefly held in the hand. The presence or absence of spontaneous vocalization, piloerection, and other fur and skin abnormalities as well as irritability is noted. Lacrimation and salivation are also observed. Other signs such as exophthalmus, crustiness around the eyes, or emaciation are recorded too. The rats are then placed on a flat surface which serves as an open field. A timer is started for 3 min during which the frequency of rearing responses is recorded. At the same time, gait characteristics are noted and ranked, and activity, tremor, convulsions, and abnormal posture are evaluated. At the end of the third minute, the number of fecal boluses and urine pools on the absorbent pad is registered. Then, a reflex test that consists of recording each rat's response to the frontal approach of the blunt end of a pen, a touch of the pen to the posterior flank, and an auditory click stimulus is used. The responsiveness to a pinch on the tail and the ability of pupils to constrict in response to light are then assessed. These measurements are followed by a test for the aerial righting reflex, then by the measurements of forelimb and hindlimb grip strength, body weight, rectal temperature, and finally hindlimb landing foot splay. The whole battery of tests requires approximately 6–8 min per rat. Motor activity data are collected using an apparatus for testing

TABLE 33.1. Functional observational battery (FOB)

	Scored values only									
Marker	**−2**	**−1**	**0**	**1**	**2**	**3**	**4**	**5**	**6**	**7**
Posture				Sitting or standing	*Rearing*	*Asleep*	Flattened	Lying on side	Crouched over	Head bobbing
Catch difficulty				Passive	*Normal*	Defense	Flight	Escape	Aggression	
Ease of handling				Very easy	Easy	Moderately difficult	Difficult			
Muscular tonus	Atonia	Hypotonia	*Normal*	Hypertonia	Rigidity	Fasciculations				
Lacrimation			*None*	Slight	Severe	Crusta	Colored crusta			
Palpebral closure				*Open*	Slightly	Half-way	Completely shut	Ptosis		
Endoexophthalmus		Endo	*Normal*	Exo						
Piloerection			*No*	Yes						
Skin abnormalities			*Normal*	Pale	Erythema	Cyanosis	Pigmented	Cold	Injury	
Salivation			*None*	Slight	Severe					
Nose secretion			*None*	Slight	Severe	Colored				
Clonic movements			*Normal*	Repetitive	Nonrhythmic	Mild tremors	Severe tremors	Myoclonic	Clonic	
Tonic movements			*Normal*	Contraction of extensors	Opisthotonus	Emprosthotonus	Explosive jumps	Tonic convulsions		
Gait			*Normal*	Ataxia	Overcompensation of hindlimb movement	Feet point outwards from body	Forelimbs are extended	Walks on tiptoes	Hunched body	Body is flattened against surface

Gait score			*Normal*	Slightly impaired	Somewhat impaired	Totally impaired		
Mobility score			*Normal*	Slightly impaired	Somewhat impaired	Totally impaired		
Arousal (level of unprovoked activity)			Very low	Sporadic	Reduced	*Normal*	Enhanced	Permanent
Tension		*None*	Partial (ears)	Stupor				
Stereotypy		*None*	Head weaving	Body weaving	Grooming	Circling	Others	
Bizarre behavior		*None*	Head	Body	Self-mutilation	Abnormal movements	Others	
Approach response			No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction	
Touch response			No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction	
Click response			No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction	
Tail-pinch response			No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction	
Pupil size	Miosis	*Normal*	Mydriasis					
Pupil response		No reaction	*Normal reaction*					
Righting reflex			*Normal*	Slightly uncoordinated	Lands on side	Lands on back		

a spontaneous motor activity of laboratory animals. The animals are placed for a short period (10 min) in the measuring cage and their movement (total horizontal activity, stereotypical activity, rearing, jumping, scratching, and total vertical activity) is recorded.

B. Performance on the RAM Task

RAM sessions are conducted using an eight-arm commercially available radial maze measuring 137.2 cm in diameter. The center of the maze is a plastic octagon hub measuring 26.67 cm across, with a Plexiglass lid and wire grid floor. A Plexiglass arm with a wire mesh floor is attached to each of the eight sides of the hub. The entrance to each arm contains a motorized guillotine door allowing access to and from the hub. Each arm's runway contains two floor-mounted switches, which are depressed by the weight of the rat when present in the proximal and distal portion of the runway, respectively. The terminal portion of each arm contains a food dispenser, for delivering food pellets, connected to a trough that is outfitted with the photoemitter/detector unit that can detect access by the rats. Experiments are controlled and monitored using a commercial hardware interface and a microcomputer using the L2T2S software control system (Coulbourn Instruments). For the RAM task, four of eight arms are ''baited''. That is, a single food pellet is available upon a nose-poke into the food trough at the terminal portion of four arms. Each rat is randomly assigned a maze configuration of four baited arms from 37 possible configurations which excludes more than two consecutive baited arms. Thus, the same configuration of baited arms is used for a particular rat for each of the sessions, but different configurations can be used for different rats. Sessions begin with the rat placed in the center hub compartment and the doors to the eight arms are raised. The rat is then free to explore the maze to obtain the food rewards available from the four baited arms. The session is terminated when a rat obtains all four food rewards or 15 min have elapsed. If a rat does not complete the maze within 15 min, a completion time of 15 min is assigned and errors are analyzed. Failure to complete the maze, however, is infrequent and only occurs during the initial few sessions on the maze. No familiarity training with the maze is conducted prior to the first session. The major dependent variables characterizing performance on the RAM task are the time to complete the maze and the number of errors made. Errors are designated as occurring when a rat chooses an unbaited arm (reference memory error) or when a rat returns to a baited arm after obtaining the food reward (working memory error) (Genovese *et al.*, 2006).

C. Acoustic Startle Response and Pre-pulse Inhibition

The animals are tested for acoustic startle response (ASR) and pre-pulse inhibition (PPI) in the SM100 Startle Monitor system. The system is usually programmed for six types of white-noise burst stimulus trials: no stimulus (background, 60 dB), pre-pulse (70 dB), pulse (100 dB and 120 dB), pre-pulse plus pulse (70 dB + 100 dB and 70 dB + 120 dB). Each trial type is presented ten times in ten blocks. Stimuli are presented in random order to avoid order effects and habituation. The inter-trial interval can vary from 9 to 16 s. All animals are regularly handled before individual tests in order to minimize handling-related stress. Animals are pair matched according to baseline values into the experimental groups using the average of the response to 100 dB and 120 dB. The tested animals are restrained loosely in holders that are placed on a sensing plate transforming movements of the body (jerks) into an analog signal through an interface. Finally, the percentage pre-pulse inhibition measures are calculated as the difference between the pulse alone and multiplied by 100. Percentage scores are typically used to minimize the effect of individual variation of startle amplitude on pre-pulse inhibition (Mach *et al.*, 2008).

D. Performance on Y-Maze

Cognitive functioning can be tested using a Y-maze with averse motivation by a strong electric footshock, evaluating learning and spatial memory (Koupilova *et al.*, 1995). The Y-maze is a fully automated apparatus used for the study of behavior of laboratory rats. It is a plastic box consisting of a square start area (285 × 480 mm) separated by a Plexiglass sliding door from two trapezoid, black and white arms – choice area (140 × 324 mm). The grid-floor in the start and choice area is electrifiable. The animal (usually rat) is placed on the start area and after 48 s electric footshocks (60 V, 50 Hz, duration 0.5 s) are applied at 5 s intervals. The rats try to avoid the shock by escaping to one of two arms. In the case of a rat moving to the wrong (dark) arm, the rat fails to avoid further footshock. The animals are taught spatial discrimination with the preference of the black or white arm in the Y-maze. The latency to enter the correct arm is measured and the number of wrong entries is counted. Before exposure to nerve agent, the rats are trained to avoid footshock by moving to the correct (white) arm in the Y-maze. It usually takes 4 weeks of training to reach the criterion which was 80% or more correct averse behavior (moving to the correct arm) within less than 1.5 s. During the training, ten sessions (two trials/session) per week lasting 4 min are realized. The exposure starts the day after the animals reached this criterion. The latency time to enter the correct arm by nerve agent-exposed rats and the number of entry errors are compared to the values obtained from the control rats exposed to the pure air instead of nerve agent.

E. Performance on T-Maze

Cognitive functioning can be also tested using a T-maze, consisting of five segments, a starting and a goal compartment

to evaluate learning, spatial memory and spatial orientation (Koupilova and Herink, 1995). The rats are trained, with the food reward, to run through the maze in less than 10 s without entering the side arm. The time necessary to reach the goal box is recorded. Before exposure to nerve agent, the rats are trained to reach the goal box as soon as possible by moving to the correct segment in the T-maze. It usually takes 4–6 weeks of training to reach the criterion which was 80% or more correct behavior. The exposure starts the day after the animals reached this criterion. The time of reaching the goal box by nerve agent-exposed rats is compared to the values obtained from the same rats immediately before nerve agent exposure and from control rats exposed to pure air instead of nerve agent.

F. Performance on Morris Water Maze

The water maze is often used for the evaluation of effects of various compounds on memory functions, i.e. memory formation, consolidation and retrieval effects due to its advantages and broad utilization. The Morris water maze (WM) is a widely used measurement of visuospatial learning that has been demonstrated to have high validity in identifying cognitive effects of various brain lesions and the effects of drugs used to treat cognitive deficits (Morris, 1984; Myhrer, 2003). Special motivation such as food and water deprivation is not required for the WM performance. The effect of odor cue is eliminated in the WM. In addition, rats are forced to swim in the WM. They cannot choose whether or not to move, so failure to respond is not a confound (Shukitt-Hale *et al.*, 2004). The place learning version with submerged platform can be used for working memory tests (Myhrer, 2003). The WM can be used to measure spatial learning and memory in the case of the evaluation of cognitive impairment in rats because of mentioned advantages.

The rats perform cognitive tasks that require spatial learning and memory – the ability to acquire a cognitive representation of location in space and the ability to effectively navigate the environment in the WM (Shukitt-Hale *et al.*, 2004). Memory alterations appear to occur mostly in secondary memory systems and are reflected in the storage of newly acquired information (Bartus *et al.*, 1989; Joseph, 1992). It is thought that hippocampus mediates allocentric spatial navigation (i.e. place learning) and prefrontal cortex is critical to acquiring the rules that govern performance in particular tasks (i.e. procedural knowledge), while the dorsomedial striatum mediates egocentric spatial orientation (i.e. response and cue learning) (McDonald and White, 1994; Oliviera *et al.*, 1997).

The water maze consists of a black circular pool (180 cm diameter × 80 cm high) filled to a depth of 25 cm with water of room temperature (Raveh *et al.*, 2002). The pool is imaginarily divided into four same compartments numbered 1–4 clockwise. The black antireflective circular escape platform (15 cm diameter) is placed into compartment no. 1 or 4, 20 cm off the pool wall. The platform is sunk 2 cm below water surface, so it is not visible from the rats' view owing to the water mirror effect. The yellow rectangle (30 cm × 40 cm) is fixed on the pool wall, immediately close to the platform, as the spatial conditional cue (Robinson *et al.*, 2004). Its place is variable according to the platform. Another dark rectangle is randomly fixed on the pool wall in different compartments (without platform) as the negative conditional cue. Round the pool, there are several stable extramaze cues in the room that the rat could use to navigate the maze (Morris, 1984). However, the impact of extramaze cues is not significant due to high maze walls.

III. LONG-TERM BEHAVIORAL EFFECTS OF ACUTE HIGH-LEVEL EXPOSURE TO NERVE AGENTS

Much of the data regarding long-term neurological sequelae to exposures to cholinesterase inhibitors in humans have been gathered following accidental exposures to organophosphorus (OP) compounds (pesticides as well as nerve agents). Nevertheless, the extrapolation from these exposures to prediction of effects from nerve agent is difficult because:

- the cholinergic crisis caused by acute, severe intoxication with the OP pesticides is generally much longer than that caused by OP nerve agents
- OP pesticides-induced delayed peripheral neuropathy can be caused by nerve agents only at doses many times greater than the LD_{50} (Davis *et al.*, 1960)
- a delayed manifestation of OP poisoning has not been described after administration of nerve agents to animals or in the instances of nerve agent poisoning in humans (Sidell, 1997).

There have been descriptions of the acute effects in humans that follow high-dose exposure ($\geq LD_{50}$) to nerve agents soman, sarin, and VX (Inoue, 1995; Nakajima *et al.*, 1997; Nozaki *et al.*, 1995; Sidell, 1974). The similar cluster of behavioral symptoms (anxiety, psychomotor depression, intellectual impairment, and sleep disturbance) was observed in the immediate period following resolution of the acute signs of intoxication and then slowly faded with time, sometimes taking months to be fully resolved. The CNS symptoms noted following short-term exposure of humans to diisopropyl fluorophosphate (DFP) were excessive dreaming, insomnia, jitteriness and restlessness, increased tension, emotional lability, subjective tremulousness, nightmares, giddiness, drowsiness, and mental confusion. CNS symptoms were correlated with the depression of red blood cell acetylcholinesterase (AChE; EC 3.1.1.7) to 70 and 60% of original activity and they disappeared within 1 to 4 days (Grob *et al.*, 1947). It was also noted that more severely exposed individuals and those with multiple exposures tended to display persistent symptoms that included forgetfulness, irritability, and confused

thinking, although the duration of these persistent symptoms was never clearly defined (Holmes and Gaon, 1956). These CNS symptoms are virtually identical to those that have been reported to occur following high-level exposure to nerve agents. It was shown in the study of human sarin poisoning that sarin-induced behavioral effects were virtually identical to those reported for DFP. These effects coincided with the depression of plasma ChE and red blood cell AChE activity to approximately 60 and 50% of original activity (Grob and Harvey, 1958). The behavioral symptoms such as anxiety, psychomotor depression, a general intellectual impairment consisting of difficulties in concentration and retention, and sleep impairment generally involving insomnia due to excessive dreaming were also described during human poisoning with nerve agent VX (Bowers *et al.*, 1976).

The exposure to high doses of OP compounds including nerve agents has been demonstrated to result in severe brain neuropathology that involves not only neuronal degeneration and necrosis of various brain regions (Lemercier *et al.*, 1983; McLeod *et al.*, 1982; Petras, 1981) but also persistent severe alteration in behavior and cognitive incapacitation especially impairments of learning and memory (Bushnell *et al.*, 1991; McDonald *et al.*, 1988). The most significant injury caused by OP poisoning is neuronal degeneration of the hippocampus that is associated with spatial learning and memory. Therefore, impairment of cognitive functions, especially incapacitation of learning and memory, belongs to the most frequent central signs of acute OP poisoning (Marrs, 1993; McDonald *et al.*, 1988). In addition, the adverse effects of OP compounds on cognition functions, such as learning and memory, may persist for quite some time after termination of toxicant exposure. The results from several studies have demonstrated the presence of OP compounds-induced learning impairments several days after the classic signs of OP toxicity have subsided (Buccafusco *et al.*, 1990; Bushnell *et al.*, 1991; McDonald *et al.*, 1988). Behavioral effects are typically evident before the occurrence of physical symptoms. These effects were associated with whole blood ChE inhibitions of >60%.

Several studies of the long-term effects of the sarin exposure victims from Japan have been published. Exposure to nerve agents in humans was found to produce effects that include cognitive deficits and memory loss (Hatta *et al.*, 1996; Hood, 2001; Okudera, 2002). Eighteen victims of the Tokyo subway incident were evaluated at 6 to 8 months after exposure (Yokoyama *et al.*, 1998). Sarin-exposed individuals scored significantly lower than controls on a digit symbol substitution test, and scored significantly higher than controls on a general health questionnaire (GHQ, psychiatric symptoms) and a profile of mood states (POMS, fatigue). The elevated scores on the GHQ and POMS were positively related to the increased PTSD (post-traumatic stress disorder) scores and were considered to be due to PTSD (Yokoyama *et al.*, 1998). There have been two brief reports of severely poisoned nerve agent victims (one sarin and one VX) in Japan who experienced retrograde amnesia, possibly due to prolonged periods of seizures and/or hypoxia (Hatta *et al.*, 1996; Nozaki *et al.*, 1995). Symptoms related to sarin exposure in Japan still exist 1–3 years after the incident and include fatigue, asthenia, shoulder stiffness, and blurred vision (Abu-Qare and Abou-Donia, 2002).

The existence of long-term behavioral effects following acute exposure to high doses of nerve agents was many times verified with the help of laboratory experiments on animals. There are numerous studies in animals showing that survivors of high-level OP exposure can experience subtle but significant long-term neurological and neuropsychological outcomes that are detectable months or even years following the recovery from acute poisoning (Brown and Kelley, 1998). Exposure of animals to nerve agents was shown to produce neurotoxicity in the CNS areas associated with cognition and memory functions (Koplovitz *et al.*, 1992; Petras, 1994). There are a few studies that revealed changes in the brain following sublethal nerve agent exposure that involve not only the cholinergic system but also the glutamatergic system (Lallement *et al.*, 1992; McDonough and Shih, 1997). Excitotoxic injury caused by increased levels of glutamate has repeatedly been shown to cause cognitive dysfunction (O'Dell *et al.*, 2000). Therefore, the disruption of cognitive functions, especially spatial and working memory, seems to be the most frequent and the most observable behavioral effect of nerve agent poisoning. The studies show changes in the brain following sublethal nerve agent exposure that lead to memory and attention deficits that normally involve the hippocampus (Hatta *et al.*, 1996; Miyaki *et al.*, 2005; Nishikawi *et al.*, 2001). The role of hippocampus in complex visuospatial learning and memory has been well established. The high concentration of NMDA and AMPA glutamate receptors, which play a key role in hippocampal-mediated learning and memory, also makes the hippocampus highly vulnerable to glutamate-induced excitotoxic injury from nerve agent poisoning (Filliat *et al.*, 2007; Lallement *et al.*, 1992; Shih *et al.*, 1990).

Following a high-dose exposure (above 0.5 LD_{50}) seizures are a prominent sign of nerve agent intoxication and these prolonged seizures can produce neural lesions (McDonough and Shih, 1997). Thus, neurological and behavioral deficits are predictable long-term effects following exposure to such doses of nerve agents. Animals exposed to high (convulsive) doses of nerve agent can develop spontaneous seizures, and display hyperactive and aggressive behavior and profound deficits in learning and/or performance of a variety of behavioral tasks. Animal studies have demonstrated deficits in acquisition of several types of operant tasks, performance of serial probe recognition task, maze learning, and passive avoidance learning following acute poisoning with nerve agents (McDonough *et al.*, 1986; Modrow and Jaax, 1989; Raffaele *et al.*, 1987).

The inhalation exposure to high-level sarin induced in rats impaired memory processes seen at 1 month post-exposure

with no recovery of cognitive function during the 6 month follow-up period. In the open field, sarin-exposed rats showed a significant increase in overall activity with no habituation over days. In a working memory paradigm in the water maze, the same rats showed impaired working and reference memory processes with no recovery. These data suggest long lasting impairment of brain functions in surviving rats following a single sarin exposure. Animals that seem to fully recover from the exposure, and even animals that initially show no toxicity signs, develop some adverse neurobehavioral changes with time (Grauer *et al.*, 2008). These findings are in accord with reports on long-term behavioral impairment following exposure to OP pesticides used in agriculture (Wesseling *et al.*, 2002). Similarly, long-term follow-up of victims of the sarin attacks in Japan demonstrated neurological as well as emotional and cognitive changes up to 7 years post-exposure (Miyaki *et al.*, 2005; Ohbu *et al.*, 1997; Yokoyama *et al.*, 1998).

Generally, according to high-dose exposure studies, animals exposed to nerve agents that exhibit seizures that are not promptly controlled develop brain damage and subsequent neurobehavioral problems. Animals that do not develop seizures or those that are rapidly and effectively treated with drugs that stop the seizures suffer no brain lesion and display no long-term neurobehavioral deficits.

IV. CHRONIC BEHAVIORAL EFFECTS OF SINGLE OR REPEATED LOW-LEVEL EXPOSURE TO NERVE AGENTS

Anticholinesterase compounds such as nerve agents can alter behavioral functions even after small subtoxic doses. There are very few data on human exposures. Based on the data describing the signs and symptoms in accidentally exposed humans, some long-term health effects, including behavioral effects of repeated subclinical exposures to OP compounds, were observed (Wesseling *et al.*, 2002). When the workers were exposed to small amounts of nerve agents they showed mild toxic signs of exposure including CNS effects such as insomnia, excessive dreaming, restlessness, drowsiness, and weakness (Craig and Freeman, 1953). It was shown that psychological symptoms are probably more common than usually recognized and may persist in more subtle forms for much longer (days, weeks) than physical symptoms (Sidell and Hurst, 1997). Recently, a dose–response association was found between low-dose exposure to sarin and cyclosarin inhalation during the 1991 Gulf War and impaired neurobehavioral functioning as well as subtle CNS pathology as revealed by MRI study (Heaton *et al.*, 2007; Proctor *et al.*, 2006). It is interesting that functional impairments were detected even in people who initially developed only mild or no signs of sarin or cyclosarin toxicity. These data correspond to the published epidemiological studies showing alterations in cognitive functions, impaired memory, and concentrations in humans after chronic low-dosage occupational exposure to OP insecticides (Parrón *et al.*, 1996; Stephens *et al.*, 1995). Increased reported forgetfulness and difficulties in thinking, exposure-related increases in work-related tension, sleep disturbance, restlessness, and nervousness have been documented among sheep farmers exposed to OP pesticides (Beach *et al.*, 1996; Stephens *et al.* 1995).

Based on the experimental animal data, the progression of signs, their neuropharmacological basis, and toxic consequence elicited from acute high-dose exposures have been well characterized (McDonough and Shih, 1993; Shih *et al.*, 2003). However, much less is known about the long-term effects of repeated low-dose nerve agent exposure. Several comprehensive reviews on the long-term health effects of exposure to low-level nerve agent exposure have been published (Moore 1998; Romano *et al.*, 2001).

It is known that a significant, clinically manifested AChE inhibition in the central nervous system leading to the neuronal degeneration of some brain regions including the hippocampus, associated with spatial learning and memory, is not necessary for clinically manifested cognitive impairments. This fact corresponds with earlier published data about neurological and neurophysiological outcomes detectable months or even years following recovery from acute OP poisoning (Savage *et al.*, 1988; Yokoyama *et al.*, 1998). It is very difficult to find the real reason for the memory impairments in the case of low-level nerve agent exposure. Recently, a temporal relationship has been demonstrated between OP-induced impairment in performance of a spatial memory task and the protracted decrease in the expression of cholinergic receptors in specific brain regions (including the hippocampus) following the asymptomatic exposure to OP compounds (Stone *et al.*, 2000). Nerve agent-induced impairment of cognitive functions is probably caused by subsequent desensitization and internalization of cholinergic receptors as a reaction of nerve agent-exposed organisms on hyperstimulation of cholinergic receptors, especially in parts of the brain with a high density of cholinergic synapses such as the hippocampus (McDonald *et al.*, 1988; Stone *et al.*, 2000). This means that a decrease in the number of cholinergic receptors in the hippocampus following low-level exposure to OPs without significant AChE inhibition could cause memory impairments.

In the available literature on repeated low-dose exposure to nerve agents, soman is the nerve agent studied most often. Mice, rats, guinea pigs, and primates were used to investigate repeated low-dose soman exposure. The effects of repeated soman exposures ranged from performance decrements on a well-learned compensatory tracking task (Blick *et al.*, 1994b) to development of attention deficits (Gause *et al.*, 1985) and hyperreactive responses to handling (Shih *et al.*, 1990). Unlike soman, the amount of literature regarding the effects of repeated low-level exposure to sarin is rather sparse and sometimes conflicting. Rhesus monkeys exposed to low levels of intramuscular sarin showed no signs of adverse health or long-term

behavioral effects (Burchfiel *et al.*, 1976). In contrast, it has been observed in rats and mice that intraperitoneal injections of subtoxic doses of sarin or soman decreased locomotor activity, altered behavior on the plus-maze and elevated horizontal bridge tests (Baille *et al.*, 2001; Nieminen *et al.*, 1990; Sirkka *et al.*, 1990). It was also shown that repeated low-level sarin inhalation in rats at clinically asymptomatic doses was disruptive to neurophysiological function and caused long-term memory impairments (Kassa *et al.*, 2001a, b).

The results of the study related to the measurement of sarin-induced alteration of behavioral and neurophysiological functions at 3 months following low-level sarin inhalation exposure of rats showed a significant alteration of mobile activity and gait characterized by ataxia and an increase in stereotypical behavior. These signs were observed in rats repeatedly exposed to sarin at clinically asymptomatic doses or singly exposed to sarin at doses causing mild muscarinic signs of exposure. These animals had awkward hindlimbs and their mobility was markedly diminished (Kassa *et al.*, 2001d). Spatial discrimination in the Y-maze was also altered in rats exposed to low levels of sarin. While spatial orientation of rats singly exposed to clinically asymptomatic doses of sarin was significantly influenced for a short time only (1 or 2 h following exposure), the rats repeatedly exposed to clinically asymptomatic doses of sarin showed a decrease in Y-maze performance for a relatively long time (until the third week following the exposure) (Kassa *et al.*, 2004). The significant impairment of spatial memory of rats exposed to clinically asymptomatic concentrations of sarin was also observed when cognitive functions were evaluated with the help of T-maze performance. Rats exposed to low-level sarin showed a significant decrease in T-maze performance for a short time (until the first day following the exposure). In addition, the effects of low-level sarin inhalation exposure were dose dependent. When the rats were exposed to low-level sarin causing moderate signs of poisoning, their time of passage through the maze was more lengthened at 1 and 2 h following the inhalation exposure compared to the rats exposed to clinically asymptomatic levels of sarin (Kassa *et al.*, 2001c).

A single exposure to another nerve agent, cyclosarin, at concentrations that do not produce convulsions or severe clinical signs of toxicity can also produce performance deficits on learned behavioral tasks. However, with repeated exposure, the deficits are not persistent and recovery is complete. In addition, exposure concentrations not producing any evaluated clinical signs of toxicity, other than temporary miosis (in the case of inhalation exposure), do not produce performance deficits on the behavioral tasks (Genovese *et al.*, 2006).

Reports in the literature of animal studies show that nerve agents can be administered repeatedly with minimal overt neurobehavioral effects if care is taken in choosing the dose and the time between doses (Sterri *et al.*, 1980, 1981). The repeated low-level nerve agent exposure made the cognitive impairments longer and higher compared to the single nerve agent exposure. The repeated exposure to low doses of soman can produce small, transient performance decrements only, probably due to the development of a physiological and behavioral tolerance to low levels of ChE activity (Blick *et al.*, 1994a, b). Nevertheless, a progressive and long-lasting inhibition of ChE in CNS following repeated administration of low doses of nerve agent soman was demonstrated (Hartgraves and Murphy, 1992). This study was corroborated by Olson using nerve agent sarin (Olson *et al.*, 2000). Generally, repeated or long-term exposure to low levels of nerve agents can cause neurophysiological and behavioral alterations (Abu-Quare and Abou-Donia, 2002).

The rats repeatedly exposed to sarin at doses corresponding to $0.5 \times LD_{50}$ (three times per week, s.c.) showed an increase in acoustic startle and a decrease in distance explored in the open field 2 weeks after sarin exposure. On the other hand, no effect of sarin exposure on passive avoidance was noted at the same time after sarin poisoning. Brain regional AChE was not affected at any time after sarin exposure, but muscarinic receptors were down-regulated in the hippocampus, caudate putamen, and mesencephalon in the sarin group at 2 weeks after sarin exposure. Thus, down-regulation of muscarinic receptors in the hippocampus as a reaction to acetylcholine accumulation at muscarinic receptor sites based on AChE inhibition can be considered a cause of behavior performance deficits, especially disruption of cognitive functions (Scremin *et al.*, 2003). In addition, protracted impairment of cognitive functions in rats exposed repeatedly to low-level organophosphorus compounds may be associated with a decreased rate of AChE recovery in the hippocampus (Prendergast *et al.*, 1997).

The results from several studies have demonstrated the presence of OP-induced learning impairments several days after the behavioral signs of OP toxicity have subsided (Bushnell *et al.*, 1991, McDonald *et al.*, 1988). Chronic exposure to OP compounds can also result in specific long-term cognitive deficits even when signs and symptoms of excessive cholinergic activity are not present (Prendergast *et al.*, 1998). Thus, the significant, clinically manifested AChE inhibition in the CNS leading to the neuronal degeneration of some brain regions including the hippocampus is not necessary for the clinically manifested cognitive impairments. This conclusion corresponds with earlier published data about neurological and neurophysiological outcomes detectable months or even years following recovery from acute OP poisoning (Savage *et al.*, 1988; Yokoyama *et al.*, 1998). A current study attempts to show a temporal relationship between OP-induced impairment in performance of a spatial memory task and the protracted decrease in the expression of cholinergic receptors in specific brain regions caused by asymptomatic exposure to an OP compound (Stone *et al.*, 2000). In addition, low-level

OP-induced memory impairment may be associated with a decreased AChE recovery in the hippocampus relative to the cortex. This decreased rate of enzyme recovery may contribute to hippocampal toxicity undelying protracted impairment of working memory and other cognitive functions (Prendergast *et al.*, 1997).

Repeated or chronic low-level nerve agent exposure can cause a prolonged inhibition of extracellular AChE leading to a prolonged increase in extracellular acetylcholine (ACh). The prolonged availability of ACh in the synaptic clefts results in feedback inhibition on muscarinic, presynaptic receptors to decrease further ACh release (Russell *et al.*, 1985). The greater ACh release in the nerve agent-exposed group may be due to the known down-regulation of muscarinic receptors in response to chronic nerve agent exposure (Churchill *et al.*, 1984). Neurochemical analyses showed that the normal brain neurotransmitter and receptor homeostasis is disrupted even at 10–12 days after 2 weeks of chronic nerve agent exposure at least in the striatum but probably throughout the whole cholinergic system in the brain (Shih *et al.*, 2006).

V. CONCLUDING REMARKS AND FUTURE DIRECTION

Exposure to high doses of nerve agents has been demonstrated to result in severe brain neuropathology that involves not only neuronal degeneration and necrosis of various brain regions but also persistent severe alterations in behavior and cognitive functions, especially impairment of learning and memory. The most significant injury caused by nerve agent poisoning is neuronal degeneration of the hippocampus which is associated with spatial learning and memory. Therefore, impairment of cognitive functions, especially incapacitation of learning and memory, belongs to the most frequent central signs of acute nerve agent poisoning. In addition, the adverse effects of nerve agents on cognitive functions, such as learning and memory, may persist for a relatively long time following the termination of nerve agent exposure.

Behavioral alterations and impairments of cognitive functions were found following acute exposure to nerve agents with the absence of any classic signs of cholinergic toxicity. It was shown based on the experimental results that not only convulsive doses but also clinically asymptomatic doses of nerve agents can cause subtle long-term neurophysiological and neurobehavioral dysfunctions. The neurological and neurophysiological outcomes are detectable months or even years following the recovery from acute poisoning. This probably means that systems other than the cholinergic nervous system can be involved in nerve agent-induced long-term signs of alteration of neurological and neurophysiological functions. Thus, it is necessary in the future to find new markers describing noncholinergic outcomes of low-level nerve agent exposure.

The long-term behavioral toxicity of nerve agents, especially the alteration of cognitive functions (T-maze, Y-maze, Morris maze test) due to nerve agent-induced delayed toxicity, seems to be connected with the neuropathological damage observed in the hippocampus. Thus, neuropathology of the hippocampus connected with the alteration of cognitive functions can occur after high-level as well as repeated or long-term low-level nerve agent exposure.

Neurochemical analysis of repeated or low-level nerve agent exposure provokes the suggestion that the prolonged nerve agent-induced alteration in brain chemistry may be a pharmacological basis for neurobehavioral changes. Thus, it is necessary to follow brain homeostasis during acute as well as chronic nerve agent exposure.

Repeated or long-term exposure to low levels of nerve agents can cause neurophysiological and behavioral alterations due to down-regulation of muscarinic receptors in the hippocampus as a reaction to acetylcholine accumulation at muscarinic receptor sites based on AChE inhibition. This phenomenon is considered to be the cause of behavior performance deficits, especially disruption of cognitive functions.

CHAPTER 34

Cardiovascular System as a Target of Chemical Warfare Agents

CSABA K. ZOLTANI

The views and opinions expressed are the author's and do not constitute official views of the US Department of the Army.

I. INTRODUCTION

Upon contact with toxicants, the heart reacts immediately by changes in its electrical homeostasis. Ancillary indicators, i.e. changes in the metabolites in body fluids, are time delayed and initially less useful for diagnosis and for selection of countermeasures. This chapter describes how the heart is affected by and reacts to various chemical warfare agents (Balazs, 1981; Baskin, 1991; Acosta, 2001; Simeonova and Fishbein, 2004). The first section gives an overview of the anatomy and functioning of the heart (Opie, 1998; Murphy and Lloyd, 2007) with emphasis on the constituents most vulnerable to toxic presence. The importance of cardiac neuronal changes as possible indicators of exogenous effects is underscored. The normal electrical state and signature of cardiac toxicity are described. This is followed in detail by the palette of military warfare agents, their modes of action at the cellular level, including description of their expression in the changed morphology of the tissue and modified electrical state (Romano *et al.*, 2008; Ellison, 2008). The effect on the heart of the different poisons is strongly dose related. The references give a good summary of the expected effects of each of the anticipated conditions. Electrocardiograms (ECGs) (Wexler *et al.*, 1947; Holstege *et al.*, 2006; Karki *et al.*, 2004; Delk *et al.*, 2007), illustrating the effect of the toxicants, are given where available. Recommended antidotes for the discussed toxicants are given.

II. BACKGROUND

A. Cardiac Anatomy

The timed delivery of oxygenated blood to all parts of the body is the function of the four-chambered pump, the heart. It is enclosed in a double-layered sac, the pericardium, with the inner layer, the visceral pericardium, anchoring the heart and the outer layer attached to the sternum. A cardiac skeleton anchors the four heart valves and the atria and ventricles. The thick wall separating the two ventricles, the interventricular septum, houses the Purkinje fibers, which play an important part in the electrical activity of the heart (Murphy and Lloyd, 2007).

Deoxygenated blood from the body enters the heart by the vena cavae and empties into the right atrium. Through the tricuspid valve blood then transits into the right ventricle and via the pulmonic valve enters the lungs, where it is oxygenated. It returns to the heart through the pulmonary veins and the atrium to the left ventricle. This muscular pump redistributes the oxygenated blood to all parts of the body.

The heart is mediated by an electrical system that is easily disturbed by toxicants changing the timing, flow, and magnitude of the electrical pulses and thus interfering with the required pumping action. The activity of the heart is myogenic, i.e. the activity is initiated by the heart itself. Various components of the heart, the sinoatrial (SA) node, atrioventricular (AV) node, and the Purkinje fibers are capable of pacemaker activity. Healthy atrial and ventricular tissue does not engage in pacemaker activity. The primary pacemaker is the SA node, but in diseased or affected states the secondary pacemakers take over.

The SA node lies in the right atrium, in an epicardial location and functions as the primary source of the electrical impulse formation. It consists of specialized muscle cells, smaller than ventricular cells containing few contractile elements. Due to its location, the action potential generated traverses the atria first, causing the primary contraction. The action potential is relayed to the AV node, the conduit for the electrification of the ventricles. The signal must pass through the AV node, otherwise the atria and the ventricles are electrically insulated from each other. A time delay in transmission is needed for the atria to be emptied of blood.

The AV node is a subendocardial right atrial construct that is located within a fibrous stroma in the triangle of Koch. It is connected to both sympathetic and parasympathetic nerves. The bundle of His arises from the distal section of the AV node and goes to the summit of the

ventricular septum. It is the only nonpathologic electrical conduction between the ventricles. The bundle of His divides into the left and right bundle branches which then become the Purkinje fibers that interweave the contractile cells of the ventricle and speed the excitation throughout the ventricles.

Action potential of the cardiac myocytes is initiated by inward sodium current in atria and ventricles with inward calcium currents contributing to the upstroke in the SA and AV nodes. Slow inward currents result in lower resting and activation potentials. In the latter, membrane potentials range from −40 to −70 mV and activation threshold lies in the range −30 to −40 mV and shows phase 4 depolarization. These cells are modulated by acetylcholine (ACh) and catecholamine. The duration of the action potential depends on the outgoing potassium current durations with the inward calcium currents of lesser importance. It is longest in the Purkinje fibers. Resting potentials of atrial and ventricular cells range from −80 to −90 mV, with activation thresholds in the −60 to −70 mV range. Impulse conduction ranges up to 300 V/s in atrial and ventricular cells and up to 900 V/s in the Purkinje tissue.

B. Innervation of the Heart

The autonomic nervous system guides the electrical and mechanical functions of the heart. The heart is innervated by both the sympathetic and parasympathetic systems, which have opposite effects and are activated reciprocally. They play important roles in arrhythmia susceptibility. Sympathetic stimulation originates from the intermediolateral column of the thoracic spinal cord. Its neurotransmitter, norepinephrine, is released from neurons of postganglionic fibers of stellate ganglia and epinephrine is released from the adrenal medulla. Both of these act on cardiac β adrenergic receptors. Sympathetic nerves are predominantly on the epicardial surface. Receptors for norepinephrine on cardiac muscle are of the β-adrenergic kind. Postganglionic sympathetic neurons innervate the SA and AV nodes, the conduction system and the myocardial fibers in the ventricles. Epinephrine, an amine, is the primary endogenous catecholamine produced in the adrenal medulla and regulates organic metabolism. It stimulates β_1 receptors, enhances ventricular contractility and enhances SA nodal cell phase 4 depolarization, that is, impulse generation (Lilly, 2003).

The cholinergic, i.e. parasympathetic system, acts through the vagal nerves by release of acetylcholine (ACh) that opposes the sympathetic stimulation. Parasympathetic preganglionic neurons originate in the medulla. Parasympathetic fibers terminate mainly on cells of the atria. Parasympathetic innervation is denser in the SA and AV nodes than the left ventricle. The right vagus nerve innervates the SA node. The neurotransmitter ACh and adenosine promote susceptibility to atrial fibrillation, and shorten atrial refractoriness. Excessive stimulation causes bradyarrhythmia. The left vagus nerve innervates the AV node where excessive stimulation results in AV block. Receptors for ACh are of the M2 muscarinic type and ACh binding to muscarinic receptors inhibits cAMP production. ACh has a negative chronotropic effect (slows heart), slows conduction (negative dromotropic effect), and also has a negative inotropic effect (decreases strength of contraction). The latter is through the activation of the current $I_{K,ACh}$ resulting also in shortening the action potential. ACh has three actions on cardiac muscle: (1) it activates ACh-sensitive K-current, $I_{K,ACh}$, (2) it inhibits the voltage, time-dependent inward calcium current I_{Ca}, and (3) it inhibits the hyperpolarization-activated inward current I_f, important for pacemaking. Ventricular muscle is not affected by vagal stimulation.

There are anatomical physiological differences between the sympathetic and parasympathetic systems. The parasympathetic ganglia lie within or close to the organ that postganglionic nerves innervate, while sympathetic ganglia lie closer to the spinal cord. There is limited parasympathetic innervation of the ventricles compared to the atria. The vagal nerve fibers are mostly intramural. The heightened adrenergic activation in the ventricles is potentially arrhythmogenic.

All catecholamine receptors are metabotropic. They act by initiating metabolic processes affecting cellular functions. β-adrenergic receptors, receptors for epinephrine, and norepinephrine act by stimulatory G proteins to increase cAMP in the post-synaptic cell. cAMP binds to and activates protein-kinase enzyme.

Disturbed balance between the parasympathetic and the sympathetic systems can result in disturbances in cardiac function. As discussed later, chemical warfare agents play an important role in disturbing this balance.

C. Neuropeptides

Vasoactive intestinal peptide (VIP), a neurotransmitter, is found in extrinsic and intrinsic nerves of the heart. VIP is released by the vagal nerve, and its effect is to increase I_f and pacemaker rates (Chang *et al.*, 1994; Accili *et al.*, 1996). VIP release takes place under high-frequency stimulation. As an internal brake, it limits the ability of ACh to excessively suppress the sinus node and other pacemakers. It also has an effect on the calcium-activated potassium channel.

VIP acts as a parasympathetic neurotransmitter in its involvement in the post-synaptic control of the heart. VIP is exactly opposite in its action to that of ACh. Vagal activity, causing release of ACh, slows the heart but co-release of VIP leads to tachycardia due to VIP preferring receptors leading to an increase in adenylate cyclase and accumulation of cAMP.

Neuropeptide Y (NPY) suppresses the pacemaker current I_f. Colocalized with norepinephrine in sympathetic nerve terminals on the heart, it is released with catecholamines during sympathetic neural activation. NPYs on cardiomyocytes have surface membrane binding sites and

suppress contractility in concentrations from 10^{-9} and above. In ventricular myocytes, the L-type Ca^{2+} current, as well as the delayed rectifier potassium currents, are suppressed.

D. Energetics of the Heart

The heart requires a continuous supply of energy to be able to sustain its pumping action. Most of the energy is derived from fatty acids. Under ischemic or anaerobic conditions, glycolysis comes into play consuming large amounts of glucose with the adverse effect of the formation of lactic acid (Jafri *et al.*, 2001).

More than 95% of the metabolic energy is used in the form of adenosine triphosphate (ATP). Its concentration in a myocyte is about 10 mM. ATP is synthesized by oxidative phosphorylation in the mitochondria. There, acetyl CoA is broken down to CO_2 and hydrogen atoms. Electrons are pumped out to form a proton gradient across the mitochondrial membrane. The protons reenter the mitochondria and combine with oxygen, eventually forming water.

The glycolytic pathway under hypoxic conditions produces only a limited amount of ATP. Pyruvate formed in glycolysis is transported into the mitochondria where CO_2 is formed through cellular respiration. From each glucose molecule, 28 ATP molecules are formed in anaerobic glucose metabolism. The heart also has an energy reserve in the form of phosphocreatine (PCr), which is an immediate precursor of ATP. In the reverse Lohman reaction, creatine kinase (CK) favors the maintenance of the ATP concentration at required levels. The energy released during hydrolysis of the phosphoanhydride bond in ATP powers energetically unfavorable processes, such as the transport of molecules against a concentration gradient.

During conditions of hypoxia, ATP is first degraded to adenosine diphosphate (ADP), then to adenosine monophosphate (AMP), and then to adenosine. The latter diffuses into the circulating blood where adenosine concentration rapidly increases under conditions of cellular damage. The action of adenosine is anti-inflammatory as well as inhibitory.

E. Electrophysiology

The sinoatrial node (SA), consisting of spindle-shaped cells, initiates the electrical activity of the heart. From its location in the right atrium in proximity to the superior vena cava, the electrical activity spreads to the atria whose cells are larger than those of the SA. The pulse from the atria spreads to the atrioventricular node (AV), the gateway to the ventricles. The atria and the ventricles are electrically isolated. The AV node also slows down the electrical activity giving the atria time to fill. The bundle of His is the upper end of the electrical path, which through the Purkinje fibers allows the electrical signal to activate the ventricles and thus to pump the blood.

Each cell's activity goes through four phases of the action potential. The morphology of each type of cell is different. Also, the kinds of electrolytes moved, and their quantity and speed are dictated by environmental conditions, detailed in Carmeliet and Vereecke (2002). Xenobiotic interference with the transmission of the ions changes the electrical homeostasis, and commences breakdown in the state of the tissue. The membrane currents, pump, and exchanger of importance in this regard are given in Table 34.1. Anionic chloride currents, especially swelling activated, play an important role in the case of cyanide intoxication (Baumgarten and Clemio, 2003).

III. SIGNATURES OF CARDIAC TOXICITY

A. The Electrocardiogram as Diagnostic Tool for Poisoning

1. Recorded Morphological Changes on the ECG

At present, morphological changes of ECG are insufficient to make a definite diagnosis on the nature of a poisoning. Without access to and comparison with a pre-incident ECG, the deductions may be erroneous. On the other hand, poisons cause definite changes in timing and morphology of the ECG of affected individuals (Delk *et al.*, 2007; Holstege *et al.*, 2006; Gussak *et al.*, 2004; Surawicz, 1995; Surawicz

TABLE 34.1. Membrane currents, pump and exchanger of importance

Current	Function/origin	Effect
I_{Na}	Voltage-gated Na^+ current	Depolarization
I_{K^+}	Voltage-gated K^+ channel	
$I_{Ca^{2+}}$	L-type Ca^{2+} current	
$I_{Cl^-\,swell}$	Activated by cell swelling	Cell swelling
$I_{K,ATP}$	Activated by fall in intracellular ATP	Fall in ATP
I_f	Hyperpolarization-activated current carried by Na^+ and K^+ in sinoatrial and AV node cells and His-Purkinje cells and contributing to phase 4 depolarization	
$I_{K,ACh}$	Parasympathetic control of the heart	ACh
Na^+/K^+-ATPase	Moves Na^+ out, K^+ into cell against concentration gradient using ATP for energy	Stimulated by α, β recap. via PKA, PKC
Na/Ca	Exchanges intracellular Ca^{2+} for extracellular Na^+	Responsible for DAD

and Knilans, 2008; Dalvi *et al.*, 1986; Zoltani and Baskin, 2007).

Disequilibrium in the electrolyte balance can provide diagnostic clues. For example, hyperkalemia causes tall T-waves in leads II, III, V_2 to V_4, when the potassium balance exceeds 5.5 mmol/l. In conjunction, the amplitude of the P wave is reduced and QRS is widened. Hyperkalemia is usually present when the amplitude of the T-wave is higher than that of the R-wave. With increasing potassium concentration, P-waves widen and eventually disappear. Accentuated hyperkalemia results in asystole.

Hypokalemia results in decreased T-wave amplitude and ST-segment depression; however, accurate QT interval measurement is difficult. Malignant ventricular arrhythmias result when potassium concentrations become very low. Hypercalcemia shortens the QT interval while hypocalcemia produces ST-segment prolongation.

Left bundle branch block (LBBB) is characteristic of poisoning and is defined by Zimetbaum *et al.* (2004) as QRS $>$ 0.12 s with delayed intrinsicoid deflection in the V_1, V_5, and V_6 leads greater than 0.05 s. The risk of arrhythmia is greatest when QRS is $\geq$0.11 s. Right bundle branch block (RBBB) greater than 0.12 s is a fairly good predictor of arrhythmic death.

Blockade of potassium, sodium, calcium channels, β-adrenergic receptor sites, and the Na^+/K^+-ATPase pump change the ECG and may give an indication of the type of poisoning present in the tissue (Delk *et al.*, 2007).

Reductions in the outward potassium ion flow prolong QT, a harbinger of Torsade de Pointes (TdP), and ventricular fibrillation (VF). Sodium channel blockers delay the entry of sodium ions, widening the QRS complex. In extreme cases, asystole ensues. A subsidiary event may be ventricular tachycardia degenerating into VF.

For control of tachyarrhythmia, calcium channel blockers are used. Blockade of these channels decreases contractility and SA and AV node depolarization. Blocking β_1 receptor sites within the myocardium reduces the intracellular calcium concentration and the contractility. The potassium concentration is increased, an undesirable effect when the β_2 receptors are blocked.

Inhibition of the Na^+/K^+-ATPase pump results in $[K^+]_o$ and intercellular $[Na^+]_i$ increases in turn increasing the intracellular calcium concentrations.

2. Long QT

An important predictor of arrhythmia is changes in the duration of the QT trace, the time for ventricular repolarization, displacement of the ST-segment, and changes in the pattern of T-waves that may sometimes be seen as a T and U wave (Roden, 2004, 2008). It can be linked to ventricular tachycardia, including TdP. Lengthened QT increases the time available for intracellular calcium accumulation, enabling early after-depolarization (EAD) in the Purkinje fibers, and activates calmodulin (CaM) and calmodulin kinase (CaMK). CaMK is believed to enhance after-depolarization, triggering TdP. CaMK increases L-type calcium channel activity. Anderson (2006) reported that inhibition of CaMKII can prevent cellular arrhythmia where QT-prolongation is present (Zoltani and Baskin, 2007).

During the plateau phase of the action potential, there is a delicate balance between the L-type Ca^{2+} channels and the slowly and rapidly activating cardiac delayed rectifier currents, I_{Ks} and $I_{Kr.}$ Due to the slow onset of I_{Ks} activation during the rectification of $I_{Kr,}$ a limited amount of repolarizing current flows. The L-type Ca^{2+} channels are time-dependently inactivated while an outflowing potassium current takes place. With a net outflow of ions, repolarization takes place. It is critical that the I_{Kr} deactivates slowly. Thus small changes in the inward or outward conductance, i.e. the amount of current leaving or entering, has a deciding influence on the length of the repolarization. The effect of poisons on these processes plays an important role in determining the QT-segment length.

B. Biochemical Markers of Tissue Injury

Chemical markers are released into the bloodstream following injury of the cardiac muscle. Three types of troponin, as well as elevated creatine kinase–MB (CK–MB) levels, are indicators of cardiac tissue damage (Apak *et al.*, 2005; O'Brien, 2008).

Cardiac troponin complex consists of three parts. Troponin T facilitates contraction, troponin I (cTnI) inhibits actin–myosin interactions and troponin C binds to calcium ions. Troponin I and T are specific to the heart. In the course of cell damage, cardiac troponin is released from myocytes, facilitated by increased membrane permeability that allows smaller troponin fragments to traverse the membrane.

In cancer patients undergoing high-dose chemotherapy, elevated troponin I and CK–MB are predictors of ventricular systolic dysfunction, and thus indicators of cardiac damage. Immunological ultraviolet-array is used for the determination of the level of CK–MB, where an elevation greater than twice normal (Hochholzer *et al.*, 2008) is taken as an indicator of myocardial infarction. Cardiac troponin is measured by electrochemiluminescent immunoassay. According to the European Society of Cardiology/American College of Cardiology, troponin values greater than 0.03 μg/l are taken as pathogenic. Cardiac impairment is indicated by the presence of troponin. The release of the enzymes has been linked to a mismatch between oxygen demand and expenditure in the tissue, lessening of the time available for diastolic coronary perfusion, catecholamine release, and intense sympathetic stimulation. Warfare agent associated cardiac toxicity is characterized by these conditions.

Is the increased level of troponin due to damage to the heart muscle? In-depth studies by Jensen *et al.* (2007) and by Blich *et al.* (2008) note that stroke victims without acute myocardial infarction have elevated troponin levels. Jensen and colleagues, in fact, state that there is ''no convincing evidence that the release of troponin is due to neurologically

mediated microvascular change'' in cases where there were no cardiac symptoms before the stroke. Thus, until convincing proof is presented, increase in the presence of marker enzymes can be taken as an indicator of damage due to toxins in the cardiac tissue.

Creatine kinase is a protein necessary for ATP generation. One of its forms, CK–MB, is found mainly in the myocardium and upon tissue damage, such as myocardial infarction (MI), becomes elevated. It takes up to 24 h for the elevated level to reach its peak. A difficulty resides in the fact that unlike troponin, an assay does not allow us to distinguish between cardiac and skeletal muscle damage. Also, in about a third of MI cases while CK–MB levels stay neutral, troponin elevation is noted. The normal level of troponin in the blood is less than 0.3 μg/l while for CK–MB it is less than 3.0 ng/ml. For humans, the CK is in the range of 55–170 IU/l (international units per liter) and is less specific than CK–MB for cardiac tissue damage.

IV. INDICES OF THE TOXICITY OF WARFARE AGENTS

A. Classes of Warfare Agents

Three broad classes of warfare agents are considered: organophosphate nerve agents (Newmark, 2007; Munro *et al.*, 1994), the cyanides (Baskin *et al.*, 2009), and a third general category that is less weaponized but whose effects are important as potential terror agents, the arsenics and ricin.

The classes of nerve agents of primary interest are the ''G'' agents, first synthesized in Germany. Denser than air, these agents hug the ground and represent a vapor hazard due to their volatility. Tabun (GA), sarin (GB), and primarily soman (GD) are the ones most widely used. ''V'' (venomous) agents were developed in the United Kingdom. VX is more toxic than the G agents. Cyanides are less weaponized but also of concern. Arsenic and ricin are more terror threats than battlefield weapons. Novichok, developed in the Soviet Union, is the most potent nerve agent but on which there is little publicly available information.

B. Background

Chemically induced cardiac failure has been the subject of a number of works. Balazs and Ferrans (1978), Baskin (1991), and Acosta (2001) give an overview of the subject. Hypoxia is one of the effects of the decreased availability of ATP which depresses contraction in the muscle. The energy that is supplied by the phosphate bonds is possible only as long as aerobic glycolysis and oxidative phosphorylation are maintained. Under anoxic conditions, this is no longer possible and with the adrenergic stimulus continuing, calcium accumulation in the mitochondria leads to impairment of function, eventually causing dose-related lesions (Suzuki, 1968).

C. Signatures of Toxicity

Warfare agent-supplied xenobiotics disturb cardiac homeostasis. The main changes of concern include the following:

- morphological tissue changes
- enhanced neural stimulation
- release of neuropeptides
- activation of usually dormant cardiac currents
- alteration in the storing and movement of ions
- disturbances in energy use and storage.

Ferrans *et al.* (1969) noted ultrastructural changes in myofibrils, including mitochondrial swelling and disorganization. Catecholamines also produce changes in the activity of oxidative enzymes. The decline in the activity progresses to the point where necrosis is evident. Ancillary effects include loss of myocardial potassium and an increase in interstitial fluid. Intracellular calcium overload also develops as noted by Fleckenstein *et al.* (1974). It has been hypothesized that necrosis due to catecholamine overload may be caused by a defect in energy supply needed for the maintenance of cellular processes.

At low concentrations, the catecholamines, epinephrine, and norepinephrine exert positive inotropic effects on the myocardium. High concentrations, however, can cause cardiac lesions (Balazs and Ferrans, 1978; Inoue *et al.*, 1998). Even physiologic concentrations, when extended over time, lead to cardiac damage as shown by Szakacs and Mellman (1960). The LD_{50} of norepinephrine in rats is 680 mg/kg, but at doses as low as 0.02 mg/kg, focal necrotic lesions are produced.

The oxidation product of catecholamine is adrenochrome whose accumulation has also been linked to myocardial necrosis, and morphological and subcellular alteration (Yates and Dhalla, 1975). Singal *et al.* (1982) showed that administration of adrenochrome to rats also induced heart arrhythmias. Free radicals may also contribute to these processes. It has been suggested that catecholamines may activate β-adrenergic receptors, stimulating adenylate cyclase, and thus elevating cAMP. This in turn activates protein kinase, increasing the phosphorylation of slow calcium channels possibly resulting in overflow of calcium leading to necrosis preceded by swollen sarcoplasmic reticulum (SR), altered enzymatic activities, and lower ATP.

Cyanide primarily blocks oxidative phosphorylation and ATP production. Every heart beat uses up to 2% of the energy available to the cell. Arsenic primarily causes long QT (LQT) interval on the ECG, by blocking the fast potassium current, an action that is a precursor to ventricular fibrillation.

The activation of dormant currents by the presence of xenobiotics, including cell swelling, radically changes the electrical homeostasis of the tissue (Zoltani and Baskin, 2007). Toxicities of major weaponized agents are given in Table 34.2.

D. Nerve Agents

There is a difference in distribution of nerve agents for different organs of the body as well as different locations within the heart. Roth *et al.* (1993) detail effects on the heart. Also, soman is deposited in ''depots'' where time-release effects cause unsuspected difficulties in treatment.

1. Mechanism of Action

Nerve agents are OP compounds, which irreversibly inhibit AChE, leading to ACh accumulation, and cause over-stimulation of muscarinic and nicotinic ACh receptors. The effect at the SA node, the primary heart control site, is inhibitory and bradycardia results. VX primarily affects neurotransmitter receptors, those of norepinephrine, and also affects the central nervous system (CNS) not related to AChE inhibition.

Toxicants change the homeostatic distribution and timing of the presence of electrolytes, enzymes and other constituents of myocytes and their environment. These changes affect and determine the current flow, in turn affecting the electrical state and possibly signaling the onset of electrical instability. Table 34.2 shows toxicities of weaponized nerve agents.

2. Electrocardiographic Signature of OPs

Disturbances in the electrical activity of the heart caused by xenobiotics are readily discernible in a surface electrocardiogram (Yurumez *et al.*, 2008; Dalvi *et al.*, 1986; Chuang *et al.*, 1996; Chhabra *et al.*, 1970).

OPs cause QT prolongation on the ECG that subsequently can degenerate into TdP. In one reported OP case, 79.7% had QT prolongations with ST segment and T wave abnormalities (Karki *et al.*, 2004; Rubinshtein *et al.*, 2002; Saadeh, 2001; Saadeh *et al.*, 1997). Changes are ultimately expressed in arrhythmia, ventricular fibrillation and TdP, and severe disturbance of the energy homeostasis of the heart.

TABLE 34.2. Toxicities of weaponized agents

Agent	LCt_{50} (mg-min/m^3)	ICt_{50} (mg-min/m^3)	LD_{50} (mg/kg)
GA	400	300	14.28
GB	100	75	24.28
GD	70		5.0
VX	50	35	0.1428
Cyanide	2500–5000		1.1

An initial indicator of an impending arrhythmia is prolongation of the QT interval. The lengthening can be caused by reduction in the outward currents or increased inward currents, i.e. imbalance of inward and outward currents during the second and third phases of the cardiac cycle, i.e. the $I_{Kr,}$ $I_{Ks,}$ the $I_{Ca(L)}$, and I_{Na} currents. These currents can generate early after-depolarization (EAD) and trigger activity at the end of repolarization. Primary sites are the Purkinje fibers and the mid-myocardial M cells. In the Purkinje fibers, at higher positive resting potentials than the ventricles, blockade is voltage dependent with increased block in the depolarized tissue. The failure of complete repolarization leads to dispersion of refractoriness and enhanced arrhythmogenicity. Acquired LQT involves pause-dependent or short–long–short RR interval sequences on the ECG, and enhancement of sympathetic nervous system tone. LQT is favored in cases of severe bradycardia, hypokalemia, and conditions that lead to early after-depolarization. LQT may not be a sufficient condition for TdP. Stimulation of adrenergic receptors plays a significant role but it can enhance or inhibit after-depolarization.

The electrical activity of the heart is modulated by hormones and neurotransmitters. Xenobiotics disturb their balance. The parasympathetic system releases ACh and the sympathetic system releases catecholamines (norepinephrine and epinephrine). These bind to α and β types of receptors. α_1-receptors are present on the post-synaptic member of the organ and mediate vasoconstriction and stimulation of Na^+/K^+-ATPase, the Na^+/Ca^{2+} exchanger, and the Na^+/H^+ exchanger. This affects the I_{KATP} and inhibits the I_{Na^+} and I_{to}. The α-receptor stimulation thus effectuates depolarization, and the α_2-receptor inhibits norepinephrine release.

Cardiac β_1-receptors and atrial and ventricular β2-receptors take part in positive inotropic response. Inhibition of catecholamines at β-adrenergic receptor sites interrupts the production of cAMP and inhibits calcium influx producing a negative inotropic effect that yields a reduction in the heart rate.

The main effect of adrenergic stimulation is to enhance the intracellular adenylyl cyclase activity. This in turn increases cyclic adenosine monophosphate levels. Protein kinase A is activated which modulates, i.e. phosphorylates, calcium and potassium channels. Phosphorylation of the calcium channel increases the inward current leading to early after-depolarization.

β_1-Adrenergic stimulation increases the activity of the Na^+/K^+ pump and inhibits early after-depolarization. Hyperpolarization of resting membrane potential counteracts automaticity, leading to a decrease in heart rate. α_1-Adrenergic stimulation hyperpolarizes membranes, and enables early after-depolarization and TdP by blocking potassium channels. Release of norepinephrine enhances α_1-adrenergic stimulation facilitating early after-depolarization (Schomig *et al.*, 1984). In long QT, increased sympathetic discharge may induce both bradycardia and TdP. Increased adenosine

increases ventricular refractoriness and sympathetic tone setting the conditions for re-entrant arrhythmias. Hypokalemia prolongs cardiac action potential and may be the precursor of early after-depolarization. The net outward potassium currents are reduced and the inward calcium current is increased.

3. Toxic Effects of OPs on the Heart

The anticholinesterase effects of OP nerve agents depend on the sites where they act. The muscarinic effects in the heart act through the parasympathetic system, while the nicotinic effects act through the sympathetic system. Agents like tabun, sarin, and soman, analogous to acetylcholine, are capable of changing the receptor sites, which increases the conductance of electrophysiological signals related to the enhancement of neuromuscular function. VX, on the other hand, counteracts the effect of ACh, interrupting neuromuscular function.

ACh is a neurotransmitter that is present in the parasympathetic nervous system and is stored in vesicles. Its function, under normal circumstances, is terminated by AChE that is present in both the pre- and post-synaptic membranes. OPs inhibit AChE by electrophilic (a reactant which accepts an electron pair from a molecule with which it forms a covalent bond) attack of the enzyme. The neurotoxicity of OPs was exploited in the development of nerve gases. The key to the understanding of OP inhibition of AChE is the enzyme's serine hydroxyl group behavior. Normally, it attacks ACh at the carboxyl carbon yielding a covalent bond between the enzyme and the ACh substrate. The transiently acetylated enzyme is next hydrolyzed and the active enzyme site is regenerated. The active serine hydroxyl group is attacked by the electrophilic phosphorus of the OP instead of the ACh. A covalent, nonhydrolyzable bond is formed between the enzyme and the OP, leaving the enzyme in an inactivated form. Release of an alkyl chain further strengthens the phosphorus–enzyme bond. With AChE inactivated, the amount of ACh present increases, resulting in overstimulation of the tissue. The pathophysiological effects that result can be explained by the overabundance of the ACh. Overstimulation of muscarinic receptors in the heart leads to bradycardia.

V. SPECIFIC WARFARE AGENTS OF CONCERN REGARDING THE HEART

A. Nerve Agents

The heart may be affected by both muscarinic and nicotinic effects. In the former, stimulation of the parasympathetic nerve endings, while in the latter, excess ACh on the nicotinic receptors, is of importance. The cardiovascular effects are tachycardia caused by the overstimulation of the sympathetic system, bradyarrhythmias, atrioventricular block, hypotension and QT prolongation, VF, and TdP (Grmec *et al.*, 2004).

OP intoxication manifests itself in three phases. First, a nicotinic phase hypertension and sinus tachycardia occurs. This is followed by sinus bradycardia and parasympathetic overstimulation and ST-segment changes on the ECG and rhythm disturbances. During the last phase TdP and sudden cardiac death occur. According to Ludomirsky *et al.* (1982), a QTc of 580 ms signals high probability of sudden cardiac death. Roth *et al.* (1993) and Kiss and Fazekas (1979) give further insight from actual cases.

A breakdown of actual cardiac symptoms for OP poisoning in hospital admissions is given by Karki *et al.* (2004) and also by Saadeh *et al.* (1997). Sixty-seven percent of the acute OP cases had QT prolongation, 24% experienced ST-segment elevation, and 17% had inverted T-waves. Nine percent had atrial tachycardia, 9% ventricular tachycardia, and 4% had ventricular fibrillation. Sinus tachycardia was observed in 35% of admissions while sinus bradycardia was noted in 28%. Noting that acidosis and electrolyte derangement play a major role in the development of cardiac events, they recommend ''atropine in adequate doses very early in the course of the illness'' as the strategy to be implemented.

OPs are known to induce time-delayed neurotoxicity. This is due to the inhibition of an esterase in nerve tissue, neuropathy target esterase (NTE), that is also found in muscle and blood cells. The NTE level in the blood is an indicator of the inhibition of the enzyme. Inhibition of NTE and aging, the process of following the OP binding to an active esterase site that prevents the reactivation of the site, is important for selection of an antidote against certain OP nerve agents. It is of primary concern for Novichok agent. There is little information available on OP-caused neurotoxicity and the cardiac toxicity.

1. VX

The most toxic nerve agent available in the West is VX. It is an inhibitor of AChE, which acts by increasing the ACh at the nerve synapses. Toxicity sets in when more than 50% of the AChE enzyme is inhibited. The $AChE_{50}$ value for VX is taken as 0.023 mg/kg for an oral dose (Sidell, 1974). Activity of RBC-AChE and plasma butyrylcholinesterase (BChE) are other markers of toxicity of OPs. In tests on human volunteers 1 μg of VX/kg by i.v. infusion showed a depression in AChE activity of more than 50% but for these tests no cardiac symptoms were recorded. VX produces intense stimulation of nicotinic ACh receptor ion channels and muscarinic ACh receptors. Though not recorded in human volunteer tests, cardiac effects are known to take place, based on animal studies. VX exposure produces positive inotropic effects. Arrhythmia was noted in rats and dogs (Robineau, 1987; Robineau and Guittin, 1987). In guinea pigs treated with VX, delayed after-depolarization was found (Corbier and Robineau, 1989). The effect of VX is ascribed to inhibition of the rat cardiac Na^+/K^+-ATPase α_1 isoform. At 1 μM concentration, the inhibition is 35% (Robineau *et al.*, 1991). Physostigmine, hyoscine, and HI-6 are under investigation as antidotes (Wetherell *et al.*, 2006, 2007; Kuca *et al.*, 2007; Munro *et al.*, 1994).

TABLE 34.3. Effect of OP on the electrophysiology of cardiac tissue

	Lesions				
AChE	**Anoxia**	**Acidosis**	**Modulated ion concentration**	**Release of catecholamines**	**Second messenger (VIP, others)**
ACh overload causes bradycardia, slows conduction in AV, prevents hydrolysis $[Ca^{2+}] \uparrow \rightarrow I_{K,ACh} \uparrow$	Lowers ATP, cAMP; ATPase inhibition $I_{K,ATP} \uparrow$ (activated), AP shortened	pH ↓, Na^+/H^+ exchange ↑, [ATP] ↓, $[K^+]_o$ ↑, reduces I_{Kr} by increasing rate of deactivation, shifts voltage dependence of activation to more positive potentials, $g_K \uparrow$	$[K^+]_o \uparrow$ effect on velocity of propagation, inexcitability	Prolongs AP, $[Na^+] \uparrow$, Na^+/K^+-ATPase antagonized DAD enhanced difference for α, β receptors	Adenylate cyclase activation
Antagonizes adenylyl cyclase		Cytoplasmic $[Ca^{2+}] \uparrow$ slows repolarization, reduces max. diastolic potential	$[Na^+] \uparrow Na^+/K^+$ pump inhibition, Na^+/Ca^{2+} exchanger $\rightarrow Ca^{2+}$ influx	α stimulation: reperfusion arrhythmia, calcium overload, gap junction conductance ↓, exchanger stimulation, activitates Na^+/K^+ pump	$I_f \uparrow$, cAMP ↑, → HR ↑OP reduces cAMP $\rightarrow Ca^{2+}$ influx, inhibits adenylate cyclase, stimulates ATP, $I_K \uparrow$, affects $I_{Ca(L)}$, EAD, DAD → arrhythmia
Arrests cAMP synthesis, depresses I_f (pacemaker current)		$I_{Ca(L)} \downarrow$, $I_{Na} \downarrow$ (inactivation of fast Na^+ channel), decreased excitability, CO_2 accumulation	$[Ca^{2+}] \uparrow Na^+/Ca^{2+}$ exchanger ↓reduced SR uptake		
ACh inhibits adenylate cyclase			$[Mg^{2+}] \uparrow$(hydrolysis of ATP), activates enzymes, reduces $I_{Ca(L)}$, I_{K1}, $I_{K,ACh}$, I_{KATP}, I_{Ks}	β stimulation: adenylate cyclase, elevates cAMP, increases calcium influx, I_f activation, triggered activity improves modal conduction	
			Intermediate stage		
			AF, VF		

g – conductivity of the tissue; [..] – concentration; $I_{(.)}$ – ionic current with the subscript denoting the channel type; ↑ – increase; ↓ – decrease; → – yields

2. Tabun (GA)

GA, a unitary chemical munition, inhibits AChE, the enzyme responsible for the breakdown of the neurotransmitter ACh. When inhaled, its toxicity is half that of sarin. It depresses plasma and RBC-AChE activities significantly in the blood. At 20–25% of red blood cell AChE baseline, the effect of the nerve agent becomes noticeable. There is no evidence of systemic toxicity other than the cholinesterase activity (Parker *et al.*, 1990; Munro *et al.*, 1994). GA has not been shown to produce OPIDN except at extremely high doses. The cardiac effect of GA conforms to OP-caused arrhythmias and AV block.

3. Sarin (GB)

Sarin was involved in terrorist attacks in Japan (Okumura *et al.*, 2003; Okudera, 2002). The increase in sympathetic and parasympathetic tone results in tachycardia, ST-segment modulation (Abraham *et al.*, 2001), and arrhythmia. Inhibition of cholinesterase within the neuroeffector junction also affects nerve impulse transmission by direct action. Direct action on muscarinic or nicotinic ACh receptors (Somani *et al.*, 1992) is observed when the blood level of sarin exceeds the micromolar level. Sarin inhibits RBC-AChE 80–100% as well as plasma-BChE between 30 and 50% (Grob and Harvey, 1958). It also binds to aliesterase, an enzyme that contributes to ester-link hydrolysis.

Sarin exhibits OP-delayed cardiotoxicity. Allon *et al.* (2005) suggest epinephrine-induced arrhythmias as a possible cause in cases of sarin intoxication. The hypothesis is supported by Khositseth *et al.* (2005) who showed that epinephrine changes T-waves in the ECG where AT prolongation already exists.

4. Soman (GD)

The most widely used nerve agent, soman (GD), exerts a defining effect on cardiovascular function. Myocardial degeneration and necrosis was noted by Britt *et al.* (2000) in soman-exposed rhesus macaques. Generally, upon contact, bradycardia and modulated cardiac output are followed by hypotension and changes in the ECG. Notably, AV conduction modulation, QT extension, T-wave and ST-segment changes characteristic of myocardial infarction, and ACh-induced coronary vasospasm are noted. For OP's cardiac effects, important references include Sidell (1974), Luzhnikov *et al.* (1975), Kiss and Fazekas (1979, 1983), and Anastassiades and Ionnides (1984). McKenzie *et al.* (1996) also showed that in swine a dose of $2 \times LD_{50}$ soman i.v. increased coronary sinus plasma ACh by 314% and decreased coronary blood flow to 55% of control. The evidence indicates OP-caused deaths are due to ACh-caused coronary vasospasms that culminate in MI. This is seen as VF on the ECGs. Recently, the Food and Drug Administration (FDA) approved pyridostigmine bromide as a pretreatment for soman poisoning (Newmark, 2007).

5. Novichok

In the open literature little is known about these agents developed in the Soviet Union. They are assessed to be five to ten times more toxic than VX (Ellison, 2008; Smithson *et al.*, 1995). The toxicity of these binary agents does not rely primarily on the inhibition of AChE, but it is thought that it causes permanent neuropathy. Consequently, conventional nerve agent antidotes may not work. Reactive oximes such as potassium 2,3-butanedione monoximate may be useful in detoxification. No published information is available on cardiac pathologies caused by Novichok agents.

B. Antidotes for OP Nerve Agents

Enzymatic hydrolysis is a primary route for elimination of nerve agents. Specifically, treatment for OP intoxication includes atropine, a muscarinic receptor antagonist, an anticonvulsant such as diazepam, and a cholinesterase reactivator, an oxime. It has been found that drug-induced inhibition of ACh release and accumulation in the synaptic cleft, such as adenosine receptor antagonist early in the OP intoxication, improves the chances of survival. Some AChE reactivators, such as bispyridinum oximes, HI 6 and HLö 7 with atropine, are quite effective.

C. Cyanide

Classified as a blood agent, cyanide is usually deployed as hydrogen cyanide and cyanogen chloride. Considerable literature exists on the effects of cyanide (Meredith *et al.*, 1993; Suzuki, 1968; Vick and Froehlich, 1985; Baskin *et al.*, 2009). Cyanide binds irreversibly to its target sites. In the human host it preferentially accumulates in the hypothalamus and neural tissue. Its concentration in red blood cells is much greater than in plasma. Lethal dose is of the order of 1 mg/kg or inhalation of 50 ml of hydrogen cyanide gas.

1. Toxicity

Cyanide binds to Fe^{3+} in heme-containing proteins. This inhibits the terminal cytochrome complex IV of the electron transport chain. The blocklock of complex IV by cyanide depletes ATP culminating in cell death. Oxygen is unable to reoxidize the reduced cytochrome a3. Thus cellular respiration is inhibited as well as ATP production, in essence depriving the cells, tissue, and ultimately the whole body of oxygen. Hypoxia evolves into metabolic acidosis and decreased oxygen saturation. The extent of lactic acidosis indicates the severity of the cyanide poisoning (Naughton, 1974). In a collapsed individual, plasma lactate is an indicator of cyanide poisoning (Baud *et al.*, 2002). In severe cyanide poisonings, up to 98% of the cyanide in the bloodstream is tightly bound to red blood cells. The ancillary response is myocardial depression and decline in cardiac output. Bradycardia, hypotension, and cardiac arrhythmia then develops into ventricular fibrillation and cardiovascular collapse.

In severe cyanide poisonings, autonomic shock due to the release of biogenic amines plays a role. The coronary arterial vasoconstriction, resulting in an increase in central venous pressure, leads to the observed shock-like state that is not attributable to inhibition of cytochrome oxidase (Vick and Froehlich, 1985). In the liver CN is metabolized by rhodanese to thiocyanate, which is excreted in the urine.

Hypoxia is one of the signatures of cyanide poisoning. One of its markers is that ATP declines to about 10% of the normal value. Since ATP forms the substrate for adenylate cyclase, the slow channels are affected lowering the slow calcium current and depressing the contraction. In CN poisoning, as in ischemia, oxidative metabolism is blocked and acidosis is enhanced. Acidosis depresses contractility and metabolism while sparing ATP supplies.

A dose of 0.54 mg of hydrogen cyanide per kg of body weight is fatal, with an average of 1.4 mg as shown by Gettler and Baine (1938). Their data indicate that the heart absorbs the second most amount of cyanide per organ weight. On the other hand, in sublethal exposure, cyanide-fed rabbits (Okolie and Osagie, 2000) do not show the hemorrhaging in the cardiac tissue noted by Suzuki (1968). Cyanide also causes decline in $[K^+]_i$, i.e. significant hypokalemia, and an increase in $[Na^+]_i$. These changes were not reflected in the skeletal muscle (Karzel *et al.*, 1974). Cyanide caused decline in ATP, the energy source of the cell, to less than 10% of the normal value, which activates the otherwise dormant potassium channel and the outward current I_{KATP}. These changes result in shortening of the AP and decrease in the contraction.

Cyanide also causes endogenous catecholamine release (Kanthasamy *et al.*, 1991; Kawada *et al.*, 2000; Schomig *et al.*, 1995; Inoue *et al.*, 1998). Inoue *et al.* (1998) also point out that cyanide-produced depolarization increases intracellular calcium due to the suppression of the potassium channels and activation of the voltage-dependent calcium channel. Anoxia induces suppression of the sodium pump and activates cation channels due to the decrease in ATP. A further consequence of the presence of cyanide in the tissue is inhibition of the Na^+/Ca^{2+} exchanger (NCX) (Ju and Allen, 2005). NCX is important for the pacemaker currents. Metabolic inhibition of NCX reduces the firing rate of pacemaker cells.

Cyanide poisoning is marked by metabolic acidosis and a large anion gap. The latter is a consequence of the blocked oxidative phosphorylation and the increased rate of glycolysis. Maduh *et al.* (1990) showed that cyanide also affects H^+ and thus the pH of the tissues. In turn, the Ca^{2+} transport process is disrupted, leading to a rise in cystolic $[Ca^{2+}]$. Acidification depolarizes the cell membrane and changes the potassium conductance.

Cyanide also exerts a strong influence on the vagus nerve and thus on the VIP that under normal conditions exerts a strong inotropic and chronotropic effect. VIP stimulates adenylyl cyclase activity. In ventricular myocytes, VIP potentiates voltage-gated Ca^{2+} channel currents and also acts on pacemaker currents.

As shown by Lederer *et al.* (1989) and later by Goldhaber *et al.* (1991), contractile failure, i.e. twitch shortening, is caused by cyanide. It is said to be due to failure of activation of the Ca^{2+} current. Electrocardiographic manifestations of CN poisoning are shown in Katzman and Penney (1993) and Wexler *et al.* (1947), described in Zoltani *et al.* (2004), and summarized in Table 34.4.

The ECG of an individual executed by inhalation of cyanic acid revealed that initially, between the first and third minutes, a heart rate slowing was discernible with the disappearance of the P-wave. Later the heart rate increased slightly. T-waves showed an increase in amplitude and a marked shortening of the ST-segment. One subject, unlike some others in this cohort, showed normal AV conduction until ventricular tachycardia and ventricular fibrillation developed.

2. Antidotes for CN Poisoning

Bhattacharya *et al.* (1995) and Cummings (2004) described the following approaches:

1. Use of a nitrite (oxidizing agent such as sodium nitrite) to change the ferrous ion of hemoglobin to a ferric ion. The created methemoglobin binds cyanide forming cyanmethemoglobin. One drawback, however, is that impairment of oxygen transport occurs, i.e. the amount of hemoglobin available is reduced. Amyl nitrite to generate methemoglobin is no longer preferred, since it does not bind enough cyanide.
2. Sulfur donors for conversion of cyanide to thiocyanate by rhodanese or other sulfur transferases, that is, a source of sulfur. For moderate poisoning, sodium thiosulfate is the usual choice.
3. Use of cobalt chemistry that chelates the cyanide directly such as hydroxycobalamin.
4. Hydroxocobalamins, precursors to vitamin B_{12}, are preferred in France and elsewhere in Europe. Hydroxocobalamin binds cyanide to form cyanocobalamin. It does not interfere with tissue oxygenation but large doses are required to be effective.
5. In the UK, dicobalt edentate, which chelates the cyanide directly, is preferred, but assurance that cyanide poisoning is present is needed since this antidote contains cobalt, which can be toxic.

VI. OTHER TERROR AGENTS

A. Arsenic

Arsine blood agents were first developed for battlefield use during World War I. Due to difficulties with dispersion, they were never used. Arsenic, however, has potential use as a terror agent (Ellison, 2008; Sidell *et al.*, 1997).

Arsine is the simplest compound of arsenic. It is colorless and 2.5 times denser than air with an odor resembling garlic. Arsine binds to hemoglobin of the red blood cells destroying them. Poisoning kills by allosteric inhibition of metabolic

TABLE 34.4. Effect of CN on the electrophysiology of cardiac tissue

P	QRS	ST	T	Remarks	Reference
Disappearance (auricular arrest)	Change in amplitude, right axis deviation	Shortening, disappear	Incr. amplitude, origin of T-waves on QRS	0.11–0.20 mg/kg NaCN, inhalation, AV dissociation, HR↓, BBB, initial bradycardia, AV block, asystole	Wexler *et al.* (1947) (man)
	Lengthened	Absent or depressed, elevated after 20 s	Increased, decreased over time, T starts on top of R, diphasic, negative	0.4–0.8 mg/kg NaCN HR↓, bradycardia, Wenckebach, heart block, V-flutter, VF	Leimdorfer (1950) (cats)
		Short, shifted toward T-wave	Tall T, surpassing R, sometimes inverted	0.1 mg/kg NaCN, bradycardia, incomplete AV blockade, VF	Paulet (1955) (dog)
	Abnormal	Elevated, shortened	T-wave beginning high on QRS	0.3–0.6 sodium nitrite as antidote with sodium thiosulfate, atrial fibrillation	DeBusk *et al.* (1969) (man)
	Narrow QRS	Nonspecific ST-T changes in anterior chest leads, shortened ST-segment	Fusion of T-wave into QRS, sharp rise of T-wave	Sinus tachycardia, acidosis with high anion gap	Chin *et al.* (2000) (man)
	Q-wave present in lead III, persisted after treatment of acidosis	Deviation of 4 mm in leads II, III, aVF, 2 mm in V_6, ST depression of 2–4 mm in V_1–V_4, I, aVL leads, normalization of ST-segment in precordial leads	T-wave inversion in II, III, aVF, V_5 and V_6 leads	Acidosis, CN level of 3 μg/ml, anion gap present	Sanchez *et al.* (2001) (man)

↑ – increase; ↓ – decrease.

enzymes. Arsenic disrupts ATP production. Arsenic inhibits pyruvate dehydrogenese, uncoupling oxidation phosphorylation. Arsenic poisoning also occurs through arsenic–oxygen compounds, especially arsenic trioxide, As_2O_3 (ATO), which is 500 times more toxic than pure arsenic.

ATO has been effectively used as a remedy for relapsed acute promyeloctic leukemia, but with the side effect that it causes QT interval prolongation, possibly heralding ventricular arrhythmia (Chiang *et al.*, 2002). Abnormalities in $I_{Ca(L)}$ in myocytes were also noted (Sun *et al.*, 2006). ATO's direct effect on cardiac repolarization with its effect on I_{Kr} was also noted by Haverkamp *et al.* (2000). ATO also causes cellular Ca^{2+} overload and augments APD (Yamazaki *et al.*, 2006). Chronic arsenic exposure leads to QT prolongation blockage of I_{Kr}, TdP, and T-U alternans, and changes in the T-wave result (Little *et al.*, 1990; Ficker *et al.*, 2004).

It has been suggested that potassium ion channel alteration induced by arsenic may be related to hERG trafficking defects. ECG changes in arsenic poisonings have been reported by Fennel (1981) and also by Glazener *et al.* (1968). The T-waves are domed. ECG changes, especially where arsenic involvement is not severe, are reversible. Hemodialysis and BAL (dimercaprol) therapy has been found to be effective. Sun *et al.* (2006) in a recent publication suggest that choline can normalize QT interval abnormality by inhibiting $[Ca^{2+}]_i$ and $I_{Ca(L)}$ in ventricular myocytes when ATO is present. Arsenic intoxication results in widened QRS by 0.06 s and prolonged QT (Ahmad *et al.*, 2006). Ventricular tachycardia and VF have been reported by Goldsmith and From (1980) and St Petery *et al.* (1970).

B. Ricin

Ricin, a toxic glycoprotein derived from the castor bean, causes hypotension and myocardial hemorrhage. The Center for Disease Control and Prevention (CDC) lists it as a category B agent due to its easy availability as a terrorist weapon. Only a limited amount of information is available

in the open literature on ricin's effect on the heart. The medical files of Georgi Markov, the Bulgarian journalist, assassinated in London with what was assumed to be ricin, are not publicly available (Crompton, 1980).

Ricin is a glycoprotein made up of two chains linked by a disulfide bond. Its toxicity results from one of the chains inhibiting protein synthesis by irreversibly inactivating eukaryotic ribosomes (Audi *et al.*, 2005). The lethal dose of ricin has been set at 1 to 20 mg/kg of body weight (Bradberry *et al.*, 2003). Christiansen *et al.* (1994) and Ma *et al.* (1996, 1995) performed extensive experiments on rabbits. Their main findings include the following:

1. Ricin caused vasodilatation and increased endothelial-dependent vascular relaxation resulting in hypotension.
2. Ricin disturbed calcium homeostasis leading to cell necrosis.
3. Ricin reduced both systolic and diastolic left ventricular function.
4. Ricin caused myocardial hemorrhage.

Balint (1974) and later Zhang *et al.* (1994) found that at the lethal dose in rabbits, ricin caused hemorrhage and necrosis. Christiansen *et al.* (1994) found that the release of norepinephrine from sympathetic nerves in the vasculature is not impaired by ricin. The CDC, under signs and symptoms of ricin poisoning that may be encountered, cite cardiovascular collapse (hypovolemic shock).

ECG abnormalities in children who ingested castor beans have been noted by Kaszas and Papp (1960). These include QT interval lengthening, repolarization changes, and intraventricular conduction disturbances. Crompton (1980) later reported on experiments on pigs that experienced hemorrhagic lesions and an abnormal ECG due to ricin. At the present time, no antidotes or effective therapy are available to counteract the effects of ricin.

VII. CONCLUDING REMARKS AND FUTURE DIRECTION

Per organ weight, the heart is the second most preferred depository for several of the warfare agents used. Disturbance of the electrical homeostasis, the cellular energy production, and breakdown of the electrical control network within the tissue are mostly affected.

Areas that need further insight include the following:

- time-delayed effect of OPs
- means of reactivation, i.e. overcoming ''aging'' of OP-based agents
- the effect of genetic factors and state of the fitness of the cardiac system in combating the effect of xenobiotics
- mechanism of toxicity involving neuropathy target esterase (NTE).

Human data for various cardiotoxic scenarios are unavailable. These include, at the time of this writing, ricin poisoning. The means of prompt identification of the particular xenobiotic causing poisoning remains an urgent task. Progress in metabolomics, the identification biomarkers that result from metabolic changes caused by the presence of xenobiotics, will enable the development of chip-based rapid-responding assaying devices.

CHAPTER 35

Skeletal Muscle

RAMESH C. GUPTA, WOLF-D. DETTBARN, AND DEJAN MILATOVIC

I. INTRODUCTION

Skeletal muscle is a target organ for a variety of chemicals. Adverse or toxic effects on skeletal muscles can range from minor muscle weakness or slight pain to complete paralysis. Next to the brain, skeletal muscles are major targets for the toxicity of organophosphate (OP) nerve agents. Morbidity and mortality associated with OP intoxication is due to the effects of these compounds on skeletal muscles in general and muscles of respiration in particular. Deaths from overdose of OPs are due in part to respiratory paralysis by depolarizing neuromuscular blockade. Understanding the skeletal muscle system in the context of OP poisoning is interesting, yet very complex because muscles containing different fiber types often respond differently even to the same OP compound. The distinct features of slow and fast muscles are the most fascinating aspects of skeletal muscles in this area of research.

Skeletal muscles are enriched with cholinergic as well as noncholinergic elements that are directly or indirectly modulated by OP nerve agents. Motor innervation plays an important role in the regulation of many properties of skeletal muscles, including neuromuscular activity. Changes in the activities of acetylcholinesterase (AChE) and choline acetyltransferase (ChAT) appear to greatly modulate neuromuscular activity and can modifies neuromuscular transmission. At the cholinergic synapse, AChE plays an important role in the removal of acetylcholine (ACh) from the synaptic cleft. Inhibition of this enzyme by compounds such as OP nerve agents profoundly modifies neuromuscular transmission as seen in twitch potentiation, fasciculation, muscular weakness, and muscle cell death by necrosis or apoptosis. Being rich in metabolism, skeletal muscles are very vulnerable to OP-induced oxidative/nitrosative stress due to excess free radical generation. In the past two decades, interest in skeletal muscles has been enormous because of their involvement in intermediate syndrome and tolerance development related to the toxicity of OPs. OP-induced effects on skeletal muscles can occur at one or multiple sites (the nerve fiber, the nerve terminal, the junctional cleft, the motor endplate, or the myofibrils). This chapter describes structural and functional aspects of skeletal muscles in the context of OP nerve agents' toxicity.

II. BEHAVIORAL EFFECTS

In general, exposure to sublethal signs-producing doses of an OP nerve agent exerts prominent motor, behavioral, and autonomic symptoms. The motor symptoms are fasciculations, fibrillations, and body tremors. Fasciculations and fibrillations are due to antidromic neural discharge from excess junctional ACh, while tremors are of a central origin (Gupta *et al.*, 1986; Misulis *et al.*, 1987). A comparative description of behavioral toxicity of OP nerve agents (soman, sarin, tabun, and VX) from experimental studies is provided here in brief. Different nerve agents require different concentrations to produce equitoxic effects, degree of AChE inhibition, and myonecrosis. Acute symptoms of equal severity in male Sprague-Dawley rats by soman, sarin, tabun, and VX can be achieved at a dose of 100 μg/kg, 110 μg/kg, 200 μg/kg, and 12 μg/kg, s.c., respectively (Gupta *et al.*, 1987a, b, 1991). Based on the equitoxic doses, VX is the most toxic and tabun is the least toxic OP nerve agent.

Rats receiving an acute dose of soman (100 μg/kg, s.c.) exhibit onset of toxicity such as salivation, muscle fasciculations, and severe tremors within 5–15 min. Within 20–30 min, signs of toxicity are maximal and can persist for 4–6 h. Thereafter, the intensity is reduced to a mild form but the signs of toxicity can still be observed after 24 h. Rats usually become free of obvert signs after 72 h. With VX, onset of symptoms and appearance of maximal severity are delayed by approximately 20 min compared to other nerve agents (Gupta *et al.*, 1987a, b, 1991). During peak toxicity of soman, signs such as complex posturing movements and tremors are indicative of pronounced CNS effects as compared to the moderate peripheral muscle fasciculations. Muscle fasciculations superimposed upon this activity are less prominent than the signs of gross motor unit activity. This is in contrast to the OP compound diisopropylphosphorofluoridate (DFP), which exerts greater peripheral activity with fasciculations and fewer central toxicity signs (Gupta *et al.*, 1985, 1986, 1987a, b). This suggests that AChE inhibitors differ in their propensity to produce central or peripheral effects and that peripheral effects are required for muscle necrosis (Gupta *et al.*, 1985, 1986, 1987a, b; Misulis *et al.*, 1987).

III. CHOLINERGIC SYSTEM

Key elements of the cholinergic system include a neurotransmitter, ACh, an enzyme, AChE, that hydrolyzes ACh, and an enzyme, ChAT, that synthesizes ACh. All skeletal muscles contain these cholinergic components, but their quantities can significantly vary from muscle to muscle, i.e. fast fiber containing muscle has greater values than the slow fiber or mixed fiber containing muscle.

A. Normal Activity of AChE and its Molecular Forms

Muscle acetylcholinesterase (AChE, E.C. 3.1.1.7) is partly concentrated in the endplate region, i.e. 20–40% of the total amount found in the whole muscle (Hall, 1973; Younkin *et al.*, 1982). Using histochemical technique, Müntener and Zenker (1986) demonstrated the presence of AChE in the sarcoplasm of limited areas in sections of normal rat muscles. Normal activity of AChE varies from muscle to muscle, i.e. higher AChE activity is found in the fast fiber (type II fibers in general, and type IIB fibers in particular) than in the slow fiber (type I fiber) containing muscle. Enzyme activity in mixed fiber muscle is found in between the values of slow and fast muscles (Table 35.1). AChE plays an essential role in the removal of ACh at the neuromuscular junction (NMJ). Inhibition of AChE activity, which results in accumulation of ACh, profoundly modifies neuromuscular transmission by producing fasciculations and twitch potentiation. At high rates of stimulation, the muscle is unable to maintain a normal contraction, and muscle hyperactivity often ensues in muscle fiber necrosis.

It is well established that AChE exists in nerves and muscles in a range of globular and asymmetric molecular forms. A wide variety of sedimentation profiles have been established for AChE molecular forms in different mammalian muscles (Massoulie and Bon, 1982). The variations seen in the ratios of these molecular forms between different muscles are wide and complex. Qualitative and quantitative variations exist among different species, as well as young versus adult (Barnard *et al.*, 1984). In the rat extensor digitorum longus (EDL, a fast twitch muscle), the G_1 (4S), G_4 (10S), and A_{12} (16 S) molecular forms are predominant, while in soleus (SOL, a slow twitch muscle) and diaphragm (a mixed muscle) a fourth major molecular form is also present, the A_8 (12S). In rat SOL, the majority of the total AChE activity is contributed by the 12S and 16S forms; whereas in the diaphragm 4S and 10S and in the EDL 4S (Grosswald and Dettbarn, 1983a, b; Patterson *et al.*, 1987) (Table 35.2).

In the rat, the 16S form is found in high concentration at the endplates and it is thought to be involved in neuromuscular transmission (Hall, 1973). The different molecular forms of AChE in SOL and EDL have apparent K_m values similar to that previously found in the diaphragm muscle (Hall, 1973; Grosswald and Dettbarn, 1983a, b). There appears to be no difference between catalytic sites of the molecular forms of AChE in fast EDL and slow SOL muscles, despite the different molecular form patterns and activity in three muscles.

B. Inhibition of AChE and its Molecular Forms by Nerve Agents

In general, following an acute exposure to OP nerve agents, signs of cholinergic toxicity appear within a few minutes and are caused by irreversible inhibition of AChE activity in neuronal tissues. Inhibition of AChE causes excess accumulation of ACh at central and peripheral synaptic sites leading to failure of neuromuscular, respiratory, and cardiovascular functions. For some OP compounds, a close relationship exists between severity of the toxic signs and the inhibition of AChE during the acute phase of intoxication. The observable toxic effects usually do not persist for more than 4–6 h, while recovery of AChE activity occurs at a much slower rate, such as 7–14 days or even 3–4 weeks depending on the tissue and the inhibitor.

Gupta *et al.* (1987a) demonstrated that selective inhibition of AChE activity in skeletal muscles was apparent within 1 h of soman administration (100 μg/kg, s.c.) in rats when SOL showed the maximum inhibition (87%), whereas EDL showed the least inhibition (47%). AChE activity in skeletal muscles was maximally depressed during the following 3–6 h, the time when animals showed severe signs

TABLE 35.1. Normal values of acetylcholinesterase (AChE) and butyrylcholinesterase (BuChE) activity in rat skeletal muscles

Muscle	AChE activity (μmol substrate/g/h)	BuChE activity (μmol substrate/g/h)
EDL (fast fiber muscle)	105.8 ± 1.0	9.7 ± 0.8
Soleus (slow fiber muscle)	60.1± 1.2	10.3 ± 0.3
Diaphragm (mixed fiber muscle)	78.3± 1.6	10.2 ± 0.2

The substrates used were acetylthiocholine iodide and butyrylthiocholine iodide for AChE and BuChE activity, respectively

Each value represents mean ± SEM ($n = 5$–6)

TABLE 35.2. Total AChE activity and percent contribution of molecular forms to total AChE activity in rat skeletal muscles

			Molecular forms			
		Total activity	**A_{12} (16S)**	**A_8 (12S)**	**G_4 (10S)**	**G_1 (4S)**
EDL	w/ PI	93.8 ± 7.5	18.7 ± 1.8	–	26.4 ± 3.5	54.9 ± 4.1
	w/o PI	102.9 ± 4.7	18.7 ± 1.6	–	30.2 ± 2.8	51.1 ± 3.1
Soleus	w/ PI	53.6 ± 4.7	26.8 ± 1.9	33.7 ± 2.3	15.2 ± 1.0	24.3 ± 0.9
	w/o PI	61.4 ± 5.3	25.9 ± 2.2	33.0 ± 2.2	16.3 ± 1.3	24.8 ± 1.4
Diaphragm	w/ PI	81.4 ± 6.1	26.9 ± 1.4	14.2 ± 0.9	28.8 ± 0.3	30.1 ± 1.7
	w/o PI	89.5 ± 4.9	24.6 ± 1.8	14.8 ± 0.9	29.7 ± 1.7	30.9 ± 1.5

Activity values are expressed as μmol ACh hydrolyzed/g/h tissue for total activity and as a percentage of the total distribution for molecular forms. Values are the mean ± SD ($n = 6$ to 8 muscles), w/ PI – protease inhibitors present; w/o PI – protease inhibitors absent. No statistical significance was found comparing the presence vs absence of protease inhibitors for values of the individual molecular forms or total activities

of toxicity. Recovery was clearly apparent during 3–7 days in all three skeletal muscles (SOL, EDL, and diaphragm). Seven days after soman treatment, enzyme recovery was >90% in EDL and diaphragm compared to 75% in SOL (Gupta *et al.*, 1987a). Within 1 h, all molecular forms of AChE were reduced to less than 10% of control in SOL and diaphragm. In EDL the 16S form, mainly localized at the NMJ, was not affected at this time, while the 10S form was completely inhibited and the 4S form was reduced to 50%. Further inhibition was seen after 24 h but even then the 16S form was the least inhibited in EDL. After 3 days of soman treatment, the AChE molecular forms in all three muscles showed signs of recovery. This was particularly evident in the 16S form in EDL and diaphragm where it appeared to be approximately 75% of controls. In the SOL the 16S form had recovered to only about one-third of the control when measured after 3 days. Seven days after soman, the 16S and 4S forms in the EDL and diaphragm had fully recovered. The activities of the 10S EDL form and the 10S and 12S diaphragm forms were still reduced, while in the SOL the activity of all forms remained below the control.

In similar experiments, tabun (200 μg/kg, s.c.) produced differential AChE inhibition in various skeletal muscles (SOL = diaphragm > EDL) which was similar to that seen with soman (Gupta *et al.*, 1987a, b). The varying degrees of AChE inhibition in the skeletal muscles treated with tabun, however, correlate well with the observed difference in the number of myonecrotic lesions, i.e. the greater the AChE inhibition (during the initial 24 h period), the higher the number of lesions found in diaphragm and SOL. EDL, with a low level of AChE inactivation, had the lowest number of lesions. This observation was in agreement with a similar pattern of histochemical observations following soman and sarin (Meshul *et al.*, 1985; Gupta *et al.*, 1987a, 1991).

The reason for this difference in susceptibility to a particular nerve agent may be due to: (1) variations in location of AChE in different muscles (Grosswald and Dettbarn, 1983a), (2) changes in ACh release due to

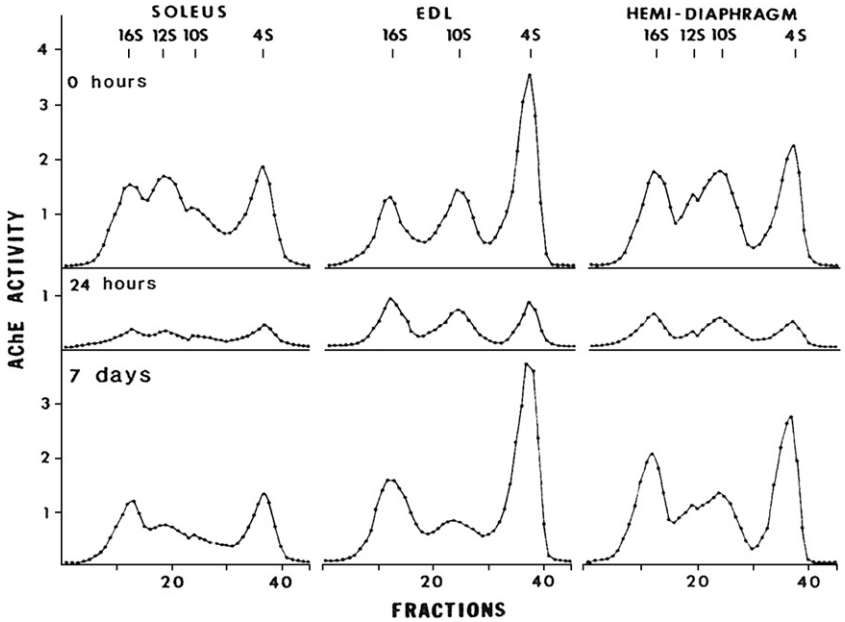

FIGURE 35.1. Representative profiles of the activity of the AChE molecular forms in soleus, EDL, and hemidiaphragm muscles. Profiles at the top of each column are from untreated muscles followed by profiles of activity of AChE molecular forms of muscles 24 h and 7 days, respectively, after receiving an acute dose of soman (100 μg/kg, s.c.). The AChE activity scale is in arbitrary units based on the μmole substrate hydrolyzed/min by the enzyme activity in each fraction. The sedimentation values of the AChE molecular forms are given in the profiles of untreated muscles above the associated peaks. Sedimentation values were determined by the location of the added sedimentation standards, β-galactosidase (16.0 S), catalase (11.1 S), and alkaline phosphatase (6.1 S), following velocity sedimentation of the gradients.

a different firing pattern (Misulis *et al.*, 1987), and (3) pharmacokinetic variables which influence the delivery of a particular OP compound. With tabun toxicity, inhibition and recovery of AChE molecular forms, especially the 16S form associated with the neuromuscular junction (endplate region), corresponded well with the appearance and disappearance of necrotic lesions. The delay in the molecular form's return to normal is due to the fact that the heavier molecular forms (16S, 12S, and 10S) are based on an assembly of the monomeric 4S form. Synthesis of the 4S form is increased when the assembly of the heavier forms lags behind.

Following an acute exposure to sarin (110 µg/kg, s.c.), AChE activity in skeletal muscles was reduced to 23% in SOL and 48% in diaphragm within 1 h, while EDL AChE was significantly unaffected. By 24 h, however, a still greater inhibition was seen for these muscles, and in EDL, AChE activity was reduced to 43%. In an early phase, recovery of AChE was rapid, but still not complete when measured after 7 days of treatment. Activities of the AChE molecular forms, after 1 h of sarin injection, were significantly depressed in SOL and diaphragm, while those in the EDL showed significant inhibition only after 24 h. By day 7 in SOL, activities of the 4S and 10S molecular forms of AChE had recovered to higher than control levels, while in diaphragm a significant shift toward the 4S molecular form had taken place so that the AChE profile resembled that of a control EDL. In EDL, the activity of 4S and 16S molecular forms recovered at a faster rate than the 10S molecular form.

Within 1 h of VX administration (12 µg/kg, s.c.), AChE activity of all three skeletal muscles was reduced to between 8 and 17% of control with incomplete recovery by the end of 7 days. At the same time, VX caused significant inhibition in the activity of all molecular forms in all three muscles. In EDL, the activity of 4S and 10S showed significant recovery 24 h later, while those of SOL and diaphragm remained inhibited. By day 7, the activity of all forms had recovered and an excess activity was seen in the 4S form of EDL and diaphragm, shifting the latter profile toward that of the EDL and contributing a higher protection to the total AChE activity.

C. Butyrylcholinesterase

Compared to AChE activity, butyrylcholinesterase (BuChE, E.C. 3.1.1.8) activity in skeletal muscles is significantly less (Table 35.1). Also, unlike variable AChE activity, all three

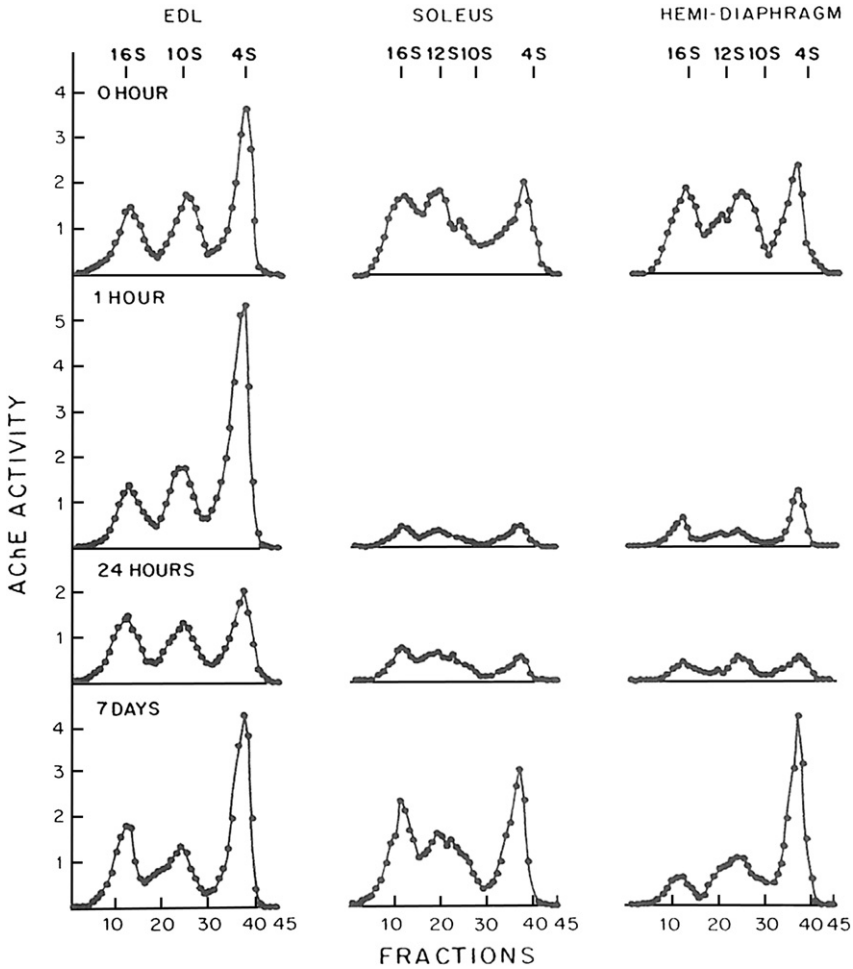

FIGURE 35.2. Representative profiles of the AChE molecular forms in EDL, soleus, and hemidiaphragm muscles from rats following an acute sublethal injection of sarin (110 µg/kg, s.c.). Profiles at the top of each column are from untreated muscles. Subsequent profiles are of the activity of the AChE molecular forms 1 h, 24 h, and 7 days, respectively, after sarin treatment. For further details, see legend to Figure 35.1.

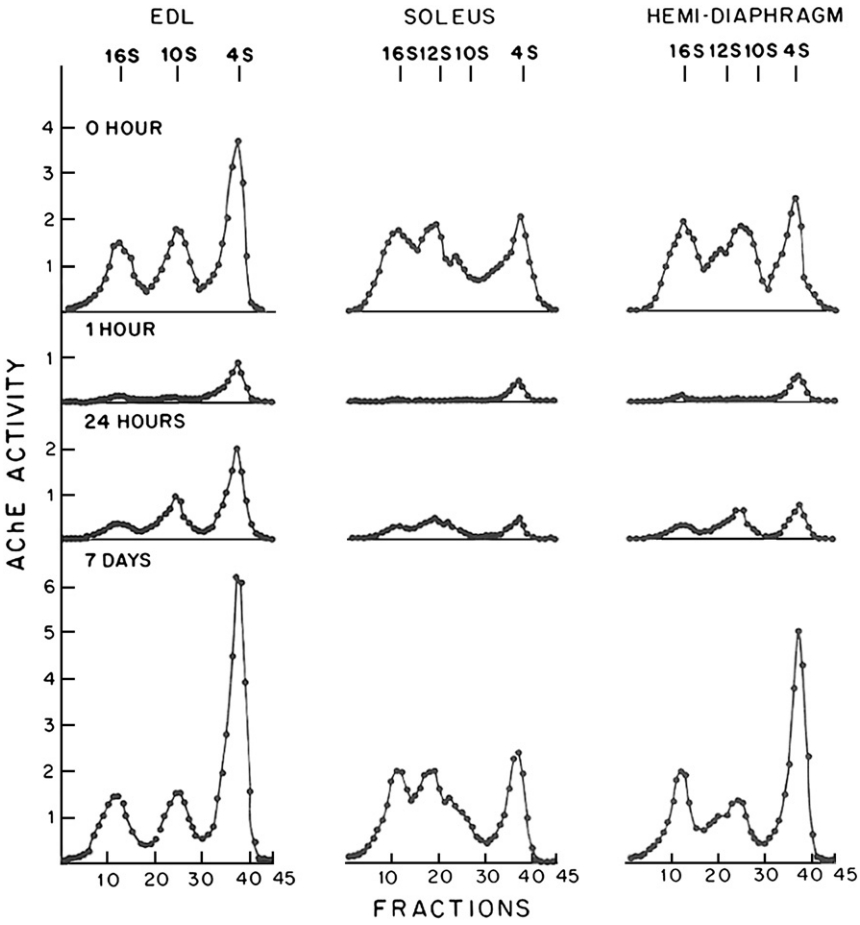

FIGURE 35.3. Representative profiles of the activity of the AChE molecular forms in EDL, soleus, and hemidiaphragm muscles from rats following an acute sublethal injection of VX (12 µg/kg, s.c.). For further details, see legend to Figure 35.1.

muscles (SOL, EDL, and diaphragm) contain equal levels of BuChE activity. Following soman administration (100 µg/kg, s.c.) in rats, BuChE activity in skeletal muscles was maximally inhibited only after 24 h. At this time, SOL was greatly affected (98%), followed by diaphragm (87%) and EDL (60%). A rapid recovery of BuChE was noticed during 48–72 h after soman treatment and the enzyme activity returned to the baseline values when measured after day 7 (Gupta *et al.*, 1987a).

Tabun (200 µg/kg, s.c.) caused significant inhibition of BuChE activity within 1 h in skeletal muscles (SOL, EDL, and diaphragm; 14%, 50%, and 35% remaining activity, respectively), but the maximal inhibition appeared after 3 h in SOL (6% remaining activity), and after 24 h in diaphragm and EDL (7 and 11% remaining activity, respectively) (Gupta *et al.*, 1987b). Unlike AChE, the recovery rate of BuChE appeared to be rapid, as the enzyme activity in diaphragm and EDL recovered to baseline values by day 7. At this time, SOL BuChE activity still remained significantly inhibited. After 1 h of sarin administration (110 µg/kg, s.c.), BuChE activity was significantly inhibited in SOL and EDL (78 and 79% remaining activity, respectively), but not in diaphragm. With sarin, maximal BuChE inhibition was noted after 24 h in SOL, EDL, and diaphragm (39, 71, and 43% remaining activity, respectively). In similar studies, within 1 h VX (12 µg/kg, s.c.) caused significant and maximal inhibition of BuChE in all three muscles (29, 60, and 60% remaining activity, respectively). When measured after 24 h, EDL and diaphragm showed marked recovery, while SOL still had 41% inhibition. All three muscles showed complete recovery of BuChE when measured after 7 days.

D. Choline Acetyltransferase

Existence of choline acetyltransferase (ChAT, acetyl-CoA-choline *O*-acetyltransferase, EC 2.3.1.6) in skeletal muscles is probably of neural origin, and its activity varies among skeletal muscles. ChAT activity can be altered by increased or decreased neuromuscular activity. It appears that neuromuscular activity exerts a regulatory influence on neuronal production of ChAT. Alterations in ChAT activity in response to variations in muscular activity represent changes in enzyme synthesis, although effects on catabolism of the enzyme or on exoplasmic transport of enzyme to the nerve terminal cannot be ruled out. Acute exposure to an OP compound DFP (1.5 mg/kg, s.c.) caused insignificant increase, while repeated administration at low dosage (0.5 mg/kg/day for 5 days) resulted in significant increase in ChAT activity (diaphragm 140%, EDL 150%, and SOL

156%). Significant increase in ChAT activity was noted even after 2 weeks of repeated administration.

E. Acetylcholine Receptors

Acetylcholine receptors (AChRs) are of two types: muscarinic (mAChR) and nicotinic (nAChR) based on the agonist activities of the natural alkaloids, muscarine and nicotine, respectively. These receptors are functionally different. The muscarinic type being G-protein coupled receptors mediate a slow metabolic response via second messenger cascades, while the nicotinic type are ligand-gated ion channels, which mediate a fast synaptic transmission of the neurotransmitter. Skeletal muscles are enriched with nAChRs and are devoid of mAChRs.

The nAChRs, with a molecular mass of 290 kDa, are composed of five receptor subunits (α, β, δ, ϵ, γ) arranged symmetrically around the central pore. Adult muscle is composed of $\alpha 2\beta\alpha\delta\gamma$, whereas fetal muscle has $\alpha 2\beta\delta\epsilon$ (Mishina *et al.*, 1986). Experimental studies of the late 1970s revealed that in relatively immature muscle cells, the AChRs are distributed uniformly over the entire sarcolemma (Bevan and Steinbach, 1977). At about the time of the initial innervation, aggregation/clusters of AChRs appear, in addition to the relatively low-density receptors (Braithwaite and Harris, 1979). During the course of embryonic development, the low-density receptors disappear and almost all AChRs in the adult muscle fibers are localized to the region of the NMJ (Fambrough, 1979). Sohal and Boydston (1982) suggested that neither the total receptor content nor the ability of the receptors to cluster seems an essential element for the formation and maintenance of the morphological aspects of the NMJs or for the growth and maturation of the muscle. It is yet to be established what exactly, if any, role nAChRs have in the formation of the NMJ.

At the mammalian NMJ, where nAChRs are localized, stimulation of the presynaptic nerve causes the release of the neurotransmitter ACh from the nerve terminals. Released ACh diffuses across the gap, separating nerve and muscle cells and interacts with specific receptors associated with the postsynaptic muscle membrane to produce increased membrane permeability to some cations. When two molecules of ACh bind to an nAChR, a conformational change occurs in the receptor, resulting in the formation of an ion pore. The nAChRs are a family of cationic channels whose opening is controlled by ACh and nAChR agonists and they are the key molecules in cholinergic nicotinic transmission at the NMJ. At this site, the opening of a pore produces a rapid increase in the cellular permeability of Na^+ and K^+ ions, resulting in the depolarization and excitation of the muscle cell, thereby producing a muscular contraction. A number of studies have shown that adult vertebrate muscle fibers are highly sensitive to ACh only in the region of the NMJ. Muscle fibers of fetal and neonatal rats are also sensitive to ACh in regions outside the NMJ.

It is established that excessive ACh or long-acting cholinomimetic agents can produce muscle paralysis due to prolonged depolarization of the endplate, a phenomenon referred to as depolarization block. Prolonged transmitter (ACh) receptor (nAChR) interactions, as a result of the high concentrations of accumulated ACh, produce a depolarization block, similar to that seen with agents such as decamethonium. Furthermore, there is a possibility of the same post-junctional area being activated repeatedly, resulting in desensitization of receptors (desensitization block). These forms of neuromuscular block usually produce muscle weakness and paralysis.

The binding site for cholinergic effectors is believed to reside primarily in the α-subunits. Evidence for this fact is based on affinity labeling experiments in which analogs of ACh (bromoacetylcholine and 4-(-*N*-maleimidophenyl) trimethylammonium) have been shown to label only the α-subunits. Receptors also demonstrate high-affinity binding of the polypeptide α-neurotoxins, such as α-bungarotoxin (αBT), which interacts specifically and in an essentially irreversible manner with nAChRs. At the nAChRs, αBT competes for binding with both cholinergic agonists (e.g. carbamylcholine chloride and decamethonium bromide) and antagonists (e.g. curare) (Karlin, 1980). Berg *et al.* (1972) reported binding of αBT to AChRs in rat diaphragm muscle and found that 90% of the binding that occurred was ''endplate-specific''.

Toxicity of OP nerve agents and pesticides is primarily due to inhibition of AChE, but some of the effects are unrelated to this mechanism. The exact mechanism by which OP nerve agents and other anti-AChE compounds affect nAChRs is yet to be elucidated. Some of the biochemical and morphological alterations have been attributed to an excess amount of ACh in the synaptic cleft resulting from AChE inactivation (Roberts and Thesleff, 1969; Chang *et al.*, 1973; Kawabuchi *et al.*, 1976). Many anti-AChE agents have been shown to produce postsynaptic morphological, biochemical, and electrophysiological alterations in adult mammalian skeletal muscle after acute and long- term treatment (Fenichel *et al.*, 1972; Laskowski *et al.*, 1977; Hudson *et al.*, 1978; Kawabuchi *et al.*, 1976). Normally, at the motor endplate, the small electrical nerve impulse releases the chemical transmitter ACh which diffuses across the synaptic membrane and attaches to the postsynaptic receptors on the muscle membrane. But during AChE inhibition by OPs and CMs, unhydrolyzed ACh does not diffuse from the cleft, but repeatedly combines with post-synaptic receptors. The prolonged presence of ACh in the synaptic area appears to cause some of the myopathic changes. This was supported by observations of paraoxon causing antidromic firing and increasing spontaneous miniature endplate potential frequency to 38 times control rates (Laskowski and Dettbarn, 1971).

In an early study, Gupta *et al.* (1986) demonstrated that an acute exposure to DFP (1.5 mg/kg, s.c.) changed neither nAChR density (Bmax) nor the affinity constant (K_D) in the

diaphragm muscle. Subchronic DFP treatment (0.5 mg/kg/day, s.c. for 5 days) caused marked decrease in the B_{max} (56%), without significant change in K_D. Chronic treatment with anti-AChEs reduced the total number of nAChRs in the range 42–45% in the endplate region (Chang *et al.*, 1973; Noble *et al.*, 1979). Later studies revealed that in sublethal doses, OPs induce symptoms which cannot be solely attributed to AChE inhibition, indicating a direct interaction with postsynaptic nAChRs (Menking *et al.*, 1990). Tattersall (1990) investigated the effects of DFP, sarin, soman, VX, and ecothiophate on the nAChR ion channel at the adult mouse muscle endplate by using single channel recording techniques. DFP, sarin, and soman had no effect on open times at concentrations up to 100 µM, but ecothiophate and VX were found to have voltage- and concentration-dependent open-channel-blocking actions at concentrations of 1–50 µM. In similar experiments, Bakry *et al.* (1988) examined direct actions of OP anti-ChEs on nAChRs. These authors found that OP nerve agents and ecothiophate bind to AChRs, inhibit or modulate binding of radioactive ligands to these receptors, and modify events regulated by them. The OP anti-ChEs also bound to allosteric sites on the nAChR (identified by inhibition of ^{3}H-phencyclidine bonding), but some bound also to the receptor's recognition site (identified by inhibition of ^{125}I-αBT binding). Soman and ecothiophate in micromolar concentrations acted as partial agonists of the nAChR and induced receptor desensitization. On the other hand, VX acted as an open channel blocker of the activated receptor and also enhanced receptor desensitization. Membrane fragments from Torpedo electric organs were used to determine these interactions using ^{3}H-phencyclidine as a probe. The results were consistent with the hypothesis that OPs bind to, and irreversibly phosphorylate, an allosteric site on the ion channel associated with the nAChR.

In the context of OP toxicities, it needs to be emphasized that for a normal muscle contraction, the ratio of AChE to nAChRs is crucial in determining the minimum AChR density. Since the AChE recovers at almost the same rate as do the AChRs, a balance of AChE to AChR is maintained over the postsynaptic surface during recovery. A relatively constant ratio of AChE to AChR is very important for maintaining normal neuromuscular function.

IV. NONCHOLINERGIC SYSTEM

A. Muscle Excitotoxicity

Involvement of the cholinergic neurotransmitter ACh in muscle excitotoxicity has been known for a long time. Waerhaug and Ottersen (1993), by using quantitative electron immunocytochemistry, demonstrated the glutamate-like immunoreactivity at rat NMJ, and it was suggested that glutamate and ACh are co-released at the NMJ. Glutamate might be a mediator or modulator of neuromuscular transmission. It has also been established that glutamate receptors present at the NMJ are predominantly an *N*-methyl-D-aspartate (NMDA) subtype. In an early study, Koyuncuoglu *et al.* (1998) demonstrated that the blockade of NMDA receptors, the inhibition of glutamate release, or the suppression of glutamate production, attenuates the contractions of the rat-isolated hemidiaphragms elicited by indirect electrical stimulation. Furthermore, it has also been demonstrated in *in vivo* studies that the noncompetitive NMDA receptor antagonist, memantine, blocks the AChE inhibitors (DFP, soman, sarin, tabun, and VX)-induced muscle fasciculations, suggesting an involvement of NMDA receptors (Gupta and Dettbarn, 1992; McLean *et al.*, 1992). Of course, memantine also exerts several other pharmacological actions, including nicotinic ACh receptor blockage. Unlike the well-understood role of cholinergic excitotoxicity, the role of glutamate excitotoxicity is yet to be established in AChE inhibitor-induced muscle toxicity.

B. Oxidative/Nitrosative Stress

Although the exact mechanism underlying skeletal muscle damage by OP nerve agent-induced hyperactivity still remains unclear, mounting evidence indicates that free radicals play an important role. During normal conditions, free radicals are generated at a low rate and subsequently taken care of by the well-developed scavenger and antioxidant systems. However, during exhaustive hyperactivity of the skeletal muscles caused by anti-ChE, excessive amounts of reactive oxygen species (ROS) and reactive nitrogen species (RNS) (hereafter referred to as ROS) are generated and exceed the capacity of the muscle defense system, thus producing oxidative stress. Excessively generated ROS can cause muscle injury by reacting with cellular components, such as membrane phospholipids, mitochondrial enzymes/proteins and nucleic acids. Consequently, this leads to skeletal muscle cell apoptosis/necrosis, inflammation, and loss of cell viability.

It appears that a causal relationship exists between excitotoxicity, ROS, lipid peroxidation, and muscle cell injury/death. One of the well-recognized targets of ROS-induced injury is peroxidation of lipids and the formation of prostaglandin F_2-like compounds, such as F_2-isoprostanes (F_2-IsoPs). A number of studies have shown that the assay of these compounds provides an accurate measure of lipid peroxidation both *in vitro* and *in vivo* (Morrow *et al.*, 1992; Roberts and Morrow, 2000; Dettbarn *et al.*, 2001). Quantification of F_2-IsoPs and nitric oxide (NO) in skeletal muscles (SOL, EDL, and diaphragm) has provided strong evidence that AChE inhibitor-induced toxicity initiates lipid peroxidation and muscle cell injury (Dettbarn *et al.*, 2001; Gupta *et al.*, 2001a, b; Milatovic *et al.*, 2001). In an earlier study, Yang and Dettbarn (1998) reported a significant increase of F_2-IsoPs in diaphragm muscle (156%) 1 h after DFP injection (1.7 mg/kg, s.c.), at the time when muscle hyperactivity was maximal.

The primary reason for the increased generation of ROS appears to be the decreased rate of ATP synthesis in the mitochondria, which is related to a loss of cytochrome oxidase (COX) activity. COX is the terminal complex in the mitochondrial respiratory chain, which generates ATP by oxidative phosphorylation. During intense muscle hyperactivity, the activity of COX is reduced, leading to an increase in the electron pressure within the electron transport chain and to increased ROS production (Soussi *et al.*, 1989; Gollinick *et al.*, 1990; Yang and Dettbarn, 1998; Zivin *et al.*, 1999). More than 90% of the O_2 consumption in the cells is catalyzed by COX. The chance of intermediary products, such as superoxide anion, hydrogen peroxide, and the hydroxyl radical, escaping is small under conditions where COX remains active. A reduced capacity of this enzyme, however, increases the risk for an incomplete reduction of O_2 and further O_2 radical formation (Sjodin *et al.*, 1990).

Another enzyme contributing to increased ROS generation is xanthine oxidase (XO). During normal conditions, 80–90% of native XO exists as xanthine dehydrogenase (XD), but during metabolic stress and increased Ca^{2+}, XD is converted to a reversible oxidase form. XO uses molecular O_2 instead of NAD^+ as an electron acceptor. Molecular O_2 is thereby reduced and the superoxide radical (O_2^-) is formed. During hyperactivity of the muscle by AChE inhibitors, regeneration of ATP is insufficient, not due to the lack of O_2, but due to greater utilization and impaired synthesis of ATP (Gupta *et al.*, 1994, 2000a, b, 2001a, 2002). Unlike ischemia, O_2 is present during oxidative stress caused by prolonged contractile activity. This suggests that subsequent to the conversion of XD to XO, O_2 is continuously univalently reduced to superoxide anions. This occurs during oxidative stress when ATP utilization exceeds the rate of ATP synthesis during increased muscle activity (Gollinick *et al.*, 1990). Yang and Dettbarn (1998) provided direct evidence for the role of COX and XO in muscle injury by its hyperactivity, showing that during DFP-induced muscle hyperactivity, a decrease in COX activity and an increase in XO activity occurred. Blockage of muscle fasciculations provided prevention of these enzyme changes.

Another ROS contributing to oxidative stress is peroxynitrite ($ONOO^-$), which is formed by the reaction of nitric oxide (NO) with superoxide (O_2^-) (Huie and Padmaja, 1993). $ONOO^-$ has the potential to modify biomolecules through several different mechanisms, and is a good candidate for mediation of the NO-dependent pathophysiological process (Brunelli *et al.*, 1995). Under normal conditions, NO, which is a free radical gas (synthesized in a reaction catalyzed by NO synthase), is widely regarded as a multifunctional messenger/signaling molecule, and is thought to have two physiological functions in skeletal muscle. One, to promote relaxation through the cGMP pathway (Schmidt *et al.*, 1993), and two, to modulate muscle contractility that is dependent on reactive oxygen intermediates (Abramson and Salama, 1989). At the NMJ, NO appears to be a mediator of: (1) early synaptic protein clustering, (2) synaptic receptor activity and transmitter release, and (3) downstream signaling for transcriptional control (Blottner and Luck, 2001). NO has also been demonstrated to modulate excitation–contraction coupling in the diaphragm muscle (Reid *et al.*, 1998). Within skeletal muscle cells, all three known NO synthase (NOS) isoforms (neuronal, nNOS; endothelial, e-NOS; and inducible, iNOS) are present, but nNOS, which is Ca^{2+} dependent, seems to predominate, and is concentrated at the sarcolemma and postsynaptic surface of the NMJ (Silvango *et al.*, 1996; Stamler and Meissner, 2001; Wang *et al.*, 2001). In a recent study, NOS has been demonstrated to play the role of mechanosensor in skeletal muscle fibers (Smith *et al.*, 2002). Neuronal NOS in skeletal muscles is involved in the regulation of metabolism and muscle contractility (Stamler and Meissner, 2001). Kobzik *et al.* (1994) reported for the first time that the NOS activity of individual muscles could be correlated primarily with type II fibers (being highest in the EDL), while Grozdanovic *et al.* (1995) and Frandsen *et al.* (1996) found the distribution of nNOS homogeneous.

Data presented in Table 35.3 show the levels of citrulline (determinant of NO/NOS) in skeletal muscles of control rats and those treated with an acute dose of DFP (1.5 mg/kg, s.c.). Analyses of control muscles revealed markedly higher citrulline levels in the soleus, followed by the EDL and diaphragm. The observed higher level of NO in the soleus could be due to a greater activity of NOS. Within 1 h of DFP exposure, when rats exhibited signs of peak severity and maximal reduction of AChE activity (90–96%), the levels of citrulline were maximally increased (272–288%), and remained significantly elevated in all three muscles (>twofold) when measured after 2 h. The finding of elevated NO by DFP-induced muscle hyperactivity (Gupta *et al.*, 2002) was supported by previous studies that increased muscle contractility generates significantly greater quantities of ROS/RNS (Yang and Dettbarn, 1996; Narayan *et al.*, 1997; Clanton *et al.*, 1999). A significant increase in NO is known to cause inhibition of mitochondrial function and thereby appears to be the cause of the impaired synthesis of ATP.

TABLE 35.3. Citrulline levels (nmol/g) in skeletal muscles of rats after 1 h of DFP (1.5 mg/kg, s.c.) injection

Treatment	Soleus	EDL	Diaphragm
Control	451.2 ± 5.3 (100%)	381.3 ± 8.2 (100%)	331.2 ± 9.9 (100%)
DFP	1227.1 ± 47.2^a (272%)	1061.0 ± 38.9^a (278%)	952.3 ± 49.8^a (288%)

Values are means ± SEM ($n = 4$–5). [a]Significant difference between control and DFP-treated rats ($p < 0.05$)

C. High-Energy Phosphates Depletion and Myonecrosis

In the recent past, interest in the role of energy metabolites (especially ATP) in chemical-induced mitochondrial/cytotoxicity has been reinvigorated, since ATP appears to be a switch to decide whether cells die from apoptosis or necrosis. Muscle necrosis is probably caused by increased contractile activity in individual muscle fibers. In normal cells, the mitochondrial Ca^{2+} content is relatively low compared to that in the cytoplasm. However, abnormally high cytosolic Ca^{2+} levels (due to NMDA receptor activation and impaired Ca^{2+} extrusion which is an energy-dependent process) perturb many cellular processes. The major changes include: (1) reduced cytochrome-c oxidase activity, (2) increased xanthine oxidase activity, (3) mitochondrial damage due to excessive mitochondrial Ca^{2+} accumulation, (4) reduced ATP synthesis, and (5) increased production of O_2^- and NO^-, resulting in increased $OONO^-$ formation. The extreme vesiculation and disruption of the sarcoplasmic reticulum (SR) under the endplate as well as the swollen mitochondria may reflect Ca^{2+} overloading of the muscle Ca^{2+}-binding capacity, which could result in high sarcoplasmic Ca^{2+} levels leading to the necrosis (Salpeter *et al.*, 1979, 1982). The control of intracellular Ca^{2+} concentration is of great importance to muscle fibers and a transient rise leads to contraction. An increased net influence of Ca^{2+} forces the mitochondria and SR to maintain Ca^{2+} homeostasis by sequestering the excessive amounts of this ion. This is an energy consuming process and occurs in preference to ATP formation. The ensuing lack of energy ultimately causes the free sarcoplasmic Ca^{2+} to rise and excessive ROS formation, leading to necrosis. The energy required for muscle contraction is derived from the breakdown of ATP. As soon as ATP is broken down, it is promptly restored in the so-called ''Lohman reaction'' at the expense of phosphocreatine (PCr).

Data presented in Table 35.4 show the levels of high-energy phosphates (ATP and PCr) and their metabolites in skeletal muscles of control rats and those treated with an acute dose of DFP (1.5 mg/kg, s.c.). Analyses of control muscles revealed the levels of ATP and PCr to be higher in the EDL, followed by the diaphragm and the soleus. The values of energy charge potential (ECP = ATP + 0.5ADP/TAN) in soleus, EDL, and diaphragm were $0.86 \pm < 0.01$, $0.91 \pm < 0.01$, and $0.86 \pm < 0.01$, respectively. At the time of maximal severity, i.e. 1 h after DFP exposure, the levels of ATP, total adenine nucleotides (TAN = ATP + ADP + AMP), PCr, and total creatine compounds (TCC = PCr + Cr) were maximally reduced in all three muscles, and remained reduced to the same degree when determined after 2 h. Similar results were found with soman toxicity.

AChE inhibitors cause depletion of energy-rich phosphates (ATP and PCr) due to a combination of impaired synthesis and greater utilization of ATP during muscle hyperactivity. In fact, the time course of necrosis correlates with the reduced levels of PCr, the reduction of which may have been the result of an increased demand for energy and a low rate of ADP phosphorylation, caused by an increased level of sarcoplasmic Ca^{2+}. AChE inhibitor-induced increases in NO (Table 35.3) can exert cellular toxicity primarily by depleting energy stores through multiple mechanisms: (1) by prolonging poly-(ADP-ribose) polymerase activation, (2) by inhibiting mitochondrial enzymes, such as COX, aconitase, creatine kinase, and (3) by

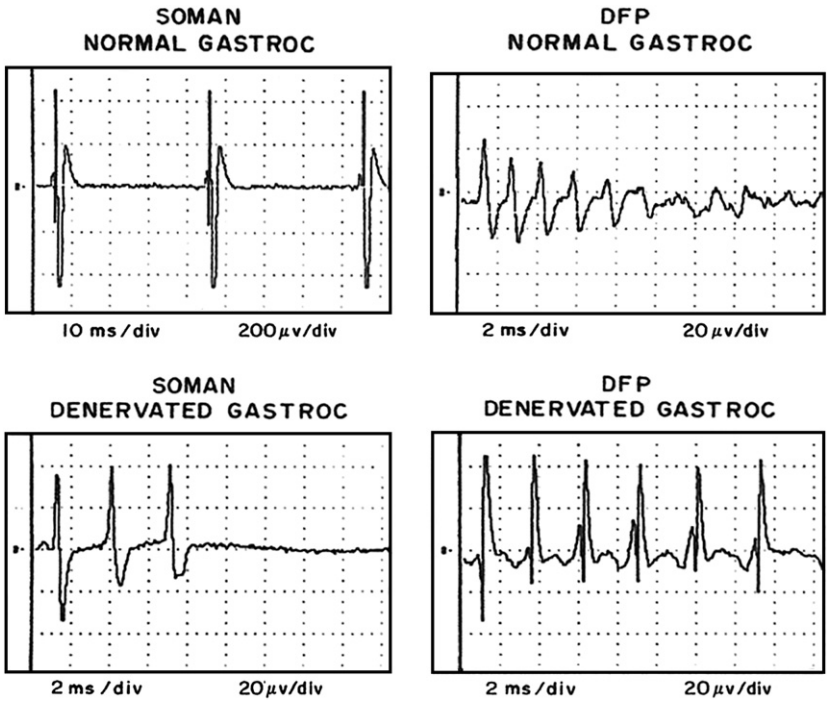

FIGURE 35.4. Electromyographic recordings from normal and acutely denervated lateral gastrocnemius in response to soman (100 μg/kg, s.c.) or DFP (1.5 mg/kg, s.c.). Left, soman; right, DFP; top, nondenervated muscle; bottom, denervated muscle. Note the difference in time base and voltage scale. The differing morphology of the normal DFP waveform is due to electrode orientation and distance from the muscle fiber and does not represent a systematic difference between the effects of individual agents.

inhibiting the glycolytic enzyme phosphofructokinase. NO, at nanomolar concentrations, can directly and specifically inhibit mitochondrial respiration by competing with molecular O_2 for binding to COX, thereby causing inhibition of ATP synthesis (Brown and Cooper, 1994; Giulivi, 1998). Other factors which contribute to the decline of energy metabolites may include damage to mitochondria, a higher rate of ATP utilization needed to generate NAD^+ in the ADP-ribosylation of nuclear proteins, enhanced influx of sarcoplasmic Ca^{2+}, and an increased number of contractile protein cross-bridges, in addition to the release of ATP in concert with ACh from the nerve terminals. The net effect of AChE inhibitor-induced muscle hyperactivity is a reduced cellular energy level.

V. MUSCLE ACTIVITY – EMG

AChE inhibitors (DFP, 1.5 mg/kg, s.c. or soman, 100 μg/kg, s.c.) at a toxic signs-producing sublethal dose elicit prominent motor, behavioral, and autonomic symptoms. As mentioned earlier, the motor symptoms are fasciculations, fibrillations, and body tremors. Fasciculations and fibrillations are due to antidromic neural discharge from excess junctional ACh, while tremors are of central origin. Misulis *et al.* (1987) observed a difference in the pattern of motor symptoms in rats treated with soman or DFP. Soman produces complex posturing movements and tremors affecting virtually the entire body, while DFP produces movements that are similar to fasciculations or myokymia. Muscle fiber necrosis is also more frequent at symptom-producing doses of DFP than equivalent doses of soman. This suggests that the AChE inhibitors differ in their propensity to produce central or peripheral effects and that peripheral effects are required for muscle necrosis.

Electromyographic (EMG) findings indicate that soman and DFP produce different responses (Figure 35.4). The majority of the motor symptoms induced by soman are due to impulses descending from the CNS, and a proportion of these symptoms are epileptiform activity. This activity is not generated at spinal levels. In contrast, DFP produces motor symptoms mainly by peripheral action that is dependent on a functioning nerve terminal (Misulis *et al.*, 1987). Anderson (1987) also demonstrated that DFP and soman have opposite effects on skeletal muscle contracture during tetanic stimulation. DFP significantly decreased the ability of rat skeletal muscle to maintain a contracture. Soman, on the other hand, increased muscle force in a frequency-dependent manner. The opposite actions of DFP and soman on muscle contractility might be the consequence of a difference in effects of these two agents on postsynaptic muscle ACh receptors. The finding of Anderson (1987), i.e. increase in contracture following soman, was somewhat surprising in view of the work of Dettbarn (1984) and Gupta *et al.* (1987a, b), who reported that soman is as effective as other AChE inhibitors in producing muscle necrosis (Table 35.6). However, Meshul *et al.* (1985) reported that soman appears to spare motor endplates from structural damage and thereby may account for maintaining muscle function (Anderson, 1987). In essence, different AChE inhibitors can produce opposite effects on muscle contracture.

VI. MUSCLE FIBER HISTOPATHOLOGY

By using actomyosin ATPase reaction, analysis of untreated rat slow muscle soleus (SOL) revealed predominantly type 1 fibers with a few type 2A and 2B fibers. In contrast, the fast muscle EDL is composed predominantly of type 2 fibers with few type 1 fibers. Total fiber numbers are approximately 1,800 in SOL and 2,500 in EDL (Gupta *et al.*, 1989).

It is well established that OP pesticides and nerve agents and some carbamates in a single sublethal dose are sufficient to cause muscle fasciculations, and induce myopathy (histopathological changes) in the diaphragm, soleus, EDL, sternomastoid, gastrocnemius, triceps, and tibialis muscles of experimental animals. Pathological changes in skeletal muscles by AChE inhibitors are observed in the region adjacent to the motor endplate. Patterson *et al.* (1987) determined the necrotic lesions by assessing endplates in skeletal muscles of rats acutely intoxicated with DFP (1.5 mg/kg, s.c.). In SOL, these are only found in the midsection of the muscle, while in EDL the endplates are found throughout the muscle length. In EDL, the fibers are innervated at different levels throughout the length of the muscle, while in SOL the nerve makes functional contact in the midsection only. No endplates or lesions are found outside this area.

Gupta *et al.* (1985, 1986) found the highest number of lesions in all three muscles (diaphragm, SOL, and EDL) of rats within 24 to 48 h after a single injection of DFP (1.5 mg/kg, s.c.), when the inhibitory effect on AChE activity was also maximal (Table 35.5). The diaphragm muscle had the highest number of lesions, followed by the EDL and SOL.

Data on soman (100 µg/kg), sarin (110 µg/kg), tabun (200 µg/kg), and VX (12 µg/kg) are presented in Table 35.6. Following soman treatment, the numbers of necrotic fibers in the SOL and the diaphragm were found to increase up to 24 h and no new lesions appeared subsequently. By day 7, these two muscles appeared to have fully recovered from the soman effect, since no necrotic fibers were seen. In EDL, no morphological changes were seen at any time. While the acute toxic effects of tabun are more or less similar to soman, there are also some significant differences between these two agents. Unlike soman, tabun caused prolonged AChE inhibition and progressive development of muscle necrosis over a period of 3 days. While the primary toxic effect of tabun is due to inhibition of AChE activity, some of the differences seen in regard to other nerve agents may be due to additional actions of the cyanide group that is released during AChE inhibition. Effects such as prolonged inhibition of AChE and increasing number of lesions seen up to the third day may be due to the leaving acidic group CN. The inhibitory effect of CN on oxidative metabolism could result in reduced *de novo* synthesis, delaying synthesis of AChE and prolonged inhibition of Ca^{2+} sequestration into the sarcoplasmic reticulum of skeletal muscles. Therefore, in the context of OP nerve agent-induced myopathy, soman, sarin, tabun, or VX caused the greatest number of lesions in diaphragm, followed by SOL, and least in the EDL during 24 to 48 h (Gupta *et al.*, 1987a, b, 1991). With all four nerve agents, the greatest number of lesions occurred in animals exhibiting severe muscle fasciculations (Gupta *et al.*, 1986, 1987a, b, 1991; Inns *et al.*, 1990; Bright *et al.*, 1991). These authors also demonstrated that by day 7, muscles recovered from soman-induced myopathy but not from any other nerve agents since the necrotic lesions were still evident.

The earliest lesions are focal areas of abnormality in the subjunctional section of the muscle fiber adjacent to the motor endplate including eosinophilia and sarcoplasmic swelling (Laskowski *et al.*, 1977; Gupta *et al.*, 1985, 1986; Patterson *et al.*, 1987). Mitochondria are disrupted as evidenced by clumping of highly reactive material of the lactate dehydrogenase (LDH) and reduced nicotinamide adenine dinucleotide (NADH) reactions. These focal changes progress to a breakdown of subjunctional fiber architecture, loss of striations, followed by phagocytosis. Longitudinal sections reveal that the necrosis affects only a small segment of fiber lengths. During latter stages, progressively greater lengths of muscle fibers are affected

TABLE 35.5. Number of necrotic fibers following a single sublethal injection of DFP (1.5 mg/kg, s.c.)

Time after DFP administration	Soleus		EDL		Diaphragm	
	AChE	Lesions	AChE	Lesions	AChE	Lesions
Control	100%	0	100%	0	100%	0

Value are means ± SEM of necrotic lesions (n=5)

(Gupta *et al.*, 1986; Patterson *et al.*, 1987). Serial cross-sections of 10 µm thickness indicate that the number of lesions correlates with the greatest density of endplates (Patterson *et al.*, 1987). The longer the delay between injection and sacrifice, the greater the special extent of the lesions. A significant increase in blood creatine kinase (CK) activity coincides with appearance of myonecrosis, indicating destruction of the muscle membrane (Sket *et al.*, 1989; Gupta *et al.*, 1991, 1994).

Subjunctional changes in the muscle fibers, such as super-contraction of subjunctional sarcomeres, as well as disruption of cytoarchitectural organization, are always present (Gupta *et al.*, 1986, 1987a, b, 1991; Inns *et al.*, 1990; Bright *et al.*, 1991). The initial changes are in the mitochondria which first swell and then show lysis of the central cristae. Myelin figures beneath the endplate are frequently observed while the region more distal to the endplate is less affected. The nucleoli of the muscle cell nuclei are enlarged and move to the periphery of the nucleus. This myopathy can be induced with OP prototype compound DFP (Leonard and Salpeter, 1979; Gupta *et al.*, 1986; Misulis *et al.*, 1987; Patterson *et al.*, 1987, 1988; Sket *et al.*, 1991a, b), or OP nerve agents soman, sarin, tabun, and VX (Gupta *et al.*, 1987a, b, 1991; Inns *et al.*, 1990; Gupta and Dettbarn, 1992).

Laskowski *et al.* (1975) reported the ultrastructural changes in the subsynaptic folds that were quite varied even between muscle fibers from the same diaphragm of rats acutely treated with paraoxon. The fact that some endplates were totally degenerated after 2 days of paraoxon treatment while others appeared almost normal even after 5 days indicates that some endplates are more resistant than others. The most consistent change at the endplates was the presence of vesicular structures in the synaptic clefts. Some regions of the subsynaptic folds contained varying sizes of vacuoles and vesicles. There appears to be a wide variation in the severity of the lesions in the subsynaptic folds even in the same muscle. After 2 days of paraoxon treatment, the muscle surrounding the motor endplate often showed less cytoarchitectural organization than control muscles. Myelin figures beneath the endplate were frequently observed, while the region of muscle distal to the endplate was less severely affected.

Despite the diversity of structures of chemicals described above, the induced myopathic changes are the same, suggesting involvement of a common mechanism. This mechanism is inhibition of AChE. From several studies, it is evident that OP-induced myopathy is dose dependent and depends on both a critical duration and degree of enzyme inhibition. It has been demonstrated that the faster the rate of AChE inactivation, the higher the number of necrotic lesions found indicating a correlation between AChE inhibition and the number of necrotic fibers, thus supporting the role of ACh in the generation of myopathy (Wecker *et al.*, 1978a, b; Gupta *et al.*, 1986, 1987a, b, 1991). Muscle fiber necrosis depends on a rapid, critical reduction and duration of suppressed AChE activity. Regardless of the inhibitor involved, AChE inhibition >80% for about 2 h is necessary to initiate severe muscle fiber necrosis. AChE inhibition resulting in an excess of acetylcholine (ACh) and its prolonged functional

interactions with the ACh receptors is responsible for producing lesions. However, some anti-ChEs have been shown to interact directly with the nicotinic receptors (Tattersall, 1992). The OP compounds acting directly on postsynaptic membranes or on components of the muscle cell were also considered in the etiology of myopathy (Laskowski and Dettbarn, 1971). However, the finding that prior injection of either tubocurarine or α-bungarotoxin (Koelle and Gilman, 1949; Salpeter *et al.*, 1979) prevented the development of the myopathy proved conclusively that neither the OP agent *per se* nor ACh by itself caused the damage, but that the damage was the result of changes that followed transmitter–receptor interaction. Tubocurarine and alpha-bungarotoxin, by occupying the post-junctional receptors, prevent the ACh from interacting with the receptor. Furthermore, studies have shown that increased ACh may be an important trophic neurotransmitter involved in the pathophysiology of myopathy. The primary defect is at both presynaptic and postsynaptic sites. This not only supports the concept of an abnormal neurotrophism as a mechanism of myopathy but also allows the possibility that the primary defect is in the cholinergic system of nerve and muscle.

There is ample evidence that ACh accumulation is involved in causing Ca^{2+} influx into skeletal muscle fibers during anti-ChE poisoning. Evidence for the involvement of locally elevated levels of ACh was further confirmed since denervation prevented myopathy (Ariens *et al.*, 1969; Fenichel *et al.*, 1972; Wecker and Dettbarn, 1976; Dettbarn, 1984) or nicotinic ACh receptor blockade with alpha-bungarotoxin (Leonard and Salpeter, 1979). Wecker and Dettbarn (1976) clearly demonstrated that transection of the phrenic nerve to the rat hemidiaphragm prevented myopathic development, while in the contralateral innervated hemidiaphragm the number of lesions was increased. Thus, the common denominator is muscle hyperactivity, such as fasciculations (Gupta *et al.*, 1986, 1987a, b, 1991; Adler *et al.*, 1992). In similar experiments, Fenichel *et al.* (1972) observed that the number of lesions produced by paraoxon in rat soleus, gastrocnemius, and quadriceps muscles were greatly reduced by prior sciatic nerve section or by prior administration of hemicholinium. In addition to inhibition of AChE activity, paraoxon produced a rapid transient increase in ACh release from motor nerve terminals in the rat diaphragm (Laskowski *et al.*, 1977).

Accumulation of ACh in the nerve terminal stresses the metabolic capacity of the muscle, initially enhancing muscle contraction, but then surpassing the ability of the muscle to maintain functional and structural integrity (Salpeter *et al.*, 1979; Dettbarn, 1984; Gupta *et al.*, 1986; Gupta and Dettbarn, 1987). The longer the muscle hyperactivity lasts, the greater the number of necrotic muscle fibers found (Dettbarn, 1984; Gupta *et al.*, 1985, 1986, 1987a, b).

In the context of OP-induced myopathy, the role of Ca^{2+} as a cell death trigger is very important. *In vitro* experiments with the nonhydrolyzable cholinergic agonist carbamylcholine produce similar alterations to those observed with the AChE inhibitors *in vivo*. In these experiments, excessive Ca^{2+} influx was thought to contribute to the myopathy (Leonard and Salpeter, 1979, 1982). The increased rate of postsynaptic stimulation that accompanies fasciculations and the concomitant influx of Ca^{2+} may initiate the changes in subjunctional mitochondrial morphology. These authors found that both alpha-bungarotoxin and Ca^{2+} depletion prevented DFP-induced myopathy in a nerve–muscle preparation *in vitro.* The swelling of mitochondria with a parallel release of sequestered Ca^{2+} thus evokes contraction of subjunctional sarcomeres and leads to subjunctional fiber damage. *In vivo* experiments in mice with sarin (25–150 μg/kg, s.c.) also revealed a similar role of Ca^{2+} in muscle fiber damage (Inns *et al.*, 1990). Ca^{2+} was found in the diaphragm of those mice to which sarin had been administered at doses of 50 μg/kg or above. Calcium accumulation, which was confined to the region of the motor endplates, occurred earliest and remained the longest in the diaphragm from those animals receiving the highest doses of sarin. Generally, Ca^{2+} accumulation can be detected on day 1 after injection and none after day 7. This observation coincides with the duration of appearance and disappearance of muscle lesions. These authors suggested that Ca^{2+} is among a series of events which ultimately lead to myonecrosis. Mitochondrial damage by excessive Ca^{2+} is expected to cause a partial or complete depletion of ATP synthesis and consequently excessive generation of oxygen- and nitrogen-free radicals and eventually myotoxicity (Gupta and Dettbarn, 1987, 1992; Gupta *et al.*, 2001a, b, 2002). In conclusion, following an acute exposure to an OP compound at a higher dose, a causal relationship exists between a critical level of AChE inhibition, Ca^{2+} accumulation, and appearance of muscle fiber necrosis.

Chronic exposure (30–60 days) of rats to paraoxon, at doses (0.05–0.1 mg/kg, s.c./day) that do not produce parasympathomimetic effects, led to necrosis of muscle fibers in diaphragm muscle which was qualitatively similar to that following the administration of a single high dose of paraoxon (0.23 mg/kg, s.c.). The lesion was characterized by the presence of central nuclei, fiber splitting, and breakdown of fiber architecture followed by phagocytosis and necrosis. With either dose, AChE inhibition occurred in the endplate regions and not in the nonendplate regions (Wecker and Stouse, 1985).

VII. MUSCLE CYTOTOXICITY BIOMARKERS

A. Creatine Kinase (CK) and CK Isoenzymes

CK catalyzes the synthesis of ATP and PCr in a reversible Lohmann reaction. Data presented in Table 35.7 show the normal distribution of CK and its isoenzymes in skeletal muscles of untreated control rats. The findings revealed that the fast muscle EDL had the maximal CK activity, followed

TABLE 35.7. Normal distribution of CK and CK isoenzymes in skeletal muscles and serum of rats

	Total CK	CK isoenzymes		
		CK-BB (CK-1)	CK-MB (CK-2)	CK-MM (CK-3)
Soleus	2,062,800 ± 71,065 (100)	ND	ND	2,062,800 ± 71,065 (100)
EDL	4,659,125 ± 185,583 (100)[a,b]	ND	ND	4,659,125 ± 185,583 (100)[a,b]
Diaphragm	3,018,240 ± 110,777 (100)	ND	ND	3,018,240 ± 110,777 (100)
Serum	3,769 ± 240 (100)	576 ± 45 (15.3)	148 ± 17 (3.9)	3,086 ± 209(80.8)

Values expressed in terms of IU/L are presented as means ± SEM ($n = 4$–6)
Numbers in parentheses are percentages of isoenzymes to total CK activity (100%)
ND – none detected

[b]Significant difference between EDL and diaphragm ($p < 0.001$)

by diaphragm, with the lowest in the soleus. Electrophoretic separation of CK isoenzymes in all three muscles revealed the existence of only CK-MM isoenzyme. Further separation of CK-MM isoenzyme for subforms showed only CK-MM3 in all three muscles. Compared to muscles, serum had very little CK activity; however, the CK consisted of three distinct isoenzymes: CK-BB (15.3%), CK-MB (3.9%), and CK-MM (81.8%). Further electrophoresis of serum CK-MM isoenzyme revealed the presence of three subforms: CK-MM1 (6.3%), CK-MM2 (24%), and CK-MM3 (69.7%) (Gupta *et al.*, 1994). Literature abounds showing that the CK-MM3 subform secretes from muscles into the plasma, where it converts into the MM2 and MM1 subforms by carboxypeptidase-N2.

Within 1 h of exposure to carbofuran (1.5 mg/kg, s.c.), CK activity was significantly reduced in soleus, while increased in diaphragm. At the same time, activities of CK and all three CK isoenzymes were significantly elevated in serum. An important finding was that carbofuran or methyl parathion caused a shift in the serum CK-MM subform, i.e. higher sequential conversions of CK-MM3 subform to CK-MM2 and CK-MM2 to CK-MM1, possibly due to enhanced carboxypeptidase-N2 activity (Gupta *et al.*, 1994).

B. Lactate Dehydrogenase (LDH) and LDH Isoenzymes

LDH catalyzes the synthesis of lactate and pyruvate in a reversible reaction, and is commonly used as a biomarker of cell damage or death. Normal distribution of LDH and its isoenzymes in skeletal muscles of rats revealed that in controls, LDH activity was found to be highest in the EDL, followed by diaphragm, and lowest in the soleus (Table 35.8). Compared to muscles, the enzyme activity was meager in serum. It was interesting to note that all three muscles and serum contained all five electrophoretically distinct LDH isoenzymes, although with varying quantities. Each muscle presented a characteristic LDH isoenzyme pattern. For example, EDL contained a large proportion of LDH-5 (62.6% of total activity) and very little LDH-1 (3.5%). Soleus, on the other hand, had a very small amount of LDH-5 (11.3%) and about 20% each of the other four isoenzymes (LDH-1 through LDH-4). In general, values of LDH isoenzymes in diaphragm were intermediate to the EDL and soleus. Diaphragm had predominantly LDH-5 and LDH-4 (40% and 27.7%, respectively). In control serum, isoenzyme LDH-5 was 87% of the total LDH activity (100%).

Total LDH activity was significantly enhanced in EDL, diaphragm, and serum by carbofuran (1.5 mg/kg, s.c.) or methyl parathion (5 mg/kg, i.p.) within 1 h of injection. Each AChE inhibitor caused marked elevation of all five isoenzymes in serum, with maximum increases in LDH-1 and LDH-4 (three-fold). Unlike serum, muscle LDH isoenzymes depicted variable patterns by carbofuran or methyl parathion intoxication. A significant decline in ATP appears to be the mechanism involved in leakage of cytoplasmic/mitochondrial enzymes into circulation (Gupta *et al.*, 1994).

VIII. SKELETAL MUSCLES AND TOLERANCE DEVELOPMENT

Repeated application for a prolonged period of OP nerve agents or pesticides in concentrations that initially do not produce obvious symptoms of toxicity can lead to a limited degree of adaptation as seen in a reduction of the duration and intensity of muscle fasciculations, behavioral tolerance, and muscle fiber necrosis (Wecker and Dettbarn, 1976; Gupta *et al.*, 1985, 1986). Various cholinergic mechanisms in skeletal muscles underlying this phenomenon have been well documented, including: (1) reduced cholinergic binding sites of muscarinic and nicotinic receptors, (2) reduced uptake of choline, and (3) stimulation of AChE synthesis (Gupta *et al.*, 1985, 1986). In an *in vivo* subchronic study (DFP, 0.5 mg/kg, s.c./day for 14 days) in male rats, Gupta and Dettbarn (1986) demonstrated complete recovery of protein synthesis in skeletal muscles (soleus, EDL, and diaphragm) during the tolerance phase (day 14) from inhibition of protein synthesis observed during the toxicity phase (day 5). Further, during the toxicity phase (day 5),

inhibition of *in vivo* protein synthesis was comparable to that seen with an acute dose of DFP (1.5 mg/kg, s.c.). Additional mechanisms that may contribute to general tolerance are the availability of other serine active site enzymes such as carboxylesterase (CarbE) and butyrylcholinesterase (BuChE). Although the functional role of these enzymes is unknown, binding to and inhibition of these enzymes reduce the free concentration of inhibitors otherwise available to interact with AChE (Gupta *et al.*, 1985). This is supported by studies showing that the toxicity of OPs can be potentiated by inhibition of CarbE, and tolerance to soman develops when plasma CarbEs recover during chronic exposure (Sterri *et al.*, 1981).

A major mechanism causing adaptation to the necrotic action of DFP at the NMJ is the reduction of nicotinic ACh receptors (B_{max}, 56%) without significant change in affinity (K_D). This loss of receptors can also explain the disappearance of fasciculations that was observed between days 3 and 5 of treatment (Gupta *et al.*, 1986). Whether presynaptic receptors regulating fasciculations are involved in this process remains to be determined. Changes in the postsynaptic receptor density could occur as an adaptation mechanism of the cell to the excessive cholinergic stimulation caused by AChE inhibition. In an earlier report, Chang *et al.* (1973) demonstrated a significant decrease in nicotinic ACh receptor density in rat diaphragm following repeated injections of neostigmine. The loss of ACh receptors may be caused by a reduction of junctional folds (Laskowski *et al.*, 1975) on which most of the nicotinic ACh receptors are located. Changes in the ionic milieu, especially increases in Ca^{2+} caused by the increased neuromuscular activity during the DFP-induced fasciculations, may be involved in the loss of secondary junctional folds. In essence, at the NMJ, the two major mechanisms leading to adaptation are: (1) an increased recovery of AChE activity as a result of *de novo* synthesis (Gupta *et al.*, 1986), and (2) a reduction in nicotinic ACh receptor binding sites (Gupta *et al.*, 1985, 1986, 1987a, b). The other mechanism supporting this tolerance development is an increase in nonspecific binding sites for DFP as seen in the recovery of CarbEs activity during days 5–14 (Gupta *et al.*, 1985, 1986). Lastly, mechanisms such as modification of ACh release from presynaptic sites may be an additional contributing factor (Carlson and Dettbarn, 1983, 1987, 1988).

IX. SKELETAL MUSCLE INVOLVEMENT IN INTERMEDIATE SYNDROME

The organophosphate (OP) insecticide-induced intermediate syndrome (IMS) was reported for the first time in human patients in Sri Lanka in 1987 (Senanayake and Karalliede, 1987; Karalliede and Henry, 1993). Thereafter, this syndrome has been reported in South Africa (1989), Turkey (1990), Belgium (1992), India (2003), and many other countries. IMS is clearly a separate entity from acute

cholinergic crisis and delayed neuropathy. IMS is a life-threatening complication of OP poisoning, which most commonly occurs 48–72 h after exposure. In a recent case, Paul and Mannathukkaran (2005) reported IMS with the carbamate insecticide carbofuran. So far, IMS has not been documented with OP nerve agents. Clinically, IMS is characterized by acute respiratory paralysis and weakness in the territories of several cranial motor nerves, neck flexors, facial, extraocular, palatal, nuchal, and proximal limb muscles. Despite severe AChE inhibition, muscle fasciculations and muscarinic receptor-associated hypersecretory activities are absent. Based on EMG findings from OP-poisoned patients and experimental studies on laboratory animals, scientists have found that the defect in IMS is at the neuromuscular endplate and postsynaptic level, but the effects of neural and central components in muscular weakness have not been ruled out. EMG in the early stages reveals marked decrements at low rates of repetitive nerve stimulation and increments at a high rate, suggesting diverse types of impaired neuromuscular transmission. IMS seems to be due to persistent AChE inhibition at the endplate, presumably leading to combined pre- and postsynaptic impairment of neuromuscular transmission. Currently, very little is known about the type of damage at the motor endplate or about risk factors associated with IMS. For details on the involvement of muscles in IMS, readers are referred to a recent publication by De Bleecker (2006).

X. PREVENTION/TREATMENT OF MYOPATHY

Poisoning by anticholinesterase OP nerve agents is often characterized by abnormal muscle activity (such as fasciculations) and myopathy (muscle fiber necrosis). The severity of necrosis appears to be correlated with the frequency and duration of the fasciculations. Gupta *et al.* (1985, 1986, 1987) and Misulis *et al.* (1987) demonstrated that both soman and DFP produced muscle toxicity, although soman had its predominant action through CNS stimulation while DFP had prominent PNS as well as CNS activation. The fact remains that excess activation of muscle fibers due to sustained interaction between ACh and the ACh receptor, regardless of whether it arises indirectly from CNS or directly from PNS stimulation, results in muscle lesions (Gupta *et al.*, 1986, 1987a, b).

Various pharmacologic and therapeutic drugs have been tested to prevent or treat myopathy. Drugs effective in treatment of neuromuscular signs of anti-ChE toxicity include: (1) oximes that reactivate the phosphorylated AChE (Wecker *et al.*, 1978a), (2) subparalyzing as well as paralyzing doses of *d*-tubocurarine (Patterson *et al.*, 1987; Clinton and Dettbarn, 1987), (3) atropine sulfate/atropine methyl nitrate (Patterson *et al.*, 1987; Clinton *et al.*, 1988), (4) diazepam, and (5) creatine phosphate (Clinton *et al.*, 1988). In several studies, reversible AChE inhibiting carbamates, atropine, or anticonvulsants were given in combination with oxime to achieve an optimal effect. Some of the drugs, including AChE reactivators, muscarinic and nicotinic ACh receptor blockers, NMDA receptor antagonists, anticonvulsants, antioxidants, etc., are described here in brief for their prophylactic/therapeutic efficacy. It should be noted that some of these agents, however, produce toxicity when given for an extended period of time, thereby limiting their utility.

A. AChE Reactivators and ACh Receptor Blockers

The standard treatment of nerve agent-induced muscle toxicity calls for: (1) reactivation of the phosphorylated AChE with an oxime, and (2) blockage of the nicotinic ACh receptor sites from the stimulating action of ACh with *d*-tubocurarine. Oximes such as obidoxime, pralidoxime (2-pyridine aldoxime methochloride, 2-PAM) and a few others have been found very effective when given in combination with other drugs such as atropine, *d*-tubocurarine, diazepam, etc. Effectiveness of pretreatment with oximes varies with the chemical structures of the nerve agents and depends on the time after exposure. For example, it has been

established that HI-6 effectively activates AChE inhibited by soman, while TMB-4 is known as one of the most efficient reactivators of tabun-inhibited enzyme. In *in vivo* studies, Jovanovic (1983) evaluated two bis-pyridinium oximes (BDB-27 and HGG-12) on neuromuscular blockade induced by nerve agents (sarin, soman, tabun, and VX) in rats, and effectiveness was compared with the two most potent oximes (HI-6 and TMB-4). It was found that BDB-27 was equal or superior to HI-6 in sarin, soman, and VX and to TMB-4 in tabun-poisoned animals. The potency of HGG-12 was equal to HI-6 only in soman poisoning, but much less pronounced against neuromuscular blockade induced by the other nerve agents. In general, oxime therapy becomes progressively ineffective with time due to changes in the enzyme–inhibitor complex which loses an alkyl radical. This so-called aged phosphorylated enzyme complex is resistant to oxime reactivation (Radic and Taylor, 2006). Thus, prevention of formation of the enzyme–inhibitor complex seems to be one of the preferred strategies in treatment of myopathy.

The best pretreatment should include the agents that prevent access of the nerve agent to AChE without affecting its activity or a combination of the drugs that would decrease the release of ACh from nerve terminals and/or partially block access to the nicotinic as well as the pre- and postsynaptic muscarinic receptors. So far, timely administration of atropine sulfate or atropine methyl nitrate in combination with an oxime, such as 2-PAM or diazepam, is currently the treatment of choice for OP poisoning. Atropine has been shown to modify ACh receptor interaction at the NMJ postsynaptically by shortening the opening time of the ion channel and possibly by lowering Na^+ conductance (Katz and Miledi, 1973). Despite the fact that atropine is up to 2,000 times less potent than *d*-tubocurarine at nicotinic sites (Beraneck and Vyskocil, 1967), atropine sulfate has been observed to reduce motor activity and muscle necrosis caused by AChE inhibitors (Clinton and Dettbarn, 1987). Atropine methyl nitrate is four times more potent than atropine sulfate in its peripheral effects (Malick and Barnett, 1975; Lonnerholm and Widerlov, 1975) and as expected has been confirmed to ameliorate peripheral motor activity caused by AChE inhibitors than atropine sulfate (Clinton *et al.*, 1988). Atropine methyl nitrate (16 mg/kg, s.c.) failed to ameliorate the central effects of both soman and DFP (Clinton *et al.*, 1988) due to its quaternary structure that hinders its passage across the blood–brain barrier (Lonnerholm and Widerlov, 1975).

Earlier studies with *d*-tubocurarine and atropine indicated that nicotinic and muscarinic ACh receptor blockers can modulate the release of ACh induced by an inhibitor of AChE (Carlson and Dettbarn, 1987, 1988). The effects of these drugs, whether inhibiting or stimulating ACh release, are concentration dependent and determined by the frequency of nerve activity (Bowman, 1980; Wessler *et al.*, 1987a, b). Therefore, drugs that reduce axonal hyperexcitability by decreasing amount of ACh released from the nerve terminals without interfering with normal transmission provide another pretreatment possibility. Protection against DFP-induced myopathy was achieved by using small concentrations of atropine sulfate (16 mg/kg, s.c.) or atropine methyl nitrate (16 mg/kg, s.c.) and *d*-tubocurarine (75 µg/kg, s.c.) that prevented fasciculations and muscle necrosis without interfering with the normal neuromuscular function (Patterson *et al.*, 1987). In this study, pretreatment agents acted presynaptically by preventing DFP-induced backfiring and muscle fasciculations possibly by reducing the release of ACh. The protective drugs in the concentrations used had no significant effect on the normal characteristics of conduction and transmission. Carlson and Dettbarn (1987) showed that *d*-tubocurarine or atropine sulfate in subparalytic concentrations prevented the increases in miniature endplate potential (MEPP) frequency when given prior to an AChE inhibitor or attenuated the increased frequency to normal when given after the increase of frequency. At a subparalytic dose *d*-tubocurarine (50 µg/kg, i.v.) is known to suppress fasciculations by preventing repetitive firing of nerve terminals. Furthermore, *d*-tubocurarine and atropine sulfate reduced Ca^{2+} influx and ACh release (through presynaptic receptors), which is associated with repetitive activity as seen during AChE inhibitor-induced antidromic firing.

B. NMDA Receptor Antagonist

In a series of *in vivo* experiments, rats receiving a sublethal dose of soman (100 µg/kg, s.c.), sarin (110 µg/kg, s.c.), tabun (200 µg/kg, s.c.), VX (12 µg/kg, s.c.), or DFP (1.5 mg/kg, s.c.) developed seizures and severe muscle fasciculations within 15–20 min that lasted for about 4–6 h. Marked inhibition of AChE activity and necrotic lesions in skeletal muscles (soleus, EDL, and diaphragm) became evident between 1 and 24 h post-injection and persisted for several days. Pretreatment of rats with NMDA receptor antagonist memantine (18 mg/kg, s.c.) together with atropine sulfate (16 mg/kg, s.c.), 60 min and 15 min, respectively, prior to DFP or nerve agents, significantly attenuated AChE inhibition, and prevented myonecrosis and muscle fasciculations as well as other signs of behavioral toxicity. No muscle fasciculations were seen at any time (Gupta and Dettbarn, 1992).

Protection of AChE inhibition was greater when memantine was given prophylactically than therapeutically. It is important to mention that memantine itself does not influence normal activity of AChE in non-OP-treated animals. Although the precise mechanism involved in reduction of AChE inhibition by memantine against nerve agents is yet to be elucidated, spontaneous reactivation as the cause of the remaining high enzyme activity was ruled out since the enzyme activity was determined within a short period of time, i.e. 1 h after acute intoxication with soman, sarin, tabun, VX, or DFP (Gupta *et al.*, 1986, 1987a, b, 1991; Gupta and Dettbarn, 1992), and AChE activity remained low when only atropine sulfate (16 mg/kg, s.c.) was used. Studies by McLean *et al.* (1992) revealed that memantine

did not prevent inhibition of AChE by edrophonium, an anionic site inhibitor, or by decamethonium, a peripheral site inhibitor of AChE. Thus, memantine appears to bind to a different modulatory site to protect this enzyme's activity. The other mechanisms by which memantine might have attenuated AChEI's toxicity may include:

- reduced reflex excitability of both flexors and extensors (Wand *et al.*, 1977)
- reduced high frequency of repetitive activation of peripheral nerves by reducing the permeability of Na^+ and Ca^{2+} in axonal membranes (Wesemann and Ekenna, 1982; Wesemann *et al.*, 1983)
- blockage of nicotinic ACh receptor-ion channel complex (Masuo *et al.*, 1986)
- prevention of neural hyperexcitability (McLean *et al.*, 1992)
- central muscle relaxation (Grossman and Jurna, 1977)
- reduced seizures by uncompetitive NMDA receptor blockage (Danysz *et al.*, 1994; Carter, 1995; Parsons *et al.*, 1999)
- prevention of cellular energy depletion (Gupta and Goad, 2000).

Although not all of these mechanisms have yet been investigated in the protection of OP nerve agent-induced myopathy by memantine, it appears that memantine provides protection by multiple mechanisms. It needs to be mentioned that no significant change occurred in AChE activity in skeletal muscles of OP-untreated rats receiving memantine and atropine sulfate. Prophylactic administration of memantine and atropine sulfate also blocked the AChEI-induced increase in levels of citrulline and F_2-isoprostanes, markers of NO synthesis and lipid peroxidation, respectively. Memantine has the advantage of providing prophylactic benefits without producing sedation or any other side effects. Thus, memantine may prove to be a superior drug to many other agents.

C. Anticonvulsants and Anesthetics

Prevention or treatment of myopathy becomes difficult since individual AChEIs differ in their major sites of action. As mentioned earlier, soman-produced muscle hyperactivity generated mainly in the CNS, while DFP-induced hyperactivity arose approximately equally from the CNS and the peripheral nerve and NMJ. Clinton *et al.* (1988) reported that in the case of both soman (90 µg/kg, s.c.) and DFP (1.5 mg/kg, s.c.) poisoning, ketamine (25 mg/kg, s.c.) reduced centrally generated motor activity, while atropine methyl nitrate (16 mg/kg, s.c.) and sodium phenytoin (15 mg/kg, i.v.) had no significant effect. It was suggested that the effectiveness of ketamine may alter patterns of neuronal firing by reducing high-frequency neuronal discharges that are characteristic of seizures (McLean and MacDonald, 1986). Ketamine is known to act on sodium channels by producing a dose-dependent reduction of inward sodium current in a manner similar to that of local anesthetics, with a resultant suppression of high-frequency neuronal bursts, which are manifested as excess muscle activity seen with OP poisoning. Since ketamine and drugs in its class also have specific anticholinergic effects at both nicotinic and muscarinic (more potent at nicotinic than at muscarinic) receptors (Kloog *et al.*, 1977), it may be a direct antagonist in the CNS against the cholinergic activation caused by AChEIs (Gupta *et al.*, 1987a, b). Additionally, ketamine can inhibit excitation–contraction coupling within the muscle by altering Na^+ conductance at the muscle membrane (Marwah, 1980a, b).

Clinton *et al.* (1988) demonstrated that the anticonvulsant phenytoin did not reduce motor activity of central origin induced by either soman or DFP. Phenytoin suppresses sustained high-frequency neuronal firing through a membrane potential-dependent blockade of Na^+ channels with resulting inhibition of nonsynaptic events involved in epileptogenesis (MacDonald and McLean, 1986; McLean and MacDonald, 1986; Yaari *et al.*, 1986). The failure of phenytoin to control the seizures induced by AChEIs suggests that they may not result from the same mechanisms of epileptogenesis as seizures produced by maximal electrical shock, against which phenytoin is most effective.

Conventional anticonvulsant compounds have been reported to provide limited protection against nerve agent-induced seizures and muscle necrosis when given therapeutically (Lipp, 1972; Clinton *et al.*, 1988). Sedation, tolerance, and abuse potential, however, limit prophylactic use of benzodiazepine compounds.

In animal models, clonidine has also been reported to prevent nerve agent-induced seizures (Buccafusco *et al.*, 1988). Prophylactic use of clonidine may be limited by the marked ataxia and sedation produced by this drug in effective concentrations.

D. Antioxidants and Spin-Trapping Agents

During hyperactivity of the muscles by anti-ChE toxicity, excessive amounts of ROS/RNS can be generated and exceed the capacity of the muscle defense system, thus producing oxidative stress. Excessively generated ROS/RNS can cause muscle injury by reacting with cellular components, such as membrane phospholipids, mitochondrial enzymes/proteins and nucleic acids. There are several points in excitotoxicity mechanisms where antioxidants can intercept, but prevention of the generation of ROS and their scavenging are of special interest. An antioxidant such as the lipid-soluble vitamin E (α-tocopherol) is an excellent blocker of ROS production as it extracts hydrogen and interrupts lipid peroxidation. Vitamin E mainly acts as a chain-breaking antioxidant and radical scavenger, protecting cell membranes against oxidative damage. There are reports demonstrating that vitamin E concentrates in the mitochondria, the major site for the generation of ROS as well as energy metabolites. Therefore, vitamin E regulates ROS production, maintains

oxidative phosphorylation in mitochondria, and accelerates restitution of high-energy metabolites.

Electron spin resonance (ESR) spectroscopy using spin traps allows direct identification and characterization of ROS. A synthetic spin-trapping agent such as phenyl-*N*-*tert*-butylnitrone (PBN) is capable of scavenging many types of free radicals. This compound is widely used to trap ROS in a variety of physical, chemical, and biological studies using electron magnetic resonance spectrometry. PBN is known to be concentrated in the mitochondria, where it reacts with ROS and forms stable adducts, and thereby maintains normal levels of energy metabolites. In addition, PBN has other pharmacological actions, such as: (1) reversible Ca^{2+} channel blockade (Anderson *et al.*, 1993), (2) a direct reversible interaction with AChE against phosphorylation by DFP (Zivin *et al.*, 1999; Milatovic *et al.*, 2000a, b), (3) protection of COX activity (Milatovic *et al.*, 2001), and (4) induction of hypothermia (Pazos *et al.*, 1999).

Pretreatment with PBN (75, 150, or 300 mg/kg, i.p.) 30 min prior to DFP injection (1.7 mg/kg, s.c.) in a dose-dependent manner protected AChE activity from inhibition, and prevented muscles from undergoing necrosis and rats from fasciculations (Milatovic *et al.*, 2000a, b). The protective mechanism of PBN is thought to be due to its ROS/RNS scavenging property. Treatment with PBN 20 min after DFP exposure neither prevented fasciculations nor protected AChE activity. While the role of PBN as an antioxidant is well established, its prophylactic effect against excitotoxicity induced by an AChEI is due to its protection of AChE from critical inhibition (Milatovic *et al.*, 2000a, b). Unlike PBN, vitamin E neither prevented DFP-induced muscle fasciculations nor protected AChE. Like vitamin E, PBN also concentrates in the mitochondria, thereby it can regulate ROS production, maintain oxidative phosphorylation, and accelerate restitution of high-energy metabolites.

E. Creatine and Phosphocreatine

Inhibition of AChE leads to unremitting stimulation of muscles, which in turn, causes marked depletion of high-energy phosphates (HEP), such as ATP and phosphocreatine (PCr) and their major metabolites (Gupta and Dettbarn, 1987). If this stimulation is sufficiently low in intensity or brief in duration, cellular recovery will ensue without lasting consequences. If, however, intense cholinergic stimulation is allowed to persist, a self-reinforcing cycle of cellular damage is set into motion. Phosphocreatine (PCr) is the immediate precursor of ATP and in a reversible Lohman reaction where PCr is synthesized only from ATP, the decline in PCr is always greater than in ATP. ATP depletion for several hours to approximately 30–40% of normal levels leads to a fall in the mitochondrial membrane potential that is associated with: (1) reduced energy production (due to decrease in complex I and complex IV activities), (2) impaired cellular calcium sequestration, (3) activation of protease/caspases, (4) activation of phospholipases, (5) activation of nitric oxide synthase (NOS), and (6) excessive generation of ROS/RNS. Several of these steps are associated with exacerbation and propagation of the initial depletion of ATP; most notable are the decreases in complex I and complex IV activities, the impairment of mitochondrial calcium metabolism that regulates ATP production even in the face of a constant supply of substrates, and the generation of nitric oxide, which binds reversibly to cytochrome c oxidase (COX) in competition with oxygen, with subsequent sensitization to hypoxia. During the course of the excitatory process, such as muscle hyperactivity, a high rate of ATP consumption coupled with the inhibition of oxidative phosphorylation compromises the cell's ability to maintain its energy levels, and excessive amounts of ROS and RNS are generated. Thus, the combination of impaired synthesis of ATP with its greater utilization during muscle hyperactivity appears to result in a significant depletion of ATP.

Since the major energy sources are ATP and PCr, an increase of both compounds in muscles through administration of creatine appears to sustain ATP levels under stress conditions. This is supported by the findings that rats pretreated intravenously with PCr showed reduced muscle necrosis otherwise seen following DFP treatment. PCr did not attenuate the DFP-induced muscle fasciculations generating the necrosis (Clinton and Dettbarn, 1987).

XI. CONCLUDING REMARKS AND FUTURE DIRECTION

Skeletal muscles are the target for a variety of chemicals, especially OP nerve agents. These agents modulate structural and functional properties of the muscles, and the toxic effects can vary from minor chest pain, muscle cramps in the legs to complete paralysis or even death. Both *in vivo* and *in vitro* data strongly implicate that although OP nerve agents initially exert acute toxicity by excitotoxicity involving the cholinergic system, additional noncholinergic mechanisms that contribute to these effects include glutamatergic system and excess generation of free radicals (ROS/RNS) and alterations in antioxidant and the scavenging system, causing oxidative stress, lipid peroxidation, high-energy phosphates depletion, and muscle necrosis. Wide variations exist between slow and fast fiber-containing muscles and they further appear to respond differently to each OP nerve agent. Available sensitive biomarkers are indicative of cytotoxicity and mitochondrial toxicity. Myopathy induced by AChE inhibiting OP nerve agents is a serious concern, since it is untreatable in most circumstances. Instead, prevention seems a better option. More potent AChE reactivators need to be developed for better therapeutic efficacy against OP nerve agent-induced myopathy.

Acknowledgments

The authors would like to thank Mrs Kristie Rohde and Mrs Robin B. Doss for their technical assistance in the preparation of this chapter.

CHAPTER 36

Reproductive Toxicity and Endocrine Disruption of Potential Chemical Warfare Agents

TIMOTHY J. EVANS

I. INTRODUCTION

Reproduction is a critical biological process in all living systems and is required for species survival. The immediate, short-term, toxicological concerns regarding chemical warfare and acts of agricultural and industrial terrorism are concerned primarily with human and animal incapacitation and mortality. Logically, most of the currently available literature on these aspects of warfare and terrorism focuses on these immediate adverse health effects and their sequelae. However, the entire scope of the effects of these toxic insults can involve severe emotional and financial distress, as well as diminished prognosis for long-term survival of exposed human and animal populations, arising from toxicant-induced abortions, congenital defects, and infertility. It is therefore important that individuals working in human and veterinary medicine, the military, public health, government regulatory agencies, industry and agriculture, as well as public policy makers, be familiar with some of the potential adverse reproductive effects of these types of toxicants on exposed humans and animals. This chapter will review what is currently understood about the potential effects of chemical warfare agents, nuclear fallout, and hazardous industrial and agricultural wastes on human and animal reproductive function.

For the purposes of this chapter, the term ''reproduction'' will be used primarily in reference to vertebrate species of animals (especially mammals) and will be inclusive of ''development'' (Figure 36.1), which is sometimes treated as a separate topic in toxicology texts. This particular chapter emphasizes what is currently known about the adverse effects of known chemical warfare agents and selected environmental contaminants on male and female reproductive function, as well as xenobiotic-induced effects on the growth, maturation, and sexual differentiation of the embryo and fetus. Endocrine disruption is an extremely common mechanism of action for xenobiotics associated with impaired reproductive function and will be discussed along with reproductive toxicity in this chapter. Efforts will be made to clarify the currently used terminology related to these topics and to provide the reader with a brief description of proposed mechanisms of action and observed reproductive outcomes associated with selected toxicants which might be relevant to chemical warfare and/or acts of terrorism.

Unfortunately, although there is relative lack of information documenting long-term, reproductive effects of the types of toxicants covered in this book, space constraints still limit the amount of information which can be presented in this chapter. There are a number of recently published textbooks and book chapters which cover some of these and related subjects in greater detail and provide information which is complementary to what is presented in this chapter (Capen, 2008; Evans, 2007; Foster and Gray, 2008; Golub, 2006a, b; Gupta, 2006, 2007c; Naz, 2005; Rogers and Kavlock, 2008; Romano *et al.*, 2008; Senger, 2003). This is especially true with respect to normal reproductive anatomy and function (Evans, 2007; Senger, 2003), and the reader is directed to these publications and the other references cited in this chapter in order to gain additional insight into specific areas of reproductive function and toxicology.

It is important that the reader understand that the areas of toxicology involving the long-term effects of chemical warfare agents and environmental contaminants, reproductive toxicity, in general, and endocrine disruption, in particular, are in continual flux. New data and exceptions to ''classical'' mechanisms of action are being reported on a regular basis, and there continues to be ongoing debate about the effects of chronic low-level exposures to toxicants available for or arising from military and terrorist activities and various aspects of normal, as well as xenobiotic-induced abnormal reproductive function. Every effort has been made to accurately represent what is currently understood about the topics of discussion in this chapter. Controversial topics or those currently still subject to debate within the scientific community have been noted wherever possible.

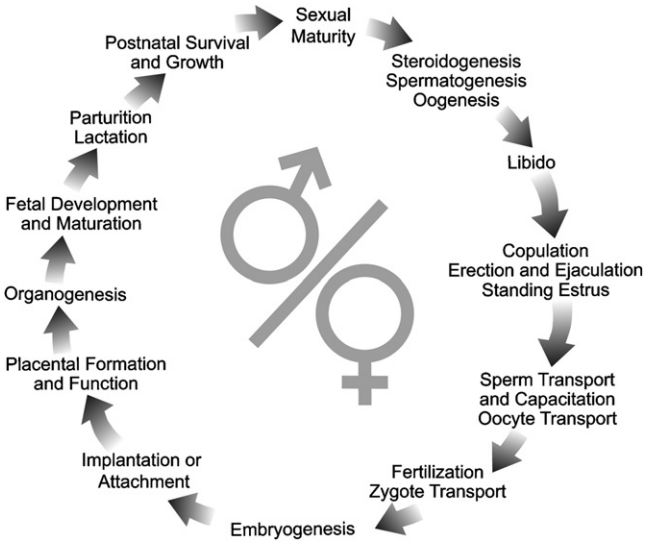

FIGURE 36.1. The multiple steps involved in reproductive development and function in both males and females are shown schematically to illustrate the complexity of reproduction in mammalian species and to demonstrate the various stages in the reproductive process which can be targeted for toxic insult. This figure was adapted, with permission, from Ellington, J.E., Wilker, C.E. (2006). *Small Animal Toxicology*, 2nd edition (M.E. Peterson, P.A. Talcott, eds). Elsevier Saunders, St Louis (modifications and artwork courtesy of Don Connor).

II. IMPORTANT DEFINITIONS AND CONCEPTS

A. Chemical Warfare Agents

For the purposes of this chapter, ''chemical warfare agent'' (CWA) will be used as a fairly comprehensive term to refer to a diverse group of toxicants commonly discussed within the context of chemical incapacitation for crowd control during riots or death or incapacitation associated with military use or terrorism. The lacrimatory and irritant riot control agents will include α-chlorbenzylidene malonitrile (CS), dibenz (b,f)-1:4 oxazepine (CR), ω-chloroacetophenone (CN) and oleoresin of capsicum (OC pepper spray) (Salem *et al.*, 2008a). The CWAs currently of greatest interest and for which the greatest amount of data have been gathered are arsenicals, chlorine gas, phosgene and phosgene oxime, sulfur mustard, ricin, hydrogen cyanide and cyanide-related compounds, and organophosphate nerve agents (Kikilo *et al.*, 2008; Wismer, 2007).

B. Environmental Contaminants Associated with Industrial or Agricultural Terrorism

For the sake of completeness, this chapter will also discuss the adverse reproductive effects of potential toxicants, such as ionizing radiation, pesticides and other organic environmental contaminants, as well as heavy metals, which are known to adversely affect reproductive function. While all of these potential toxicants have been or are currently being released into the environment in generally low concentrations as a consequence of normal industrial and agricultural activities, the results of accidents, such as those which occurred in Chernobyl, in the former Soviet Union (ionizing radiation), Bhopal, India (methyl isocyanate or MIC), Seveso, Italy, and Times Beach, Missouri (dioxins), and Minamata, Japan, and Basra, Iraq (methyl mercury), underscore the potential impact that large-scale, industrial or agricultural terrorism-related releases of these contaminants could have on populations of humans and animals. In fact, these environmental contaminants have the potential to become ''low-tech'' CWAs in the hands of terrorists and less sophisticated military organizations.

C. Reproduction

As represented in Figure 36.1, reproduction in humans and domestic, wild, and laboratory vertebrate animals encompasses the wide range of physiological processes and associated behaviors and anatomical structures involved in the production of the next generation and the survival of a given species of animal (Evans, 2007; Senger, 2003). The physiological processes involved in reproduction generally include the following: (1) gametogenesis (production of sperm or ova) and the pre- and peri-pubertal changes leading up to its onset; (2) release of gametes [i.e. sperm transport and maturation, penile erection and ejaculation of sperm (mammals), copulation between a male and a female of the same species (several vertebrate classes) and ovulation of oocytes]; (3) formation of the zygote (i.e. sperm storage, capacitation, and other processes leading to fertilization, or union, of a single sperm with an egg); (4) embryonic and fetal development during the incubation process in egg-bearing vertebrates or, especially in the case of mammals, during pregnancy (gestation) [i.e. activities related to the initiation and progression of zygote cleavage, blastocyst formation, separation of the germ layers, placentation (mammalian species), neurulation and organogenesis (including sexual differentiation)]; (5) ''birth'' of a single or multiple offspring (hatching in oviparous vertebrates); and, finally, in mammalian species, (6) the initiation and maintenance of milk production (lactation) for the postpartum nutrition of offspring (Evans, 2007).

D. Reproductive Toxicity

For the purposes of this chapter, ''reproductive toxicity'' will refer to any manifestations of xenobiotic exposure, including ''endocrine disruption'' (see discussion below), reflecting adverse effects on any of the physiological processes and associated behaviors and/or anatomical structures involved in animal reproduction or development (Figure 36.1). This is a fairly broad definition which encompasses developmental toxicity, as well as any toxic

effects of post-pubertal exposures to xenobiotics on either male or female reproduction. ''Developmental toxicity'' refers to any adverse effect on the developing organism associated with either pre-conception parental exposures to toxicants or post-conception xenobiotic exposures to the embryo, fetus, or pre-pubertal offspring, and adverse effects associated with developmental toxicity of xenobiotics might not necessarily be observed until after the affected individuals have reached sexual maturity (Eaton and Klaassen, 2001; Evans, 2007; Hodgson *et al.*, 2000).

1. Teratogenesis

The term ''teratogenesis'' is derived from the Greek word for monster (*teras*) and is a form of developmental toxicity (Rogers and Kavlock, 2008). ''Teratogenesis'' refers specifically to developmental defects induced by toxicant exposures occurring between conception and birth (Eaton and Klaassen, 2001; Evans, 2007; Hodgson *et al.*, 2000; Rogers and Kavlock, 2008). The types of abnormalities that are typically associated with teratogenesis include embryonic or fetal death; morphological, functional and/or neurobehavioral abnormalities; and decreased growth rate and/or birth weight (Evans, 2007; Rogers and Kavlock, 2008).

With respect to teratogenesis, there are six basic tenets of teratology, first defined by J.G. Wilson in 1959, which need to be kept in mind whenever gestational exposure to a teratogenic xenobiotic is suspected or when a chemical is being evaluated for its teratogenic potential (Evans, 2007; Wilson, 1977):

1. Susceptibility to teratogenesis depends on the genotype of the conceptus and the manner in which it interacts with environmental factors.
2. Susceptibility to teratogenic agents varies with the developmental stage at the time of exposure.
3. Teratogenic agents act in specific ways (mechanisms) on developing cells and tissues to initiate abnormal embryogenesis.
4. The final manifestations of abnormal development are death, malformation, growth retardation, functional disorder.
5. The access of adverse environmental influences to developing tissues depends on the nature of the influences (agent).
6. Manifestations of deviant development increase in degree as dosage increases from no effect to the totally lethal level.

2. Mechanisms of Reproductive Toxicity and Teratogenesis

In general, normal reproduction and development require rapidly replicating and differentiating cells undergoing mitosis and, within the gonads, meiosis. There are a wide range of specific mechanisms of action by which xenobiotics can adversely affect reproductive function, including embryonic and fetal development. Many of these mechanisms are the same as those for toxicants affecting other organ systems and essentially involve some sort of toxicant-induced interference with the cell cycle, cellular dysregulation, and alterations in cellular maintenance which, when possible, the body attempts to repair, either successfully or unsuccessfully (Gregus, 2008). Oxidative damage and interference with normal enzymatic reactions are two common mechanisms by which xenobiotics and, especially, some CWAs (Smith *et al.*, 2008) can cause the dysregulation and altered maintenance of cells within various organs and tissues.

Teratogenesis can be associated with each of the following mechanisms of action: (1) excessive cell death; (2) interference with apoptosis; (3) reduced cellular proliferation rate; (4) failed interactions between cells; (5) impaired morphogenetic movements; (6) reduced synthesis of components essential for growth and development; (7) mechanical disruption; and (8) alterations in pH (Evans, 2007; Hood, 2006; Hood *et al.*, 2002). Some teratogens are capable of more than one mechanism of action, and it is important to keep in mind that the observed developmental abnormalities associated with exposure to any given teratogen will in large part be dependent on the timing of the exposure to that xenobiotic during gestation. Familiarity with the timing of important developmental events in species of interest is critical in the diagnosis and prevention of teratogenesis, as well as the design of experiments investigating the teratogenic potential of different chemicals in animal models (Evans, 2007).

Normal reproduction and development require signaling within and between a variety of diverse organs, and, in sexual reproduction and mammalian pregnancy, critical communication even takes place between distinctly different organisms (i.e. male and female and mother and offspring, respectively) (Evans, 2007). It should be remembered that premature parturition or abortion can be induced by any circumstances which cause fetal or, potentially, maternal stress and initiate the cascade of endocrine and neural signaling events which would normally lead to parturition. Any sublethal intoxication or emotionally traumatic event in a pregnant woman or animal has the potential to threaten fetal survival.

The dependency of reproductive function on signaling pathways inclusive of gene transcription makes this physiological process especially prone to adverse effects associated with xenobiotic-induced disruption of or interference with cell-to-cell, organ-to-organ and/or even animal-to-animal communication. Many of the mechanisms which interfere in some way with physiological signaling activity can be classified as forms of ''endocrine disruption'' (see discussion below), but there is a great deal of overlap between the various different mechanisms for reproductive toxicity. The level of exposure to a particular toxicant is an important determinant of what toxic effects are observed,

and xenobiotics which ''disrupt'' endocrine pathways can do so without interactions with endogenous receptors, using mechanisms of action which can cause other forms of toxic insult at various dosages.

3. Reproductive Toxicants

Any xenobiotic associated with adverse effects on development of male or female reproductive function can be classified as a ''reproductive toxicant'' (Evans, 2007; Rogers and Kavlock, 2008). Even chemicals adversely affecting animal well-being have a potential negative impact on development and reproductive function. This chapter will attempt to focus on toxicants which are available for or could arise from military and terrorist activities and specific mechanisms of actions which have a direct effect upon the male and/or female reproductive tract or which target normal embryonic and/or fetal growth and maturation (Evans, 2007).

4. Teratogens

The subclass of reproductive toxicants capable of inducing teratogenesis is referred to as ''teratogens''. Some teratogenic chemicals induce their adverse effects indirectly on the fetus by altering maternal synthesis of essential nutrients or by other mechanisms which do not require their transport across the placenta. However, many teratogens directly affect fetal development by crossing the ''placental barrier'' and entering the fetal circulation. The passage of nutrients, hormones, and other endogenous, as well as exogenous, substances across the placenta has been traditionally thought of by some references as primarily a function of the intimacy (i.e. number of tissue layers) between the maternal and fetal circulations, especially with respect to maternal immunoglobulins which cross some types of placentation but not others (Evans, 2007). While it is true that placental characteristics, such as thickness, surface area, carrier systems, and lipid-protein characteristics, can influence the passage of xenobiotics across the placenta and that the placenta is generally impermeable to chemicals with molecular weights greater than 1,000 Da, most xenobiotics have molecular weights less than 500 Da and cross the placenta by simple diffusion (Foster and Gray, 2008). It is currently thought that a potential teratogen's molecular size, degree of ionization, protein binding, and lipid solubility are the most important determinants of that chemical's ability to move from the maternal circulation across the placenta into the fetal circulation (Evans, 2007; Foster and Gray, 2008; Rozman and Klaassen, 2001; Senger, 2003). Some toxic xenobiotics can be actively transported by mechanisms intended for structurally similar endogenous molecules (Rozman and Klaassen, 2001), and there is some experimental evidence to suggest that transplacental transport of lead can mimic that of calcium (Evans, 2007; Evans *et al.*, 2003).

5. Endocrine Disruption

''Endocrine disruption'' is a developing, multidisciplinary area of research, involving aspects of both toxicology and endocrinology (McLachlan, 2001) and is a potential mechanism of action for many toxicants, especially those affecting reproduction. This term has been defined in a variety of different ways, depending on the circumstances and the intended audience. Endocrine disruption can also be defined fairly narrowly with respect to toxicant origin (synthetic versus naturally occurring); source or site of toxicant exposure (exposure from warfare- or terrorism-related activities versus exposure from environmental contamination); xenobiotic mechanism of action (receptor agonism and/or antagonism versus other mechanisms independent of direct interactions between xenobiotics and receptors); and/or the timing of exposure (prenatal versus postnatal exposures) (Evans, 2007; Krimsky, 2000, 2001). However, the definition of endocrine disruption used in this and another book chapter previously written by the author (Evans, 2007) will be fairly broad and will encompass the effects of any synthetic or naturally occurring xenobiotic which can affect the endocrine system of exposed individuals (i.e. the balance of normal hormonal functions) and, as a result of exposure, cause physiological alterations (Evans, 2007; Hodgson *et al.*, 2000; Keith, 1997). Within the broad scope of this definition, reproduction, including prenatal and pre-pubertal development, certainly would be expected to be one of the physiological functions most profoundly affected by chemicals associated with chemical warfare or environmental contamination capable of endocrine disruption; however, adverse effects on other, nonreproductive endocrine systems can also be associated with exposures to xenobiotics (Evans, 2007; Guillette, 2006). Thyroid function, glucocorticoid metabolism, and other endocrine as well as enzymatic factors associated with adipogenesis have recently been shown to be susceptible to interference by several different classes of chemical compounds (Capen, 2008; Cooke and Naz, 2005; Evans, 2007; Guillette, 2006; Grün and Blumberg, 2006; Newbold *et al.*, 2005, 2006).

6. Mechanisms of Endocrine Disruption

Although the imitation and/or inhibition of the actions of androgens and, especially, estrogens by xenobiotics is what was first referred to as endocrine disruption, both the multidisciplinary area of study and mechanism of action generally referred to as endocrine disruption have evolved over the years to encompass a wide range of specific mechanisms of action which can ultimately result in adverse effects on invertebrate and/or vertebrate animals (Evans, 2007; McLachlan, 2001). Endocrine disruption involves many mechanisms of action which can ultimately result in adverse effects on animal species. The mechanisms of action involved in endocrine disruption can include effects which are mediated directly by interactions between the xenobiotic and an endogenous hormone receptor (i.e. the

xenobiotic functions as a ligand for an endogenous receptor and a receptor–ligand complex is formed), as well as those adverse effects which alter hormonal functions without direct interactions between the toxicant and an endogenous receptor (Capen, 2008; Evans, 2007; Keith, 1997). It should also be noted that a given xenobiotic can potentially disrupt the normal balance of hormonal function by more than one mechanism which is independent of direct interactions between the toxicant and an endogenous hormone receptor (Evans, 2007).

''Classic'' endocrine disruption can involve imitation or mimicry of the interactions between cellular receptors and endogenous hormones (i.e. receptor agonism) and/or a blockade or inhibition of the formation of receptor–hormone complexes (i.e. receptor antagonism) (Evans, 2007; McLachlan, 2001), and both genomic and non-genomic physiological responses can be affected by this mimicry or blockade of endogenous hormone receptor-mediated activity (Evans, 2007; Thomas and Khan, 2005). Endocrine disruption can also be mediated by the complex interactions between the endogenous aryl hydrocarbon receptor (AhR) and its major agonists, which are xenobiotics belonging to the class of environmental contaminants referred to collectively as ''halogenated'' or ''polyhalogenated aromatic hydrocarbons'' (HAHs or PAHs, respectively) (Evans, 2007; Safe, 2005).

Endocrine disruption which is independent of interactions between xenobiotics and endogenous hormone receptors can occur in a variety of different ways, including alterations in the number of hormone receptor sites (up- or down-regulation) or direct or indirect hormone modifications which alter hormonal function (Evans, 2007; Keith, 1997). Xenobiotics can change the rate of synthesis or destruction of endogenous hormones and can alter how hormones are stored, how they are released into and/or transported within the circulation, or even how they are eventually cleared from the body (Capen, 2008; Evans, 2007; Keith, 1997; Sikka *et al.*, 2005). Any xenobiotic toxic to hormone-producing organs or tissues (e.g. testis and ovary) also has the potential to decrease hormone synthesis and thereby indirectly cause endocrine disruption (Devine and Hoyer, 2005; Evans, 2007).

In addition to the aforementioned mechanisms of endocrine disruption, there has recently been increasing interest in the association between prenatal exposures to some hormonally active toxicants and the postnatal development of neoplasia (cancer) involving the reproductive tract, as well as the occurrence of transgenerational or vertically transmitted adverse reproductive effects (Crews and McLachlan, 2006). Either genetic mutations [i.e. alterations in the genotype or deoxyribonucleic acid (DNA) sequence] or epigenetic changes, such as DNA methylation of CpG nucleotides in the promoter regions of genes, which are heritable but nongenetic modifications in the properties of a cell (inherited phenotypic alteration without genotypic change), are possible explanations for these phenomena (Crews and McLachlan, 2006; Evans, 2007; McLachlan, 2001). Patterns of DNA methylation are generally established during development at the gastrulation stage (i.e. lineage-specific pattern in somatic cells) and after sex determination (i.e. germ line-specific lineage pattern in the gonad), and DNA methylation can facilitate genomic imprinting, which results in the expression of the allele from only one parent (i.e. monoallelic expression) (Anway and Skinner, 2006; McLachlan, 2001).

7. Endocrine Disrupting Chemicals, Endocrine Disruptors, and Hormonally Active Agents

Any reproductive toxicant capable of endocrine disruption can also be considered an endocrine disrupting chemical (EDC) or an endocrine disruptor. Another term frequently used with respect to endocrine disruption, especially regarding xenobiotics which interact with endogenous hormone receptors, is hormonally active agent (HAA). In most instances, ''endocrine disrupting chemical'', ''endocrine disruptor'', or ''hormonally active agent'' can be used interchangeably to discuss the actions of a given xenobiotic (Evans, 2007).

III. THE REPRODUCTIVE TOXICITY OF SELECTED TOXICANTS

It should be remembered that the use of CWAs will invariably be associated with wars, acts of terrorism, revolutions, and civil unrest, all of which do not occur in a vacuum and will be concurrent with emotional stress, famine, and other conditions leading to reproductive failure. As a result, information is relatively lacking with respect to specific, adverse reproductive effects, as well as endocrine disruption, related to acute and, particularly, low-level, chronic exposures to many potential CWAs. In addition, much of the information which does exist regarding the long-term reproductive and teratogenic effects of these types of weapons is, unfortunately, somewhat contradictory. While it is possible that exposures to some CWAs might not generally be associated with serious, adverse reproductive effects, the discrepancies between the results of different studies are probably, in part, due to variability in individual responses to specific toxicants and the complexity of analyses of human epidemiological data. In addition, differences in dosing regimens, routes of exposure, and the animal models utilized for *in vivo* studies can confound comparisons of experimental results. The relative insensitivity of many reproductive endpoints might also contribute to the impression that some chemical weapons do not adversely affect reproductive function.

The embryo and fetus, without a developed blood–brain barrier and with only rudimentary DNA repair mechanisms and hepatic detoxifying and metabolizing capabilities, are especially susceptible, as compared to adults, to the adverse effects of low-level exposures to xenobiotics (Evans, 2007;

Newbold *et al.*, 2006). There has recently been increasing concern within the regulatory, public health, and scientific communities about the effects of prenatal exposures to potential reproductive toxicants, especially those capable of endocrine disruption, on humans and animals. In order to increase our understanding of the long-term, adverse reproductive effects associated with warfare and acts of terrorism, public knowledge of the use of CWAs or awareness of massive releases of reproductive toxicants associated with confirmed acts of terrorism should result in increased surveillance for phenotypic abnormalities in the most susceptible populations of humans and animals exposed during embryonic, fetal, and early postnatal development. Based on these epidemiological observations, carefully designed experiments mimicking ''real life'' exposures can be performed in multiple laboratory animal species, using sensitive biomarkers of toxic insult to reproductive development and function, to further elucidate the adverse reproductive effects of xenobiotic exposures likely to be associated with military and/or terrorist activities.

Our relative lack of understanding of the effects of CWAs and other xenobiotics on reproductive function can also be attributed to the complexity of the entire reproductive process and the mechanisms by which it is regulated. It should be evident from Figure 36.1 that maximum reproductive efficiency, including normal embryonic and fetal development, is dependent on the structural and functional integrity of multiple organs and tissues, as well as various physiological processes and signaling pathways within and (with respect to sexual reproduction and pregnancy) between individuals. Putative reproductive toxicants can affect one or several different steps in the reproductive process, depending on the physiological timing, duration, and level of exposure (Evans, 2007; Foster and Gray, 2008).

In ''real life'', humans and animals can be exposed to some toxicants both pre- and postnatally. Many organic xenobiotics have the potential to bioaccumulate within exposed individuals, possibly affecting future generations by way of genetic and epigenetic effects. However, reproductive endpoints, such as conception rates and sperm counts, are relatively insensitive, and subtle, toxicant-induced changes in reproductive efficiency can be overlooked or missed (Evans, 2007).

Much of the evidence for the adverse reproductive effects of selected toxicants will be based on cases involving wildlife exposures to environmental contaminants or on the experimental results of research exposing laboratory animals to large, pharmacological doses of potential toxicants. When available, data will be presented from accidental or intentional human and domestic animal exposures to toxicants associated with riot control and chemical warfare or with environmental catastrophes where incidences of infertility, abortion, and teratogenesis have been traced over the course of a number of years.

From an epidemiological perspective, it can be extremely challenging to determine the exact cause of reproductive abnormalities in humans and animals. Questions will often remain as to whether the observed poor reproductive outcomes associated with acute exposures to toxicants are due to direct effects of these chemicals on reproductive function or are secondary to toxicant-induced systemic disease and its accompanying stress (e.g. abortions and preterm births in intoxicated, pregnant women or animals). There are multiple factors, including exposures to mixtures of toxicants and other concurrently occurring causes of reproductive failure, which need to be taken into consideration in heterogeneous populations where exposures to toxic agents are not uniform between individuals. This is especially true in instances when there is a significant time interval between exposure to potential toxicants and the observed reproductive outcomes.

A. The Reproductive Toxicity of Riot Control Agents

The major lacrimatory and irritant riot control agents include α-chlorbenzylidene malonitrile (CS), dibenz (b,f)-1:4 oxazepine (CR), ω-chloroacetophenone (CN), and oleoresin of capsicum (OC pepper spray) (Salem *et al.*, 2008a). Exposure of pregnant women or animals to these compounds could be expected to be associated with maternal and/or fetal stress, which could potentially lead to the induction of premature parturition (Evans, 2007). Although the riot control agents CS and CN are both alkylating agents, with at least the potential to adversely affect embryonic and fetal development, neither of these chemicals has yet been found to be embryotoxic or teratogenic (Salem *et al.*, 2008a; Sanford, 1976). Limited studies performed with laboratory animals suggest that CR is neither embryotoxic nor teratogenic and that OC, with the possible exception of a slightly reduced crown–rump length, is not associated with any adverse effects on reproductive function (Salem *et al.*, 2008a).

B. The Reproductive Toxicity of CWAs

Given current global politics and the ''War on Terrorism'', pertinent information regarding many newer potential CWAs is very likely to be unavailable for public review. In order to be as complete as possible, some of the more historical and currently available CWAs will be discussed in the context of their primary, immediate, adverse effects on humans and animals. By organizing this discussion in that manner, the potential adverse reproductive effects of ''new'' CWAs can be anticipated based on the similarities of those toxicants to existing chemical weapons. For simplicity, CWAs will be broadly classified as vesicants (i.e. blistering agents), inhibitors of protein synthesis (e.g. ricin), inhibitors of cellular respiration or ''blood agents''

(e.g. hydrogen cyanide and cyanide-related compounds), and nerve agents (i.e. organophosphate compounds).

1. Vesicants

a. Arsenicals

While arsenicals will be discussed in this chapter with respect to their use in chemical warfare, the metalloid element arsenic, which is classified as a carcinogen, is also a potential environmental contaminant. Arsenicals continue to have important industrial and agricultural uses, and arsenic-containing feed additives, pesticides, and wood preservatives are all still readily available. In general, arsenic binds to sulfhydryl groups, with the activities of thiol-containing enzymes, including those involved in cellular energy production, frequently being adversely affected (Wismer, 2007). Increased capillary permeability is also associated with many acute intoxications involving arsenic.

It is important when discussing the toxicity of arsenicals to distinguish between the effects of organic and inorganic forms of arsenic. Several organic arsenicals, including Lewisite [dichloro (2-chlorovinyl) arsine or Agent L], diphenylcyanoarsine, and diphenylchloroarsine, have been used as vesicants and systemic toxicants (Ishii *et al.*, 2004; Wismer, 2007). Like other arsenicals, Lewisite has been associated with fetal death in laboratory animals; however, Lewisite is reported not to be teratogenic (Wismer, 2007). In contrast, a degradation product of diphenylcyanoarsine and diphenylchloroarsine, diphenylarsinic acid, has recently been associated with abnormal brain development in humans (Ishii *et al.*, 2004). Inorganic forms of arsenic, particularly arsenite and arsenate, have been associated with neoplasia, estrogenic activity, and testicular and ovarian toxicity, as well congenital neural tube, skeletal, and gonadal abnormalities, in laboratory rodents (Golub, 2006b). Epidemiological evidence in human populations has suggested that acute arsenic exposures with sublethal, maternal toxicity, and subchronic exposures to elevated arsenic concentrations in drinking water have both been associated with increased incidences of abortions, stillbirths, and pre-term deliveries (Golub, 2006b).

b. Chlorine Gas

Chlorine (Cl_2) is one of the more commonly produced chemicals in the USA, and chlorine gas is a potent oxidant which is very irritating and, potentially, corrosive (Kikilo *et al.*, 2008; Smith *et al.*, 2008; Wismer, 2007). Chlorine gas is used as a pulmonary and choking agent, and exposure is frequently associated moderate to severe, painful irritation of the eyes and respiratory tract (Wismer, 2007). Such stressful, sublethal exposures in late-gestational women or animals might be expected to be associated with the induction of premature parturition and, possibly, abortion. Oxidative stress can definitely have adverse effects on reproductive function, but the chronic disease usually associated with chlorine gas exposure is primarily related to the ocular and respiratory systems (Smith *et al.*, 2008). The limited information available on the reproductive effects of chlorine gas indicates that it is teratogenic (Wismer, 2007).

c. Phosgene and Phosgene Oxime

The most important industrial use of phosgene (Agent CG or carbonyl chloride) is in the production of isocyanates (Kikilo *et al.*, 2008), and MIC exposure is discussed with respect to its accidental release in Bhopal, India. Phosgene is classified as a choking agent, and it acylates sulfhydryl, amine, and hydroxyl groups. Phosgene oxime (Agent CX), a halogenated oxime, is a nonpersistent, chemical blistering agent, which, like phosgene, interacts with sulfhydryl and amine groups (Wismer, 2007). Other than possible adverse reproductive outcomes related to maternal and/or fetal stress or increased dermal absorption of concurrently used CWAs, phosgene oxime is unlikely to have direct adverse effects on reproductive function.

d. Sulfur Mustard

Sulfur mustard [*bis*-(2-chloroethyl) sulfide; mustard gas, Agents HD, H or HS] and analogs, such as 2-chloroethyl ethyl sulfide (CEES), are vesicants which can damage cells by alkylation of macromolecules [i.e. DNA, ribonucleic acid (RNA), and proteins], oxidative stress, glutathione depletion, and inflammation (Dacre and Goldman, 1996; Smith *et al.*, 2008; Watson and Griffin, 1992; Wismer, 2007). Similar to ionizing radiation and a variety of other radiomimetic alkylating agents, such as busulfan, cyclophosphamide and nitrogen mustard, sulfur mustard and its analogs can target rapidly dividing cells in multiple organs, including the testes and ovaries, as well as the developing embryo and fetus (Foster and Gray, 2008; Hurst and Smith, 2008; Rogers and Kavlock, 2008; Wismer, 2007). Consistent with DNA alkylation, as well as, possibly, other mechanisms of action, men exposed to sulfur mustard gas have been reported to have lower sperm counts and testosterone concentrations for several weeks following respiratory exposure, and Iraqi use of mustard gas has been associated with alterations in the infant sex ratio and an increase in some birth defects in children (Azizi *et al.*, 1995; Pour-Jafari, 1994; Wismer, 2007).

However, despite the epidemiological and laboratory animal evidence indicating that sulfur mustard is a teratogen and reproductive toxicant in humans and animals (Azizi *et al.*, 1995; Pour-Jafari, 1994; Wismer, 2007), contradictory research data involving several different routes of exposure have suggested no adverse sulfur mustard-related reproductive effects, especially at levels of exposure not associated with maternal intoxication (Dacre and Goldman, 1996; Watson and Griffin, 1992; Wismer, 2007). While, based on its mechanisms of action, it appears that exposures to sulfur mustard should be associated with several potential adverse reproductive outcomes, including maternal and/or fetal stress-induced premature parturition, additional mustard gas

inhalation experiments should be performed in rodent and nonrodent animal models to confirm this suspicion.

2. Inhibitors of Protein Synthesis

a. Ricin

The seeds of the ubiquitous castor bean plant (*Ricinus communis*) contain high concentrations of a highly toxic, relatively stable, heterodimeric, glycoprotein toxin, ricin, which is a type 2 ribosome-inactivating protein (RIP) (Burrows and Tyrl, 2001; Millard and LeClaire, 2008; Salem *et al.*, 2008b). The inhibition of protein synthesis by ricin and related type 2 RIPs has been associated with endothelial toxicity, and, depending on the route of exposure, severe gastrointestinal or respiratory disease and death (Millard and LeClaire, 2008). While it would be anticipated that acute, sublethal ricin intoxication would be associated with abortion or pre-term delivery secondary to maternal and/or fetal stress, ricin has also been shown to have direct adverse effects on reproductive function in female rabbits, causing abortion and inhibiting ovulation and implantation in this species (Salhab *et al.*, 1999). Because of the availability of the raw ingredients and the relative ease of its extraction, ricin has the potential to be a ''low-tech'' alternative for terrorist attacks targeting public water supplies (Salem *et al.*, 2008b). Additional research is needed in order to have a better idea of the adverse reproductive effects which would be anticipated with sublethal and/or chronic exposures to ricin and related toxins (Millard and LeClaire, 2008).

3. Inhibitors of Cellular Respiration (''Blood Agents'')

a. Hydrogen Cyanide and Cyanide-Related Compounds

With respect to their use in chemical warfare and, most likely, acts of terrorism, hydrogen cyanide [Agent AC, hydrocyanic acid (liquid form), or prussic acid], cyanogen halides and other cyanide-related compounds are frequently described as a ''blood agents'' (Kikilo *et al.*, 2008; Wismer, 2007). The major mechanism of action associated with acute cyanide intoxication is the formation of a stable complex with the ferric iron (Fe^{3+}) in cytochrome oxidases, resulting in cytotoxic hypoxia from the inhibition of cellular respiration, oxygen utilization and energy production (Ballantyne and Salem, 2008; Wismer, 2007). As a result of the rapid lethality of this class of compounds, very few studies have been conducted to investigate the adverse reproductive effects of hydrogen cyanide and cyanide-related compounds (e.g. cyanogen halides, cyanides, and nitriles). However, there is evidence to suggest that cyanide exposure in laboratory animals and livestock exposures to plants containing cyanogenic glycosides can be associated with embryonic and fetal death, as well as teratogenesis (Ballantyne and Salem, 2008; Burrows and Tyrl, 2001; Wismer, 2007). In addition, it would be anticipated that sublethal cyanide-induced hypoxia could cause enough maternal and/or fetal stress to result in abortion or pre-term deliveries.

4. Nerve Agents

a. Organophosphate Nerve Agents

The development of easily disseminated nerve agents as chemical weapons has been of interest to both military strategists and terrorist organizations because of the ability of these chemicals to rapidly incapacitate and kill opposing forces, as well as civilian populations. The major chemical nerve agents, tabun (Agent GA), sarin (Agent GB), soman (Agent GD), cyclosarin (Agent GF), and Agent VX, are extremely toxic, and even very brief exposures to these nerve agents can be lethal (Kikilo *et al.*, 2008; Watson *et al.*, 2006; Wismer, 2007). These chemicals are classified as organophosphorus, organophosphate, or ''OP'' compounds, and their mechanism of action involves the competitive and irreversible inhibition of acetylcholinesterase (AChE) (Gupta, 2007a; Watson *et al.*, 2006; Wismer, 2007). Commonly used OP and carbamate pesticides also inhibit AChE, and these chemicals, although generally less potent than those designed for use as CWAs, usually have longer lasting effects and the potential to be used as low-tech chemical weapons.

There have been some discrepancies between the results of various studies evaluating the reproductive toxicity of different OP compounds. While decreased libido has been observed in men following acute exposures to both OP nerve agents and insecticides, this ''reproductive'' effect is most likely related to the neurobehavioral effects, such as post-traumatic stress disorder, associated with acute exposures to these chemicals (McDonough and Romano, 2008). Some nerve agents have been associated with post-implantation morbidity and mortality in laboratory animals (Wismer, 2007), but rats and rabbits exposed to soman did not apparently experience fetal toxicity or prenatal mortality, even with maternal illness (Wismer, 2007). Similarly, low-level exposures to other nerve agents, as well as some insecticides, have not consistently resulted in impaired fertility and developmental abnormalities (McDonough and Romano, 2008). However, adverse reproductive effects have recently been reported by several authors in association with OP insecticide exposures (Joshi *et al.*, 2007; Peiris-John and Wiskremasinghe, 2008; Sikka and Gurbuz, 2006). Chlorpyrifos exposure has resulted in decreased sperm counts and testosterone concentrations, as well as testicular degeneration, in laboratory animals (Joshi *et al.*, 2007). Similar abnormalities have also been observed in humans following low-level exposures to OP insecticides (Peiris-John and Wiskremasinghe, 2008; Sikka and Gurbuz, 2006). It has been reported that OP insecticides can cause disturbances in the feedback loops within the hypothalamic–pituitary–adrenal axis, thereby affecting the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (Sikka and Gurbuz, 2006), and some members of this class of pesticides have even been reported to have antiandrogenic activity

(Kitamura *et al.*, 2006). In addition, exposures to OP insecticides can cause oxidative stress leading to increased apoptosis within the testes (Sikka and Gurbuz, 2006).

As mentioned previously, maternal and/or fetal stress associated with sublethal exposures to OP insecticides could lead to an increased incidence of abortions or pre-term births in intoxicated pregnant women and animals. Because of lower levels of detoxifying enzymes (i.e. paraoxonase), the fetus appears to be more susceptible to OP intoxication than adults, and developmental neurotoxicity and growth retardation have been associated with low-level, prenatal exposures of humans to OP insecticides (Desaiah, 1998; Eskanazi *et al.*, 2008; Peiris-John and Wickremasinghe, 2008). In addition to the maternal and fetal effects, OP insecticides can also have direct toxic effects on the placenta, possibly involving (depending on the species) AChE inhibition within the placental cholinergic system (Pelkonen *et al.*, 2006).

Since the effects of OP insecticides are generally longer lasting and more diverse than those of OP nerve agents, extrapolations between OP insecticides and nerve agents need to take into consideration the toxicokinetic and toxicodynamic differences between these two classes of OP compounds (McDonough and Romano, 2008). Given their frequent occupational use and the duration of the toxic effects of OP insecticides, it is probably more likely that adverse reproductive outcomes will be investigated and observed with exposures to these compounds than with exposures to nerve agents specifically designed for immediate incapacitation without environmental persistence. Depending on the circumstances, acute or low-level exposures to OP nerve agents might not be associated with overt effects on reproductive function, especially when direct, toxicant-induced effects on reproductive performance are of secondary importance to neurological and/or psychological concerns and the reproductive endpoints being assessed are relatively insensitive. Duration, route, and amount (i.e. dose) of nerve agent exposure, the developmental period during which exposure occurs, and the reproductive endpoints and animal species being evaluated are factors which will need to be taken into consideration in the design of future studies investigating the direct effects of nerve agents on fertility and embryonic and fetal development.

5. The Reproductive Toxicity of Environmental Contaminants Resulting from Acts of Terrorism

Not all acts of chemical warfare will necessarily involve weapons specifically designed for that purpose. Especially in instances of terrorism or military attacks involving nongovernmental militias or governments with limited weapons resources, chemical warfare can be low tech and make use of toxic chemicals in commercially available products or those hazardous materials present at manufacturing, processing, or storage facilities. Ionizing radiation can be released into the environment through strategic military use of nuclear weapons or from nuclear accidents involving municipal power plants, nuclear-powered aircraft carriers, and submarines or the explosion of misplaced, misused, or stolen nuclear ''weapons of mass destruction''. In addition, many potential reproductive toxicants, including pesticides, are routinely used in various manufacturing and agricultural processes. Acts of terrorism or military strikes on industrial or agricultural complexes have the potential to greatly increase the exposure of humans and animals to a large number of different toxicants in the air, water, soil, and food chain.

Depending on the circumstances, both short- and long-term (i.e. immediate and delayed) morbidity and mortality can be observed in environmental disasters. In these types of catastrophic events, illness and death can be due to the direct effects of toxicants, or they can arise secondarily from other factors associated with the environmental release of xenobiotics. Related conditions, such as famine, can accompany disasters and negatively impact reproductive function in humans and animals. The very real or, in some cases, imagined or exaggerated threats to human and animal welfare from environmental contaminations can be associated with instances of mass fear, panic, and emotional incapacitation. These psychological stresses can affect reproductive function and, especially, gestational length and fetal survival in humans and animals. Emotional responses are naturally heightened with toxic exposures involving pregnant women and children.

6. Ionizing Radiation

Ionizing radiation can target rapidly dividing cells in multiple organs, including the testes and ovaries, as well as the developing embryo and fetus (Cockerham *et al.*, 2008; Foster and Gray, 2008; Rogers and Kavlock, 2008). Exposure of males to ionizing radiation can result in diminished spermatogenesis and testosterone production by the testes, with increased secretion of LH and FSH by the anterior pituitary (Cockerham *et al.*, 2008). Consistent with these effects, Ukrainian workers involved in the cleanup of radioactive materials after the Chernobyl nuclear accident had increased ultramorphological sperm abnormalities (Cockerham *et al.*, 2008; Fischbein *et al.*, 1997). Similar to the radiation-induced endocrine effects observed in the testes, ovarian steroid production is reduced by exposure to ionizing radiation (Cockerham *et al.*, 2008). Depending on the timing and dose of the radiation exposure, ionizing radiation can cause pubertal failure, ovarian failure, or premature menopause in women. Clusters of Down syndrome in Belarus 9 months following the explosion at the Chernobyl nuclear power plant suggest a radiosensitive phase of oogenesis in mammals around the time of ovulation and conception (Zatsepin *et al.*, 2007). High radiation exposure in late-gestational women or pregnant animals has the potential to cause abortion or pre-term births associated with maternal and/or fetal radiation sickness and stress. Depending on the stage of development and the dose of radiation, exposure of the conceptus, embryo, or fetus to

ionizing radiation can result in lethality or morphologic abnormalities (Cockerham *et al.*, 2008), and observations in humans and animals after the Chernobyl incident are consistent with these developmental effects (Østerås *et al.*, 2007; Peterka *et al.*, 2007). In addition, anxiety associated with exposures of pregnant women to ionizing radiation from the Chernobyl nuclear accident reportedly led to increased incidences of induced abortions in several European countries, even in instances where the exposure was minimal (Cordero, 1993).

7. Pesticides and Other Organic Contaminants

Pesticides and other organic contaminants are ubiquitous in both industrial and agricultural settings. Acts of terrorism have the potential to increase the exposure of humans and animals to these types of xenobiotics in the environment by targeting industrial and agricultural complexes. The massive release of pesticides, in particular, has the potential to be a readily available means of inciting fear and inducing morbidity and mortality in humans and animals. In fact, as mentioned previously, carbamate and OP insecticides have the same basic mechanism of action as the previously discussed AChE-inhibiting nerve agents, and MIC, an intermediate in the production of carbamate insecticides, contains a cyanide moiety.

There have been many, well-documented instances of reproductive abnormalities in species of wildlife living in environments contaminated by a wide range of industrial and/or agricultural chemicals (Evans, 2007; Guillette, 2006; Hess and Iguchi, 2002; Jobling and Tyler, 2006; MacLaclan, 2001; MacLaclan *et al.*, 2006). Wildlife populations are very likely sentinels for exposure to reproductive toxicants because of the contamination of the aquatic habitats in which many of them live and the bioaccumulation of some organic chemicals in predators (Hess and Iguchi, 2002). There is also recent evidence to suggest that domestic animals can act as potential sentinels for human exposure to endocrine disruptors and that hyperthyroidism in cats might be associated with exposure to polybrominated diphenyl ethers (PBDEs) (Dye *et al.*, 2007).

Based on the observations of reproductive toxicity (including endocrine disruption) in wildlife and domestic animals, as well as ongoing concerns about reproductive dysgenesis in human populations and the observed effects of industrial accidents involving MIC and dioxins, there has been increasing interest in the effects of prenatal exposures of humans to suspected endocrine disruptors and other reproductive toxicants. However, when impaired reproductive function is discovered in adults, it is difficult to comment with complete certainty on the relative contributions of pre- versus postnatal exposures to reproductive toxicants. There is a wide array of pesticides and other organic environmental contaminants which have the potential to adversely impact reproductive function. Specific epidemiological or laboratory studies suggesting adverse reproductive effects of exposures to these xenobiotics will be discussed with respect to observed abnormalities in male and female reproductive function, as well as embryonic and fetal development.

a. Adverse Effects of Pesticides and Other Organic Contaminants on Male Reproductive Function

''Androgenization'' or a state of indeterminate sexual development encompasses both feminization and demasculinization in males and, similar to the testicular dysgenesis syndrome (TDS) described in humans, has been observed in populations of various vertebrates, including fish, amphibians, reptiles, birds, and mammals (Edwards *et al.*, 2006; Evans, 2007). Adult and immature amphibians exposed to the herbicide atrazine and hatchling, juvenile, and adult male alligators originating from a lake previously contaminated with DDT and other persistent, bioaccumulated pesticides have been reported to exhibit varying patterns of androgenization (Evans, 2007; Hayes *et al.*, 2006; Milnes *et al.*, 2006). Although still somewhat controversial, there is evidence to support the observation that sperm counts in men within some industrialized regions of the world have been decreasing over the last several decades (Jørgensen *et al.*, 2006; Skakkebæk *et al.*, 2006; Swan *et al.*, 2000). The findings of epidemiological studies have suggested a relationship between decreased anogenital distance and prenatal exposures of male infants and phthalates used as plasticizers, as well as a correlation between reduced semen quality in men within certain regions of the USA and the metabolites of several economically important herbicides (Swan *et al.*, 2003a, b, 2005). In addition, a recently completed epidemiological study in Italy has demonstrated a significant relationship between postnatal exposure to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and abnormal semen and endocrine parameters in men (Mocarelli *et al.*, 2008).

The dicarboximide fungicides, vinclozolin and procymidone, and/or their metabolites inhibit the binding of androgens to nuclear androgen receptors and can demasculinize and feminize the prenatally exposed male fetus or induce important alterations in pre- or peripubertally exposed offspring (Evans, 2007; Gray *et al.*, 2006; Monosson *et al.*, 1999). While still subject to debate among scientists, vinclozolin has also been reported to be capable of inducing epigenetic modifications which facilitate the occurrence of transgenerational or vertically transmitted reproductive abnormalities (Anway *et al.*, 2005; Anway and Skinner, 2006). Linuron, p,p′-DDE, prochloraz, PBDEs, and selected OPs can function as androgen receptor antagonists (Gray *et al.*, 2006; Kitamura *et al.*, 2006), and AhR-mediated effects of TCDD can interfere with the biosynthesis of testosterone and disrupt testosterone signal transduction pathways (Jana *et al.*, 1999; Mocarelli *et al.*, 2008; Sikka *et al.*, 2005).

The testes have xenobiotic biotransformation capabilities within both Leydig and Sertoli cells (Thomas and Thomas, 2001). While many toxicants and/or their metabolites are capable of producing relatively nonspecific effects, such as

oxidative stress, there are a number of pesticides and other organic compounds which target specific cell populations within the testes. Several toxicants targeting Sertoli cells, including diethylhexyl phthalate (DEHP) and 2,5-hexanedione (a metabolite of *n*-hexane), have age- and species-specific effects (Creasy and Foster, 2002; Foster and Gray, 2008; Thomas and Thomas, 2001). Tri-*o*-cresyl phosphate (TOCP), an industrial chemical used in lacquers and varnishes and associated with some organophosphate insecticides, inhibits LH-induced steroidogenesis in the Leydig cells but, after Leydig cell-mediated conversion to its active metabolite, causes morphological abnormalities in Sertoli cells (Creasy and Foster, 2002; Evans, 2007; Thomas and Thomas, 2001).

As mentioned previously with regard to sulfur mustard, a variety of radiomimetic alkylating agents, including busulfan, cyclophosphamide and nitrogen mustard, can target rapidly dividing mitotic or meiotic germ cells in the testes. In some instances, xenobiotics can target a specific population of germ cell precursors, such as spermatogonia spermatocytes or round or elongate spermatids (Creasy and Foster, 2002; Evans, 2007; Foster and Gray, 2008). TCDD appears to adversely affect several populations of spermatozoal precursors and alters the sex ratio in favor of female offspring (i.e. decreased viability of Y chromosome-bearing sperm) (Foster and Gray, 2008; Ishihara *et al.*, 2007; Mocarelli *et al.*, 2008; Thomas and Thomas, 2001).

b. Adverse Effects of Pesticides and Other Organic Contaminants on Female Reproductive Function

A wide range of agricultural and industrial chemicals have estrogenic and/or antiestrogenic activities (Evans, 2007), and some of the synthetic xenobiotics most commonly discussed with respect to these activities include DDT, polychlorinated biphenyls (PCBs), and TCDD (MacLachlan, 2001). Effluents from industrial and agricultural activities have been shown to have androgenic activities and are associated with masculinization of female fish (Evans, 2007; Gray *et al.*, 2006; Orlando *et al.*, 2004).

The effects of toxicants on specific cell types within the ovaries are not as well understood as they are in the testes (Thomas and Thomas, 2001). Many female reproductive toxicants do not actually target particular cell lines but, rather, disrupt the endocrine milieu of the tubular genitalia or cause changes in ovarian structures secondary to alterations in the hypothalamic–pituitary–gonadal axis (Yuan and Foley, 2002). Like the testes, the ovaries also have some xenobiotic biotransformation capabilities, and oxidative damage can adversely affect ovarian structure and function (Thomas and Thomas, 2001; Yuan and Foley, 2002). Phthalates and TCDD can delay or decrease ovulations, and, like sulfur mustard and ionizing radiation, some of the alkylating agents reported to adversely affect rapidly dividing germ cells within the testes can also adversely affect primordial follicles within the ovary (Devine and Hoyer, 2005; Thomas and Thomas, 2001). Several PAHs [i.e. BaP, 3-methylcholanthrene (3-MC) and DMBA] and 1,3-butadiene appear to target oocytes in preantral follicles, and DMBA can adversely affect antral follicular development (Devine and Hoyer, 2005; Evans, 2007).

c. Adverse Effects of Pesticides and Other Organic Contaminants on Embryonic/Fetal Development

As has been emphasized previously, the developing fetus undergoing phenotypic sexual differentiation is particularly susceptible to the adverse effects of various agonists and antagonists of estrogen and androgen receptors (Evans, 2007; Hess and Iguchi, 2002). A large number of xenobiotics, including many pesticides (e.g. carbamates, OPs, organochlorines, and pyrethroids) and other potential organic environmental contaminants, have been recognized as potential teratogens in humans and animals (Desaiah, 1998; Evans, 2007; Rogers and Kavlock, 2008). Alkylating agents with radiomimetic activity, such as busulfan, cyclophosphamide, and nitrogen mustard, cause teratogenesis by targeting rapidly replicating cells (Rogers and Kavlock, 2008). TCDD has been found to be teratogenic both in laboratory animals exposed experimentally (Aragon *et al.*, 2008; Kransler *et al.*, 2007) and in humans exposed following an accidental release in Seveso, Italy, in 1976 (Alaluusua *et al.*, 2004). Accidental exposure to MIC in Bhopal, India, in 1984 resulted in a significant increase in spontaneous abortions and neonatal mortality in humans (Varma, 1987; Varma and Mulay, 2006), and these epidemiological data were corroborated by the results of a subsequent rodent experiment (Varma, 1987). In addition, some xenobiotics can cause fetal death and abortion by having direct toxic effects on the placenta, rather than on the fetus itself (Gupta, 2007c; Pelkonen *et al.*, 2006).

8. Heavy Metals

Heavy metals are routinely used in various manufacturing processes and are contained within many products commonly used by humans. Acts of terrorism have the potential to increase the environmental exposure of humans and animals to heavy metals by targeting industrial complexes and sewage treatment facilities. Because a number of heavy metals have the potential to affect different stages of reproductive function by different mechanisms of action, the adverse effects of metals on male and female reproduction and embryonic and fetal development will be discussed separately.

a. Adverse Effects of Heavy Metals on Male Reproductive Function

Excessive cobalt can potentially interfere with normal spermatogenesis, and even generalized hypoxia related to increased blood viscosity which affects the testes (Evans, 2007; Thomas, 1995). Chromium and vanadium have also been associated with adverse reproductive effects, and cisplatinum exposure has been associated with the death of spermatocytes and spermatids, as well as disruption of

Sertoli cell tight junctions (Evans, 2007; Thomas, 1995; Thomas and Thomas, 2001). Exposure of male laboratory animals to organotin compounds has been associated with reduced testicular size, alterations in testicular morphology, and impaired spermatogenesis (Ema and Hirose, 2006; Evans, 2007).

Lead and cadmium are ubiquitous heavy metals and have both been associated with testicular toxicity and impaired fertility in a number of species. Divalent lead is known to interact with physiological processes involving calcium and generally has an affinity for sulfhydryl groups (Evans, 2007). Lead is reported to be toxic to germ cells as well as Leydig cells and can suppress anterior pituitary secretion of LH and FSH (Evans, 2007; Thomas and Thomas, 2001). Lead also appears to be able to adversely affect the ability of spermatozoa to fertilize ova; however, this effect, like others associated with lead exposure, appears to be dependent on age and individual variations in susceptibility, adaptation, and reversibility (Evans, 2007; Sokol, 2006). Like lead, cadmium is thought to adversely affect male reproduction by inhibition of spermiation, as well as by interactions with the hypothalamic–pituitary–gonadal axis and adverse effects on the endothelium of the testicular and epididymal vasculature (Akinloye *et al.*, 2006; Creasy and Foster, 2002; Evans, 2007; Thomas, 1995). Cadmium can also alter the junctional complexes between adjacent Sertoli cells and disrupt the integrity of the blood–testis barrier (Akinloye *et al.*, 2006; Evans, 2007; Thomas and Thomas, 2001).

b. Adverse Effects of Heavy Metals on Female Reproductive Function

The ovaries do not appear to be as sensitive to the toxic effects of heavy metals as do the testes (Evans, 2007; Thomas, 1995). The neuroendocrine function of the hypothalamic–pituitary–gonadal axis appears to be targeted by lead in the female, as well as in the male (Evans, 2007). Anterior pituitary release of FSH and LH and ovarian steroidogenesis can be inhibited by cadmium (Evans, 2007; Hoyer, 2006; Thomas, 1995). Exposure of female laboratory animals to organotin compounds has been associated with reductions in follicular development and size, as well as the formation of corpora lutea, and it has recently been suggested that tributyltin and cadmium might also have estrogenic activities (Ema and Hirose, 2006; Evans, 2007; Golub, 2006b).

c. Adverse Effects of Heavy Metals on Embryonic/Fetal Development

Several heavy metals have been identified as teratogens and possible abortifacients in humans and animals, and the adverse effects of prenatal lead exposure on the developing nervous systems of both human and laboratory animal species have been well documented (Evans *et al.*, 2003; Rice, 1998; Rogers and Kavlock, 2008). Prenatal exposure to organotins has been associated with pregnancy loss and impaired ossification in rodents (Ema and Hirose, 2006). The outcomes of an industrial accident in Japan and misuse of contaminated grain in Basra, Iraq, clearly demonstrated the developmental neurotoxicity of organic mercury (i.e. methyl mercury and related compounds) in humans and animals (Chang and Guo, 1998; Cordero, 1993; Golub, 2006b). Other heavy metals, including cadmium, have been associated with placental toxicity, as well as developmental neurotoxicity (Gupta, 2007b; Hastings and Miller, 1998), and it has been recently reported that cadmium and other metals or metalloids might also have estrogenic effects (Golub, 2006b).

IV. CONCLUDING REMARKS AND FUTURE DIRECTION

Reproduction is a critical biological process, required for financially viable livestock production, as well as long-term survival of human and animal populations. Toxicant-induced abortions, congenital defects and infertility can have devastating effects on humans, domestic animals, and wildlife species. There is growing global concern about all of the potential adverse effects, including those on reproduction, of exposures to CWAs, and other xenobiotics resulting from military or terrorist activities. The information presented in this chapter was intended to familiarize the reader with terminology and concepts pertinent to reproductive toxicity, including endocrine disruption, and to provide an overview of what is understood about the adverse reproductive effects of selected toxicants. It is hoped that the information and references provided in this chapter will assist readers in making informed decisions in their interpretation of experimental or epidemiological data and their preparation for future experiments or clinical investigations.

SHASHI K. RAMAIAH AND ATRAYEE BANERJEE

I. INTRODUCTION

Xenobiotic-induced liver injury has become the most frequent cause of acute liver failure in humans in the USA and around the world, exceeding all other causes combined (Watkins and Seef, 2006). Owing to its detoxification mechanisms, the liver protects the individual against xenobiotic-induced injury. Certainly, the liver toxicity caused by chemical warfare agents is a potential area of concern.

Chemical-induced liver injury is encountered in a variety of circumstances. Some natural toxins such as the peptides of *Amanita phalloides*, the pyrrolizidine alkaloids, the toxin of the cycad nut, and other plant toxins are hazards posed by the environment. Some mycotoxins are ingested unknowingly because of feed contamination due to climatic conditions favorable to fungal growth. Other circumstances of exposure to hepatotoxins include contamination of water supply with cyanobacterial toxins, which led to the tragic death of 60 patients in a hemodialysis clinic in Brazil in 1996 (Jochimsen *et al.*, 1998).

Research in the last decade has focused on elucidating different mechanisms for chemical-induced liver injury. Investigators have attempted to understand the basis for hepatic injury. The goal of this chapter is to provide a basic understanding of liver pathophysiology and to introduce the general concepts of liver injury. The chapter also describes few examples of chemical warfare agents that can inflict liver damage.

II. STRUCTURAL ORGANIZATION OF THE LIVER

Hepatic lobule and hepatic acinus are relatively well-accepted models to describe the structure and functional aspects of the liver. Histologically, the hepatic lobule is a hexagonal region of the liver parenchyma around the central vein. Typically, six portal triads, consisting of branches from the portal vein and hepatic artery as well as bile ductules, border the edge of the lobule. Cords of hepatocytes are arranged radially around the central vein and blood sinusoids form between them. The hepatic parenchyma is divided into three zones based on the proximity to the central vein. The area closest to the central vein is termed centrilobular, the area near the portal triads is periportal, and the area between the centrilobular and periportal parenchyma is termed midzonal.

Alternatively, hepatic acinus is defined as the structural and functional unit in the liver based on the hepatic microcirculation. In simple terms, the hepatic acinus is defined as a parenchymal mass organized around the portal triad. Within the acinus, blood drains from the portal area via the sinusoids into the central hepatic vein. The acinus is arbitrarily divided into zone 1 which corresponds to the periportal zone of the hepatic lobule, zone 2 which corresponds to the midzonal parenchyma, and zone 3 which corresponds to the centrilobular zone. The majority of blood supply to the liver is from the portal vein. Approximately 60 to 80% of the blood originates from branches of the portal vein and supplies nutrients and toxins from the gastrointestinal tract while 20 to 40% of the blood originates from the hepatic artery supplying oxygen (Treinen-Moslen, 2001). The blood from the portal vein and hepatic artery is mixed in the penetrating vessels which then enter the sinusoids. Blood flows sequentially through zone 1, zone 2, and zone 3 before draining via the central vein. Because of this preferential blood circulation, hepatocytes in zone 1 receive blood that is 9 to 13% oxygenated whereas zone 3 is relatively hypoxic, the blood is 4 to 5% oxygenated and nutrient depleted (Treinen-Moslen, 2001).

In addition to hepatic parenchymal cells which are hepatocytes, hepatocyte stem cells, termed oval cells, are reported to be located in the canals of Hering where bile canaliculi from the hepatic cords converge on bile ductules of the portal triad. It is postulated that new hepatocytes travel down hepatic cords to replace the aging and damaged zone 3 hepatocytes.

Sinusoids lined by specialized endothelium are blood channels located between hepatocyte cords. The endothelial lining of the sinusoids is discontinuous and has fenestrae to facilitate movement of fluid and molecules less than 259 kDa (Treinen-Moslen, 2001; Plumlee, 2004; Watkins, 1999). This material enters the space of Disse, which is located between the endothelium and the hepatocytes. Within the space of Disse, hepatocytes contact free and protein-bound molecules which may be absorbed by diffusion or active transport.

A. Hepatic Functional Capacity

The liver contributes to a plethora of functions. Liver filters the blood drained from the gastrointestinal tract via the portal vein for xenobiotics, endotoxins, ammonia, and other bacteria-derived products (Treinen-Moslen, 2001; Plumlee, 2004). The liver is directly involved in glucose homestasis (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004), cholesterol synthesis and uptake (Treinen-Moslen, 2001), synthesis of proteins such as clotting factors, albumin, and very low density lipoprotein (Treinen-Moslen, 2001; Plumlee, 2004), storage of glycogen, lipids, minerals, and vitamins (Plumlee, 2004), metabolism and excretion of hemoglobin breakdown products (Plumlee, 2004), steroid hormones (Brown, 2001), and drug metabolites.

There is remarkable regiospecificity and metabolic diversity of the hepatic zones to accommodate its numerous functions. In addition to differences in oxygen gradients (zone 3 hepatocytes are oxygen depleted compared to zone 1 hepatocytes), hepatocytes of zone 3 in particular are rich in drug-metabolizing enzymes. Zone 3 hepatocytes are involved in glycolysis and lipogenesis (Plumlee, 2004) and zone 1 hepatocytes are mitochondria rich (Treinen-Moslen, 2001; Plumlee, 2004). Functions of zone 1 hepatocytes include bile salt extraction, fatty acid oxidation, gluconeogenesis, and protein synthesis (Treinen-Moslen, 2001; Plumlee, 2004; Piñeiro-Carrero and Piñeiro, 2004). Zone 1 hepatocytes have the highest levels of glutathione (Treinen-Moslen, 2001).

Bile secretion is a major function of the liver. Bile is composed of bile salts, bilirubin, glutathione, phospholipids, cholesterol, proteins, organic anions, metals, and conjugated xenobiotics (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004). Bile salts and bilirubin enter bile canaliculi via active transport through hepatocyte membranes. Canaliculi are dynamic structures located between hepatocytes and formed by hepatocyte membranes (Treinen-Moslen, 2001; Plumlee, 2004). Energy-dependent transport exists for certain hormones, drugs, and other xenobiotics. These include a group of multiple drug resistance p-glycoproteins that transport lipophilic cationic drugs, estrogens, phospholipids, and canalicular multiple organic anion transporters involved in movement of molecules conjugated to glutathione, glucuronide, and sulfate. Metal and mineral transport is important for mineral homeostasis and occurs through facilitated diffusion and receptor mediated endocytosis across the sinusoidal membrane. Lysosomes are involved in storage and export of metals and minerals into canaliculi.

Canaliculi enter canals of Hering in the portal triad and lead to intrahepatic bile ducts which coalesce to form the hepatic bile duct. The bile duct empties the bile into the gall bladder which then is released into the duodenum. Bile that is excreted into the small intestine enhances nutrient uptake, protects enterocytes from oxidation, and facilitates excretion of xenobiotics and endogenous waste in the feces (Treinen-Moslen, 2001).

B. Hepatic Cellular Components

In addition to the hepatocytes and the hepatocytic stem cells (oval cells) which are parenchymal in origin there are four types of nonparenchymal cells present within the liver. The nonparenchymal cells include the endothelial cells lining the sinusoids, bile duct epithelium, Kupffer cells, which are resident macrophages, the Stellate cells, also called Ito cells or fat storing cells, and the pit cells or large granular lymphocytes. In the rat, hepatocytes represent about 60% of the total cell number and 80% of hepatic tissue volume. Nonparenchymal cells in the rat are estimated to constitute about 30% of total cellular population, but comprise only 6–7% of tissue volume due to their small size relative to hepatocytes (Dahm and Jones, 1996).

Kupffer cells represent 80% of the fixed macrophages in the body. These cells are mostly located within the sinusoidal lumina in close association with endothelial cells. Kupffer cells function as phagocytes, ingesting foreign material which may arrive through the portal circulation (Treinen-Moslen, 2001; Plumlee, 2004) as well as apoptotic or necrotic hepatocytes. Kupffer cells have other immune functions in that they act as antigen presenting cells and secrete various cytokines. Kupffer cells may store minerals and are also involved in the pathogenesis of a variety of liver diseases induced by toxins such as ethanol (Laskin, 1990; Thurman *et al.*, 1998).

Stellate cells are located within the sinusoids and store fat and vitamin A (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004; Plumlee, 2004). In the event of liver injury, stellate cells may become activated to a myofibroblast-like phenotype (Plumlee, 2004; Maddrey, 2005). Activated stellate cells produce collagen and play a role in the pathogenesis of hepatic fibrosis.

Pit cells are natural killer cells which have antineoplastic actions (Treinen-Moslen, 2001; Plumlee, 2004). They are also involved in granuloma formation (Plumlee, 2004).

III. FACTORS INFLUENCING HEPATIC TOXICITY

A. Preferential Hepatic Uptake

As mentioned above, the liver has a dual blood supply. The hepatic artery delivers material from the systemic circulation and the portal blood flow delivers directly from the gastrointestinal system. The portal system is involved in the ''first pass effect'', where the nutrients and xenobiotics that are absorbed from the stomach and intestines are filtered through the liver before reaching the systemic circulation (Treinen-Moslen, 2001). The space of Disse allows close contact between circulating plasma, plasma proteins, and hepatocytes, allowing for rapid diffusion of lipophilic compounds across the hepatocyte membrane. Some compounds are specifically taken up by sinusoidal transporters, including

phalloidin from several species of mushrooms in the genus *Amanita*, microcystin produced by the cyanobacteria *Microcystis aeruginosa*, and bile acids.

Liver cells have the potential to accumulate high levels of metals and vitamins, which can lead to toxic injury. Excessive vitamin A storage in stellate cells acutely leads to activation and proliferation of these cells (Treinen-Moslen, 2001), while chronic high levels can lead to hepatic fibrosis and portal hypertension, precipitating increased fibrosis (Piñeiro-Carrero and Piñeiro, 2004; Zimmerman, 1999; Maddrey, 2005). The liver is also responsible for iron homeostasis. There is a receptor mediated uptake of iron from the sinusoids and sequestration in storage proteins such as ferritin. High levels of iron cause lipid peroxidation of zone 1 hepatocytes (Treinen-Moslen, 2001). A common example of hepatic accumulation of metals is copper mediated liver toxicity noted in certain breeds of dogs (Bedlington terriers, Dobermans, and Dalmatians) where copper is stored within lysosomes of hepatocytes resulting in progressive accumulation of copper resulting in liver necrosis (Rolfe and Twedt, 1995).

B. Xenobiotic Metabolic Bioactivation

Most xenobiotic agents absorbed by the small intestine are highly lipophilic. Renal excretion is the primary mechanism of xenobiotic removal, but kidney excretion of lipophilic compounds, which are frequently protein bound in the circulation, is poor (Sturgill and Lambert, 1997; Watkins, 1999; Dahm, 1996). Such lipophilic compounds must be metabolized to increase their water solubility for excretion (Sturgill and Lambert, 1997; Zimmerman, 1999; Dahm and Jones, 1996). Microsomal enzymes within the liver add functional groups or conjugate xenobiotics to water-soluble molecules to facilitate excretion. While these reactions often function in the detoxification of compounds, there is significant potential for toxification (Zimmerman, 1999). Examples of phase I reactions include oxidation, reduction, and hydrolysis. Phase I enzymes, which are predominantly located in zone 3 of the hepatic lobule, may produce reactive metabolites.

Many hepatic enzymes are present in the smooth endoplasmic reticulum of the hepatocyte. When liver tissue is homogenized, the endoplasmic reticulum breaks down into small vesicles known as microsomes, thus these enzymes are termed microsomal enzymes. As a rule, microsomal enzymes require oxygen and NADPH to function (Brown, 2001; Dahm and Jones, 1996). Most phase I enzymes contain heme, giving them a red coloration, and they absorb light at a wavelength of 450 nm. Most cytochrome P450s act as mixed function oxidases (MFOs). Genes for cytochrome P450s are highly conserved in mammals. There are three gene families, CYP1, CYP2, and CYP3, and more than 36 cytochrome P450 isoenzymes have been identified in animals (Dahm and Jones, 1996; Watkins, 1999).

Oxidation is the major phase I reaction produced by the group of cytochrome P450s. Important substrates for CYP450s include steroid hormones and lipid-soluble drugs (Brown, 2001). Oxidative reactions frequently lead to the formation of highly reactive epoxides. These toxic metabolites are usually detoxified rapidly by phase II conjugation or other mechanisms, such as microsomal epoxide hydrolases (Piñeiro-Carrero and Piñeiro, 2004; Watkins, 1999).

Non-cytochrome P450 enzymes may also be involved in oxidative reactions. One such enzyme is alcohol dehydrogenase whose substrates include vitamin A, ethanol, and ethylene glycol. Aldehyde dehydrogenase is another enzyme. Most reduction reactions also involve microsomal enzymes, with the exception of ketone reduction. Nitro compounds are reduced to amines and volatile anesthetics undergo dehalogenation by microsomal enzymes. Hydrolysis reactions are involved in metabolism of compounds with amide bonds or ester linkages, as in the conversion of aspirin to salicylate (Brown, 2001).

C. Phase II/Conjugation Reactions

Phase II enzymes may be cytosolic or microsomal (Brown, 2001; Dahm and Jones, 1996). Phase II enzymes are predominantly involved in conjugating phase I metabolites or xenobiotics with functional groups. Phase II metabolites are rarely reactive, but there are a few exceptions, such as the glucuronide of the nonsteroidal anti-inflammatory drug diclofenac and the glutathione conjugate of α-naphthothiourea (ANTU). Phase II enzymes conjugate a polar group to the substrate at a hydroxyl group, carboxyl group, amino group, or sulfhydryl group produced through the actions of phase I microsomal enzymes. Polar molecules that are added to the substrate include glucuronic acid, sulfate derived from sulfuric acid ester, acetate, glutathione, methyl groups derived from methionine, and amino acids such as glycine and cysteine. These polar groups significantly increase water solubility of the substrate facilitating rapid renal or biliary excretion.

Glucuronidation is the most common phase II reaction in humans, though it is deficient in the neonate (Sturgill and Lambert, 1997; Piñeiro-Carrero and Piñeiro, 2004; Brown, 2001). Substrates for glucuronidation usually include steroid hormones, thyroxin, and bilirubin as well as many drugs, including salicylates and acetaminophen. Glucuronyl transferases are microsomal enzymes that catalyze the transfer of glucuronide from uridine 5′-diphosphate (UDP) (Watkins, 1999). UDP may be depleted in patients overdosed with acetaminophen or other drugs that undergo this detoxification pathway. Products of glucuronidation may be excreted in the bile or urine. Those excreted in the bile may undergo hydrolysis in the intestine, which leads to reabsorption of the parent compound in a phenomenon called enterohepatic cycling (Brown, 2001). Similar to CYP 450 enzymes, some agents can also induce glucuronyl transferases, such as phenobarbital (Sturgill and Lambert, 1997).

Sulfation is the primary conjugation reaction for substrates with phenol groups or aliphatic alcohols (Sturgill

and Lambert, 1997; Brown, 2001). These reactions are catalyzed by sulfotransferases in the cytoplasm. Agents that undergo sulfation include acetaminophen, morphine, ascorbic acid, and endogenous compounds like chondriotin, heparin, and some steroids. The pool of available sulfates may become saturated in drug overdoses.

Drugs with amine and hydrazine groups may be conjugated to acetate (Sturgill and Lambert, 1997). Sulfonamides often undergo acetylation (Brown, 2001). *N*-acetyltransferase is an enzyme in the cytoplasm involved in acetylation reactions.

Glutathione (GSH) and cysteine both have sulfhydryl groups which readily bind many phase I metabolites (Brown, 2001). GSH is a free radical scavenger that prevents membrane damage from reactive metabolites. These reactions may be spontaneous or catalyzed by GSH peroxidases, selenium-dependent enzymes. Because these enzymes are cytosolic, damaged membrane phospholipids must be released by phospholipase A2 for detoxification. GSH is also involved in reduction and recycling of other antioxidants such as vitamins E and C (Dahm and Jones, 1996). When oxidized, GSH forms a dimer which must be reduced by GSH reductases, NADPH-dependent enzymes. GSH may be depleted in the overdosed patient or due to fasting (Sturgill and Lambert, 1997; Piñeiro-Carrero and Piñeiro, 2004; Dahm and Jones,1996). *N*-acetylcysteine is frequently used to replenish GSH.

D. Phase III Reactions

In addition to phase I and II biotransformation enzymes, studies suggest the involvement of hepatic transporter systems involved in drug efflux from hepatocytes as a means for the liver to rid itself of foreign chemicals. These are termed phase III transporter systems. Several transporter families which mediate uptake of chemicals into liver and excretion of chemicals from liver into blood and/or bile have been cloned and identified. In general, the organic anion transporting polypeptide family (Oatps) along with organic cation transporter 1 (Oct1) and organic anion transporter 2 mediate uptake of a large number of xenobiotics from blood into liver. Conversely, multidrug resistance proteins (Mdrs), multidrug resistance associated proteins (Mrps), and breast cancer resistance protein (Bcrp) mediate efflux of xenobiotics from liver into bile or blood (Klaassen and Slitt, 2005).

E. Pathologic Manifestations of Hepatic Injury

1. Hepatic Steatosis/Fatty Liver

Hepatic steatosis is the accumulation of fat droplets within the hepatocytes. Steatosis is usually a common response noted with a variety of liver toxicants and represents a potentially reversible injury to hepatocytes (Treinen-Moslen, 2001). Grossly, the affected liver will be swollen with rounded edges, friable, and light brown to yellow in color. Compounds that produce prominent steatosis include the antiepileptic drug valproic acid and the antiviral agent fialuridine. Other toxins that may cause hepatic steatosis include aflatoxin and white or yellow phosphorus. Although steatosis has been considered benign and reversible, there are recent reports that suggest the progression of the steatosis stage to steatohepatitis, fibrosis, and cirrhosis (Ramaiah *et al.*, 2004). Recently, there is a syndrome noted in obese individuals, who are often type 2 diabetics, called nonalcoholic fatty liver disease (NAFLD) where hepatocytes are markedly steatotic and there is a marked inflammatory component (Diehl, 2005). Other disorders that result in fatty livers include hepatotoxic chemicals such as thioacetamide, ethanol, and carbon tetrachloride. It should be noted, however, that several endocrine abnormalities result in steatosis, thus assigning the cause to a specific etiology should be done with caution.

Steatosis is termed microvesicular if the fat droplets are small and do not completely displace the nucleus. Microvesicular steatosis likely indicates a slow lipid accumulation (Plumlee, 2004; Bastianello, 1987) and may indicate a deficiency in mitochondrial β-oxidation of fatty acids. It is a relatively severe form of steatosis and has been associated with some toxins including aflatoxin in primates and dogs (Zimmerman, 1999; Bastianello, 1987) and valproic acid in humans (Sturgill and Lambert, 1997; Zimmerman, 1999). In contrast, macrovesicular steatosis describes hepatocytes containing large, usually single fat droplets that displace the hepatocyte nucleus to the periphery of the cytoplasm. Macrovesicular steatosis indicates an imbalance between fatty acid uptake and secretion of very low density lipoproteins. This may be due to increased triglyceride mobilization, decreased fatty acid oxidation, decreased synthesis of very low density lipoproteins, or other metabolic anomalies (Plumlee, 2004; Treinen-Moslen, 2001; Sturgill and Lambert, 1997; Zimmerman, 1999).

2. Steatohepatitis

Steatohepatitis is the accumulation of lipids and the presence of inflammatory cells within hepatic parenchyma. Steatohepatitis is usually the next stage of steatosis if untreated (Bautista, 2002; French, 2003; Lieber, 1994). The inflammatory cells are usually neutrophils and mononuclear leukocytes. Conditions usually associated with steatohepatitis are alcoholic liver disease, NAFLD, and endotoxemia secondary to intestinal disease. Any toxic compounds that cause steatosis can also result in steatohepatitis if the condition is left untreated. Steatohepatitis may progress to fibrosis/cirrhosis and hepatocellular carcinoma if the inciting cause is not removed or treated (Diehl, 2002).

3. Apoptosis Versus Necrosis

Two forms of cell death are described within hepatocytes, apoptosis and necrosis. As with other organs, apoptosis is often called ‘‘programmed cell death’’ and is a normal physiologic process. Individual cells are affected (Dahm and Jones, 1996), cell death is not associated with

inflammation, and normal architecture of the hepatic parenchyma is maintained allowing regeneration (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004). Apoptotic cells undergo cell shrinkage and nuclear condensation and pyknosis, but mitochondrial function (Piñeiro-Carrero and Piñeiro, 2004) is maintained and the cell membrane remains intact (Zimmerman, 1999). Apoptotic cells are occasionally seen in the centrilobular area but are rapidly phagocytosed by macrophages and other hepatocytes (Plumlee, 2004). Apoptosis may be induced by xenobiotics due to oxidative stress (Piñeiro-Carrero and Piñeiro, 2004), decrease in apoptotic suppressors, or enhanced expression of apoptosis genes (Dahm and Jones, 1996).

Necrosis is the predominant form of cell death in most hepatotoxic insults. The term ''necrotic'' is used to describe ''dead and dying'' cells which are often identified by homogeneous eosinophilic cytoplasm on H&E stained liver sections with variable loss of nuclear and cellular detail. Degenerative changes to the hepatocyte may precede necrosis. During necrosis, cells lose osmotic homeostasis and there is swelling of hepatocytes as observed microscopically and organelles on an ultrastructural basis (Treinen-Moslen, 2001; Dahm and Jones, 1996). Energy production fails due to loss of calcium homeostasis (Dahm and Jones, 1996; Zimmerman, 1999). Eventually there is rupture of the cell membrane and leakage of cell contents.

Necrosis is often initiated by damage to membranes, either the plasma membrane of the cell or the membranes of organelles, particularly the mitochondria (Zimmerman, 1999). Cell membrane damage is often caused by membrane phospholipid peroxidation. Plasma membrane damage interferes with ion regulation, calcium homeostasis, energy production, and decrease in the ability of that organelle to sequester calcium. Inhibition of protein synthesis is an alternate mechanism that may cause cell necrosis. Toxins that act in this way include phalloidin and related mushroom toxins, which inhibit the action of RNA polymerase and therefore mRNA synthesis (Piñeiro-Carrero and Piñeiro, 2004).

4. Hepatic Pigment Accumulation

Various substances may accumulate within hepatocytes or Kupffer cells. These substances may be visible by microscopy as pigment. Occasionally, these pigments lend a grossly visible tint to the liver. Bile pigment may accumulate in canaliculi and bile ducts, particularly in zone 3, leading to a yellow to green color (Plumlee 2004; Zimmerman, 1999). Iron in the form of hemosiderin is stored in the liver as a yellow–brown pigment which may be visualized using Pearl's Prussian blue. Copper may be yellow–brown and is visualized using Rhodenase. Lipofuscin may be present within hepatocytes as a senile change. This yellow–brown pigment represents lipid accumulation within lysosomes.

5. Hepatic Cholestasis

Cholestasis may be transient or chronic (Treinen-Moslen, 2001) and may be subdivided into canalicular cholestasis and cholangiodestructive cholestasis. Canalicular cholestasis can be produced by drugs/chemicals that damage the bile canalicular structures and function. A key component of bile secretion involves several ATP-dependent export pumps such as the canalicular bile salt transporter that moves bile salts and other transporters that export bile constituents from the hepatocyte cytoplasm to the lumen of the canaliculus. Some of the drugs bind these transporter molecules resulting in the arrest of bile formation or movement within the lumen of the canalicular system (Klaassen and Slitt, 2005). Secondary bile injury can result if there is cholestasis due to the detergent action of bile salts on the biliary epithelium or hepatocytes in areas of cholestasis. Cholestasis can occur simply as a result of physical obstruction of canaliculi within the liver parenchyma (intrahepatic) or outside the liver (extrahepatic). Causes of cholestasis may include hepatobiliary tumors, endotoxemia, hepatocyte swelling, and intraductal crystals such as calcium salts of plant saponins. Disruption of actin filaments within the hepatocyte may cause cholestasis by preventing the normal pulsatile contractions that move bile through the canalicular system to the bile ducts. Drugs that bind to actin filaments such as phalloidin, those that affect cytoskeletal assembly such as microcystin, and those that affect calcium homeostasis and cellular energy production can generate this type of energy.

Cholangiodestructive cholestasis is caused by bile duct obstruction which may be intrahepatic or extrahepatic. Bile duct injury may lead to sloughing of epithelial cells into the lumen, cell edema, and inflammation, which may contribute to obstruction (Treinen-Moslen, 2001; Plumlee, 2004). Chronic lesions associated with cholangiodestructive cholestasis typically include bile duct proliferation and periductular fibrosis. Vanishing bile duct syndrome, characterized by a loss of bile ducts, has been seen in chronic cholestatic disease in humans (Zimmerman, 1999; Treinen-Moslen, 2001) and has been produced experimentally in dogs (Uchida, 1989).

6. Hepatic Fibrosis/Cirrhosis

Fibrosis usually results from chronic inflammation which can be the result of continuous exposure to a variety of hepatotoxic chemicals such as organic arsenicals, vinyl chloride, or high doses of vitamin A (Zimmerman, 1999), chronic ethanol ingestion and nonalcoholic fatty liver disease. Fibrosis usually occurs around the portal area, in the space of Disse, and around the central veins. This results in loss of liver architecture and function. The hepatocytes are replaced with fibrous material and thus there is hepatocyte loss. Periportal fibrosis may lead to portal hypertension.

7. Cirrhosis

Hepatic cirrhosis is typically the end stage of liver disease. Cirrhosis describes an irreversible change (Treinen-Moslen, 2001) characterized by accumulation of excessive collagen deposition in the form of bridging fibrosis which disrupts the hepatic architecture. Cirrhosis may be micronodular or macronodular depending on the amount of fibrosis and tissue regeneration. Liver transplantation is the only solution to restore adequate liver function in human medicine.

8. Patho-Mechanisms of Hepatic Injury

Mechanisms of liver injury have been divided into two categories, intrinsic and idiosyncratic. Intrinsic injury may lead to steatosis, necrosis, cholestasis, or a mixed form of damage, often with minimal inflammation (Sturgill and Lambert, 1997). Intrinsic liver injury is a predictable, reproducible, dose-dependent reaction to a toxicant (Sturgill and Lambert, 1997; Zimmerman, 1999; Piñeiro-Carrero and Piñeiro, 2004; Dahm and Jones, 1996). A threshold dose exists for xenobiotics causing intrinsic liver injury. There is commonly a predictable latent period between the time of exposure and clinical evidence of liver injury. This type of liver injury accounts for the vast majority toxic liver injury and is often caused by reactive products of xenobiotic metabolism, most commonly electrophiles and free radicals. A few drugs cause intrinsic liver injury without bioactivation. An abbreviated summary of mechanisms of intrinsic liver injury is illustrated in Figure 37.1.

Idiosyncratic responses are, by contrast, unpredictable responses to a drug or other toxicant. They are rare, non-dose dependent, and often associated with extrahepatic changes (Sturgill and Lambert, 1997; Piñeiro-Carrero and Piñeiro, 2004; Zimmerman, 1999; Shenton, 2004). Idiosyncratic drug reactions often occur after sensitization followed by reexposure to a drug. There is a usually a delay of 1–5 weeks, and occasionally several months, between the time of the first dosing and the time clinical signs become evident, but onset is expedited with rechallenge (Watkins, 1999; Sturgill and Lambert, 1997; Dahm and Jones, 1996). Hepatic changes associated with idiosyncratic drug reactions include necrosis and cholestasis, or both, and there is often an inflammatory response involving macrophages and eosinophils. Extrahepatic clinical signs may include pyrexia, rash, and peripheral eosinophilia. Some idiosyncratic drug reactions resemble serum sickness. Some of the mechanisms of liver injury are described in more detail below.

FIGURE 37.1. Multiple metabolic pathways involved in the mediation of hepatic injury for any compound. The liver is central to xenobiotic (and some endogenous compounds) metabolism which produces water-soluble products amenable to urinary or biliary excretion. Some compounds undergo metabolic activation to produce free radicals, electrophiles, or other toxic products that may induce hepatic injury.

F. Oxidative Stress and Free Radicals with Classic Examples

Free radicals are generated from within hepatocytes in several ways, such as ionizing radiation, oxidative metabolism by cytochrome P450, reduction and oxidation (redox) reactions that occur during normal metabolism, transition metals such as iron and copper, and from nitric oxide generated by variety of inflammatory cells. The reactive species generated result in lipid peroxidation of membranes, oxidative modification of proteins, and lesions within DNA (Crawford, 1999).

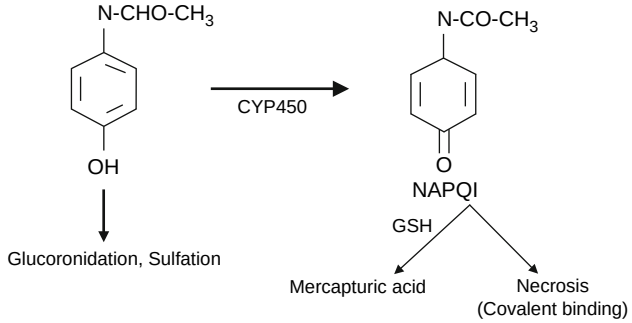
Free radicals have unpaired electrons, making them highly reactive. They may be formed by one electron oxidation or reduction reactions, leading to cationic or anionic radicals, respectively (Dahm and Jones, 1996). Alternately, hemolytic bond scission leads to neutral radical formation. Oxygen free radicals result from metabolic processes, leukocytic respiratory burst, or to the effects of ionizing radiation. Hydroxyl radicals, superoxide radicals, and hydrogen peroxide are major reactive oxygen species. The free radical nitric oxide ($NO^{\cdot}$), an important cell signaling agent released by leukocytes, may react with superoxide to form peroxynitrite.

Free radicals cause peroxidation of phospholipids within the plasma membrane of the cell as well as the membranes of the mitochondria and endoplasmic reticulum. The

radicals act by removing a proton (H^+) from a methylene carbon within a polyunsaturated fatty acid, forming a lipid free radical. This lipid free radical may then abstract a proton from a neighboring polyunsaturated fatty acid, generating more lipid free radicals. It is estimated that this can occur four to ten times per initiation. Effects of lipid peroxy radicals on the cell membrane include increased permeability, decreased fluidity, and inactivation of membrane proteins (Dahm and Jones, 1996). Additionally, mitochondrial membranes lose polarity (Watkins, 1999).

Lipid peroxy radicals can react with metal ions stored within the hepatocyte, generating more lipid radicals. It is estimated that propagation by this mechanism can occur in four to ten steps per initiation (Dahm and Jones, 1996). The most frequent mechanism of free radical production leading to hepatocellular injury involves phase I metabolism of xenobiotics and the cytochrome P450 system. Phase I metabolism may lead to bioactivation of the substrate to a high energy reactive intermediate molecule in preparation for phase II conjugation reactions. However, in circumstances such as overdosage, phase I products may accumulate. Lesions produced by these compounds are mostly centrilobular because the cytochrome P450s responsible for metabolism are mostly situated in the centrilobular areas of the liver.

The classic examples of this process are cell death resulting from carbon tetrachloride and acetaminophen toxicosis (Figure 37.2). Acetaminophen has a hydroxyl group that can undergo immediate phase II conjugation reactions. Indeed, at therapeutic doses 90% of this substrate undergoes glucuronide or sulfate conjugation in humans (Sturgill and Lambert, 1997; Court, 1997). These are major metabolic pathways in most species, but glucuronyl transferase deficiency in cats in part explains the sensitivity of felines to this drug.



Adopted from Veterinary Toxicology, Gupta, R (edt), 1st edition, 2007, p155, with permission from Academic Press

FIGURE 37.2. Metabolism and mechanism of acetaminophen toxicity. Bioactivation of acetaminophen by P450 enzymes results in the formation of the reactive intermediate (NAPQI) which forms covalent protein adducts with glutathione which is then converted to mercapturic acid. When the amount of the reactive metabolite formed exceeds the glutathione available for binding, the excess metabolite binds to tissue molecules resulting in centrilobular hepatic necrosis.

Acetaminophen in itself is not considered toxic. Cellular injury is caused by the unstable metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI; Figure 37.2). Under normal conditions in humans, 5% of a dose of acetaminophen is oxidized to NAPQI, which is rapidly neutralized by conjugation with glutathione (Sturgill and Lambert, 1997; Maddrey, 2005; Figure 37.2). Toxic levels of NAPQI may accumulate under certain conditions, as when large amounts of substrate are available for metabolism due to either large ingestions or inadequate glucuronidation. Metabolism of acetaminophen to NAPQI is increased in individuals who regularly consume alcohol or take medications that induce microsomal enzymes, e.g. antiepileptic therapy. The hepatic pool of glutathione becomes overwhelmed and depleted permitting the accumulation of NAPQI. Possible additional risk factors that lower the threshold for hepatotoxicity have been identified and include fasting and malnutrition, which deplete glutathione reserves (Treinen-Moslen, 2001; Sturgill and Lambert, 1997; Piñeiro-Carrero and Piñeiro, 2004; Dahm and Jones, 1996).

The reaction that produces NAPQI generates superoxide anions as a by-product. Interactions of NAPQI with other cellular molecules also generate reactive oxygen species, leading to oxidative stress on the hepatocyte (Zimmerman, 1999; Dahm and Jones, 1996). The role of calcium and Kupffer cell activation have been implicated as contributing factors for acetaminophen-induced liver injury by producing reactive nitrogen species (Treinen-Moslen, 2001).

NAPQI also acts as an electrophile, targeting the mitochondria in particular. This reactive metabolite forms covalent adducts with cellular molecules, particularly proteins with thiol groups. Other targets besides mitochondrial proteins include plasma membrane proteins involved in calcium homeostasis and adenine nucleotides (Dahm and Jones, 1996; Sturgill and Lambert, 1997).

G. Disruption of Calcium Homeostasis

Calcium ions (Ca^{2+}) are important for the mediation of hepatic injury. Cytosolic free calcium is maintained at relatively low concentrations compared to the extracellular levels. The majority of intracellular calcium is sequestered within the mitochondria and endoplasmic reticulum. Membrane associated calcium and magnesium ATPases are responsible for maintaining the calcium gradient (Farrell *et al.*, 1990). Significant and persistent increases in the intracellular calcium result from nonspecific increases in permeability of the plasma membrane, mitochondrial membranes, and membranes of the smooth endoplasmic reticulum. Calcium pumps in the mitochondrial membrane require NADPH, thus depletion of available NADPH can cause calcium release from mitochondria (Cullen, 2005).

Elevated cytoplasmic calcium activates a variety of enzymes with membrane damaging effects. The major enzymes that are involved in activation by calcium include

ATPases, phospholipases, proteases, and endonucleases. Thus increased calcium causes increased mitochondrial permeability and induction of apoptosis and necrosis. Calcium is required for maintenance and function of the cytoskeleton as well (Delgado-Coello *et al.*, 2006; Dahm and Jones, 1996).

Although cell injury results in increased calcium, which causes a variety of damaging effects, the cause and effect relationship of calcium in cell damage is not known. The chemicals that cause liver damage by this mechanism include quinines, peroxides, acetaminophen, iron, and cadmium.

H. Inhibition of Mitochondrial Function

Mitochondria function in the production of energy, in the form of ATP, for the cell by oxidative phosphorylation. Hepatocytes are highly metabolically active and require a continuous supply of ATP. Hepatocytes active in detoxification or replacement of damaged tissue have higher ATP requirements still (Dahm and Jones, 1996). Compounds that may disrupt mitochondrial oxidative phosphorylation include bile acids and amiodarone. Mitochondria are also critical to modulation of cell redox status, osmotic regulation, pH control, and cytosolic calcium homeostasis and cell signaling. Mitochondria are important targets for virtually all types of injurious stimuli, including hypoxia and toxins. Mitochondria are targeted by oxidants, electrophiles, lipophilic cations, and weak acids. Damage is often precipitated by increases in cytosolic calcium.

Hepatic injury is frequently accompanied by morphological changes in mitochondria. Mitochondrial changes evident as structural abnormalities include greatly increased size and the development of crystalline inclusions. These changes are usually regarded as pathologic, reflecting as either a protective or degenerative response to injury. Mitochondrial damage may result in the formation of high conductance channels, the so-called mitochondrial permeability transition, in the inner mitochondrial membrane. This is an irreversible change and, because membrane potential is critical for mitochondrial oxidative phosphorylation, constitutes a deathblow to the cell.

Oxidative phosphorylation produces reactive oxygen species (Watkins, 1999). These are deactivated by antioxidants present within the mitochondrion. Glutathione is present within mitochondria as a scavenger for peroxides and electrophiles. Synthesis of glutathione requires ATP and takes place outside of the mitochondrion. Greater than 90% depletion in glutathione reserves decreases the ability of the mitochondrion to detoxify reactive oxygen species produced by oxidative phosphorylation. Glutathione *S*-transferase, the enzyme required for recycling of glutathione, may become overwhelmed by toxicants and reactive metabolites (Dahm and Jones, 1996).

Xenobiotics may cause cell death by their effects on mitochondrial DNA. Some antiviral dideoxynucleoside analogs can disrupt mitochondrial DNA synthesis through the inhibition of DNA polymerase gamma, leading to depletion of mitochondria and consequent hepatocyte death.

Chemicals that damage mitochondrial structure, enzymes, or DNA synthesis can disrupt beta oxidation of lipids and oxidative energy production within hepatocytes. Prolonged interruption of beta oxidation leads to microvesicular steatosis which can progress to macrovesicular steatosis. This sequence of events has been noted with alcoholic and nonalcoholic steatohepatitis. The role of mitochondria has been extensively studied with nonalcoholic fatty liver disease, a major issue in human medicine. Alcoholic steatosis and other forms of hepatic steatosis have been linked to impairment of ATP homeostasis and mitochondrial abnormalities have been reported in a growing body of literature.

There are several drugs that inhibit beta oxidation of fatty acids in mitochondria leading to lipid accumulation, such as aspirin, valproic acid, and tetracyclines.

I. Disruption of Cytoskeleton

Changes in intracellular calcium homeostasis produced by active metabolites of xenobiotics may cause disruption of the dynamic cytoskeleton. There are a few toxins that cause disruption of the cytoskeleton through mechanisms independent of biotransformation. Microcystin is one of these toxins. Microcystin is produced by the cyanobacterium *Microcystis aeruginosa*. Similar toxins are produced by other species of cyanobacteria. The hepatocyte is the specific target of microcystin, which enters the cell through a bile-acid transporter. Microcystin covalently binds to serine/threonine protein phosphatase, leading to the hyperphosphorylation of cytoskeletal proteins and deformation of the cytoskeleton (Treinen-Moslen, 2001).

Phalloidin and related toxins found in some mushrooms, including *Amanita phalloides*, act by binding tightly to actin filaments and preventing cytoskeletal disassembly (Treinen-Moslen, 2001).

1. Cholestatic Mechanisms

Sinusoidal transporters and canalicular transporters are involved in the movement of bile salts from the sinusoids into the canaliculi. Within the hepatocyte, transcytosis is mediated by cytoskeletal transport mechanisms. Bile is moved within the canaliculi through actions of the hepatocyte cytoskeleton causing contraction of the canalicular lumina (Treinen-Moslen, 2001). Xenobiotics acting on any of the above systems may influence bile transport and secretion.

Most chemicals that cause cholestasis are excreted in the bile, including the mycotoxin sporodesmin which concentrates 100-fold in the bile (Treinen-Moslen, 2001).

α-Naphthothiourea (ANIT) is a hepatotoxicant that damages bile duct epithelium and hepatocytes. The drug is used experimentally in rodents as a model of intrahepatic

cholestasis. A single dose of ANTU induces acute cholangeitis; prolonged exposure causes bile duct hyperplasia and biliary fibrosis. Although the biochemical and histological features of ANTU toxicity are well documented, the mechanism by which ANTU causes liver injury remains uncertain. *In vivo*, ANTU does not cause liver damage until it appears in bile (Jean and Roth, 1995).

This drug is initially detoxified in hepatocytes by conjugation with glutathione. ANTU–glutathione complexes are secreted into bile, but they are unstable and rapidly dissociate. This exposes biliary cells to high concentrations of the parent compound, which presumably causes direct cytotoxicity. The reappearance of ANTU in bile also leads to enterohepatic cycling, reuptake of the drugs in the intestine, and repetitive rounds of glutathione conjugation and secretion. This not only delays elimination of the drug but depletes glutathione progressively from hepatocytes and leads to hepatocellular damage. In addition, ANTU is known to cause hepatotoxicity by neutrophil and platelet dependent mechanisms (Jean and Roth, 1995).

2. Idiosyncratic Reactions

Many idiosyncratic drug reactions are believed to be immune mediated. Neoantigens may result from adducts formed from the interaction of reactive drug metabolites with cellular proteins. These neoantigens may be processed by Kupffer cells or other antigen presenting cells, transported to the cell surface, and presented as antigens. Cell and antibody mediated immune response may cause severe liver damage. Various drugs are believed to cause immune mediated idiosyncratic reactions in humans, including halothane, diclofenac, phenytoin, and sulfonamides (Zimmerman, 1999; Treinen-Moslen, 2001; Sturgill and Lambert, 1997; Watkins, 1999).

Liver injury can be a result of both direct cytotoxicity and antibody dependent cellular toxicity. Alcoholic liver disease is another example of possible immune mediated damage. Acetaldehyde, produced by metabolism of ethanol, forms adducts with hepatic proteins similar to halothane, resulting in higher antibody titers to which some of the liver damage following ethanol ingestion may be attributed (Ramaiah *et al.*, 2004). However, the role of immune mediated liver damage following ethanol ingestion is minimal compared to other known mechanisms of alcohol liver damage.

IV. WARFARE AGENTS AFFECTING LIVER

A. Fungal and Plant Toxins

1. Microcystins

The microcystins are hepatotoxic products of freshwater blooms of cyanobacteria of *Microcystis*, *Anabena,* and *Oscillatoria* species (Chen *et al.*, 1993; Luu *et al.*, 1993), with *Microcystis aeruginosa* being the most common. Nearly 60 microcystin cyclic hepatopeptides have been identified of which microcystin-LR, also known as the fast death factor, is the most common, and the toxin of choice to be weaponized (Craig *et al.*, 1993; Rinehart *et. al.*, 1994). This toxin has been reported to be responsible for the deaths of wild animals and agricultural livestock (Carmichael, 1988). A potential threat to the health of humans has been recognized in countries where water supplies are contaminated with cyanobacteria (Yu, 1989). In 1996, microcystin-LR was also implicated in the death of 50 Brazilian dialysis patients (Jochimsen *et al.*, 1998).

This potent mammalian liver toxin (Carmicheal, 1988) acts by altering the hepatocyte cytoskeleton actin filaments leading to disruption of the structural integrity of the sinusoids. This causes massive necrosis in the liver leading to cell death. The toxic effects of microcystin-LR have been reported due to the presence of 3-amino-9-methoxy-10-phenyl-2,6,8 trimethyl deca,4,6 dienoic acid (ADDA), which is believed to be essential for its functioning. In addition, microcystins are known to be potent and specific inhibitors of catalytic subunits of protein phosphatases-1 and 2A (Cohen and Cohen, 1989; Yoshizawa *et al.*, 1991; Honkanen *et al.*, 1990), and activate the enzyme phosphorylase b. Microcystin administered intraperitoneally in mice caused disruption of bile flow in <10 min, and death within a few hours due to hypovolemic shock induced by interstitial hemorrhage following liver necrosis (Carmicheal, 1988). Death was also reported within hours of administration of aerosol (LD_{50}, 67 μg/kg body weight) in mice. In humans, microcystin ingestion leads to diarrhea, vomiting, weakness, and pallor, with death occurring in a few hours if a lethal dose is taken.

2. Aflatoxins

Aflatoxins were first isolated more than 40 years ago after the outbreak of disease and deaths in turkeys. These toxins are produced as secondary metabolites by the fungi *Aspergillus flavus* and *Aspergillus parasiticus*, at temperatures between 24 and 35°C and humidity exceeding 7% (Williams *et al.*, 2004). These fungi are known to infect a variety of crops like peanuts, walnuts, pecans, pistachios, and corn.

Aflatoxins are bisfuran polycyclic compounds, and depending on the characteristic blue or green fluorescence produced under ultraviolet light, these compounds are known as aflatoxin B_1, B_2, G_1, and G_2, respectively. Although these compounds have been recognized as potent mutagens and carcinogens, they are still not as toxic as botulinum or ricin. Before the Gulf War, aflatoxins were not recognized as biological warfare agents; however, they were weaponized by Iraq for missile delivery, and at present they can be considered as agents for biological warfare (Marshall, 1997; Zilinskas, 1997).

Of the several aflatoxins, aflatoxin B_1 (AFB_1) is the most prevalent and the most potent toxin. AFB_1 is converted to an unstable metabolite, the 8,9-epoxide, is highly electrophilic, and forms covalent adducts with RNA, DNA, and proteins

(Roebuck and Maxuitenko, 1994). In addition, aflatoxin M_1, a metabolite of AFB_1, has been found in the milk of cows fed AFB_1.

AFB_1 is acutely toxic in all species, with an LD_{50} ranging from 0.5 mg/kg for the duckling to 60 mg/kg for the mouse (Wogan, 1973). Acute exposure to AFB_1 has been reported to cause hepatic lesions with edema, bililary proliferation, and parenchymal cell necrosis. In addition, aflatoxin B_1 poisoning has been reported to cause jaundice, rapidly developing ascites and portal hypertension with high mortality resulting from massive gastrointestinal bleeding. In children, aflatoxin produces a condition called Reye syndrome resulting in disturbed consciousness, fever, convulsions, and vomiting (Palmgren and Ciegler, 1983).

3. Ricin

Ricin, a potent plant toxin, is extracted from the seeds of castor plants (*Ricinus communis*), and has been considered a warfare agent since World War I. Although ricin is not as toxic as botulinum or anthrax, easy availability and lack of specific antidote make it a weapon of choice. Being a ribosome inactivating protein, a single molecule of ricin reaching the cytosol can kill that cell as a consequence of protein synthesis inhibition (Eiklid *et al.*, 1980). Human exposure can be through ingestion and inhalation; however, compared to oral exposure, inhalation of ricin has been reported to be more harmful. In humans the lethal dose has been reported to be 5–10 μg/kg body weight.

In addition to pulmonary toxicity, ricin has been reported to be a major hepatotoxicant (Kumar *et al.*, 2003). Studies by Muldoon *et al.* (1992) reported that humans exposed to ricin experience increased hepatic transaminase and lactate dehydrogenase activities. Furthermore, mice treated with ricin experience significant oxidative stress, resulting in hepatic glutathione depletion and lipid peroxidation (Muldoon and Stohs, 1991). Elevation of lipid peroxidation is reported to originate mainly from the damaged Kupffer cells, which are believed to be the target of this toxin in the liver (Skilleter, 1981). The high sensitivity of Kupffer cells has been ascribed to the ability of ricin to bind to the mannose receptors present on these cells (Skilleter, 1981; Magnusson, 1993).

B. Bacterial (Anthrax)

Anthrax is a disease caused by the spores of the bacterium *Bacillus anthracis*, and is a recognized biological warfare agent. In the USA (2001), anthrax was deliberately spread through the postal system by sending letters with powder containing anthrax. This resulted in 22 cases of anthrax infection. Inhalation and cutaneous exposure are the main routes of infection. Recent studies have revealed that laboratory animals infected with anthrax have developed significant liver injury. Studies by Moayeri *et al.* (2003) reported that mice infected with *B. anthracis* developed extensive liver necrosis in addition to pleural edema. Liver lesions in these animals ranged from small hemorrhagic infarcts to large areas of centrilobular coagulative necrosis. A significant increase in alanine aminotransferase and aspartate aminotransferase was also observed in these animals. Liver dysfunction was also indicated by decreased serum albumin levels in these animals in response to toxin over time.

V. CONCLUDING REMARKS AND FUTURE DIRECTION

In spite of significant advances in our knowledge of the mechanisms of liver damage, scientists seem to have a long way to go before all the mechanisms of toxicity in liver for a given chemical are completely established. In the meantime, new platforms (such as multiplex, multi color flow cytometry, meso-scale discovery) and new ''omics approaches'' have provided added tools for researchers to obtain breakthroughs in the area of liver toxicity. Clearly, current reports on the number of warfare agents targeting the liver are limited and with further research and case studies, these numbers will continue to grow. With the changing political global climate and the potential for chemical warfare agents, target organ toxicities, especially the liver, will likely gain attention.

CHAPTER 38

Renal Toxicity

MANU SEBASTIAN

I. INTRODUCTION

The kidneys are the primary organ responsible for water and electrolyte homeostasis, thereby playing an important role in total body homeostasis. The kidneys help to maintain this homeostasis by performing functions which include excretion of metabolic waste products and foreign chemicals, regulation of water and electrolyte balances, regulation of body fluid osmolality and electrolyte concentrations, regulation of arterial pressure, regulation of acid–base balance, secretion, metabolism, and excretion of hormones and gluconeogenesis. A toxic insult to the kidneys can disrupt any or all of these functions. This chapter describes detailed toxicity of chemicals that target the renal system.

II. RENAL ANATOMY AND PHYSIOLOGY

Kidneys in mammals are paired organs that lie ventral and adjacent to the lumbar vertebrae. The medial side of each kidney contains an indented region called the hilum, through which pass the renal artery and vein, lymphatics, nerve supply, and ureter, which carries the final urine from the kidneys to the bladder. The kidney is surrounded by a tough fibrous capsule that protects its inner structures. If the kidney is dissected from top to bottom, the two major regions that can be visualized are the outer cortex and the inner region referred to as the medulla. The cortico-medullary ratio is approximately 1:2 or 1:3 in domestic animals. The medulla is divided into multiple cone-shaped masses of tissues called renal pyramids. The base of each pyramid originates at the border between the cortex and medulla and terminates in the papilla which projects into the renal pelvis, a funnel-shaped continuation of the upper end of the ureter. Kidneys of small mammals such as rat, mouse, and rabbit have a single papilla and are called unipapillate. Large mammals, including humans, have more than one papilla per kidney and so are called multipapillate. Cynomolgus monkey kidney is unipapillate with fusion of renal pyramids into relatively short crest-like papilla. Human kidney has no external lobulation but bovine kidney has external lobulation. With regard to anatomy and physiology, pig kidney is similar to human kidney. The outer border of the pelvis is divided into open-ended pouches called major calyces that extend downward and into minor calyces, which collect urine from the tubules of each papilla. The walls of the calyces, pelvis, and ureter contain contractile elements that propel the urine toward the bladder (Ellenport, 1975).

The nephron is the functional unit of the kidneys. Each human kidney contains approximately one million nephrons and each is capable of forming urine. The nephron consists of a tuft of glomerular capillaries called the glomerulus, through which large amounts of fluid are filtered from the blood, and a long tubule, in which the filtered fluid is converted into urine. The glomerulus, which is the filtering unit of the kidneys, is made up of a network of branching and anatomizing capillaries, which have high hydrostatic pressure compared to other capillaries in the body. These capillaries are composed of endothelial cells that have attenuated and fenestrated cytoplasm which allow the passage of molecules. Those compounds with a molecular weight of about 60,000 daltons pass through the glomeruli into the tubular lumen to be excreted with urine. The glomerular capillaries are covered by epithelial cells and the total glomerulus is encased in Bowman's capsule with a space, which is called the Bowman's space. Fluid filtered from the glomerular capillaries flows into the Bowman's space and then into the proximal tubule. The fluid collected in the proximal tubule flows into the loop of Henle, which dips into the renal medulla. Each loop is made up of an ascending and descending limb. The walls of the descending limb and the lower end of the ascending limb are very thin and are called the thin segment of the loop of Henle. After the ascending limb of the loop has returned partway back to the cortex, its walls become much thicker and it is called the thick segment of the ascending limb. Approximately 25% of the filtered Na^+ and K^+ and 20% of the filtered water are reabsorbed by these segments of the loop of Henle.

The glomerular filtration rate is regulated by the macula densa, which is composed of specialized cells located between the end of the thick ascending limb and the early distal tubule, with close proximity to the afferent arteriole. The function of the macula densa is to prevent massive losses of fluid/electrolytes in impaired tubular resorption. After passing this area, the fluids enter the distal tubule, which lies in the renal cortex and moves to the connecting tubule, leading to the cortical collecting tubule. The initial eight to ten collecting ducts join to form a single, larger

collecting duct that runs downwards into the medulla and becomes the medullary collecting duct. The collecting ducts merge to form progressively larger ducts that eventually empty into the renal pelvis through the tips of renal papillae.

Blood flow to the two kidneys is approximately 22–25% of the cardiac output. The kidneys are supplied by the renal artery which enters the kidneys through the hilum and then branches progressively to form the interlobar arteries, arcuate arteries, interlobular arteries (also called radial arteries), and afferent arterioles, which lead to the glomerular capillaries. The distal ends of each glomerulus coalesce to form the efferent arteriole, which leads to a secondary capillary network, the peritubular capillaries which surround the renal tubules. The cortex receives approximately 90% of the blood flow compared to the medulla or papillae so blood-borne toxic molecules reaching the kidneys have a more toxic effect on the cortex, as compared to the medulla or renal papillae. The interstitial space is occupied by the fenestrated peritubular capillaries and a small number of fibroblast-like cells. Increase in thickness of interstitial space in pathological conditions is due to edema, proliferation of fibrous tissue, or infiltration of inflammatory cells (Guyton and Hall, 2006).

A. Biotransformation and Excretion

Gastrointestinal tract, lungs, skin, and other special routes of administration (e.g. intravenous) are the route of entry of xenobiotics into the body which then reach the blood and are eventually distributed throughout the body. The rate of distribution of xenobiotics or their metabolites to an organ or tissue depends on the blood flow and the rate of diffusion out of the primary capillary bed into the cells of a particular organ. The kidneys, being an organ which receives 25% of the cardiac output, are exposed to several xenobiotics and their metabolites. Kidneys, along with liver, are the two important organs in the body which concentrate toxicants. A classic example is metallothionein, a protein which binds to cadmium and zinc with high affinity in the kidneys and liver (Rozman and Klaassen, 2001). Toxic effects of xenobiotics on an organ are by the action of the parent compound or through the metabolites produced as a result of bioactivation via metabolism (biotransformation). Thus, toxicants can induce nephrotoxicity by the parent compound (e.g. gentamicin), the biotransformed molecules in other organs like the liver (e.g. hepatic biotransformation of haloalkene) and by biotransformation in the kidneys (e.g. chloroform). Biotransformation reactions are catalyzed by Phase I and Phase II enzymes which convert the parent compounds to more polar and hydrophilic metabolites, and are thereby excreted more rapidly or converted to reactive chemical species which can induce toxicity. The important Phase I enzymes present in the kidneys are cytochrome P450, prostaglandin synthase, and the reductases. Although cytochrome P450 is present in the kidneys, the concentration is only approximately 10% of that in liver. The highest concentration of cytochrome P450 is present in the renal cortex (the majority are in the proximal tubular epithelial cells) with small amounts in the medulla. The compounds which are biotransformed by cytochrome P450 in the kidneys are acetaminophen (acute overdosage), cephaloridine, chloroform, and ochratoxin (partially). Prostaglandin synthase, another Phase I enzyme, is found primarily in the medullary interstitial and collecting duct cells. Phase I enzymes capable of catalyzing a reduction reaction (reductases) are also present in the kidneys and are involved in the reduction of the 5-nitro group in 5-nitrofurans to reactive chemical species, leading to nephrotoxicity. The important Phase II enzymes present in the kidneys are UDP-glucuronosyltransferases (UGT), sulfotransferases, and glutathione-*S*-transferases. The liver possesses the highest UGT concentration. UGT may contribute to acute or chronic toxicity associated with clofibrate, diclofenac (an NSAID), and other NSAIDs. The substrates for glutathione-*S*-transferases include haloalkenes, acrolein, etc. (Rankin and Valentovic, 2004).

The kidneys are one of the most important organs for the excretion of xenobiotics and their metabolites. The different mechanisms by which the toxicants are removed by the kidneys are glomerular filtration, tubular excretion by passive diffusion, and active tubular secretion. The xenobiotics that enter the blood reach the kidneys, are filtered through the large pores of the glomerular capillaries (70 nm size), pass the tubular lumen, and eventually are excreted through the urine. The removal of toxicants through the kidney tubule is mainly dependent on the water solubility of the toxicant. Those xenobiotics which are biotransformed to more water-soluble products (more polar) are excreted with the urine, while those toxicants with high lipid solubility (high lipid/water partition coefficient) are reabsorbed across the tubular cells into the blood stream. Toxicants can be excreted by passive diffusion through the tubules. The flow of urine is important for maintenance of the concentration gradient necessary for this process. Toxicants are also excreted into the urine by an active transport process with secretion by a transporter. These transporters are localized in the proximal tubules. The important transporters localized on the basolateral membranes of the proximal tubular cells are organic anion transporter (OAT), organic cation transporter (OCT), and a few members of the organic anion transporting polypeptides (OATP). These transporters are involved in the uptake of organic acids (OAT) and a number of cations (OCT) into the renal tubular cells. Multi-resistant drug protein (Mrp) found on the luminal brush border of the tubular epithelium moves xenobiotics from the proximal tubule cells into the lumen. The organic anion transporting polypeptides (OATP) and peptide transporter (Pept) are involved in the reabsorption of chemicals into the proximal tubular cells. A classic example of the action of active transport is the difference in susceptibility of cephaloridine in adult and newborn animals. In newborn animals the active uptake of cephaloridine is not well developed; hence

it is not absorbed and concentrated in the tubular cells that result in toxicity (Rozman and Klaassen, 2001). Thus tubules play an important role in the excretion of toxicants, and a toxic insult to these cells results from accumulation of toxicants in the body.

The toxic effect of many xenobiotic compounds in the kidneys is specific to the anatomical locations, i.e. proximal tubules, glomeruli, medulla/papilla, or loop of Henle. The site-selective injury observed in humans when exposed to many compounds is similar to that in domestic animals. The cause of these site-specific target injuries is multifactorial and may include detoxification mechanisms, regenerative ability, difference in blood flow, and transport and accumulation of the chemicals and their metabolites.

The proximal tubule is the specific target for several antibiotics, mycotoxins, certain antineoplastic drugs, and heavy metals. The proximal tubule can be divided into three discrete segments. The S1 segment (pars convoluta) is the initial portion of the proximal convoluted tubule; S2 is the transition between the pars convoluta and the pars recta, which consists of the end of the convoluted segment and initial portion of the straight segment; and S3 (pars recta) consists of the distal portion of the proximal segment (Figure 38.1) (Berl and Bonventure, 1998). The proximal convoluted tubule is the most common site of toxin-induced injury and there are multiple reasons for this site-specific action. These reasons include cytochrome P450 and cysteine conjugate β-lyase activity localization (those agents requiring bioactivation by these enzymes induce toxicity in this region, e.g. chloroform); selective accumulation of xenobiotics due to a relatively lose epithelium compared to the distal tubules which allow compounds to access the cells easily; increased transport of several molecules like organic anions, cations, and heavy metals resulting in increased accumulation in this area; and increased susceptibility of proximal convoluted tubular epithelial cells to ischemic injury. Compared to the proximal tubules, distal tubules are less affected by toxicant injury (Schnellmann, 2001).

The medulla/papillae are the target site for analgesics like phenylbutazone in horses. The loop of Henle is the target for fluoride ions and the glomeruli for immune complexes. The other anatomical location which is commonly affected by toxicant injury is the renal papillae. A classic example is

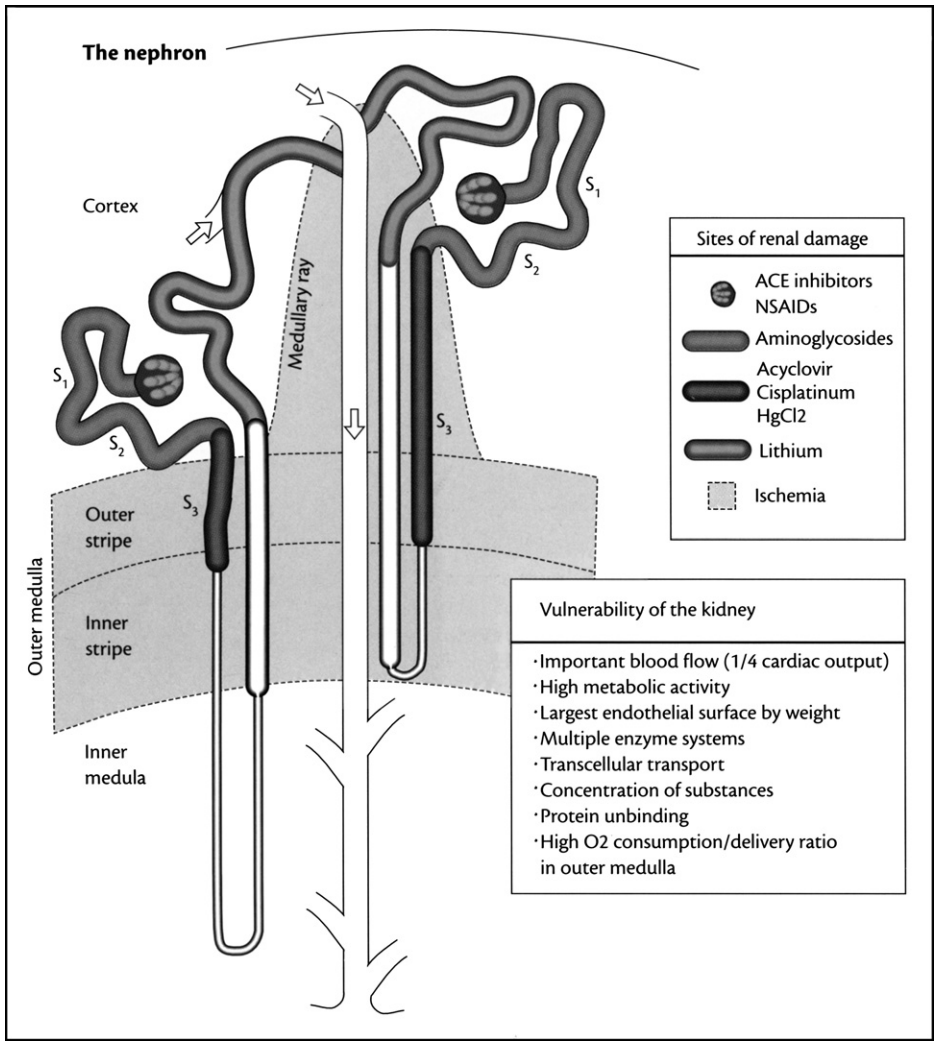

Figure 38.1. Sites of renal damage, including factors that contribute to the kidney's susceptibility to damage. ACE – angiotensin converting enzyme; NSAID – nonsteroidal anti-inflammatory drugs; $HgCl_2$ – mercuric chloride (adapted from *Color Atlas of the Diseases of the Kidney*, Vol. 1, Berl, T., Bonventre, J.V., 1998, with permission).

necrosis from analgesics in horses. The important factors for this site-specific injury are due to a high concentration of prostaglandin H synthase activity in this area (they metabolize analgesics to reactive intermediate compounds which bind to cellular macromolecules), high papillary concentration of toxicants, and inhibition of the vasodilatory prostaglandins, which result in ischemia to this area (Schnellmann, 1998).

III. TOXIC EFFECTS ON THE KIDNEY

A. Acute Renal Failure

Toxicants and toxins can produce their effects on the different anatomical locations of the kidneys by affecting the tubules, glomeruli, ducts, vessels, and interstitium. The majority of toxins manifest their effects by acute renal failure. The most important manifestation of acute renal failure is the decrease in glomerular filtration rate (GFR) which leads to an excess of urea or other nonprotein nitrogenous components in the blood (azotemia). The decrease in GFR can be due to pre-renal, renal, or post-renal causes. Renal toxicity generally leads to renal or sometimes post-renal azotemia. Post-renal azotemia is usually observed in conditions of obstruction to renal outflow or post-renal leakage. The toxic effects of chemicals on the kidneys result in reduced GFR, leading to azotemia. The different mechanisms by which toxins/chemicals induce renal failure include: (1) tubular epithelial damage, leading to formation of tubular casts and tubular blockage, (2) tubular epithelial necrosis, which leads to reabsorption of glomerular filtrate, (3) renal vasoconstriction, which leads to hypoxia and necrosis, and (4) changes in the glomerular ultrafiltration barrier. The majority of chemicals induce renal failure by direct action on the tubules.

The ultrastructural changes which lead to acute renal failure are due to the loss of cell-to-cell adhesion and cell-to-matrix adhesion which eventually results in loss of tubular integrity.

The clinical signs associated with acute renal failure are nausea, vomiting, gastrointestinal bleeding, esophagitis, gastritis, and colitis, which are all associated with azotemia. When azotemia is associated with a constellation of clinical signs and symptoms and biochemical abnormalities, it is called uremia. There is also secondary involvement of the gastrointestinal tract (uremic gastroenteritis), peripheral nerves (peripheral neuropathy), and sometimes the heart (uremic fibrinous pericarditis).

B. Chronic Renal Failure

Chronic renal failure is associated with long-term exposure to toxins and is mostly related to the secondary pathological changes triggered by the initial injury. These secondary changes are compensatory mechanisms to maintain the function of the whole kidney, but they eventually result in reduced glomerular function and tubular and interstitial changes. Once chronic changes are initiated, they progresses to an end stage kidney.

Clinical signs of chronic renal failure primarily include: (1) edema due to reduced renal perfusion leading to stimulation of the renin–angiotensin system, which stimulates aldosterone secretion leading to retention of sodium and water, (2) hypocalcemia with compensatory parathyroid activity and osteodystrophy, and (3) reduced red blood cell counts due to decreased synthesis of erythropoietin as a result of damage to the juxtaglomerular cells.

C. Pathological Correlates

The kidneys have extensive reserve capacity and hence renal diseases may be present with or without any clinical signs or clinicopathological abnormalities. Renal failure occurs or is manifest after substantial loss of the functional unit, the nephron. Renal failure represents clinical signs or laboratory abnormalities as a result of reduced renal function. Hence, measurement of renal function will aid in diagnosing a toxic insult to the renal tubules or glomeruli. The various renal functions, which can be measured to evaluate a toxic insult, include urine concentration, blood urea nitrogen (BUN), urea excretion, serum creatinine, uric acid (in birds), glomerular filtration rate, urine electrolyte clearance ratios, and changes in blood levels of calcium, phosphorus, magnesium, sodium, and potassium.

Urine analysis is one of the important methodologies to evaluate renal function and to interpret injury to the various anatomical components of the kidneys. Urine analysis involves multiple physical and chemical parameters as well as sediment analysis. The different physical characters which are evaluated to assess kidney function include volume, color, transparency, and odor. The chemical characters evaluated include ketones, protein, glucose, bilirubin, blood, urobilinogen, nitrate, and enzymes. The different sediments which aid in evaluating a toxic insult to the urinary system include epithelial cells, erythrocytes, leukocytes, casts, and crystals. The important abnormal sediments which help in diagnosing an acute failure include renal epithelial cells, pigments casts (myoglobin, hemoglobin), and crystalluria (uric acid).

Other parameters which can be measured to evaluate the function of the kidneys include urine specific gravity, BUN, serum creatinine, uric acid excretion (in birds), glomerular filtration rate (GFR), and levels of calcium and phosphorus in the serum. A reduced urine-specific gravity, increased BUN (azotemia), increased serum creatinine concentration, hyperuricemia (in birds), altered GFR, and serum calcium and phosphorus levels are all indicators of renal damage. Because of the high reserve capacity of the kidneys, many of these alterations are observed only when more than two-thirds of the nephrons are damaged (Gregory, 2003).

The gross findings in renal damage are not that evident in acute damage and may include swollen cut sections, pale renal parenchyma, and reddish discoloration. Mineralization and crystal deposits will be manifest by linear pale streaks in the cortex and medulla with a gritty consistency (mineral). Papillary necrosis is characterized by pale discoloration in the papilla and renal crest. The gross observations observed in chronic renal failure are reduced size, irregular subscapular surface, hard to section, and gritty consistency. The important histopathological observations associated with renal damage are necrosis and degeneration of tubular lining epithelium (mostly in the proximal convoluted renal tubular epithelium), regeneration, casts (protein, degenerate cells, globin) in the lumen, mineralization of the basement membranes of the tubules, glomeruli tufts, damaged capsule and blood vessels, necrosis of the renal papillae, necrosis of the glomerular matrix with hemorrhage, and increased cellularity of the glomerular tufts (proliferative glomerulonephritis) (Confer and Panciera, 2001; Sebastian *et al.*, 2007).

1. Drugs

a. Aminoglycosides

The most important toxic effects manifested by aminoglycosides are nephrotoxicity, ototoxicity, and neuromuscular blockade. Aminoglycosides accumulate in the proximal tubular epithelial cells where they are sequestered in the lysosomes and interact with ribosomes and mitochondria, resulting in cellular damage. Gentamicin and several other aminoglycosides have been associated with nephrotoxicity leading to acute renal failure in humans. Aminoglycosides account for approximately half of the drug-induced cases of nephrotoxicity in human patients. The precise mechanism remains unknown; however, studies have shown strong evidence related to the generation of several reactive oxygen species which cause renal failure. Gentamicin toxicity has been reported in dogs, where the kidneys appear pale. Histopathological changes include tubular epithelial necrosis with regeneration and mineralization. Predominantly, the proximal tubules are affected. Lesions will progress from hyaline droplet degeneration with dilated lumen to necrosis of the renal tubular lining epithelium (Sprangler *et al.*, 1980).

Experimental exposure of neomycin in calves has reported both nephrotoxicity and ototocity (demonstrated clinically). The clinical pathological observations included granular casts in urine, proteinuria and low specific gravity, azotemia, decreased creatinine clearance, polyuria, and polydipsia. The histopathological findings included renal tubular epithelial degeneration and necrosis (Crowell *et al.*, 1981).

Beta-lactam antibiotics (pencillins, cephalosporins, and carbapenems) are excreted by the kidneys and hence the kidneys are targets of toxicity. These drugs can cause interstitial nephritis, tubular necrosis, and allergic angitis. Beta-lactams behave like haptens which are then immunologically processed leading to an immunologically mediated drug injury, primarily an acute interstitial nephritis characterized by the presence of edema and focal or diffuse infiltration of inflammatory cells, frequently eosinophils, lymphocytes, and plasma cells in the renal interstitium. A definitive diagnosis is made by renal biopsy, which will reveal normal glomeruli and a patchy, but usually heavy, interstitial infiltrate with lymphocytes, plasma cells, and eosinophils (Linton *et al.*, 1980). Tubular necrosis is observed when the drug is administered at high doses.

b. Amphotericin B

Amphotericin B is an antifungal agent and a polyene macrolide class of antibiotics. Nephrotoxicity is the common adverse effect associated with amphotericin B therapy, which can lead to impairment of both glomerular and tubular function. Nephrotoxicity is caused by acute renal vasoconstriction, which leads to damage of the distal tubular epithelium. The incidence of toxicity is high and acute renal failure is common. Clinical manifestations include azotemia, renal tubular acidosis, decreased concentrating ability of the kidneys, hypokalemia, and hypomagnesemia (Fanos and Cataldi, 2000). Dogs and cats are the most commonly affected species, with more susceptibility in cats. The common histopathological findings include renal tubular necrosis, dilatation of the tubules and mineralization with mild lesions in the interstitium and glomeruli (Rubin *et al.*, 1989).

c. Cisplatin

Cisplatin is an antineoplastic drug which causes toxic changes in the kidneys, intestines, and bone marrow. Cisplatin or its metabolites are eliminated through the kidneys and hence cause renal toxicity. The highest concentration of cisplatin is observed in the cells of the S3 segment (pars recta) of the proximal tubule and this is the area of the nephron which is most susceptible to cisplatin-induced toxicity (Lieberthal and Levine, 1996). Acute renal failure is the most important toxic effect of cisplatin treatment in humans. The toxic effect on the tubular epithelial cells leading to acute tubular necrosis is believed to occur via the formation of DNA adducts and the induction of oxidative stress, which results in genotoxicity and necrosis. The pathological findings associated with cisplatin treatment in dogs include mild renal tubular atrophy and tubular necrosis (Choie *et al.*, 1981; Forrester *et al.*, 1993).

d. Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) and Analgesics

NSAIDs are the most widely used analgesics in human and veterinary medicine, and all have some toxic potential. NSAIDs cause an acute reduction in renal function, which leads to nephrotoxic acute renal failure. The abnormalities related to renal function associated with NSAID

nephrotoxicity are fluid and electrolyte disturbances, acute deterioration of renal function, nephrotic syndrome with interstitial nephritis, and papillary necrosis. NSAIDs cause toxicity of the gastrointestinal tract, kidneys, and liver. NSAIDs cause renal toxicity mainly by the inhibition of prostaglandin synthesis and renal blood flow, resulting in renal papillary necrosis. Hepatic toxicity is mostly attributed to the idiosyncratic reaction.

The common species of animals affected by NSAIDs are dogs, cats, and horses. Horses, especially when dehydrated, are susceptible to phenylbutazone toxicity and the target organ is the kidneys. A common gross observation in experimental studies conducted in horses dosed with phenylbutazone and deprived of water was a yellow–green radial streak in the renal papillae. Microscopic observations include sloughing of the renal pelvic epithelium, including the terminal lining of collective ducts with coagulation necrosis of the underlying papillary interstitium, mineralization of the calyx, necrotic papillary interstitium containing nuclear debris, and hemorrhage and dilatation of collecting ducts and cortical tubules above the area of necrotic papillae. Other lesions observed in experimental studies of horses include ulceration and erosions of the glandular portion of the stomach, submucosal edema of the small intestine, erosions and ulcers of the large colon, and ulceration of the gastric mucosa and tongue. Pathological findings in experimental studies of horses exposed to flunixin meglumine (aminonicotinic acid) were glandular mucosal erosion and ulceration of the stomach (Gunson and Soma, 1983; MacAllistar *et al.*, 1993). Renal tubular or papillary necrosis is also reported in a limited number of canine cases (Jones *et al.*, 1992).

Large doses of acetaminophen can cause renal and hepatic toxicity in rats and mice. Toxicity is characterized by renal tubular necrosis in the proximal tubules (Schnellmann, 2001). Acetaminophen toxicity has also been reported in humans. Generally, toxicosis is a result of large overdoses which result in proximal tubular necrosis. Aspirin, ibuprofen, and acetaminophen are the important analgesics, which are reported to cause toxicosis in veterinary medicine. Renal lesions including renal tubular necrosis and papillary necrosis have been reported in dogs.

Recently, a case of vulture mortality was reported from the Indian subcontinent related to NSAID toxicity. Diclofenac is a widely available veterinary NSAID in the Indian subcontinent, used in domestic livestock. Vultures were exposed to the drug when they consumed carcasses of cattle that were treated with diclofenac shortly before death. Experimental studies of this drug in vultures showed marked nephrotoxicity. The gross observations were primarily deposits of urate on the surface of internal organs related to renal failure. Histopathological findings were acute necrosis of the proximal renal tubular epithelium with minimal inflammatory response and deposits of urate crystals (Oaks *et al.*, 2004; Meteyer *et al.*, 2005).

e. Sulfonamides

Renal toxicity associated with sulfonamides is rare as most of the current pharmaceutical preparations are relatively highly soluble at the pH normally occurring in the kidneys. Toxicity occurs due to very high overdosage. Sulfonamides can cause both acute and chronic toxic effects. Animals with renal toxicity will show elevated levels of BUN and creatinine. In some animals, sulfonamide crystals will be observed in the renal pelvis as a gross finding and kidneys may be gritty in texture when cut. Histopathological observation is primarily renal tubular epithelial degeneration and necrosis due to the direct action of the crystals. These crystals are visible with polarized light only if the kidneys are processed to prevent dissolution (Jones *et al.*, 1996).

f. Tetracyclines

Tetracyclines have been reported to cause toxicity and kidneys are the primary organs. Renal tubular necrosis is the common pathological finding. Animals with renal toxicity will show oliguria, marked azotemia, moderate proteinuria, and tubular casts in urinary sediment with an inability to concentrate urine (Lairmore *et al.*, 1984).

g. Vitamin K_3 (Menadione Sodium Sulfate)

Toxicity is commonly reported in horses. In experimental studies, the gross lesion observed was enlargement and paleness of the kidneys. The microscopic lesions included diffuse or multifocal tubular necrosis and dilation with proteinaceous and cellular debris from red blood cells, neutrophils and casts, diffuse interstitial edema, and lymphocytic infiltration regeneration of the tubular epithelium. In animals that survived for 3 months, renal tubules showed degeneration, necrosis, and dilation. In chronic renal failure, following vitamin K_3 administration, the kidneys were reduced in size, the capsule adherent, and pale streaks of connective tissue were very apparent. Microscopic findings included connective tissue proliferation with mononuclear cell infiltration and moderate hypercellularity of glomeruli with few sclerotic glomeruli. The tubules were dilated but the lining epithelium appeared normal with mineral, cellular, and proteinaceous casts seen in many tubules (Rebhun *et al.*, 1984).

h. Cholecalciferol/Vitamin D_3

Vitamin D_3 toxicity in veterinary medicine is by overdosage of vitamin supplements or exposure to rodenticide. The common species affected are dogs and cats, but any species may be affected. The common clinical pathological finding is rapid increase in plasma phosphorus in acute cases, followed by an increase in plasma calcium levels. Histological findings include mineralization in multiple organs including the kidneys, lungs, myocardium, stomach, and vessels. In kidneys, mineralization of arteries as well as mineral deposition in the tubular basement membranes is observed. Diagnosis is by chemical evaluation of serum, plasma, bile,

urine, and kidneys for PTH/25-hydroxycholicalceferol and correlating pathological findings (Gunther *et al.*, 1988; Fooshee and Forrester, 1990; Talcott *et al.*, 1991). Differential diagnosis includes ethylene glycol toxicity, hypercalcemia of malignancy, chronic renal failure, and other causes of hypercalcemia.

i. Cyclosporine

Cyclosporine is a macrolide antibiotic and has been used as an immunosuppressive agent. Cyclosporine can cause both renal and nonrenal toxicity. Clinically renal toxicity consists of four discrete syndromes which include acute reversible renal functional impairment, delayed renal allograft function, acute vasculopathy, and chronic nephropathy with interstitial fibrosis. Proximal tubular epithelium is uniquely sensitive to the toxic effect. The toxic effect is characterized by isometric cytoplasmic vacuolations (several small equally sized vacuoles in cytoplasm), necrosis with or without subsequent mineralization, inclusion bodies (giant mitochondria), and giant lysosomes. Acute vasculopathy consists of vacuolization of the arteriolar smooth muscles and endothelial cells leading to necrosis. In some cases, thrombotic microangiopathy develops, characterized by thrombosis of the renal microvasculature. Long-term treatment with cyclosporine results in chronic nephropathy with interstitial fibrosis (Charney *et al.*, 2004).

j. Furazolidone

Furazolidone toxicity has been reported in goats. The gross observations included congestion in brain, liver, and kidneys. The histopathological findings included degenerative changes in the renal tubules, hepatocyte necrosis, and degeneration in the centrilobular areas (Ali *et al.*, 1984).

k. Radiocontrast agents

Radiographic contrast agent administration can lead to acute renal failure in humans due to acute decline in renal function. Patients with nephropathy associated with radiographic compounds have an acute rise in serum creatinine anywhere from 24 to 48 h after the contrast study. In most cases renal failure is nonoliguric. Urine examination often reveals granular casts, tubular epithelial cells, and minimal proteinuria, but in many cases may be entirely bland. Nephrotoxicity appears to be the result of a synergistic combination of direct renal tubular epithelial cell toxicity and renal medullary ischemia. The diagnosis can be made based on the typical course of events following administration of contrast agent along with excluding other nephrotoxins (Murphy *et al.*, 2000).

l. Statins

HMG-CoA reductase inhibitors (statins) are the most common therapeutic medication used in patients with elevated low-density lipoprotein cholesterol. Significant side effects associated with statins are infrequent. Myalgia and arthralgia are common (1–7%) but frank rhabdomyolysis is rare and is generally associated with concurrent fibrate use. The specific mechanism of toxicity is still unknown and is related to the interruption of a wide variety of metabolic functions. Renal damage associated with statins is generally due to associated rhabdomyolysis. Findings indicating acute tubular toxicity have been reported, evident by irregular vacuolated renal tubular cells, loss of tubular cells with denudation of tubular basement membranes, as well as tubular cell casts seen both on histology and in the urine (Zyl-Smit *et al.*, 2004).

m. Dietary Supplements and Alternative Medicinal Agents

Herbs, nonherbal supplements, and vitamins used in complementary and alternative medicine have been reported to cause nephrotoxicity. Chromium picolinate sold as a nutritional supplement to prevent or treat chromium deficiency has been reported to cause tubular necrosis and interstitial nephritis. Creatine supplements are used to increase high-intensity athletic performance. Although uncommon, these supplements have been reported to cause renal tubular necrosis and interstitial nephritis. L-lysine used as an immunoboosting agent in alternative medicine has been reported to cause Fanconi syndrome and tubulointerstitial nephritis. Several cases of toxicity associated with high-dose administration of vitamin C have been reported, leading to extensive oxalate deposition in renal tubules. Nephrolithiasis has been reported associated with consumption of ephedra-containing dietary supplements. *Glycyrrhiza glabra* (licorice) associated renal toxicity secondary to hypokalemia has been reported. *Hedeoma pulegioides* (pennyroyal) can lead to renal dysfunction and toxicity along with hepatic toxicity. *Thevetia peruviana* (yellow oleander) has been reported to cause renal tubular necrosis along with hepatic failure leading to death.

Several adulterants added to nonherbal supplements, vitamins, and herbal medicine preparations can cause renal dysfunction and renal failure. Aristolochic acid is used as a herbal remedy for weight loss and has been reported to cause ''Chinese herb nephropathy'' characterized by extensive interstitial fibrosis with tubular atrophy and loss. Herbal medicine preparations produced in South Asia contain potentially harmful levels of lead, mercury, and/or arsenic which can lead to renal toxicity.

Several NSAIDs such as ibuprofen, phenylbutazone, and mefenamic acid have been reported to be a contaminant in several alternative medicine preparations and these compounds cause renal toxicity as described before (Saper *et al.*, 2004; Gabardi *et al.*, 2007).

2. Metals

The main targets of heavy metal toxicity are the kidneys and central nervous system. In humans, occupational or environmental exposure of inorganic heavy metals is known to be nephrotoxic at relatively high levels of exposure, with numerous reports of tubulointerstitial nephritis possibly

leading to renal failure. Low environmental levels of these heavy metals can lead to early signs of renal dysfunction, apparent by decreased GFR (lead) or increased urinary loss of tubular enzymes (cadmium).

a. Mercury

Fungicides, preservatives, and fixatives are the main sources of mercury toxicosis. Often, toxicosis is related to accidental ingestion of obsolete mercury products. The lesions of mercury toxicosis are distributed in the gastrointestinal tract, kidneys, and sometimes in the brain (alkyl organic mercury). Inorganic mercurial salts accumulate in the renal cortex and are excreted primarily in the urine. Inorganic mercurial salts cause direct tissue necrosis and renal tubular epithelial necrosis by two mechanisms. The mercuric ion binds covalently with sulfur and inhibits sulfhydryl-containing enzymes in microsomes and mitochondria. The mercurial salts may bind to protein as mercaptides. Death occurs in acute toxicity and oliguria, and azotemia is observed in animals surviving acute exposure (Osweiler, 1996). Chronic exposure to inorganic mercury leads to an immune mediated membranous glomerulonephritis. Histopathological findings in the kidneys are primarily renal tubular degeneration and necrosis, especially in the proximal tubular epithelium. In chronic exposure, glomerulonephritis is observed due to antigen–antibody complex deposition. Diagnosis and confirmation can be made by analytical estimation in the kidneys (Jones *et al.*, 1996).

b. Cadmium

Cadmium toxicity in humans is caused by smoking, inhalation of dust and fumes, and by contaminated food. In animals, cadmium exposure is mostly by ingestion of cadmium–nickel batteries. Cadmium is concentrated in the renal tubules and to a lesser degree in the hepatocytes. Cadmium induces metallothionein (low molecular weight cysteine-rich metal binding proteins) production and forms a cadmium–metallothionein complex. This complex is filtered freely by the glomerulus and is reabsorbed by the proximal tubules. Inside the tubules, renal metallothionein is formed and once the renal metallothionein pool is saturated, free cadmium ions initiate renal tubular injury. Cadmium produces proximal tubular injury leading to increased excretion of glucose amino acids, calcium, and cellular elements. Over the course of time, injury progresses to a chronic interstitial nephritis (Osweiler, 1996; Schnellmann, 2001).

c. Arsenic

Arsenic toxicity from drinking water is a major public health concern in many countries throughout the world. If exposure is to the inorganic form, the kidneys are the target organ due to its involvement in *in vivo* biotransformation and elimination. Very few clinical cases of toxicity are reported in humans. Most clinical cases of toxicosis are reported in animals, especially cattle and dogs, by accidental exposure, but all species of domestic animals can be affected. Trivalent arsenicals inhibit cellular respiration and cause capillary dilatation and degeneration. Pentavalent inorganic arsenicals cause uncoupling of oxidative phosphorylation, leading to cellular energy deficiency. In acute toxicosis, the pathological changes are mostly limited to the gastrointestinal tract. The systemic toxicity occurring in severe acute arsenic poisoning may be accompanied by acute tubular necrosis and acute renal failure. Subacute toxicity is by exposure to low doses for several days. In subacute cases the kidneys are affected, leading to proximal tubular necrosis. The clinical signs associated with subacute toxicity are oliguria and proteinuria, followed by polyuria. Watery diarrhea exhibited in acute poisoning will also be observed. Death results due to dehydration, acidosis, and azotemia (Osweiler, 1996). Histopathological lesions consist of dilation of the vessels, submucosal congestion and edema, necrosis of the intestinal epithelium, renal tubular necrosis and fatty degeneration of the hepatocytes (Jones *et al.*, 1996). Diagnosis is by correlating the case history, pathological findings, and analytical estimation of arsenic in liver, kidneys, and other tissues (hair). Chronic arsenic ingestion is strongly associated with an increased risk of skin cancer, and may cause cancers of the lung, liver, bladder, kidneys, and colon. Chronic inhalation of arsenicals has been closely linked with lung cancer. The specific mechanism of arsenic-related carcinogenicity is unknown. Although carcinogenicity of arsenic in humans has been established, no animal model has yet been developed.

d. Copper

Acute copper toxicosis results from accidental ingestion or administration of copper containing formulations, such as anthelmintics, feed additives, foot baths used for livestock, and pesticides, including fungicides and algaecides at a toxic dose. Copper toxicosis is a problem frequently observed in sheep, as they are sensitive to excessive copper accumulation. Sheep accumulate copper in the liver in proportion to intake, where there is a slow build-up of the copper and then a sudden release, resulting in copper in the circulation. This excess copper oxidizes the erythrocyte membrane, resulting in intravascular hemolysis. Clinical signs in sheep are due to acute anemia and include weakness, anorexia, fever, pale mucous membranes, and dyspnea. Generally, the kidneys have a dark red or bluish black color (gun metal kidneys) and the liver will be pale yellow and friable. Microscopic findings include necrosis of renal tubular epithelium and hemoglobin casts (Osweiler, 1996; Maiorka *et al.*, 1998). Diagnosis is by correlating liver copper values with pathological findings and case history.

e. Fluoride

Fluoride toxicosis reported primarily in animals can be acute or chronic. Acute toxicosis is by exposure to insecticides/rodenticides and volcanic dust. Fluoride is metabolized via renal excretion and is preferentially deposited in

bones and teeth. Acute fluoride intoxication produces clinical signs and lesions of gastroenteritis and renal tubular necrosis. In a study conducted in sheep exposed to fluoroacetate, the microscopic findings in acute toxicosis included degeneration and necrosis of myocardial fibers. In a study conducted in sheep poisoned by sodium fluoride, the pathological findings included necrosis of the proximal tubular epithelial cell, necrotizing ruminitis, reticulitis, and abomasitis (Shupe, 1980; O'Hara *et al.*, 1982; Maylin *et al.*, 1987).

f. Lead

The main sources of lead exposure are paints, water, food, dust, soil, kitchen utensils, and leaded gasoline. The majority of cases of lead poisoning are due to oral ingestion and absorption through the gut. Lead poisoning in adults occurs more frequently during exposure in the workplace. Lead toxicosis affects hemoglobin synthesis by inhibiting the enzyme's delta-aminolevulinic acid synthetase and ferrochelatase, resulting in anemia. Clinical signs include indications of central nervous system involvement, anorexia, anemia, and proteinuria. Clinical pathological findings, suggestive of lead toxicosis, are basophilic stippling of erythrocytes and metarubricytosis with minimal polychromasia. Anemia may be microcytic hypochromic to normocytic normochromic (Prescott, 1983). The potential toxic effect of lead on the kidneys ranges from reversible proximal tubular dysfunction and ultrastructural changes, to chronic nephropathy. Subclinical lead poisoning in humans affects the functions of the proximal tubular lining cells and leads to renal insufficiency. Characteristics of early or acute nephropathy include dysfunction of the proximal tubules, manifesting as aminoaciduria, glycosuria, and phosphaturia with hypophosphatemia and increased sodium and decreased uric acid excretion. These effects are reversible. Characteristics of chronic lead nephropathy include progressive interstitial fibrosis, a reduction in the glomerular filtration rate, and azotemia. These effects are irreversible. The acute form of nephropathy is most frequently reported in children, while the chronic form is mainly reported in adults (Papanikolaou *et al.*, 2005). In chronic cases, the kidneys' histopathological changes are characterized by degeneration and necrosis of the renal tubular epithelium which may show regeneration. Degenerative changes of the renal epithelial cells and hepatocytes have been reported in chronic lead poisoning in dogs. Intranuclear inclusions may be visible in the renal tubular epithelial cells, but their absence does not rule out lead toxicosis (Jones *et al.*, 1996; Osweiler, 1996).

In birds, especially water fowl, lead toxicosis has been reported and lead shot may be found in the gizzard. The birds are generally emaciated with extensive muscle wasting and atrophy of the breast muscles. Changes in the kidneys are primarily renal tubular degeneration or necrosis (with or without intranuclear inclusions) (Locke and Thomas, 1996). Diagnosis is by analytical estimation and history of exposure. Liver and kidneys are the preferred samples for analysis of lead.

3. Mycotoxins

a. Citrinin and Ochratoxin

Ochratoxins are mycotoxins produced by the toxic strains of *Pencillium* and *Aspergillus* spp., mostly due to improper storage conditions of grain, peanuts, dried fruits, grapes/raisins, cheese, coffee, etc. They are also found in meat. Two different ochratoxins have been isolated and characterized (ochratoxin A and B). Of the two, ochratoxin A is the most frequently encountered and the most toxic. The subchronic and chronic effects of this toxin are of more concern than the acute toxicity. Exposure to ochratoxin A in humans has been linked to the development of Balkan endemic nephropathy (BEN). BEN is a disease that occurs in some areas of Bosnia and Herzegovina, Bulgaria, Croatia, Romania, Serbia, and Montenegro. BEN occurred in a limited geographical distribution of farming households with a high mortality from uremia. The first outbreak of the disease in endemic areas occurred simultaneously in the early 1950s, although there are indications that sporadic cases were seen previously. Due to its carcinogenic properties ochratoxin has been classified as a possible carcinogen in humans (Fuchs and Peraica, 2005).

Pigs are the most common species to be affected by ochratoxicosis. Clinical pathological changes include increased BUN values, reduced creatinine clearance, and urine specific gravity. The gross pathological changes observed in experimental studies of pigs include enteritis, pale tan discoloration of liver, edema, and hyperemia of the mesenteric and other lymph nodes. The microscopic findings are mostly confined to the kidneys and gastrointestinal tract, and include necrosis of the renal tubular epithelium most frequently affecting the proximal convoluted tubules, dilatation of the tubules, necrotizing enteritis in multiple locations, fatty degeneration of liver, and focal necrosis of lymphocytes in the germinal center of the lymph nodes (Szczech *et al.*, 1973a; Zomborszky-Kovacs *et al.*, 2002). The renal pathological changes observed in experimental studies of dogs are similar to those observed in the porcine studies and include necrosis and desquamation, predominantly in the proximal convoluted tubules, and eosinophilic granular casts in proximal and distal convoluted tubules (Szczech *et al.*, 1973b; Szczech, 1975). Ochratoxicosis has also been reported commonly in avian species. Experimental studies in young broilers with ochratoxin A show renal edema and tubular necrosis (Wyatt *et al.*, 1975; Duff *et al.*, 1987).

Citrinin is a benzopyran metabolite produced by the toxic strains of *Pencillium ochraceus* and *Aspergillus verrucosum*. Some hepatotoxic effects have been reported for citrinin but the lethal effects are largely due to the nephrotoxicity. The specific mechanism of action in the kidneys is not known, but it leads to acute tubular necrosis. In pigs, rats, and rabbits, the proximal segments are affected. Histopathological findings in different species of animals

include necrosis and desquamation of the proximal renal epithelium, basement membrane thickening, tubule dilatation and proliferation of cells in the interstitium (O'Brien and Dietrich, 2004). Experimental studies show that citrinin induces renal damage in turkeys and ducklings, along with hepatic degeneration and lymphoid necrosis (Mehdi *et al.*, 1984). For further details on the toxicity of ochratoxin and citrinin, readers are referred to a recent publication elsewhere (Gupta, 2007).

b. Fumonisins

Fumonisins are mycotoxins produced by the fungus *Fusarium moniliforme*, primarily in corn. The common species affected are equine and swine, and the target organs are brain and liver. In rats and rabbits, the kidneys are the target organ. Histopathological changes primarily affect the renal tubular epithelium at the junction of cortex and medulla and include prominent apoptosis of epithelial cells of the proximal convoluted tubules (Bucci *et al.*, 1998; Zamborsky-Kouacs *et al*. 2002).

c. Oosporein

Oosporein, which is produced primarily by *Oospora colorans* and *Caetomium trilaterale*, is observed in feed stuffs, cereals and peanuts. It has been reported to be toxic in poultry resulting in nephrotoxicity, and visceral and articular gout. The pathological observations in oosporein toxicity include necrosis of the tubular epithelial cells in the proximal tubules with basophilic casts, hyaline casts in the distal tubules with fibrosis and interstitial pyogranulomatous inflammation, urate deposits in various tissues, and proventricular enlargement with mucosal necrosis (Pegram and Wyatt, 1981; Brown *et al.*, 1987).

4. Pesticides

Pesticide toxicity is common in humans as well as in animals. The common pesticides that cause nephrotoxicity include paraquat, diquat, and zinc phosphide.

a. Paraquat and Diquat

Paraquat is a widely used bipyridyl broad-spectrum herbicide. The most common route of intoxication is ingestion. Among domestic animals, toxic exposure has been reported in cattle, sheep, horses, pigs, poultry, and dogs. Paraquat primarily affects the lungs. Kidney and liver may also be affected and the histopathological change is renal tubular epithelial degeneration. Diquat toxicity results in intracerebral hemorrhage and acute renal failure (Nagata *et al.*, 1992). Diagnosis is made by correlating history of exposure with pathological findings.

b. Zinc Phosphide

Zinc toxicosis results from ingestion of bait containing this compound or by eating tissues of zinc phosphide-poisoned animals. All domestic animals can be affected and reports are common in dogs. Zinc phosphide and aluminum phosphide both release phosphine gas when they come in contact with the acidic contents of the stomach. Both phosphine and intact zinc phosphide are absorbed from the gastrointestinal (GI) tract. The phosphine is believed to cause the majority of acute signs, while the intact phosphide may cause hepatic and renal damage later. Histopathological findings in the kidneys include renal tubular degeneration and necrosis (Casteel and Bailey, 1986). Diagnosis is by analysis of stomach contents, vomitus, liver, and kidneys for phosphine gas. Samples must be submitted frozen in airtight containers for analysis of phosphine.

5. Miscellaneous Agents

a. Ethylene Glycol

Ethylene glycol (EG) is found in many agents, including antifreeze, brake fluids, and industrial solvents. Ingestion of ethylene glycol by humans is uncommon, but when ingested, it can cause serious poisoning. It is readily absorbed from the GI tract and the maximal blood concentration is reached within 1–4 h. The half-life is 3–8 h. The estimated lethal dose of 100% EG is approximately 1.4 ml/kg. Ethylene glycol has a low toxicity, but it is biotransformed in the liver by alcohol dehydrogenase into four organic acids: glycoaldehyde, glycolic acid, glyoxylic acid, and oxalic acid. These metabolites cause central nervous system depression, and cardiopulmonary and renal failure. The rate-limiting step in the metabolism of ethylene glycol is the conversion of glycolic acid to glyoxylic acid. This results in an accumulation of glycolic acid in the blood. Glycolic acid causes severe acidosis, and oxalate is precipitated as calcium oxalate in the kidneys and other tissues. Histological examination of the kidneys reveals marked necrosis of the tubular epithelium with deposition of retractile oxalate crystals in the tubules (Figure 38.2) and collecting ducts. Although the intratubular crystals may be partly responsible

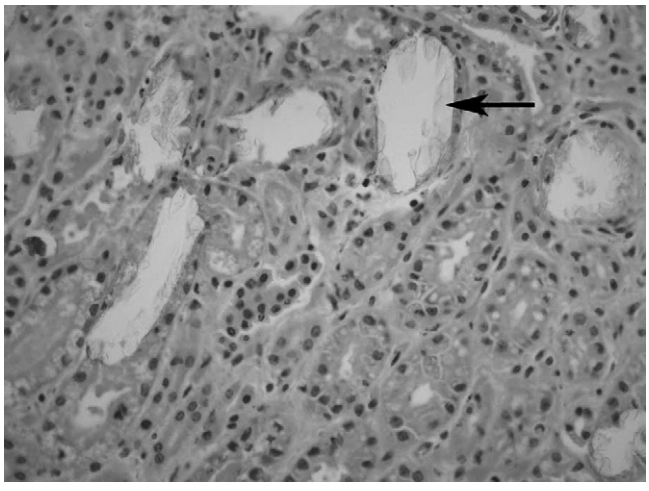

FIGURE 38.2. Ethylene glycol poisoning, canine kidney; tubules are lined by degenerate epithelium and multiple tubules contain crystalline material. Arrows show crystals in tubules. H & E stain ×40.

for renal failure, the action of toxic metabolites on the tubular epithelium is also thought to be important. In chronic cases, there will be atrophy of the tubules with interstitial fibrosis (Leth and Gregersen, 2005).

In animals, EG toxicity is common and is caused by consumption of antifreeze solution which contains up to 95% EG. Mostly cats and dogs are the affected species but there are rare reports of intoxication in other species. The common clinical and pathological findings in cats and dogs include neutrophilia, lymphopenia, azotemia, hyperphosphatemia, hypocalcemia, hyperglycemia, and decreased whole blood bicarbonate. The common findings in urine analysis include proteinuria, glucosuria, hematuria, calcium oxalate and hippurate crystalluria, and the presence of renal epithelial cells, white blood cells, and granular and cellular casts in the urine sediment.

Generally, the kidneys are firm with pale streaks at the corticomedullary junction. In some cases pulmonary edema and hyperemia of the gastric and intestinal mucosa are observed. The microscopic findings include marked renal interstitial fibrosis (in long-time survivors), mild lymphocytic infiltration in the interstitium, atrophy, degeneration and necrosis of the renal tubular epithelium with birefringent crystals, and mineralization and glomerular atrophy in some cases (Jones *et al.*, 1996). The antemortem diagnosis is by clinical pathological evaluation (increased anion and osmolal gaps, suggestive), colorimetric test kit, and GC assay in serum for EG and glycolic acid. Postmortem diagnosis is by pathological evaluation or chemical analysis of the kidneys.

b. Diethylene Glycol

Diethylene glycol (DEG) is a sweet-tasting, colorless, nonodoriferous, hygroscopic liquid commonly used in the commercial preparation of antifreeze, brake fluid, cigarettes, and some dyes. It is an excellent solvent for many relatively insoluble substances. DEG is also commonly used in human medications, such as acetaminophen and sulfanilamide, either intentionally or accidentally leading to episodes of human poisoning, several being fatal. DEG contaminated a shipment of glycerin imported to Haiti from China through Europe. This glycerin was used in numerous locally manufactured liquid pharmaceutical products, including acetaminophen syrup, and consumption of this product led to numerous cases of renal failure associated fatality (O'Brien *et al.*, 1998). Additionally, it has been used as an illegal adulterant in wine. Because of its toxicity, DEG is not allowed in food and drugs. DEG affects the CNS, heart, respiratory system, liver, pancreas, and kidneys. Biochemical changes associated with toxicity include elevated hepatic enzyme levels, as well as increased serum BUN and creatinine levels. The clinical presentation is characterized by a nonspecific febrile prodromal illness, and within 2 weeks followed by anuric renal failure, pancreatitis, hepatitis, and neurologic dysfunction, progressing to coma. Histopathology of kidney tissue demonstrates acute tubular necrosis with regeneration and interstitial edema. DEG poisoning shows extensive tubular necrosis; however, the oxalate deposition is of EG poisoning, which causes renal and cerebral damage, and has not been observed in DEG poisoning. Similar to EG, DEG is not toxic but its metabolites are. Recently, an episode of DEG associated toxicity in cough syrup medication was reported from Panama, resulting in a mortality of more than 100 people.

6. Pet Food-Related Toxicity by Melamine and Cyanuric Acid

Since March 2007, several deaths were reported in dogs and cats associated with contamination of melamine and cyanuric acid in wheat gluten and rice protein (imported from China) used for manufacturing pet food in the USA. Melamine was identified in pet food and in the urine and kidneys of the cats that consumed the pet food. Analysis of the crystals revealed that they were composed of approximately 70% cyanuric acid and 30% melamine and were extremely insoluble. Significant clinical pathologic findings included azotemia and hyperphosphatemia, consistent with acute renal failure. In some cases, leukocytosis was observed. The majority of cases had oliguria or anuria and death was due to acute renal failure. No significant gross observations were noticed except in some cases which included gastric ulcer and green–yellow fluid with green crystals within the renal pelvis. Histopathological observations included degeneration and occasional necrosis of renal tubular epithelial cells with numerous crystals (Figure 38.3) evenly distributed throughout the cortex and medulla, within renal tubules and collecting ducts. Under polarized

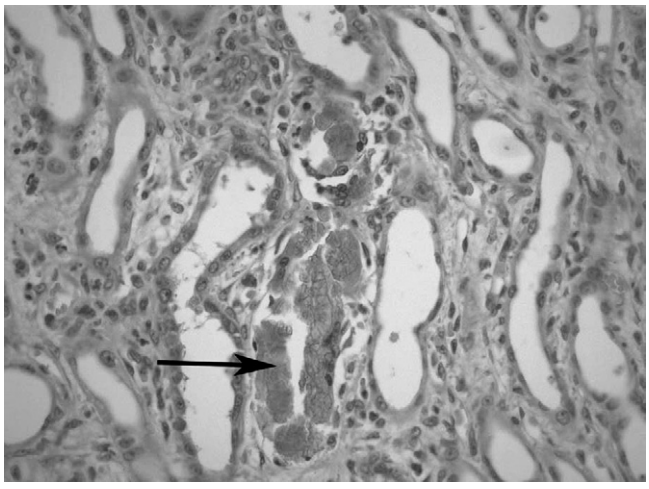

FIGURE 38.3. Melamine cyanuric acid poisoning, feline kidney; tubules are lined by degenerate, necrotic and flattened epithelium and contain crystalline material. Arrow shows crystalline material arranged in concentric pattern. H & E stain ×40.

light, these crystals showed birefringence. Many of them were round, pale brown, and appeared to have a rough surface as a result of smaller crystalline structures being arranged radially and more randomly within the entire birefringent crystal. In some areas, these crystal structures were arranged in concentric circles. The crystals were present within renal tubular epithelial cells and in the lumens of tubules, filling the lumen and at times distending the tubules. The melamine-containing crystals do not stain with Alizarin Red S or Von Kossa but do stain with Oil Red O. Calcium phosphate and calcium oxalate crystals do not stain with Oil Red O, which helps in the differential diagnosis of these crystals from crystals associated with EG toxicity (Thompson *et al.*, 2008).

7. Snake Bite

The majority of poisonous snakes in the USA are of the Crotalidae family, which includes rattle snakes, water moccasins, and copperheads. Crotalid snakes produce venoms which are mostly necrolytic and hemolyzing. Hemorrhagins in Crotalidae venom are toxic to the vessels and hence cause hemorrhage and edema at the wound site, in addition to systemic hemorrhage and shock. Marked anemia is observed due to hemolysis and extravasation. Disseminated intravascular coagulation is observed in some cases. The common initial clinical pathological changes include echinocytosis, thrombocytopenia, leukocytosis, and prolonged activated clotting time. Generally, edema and erythema, along with fang marks (Crotalidae family), may be observed at the site of bite, although it is difficult to identify due to the thick hair coat in animals. The major route of venom excretion is through the kidneys and hence kidney failure is observed in many cases of crotalid snake bites, characterized by renal tubular necrosis with protein casts, hemorrhage, and necrosis in the glomeruli (mesangiolysis). Mesangial proliferative glomerulonephritis is observed in patients who survive (Dickinson *et al.*, 1996; Sitprija and Chaiyabutr, 1999; Hacket *et al.*, 2002).

8. Raisins

Grape and raisin ingestion has been reported to cause renal toxicity in dogs. The specific mechanism of action is not known. Clinical and pathological findings include hypercalcemia, hyperphosphatemia, increased BUN, and serum creatinine concentrations, indicating renal damage.

Gross lesions are absent and microscopic findings include degeneration and necrosis of proximal renal tubular epithelium with intact basement membrane, regeneration of the tubular epithelium and mineralization. The tubules contain granular and protein casts. In some animals, fibrinous arteritis of the large colon was also observed (Eubig *et al.*, 2005; Morrow *et al.*, 2005).

IV. CONCLUDING REMARKS AND FUTURE DIRECTION

The primary function of the kidneys is to rid the body of waste materials that are either ingested or produced by metabolism, and to control the volume and composition of the body fluids. The toxins absorbed by the different routes are biotransformed and enter the blood. They are then eliminated through the urine, feces, and air. Since the kidneys receive approximately a quarter of the cardiac output, it is an important organ for the exposure of toxicants and their metabolites. Recent incidents of pet food toxicity and diethylene glycol toxicity indicate that contamination of animal and human food and drugs, respectively, can lead to severe mortality and morbidity as a result of renal toxicity.

CHAPTER 39

Ocular Toxicity of Sulfur Mustard

MARION K. GORDON, ROBERT W. ENZENAUER, AND MICHAEL C. BABIN

I. INTRODUCTION

The eye is the most sensitive organ to sulfur mustard [bis (2-chloroethyl) sulfide; HD; SM – in this chapter we refer to sulfur mustard as SM]. Although the skin's response to this vesicant is blistering, the cornea experiences microbullae formation without fully fledged blistering. Corneal SM exposure causes injuries that range from mild conjunctivitis to advanced corneal disease. As a warfare agent, SM is extremely effective because even mild ocular exposure causes some visual incapacitation and a panic and fear of blindness whose psychological impact cannot be underestimated. As for clinical symptoms, extensive military data have documented that the effects of sulfur mustard vary widely according to the exposure time and concentration of the vesicant, as well as individual susceptibility (Derby, 1919, 1920; Ireland, 1926). SM used by the Germans during WWI caused thousands of cases of eye damage (Whiting *et al.*, 1940), and during the Iran–Iraq war (1985–1988), nearly 10% of SM gas casualties exhibited severe ocular damage (Safarinejad *et al.*, 2001; Ghassemi-Broumand *et al.*, 2004; Etezad-Razavi, 2006). Soldiers with mild to moderate injuries are somewhat visually disabled for approximately 10 days with conjunctivitis, photophobia, and perhaps corneal edema (Whiting *et al.*, 1940). Severe ocular SM exposure is often repaired much more slowly, requiring months to heal (Derby, 1919). In some reported cases healing never occurred and permanent visual impairment resulted. Also, a devastating discovery was the potential for a completely healed cornea to experience a recurrence of injury years after the initial exposure (Whiting *et al.*, 1940; Duke-Elder and MacFaul, 1972; Pleyer *et al.*, 1999; Vidan *et al.*, 2002; Ghassemi-Broumand *et al.*, 2004; Javadi *et al.*, 2005, 2007; Etezad-Razavi *et al.*, 2006). The reasons for recurrence are not yet understood. This chapter describes the consequences of SM exposure to the eyes, and what has been learned in the last 100 years about treatments for exposure.

II. BACKGROUND

A. Historical Perspective

World War I (WWI) heralded the use of military offensive chemical weapons as we know them today. Medical officer Major S.J.M. Auld, MC, was a witness to the first military gas attack early in WWI, and after his service on the front, he served as a member of the British Military Mission to the USA as part of the Liaison Effort between the defense organizations of the USA and her allies. While the war still raged, he reported on the effects of mustard gas in his textbook *Gas and Flame in Modern Warfare*. According to Dr Auld, the effects of mustard gas

> are not transitory and a man put out of action by mustard gas is going to be a casualty for several weeks and perhaps longer. Mustard gas principally affects the eyes and the lungs, but in a very strong vapor or in contact with any of the actual liquid from the shell a man's skin may be burned very severely – even through his clothes. More attention has been turned to this blistering effect of the gas than to anything else, but as a matter of fact the blistering is of secondary importance and in itself does not result in the loss of many men to the line … The chief effects of the mustard gas are on the eyes and lungs. The first thing you notice is the smell – which is slightly of garlic or mustard – and irritation of the nose and throat. Neither effect is enough to make you feel gassed, and the chief symptoms develop at a later time. When the gas is strong it is apt to cause sickness and sometimes actual vomiting. Later on, the eyes inflame and get very sore, the lids swell and blister, but no permanent injury to the eyes takes place, though the victim may be temporarily blinded. The effects developed in the lungs are equally painful and consist of severe inflammation and bronchitis, which may take some time to get better and if not well looked after may develop into pneumonia. (Auld, 1918)

Data collected later in WWI and throughout the rest of the 20th century indicate that, if Auld had seen more cases, he would have concluded that permanent injury to the eye is certainly possible. No one at the time he was reporting his observations could have foreseen the delayed recurrence of eye and skin injuries, or the downstream neoplastic consequences of exposure to SM. The clinical effects from mustard exposure are related to the concentration and duration of the mustard gas vapor (Derby, 1919; Sidell *et al.*, 1997). Since the vesicating gases persist for a long time, they are effective in extremely low concentrations, provided the victim remains in the contaminated area long enough. As mentioned, severe exposures often take many months to heal, and permanent damage causing blindness is a possible sequela.

B. Pathogenesis

Several components of the eye are affected by SM exposure: the outer structures are the cornea (transparent area over the pupil), the sclera (the white of the eye), and the limbal region, which joins the two. The limbus contains the corneal stem cells. In addition, there is the eyelid (i.e. the palpebra), with its outer skin layer facing the world and its inner skin positioned directly over the eye. The conjunctiva is the transparent moist mucous membrane that lines the inner surfaces of the eyelids and covers the sclera, but not the cornea. The portion of the conjunctiva that covers the rounded surface of the eye is also called the bulbar conjunctiva. The cornea is highly innervated, so that a speck of dust feels like a boulder in the eye. As shown in Figure 39.1, the cornea has three cell layers: the epithelium faces the exterior; the stroma contains the fibroblastic-like keratocytes; and the thin diameter, evenly spaced collagen fibrils. These fibrils are unidirectional in mat-like layers, and in each layer the fibrils are at about 90 degree angles to the fibrils in the layer above and the layer below (Coulombre and Coulombre, 1958); the innermost corneal cell layer is the endothelium, which faces the anterior chamber. The endothelium pumps water out of the cornea, keeping it condensed and relatively dehydrated, which is a necessity for transparency (Oyster, 1999). Swollen edematous corneas are cloudy. Mild to moderate SM exposures generally affect only the epithelial layer of the cornea, while severe ones may involve all three cell layers.

Ocular manifestations of SM exposure are generally separated into early signs and symptoms, and late signs and symptoms. Physicians and researchers use scoring systems for how severe the typical signs and symptoms are. One such scoring system for the cornea is reported in Table 39.1. It is also important to follow the progression of healing of the symptoms. Table 39.2 gives an example of animal data showing the temporal changes occurring with regard to a symptom that is both early and late, i.e. corneal thickening. A severe exposure to rabbit eyes, such as the one shown from this experiment, would likely cause months of vision impairment in humans. As seen in Table 39.2, the effect on the corneas is worst at 1 week after exposure, but even 16 weeks after exposure the cornea is still almost twice as thick as an untreated, healthy cornea. Clearly this is a severe exposure, where the endothelium has been affected, since the cornea is unable to regain its dehydrated, condensed transparent phenotype even after 4 months.

Ophthalmologists Sir Stewart Duke-Elder and P.A. MacFaul summarized the clinical course of ocular lesions as being divided into five stages: (1) a latent period, usually of 6–8 h, after minimal initial irritation; (2) a primary edematous reaction with swelling and cellular infiltration of the cornea; (3) clinical improvement after about a week with diminution of the edema; (4) progressive vascularization of the cornea, associated with a secondary edema and a recurrence of the symptoms – a phase which tended to quieten after several weeks; and (5) recurrent and persistent ulceration in the cornea after a latent period varying from 10 to 25 years (i.e. delayed mustard gas keratitis) (Duke-Elder and MacFaul, 1972). Mild exposures may only reach stage 1. Only a small percentage of severe exposures ever reach stage 5.

A 1919 clinical summation reported the first manifestations of a severe SM exposure as being pain and irritation to the eyes. Depending on the concentration of SM, this can

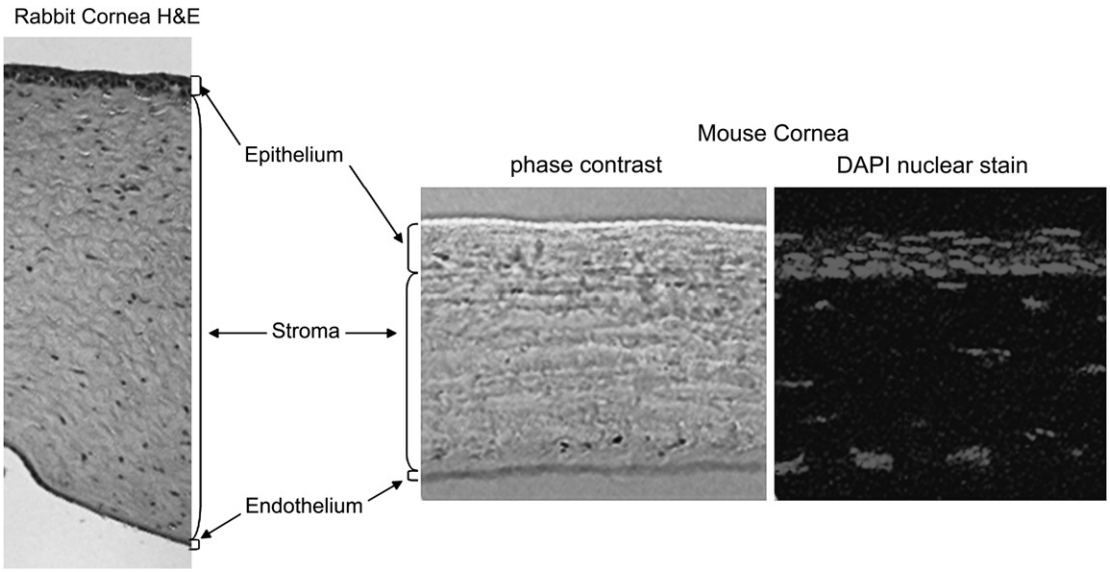

FIGURE 39.1. The three cell layers of the cornea. Shown on the left is a frozen section of an adult rabbit cornea stained with hematoxylin and eosin. On the right is a frozen section of a 6 week old mouse cornea. The mouse cornea is not fully mature until 8 weeks after birth. The left half visualizes the cornea by phase contrast microscopy. The right half shows the nuclei by DAPI staining. The density of the cells in the epithelial layer, and the paucity of keratocytes in the stromal layer are clearly seen with the nuclear stain.

TABLE 39.1. A typical scoring system for defining the degree of corneal stromal injury after SM exposure

Clinical parameter	Grade	Loss of corneal transparency	Assessment
Corneal stromal injury (opacity)	0	None	Not applicable
	1	Minimal	Slight loss in transparency
	2	Moderate	All anterior segment structures are easily discernible on examination
	3	Severe	Some anterior segment structures are not discernible on examination
	4	Diffuse	All anterior segment structures are not discernible on examination
	5	Diffuse	All anterior segment structures are not discernible on examination and perforation of the cornea has occurred

begin to be felt as early as 2–6 h after exposure. This progresses to photophobia, lacrimation, and blurred vision. The conjunctiva and eyelid become edematous, and the patient experiences blepharospasm (uncontrollable blinking) and pain (Derby, 1919). Anterior chamber inflammatory reaction is common. After several hours, the corneal epithelium begins to slough (Solberg *et al.*, 1997). All this would take the patient only through stage 2 of Duke-Elder and MacFaul's clinical course.

Most descriptions of the degree of ocular injury in humans characterize the phenotypes into three classes, each being a variant of mild, moderate, or severe. Such descriptions were developed in WWI and presented to the scientific community in an effort to understand the overall impact of mustard exposure. In March 1918, it was reported to the French Ophthalmological Society that there were three severities of SM injury, identifying them as: (1) benign, representing 10–15% of cases, with a duration of 10 to 15 days; (2) medium, about 80% of cases, with a duration of 5 to 6 weeks; and (3) severe, 3–5% of cases, where the victim experiences marked general symptoms, often developing a bronchopneumonia in addition to the ocular effects. George S. Derby, a Boston ophthalmologist, reported that this was not the experience of the British and American doctors. They saw a much, much larger percentage of mild cases, which recovered in 10–14 days (Derby, 1919). More than 20 years later, a discussion on gas injuries to the eye, held in January 1940 by the Section of Ophthalmology at the Royal Society of Medicine, agreed with the American and British views about the percentages of eye exposures that fit each class of severity. These discussants summarized the injuries from 1917 seen at the 83rd General Hospital in Boulogne, and believed the largest percentage (75%) of cases were mild. Recovery was rapid, and the soldiers were usually sent back to duty in 1–4 weeks. The moderately severe cases (15%) took about 4–6 weeks or longer to heal, with conjunctival chemosis (edema) subsiding fairly quickly. Those severely exposed developed corneal changes which resolved in longer periods of time. Of those, only a very small minority sustained permanent impairment or total loss of vision (Whiting *et al.*, 1940).

Scoring systems have elucidated the general patterns of pathogenesis for each classification of exposure. With mild exposures, the patients recover within a few days, with minimal lid erythema, moderate conjunctival changes, and minimal corneal involvement (Solberg *et al.*, 1997). A moderate exposure may first feel like a dry sensation with photophobia and severe eye pain. Chemosis and congestion of the conjunctiva are observed, as well as corneal epithelial edema and punctuate erosions. The corneal epithelium usually is repaired in 4–5 days, while the entire area takes 6 weeks or longer to heal (Solberg *et al.*, 1997). The symptoms of a severe exposure go beyond those of a moderate exposure by including blepharospasm, reduced vision, and severe pain. The limbal vasculature can be affected. Eyelids become red and swollen; there is significant chemosis and conjunctival congestion, with areas of ischemia and necrosis. There may also be iridocyclitis. The irregularities in the cornea give it an orange peel appearance. Erosions may manifest, and the epithelium may slough. Epithelial defects are prone to infection, especially to *Pseudomonas aeruginosa*. The conjunctival epithelium also necroses, with edema of the subconjunctival tissues, hemorrhaging, and leukocyte infiltration. The depth of the

TABLE 39.2. Relative index values for corneal thickness measured by ultrasonic pachymetry over time[a]

Group	Week 0	Week 1	Week 2	Week 3	Week 4	Week 5	Week 6	Week 16

necrosis in the conjunctival epithelium is much less than that in the eyelid epidermis. This difference is because the hair follicles of the eyelid can collect the SM, while the conjunctiva is a moist mucosal tissue with a protective tear film. Overall, healing after a severe exposure is often suboptimal, with vascularization and corneal cicatrization (healing with scar formation) and visual impairment (Derby, 1919; Warthin and Weller, 1919; Solberg *et al.*, 1997; Javadi *et al.*, 2005, 2007).

The pattern of injury in the human eye is analogous to that observed in animal studies. In severe SM injury, there is often full thickness corneal lesions (i.e. involving the stroma and the endothelium as well as the epithelium), and iritis, which starts to improve within 1–2 weeks. There can also be avascular necrosis in the limbus, which may diminish the number of stem cells available for repairing the corneal epithelium. A few weeks later, neovascular elements can arise from the healthy limbus and invade the corneal stroma (Petrali *et al.*, 2000; Babin *et al.*, 2004; Amir *et al.*, 2000). White opacities may occur as the vessels degenerate (Borak and Sidell, 1992). English-born ophthalmologist Dr Ida Mann found that in rabbits, about 8 weeks after a severe exposure to SM, the vessels of neovascularized corneas also regressed, leaving behind cholesterol crystals deposits. As the cholesterol worked its way to the corneal surface it caused ulcerations, leaving pits in the cornea. Mann believed that surfacing of cholesterol was the basis of delayed keratitis (Mann and Pullinger, 1942a). Mann wrote extensively on delayed keratitis, suggesting that, in her opinion, it should be called delayed ulceration (Mann and Pullinger, 1942a; Mann, 1944).

Because of the good correlation of pathology between human and animal eye exposures, animal studies offer great hope for identifying countermeasures to sulfur mustard, and for furthering the arsenal of drugs used to combat the effects of exposure.

C. Delayed Effects

Severe corneal wounds may resolve after several months, or may remain a chronic problem for years. In a small percentage (0.5%) of severely injured patients, delayed ulcerative keratopathy develops decades after SM exposure (Heckford, 1937; DeCourcy, 1943; Atkinson, 1947; Blodi, 1953, 1971; Duke-Elder and MacFaul, 1972; Dahl *et al.*, 1985; Solberg *et al.*, 1997; Javadi *et al.*, 2005, 2007). Delayed keratopathy is one of the more perplexing late sequelae of sulfur mustard ocular injury because casualties, sent home from the hospital as ''cured'' through months of treatment, became symptomatic again 25 or more years later. Photophobia, tearing, and visual deterioration were often the start of this delayed onset effect, followed by pain. Vascularization and corneal ulcerations sometimes occurred, and crystalline deposits appeared (Solberg *et al.*, 1997; Javadi *et al.*, 2005). Recurrence and remission of this phenomenon occur unpredictably. The pathogenesis is not yet understood. Mann's explanation of surfacing cholesterol may be the cause. An alternative explanation may come from the fact that some of the Iranian soldiers who experienced this delayed phenomenon showed a mixed inflammatory response without specific features when their conjunctival and corneal tissues were taken for analysis (Javadi *et al.*, 2005).

III. OCULAR TOXICITY AND TOXICOKINETICS

A. Toxicity

The toxicity associated with SM is quite profound. The Army's Chemical Defense Equipment Process Action Team estimated in 1994 that a 900 mg-min/m^3 SM vapor exposure would be lethal in 2–10 min, based on animal studies (National Research Council Review, 1997). Fortunately, in the battlefield, lethality has been limited. Only 1–3% of exposed soldiers died from SM exposure after WWI, and mortality mostly was not a direct consequence of SM, but rather the indirect effect of secondary respiratory infections. The 1999 Material Safety Data Sheet, put out by the US Army Soldier and Biological Chemical Command, USA Edgewood Chemical Biological Center, has estimated the LD_{50} of a skin exposure to sulfur mustard as 100 mg/kg. This roughly translates into as little as 7 ml of neat SM (i.e. 8.9 g) spread over the skin resulting in the death of a 80 kg adult (Department of the Army, MSDS, 1999). The cornea, of course, is more sensitive than the skin. Below we review three chief toxic effects of severe SM exposure to the cornea.

1. Corneal Opacity

An increase in hydration, separation in the collagen fibril lattice, disarrangement of the collagen fibrils, vascularization, and surface irregularities all reduce corneal transparency (Slatter, 1990; Oyster, 1999). Most, if not all, of these factors are generally present with a clinically significant challenge of SM, causing opacity. Scoring systems similar to that in Table 39.1 have been devised to quantitate the degree of opacity secondary to corneal injury (for example, see Conquet *et al.*, 1977). By using measurements such as those shown in Table 39.1 to grade SM injury in animal studies, the effect of countermeasures against the vesicant can be evaluated and compared over extended time periods.

2. Neovascularization

Neovascularization (NV) is the formation of new blood vessels from existing vessels. Figure 39.2 shows neovascularization that has developed in a rabbit cornea after a mustard exposure. Normally the cornea is avascular, and thus, to become vascularized, vessels in the periphery (the limbus and beyond) must respond to signals from the

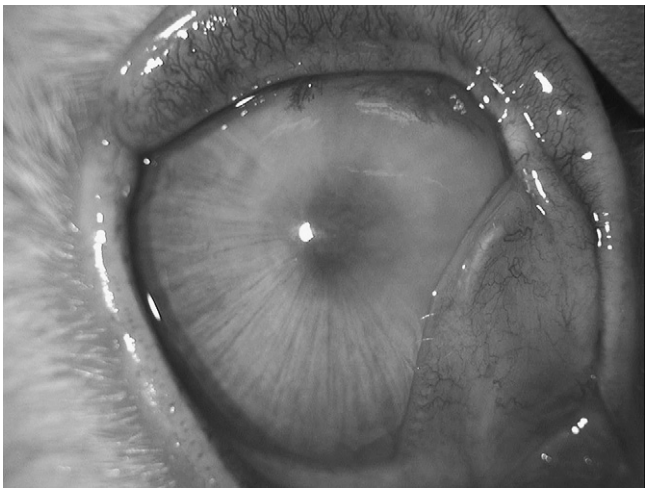

FIGURE 39.2. Typical presentation of neovascularization occurring after a neat liquid SM challenge. The NV was first noticed a couple weeks after challenge and continued to progress over time. Note the severe corneal scarring and adnexial involvement. (Courtesy of Dr John Schlager, unpublished data)

cornea. To avoid vessel ingrowth, the uninjured cornea maintains its avascularity with a carefully regulated balance of angiogenic factors and anti-angiogenic factors. The presence of angiogenic factors is essential, since these have multiple functions and are used for nonangiogenic purposes by corneal cells. Thus, their levels of activity are strictly regulated so that angiogenesis is not a favored process. However, many of the angiogenic factors (i.e. vascular endothelial growth factor, fibroblast growth factor, matrix metalloproteinases) become dysregulated or deregulated when an injured cornea mounts an inflammatory response (Chang *et al.*, 2001). NV is a very serious consequence of corneal injury and a particularly devastating sequela in moderate to severe SM exposure. The prevention, control, and elimination of NV has been, and still is, a very active area of ocular research (Dorrell *et al.*, 2007a, b; Kvanta, 2006; Lee *et al.*, 1998). As a major complication of sulfur mustard injury, NV may promote corneal scaring, edema, lipid deposition, and inflammation. Besides the obvious effect of loss of visual acuity, NV can also increase the risk of corneal graft failure (Chang *et al.*, 2001). A number of scoring systems, ranging from simple observations to elaborate image analysis techniques, have been used to quantitate the amount of corneal neovascularization present after injury (Conrad *et al.*, 1994; Proia *et al.*, 1988; Klotz *et al.*, 2000; Galardy *et al.*, 1994; Miyamoto *et al.*, 1999; Yamada *et al.*, 1999; Babin *et al.*, 2004).

3. Corneal Perforation

One of the worst consequences of SM exposure is corneal perforation. This effect can occur many weeks after exposure, and animal data are beginning to suggest that treatments for SM injury may, in themselves, contribute to toxicity. In an ongoing study, rabbits exposed to the same damaging dose of SM, then treated with prednisolone acetate over the course of 1 month with a decreasing steroid dose administration each week, had revealed no corneal perforations (John Schlager and Michael Babin, unpublished data). These data are discussed further in the treatment section below, and they strongly suggest that the toxicity and response sensitivity of any treatment must be considered in addition to the toxicity of the mustard when prescribing therapeutics for patients.

B. Human Exposure Levels Affecting the Eye

The eye, being the most sensitive organ to SM, shows irritation at concentrations ten times lower than that needed to irritate the airways (Smith and Dunn, 1991). An early experiment to show the level of toxicity of SM to the eyes was conducted on humans in 1919. Using a 10,000 liter exposure chamber, C.I. Reed of the Medical Division of the Chemical Warfare Service, United States Army, exposed individuals to exact concentrations of SM to determine what would be the smallest exposure amount that would cause ocular symptoms. To calculate what that dose might be, Reed used all the data available at the time. A lethal dose for animals was exposure to approximately 8 μg/l for 8 h. The skin of a human exposed to 2.5–5 μg/l for 0.5–1 h (i.e. 75–300 μg-min/l) showed cutaneous erythema several hours after exposure. The dose for the eyes had to be lower since it had been observed on the battlefield and in laboratory animal experiments that the eyes were more sensitive than the skin. From dog eye exposures, a 2 h challenge with 1 μg/l caused definite conjunctivitis many hours later, but a 1 h exposure did not (i.e. a 120 μg-min/l caused symptoms vs a 60 μg-min/l exposure that did not). Putting together these pieces of information, Reed reasoned that, from the available data, a 1 μg/l SM exposure for 1–2 h (60–120 μg-min/l) should not seriously affect a human, even though 8–10 h of this exposure would likely be incapacitating. Therefore, using himself as the first test subject, he exposed himself to a concentration he believed would cause only slight effects: he aspirated 12 mg SM into the 10,000 liter chamber and exposed himself for 45 min (1.2 μg/l for 45 min = 54 μg-min/l). Twelve hours after exposure Reed experienced severe blepharospasm and photophobia, as well as pronounced tearing. The severe conjuctival injection that developed persisted for 6 days, then lessened, but was still visible after a month. Overall, Reed was very surprised to find that the human eye was so much more sensitive than the dog eye. His eyes took 3 months to heal fully. In addition, Reed experienced unexpected cutaneous effects. These manifested 2 days after exposure and led to exfoliation of the skin from his trunk and face. His nasopharynx mucous membranes were also considerably exfoliated. Fortunately, he experienced no pulmonary symptoms. Reed reported that for 2 weeks he endured severe pain and tenderness around the eyes, nose, and mouth and his trunk was excruciatingly itchy.

Still on track to define the minimum concentration of SM that affects the eyes, Reed identified 13 human subjects whose skin sensitivity had already been tested and quantitated. These subjects were outfitted with a respirator canister, a nose clip, and a goggle so that the ungoggled eye would be exposed to 1.1 μg/l SM for times from 10 to 25 min (i.e. 11–27.5 μg-min/l), and the goggled eye would serve as a control. While doing these exposure experiments, he also aspirated air samples from the chamber to measure exactly the SM concentration in the air within, and found that it was about one-half (i.e. 0.48–0.58 μg/l) of what was injected into the chamber. After exposure, eight of the 13 subjects developed conjunctivitis with varying degrees of other subjective eye symptoms. Three of these eight suffered from diffuse skin erythema and itching for several days post-exposure. Reed concluded from this work that SM at 0.5 μg/l of air in less than 1 h (in actuality 10–25 min) would cause the first clinical symptoms of mild conjunctivitis. Unfortunately for Reed, he experienced recurrences of the itchy skin and tenderness around the eyes at various intervals over the course of the following year (Reed, 1920).

Battlefield air concentrations of mustard vapor in World War I were estimated to be in the range 19–33 mg/m^3 (i.e. 19–33 μg/l), and soldiers were exposed for various lengths of time (Ashkenazi *et al.*, 1991; Thorpe and Whiteley, 1939). At these concentrations, unshielded eyes exposed for only a few minutes would incur irreversible corneal damage. Exposure levels causing injury have been graded as outlined below (Ashkenazi *et al.*, 1991; Solberg *et al.*, 1997; Dahl *et al.*, 1985).

Mild (12–70 mg-min/m^3. This equals 12–70 μg-min/l – compare this with the 54 μg-min/l Reed used on himself, and the 11–27.5 μg-min/l used on his test subjects.)
Moderate (100–200 mg-min/m^3)
Severe (>200 mg-min/m^3)

The lethal concentration for humans, estimated from animal data, is considered to be 1,800–9,000 mg-min/m^3, i.e. 900 mg/m^3 for 2–10 min, as mentioned earlier (National Research Council Review, 1997). The LD_{50} is 100 mg/kg and the LCt_{50} is 1,500 mg-min/m^3 (LCt_{50} is the concentration multiplied by minutes of exposure that is lethal to 50% of those exposed) (Sidell *et al.*, 1997).

The toxicity of both neat and vapor exposures of SM to the eye is highly predictable. After a time period of no symptoms, lacrimation begins and quickly progresses to conjunctivitis, pain, blepharospasm, and photophobia. Corneal edema follows rapidly as a result of the loss of the epithelium, which allows water to enter the stroma from the precorneal tear film (Slatter, 1990). By 24 h after exposure, it is not unusual to see a 100 to 300% increase in corneal thickness evident by a substantial increase in opacification. Fluorescein staining at 24 h will reveal ulcers that may cover a majority of the corneal surface. By 48 h, evidence of healing is seen, and by 96 h, it is not unusual to have minimal staining. Fluorescein stainings of SM exposed rabbit corneas are shown in Figure 39.3.

C. Animal Toxicity Studies

The use of animals in experimental SM research dates back to the late 1800s. Theodor Leber, considered the founder of ophthalmic research (he also identified a congenital amaurosis that bears his name), exposed a single rabbit to a pure substance, SM, that his colleague, Victor Meyer, had prepared. The result was development of conjunctival lesions (Leber, 1891). In 1926, reports appeared describing animals exposed to liquid and vapor forms of SM, which were followed for up to 7 weeks to document the course of the resultant injury. Along with the gross visual documentation of the lesions, the histopathologies were also reported (Ireland, 1926).

Today, the overwhelming majority of animal ocular toxicity studies are performed in the rabbit model, and the study of SM is no exception. New Zealand white rabbits have been used extensively with both liquid SM and vapor exposures (Amir *et al.*, 2000, 2003; Bossone *et al.*, 2002; Vidan *et al.*, 2002; Babin *et al.*, 2004). Other animal models have been employed, including those using bovine and rat corneas. Many articles appear on these in the *Bulletin of Johns Hopkins Hospital*, Vol. 82, 1948. Individual articles from this volume are cited in the mechanism of action section.

The distribution kinetics of SM in the NZW rabbit eye have been determined using labeled SM, and show that the cornea has a greater affinity for the vesicant than other parts of the eye. Following the application of a 0.5 mg dose of liquid ^{14}C-SM, eyes were enucleated at 1, 6, and 24 h. This dose causes severe injury. After 1 h, only about 2% of the radioactive compound was recovered in ocular tissues. The cornea was found to contain the highest concentration of radioactivity, followed by the tarsal section of the eyelid, the aqueous humor, the nictitating membrane and the frontal sclera, including the conjunctiva (Amir *et al.*, 2003). This study correlated nicely with one published in 1946 that employed ^{35}S-labeled sulfur mustard in a 5 min vapor exposure. Enucleation after the challenge showed the highest concentration of label in the cornea, with lesser amounts in the iris, lens, and conjunctiva. If enucleation was delayed for 7 days after exposure, the SM was still found to be located primarily in the cornea (Axelrod and Hamilton, 1947).

Once the toxic effects of SM have resulted in epithelial loss, the progression of corneal edema is rapid and persistent for weeks. As noted in Table 39.2, 1 week after exposure to a 0.8 μl (1 mg) challenge, the average thickness of the rabbit corneas increased almost 2.5 times and remained at more than twice the thickness of the control contralateral naïve eye for more than 5 weeks. By 6 weeks, although not as thick, most of the exposed corneas were still above the baseline thickness values of a typical cornea (Babin *et al.*, 2004)

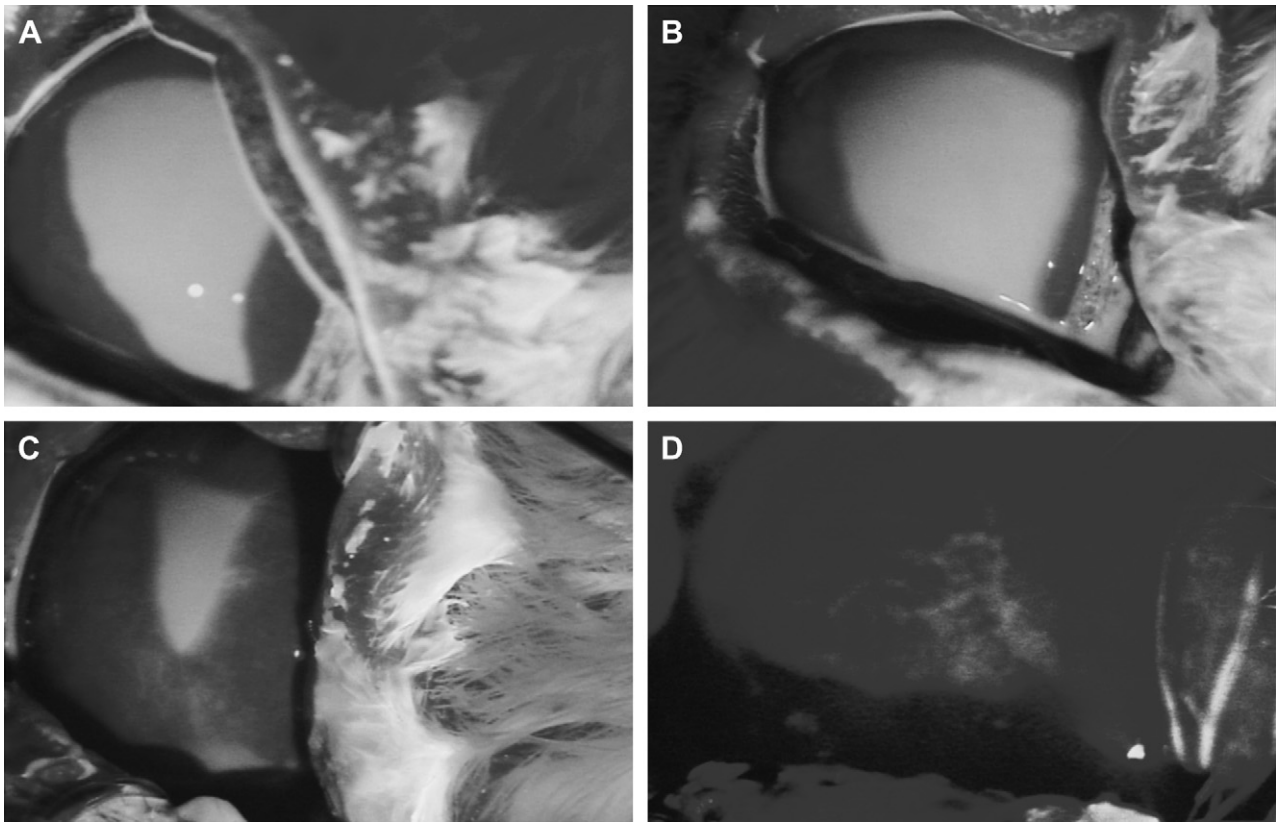

FIGURE 39.3. Fluorescein staining of rabbit cornea after sulfur mustard injury showing the extent of injury. Panel A, early damage, 24 h after challenge. The remaining panels show the progression of re-epithelialization over time: Panels B, C, and D: 48 h, 72 h, and 96 h, respectively, after SM exposure. The fluorescein penetrates into the underlying corneal stoma staining it a bright green color, which looks white or light gray in the figure.

suggesting the endothelial layer was still unable to pump water properly from the stroma. Data on neovascularization of the cornea, as well as on the long-term clinical response to SM, demonstrate that both animals and humans have a degree of individual variability in their response to SM (Kadar *et al.*, 2001; Amir *et al.*, 2004; Babin *et al.*, 2005). Reed may have suffered so badly after his self-exposure to SM because of individual variability. He may have been more sensitive to SM's effects than the majority of people.

Electron microscopy has been used to examine the toxic effects of SM exposure, viewing the cells at high magnifications. By 24 h after exposure to a 0.4 µl (0.5 mg) dose of neat SM, rabbit corneal epithelial cells showed progressive degenerative changes, including pyknosis, necrosis, and the sloughing of the epithelium. The cornea epithelium consists of 5–7 layers of cells. Sloughing occurred to cells in the superficial layers of the epithelium, as well as to the basal cells just above the basement membrane. The pathogenesis of the detachment was the result of degenerative acantholysis (i.e. epithelial dissociation) of the basal cells and the disruption of basal cell hemidesmosomes and anchoring filaments (discussed later in the mechanism of action section). Edema with the presence of inflammatory cells, mainly neutrophils and mast cells, were consistently found 24 h after exposure with this dose (Petrali *et al.*, 1997, 2000).

Toxicity studies using SM vapor have been performed on multiple animal species and documented as early as 1926 (Ireland, 1926). Unlike liquid SM exposures, vapor challenges allow the researcher greater control for restricting the mustard injury to the cornea with minimal or no damage to the eyelid and conjunctival tissues. By adjusting the size of the delivery apparatus, the entire structure of the eye can also be exposed. For example, glass goggles have been used to deliver SM vapor to the eyes of unanesthetized rabbits in a controlled environment (Amir *et al.*, 2000). Both 2 and 4 min exposures to 370 and 420 µg/l of SM have been used to produce the severe clinical lesions seen with 0.5–1 mg doses of liquid agent (Kadar *et al.*, 2001, 2005).

Because of the highly toxic and reactive nature of the vesicant, the dosing of SM in research animals can be problematic. The application technique, the dose of SM delivered, and the contact time will greatly influence the severity of the resulting lesion and affect toxicity calculations. Multiple methods for administering the minute quantities of liquid SM needed for challenge have been used. In 1926 a method for using a ''fine pipette'' to deliver ''uniform minute droplets'' of 0.5 mg SM to the cornea of

rabbits was described in the *Medical Aspects of Gas Warfare* (Ireland, 1926). In 1940 and 1942, Ida Mann and B.D. Pullinger published descriptions of a technique in which a 0.25 mm rounded-tip glass rod was successfully used to deliver multiple spots of SM to the central cornea and other regions of the rabbit eye (Mann and Pullinger, 1940, 1942b). More recently, a Gilson ''Pipetman'' P-2 pipetter (Rainin Instrument Company, Inc.) has been used to deliver a 1 mg dose to NZW rabbits (Babin *et al.*, 2004). Currently, a 10 µl Hamilton Microliter syringe attached to a Hamilton PB600 Repeating Dispenser is being tested for delivery of a 0.4 µl neat SM dose to rabbit corneas (Michael Babin, unpublished results). Any device selected to deliver liquid SM to the cornea should be adequately characterized. The precision and accuracy of the device should be determined prior to its use, and these must be within acceptable standards if one is to properly assess the toxicity of a delivered dose of SM.

IV. MECHANISM OF ACTION

As part of the world war II (WWII) war effort, investigators at the Wilmer Institute in Baltimore, including Jonas Friedenwald, Alan C. Woods, Alfred Maumenee, Roy Scholz, Heinz Herrmann, Fay Hickman, Albert Snell, Jr., Wilhelm Buschke, William F. Hughes, and others, attempted to go beyond clinical and histopathology studies of SM exposure toward understanding the mechanisms by which SM caused corneal damage. In putting together Volume 82 of the *Bulletin of the Johns Hopkins Hospital* (1948), Friedenwald concluded from their research that

> the clinically and histopathologically recognizable changes which follow chemical damage of the tissue are only remotely and indirectly connected with the initial chemical injury … the clinical and histologic reactions disclosed by routine study are, in the main, the consequences of cellular death. Once the cells are dead, the reactions have a monotonous uniformity.

Friedenwald ultimately expressed some disappointment that, after years of effort put in by the team, so much was still unknown by the late 1940s. However, several facts had been elaborated and published in the volume: threshold doses of mustard cause a transitory inhibition of mitotic activity of the corneal epithelium, and this appeared to be the most sensitive index of threshold effects. The healing of small wounds by migratory action of the cells was not disturbed during the period of mitotic inhibition (Friedenwald *et al.*, 1948a). The electrical resistance of the cornea is not affected for several hours after exposure (Friedenwald *et al.*, 1948b). Moderate doses caused epithelial nuclear fragmentation and nuclear fragility (Maumenee and Scholz, 1948; Friedenwald and Buschke, 1948). Nuclear fragmentation, however, was not the mode of death for the stromal cells. Instead, death occurred as a consequence of the keratocytes swelling and bursting. Following massive exposures, all types of corneal cells underwent pycnosis (Friedenwald, 1948). The loosening of the corneal epithelium from the stroma was also investigated (Maumenee and Scholz, 1948; Herrmann and Hickman, 1948), and indicated that the cohesion between the two layers appeared to result from the surface having protein-lipoid characteristics, disruptable by proteases such as trypsin, or the aliphatic butyl and amyl alcohols. It was concluded that the loosening between the cell layers was similar to vesication of the skin. It was also deduced that loosening involved an oxidative step because the epithelium did not separate from the stroma when cultured corneas were incubated under anaerobic conditions (Herrmann and Hickman, 1948). Immune reactions against corneal proteins were postulated to be responsible for the long-term damage observed (Maumenee and Scholz, 1948). By the end of WWII, other groups had also confirmed that SM targeted the basal epithelial cell nuclei (Gilman and Phillips, 1946; Biesele *et al.*, 1950; Mehtab, 1953).

SM gas is lipophilic, and has affinity for the lipid layer of the tear film. Because it is also electrophilic it is likely that it easily partitions into the aqueous and mucin-rich layers of the tear film to access the corneal epithelium. Thus, it is expected that the moist nature of the ocular surface is the reason why the eye is the most sensitive organ to the vesicant (Hughes, 1942; Dahl *et al.*, 1985; Solberg *et al.*, 1997; Safarinejad *et al.*, 2001). The moistness of the cornea is both good and bad: on the one hand it helps wash away the agent, but on the other hand, the layers of the tear film probably facilitate concentration of the agent at the corneal surface. Once there, sulfur mustard penetrates the cornea readily. The half-life of mustard in the cornea was found to be 3 min at 38°C and 13 min at 24°C (Kinsey and Grant, 1946).

Unfortunately, the exact mechanisms of action of SM still remain elusive. In the last 30 years, most of the data concerning the mechanism of action of sulfur mustard are derived from nonocular studies, but these are still applicable to the eye. Sulfur mustard combines with proteins, RNA, DNA, and components of the cell membrane. The modifications of DNA result in strand breaks and interstrand crosslinks (Roberts *et al.*, 1968). One possible mechanism for how the vesicant alters proliferation, transcription, and translation can be deduced from sodium chloride extracts of SM-exposed lymphocytes, where it has been found that some of the histones that package the DNA were soluble. This was elucidated by finding that the extracts, 4–24 h after SM exposure, contained three proteins that were significantly increased in amounts compared to control extracts. One protein had sustained alterations. Sulfhydryl reducing agents did not attenuate the increased levels of these proteins, nor did preincubation of the cells with cycloheximide (to inhibit protein synthesis). Microsequencing identified the altered protein as a cleavage product of histone H2B. The others were identified as intact histone H2B and histone H3. Thus, SM may disrupt the nucleosome structure by making the core

histones abnormally disengage from, or be proteolytically cleaved from, the nucleosomes (Millard *et al.*, 1994).

The highly reactive alkylating properties of SM contribute significantly to toxicity, and alkylation suggests mechanisms of action for SM that align with the ultimate pathology of SM exposure. One hypothesis for how SM acts involves poly (ADP-ribose) polymerase (PADPRP). The proposed mechanism of action starts with irreversible alkylation of purines (adenine and guanine), which causes depurination of the DNA, leading to cleavage by apurinic endonucleases. These DNA breaks activate the enzyme PADPRP, which requires nicotinamide adenine dinucleotide (NAD^+) as a substrate. Thus, the cellular levels of NAD^+ are lowered. The consequence of reducing NAD^+ levels is inhibition of glycolysis, which causes glucose-6-phosphate to accumulate. In response, the $NADP^+$-dependent hexose monophosphate shunt pathway is stimulated. This pathway induces the secretion of proteases that lead to cell pathology (Dixon and Needham, 1946; Papirmeister *et al.*, 1984, 1985; Gross *et al.*, 1985; Meier *et al.*, 1987; Mol *et al.*, 1989; Smith *et al.*, 1990; Petrali *et al.*, 1990; Yourick *et al.*, 1991; Rosenthal *et al.*, 2000). Some data have indicated that the decrease in NAD^+ leads to cell death (Meier *et al.*, 1987), although this idea has been disputed (Mol *et al.*, 1991).

Friedenwald found extracellular glutathione (GSH), a free radical scavenger, is depleted in response to SM exposure (Friedenwald *et al.*, 1948b). More recent data have generated another major hypothesis, derived from the post-1948 observation that mustard also reacts with intracellular GSH, thereby depleting it. A consequence of this rapid inactivation of sulfhydryl groups is loss of protection against oxygen-derived free radicals, specifically those causing lipid peroxidation. Through some intermediate enzymatic effects, intracellular calcium levels increase, causing cell death through the activation of proteases and phospholipases that break down membranes and the cytoskeleton, as well as activation of endonucleases that can degrade DNA (Orrenius and Nicotera, 1987; Miccadei *et al.*, 1988).

The testing of a similar hypothesis further delineates how the reduction of glutathione levels may lead to calcium mediated toxicity. With a Ca^{2+}-specific fluorescent probe, intracellular levels of calcium were found to increase, and were significantly elevated at 6 h after SM exposure. High levels of intracellular calcium enhance phospholipase A2 activity. The activity of this enzyme in response to SM was elucidated by following the increasing levels of arachidonic acid (AA). The use of AA levels as a measure of phospholipase A2 activity was justified by the fact that inhibitors of phospholipase A2 prevented release of AA from the cells. Thus, it was found that after SM exposure AA levels being released from the cell membrane were increased, implicating activation of phospholipase A2 (Orrenius and Nicotera, 1987; Elsayed *et al.*, 1989; Ray *et al.*, 1995). Released AA would decrease membrane fluidity, cause membrane damage, and result in cell death (Ray *et al.*, 1995). Glutathione consumption after SM exposure may also induce free radical-mediated oxidative stress (Elsayed *et al.*, 1992). Free radical formation resulting from inhibition of respiratory enzymes has also been hypothesized as a mechanism of SM-induced injury (Aasted *et al.*, 1987).

While alkylation of DNA is likely to play a key role in SM toxicity, one cannot underestimate the potential problems resulting from concomitant alkylation of the amino and carboxyl groups of proteins. SM affects the basal epithelial cell-specific intermediate filaments, an important component of the basal cell's cytoskeletal structure. Epidermal keratinocytes in culture treated for 5 min with 400 μM SM showed a 30% decrease in their K14 intermediate filaments after 1 h, and a 79% decrease in K14 after 2 h. K5 was decreased about 29% after 1 h, but not further unless the amount of SM was increased. It was suggested that the decrease in levels of K14 may disrupt the stability or assembly of the K14 intermediate filament polymers, thus disrupting the integrity of the cytoskeletal connection to the hemidesmosomes, which in turn tack the epithelial cells to their basement membrane (Werrlein and Madren-Whalley, 2000).

The proteins most obviously adversely affected are, indeed, those involved in the strong adhesion at the border between the epithelial and stromal layers, i.e. the basement membrane zone (Smith *et al.*, 1998), and it is unknown why this is so. The loss of the epithelial–stromal adhesion is dramatic, initiating blistering of the skin. The cornea does not blister. Although the microbullae that form between the corneal epithelium and stroma in response to SM exposure seem less dramatic, they clearly impair corneal integrity. Figure 39.4 shows some of the

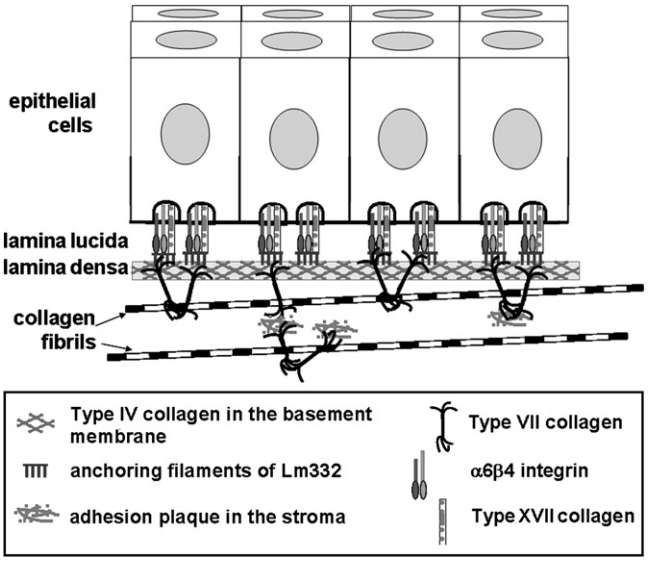

FIGURE 39.4. The epithelial–stromal border and molecular components of the anchoring complex. For simplicity, the plectin and BP230 components of the hemisdesmosome have been omitted from the diagram. Transmembranous collagen XVII and α6β4 integrin are localized to the hemidesmosome (the half circle at the base of the epithelial cells), with their extracellular domains reaching into the lamina lucida. These bind with laminin 332, which in turn binds with type VII collagen in the stroma.

components involved in the ''anchoring complex'', the structure which ''rivets'' the basal epithelial layer to the uppermost region of the stroma, i.e. Bowman's layer.

This structure is also sometimes referred to as the adhesion complex, or the attachment complex. It is composed of three multicomponent units. One unit is the electron-dense hemidesmosome. The hemidesmosome is indirectly connected to the nuclear membrane via the previously mentioned K5/K14 intermediate filaments. The hemidesmosome is comprised of plectin, BP230, and two transmembranous molecules: type XVII collagen and α6β4 integrin (Gipson *et al.*, 1989; Gerecke *et al.*, 1994). The transmembranous molecules attach to the basement membrane, and thus the basement membrane is indirectly connected to the nucleus through the hemidesmosomes and the K5/K14 intermediate filament cytoskeleton. The hemidesmosomal integrin subunits α6 and β4 were examined after SM exposure of skin, and showed a 25% decrease in the α6 integrin subunit and a 18.9% decrease in the β4 subunit (Zhang and Montiero-Riviere, 1997). The identity between hemidesmosomal components in skin and cornea suggests that, in cornea too, integrin uncoupling is another mechanism of action by which SM damages the epithelial–stromal junction.

The other two units of the anchoring complex are on the extracellular side of the basal epithelial cell surface. These are the anchoring filaments and the anchoring fibrils. The anchoring filaments are composed of laminin 332 (formerly Lm 5), and they bind to the transmembranous hemidesmosomal components, collagen XVII, and α6β4 integrin on one end, and the anchoring fibrils on the other. The anchoring fibrils are composed of type VII collagen, and are situated in the region at the base of the basement membrane, extending into the stroma. The adhesion complex is analogous to ''spot welds'' in the epithelial basement membrane, which, in regions outside of the anchoring complex, is composed of type IV collagen, laminins (other than laminin 332), and heparin sulfate proteoglycans. The interfacial matrix attachment between the basement membrane and the stroma is weak without the anchoring complexes. Thus, the complexes are necessary for corneal integrity, and a reduction in any of the components involved cannot help but compromise the integrity of adhesion between the epithelial and stromal cell layers. The SM-induced split between layers occurs above the level of type IV collagen in the basement membrane (Mol *et al.*, 1991; Petrali *et al.*, 1992). Shown in Figure 39.5 are electron micrographs of corneas, untreated or treated with half mustard (i.e. CEES).

Comparing the panels in Figure 39.5, it can be seen that the last connections to break between the epithelium and the stroma are those of the adhesion complex. The half mustard, being not as strong as SM, causes separations between the epithelial and stroma layers in between the anchoring complexes, but is not strong enough in the conditions used to disrupt the anchoring complexes themselves.

Experimental evidence suggests that, after SM exposure, alkylation and crosslinking of matrix molecules at the epidermal–dermal junction could adversely affect the ability of the epithelium to tack down once again to the

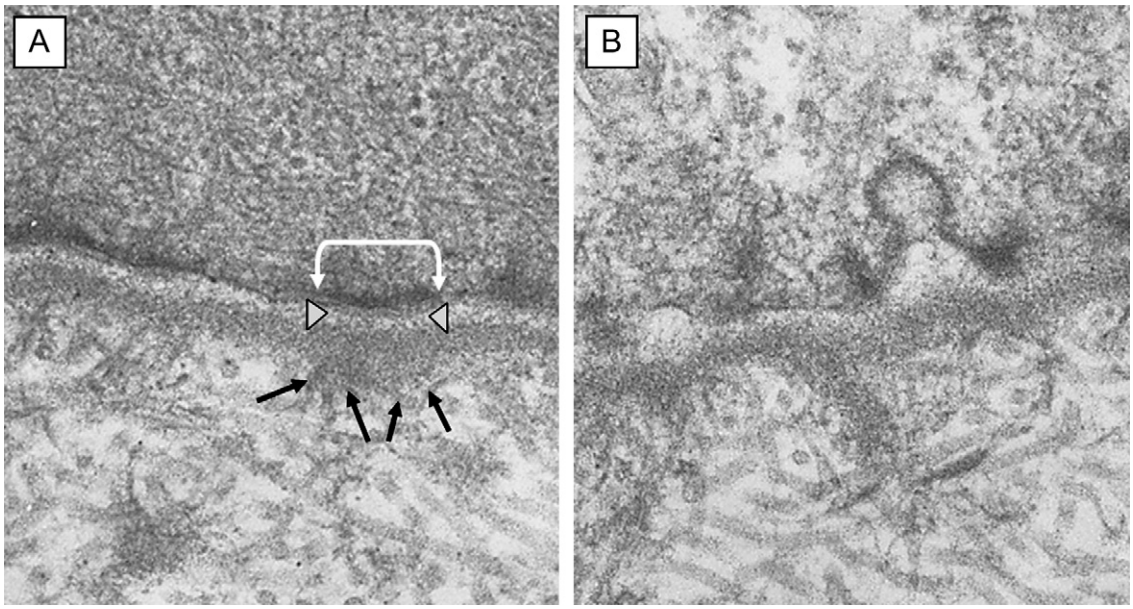

FIGURE 39.5. Electron micrographs of the rabbit corneal epithelial–stromal border. Panel A, the three structural components of the anchoring complex are shown. The hemidesmosomes are the flattened electron-dense plaques at the epithelial surface. One is indicated by an inverted white ''U'' shape with arrow ends. The anchoring filaments appear as threads in the laminina lucida. The anchoring filaments under the indicated hemidesmosome are flanked by arrowheads. A selection of the anchoring fibrils in the stroma is indicated by black arrows. Panel B, a micrograph of the epithelial–stromal junction 24 h after a 2 h exposure to 200 nmole CEES. Local separations between the epithelial and stromal layers are seen between the anchoring complexes.

dermal layer. Due to the conservation between components of the epidermal–dermal junction and the corneal epithelial–stromal junction, results from the skin apply to the cornea. *In vitro*, ^{14}C-labeled SM has been shown to alkylate laminin 111 (formerly known as Ae.B1e.B2e. laminin or Lm 1), laminin 311 (formerly known as K.B1e.B2e. laminin or Lm 6), fibronectin, and heparin sulfate proteoglycan. Not only were the molecules alkylated, they were also crosslinked via an unidentified mechanism by SM. As a consequence, fewer human skin keratinocytes were found to adhere to tissue culture dishes coated with SM treated-laminin or SM-treated fibronectin. After a 20 h incubation, ~60% fewer cells bound to SM-treated laminin than untreated laminin, and ~35% fewer cells adhered to SM-treated fibronectin compared to untreated fibronectin (Zhang *et al.*, 1995). Further studies in the mouse ear model found that, after SM exposure, most of the collagen XVII, fibronectin, laminin, and collagen IV were localized to the dermal side of the blister plane (Monteiro-Riviere *et al.*, 1999). Crosslinking of these components at this site could interfere with reattachment of the epithelium. Again, because of the close identity of components in the corneal epithelial–stromal junction with that of the epidermal–dermal junction, it is likely that these components will also be found on the stromal side of SM-induced microbullae in the cornea.

In addition to damage to the anchoring complex, one must consider that SM may adversely impact the basement membrane proper, enhancing the separation between layers. As shown in Figure 39.5, by the focal detachment of the epithelium from the stroma in regions between anchoring complexes, clearly, the basement membrane area is compromised by mustard exposure (Smith *et al.*, 1998). The gelatinases, matrix metalloproteinases-2 and -9 (abbreviated MMP-2 and MMP-9), which degrade basement membrane components and play important roles in inflammatory responses, were shown to be elevated eight-fold 24 h after SM exposure of the anterior mouse ear, as compared to untreated control ears (Shakarjian *et al.*, 2006). Activity was equally high after 7 days. Since activity assays cannot differentiate between MMP-2 and MMP-9, mRNA and protein levels were assessed, and demonstrated that MMP-9, but not MMP-2 expression, was induced by sulfur mustard exposure – Westerns indicated a nine-fold increase in MMP-9 by 7 days after exposure. Further support for this assertion is the fact that MMP-9 deficient mice are resistant to an experimentally induced form of the blistering disease bullous pemphigoid (Liu *et al.*, 1998). The two pieces of evidence together suggest the following: MMP-9 activity is turned on to remodel a wound, leaving a provisional extracellular matrix that favors cell migration and facilitates healing. This provisional matrix will ultimately be replaced by the normal matrix typical of mature, healthy tissue. SM exposure interferes with MMP-9 being appropriately turned off. The enzyme's activation may prevent reestablishment of the anchoring complexes. Thus the extracellular matrix of the basement membrane does not proceed past the provisional matrix stage (Gordon, Gerecke, Casillas and Babin, unpublished). Finally, inflammatory cell infiltration, which may occur about a day after exposure, may also play a role in delaying SM wound healing (Maumenee and Schloz, 1948). The sheer number of potential target areas in a multilayered, multicell organ that may be affected by sulfur mustard make the task of determining SM's exact mechanism of action quite difficult.

V. RISK ASSESSMENT

Assessing the risk of consequences after a corneal exposure to SM is not easy, so here we will discuss what little information is available. The cornea is composed of a lipophilic epithelium, hydrophilic stroma, and a lipophilic endothelium. Because sulfur mustard penetrates the cornea so rapidly (within about 3–5 min), if detoxification measures are available, they must be employed immediately if there is even a remote hope of minimizing ocular damage. Of course, such measures are only useful if one knows one has been exposed to sulfur mustard. Most people who have been exposed are unaware of their situation for quite some time, until symptoms manifest, but by this time, the damage is already on an irreversible course. They will incur damage, and their only recourse will be treating symptoms. Several factors determine the type and severity of injury: the SM quantity, the time the agent is in contact with the tissue, the form (solid, liquid, vapor) of SM employed, and which tissue is affected (i.e. cornea, lung, or skin).

Although eye exposures may be avoided by use of a gas mask, the mask itself presents a risk to soldiers in danger of being exposed to SM. First, it is cumbersome to carry and uncomfortable to wear, especially in desert climates. Second, as in WWI, today's wearer of the mask still has difficulty breathing through it. Third, the ability to make decisions about topographical movements may be impaired during a chemical attack since the mask impedes vision. Most importantly, the problems with the mask make the soldier think it is best not to wear it unless he is exposed, but the agent cannot usually be sensed immediately upon exposure, potentially delaying the use of the mask until injury is unavoidable.

The major long-term health risk to the eye after SM exposure is the recurrent keratitis mentioned earlier, which can take decades to manifest. Other long-term risks, such as cancer, do not involve the eye. The National Research Council Subcommittee on Chronic Reference Doses for Selected Chemical-Warfare Agents, with Oak Ridge National Laboratory and other experts, has assessed for the Army the overall cancer risk from sulfur mustard exposure. By analyzing the physical and chemical properties, the environmental fate, animal and human toxicity data, and carcinogenicity, 9.5 mg/kg per day had been proposed as the carcinogenic potency of sulfur mustard. A lower value of 1.6 mg/kg per day has been more recently considered (Crossgrove, 1999).

While the risk assessment for an accidental SM exposure is relatively low, such exposures have occurred all too frequently. For example, although chemical agents were not used during WWII, on July 1, 1942, a site-decontamination demonstration involving the use of mustard gas was staged for the members of the Civil Defense Services. This resulted in premature functioning of the demonstration weapon and accidental skin exposure to at least a dozen spectators (Grant and Ritchie, 1942). In December 1943 the USS *John Harvey* was secretly carrying a large number of mustard bombs. The ship was attacked while docked at Bari, Italy, resulting in 617 US mustard casualties (83 fatal) from shells exploded in the water and from the smoke. An undetermined number of Italian civilians were also casualties of the smoke (Alexander, 1947; Infield, 1971, 1988). Additionally, since mustard was introduced, there have been a number of nonbattlefield exposures. After WWII, large stockpiles of mustard were removed from Germany and dumped into the Baltic Sea by allied forces. In 1984, at least 23 fisherman showed varying severities of SM exposure after dredging up these same munitions (Wulf *et al.*, 1985). A half-century after WWII, a souvenir collector was injured after unearthing a buried artillery shell (Ruhl *et al.*, 1994). In China's Jilin Province, two children found a shell in July 2004 that had been left behind by the Japanese Army at the close of WWII. The shell leaked mustard, injuring their legs and hands (*Japanese Times*, 2004).

The USA has disposed of stockpiles of sulfur mustard at sea. Fisherman or boaters who come across discarded canisters, leaky from sitting in salt water, unknowingly have become exposed. In treating these exposures, if the vesicant is pervasive, it is important to decontaminate in a pre-hospital setting, and have health care providers wear appropriate personal care protection. Latex gloves are not sufficient – butyl rubber is needed. Health care workers do not need to fear the patient's blisters, since these do not contain the vesicating agent.

How dangerous are the disposed SM stockpiles? In earlier years, good records were not kept about the locations of sulfur mustard disposal sites, and thus there are ongoing efforts to find these. In 2001, the Army identified three chemical warfare material disposal sites near Hawaii, which contained sulfur mustard discarded between 1925 and 1948. The danger posed appears to be within acceptable risk levels for the following reasons: sulfur mustard hydrolyzes to thiodiglycol and HCl in seawater at approximately the same rate as it dissolves. A toxic hydrolysis intermediate, β-chloroethyl hydroxyethyl sulfide, can be produced, which also has the same hydrolysis rate as sulfur mustard. Thus, at any given time, only a few ppm of toxic mustards would likely be present in seawater surrounding submerged leaking containers of the material. However, a hard polymer layer can develop at the interface of the mustard and seawater, which protects and shields the mustard from hydrolysis. This would allow bulk mustard to potentially remain stable underwater for years. Overall, once the mustard dissolves, the rapid hydrolysis to generate innocuous products would yield very small concentrations of hazardous materials. Any SM leaking from a canister would undergo rapid hydrolysis and be diluted by diffusion facilitated by currents. The canisters are outside of regular shipping lanes, away from fishing grounds, submarine operating areas, and ocean cables (Department of the Army Information Paper, 2006). Thus, it seems likely that, for these underwater disposals, a small leak would cause little danger to humans.

VI. TREATMENTS

Our goal in this section is to report treatments that have evolved over the last 100 years, starting with what was found useful in WWI, followed by what was recommended during WWII, assuming sulfur mustard might be used, and moving on to what has been recommended in the last 25 years. Finally, we will end with what is being learned about potential countermeasures from animal studies. Again, we mention that the effect of mustard is nearly instantaneous (Sorsby, 1939), and nothing can be done to prevent the damage from exposure. For 70 years we have known that even immediate irrigation makes no difference to the subsequent injury (Juler, 1939; Poole, 1939a, b, 1940; Barrett, 1940). Yet this fact goes against what feels to be common sense, and because something must be done to help, irrigation is always recommended as a first treatment. If nothing else, this makes the patient feel that he is receiving medical attention to cope with a frightening health crisis.

A. WWI

Soldiers in WWI endured many degrees of severity of SM exposure. In their 1919 text *The Medical Aspects of Mustard Gas Poisoning*, Warthin and Weller summarized their treatment recommendations based on experience gained in the war:

> The use of any method of treatment which brings pressure upon the lids and eyeball such as tight bandaging or heavy compresses is absolutely contraindicated. For the mild cases, frequent irrigation with saturated boracic acid, the use of lightweight boracic acid compresses, hot vapor baths, and protection of the eyes by darkening of the room, or by a light gauze bandage or by the use of smoked goggles are recommended. Special care must be taken to prevent the gluing together of the eyelids by accumulation of the exudates. Should this occur the exudates should be softened and washed away with boracic acid with care to avoid forcible separation of the lids. The use of argyrols, silvol, etc., is in our opinion undesirable. The use of cocaine is considered unwise. For the severe forms the use of a 1 per cent Dakin's solution is found to be too irritating. We therefore recommend the employment of the chlorcosane solution of dichloramine-T in a strength of 0.5 to 1 per cent, or even

> stronger. We further advise that in all cases of exposure to mustard gas this solution be used as an immediate irrigant for its prophylactic effects, followed in the milder cases of injury by boracic acid irrigation and in the severe cases by repeated irrigation with the dichloramine-T solution for the prevention of secondary infection. For the treatment of the refractive errors and more permanent disturbances of vision the patient must be referred to a competent ophthalmologist (Warthin and Weller, 1919).

Sir William Lister, an experienced ophthalmologist in WWI with extensive experience in the treatment of the early stages of gassed eyes, stressed the psychological value of separating the eyelids, and of thus convincing the patient that his sight had not been irreparably damaged (Barrett, 1940). Following irrigation, a drop of oil was recommended. Liquid albolene was the least irritating. In those cases where secondary infection developed, a weak antiseptic solution was believed to be therapeutic, most often using argyrols or protargol. Atropine was recommended to be continued as long as any corneal involvement continued, and a shade or dark glasses for symptomatic relief was beneficial (Derby, 1919).

B. WWII

Mustard was not used in WWII, but the fear of its use was pervasive, and medical teams procured information about how to treat potential victims of exposure. One such piece of information was provided by the Ministry of Health in 1941 in a memorandum for medical practitioners, published in the *British Medical Journal*. It reminded medical personnel that ''Treatment of the eyes, if affected, should always be given preference over treatment of the skin'' (Ministry of Health memorandum, 1941). Unfortunately, despite the intervening years between the wars, only small advances had been made in treating SM ocular injuries. Irrigation, of course, was the first order of treatment, although damage would already be in process. Experiments using trephinated buttons of bovine corneas, performed in 1942, but published in 1946, verified this once again. At best, a therapeutic agent had 3–5 min to neutralize SM after an eye exposure (Kinsey and Grant, 1946), and people could not recognize they were gassed until about an hour or more after they were exposed.

As in WWI, WWII recommendations aimed at the relief of symptoms, the control of the lesion, and the prevention of secondary infections and complications. The patient was to be reassured he would not be blinded by the medical practitioner opening his eyelids. Bandages were not to be used. Symptomatic treatment of conjunctivitis was to be treated with irrigation, often with sodium bicarbonate solution (Sorsby, 1939; Cowell, 1939; Bickerton, 1940). Caster oil drops or liquid paraffin drops were thought to be helpful. First-aid treatment with cod-liver oil was felt to do no harm and had been found to give immediate pain relief. It also smoothed corneal roughness and eased lacrimation in patients with delayed keratitis or ulceration (Stevenson, 1939, 1940). Atropine drops were also used when the cornea was affected (Sorsby, 1939). These recommendations were not vastly different from the treatment used in WWI.

Small advances in treatment options were made. One improvement was an improvised eye irrigator, suggested by a military ophthalmologist (Stallard, 1940). As physicians planned for possible emergency care of old or middle-aged persons in air-raids, Dr Agnes Estcourt-Oswald recommended treatment with homatropine rather than atropine to minimize the danger of precipitating or increasing glaucoma (Estcourt-Oswald, 1939). Sulfanilamide preparations (albucid) were used for secondary infection of the conjunctiva, but were not really proven to be efficacious (Juler and Whiting, 1941a, b).

Among the many patients cared for by Dr Ida Mann, treatment with contact lenses resulted in improvement in visual acuity in at least half of them because the smooth glass corrected for the irregular and uneven corneal surface that was a consequence of mustard injury (Mann, 1944). This was a most significant contribution, since severe scarring from mustard could result in total blindness.

C. Post-WWII

The life story of Canadian Lieutenant Eddie Baker demonstrates a heartwarming example of progress. Baker was blinded in WWI by sniper fire. After the war, he devoted himself to improving the lives of blinded veterans. He raised the funds used to start the Canadian National Institute for the Blind (CNIB) and, later, was involved in the development of eye banks. The downstream effect of his efforts was the first cornea transplant in Canada, performed in 1956 on a WWI veteran, 40 years after he was blinded by gas (Wilton, 1996). While this is wonderful medical progress, it cannot undo the fact that there is still no antidote against SM.

Today's political climate and the estimation that at least a dozen countries have mustard in their current arsenals (Sidell *et al.*, 1997) means that the search for countermeasures against SM must not stop. Egypt had been suspected of using mustard against Yemen in the mid-1960s (Balali-Mood *et al.*, 1993). Thousands of Iranian soldiers were exposed to mustard during the Iran–Iraq conflict between 1983 and 1988 (Balali-Mood and Hefazi, 2006). In 1988, Saddam Hussein used mustard and nerve agents on his own people in the village of Halabja, causing the death of 5,000 people within less than 10 min, and maiming many thousands more. After terrorist attacks became a worldwide concern, an ''Expert Group on the Management of Chemical Casualties Caused by Terrorist Activity'' was formed by the Department of Health of Great Britain, and was chaired by Professor P.G. Blain, CBE. In October 2003, they published recommendations for treatment of SM exposure. A summary of these is: irrigate immediately to decontaminate and minimize corneal damage with large

quantities of clean water or isotonic fluids such as saline; anesthetic drops can be used during irrigation; reassure patients with eye exposure; give systemic analgesics and dark glasses; petroleum jelly can be used to prevent lid adhesion; bandages should be avoided (Department of Health, UK report, 2003). These guidelines are again essentially the same as treatments recommended in WWI. However, also added is that steroids may be used if tapered off with time, since their use may impair epithelial regeneration and collagen repair. Vitamin C may help since it is an antioxidant and may prevent damage by free radicals released at the time of injury. Acetylcysteine may be helpful since it contributes to the crosslinking of new collagen and inhibition of collagenases released at the time of tissue damage. Antibiotics may be used to prevent secondary infection if there is loss of the corneal epithelium. It seems likely that several of these recommendations are based on the panel members having familiarized themselves with the results of animal studies, such as those that implicate *N*-acetyl-cysteine in decreasing the inflammatory response and improving outcome (Anderson *et al.*, 2000).

The UK Department of Heath report also includes information on how to assess the extent of SM injury, along with providing recommendations for which types of injury require hospital admission. For example, early assessment of injuries should include visual acuity, reactivity of the pupil, extent of burns or necrosis to the eyelids, epithelial loss in the conjunctiva and limbus with necrosis and ischemia, corneal epithelial loss, edema, and stromal opacity, fibrin deposition, uveitis, iris atonicity, hemorrhage, lens opacity, lens debris and leakage. The extent of the corneal chemical injury should be graded to decide the next course of action. A grade 1 injury, which would have a good prognosis, could show epithelial damage with ischemia. A grade 2 injury, also with a good prognosis, would include corneal haze, but with iris details visible to the examiner. Only one-third or less of the limbus should be ischemic for assigning grade 2. A grade 3 injury would have a guarded prognosis, and would involve total loss of the epithelium, with stromal haze and obscured iris detail. One-third to one-half of the limbus may be ischemic. Grade 4 would represent a poor prognosis, and would be characterized by corneal opacity, with a pupil and iris that is not visible. One half of the limbus would potentially be ischemic. Intraocular damage, especially if accompanied by a raised intraocular pressure, indicates a poor prognosis. Admission to hospital is advised if there are grade 3 or 4 changes. In the long term, severe cases may require amniotic membrane transplantation and limbal stem cell allografts (Department of Health, UK Report, 2003).

D. Animal Studies

There is much research being done to identify countermeasures against mustards. The Department of Defense has traditionally funded this research in the USA, but currently NIH is contributing through a program called CounterACT. It will probably be easiest to identify treatment drugs for skin, and hardest to identify ones for lung. Therapeutics effective for SM exposures of skin may be useful for the eye, but will likely need modifications, since they may be irritating to the cornea. Vanilloids, for example, hold promise for skin (Casbohm *et al.*, 2004) but would need chemical alterations to avoid corneal irritancy while maintaining efficacy. In the next few paragraphs we will review some of the most promising therapies for mustard exposure.

Mustard exposure causes depletion of ATP in cells. Better outcomes after exposure have been demonstrated when mitochondrial substrates were provided to offset this depletion. CEES-exposed rabbit corneas have been treated after exposure with a mix of taurine, pyruvate, α-keto glutarate, and pantothenic acid. Analysis showed reduced necrosis of the cornea. Electron microscopic and other analyses showed protection against membrane damage and oxidative damage (Varma *et al.*, 1998a, b).

Anti-inflammatory drugs show promise as SM countermeasures. Dexamycine® (0.1% dexamethasone sodium phosphate and 0.5% neomycin sulfate) ophthalmic solution was used to treat NZW female rabbits after a 2 min SM vapor challenge at 342 µg/l. Two treatment regimens, one started 1 h after challenge, the other at 6 h after, were administered 3 times/day for 2 weeks. The animals were observed over the course of 3 months. The data demonstrated that neovascularization was delayed or prevented in the groups receiving Dexamycine, independent of the start time of the treatment, as compared to the group exposed to SM without a countermeasure (Kadar *et al.*, 1996).

A follow-up study used Dexamycine and Voltaren® Ophtha (diclofenac), a nonsteroidal anti-inflammatory drug, after a 2 min 390–420 µg/l SM vapor challenge to rabbit eyes. The Dexamycine and Voltaren were administered separately, or in combination, 4 times/day for 2 weeks, starting 1 h after exposure. Rabbits were clinically observed for up to 3 months. Rabbits receiving the anti-inflammatory drugs had a much improved clinical assessment score, a reduction in protein and prostaglandin E in the anterior chamber, and a reduction in corneal edema and infiltrate during the acute phase after challenge. Histological examination at 48 h revealed minimal inflammatory infiltrate present in the corneal tissue of the drug-treated groups. Dexamycine was found to be more effective than Voltaren and the combination was more effective than either drug given alone. It was also demonstrated that Dexamycine administered at a high dose for 1 day, or at a low dose for 5 days was effective in improving the outcome, compared to SM-exposed animals receiving no Dexamycine. Treatments of drug started 15 min after challenge produced similar results to treatments started 1 h after challenge. Unfortunately, none of the Dexamycine treatments reduced the occurrence of corneal erosions. These were the same as in SM exposed animals without subsequent drug treatment (Amir *et al.*, 2002).

Anti-inflammatory drugs were also used on the eyes of rabbits challenged with a 1.02 mg droplet of neat sulfur mustard. Ten minutes after exposure, the group whose eyes were to receive subsequent treatment were dosed with a 1% ophthalmic suspension of prednisolone acetate. After 2 h, the prednisolone suspension was discontinued, and a sub-Tenon's injection containing 20 mg triamcinolone and 50 mg cefazolin was immediately administered. Corneal thickness, stromal injury, neovascularization, eyelid notching and chemosis were recorded weekly for 6 consecutive weeks, and then again on week 16 after the challenge. The majority of the drug treated group had a significant reduction in corneal thickness at 2, 3, and 4 weeks, compared to the rabbits exposed to SM without post-exposure treatment. For the other parameters, significant evidence of a protective effect due to treatment was seen at 4, 5, and 6 weeks after exposure. In addition, corneal stromal injury was reduced at 2 and 3 weeks, and eyelid injury (notching) at 2 weeks. By week 3, all control SM exposed animals developed neovascularization, in contrast to one of seven animals that received post-exposure anti-inflammatory drugs. By week 6, all SM exposed animals still exhibited neovascularization, while only two of the seven drug-treated animals showed this phenotype. This study strongly suggests once again that anti-inflammatory drugs are effective in treating severe corneal injuries in the first couple of months after SM exposure (Babin *et al.*, 2004).

One of the worst consequences of SM exposure is corneal perforation. This effect can occur many weeks after exposure, and animal data are beginning to suggest that the toxicity of steroids may play a role in its occurrence. In a study of 15 rabbits challenged with 0.8 µl (1.02 mg) of liquid neat SM and treated with 20 mg of triamcinolone by sub-Tenons injection, four rabbits (27%) had lesions severe enough to cause a perforation of the cornea by 16 weeks (Babin *et al.*, 2004). When challenged at half this dose of SM (i.e. 0.51 mg) and subsequently treated with prednisolone acetate three times/day for 3 weeks, 60% of the rabbits developed corneal perforation (Bossone *et al.*, 2002). In an ongoing study, after a neat SM challenge, rabbits treated with decreasing doses of prednisolone acetate over a 1 month period were devoid of cornea perforations (John J. Schlager, Air Force Research Laboratory, and Michael C. Babin, Battelle Biomedical Research Center, unpublished data). These results suggest that the use of corticosteroids during the acute injury phase following SM exposure should be closely monitored and should follow the common practice of reducing the dose and frequency over time.

The explosion of science in the latter half of the 20th century, elucidating components of the adhesion complex between the epithelial and stromal layers of the cornea, suggest the basement membrane zone may become a target area for therapy in the future. Indeed, protease inhibitors of enzymes that remodel the basement membrane show promise as countermeasures. Using rabbits for an ocular SM vapor challenge, the matrix metalloprotease inhibitors ilomostat and doxycycline, and the serine protease inhibitor alpha-1 protease inhibitor, were administered 15 min after challenge, either alone or in combination. Groups of six rabbits were used, and drugs were delivered four times/day for 6 days of each week, over the course of 8 weeks in total. Analysis extended beyond the 8 week treatment: eyes were evaluated weekly for 12 weeks following exposure. In the 4 days after exposure, daily assessments were performed. During the first 2 weeks after challenge, the ilomostat and doxycycline groups showed better healing compared to the alpha-1 protease inhibitor animals, and all three drug treatment groups showed a significant reduction in lesion size compared to the SM exposure control group. Furthermore, ilomostat scored better than doxycycline in improving acute phase healing parameters. In the later phase of injury, after 2 weeks, both matrix metalloproteinase inhibitors significantly reduced corneal neovascularization. Surprisingly, the addition of alpha-1 protease inhibitor to either ilomostat or doxycycline negatively affected the outcome. Significant reductions in treatment efficacy were seen (Amir *et al.*, 2000, 2004).

Compared to the amount of research that has been invested in the study of SM skin injury, the eye has received relatively little attention during the last 20–30 years. The eye is, however, a target tissue that has a high potential for successful intervention against SM. There has been some use of corneal transplantation after mustard gas injury; however, there is a high risk for transplant rejection due to inflammation and vascularization of the cornea. Despite this, keratoplasty has been used successfully in some blinded Iraq–Iran conflict veterans (Richter *et al.*, 2006). It is likely to be one of the more successful techniques to restore vision to severely exposed individuals, especially if the limbus is also transplanted. This is needed to provide an additional supply of corneal epithelial stem cells, which become depleted over the years of trying to heal the SM latent wounds.

VII. CONCLUDING REMARKS AND FUTURE DIRECTION

From the 1920s until his death in the 1950s, Jonas Friedenwald, MD treated patients with eye problems and managed a varied research career touching on many vision-related areas. He concluded that

> the possibility of obtaining a completely effective detoxifying agent for mustard is rather poor, because no substance has been found which will remove mustard from its combination with proteins without destroying the proteins. Consequently, it can be hoped only that an antidote will neutralize the mustard which remains on the surface of the tissues but has not yet reacted with them when the antidote is applied. There is a brief interval between 2 and 5 minutes after exposure during which a penetrating decontaminant might be expected to be beneficial.

Since Friedenwald wrote this there is still no antidote and still no curative therapies, but there have been enormous strides generally in molecular biology, cell biology, drug development, and medicine which improve the chances of identifying suitable therapies. With the research being done today toward understanding the molecular events induced by sulfur mustard, causing eye, skin and lung injuries, there is much hope that effective post-exposure treatments will be found.

It is clear that more information is needed on the mechanisms of action of sulfur mustard, since elucidating these is currently providing the clues for identifying therapies. In the future, the cause(s) of delayed wound healing needs to be illuminated, in order that reagents or drugs to offset this effect can be developed. Perhaps this may be accomplished by researching the nature of the epithelial–stromal junction in a different manner. Research in the wound healing area, identifying individual steps in the process, induces many researchers who work on SM to ask why mustard wounds heal more slowly than other types of burn wounds. Our laboratories consider the provisional wound bed matrix to be important. For example, SPARC is a component present in the provisional wound extracellular matrix. Mice with a targeted null mutation in the SPARC gene show faster wound healing (Bradshaw *et al.*, 2002). Thus, we are asking whether SPARC is overexpressed, or aberrantly persists, in SM-induced wounds, slowing healing (Gordon, Gerecke, Chang, Casillas, and Babin, unpublished data). In addition, research in the field of wound healing suggests that we should examine the expression of components that replace the provisional matrix, i.e. the components of the final mature extracellular matrix typical of healthy, healed tissue. It is possible we may be able to improve healing of SM wounds if we find ways to promote their expression.

Ideally, the future will hold some prophylactic treatments that prevent recurrences such as corneal erosion. Perhaps this will be accomplished by mildly modulating the immune system for an extended period of time after injury. Finally, it would be beneficial to identify genetic alterations that might be used to monitor the chance of developing cancers from the SM exposure. In the mechanism of action section, we stressed that the sheer number of potential targets of SM in an organ with multiple cell layers and extracellular matrices, such as the cornea, make the task of determining the vesicant's mechanism of action very difficult. While this is undoubtedly true, there is a positive way to view the situation: the large number of potential targets provides a large number of potential intervention sites. As we improve our understanding of the mechanisms of action with animal studies, we increase our opportunities for identifying and developing successful therapeutic countermeasures.

Acknowledgments

The authors would like to acknowledge the support of collaborators John J. Schlager, Air Force Research Laboratory, Dayton, OH; Yoke-Chen Chang and Donald R. Gerecke of Rutgers University, Piscataway, NJ; and Robert P. Casillas of Battelle Biomedical Science & Technology, Columbus, OH. Thanks go to Rita Hahn of Rutgers University for the high magnification electron micrographs.

CHAPTER 40

Immunotoxicity

KAVITA GULATI AND ARUNABHA RAY

I. INTRODUCTION

Immunotoxicity is defined as adverse effects on the functioning of both local and systemic immune systems that result from exposure to toxic substances including chemical warfare agents. Observations in humans and animal studies have clearly demonstrated that a number of environmental and industrial chemicals can adversely affect the immune system. Alteration in the immune system may result in either immunosuppression or exaggerated immune reaction. Immunosuppression may lead to the increased incidence or severity of infectious diseases or cancer, since the immune system's ability to respond adequately to invading agents is suppressed. Toxic agent-induced immunostimulation can cause autoimmune diseases, in which healthy tissue is attacked by an immune system that fails to differentiate self-antigens from foreign antigens. For example, the pesticide dieldrin induces an autoimmune response against red blood cells, resulting in hemolytic anemia. Immunotoxicology deals with the effects of toxic substances and explores the mechanisms underlying these effects in a biological system.

Although immunotoxicology is a relatively new field, a considerable amount of data has accumulated during the past few years on immunotoxicity of certain xenobiotics. The majority of the research thus far carried out has been on environmental contaminants. Thus, from the defense point of view considerable work is required to investigate the immunotoxicity of several chemicals and some bacterial and fungal toxins which may be potential chemical warfare agents. Furthermore, there are several chemicals used in the defense industry to which the defense industrial workers may be constantly exposed. These chemicals, following low-level exposure to humans and animals, may cause immunological alterations. Thus immunotoxicity studies on such chemicals are being conducted to understand the potential risks of such exposure on the host's defense as well as the cellular and molecular mechanism of such immunomodulatory action.

A chemical warfare agent (CWA) is a substance which is intended for use in military operations to kill, seriously injure, or incapacitate people because of its toxicological effects. Although CWAs have been widely condemned since their first use on a massive scale during World War I, they have been used in many conflicts during the 20th century. As chemical weapons are cheap, relatively easy to produce and can result in mass casualties, they will continue to be used in future wars and terrorist attacks.

Although most of the compounds of CWAs are not persistent in the environment, repeated exposure and persistence of some of the compounds result in immunotoxicity. This chapter describes the immunotoxicity of CWAs and gives an insight into the probable mechanisms of such effects.

II. THE IMMUNE SYSTEM

The immune system is composed of several organs, cells, and noncellular components which act in an interrelated manner to protect the host against foreign organisms and chemical substances. The immune system participates in the mechanisms responsible for the maintenance of homeostasis and an altered immune system reflects the adverse changes in both internal and external microenvironments. The immune system protects organisms against pathogens or other innocuous substances like pollens, chemicals, indoor molds, potential food allergens, and environmental agents, and acts as layered defenses of increasing specificity. Most simply, physical barriers (e.g. skin) prevent pathogens and xenobiotics from entering the organism. If they breach these barriers, the innate immune system provides an immediate but nonspecific response. However, if pathogens successfully evade the innate response, there is a third layer of protection, i.e. the adaptive immune system, which is activated by the innate response. Here, the immune system adapts during an infection to improve its recognition of the pathogen and its response is then retained after the pathogen or xenobiotic has been eliminated. This immunological memory allows the adaptive immune system to respond faster with a stronger attack each time the same insult is encountered (Kindt *et al.*, 2007).

The immune system protects organisms from infection with layered defenses of increasing specificity. The layered defense includes mechanical, chemical, and biological barriers which protect organisms from toxic substances. Skin, a mechanical barrier, acts as the first line of defense against infection. In the lungs, coughing and sneezing mechanically eject pathogens and other irritants from the

respiratory tract while mucus secreted by the respiratory and gastrointestinal tract traps and entangles microorganisms and other toxins (Boyton and Openshaw, 2002). Chemical barriers also protect against infection. The skin and respiratory tract secrete antimicrobial peptides such as the β-defensins. Enzymes such as lysozyme and phospholipase A2 in saliva, tears, and breast milk are also antibacterials (Moreau *et al.*, 2001; Hankiewicz and Swierczek, 1974). In the stomach, gastric acid and proteases serve as powerful chemical defenses against ingested pathogens.

A. The Innate Immune System

The innate immune system defends the host from infection and toxicants, in a nonspecific manner. This means that the cells of the innate system recognize, and respond in a generic way, but do not confer long-lasting or protective immunity to the host. The innate immune response was initially dismissed by the immunologist as it was thought to provide a temporary holding of the situation until a more effective and specific adaptative immune response develops. But it has now been clear that it plays an important role as a dominant system of host defense in most organisms (Litman *et al.*, 2005). The major function of the innate immune system is to recruit immune cells to sites of infection and inflammation. Inflammation is one of the first responses of the immune system to infection or irritation through the production of cytokines. These cytokines released by injured cells serve to establish a physical barrier against the spread of infection. Several chemical factors are produced during inflammation, e.g. histamine, bradykinin, serotonin, leukotrienes, and prostaglandins, which sensitize pain receptors, cause vasodilation of the blood vessels, and attract phagocytes. The inflammatory response is characterized by the redness, heat, swelling, pain, and possible dysfunction of the organs or tissues involved. The fluid exudate contains the mediators for four proteolytic enzyme cascades: the complement system, the coagulation system, the fibrinolytic system, and the kinin system. The exudate is carried by lymphatics to lymphoid tissue, where the product of foreign organism can initiate an immune response.

The activation of the complement cascade helps to identify the invading substance, activate cells, and promote clearance of dead cells by specialized white blood cells. The cascade is composed of nine major components, designated C1 to C9, which are plasma proteins synthesized in the liver, primarily by hepatocytes. These proteins work together to trigger the recruitment of inflammatory cells. One of the main events is the splitting of the C3, which gives rise to various peptides. One of them, C3a (anaphylatoxin), can stimulate mast cells to secrete chemical mediators and another, C3b (opsonin), can attach to the surface of a foreign body and facilitates its ingestion by white blood cells. C5 is a powerful chemotactic of white cells and causes release of mediators from mast cells. Later components from C5 to C9 assemble in a sequence at the surface of bacteria/xenobiotics and lead to their lysis, ridding the body of neutralized antigen–antibody complexes. The main events of this system can also be directly initiated by the principal enzymes of the coagulation and fibrinolytic cascade, thrombin and plasmin, and by enzymes released from white blood cells. Further, an innate immune system leads to the activation of an adaptive immune system.

B. The Adaptive Immune System

The adaptive immune system is composed of highly specialized, systemic cells and processes that eliminate pathogenic challenges and provide the ability to recognize and mount stronger attacks each time the same pathogen is encountered. Antigen specificity requires the recognition of specific ''nonself'' antigens during a process called antigen presentation. The ability to mount these immune responses is maintained in the body by ''memory cells''. The cells of the adaptive immune system are special types of leukocytes, B cells and T cells, which constitue about 20–40% of white blood cells (WBCs). The peripheral blood contains 20–50% of circulating lymphocytes and the rest move within the lymphatic system (Kindt *et al.*, 2007). B cells and T cells are derived from the same pluripotential hematopoietic stem cells in the bone marrow, and are indistinguishable from one another until after they are activated. B cells play a large role in the *humoral immune response*, whereas T cells are intimately involved in *cell-mediated immune responses*. B cells derive their name from the bursa of Fabricius, an organ unique to birds, where the cells were first found to develop. However, in nearly all other vertebrates, B cells (and T cells) are produced by stem cells in the bone marrow (Kindt *et al.*, 2007). T cells are named after thymus where they develop and through which they pass. In humans, approximately 1–2% of the lymphocyte pool recirculates each hour to optimize the opportunities for antigen-specific lymphocytes to find their specific antigen within the secondary lymphoid tissues. Both B cells and T cells carry receptor molecules that recognize specific targets.

T cells express a unique antigen-binding molecule, the T cell receptor (TCR), on their membrane. There are two well-defined subpopulations of T cell: T helper (T_H) and T cytotoxic (T_C) cells. They can be distinguished from one another by the presence of either CD4 or CD8 membrane glycoproteins on their surfaces. T cells displaying CD4 generally function as T_H cells whereas those displaying CD8 function as T_C cells. T cells recognize a ''nonself'' target, such as a pathogen, only after antigens have been processed and presented in combination with a ''self'' receptor called a major histocompatibility complex (MHC) molecule. T_C cells only recognize antigens coupled to class I MHC molecules, while T_H cells only recognize antigens coupled to class II MHC molecules.

B cells are the major cells involved in the creation of antibodies that circulate in blood plasma and lymph, known as humoral immunity. Like the T cell receptor, B cells

express a unique B cell receptor (BCR), in this case an immobilized antibody molecule. The BCR recognizes and binds to only one particular antigen. A critical difference between B cells and T cells is how each cell ''sees'' an antigen. T cells recognize their cognate antigen in a processed form – as a peptide in the context of an MHC molecule – while B cells recognize antigens in their native form. Once a B cell encounters its cognate (or specific) antigen [and receives additional signals from a helper T cell (predominantly Th2 type)], it further differentiates into an effector cell, known as a plasma cell.

Plasma cells are short-lived cells (2–3 days) which secrete antibodies that circulate in blood plasma and lymph, and are responsible for humoral immunity. Antibodies (or immunoglobulin, Ig) are large Y-shaped proteins used by the immune system to identify and neutralize foreign objects. In mammals there are five types of antibody: IgA, IgD, IgE, IgG, and IgM. Differing in biological properties, each has evolved to handle different kinds of antigens. These antibodies bind to antigens, making them easier targets for phagocytes, and trigger the complement cascade. About 10% of plasma cells will survive to become long-lived antigen-specific memory B cells (Lu and Kacew, 2002). Already primed to produce specific antibodies, these cells can be called upon to respond quickly if the same foreign body reinfects the host. This is called ''adaptive immunity'' because it occurs during the lifetime of an individual as an adaptation to infection with that pathogen and prepares the immune system for future challenges.

A number of animal models have been developed and validated to detect the chemical-induced direct immunotoxicity. Several compounds, including certain drugs, have been shown in this way to cause immunosuppression or skin allergic responses. In this chapter, the various mechanisms of immunotoxicity are discussed by which a compound affects different cell types and interferes with immune responses, ultimately leading to immunotoxicity as well as sensitizing capacity.

III. TARGETS OF IMMUNOTOXICITY

A. Effects on Precursor Stem Cells

The bone marrow is an organ with precursor stem cells that are responsible for synthesizing peripheral leukocytes. All leukocyte lineages originate from these stem cells, but once distinct subsets of leukocytes are established, their dependence on replenishment from the bone marrow differs vastly. The turnover of neutrophils is very rapid, i.e. more than 10^8 neutrophils enter and leave the circulation in a normal adult daily so there is dependence on new formation in the bone marrow. In contrast, macrophages are long-lived and have little dependence on new formation of precursor cells. The adaptive immune system, comprising antigen-specific T and B lymphocytes, is almost completely established around puberty and is therefore essentially bone marrow independent in the adult.

As a consequence of their high proliferation rate, stem cells in the bone marrow are likely to be extremely vulnerable to cytostatic drugs and chemicals like CWAs. Lineages like neutrophils with rapid turnover will be most vulnerable and will be affected first by such treatments/exposures. After prolonged exposure, macrophages and T or B cells of the adaptive immune system are also suppressed.

B. Effects on Maturation of Lymphocytes

T lymphocytes mature in the thymus by a very complex selection process that takes place under the influence of the thymic microenvironment and ultimately generates an antigen-specific, host-tolerant population of mature T cells. This process involves cellular proliferation, gene rearrangement, apoptotic cell death, receptor up- and down-regulation and antigen-presentation processes, and is very vulnerable to a number of chemicals. Drugs may target different stages of T cell differentiation like naïve T cells, proliferating and differentiating thymocytes, antigen-presenting thymic epithelial cells and dendritic cells, cell death processes, etc. (Vos *et al.*, 1999). In general, immunosuppressive drugs may cause a depletion of peripheral T cells, particularly after prolonged treatment and during early stages of life when thymus activity is high and important in establishing a mature T cell population. In addition, suppression of T cells may result in suppression of the adaptive immune system by affecting the maturation of B cells and thus antibody level.

C. Effects on Initiation of Immune Responses

The innate and adaptive immune systems act together to eliminate invading pathogens. Ideally, T cells tailor the responses to neutralise invaders with minimal damage to the host. The recognition of autoantigens is maintained by the two distinct signals that govern lymphocyte activation. One is the specific recognition of antigen via clonally distributed antigen receptors and the other is antigen nonspecific co-stimulation or ''help'' and involves interactions of various adhesive and signaling molecules expressed in response to tissue damage, linking initiation of immune responses to situations of acute ''danger'' for the host (Vos *et al.*, 1999). This helps to aim immune responses at potentially dangerous microorganisms (nonself), while minimizing deleterious reactions to the host (self). Xenobiotics, however, can interfere with the initiation of immune responses if they act as antigens, by forming haptens or by releasing previously hidden self-antigens. They may also trigger an inflammatory response, or disturb T–B cell cooperation.

CWAs with large molecular weight can function as antigens and become targets of specific immune responses themselves. This is particularly relevant for foreign protein

pharmaceuticals, as these can activate both T and B lymphocytes. The resulting immune responses may lead to formation of antibodies, and induce specific memory which can lead to allergic responses to the drug. Immunotoxic effects may occur after repeated treatment with the same CWA. However, low molecular weight CWAs cannot function as antigens, because they are too small to be detected by T cells. Reactive chemicals that bind to proteins, however, can function as haptens and become immunogenic if epitopes derived from them prime T cells, which in turn provide co-stimulation for hapten-specific B cells. This effect is responsible for allergic responses to many new (neo) epitopes formed by chemical haptens.

Modification of autoantigens can also lead to autoimmune responses to unmodified self-epitopes. Haptenated autoantigens can be recognized and internalized by antigen presenting cells. These cells subsequently present a mixture of neo- and self-epitopes complexed to distinct class II major histocompatibility (MHC-II) molecules on their surface and neospecific T cells. Th cells provide signals for the B cell. This leads to production of either antihapten or anti-self antibodies depending on the exact specificity of the B cell. Moreover, once these B cells are activated, they can stimulate autoreactive Th cells recognizing unmodified self-epitopes. This process is called epitope (determinant) spreading and causes the diversification of adaptive immune responses. For example, injection of mercury salts initially induces response directed only to unidentified chemically created neoepitopes, but after 3–4 weeks include reactivity to unmodified self-epitopes. Thus the allergic response may gradually culminate as autoimmune responses reflecting the relative antigenicity of the neo- and self-epitopes involved (Lu and Kacew, 2002).

IV. EXPOSITION OF AUTOANTIGENS AND INTERFERENCE WITH CO-STIMULATORY SIGNALS

Self-tolerance involves specific recognition of autoantigen leading to selective inactivation of autoreactive lymphocytes at birth, but tolerance is not established for (epitopes of) autoantigens that are normally not available for immune recognition. Pharmaceuticals can expose such sequestered epitopes by disrupting barriers between the antigen and the immune system (i.e. blood–brain barrier, blood–testis barrier, cell membranes). Tissue damage, cell death, and protein denaturation induced by chemicals can largely increase the chances of such (epitopes of) autoantigens for immune recognition. Antigen recognition followed by co-stimulation of signaling molecules leads to activation of lymphocytes and initiation of immune responses. Many xenobiotics have the inherent capacity to induce or inhibit this co-stimulation due to their intrinsic adjuvant activity.

V. INDUCTION OF INFLAMMATION AND NONCOGNATE T–B COOPERATION

Cytotoxic chemicals or their reactive metabolites can induce tissue damage which results in release of proinflammatory cytokines like tumor necrosis factor α (TNFα), interleukin-1 (IL-1), and IL-6, and attracts inflammatory cells like granulocytes and macrophages. Cytokines produced during this inflammatory response activate antigen-presenting cells and accumulation of tissue debris. The epitopes of antigens on debris provide co-stimulation for Th cells, which lead to the initiation of an adaptive immune response. Reactive xenobiotics may also stimulate adaptive immune responses by disturbing the normal cooperation of Th and B cells. Normally, B cells receive stimulation from Th cells that recognize (epitopes of) the same antigen. However, when Th cells respond to nonself-epitopes on B cells, such B cells may be noncognately stimulated by the Th cell. This occurs during graft-versus-host responses following bone marrow transplantation, when Th cells of the host recognize nonself-epitopes on B cells of the graft and vice versa. This leads to T and B cell activation and results in production of autoantibodies to distinct autoantigens like DNA, nucleoli, nuclear proteins, erythrocytes, and basal membranes. Drug/chemical-related lupus is characterized by a similar spectrum of autoantibodies, and noncognate – graft-versus-host-like – T–B cooperation is therefore suggested to be one of the underlying mechanisms.

VI. REGULATION OF THE IMMUNE RESPONSE

The type of immune response elicited in response to a foreign pathogen or allergen is the result of a complex interplay of cytokines produced by macrophages, dendritic cells, mast cells, granulocytes, and lymphocytes. Immunotoxic chemicals that somehow influence the immune system can lead to either immunosuppression or immune exaggeration, i.e. hypersensitivity and autoimmunity. Hypersensitivity is an immune response that damages the body's own tissues. Hypersensitivity reactions require a pre-sensitized (immune) state of the host. They are divided into four classes (Type I–IV) based on the mechanisms involved and the time course of the hypersensitive reaction. Type I hypersensitivity is an immediate or anaphylactic reaction, often associated with allergy. Symptoms can range from mild discomfort to death. Type I hypersensitivity is mediated by IgE released from mast cells and basophils. Type II hypersensitivity occurs when antibodies bind to antigens on the patient's own cells, marking them for destruction. This is also called antibody-dependent (or cytotoxic) hypersensitivity, and is mediated by IgG and IgM antibodies. Immune complexes (aggregations of antigens, complement proteins, and IgG and IgM antibodies) deposited in various tissues trigger Type III hypersensitivity reactions. Type IV hypersensitivity (also

known as cell-mediated or delayed type hypersensitivity) usually takes between 2 and 3 days to develop. Type IV reactions are involved in many autoimmune and infectious diseases, but may also involve contact dermatitis (poison ivy). These reactions are mediated by T cells, monocytes, and macrophages. Actual development of clinical symptoms is influenced by the route and duration of exposure, the dosage of the pharmaceutical, and by immunogenetic (MHC haplotype, Th1-type versus Th2-type responders) and pharmacogenetic (acetylator phenotype, sulfoxidizer, Ah receptor, etc.) predisposition of the exposed individual. Moreover, atopic individuals that tend to mount Th2 immune responses are more susceptible to anaphylaxis triggered by an IgE response to chemical haptens than typical Th1 responders. Genetic variation in metabolism of pharmaceuticals is important as it determines the formation and clearance of immunotoxic metabolites. The slow acetylating phenotype, for instance, predisposes for drug-related lupus because reactive intermediates of phase I metabolism have an increased opportunity to bind proteins as they are only slowly conjugated.

Immune dysregulation can also be in the form of immune suppression and both innate and adaptive arms of the immune systems play crucial roles. A wide variety of physiological, pharmacological, and environmental factors can exert a negative influence on the immune system and sometimes result in immunotoxicity. Recent experimental data have shown that emotional and environmental stressors influence the functioning of the immune system and this is reflected in the various markers of specific immunity (Ray *et al.*, 1991; Koner *et al.*, 1998). Such experimental stressors consistently suppressed both humoral and cell mediated immune responses in experimental animals. Both antibody forming cell counts and antibody titer were lowered and a neuroendocrine–immune axis concept was proposed. Similar attenuations in cell mediated immune responses were also seen after such stressors and DTH responses, leukocyte/macrophage migration indices and also cytokine profiles (both Th1 and Th2 dependent). Further analysis of the mechanisms involved indicated that CNS mediated changes could have contributed to this immunotoxicity. Depletion or antagonism of brain dopamine aggravated emotional stress-induced immune suppression, whereas psychoactive drugs like benzodiazepines and opioids prevented this response (Ray *et al.*, 1992; Puri *et al.*, 1994). In another set of experiments, rats exposed to several environmental pollutants like DDT showed graded degrees of immune suppression and immunotoxicity, when the exposure lasted for a reasonably long period of time. Gradual accumulation in the various body tissues resulted in a variety of untoward effects in the immune system, which was particularly susceptible to such xenobiotic-induced damage (Banerji *et al.*, 1996; Koner *et al.*, 1998). Both humoral and cell mediated immune response were affected depending on the quantum and duration of exposure to these xenobiotics. Further, a combination of emotional stress and xenobiotic exposure had additive effects on the immunotoxicity parameters studied (Banerjee *et al.*, 1997). Recent studies revealed that such emotional stress and xenobiotic-induced immunotoxicity was accompanied by derangements in oxidative stress parameters, such as enhancements in MDA levels and lowering of GSH/SOD levels in the blood (Koner *et al.*, 1997; Ray and Gulati, 2007; Gulati *et al.*, 2007).

VII. IMMUNOTOXICITY OF CHEMICAL WARFARE AGENTS

A chemical warfare agent (CWA) is a substance which is intended for use in military operations to kill, seriously injure, or incapacitate people because of the severe pathophysiological changes induced by them in various body systems. A United Nations report from 1969 defines chemical warfare agents as ''chemical substances, whether gaseous, liquid or solid, which might be employed because of their direct toxic effects on man, animals and plants''. However, the Chemical Weapons Convention defines chemical weapons as including not only toxic chemicals but also ammunition and equipment for their dispersal. Toxic chemicals are stated to be ''any chemical which, through its chemical effect on living processes, may cause death, temporary loss of performance, or permanent injury to people and animals''. Normally, they are either liquids or solids.

Chemical agents have been used in war since time immemorial. In 600 BC Helleborus roots were used successfully by the Athenians to contaminate water supplies during the siege of Kirrha. Spartans ignited pitch and sulfur to create toxic fumes during the Peloponnesian War in 429 BC. The uses of CWAs in battlefields reached a peak during World War I and the French were the first to use ethylbromoacetate. It was followed by *o*-dianisidine chlorosulphonate, chloroacetate, chlorine, phosgene, hydrogen cyanide, diphenylchloroarsine, ethyl- and methyldichloroarsine, and sulfur mustard resulting in nearly 90,000 deaths and over 1.3 million casualties (Eckert, 1991). CWAs were most brutally used by the Germans in the gas chambers for mass genocide of Jews during World War II, and have been used intermittently both in war, as in the Iraq–Iran War, as well as in terrorist attacks in the Japanese subway stations. It is estimated that nearly 100,000 US troops may have been exposed to CWAs during operation Desert Storm (Chauhan *et al.*, 2008).

CWAs have been widely condemned since they were first used on a massive scale during World War I. However, they are still stockpiled and used in many countries as they are cheap and relatively easy to produce, and can cause mass casualties. Although the blood agent CK is extremely volatile and undergoes rapid hydrolysis, the degradation of three types of vesicant CWAs, the sulfur mustards, nitrogen mustards, and Lewisite, results in persistent products. For

example, sulfonium ion aggregates formed during hydrolysis may be persistent and may retain vesicant properties. The nerve agents include the V agent VX as well as three G agents (tabun, sarin, and soman). VX gives rise to two hydrolysis products of possible concern: EA 4196, which is persistent, and EA 2192, which is highly toxic and is possibly persistent under certain limited conditions (Small, 1984). Thus, their long-term persistence in the body may lead to alterations in the immune system of the exposed population.

CWAs can be classified in many different ways. There are, for example, volatile substances, which mainly contaminate the air, or persistent substances, which are nonvolatile and therefore mainly cover surfaces. CWAs mainly used against people may also be divided into lethal and incapacitating categories. A substance is classified as an incapacitating agent if less than 1/100 of the lethal dose causes incapacitation, e.g. through nausea or visual problems. The limit between lethal and incapacitating substances is not absolute but refers to a statistical average. Chemical warfare agents are generally classified according to their principal target organs.

1. **Organophosphate (OP) nerve agents.** These agents are extremely toxic compounds that work by interfering with the nervous system, and include soman, sarin, cyclosarin, tabun, and VX.
2. **Blister agents/vesicants.** These compounds severely blister the eyes, respiratory tract and skin on exposure, and include nitrogen mustard, sulfur mustard, Lewisite, etc.
3. **Choking agents.** These agents cause severe irritation primarily affecting the respiratory tract, and include phosgene, ammonia, methyl bromide, methyl isocyanate, etc.
4. **Blood agents.** These agents are absorbed into the blood and interfere with the oxygen carrying capacity, e.g. arsine, cyanides, carbon monoxide, etc.

Very few studies have been conducted to explore the immunomodulation and immunotoxic potential of CWAs, and there is little evidence that these drugs are associated with such undesirable, immunologically significant effects. The reason may be due to confounding factors such as stress, nutritional status, lifestyle, co-medication, and genetics (Vos *et al.*, 1999). The exposure to CWA can result in immunodepressed conditions on the one hand and to allergic and autoimmune diseases on the other. Few conventional compounds have been shown to induce unexpected enhancement of immune competence. However, introduction of biotechnologically manufactured agents like cytokines has been shown to induce unwanted immunostimulation. Drug-induced hypersensitivity reactions and autoimmune disorders are a major concern, whereas some of these chemicals also result in immunosuppression. In particular, impaired activity of the first line of defense of the natural immune system can have disastrous consequences. These are generally not influenced by the genetic predisposition of the exposed individual, but on actual outbreak of infections and the general immune status prior to exposition. This explains why immunosupressive xenobiotics are most likely to have clinical consequences in immunocompromised individuals such as young children, the elderly, and transplant recipients.

A. Nerve Agents

Nerve agents are highly toxic organophosphorus compounds (OPs) which represent potential threats to both military and civilian populations, as evidenced in recent terroristic attacks in Japan (Ohtomi *et al.*, 1996). Commonly known as nerve agents or nerve gases, these are the deadliest of CWAs. These agents have both chemical names as well as two-letter NATO codes. These are categorized as G series agents: GA (tabun), GB (sarin), GD (soman), GF (cyclosarin), and V series agents: VE, VG, VM, and VX, the letter ''G'' representing the country of origin ''Germany'' and letter ''V'' possibly denoting ''Venomous''. Their initial effects occur within 1–10 min of exposure followed by death within 15–30 min for sarin, soman, and VX, and within 30–60 min for tabun. The ease and low cost of production make sarin gas a tool of mass destruction in the hands of terrorist groups and rogue nations. While people in the immediate vicinity of a sarin attack may receive neurotoxic doses, people remote from the vicinity are likely to receive subclinical exposures.

Short- and long-term health effects from exposure to OP nerve agents and insecticide nerve agents are compiled on the basis of scientific literature published on health effects in humans and animal studies. Four distinct health effects are identified: acute cholinergic toxicity; OP-induced delayed neuropathy (OPIDN); subtle long-term neuropsychological and neurophysiological effects; and a reversible muscular weakness called ''intermediate syndrome''. Each effect has data suggesting threshold exposure levels below which it is unlikely to be clinically detectable. High-level exposure results in definitive cholinergic poisoning; intermediate-level threshold cholinergic effects include miosis, rhinorrhea or clinically measurable depression of cholinesterase; and low-level exposure results in no immediate clinical signs or symptoms. Threshold exposure levels for known long-term effects from OP nerve agent are at or above intermediate-level exposure (Brown and Brix, 1998). However, subclinical doses of sarin cause subtle changes in the brain, and subclinical exposure to sarin has been proposed as an etiology to the Gulf War Syndrome.

The wide use of cholinesterase inhibitors in various spheres of human activities and the risk of acute and chronic intoxications associated with this process prompted investigation of the role of acetylcholinesterase (AChE) and nonspecific esterases in the immunotropic effects of these chemicals. They irreversibly bind to AChE that normally catalyzes the hydrolysis of acetylcholine (ACh) at the

cholinergic synapses and neuromuscular junctions (NMJs). The inhibition of degradation results in accumulation of ACh in the cholinergic synapses, causes the overstimulation of peripheral as well as central cholinergic nervous systems, and is clinically manifested as acute cholinergic crisis (convulsions, respiratory failure, and/or death) (Marrs, 1993; Taylor, 2006).

1. Immunotoxicity

Kalra *et al.* (2002) suggested that low doses of sarin are highly immunosuppressive, and suppress glucocorticoid production. The effects of sarin exposure on the immune system are attenuated by ganglionic blockers and decreased glucocorticoid level may be a biomarker for cholinergic toxicity. In addition, nerve agents cause the activation of multiple noncholinergic neurotransmitter systems in the central nervous system (CNS) thus resulting in mutagenic, stressogenic, immunotoxic, hepatotoxic, membrane, and hematotoxic effects (Bajgar, 1992). The CNS and the immune system communicate bidirectionally, and cholinergic agents modulate the immune system. The ability of OP compounds to induce an alteration of the immune system was primarily demonstrated in animals or humans exposed to OP insecticides (OPIs). The results provide evidence that, especially neutrophil function, natural killer cell, cytotoxic T cell and humoral immune functions, and spontaneous as well as mitogen-induced lymphocyte proliferation, are altered in animals or humans exposed to OP compounds (Casale *et al.*, 1984; Hermanowitz and Kossman, 1984; Li *et al.*, 2002; Newcombe and Esa, 1992). In addition, a decreased number of cells in the spleen and thymus (Ladics *et al.*, 1994), an inhibition of chemotaxis in neutrophils (Ward, 1968), inhibition of monocyte accessory functions or inhibition of interleukin-2 production (Casale *et al.*, 1993; Pruett and Chambers, 1988) were reported following the exposure to OPs, at relatively high toxic doses.

Lee *et al.* (1979) were the first to draw attention to the possible effects of OPs on human leukocyte function. They demonstrated that lymphocyte proliferation to phytohemaglutinin *in vitro* was decreased in the presence of OPs. Although most of the studies described the results of OPI exposure, there are studies about the immunotoxic effects of highly toxic nerve agents and their by-products. Marked impairment in neutrophil chemotaxis and neutrophil adhesion and a reduction in the natural killer cell and cytotoxic T cell function were observed in workers exposed to OPIs and by-products of sarin (Hermanowitz and Kossman, 1984; Newcombe and Esa, 1992; Li *et al.*, 2002). Kant *et al.* (1991) documented a decrease in the weight of thymus, an important immune organ in severely affected soman survivors, but other tests of immune function did not show differences between control and soman-exposed rats. Samnaliev *et al.* (1996) described a decrease in the number of plaque forming cells in soman-exposed rats after the administration of sheep red blood cells as an antigen. However, Johnson *et al.* (2002) demonstrated that OP-induced modulation of immune functions can involve not only their suppression but also their activation. Similar activation of some immune functions involving ''acute phase response'' such as an increase in the synthesis of acute phase proteins, increase in release of histamine from basophile leukocytes and activation of macrophages were observed following the exposure to soman (Sevaljevic *et al.*, 1992; Newball *et al.*, 1986). Although most of the studies dealt with exposure to high doses, Kassa *et al.* (2004) confirmed that not only symptomatic but also asymptomatic doses of nerve agent sarin were able to modify various immune functions. The proportion of T lymphocytes was found to be decreased, while the B cell levels were raised. However, sarin significantly suppressed nonspecific *in vitro* stimulated proliferation of both T and B cells, which suggests that it can also block normal immune response to infection. While the lymphocyte mediated immunity is rather suppressed, the peritoneal as well as alveolar macrophages and NK cells were activated after exposure to both levels of sarin, which was explained to be the result of compensatory reactions of immune functions rather than the result of direct effects of inhalation.

Immunosuppression may result from direct action of acetylcholine upon the immune system or it may be secondary to the toxic chemical stress associated with cholinergic poisoning (Pruett *et al.*, 1992). Further, immunomodulation at low levels seems to be very complex and it is suggested that there are probably other protein targets very sensitive to some anticholinesterases including nerve agents. However, the function of these protein targets is not yet known (Ray, 1998). Some immune functions are probably stimulated due to the development of ''acute phase response'' generally characterized for inflammatory reaction of OP-exposed organism (Sevaljevic *et al.*, 1989, 1992). Other immune functions are suppressed due to immunotoxicity of OP compounds. Although these findings are difficult to extrapolate directly to low-level exposures to nerve agents, they indicate that subtle alteration of immune system could also occur in humans at exposure levels which do not cause any clinical manifestation. Post-intoxication immunodeficiency can promote infectious complications and diseases.

It has been shown that T lymphocytes have AChE located on the plasma membrane, while B cells are esterase negative (Szelenyi *et al.*, 1982). Thus, AChE inhibition by toxic agents in sublethal doses may play an important role in immunodeficiency following exposure to nerve gases. Zabrodskii *et al.* (2003) showed inhibition of AChE in T cells and the decrease in the number of esterase-positive T lymphocytes (and, to a certain extent, in monocytes and macrophages) directly correlated with suppression of T cell-dependent antibody production and to the degree of DTH reduction, on exposure to dimethyl dichlorovinyl phosphate, sarin, VX, lewisite, tetraethyl lead, and dichloroethane. This presumably involves the loss of some functions by T

lymphocytes (e.g. by Th1 cells), which leads to attenuation of T-dependent immune reactions. This can be explained by excessive acetylcholine (ACh) stimulation of muscarinic and nicotinic receptors present on T lymphocytes, as a result of which the optimal cAMP to cGMP ratio in immunocytes, essential for their proliferation and differentiation, is distorted (Richman and Arnason, 1979). Thus, the anticholinesterase effect of lewisite, TEL, and DCE may be one of the important mechanisms in the formation of T cell mediated immunodeficiency.

B. Blister or Vesicant Agents

These agents act on skin and other epithelial tissues and severely blister the eyes, respiratory tract, and internal organs, and also destroy different substances within cells of living tissue. The symptoms are variable depending upon the compound and the sensitivity of the individual. Acute mortality is low; however, they can incapacitate the enemy and overload the already burdened health care services during war time. Some of these agents are HD (sulfur mustard), HN (nitrogen mustard), L (Lewisite), and CX (phosgene oximine).

Sulfur mustard (SM) was the most widely used chemical warfare agent (CWA) in the Iran–Iraq War, resulting in over 100,000 chemical casualties between 1980 and 1988. It acts as an alkylating agent with long-term toxic effects on several body organs, mainly the skin, eyes, and respiratory system (Willems, 1989). The extent of tissue injury depends on the duration and intensity of exposure. When absorbed in large amounts, SM can damage rapidly proliferating cells of bone marrow and may cause severe suppression of the immune system (Willems, 1989).

1. Immunotoxicity

Evidence that SM causes immunosuppression in humans has emerged from several lines of investigation. The earliest evidence came from clinical observations of humans directly exposed to sulfur mustard during World War I, who showed significant changes (quantitative and qualitative) in the circulating elements of the immune system. Stewart (1918) studied ten fatal cases of mustard poisoning and observed striking depression of bone marrow production of white blood cells. Among the sulfur mustard casualties during the Iran–Iraq conflict leukopenia accompanied by total bone marrow aplasia and extensive losses of myeloid stem cells was the most common finding (Balali-Mood, 1984; Eisenmenger *et al.*, 1991). These findings provide further evidence of an association between suppression of immunologic functions and an increased incidence of infectious disease.

SM has been widely used during Iran–Iraq conflict and there are many reports of influence of SM on the respiratory system, gastrointestinal system, and endocrine system as well as the immune system (Balali-Mood, 1984; Balali-Mood and Farhoodi 1990; Emad and Razaian 1997; Sasser *et al.*, 1996; Budiansky, 1984). The influence of SM on the immune system has been the subject of many researchers since 1919 (Krumbhaar and Krumbhaar, 1919; Hektoen and Corper 1921). Early investigations on SM casualties during the Iran–Iraq War showed decreased immunoresponsiveness, expressed as leukopenia, lymphopenia, and neutropenia, as well as hypoplasia and atrophy of the bone marrow (Willems, 1989; Tabarestani *et al.*, 1990; Balali-Mood *et al.*, 1991). Chronic exposure to SM has been associated with the impairment of NK cells among workers of poison gas factories in Japan (Yokogama, 1993). Similarly, cell mediated immunity was found to be suppressed following mustard gas exposure (Zandieh *et al.*, 1990).

Leukopenia has been the first manifestation to appear within the first days of post-exposure. Thrombocytopenia and anemia followed later if the patients survived (white blood cells of some patients dropped to less than 1,000 per cm^3). Although most of these patients suffered skin burns, clinicians reported cases that had minor skin lesions and yet developed leukopenia. Bone marrow biopsies revealed hypocellular marrow and cellular atrophy involving all elements (Willems, 1989). Studies on the status of immunocompetent cells in the blood of patients exposed to sulfur mustard showed that T cell and monocyte counts dropped in 54% and 65% of the patients, respectively, from day 1 and up to 7th week post-exposure (Hassan and Ebtekar, 2002). Eosinophil counts dropped in 35% and neutrophil numbers in 60% of the patients. B lymphocyte counts were normal up to 7th week (Manesh, 1986). The majority of the patients showed increased levels of IgG and IgM during the 1st week, but the percentage decreased over the next 6 months. The percentage of patients with increased levels of C3, C4, and CH50 was somewhat higher than of healthy controls during the 1st week and up to 6th month (Tabarestani *et al.*, 1990) and remained higher 3 years post-exposure especially in the severely affected group. Eight years after exposure there was a significant increase in the number of atypical leukocytes (such as myelocytes). The severely affected group presented with significantly lower CD56 NK as well as CD4 and CD8 counts compared with healthy controls (Yokogama, 1993). Hassan and Ebtekar (2002) reported that there was no major difference between the severely affected patients and healthy controls concerning CD19 B cells, CD14 monocytes, and CD15 granulocytes. The moderately and mildly affected patients did not significantly differ in their leukocyte subset counts from the control group 8 years after exposure (Mahmoudi *et al.*, 2005). Follow-up studies on the clinical conditions of exposed Iranian victims still show that they suffer from three major problems: recurrent infection, septicemia and death, respiratory difficulties and lung fibrosis, as well as a high incidence of malignancies, septicemia, and death.

Hassan and Ebtekar (2002) suggested that patients with moderate clinical manifestations may be experiencing a shift from Th1 to Th2 cytokine patterns since leukocyte cultures from this patient group showed a decrease in IFN-γ

levels. When absorbed in large amounts, SM can damage rapidly proliferating cells of bone marrow and may cause severe suppression of the immune system (Sasser *et al.*, 1996). Moreover, this alkylating agent has been reported to produce short- and long-term suppression of antibody production in both animals and humans. It also affects complement system factors C3 and C4. Incidences of acute myelocytic and lymphocytic leukemia are reported to be 18 and 12 times higher in patients exposed to SM, in comparison with the normal group (Zakeripanah, 1991). Willems (1989) reported that exposure to SM could result in the impairment of human immune function, especially in the number of B and T lymphocytes. Hence, SM is still a potential threat to the world and effective therapeutic measures must be taken for the relief of the victims of this incapacitating agent. Ghotbi and Hassan (2002) showed that the percentage of NK cells, playing an important role in cellular immunity, was significantly lower in severe patients than in the control group. Studies on animal models have shown that alkylating agents such as SM mainly affect B cells, which is why hypogammaglobulinemia is one of the main features in animal models, whereas studies on human cases, following a treatment with cytotoxic drugs, suggest that low-dose exposure to alkylating agents impairs cellular immunity and high-dose exposure to such agents impairs both cellular and humoral responses (Marzban, 1989; Malaekeh *et al.*, 1991). There are reports suggesting that sulfur mustard can produce toxicity through the formation of reactive electrophobic intermediates, which in turn covalently modify nucleophilic groups in biomolecules such as DNA, RNA, and protein (Malaekeh *et al.*, 1991), resulting in disruption of cell function, especially cell division (Crathorn and Robert, 1966). As a result, these agents are particularly toxic to rapidly proliferating cells including neoplastic, lymphoid, and bone marrow cells. Mahmoudi *et al.* (2005) reported higher IgM levels after 16 to 20 years of exposure to SM, compared to the control group. A significant decrease in the number of NK cells in severe patients is probably due to the destructive effect of this alkylating agent on NK cell precursors in bone marrow. However, activity of NK cells was found to be noticeably above normal which possibly compensates for the reduction in the number of these cells.

Recently, Korkmaz *et al.* (2006) explained the toxicodynamics of sulfur mustards in three steps: (1) binding to cell surface receptors; (2) activation of ROS and RNS leading to peroxynitrite ($OONO^-$) production, and (3) $OONO^-$-induced damage to lipds, proteins, and DNA, leading to polyadenosine diphosphate ribose (PARP) activation. This could provide a lead for devising strategies for protection against/treatment of mustard toxicity.

In conclusion, the results suggest that exposure to SM causes a higher risk of opportunistic infections, septicemia, and death following severe suppression of the immune system especially in the case of lesions and blisters produced by these agents. As alkylating agents, they form covalent linkages with biologically important molecules, resulting in disruption of cell function, especially cell division. As a result, these agents are particularly toxic to rapidly proliferating cells including neoplastic, lymphoid, and bone marrow cells. However, there is still a paucity of information regarding the long-term immunosuppressive properties of SM in the setting of battlefield exposure to this agent.

C. Choking Agents

Choking agents act on the pulmonary system causing severe irritation and swelling of the nose, throat, and lungs, e.g. CG (phosgene), DP (diphosgene), chlorine, and PS (chloropicrin). These inhalational agents damage the respiratory tract and cause severe pulmonary edema in about 4 h, leading to death. The effects are variable, rapid, or delayed depending on the specific agent (Gift *et al.*, 2008).

Phosgene was first used as a chemical weapon in World War I by Germany and later as offensive capability by French, American, and British forces. In this conflict, phosgene was often combined with chlorine in liquid-filled shells, so it was difficult to state the number of casualties and deaths attributable solely to phosgene. In military publications, it has been referred to as a choking agent, pulmonary agent, or irritant gas. Since World War I, phosgene has rarely been used by traditional militaries, but the extremist cult Aum Shinrikyo used this agent in an attack against the Japanese journalist Shouko Egawa in 1994. Nowadays, phosgene is primarily used in the polyurethane industry for the production of polymeric isocyanates (USEPA, 1986). Phosgene is also used in the polycarbonate industry and in the manufacture of carbamates and related pesticides, dyes, pharmaceuticals, and isocyanates.

As mentioned earlier, the primary exposure route for phosgene is by inhalation. Suspected sources of atmospheric phosgene are fugitive emissions, thermal decomposition of chlorinated hydrocarbons, and photo-oxidation of chloroethylenes. Individuals are most likely to be exposed to phosgene in the workplace during its manufacture, handling, and use (USEPA, 1986). Phosgene is extremely toxic by acute (short-term) inhalation exposure. Severe respiratory effects, including pulmonary edema, pulmonary emphysema, and death have been reported in humans. Severe ocular irritation and dermal burns may result following eye or skin exposure. Chronic inhalation exposure to phosgene has been shown to result in some tolerance to the acute effects noted in humans, but may also cause irreversible pulmonary changes of emphysema and fibrosis (US Department of Health and Human Services, 1993).

Primarily because of phosgene's early use as a war gas, many exposure studies have been performed over the past 100 years to examine the effects and mode of action of phosgene following a single, acute (less than 24 h) exposure. Many studies have examined the effects of acute phosgene

exposure in animals but the human data are limited to case studies following accidental exposures.

Most studies were performed in rodents and dogs, with exposure concentrations ranging between 0.5 and 40 ppm (2–160 mg/m^3) and duration intervals ranging from 5 min to 8 h. Acute exposure studies in animals suggest that rodent species may be more susceptible to the edematous effects of phosgene acute exposure than larger species with lower respiratory volumes per body weight such as dogs and humans (Pauluhn, 2006; Pauluhn *et al.*, 2007).

Pauluhn *et al.* (2007) reported that acute phosgene exposure results in increased lung lavage protein, phospholipid content, enzyme levels, number of inflammatory cells, and lethality (LC_{50}). Rats seem to be able to survive approximately three-fold higher levels of lung edema than humans (100-fold versus 30-fold), thus rat responses in short- and long-term assays may still be relevant to humans even if it is ultimately shown that rats produce higher levels of edema following acute phosgene exposure.

1. Immunotoxicity

Acute exposure to phosgene has been shown to result in immunosuppression in animals, as evidenced by an increased susceptibility to *in vivo* bacterial and tumor cell infections (Selgrade *et al.*, 1989) and viral infection (Ehrlich and Burleson, 1991) as well as a decreased *in vitro* virus-killing and T cell response (Burleson and Keyes, 1989). Selgrade *et al.* (1989) reported that a single 4 h exposure to phosgene concentrations as low as 0.025 ppm significantly enhanced mortality due to streptococcal infection in mice. Furthermore, when the exposure time was increased from 4 to 8 h, a significant increase in susceptibility to streptococcus was seen at an exposure concentration of 0.01 ppm.

Selgrade *et al.* (1995) administered *Streptococcus zooepidemicus* bacteria via an aerosol spray to the lungs of male Fischer 344 rats immediately after phosgene exposure and measured the subsequent clearance of bacteria. They also evaluated the immune response, as measured by an increase in the percentage of polymorphonuclear leukocytes (PMN), in lung lavage fluid of uninfected rats similarly exposed to phosgene. This experiment showed that all phosgene concentrations from 0.1 to 0.5 ppm impaired resistance to bacterial infection and that the immune response is stimulated by phosgene exposure. After 4 weeks following exposure, bacterial resistance as well as immune response returned to normal.

Yang *et al.* (1995) also reported a decrease in bacterial clearance in the lungs at 24 h after infection following a single 6 h exposure to phosgene concentrations of 0.1 and 0.2 ppm. In comparison with single exposures, the multiple daily exposures extending to 4 and 12 weeks in the Selgrade *et al.* (1995) report showed a slight enhancement of effect in the 0.1 ppm group at 24 h post-infection, but no ''adaptation'', or lessening of the effect. Yang *et al.* (1995) found that if the bacteria are administered 18 h after single phosgene exposures rather than immediately, the clearance is normal which indicates that recovery from the toxic effect of phosgene is rapid.

When inhaled, phosgene either is rapidly hydrolyzed to HCl and CO_2 and exhaled (Schneider and Diller, 1989; Diller, 1985) or penetrates deep into the lungs and is eliminated by rapid reactions with nucleophilic constituents of the alveolar region (Pauluhn *et al.*, 2007). As phosgene is electrophilic, it reacts with a wide variety of nucleophiles, including primary and secondary amines, hydroxy groups, and thiols. In addition, it also reacts with macromolecules, such as enzymes, proteins, or other polar phospholipids, resulting in a marked depletion of glutathione (Sciuto *et al.*, 1996) and forms covalent adducts that can interfere with molecular functions. Phosgene interacts with biological molecules through two primary reactions: hydrolysis to hydrochloric acid and acylation reactions. Although the hydrolysis reaction does not contribute much to its clinical effects, the acylation reaction is mainly responsible for the irritant effects on mucous membranes. The acylation reactions occur between highly electrophilic carbon molecules in phosgene and amino, hydroxyl, and sulfhydryl groups on biological molecules. These reactions can result in membrane structural changes, protein denaturation, and depletion of lung glutathione. Acylation reactions with phosphatidylcholine are particularly important as it is a major constituent of pulmonary surfactant and lung tissue membranes. Exposure to phosgene has been shown to increases the alveolar leukotrienes, which are thought to be important mediators of phosgene toxicity to the alveolar–capillary interface. Phosgene exposure also increases lipid peroxidation and free radical formation. These processes may lead to increased arachidonic acid release and leukotriene production. Proinflammatory cytokines, such as interleukin-6, are also found to be substantially higher 4–8 h after phosgene exposure. In addition, studies have shown that post-exposure phosphodiesterase activity increases, leading to decreased levels of cyclic AMP. Normal cAMP levels are believed to be important for maintenance of tight junctions between pulmonary endothelial cells and thus for prevention of vascular leakage into the interstitium. Oxygenation and ventilation both suffer, and breathing is dramatically increased.

Schneider and Diller (1989) and Diller (1985) reported that inhalation of phosgene at high concentrations results in a sequence of events, including an initial bioprotective phase, a symptom-free latent period, and a terminal phase characterized by pulmonary edema. The first is an immediate irritant reaction likely caused by the hydrolysis of phosgene to hydrochloric acid on mucous membranes, which results in conjunctivitis, lacrimation, and oropharyngeal burning sensations. This symptom complex occurs only in the presence of high-concentration (>3–4 ppm) exposures but does not have any prognostic value for the timing and severity of later respiratory symptoms. The most important finding to identify during this stage is a laryngeal

irritant reaction causing laryngospasm, which may lead to sudden death. The irritant symptoms last only a few minutes and then resolve as long as further exposure to phosgene ceases.

The second phase, when clinical signs and symptoms are generally lacking, may last for several hours after phosgene exposure. The duration of the latent phase is an extremely important prognostic factor for the severity of the ensuing pulmonary edema. Patients with a latent phase of less than 4 h have a poor prognosis. Increased physical activity may shorten the duration of the latent phase and worsen the overall clinical course. Unfortunately, there are no reliable physical examination findings during the latent phase to predict its duration. However, histologic examination reveals the beginnings of an edematous swelling, with exudation of blood plasma into the pulmonary interstitium and alveoli. This may result in damage to the alveolar type I cells and a rise in hematocrit. The length of this phase varies inversely with the inhaled dose. The third clinical phase peaks approximately 24 h after an acute exposure and if lethality does not occur, recedes over the next 3–5 days. In the third clinical phase of phosgene toxicity, the accumulating fluid in the lung results in edema. Oxygenation and ventilation both suffer, and the breathing is dramatically increased. Often positive end expiratory pressure (PEEP) is required to stent open alveoli that would otherwise collapse and result in significant ventilation/perfusion (V/Q) mismatch. This hyperventilation causes the protein-rich fluid to take on a frothy consistency. A severe edema may result in an increased concentration of hemoglobin in the blood and congestion of the alveolar capillaries.

Increased levels of protein in bronchoalveolar lavage have been shown to be among the most sensitive endpoints characterizing the early, acute effects of phosgene exposure, and are rapidly reduced after the cessation of exposure (Sciuto, 1998; Schiuto *et al.*, 2003). With continuous, chronic, low-level phosgene exposure, there may be transition of edema to persistent cellular inflammation leading to the synthesis of abnormal Type I collagen and pulmonary fibrosis. An increased synthesis of Type I relative to Type III collagen can lead to chronic fibrosis (Pauluhn *et al.*, 2007). Surfactant lipids are important for maintaining alveolar stability and for preventing pulmonary edema. Pauluhn *et al.* (2007) reported that the induction of surfactant abnormalities following phosgene exposures is a key pathophysiological event leading to pulmonary edema and chronic cellular inflammation, leading to the stimulation of fibroblasts and the synthesis of ‘‘abnormal’’ collagen in pulmonary fibrosis. As discussed earlier, a breach in the chemical layer of defense followed by pulmonary edema may lead to a cascade of other immunological responses/reactions. There are limited studies, in both humans and experimental animals, to evaluate immunotoxicity of chronic low-level environmental exposures to phosgene. The lack of studies examining the effects in humans or laboratory animals from chronic exposure to phosgene is a concern and the sequela of effects leading to phosgene-induced pulmonary fibrosis is not well understood.

D. Blood Agents

Agents like SA (arsine), cyanide, and carbon monoxide are absorbed into the blood and affect its oxygen carrying capacity, and are thus termed blood agents. They are highly volatile and rapidly acting, and produce seizures, respiratory failure, and cardiac arrest. Hydrogen cyanide has been known as a potent toxicant for over 200 years. It was used as a chemical warfare agent during World War I by France. Although it is highly volatile (and was later considered ‘‘militarily useless’’ because of its volatility), no deaths from its military use during World War I were ever reported. After World War II, the importance of hydrogen cyanide as a chemical warfare agent diminished rapidly, primarily as a result of the rise of nerve agents. Although reduced in importance, there are some reports of hydrogen cyanide being used as a war gas by Vietnamese forces in Thailand territories and during the Iran–Iraq War in the 1980s (Sidell, 1992).

Hydrogen cyanide can be detoxified rapidly by humans. It is very volatile and massive amounts of the gas are needed for it to be effective as a chemical warfare agent. Cyanide is primarily an environmental contaminant of industrial processes. It is used in the metal-processing industry for electroplating, heat treating, and metal polishing and can be found in waste waters from many mining operations that use cyanide compounds in the extraction of metals, such as gold and silver, from ore.

The acute toxicity of cyanide has been well documented in humans and experimental animals. Symptoms of toxicity in humans include headache, breathlessness, weakness, palpitations, nausea, giddiness, and tremors (Gupta *et al.*, 1979). Depending on the degree of intoxication, symptoms may include ‘‘metallic’’ taste, anxiety and/or confusion, headache, vertigo, hyperpnea followed by dyspnea, convulsions, cyanosis, respiratory arrest, bradycardia, and cardiac arrest. Death results from respiratory arrest (Berlin, 1977). Onset is usually rapid. Effects on inhalation of lethal amounts may be observed within 15 s, with death occurring in less than 10 min. Hydrogen cyanide should be suspected in terrorist incidents involving prompt fatalities, especially when the characteristic symptoms of nerve agent intoxication are absent. Chronic exposure to low-level cyanide can result in neuropathies, goiter, and diabetes. Cyanide and derivatives prevent the cells of the body from using oxygen. Cyanide acts by binding to mitochondrial cytochrome oxidase, blocking electron transport, thus inhibiting enzymes in the cytochrome oxidase chain and in turn blocking oxygen use in metabolizing cells and preventing the use of oxygen in cellular metabolism. These chemicals are highly toxic to cells and in high doses may result in death. Cyanide is more harmful to the heart and brain as these organs require large amounts of oxygen.

1. Immunotoxicity

There are very few reports on immunotoxicity of the compound; however, acrylonitrile (vinyl cyanide, VCN), an environmental pollutant which is metabolized to cyanide, has been shown to be an animal and human carcinogen particularly for the gastrointestinal tract (Mostafa *et al.*, 1999; National Toxicology Program Technical Report Series, 2001). Earlier Hamada *et al.* (1998) evaluated the systemic and/or local immunotoxic potential of VCN and demonstrated that VCN induces immunosuppression as evident by a decrease in the plaque forming cell (PFC) response to SRBCs (sheep red blood cells), a marked depletion of spleen lymphocyte subsets, as well as bacterial translocation of the normal flora leading to brachial lymph node abscess. These results suggested that VCN has a profound immunosuppressive effect which could be a contributing factor in its gastrointestinal tract carcinogenicity.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

The immune system is extremely vulnerable to the action of xenobiotics for several reasons. The immune response is associated with rapidly multiplying cells and synthesis of regulatory/effector molecules and the immune system works as an amplifier for this integrated information network. Immunologic tissue damage can result from activation of the cellular and biochemical systems of the host. The interactions of an antigen with a specific antibody or with effector lymphocytes trigger the sequence of humoral and cellular events to produce the pathophysiologic effects that lead to tissue injury or disease. Stem cells often appear to be sensitive targets for therapeutic and environmental toxicants, most likely because of their rapid proliferation. Xenobiotics or various drugs that are toxic to the myelocytes of the bone marrow can cause profound immunosuppression due to loss of stem cells.

Humans are now under sustained and increasing pressure of xenobiotics exposure. Xenobiotics can stimulate the immune system as antigens by provoking a substantial immune response. Even mild disturbances of this network could result in detrimental health effects. The influence of the xenobiotics on the immune system is either suppressive or enhancing. The former leads into immunosuppression with consequent increased susceptibility to infection and cancer. The latter is associated with the development of autoimmune reactivity such as delayed hypersensitivity, atopy, systemic or organ-specific immunopathology, and granulomas formation. It is likely that overall immunosuppressive effects of xenobiotics are caused by the interference with cellular proliferation and differentiation, downregulation of the cytokine signaling, and enhanced apoptosis of immune cells. In contrast, autoimmune reactions are induced by abnormal activation of immune cells followed by dysregulated production of cytokines resulting in harmful inflammatory response.

The field of immunotoxicology is new but developing rapidly. Attempts must be made to conduct basic research to address the cellular and molecular mechanism of immunomodulatory action of various xenobiotics. The newly emerging technologies such as genomics, proteomics, and bioinformatics will be certainly helpful to investigate the interactions between the immune system and xenobiotics in their full complexities. Toxic compounds may be antigenic or act as haptens and can evoke an antibody response. If these antibodies bind to the determinant on the parent molecule which is responsible for causing toxicity, then it can lead to the biological inactivation of the parent molecule and thereby prevent toxicity. This may constitute an immunological antidote approach to neutralize the toxicity of certain compounds. Thus, passive administration of the antibodies may be used to prevent the toxic effects of the specific compound and this approach may be useful in biological or chemical warfare to protect against the toxicity of known chemicals or toxins. The antibodies can also be used to protect industrial workers against the toxic effects of known chemicals or gases during accidental exposure. Although this assumption seems logical, it will involve elaborate and time-consuming research to identify the site of the parent molecule responsible for causing toxicity, to chemically link the molecule with a large protein molecule which should be immunogenic but not toxic, and to screen various antibodies raised for their capacity to prevent the toxicity of the compound.

In view of the current global scenario, it appears that CWAs are likely to be used in different types of warfare, and it is unlikely their usage will cease in the near future. CWAs for warfare and other related activities are here to stay. These agents are not only inexpensive but easy to disseminate with the help of unsophisticated devices. Hence the medical profession should assemble on a common platform through globally recognized organizations like the WHO and put in efforts to monitor, research, and study the scientific and medical aspects of CWAs in the interest of humankind. Guidelines should be regularly updated on the prevention and management of CWA-induced insults and thereby aim to reduce morbidity and mortality. Nations worldwide should ensure that adequate supplies of antidotes (wherever available), protective equipment, and decontamination devices are available in adequate quantities and at all times. The need of the hour is a multisectorial approach involving health, defense, agriculture, and environmental specialists, with clearly defined roles of each, for establishing and maintaining effective, robust, and sustainable strategies to countermeasure this threatening situation.

CHAPTER 41

Dermal Toxicity of Sulfur Mustard

DONALD R. GERECKE, JOSHUA P. GRAY,* MICHAEL P. SHAKARJIAN, AND ROBERT P. CASILLAS

I. INTRODUCTION

Skin integrity is in part determined by the interaction of a number of proteins that form a continuum of molecules linking together to ensure the epidermis and dermis are tightly attached to one another. These macromolecules include the keratins that form the intermediate filaments in the cytoplasm of keratinocytes, integrins which are made of two subunits and found in the hemidesmosomes of the basal keratinocyte membrane, and a variety of laminins, collagens, and their receptors, situated both in the basement membrane that separates the epidermis from the dermis, and in the dermis itself. Any chemical agent that disrupts this continuum of linking proteins will result in a breach in skin integrity and ensuing histopathology (Uitto *et al.*, 2007). One such compound is the alkylating agent sulfur mustard [bis(2-chloroethyl) sulfide; HD; SM], which causes detachment of the epidermis from the dermis. (This chapter uses the abbreviation SM for sulfur mustard since in civilian dermatological research HD is the abbreviation for the hemidesmosome, an important morphological structure found in the cell membrane of keratinocytes.) Skin exposure to SM starts a complex series of events with a host of normal skin responses to wounding which interact with, influence, and regulate each other to result in cutaneous toxicity. Various mediators of injury that regulate inflammation, immune responses, cell death, and a number of signaling pathways have been implicated in the process. This chapter describes our current knowledge of the cutaneous actions of SM, discussing the basic mechanism of action and mediators involved, to provide for the reader a comprehensive understanding of the histopathology of SM-exposed skin. The injury process is described and SM-induced injury is compared to other types of wound injury. Additionally, various SM-injury models are described and potential therapeutic countermeasures discussed.

*Joshua P. Gray is a Professor of Chemistry at the US Coast Guard Academy. The views expressed here are his own and not those of the Academy or other branches of the US government.

II. BACKGROUND

A. Military Use

Sulfur mustard, a vesicant or blistering agent, has been used intermittently as a chemical warfare agent since 1917 when Germany first used it as a weapon against British soldiers in Ypres, Belgium. Subsequently in the 1930s it was reported to be used by Italy against Abyssinia (Ethiopia), Poland against Germany, and Japan against the Chinese. During the 1960s SM was allegedly used by Egypt against Yemen. The last well-documented use in the 1980s was by Iraq against Iran and the Kurds (Papirmeister *et al.*, 1991a).

B. Wound Repair

Even repair of the simplest skin wound requires the coordination of a number of physiological processes and events. The tissue injury causes blood vessel disruption and an activation of the inflammatory pathway that releases a battery of mediators. Re-epithelialization requires activation of additional pathways and the initiation of specific events at specific times, such as extracellular matrix remodeling and the proliferation and migration of keratinocytes. If these events are not precisely coordinated, the end result can be delayed healing and/or scar formation. Since the repair process is complicated, a review of the wound healing events in dermal injury might be helpful. There are at least three phases to wound healing following dermal injury (Gurtner *et al.*, 2008). (1) Inflammation (first 24–48 h). This phase occurs early and involves activation of the coagulation cascade, inflammatory pathways, and immune system. These biological processes involve an attempt to maintain homeostasis by preventing blood and fluid loss, removing dead tissue, and preventing infection. (2) Wound repair phase (2–10 days after injury). This phase involves the proliferation and migration of several cell types. Keratinocytes migrate over the injured dermis, endothelial cells proliferate to form new blood vessels, and fibroblasts differentiate into myofibroblasts in order to initiate wound contraction. (3) Remodeling phase (2–3 weeks post-injury). This phase results in the final wound repair. All the activated cellular processes turn off. Many cell types undergo apoptosis or leave the wound site.

The extracellular matrix is remodeled and resumes normal functions.

These same basic phases are applicable to the injury caused by SM, but the pathology frequently is more severe than other types of dermal wounds and the basic timing of the various phases may be extended in SM injury (Papirmeister *et al.*, 1991a; Dacre and Goldman, 1996; Balali-Mood and Hefazi, 2006). Normal clothing provides little protection to the skin from a liquid or vapor exposure to SM. Once in contact with the skin, the lipophilic properties of SM allow it to rapidly penetrate the epidermal barrier, while its high reactivity and bifunctional nature lead to alkylation of a wide range of molecules (Figure 41.1). The ultimate injury caused by SM is highly dependent on the dose and length of exposure to the agent resulting in a wide range of histopathology. Erythema, resembling sunburn, may be the mildest and earliest form of skin injury (Figure 41.2), occurring 2 to 48 h post-SM exposure (USAMRICD, 2007). The erythema may be accompanied by pruritus or burning pain and small vesicles may eventually develop which coalesce to form bullae. Fluid-filled blisters increase in size, their color ranging from yellowish to tan. The fluid itself does not contain active alkylating agent, nor is it a vesicant. When SM is applied as a liquid, the exposure concentration is even higher than a vapor application and severe lesions are more likely. The resultant wounds are prone to secondary infections and may cause chronic ulcers that are resistant to wound repair. There may be permanent pigmentation changes in the skin after exposure to SM. Clearly, the effects of SM on skin are complex and involve many systems and pathways. The following sections attempt to address the mechanism of action of SM and the systems and pathways involved in an organized way.

III. PATHOGENESIS

The bulk of what is known about human skin injury from SM has been gathered from victims of the military use of the compound (Balali-Mood and Hefazi, 2006; Hefazi *et al.*, 2006; Requena *et al.*, 1988). Nevertheless, there are several reports where the cutaneous vesicating effects of SM were studied experimentally in human subjects (Papirmeister *et al.*, 1991a, b; Dacre and Goldman, 1996). In one comparative study (Daily *et al.*, 1994) 12 volunteers had forearm vapor cup applications of SM, trifunctional nitrogen mustard (HN3), and lewisite. The conclusions were

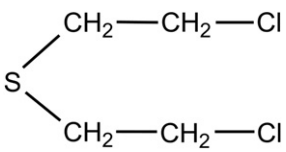

FIGURE 41.1. Chemical structure of sulfur mustard [bis(2-chloroethyl) sulfide].

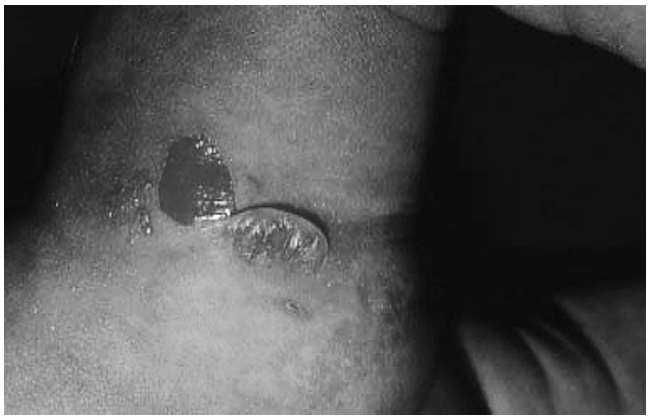

FIGURE 41.2. Fluid-filled bullous of patient with epidermolysis bullosa caused by truncated gamma-2 polypeptide chain of laminin-332 (formerly laminin 5, a heterotrimeric glycoprotein).

that SM exposure caused the largest vesicles formed, the earliest peak vesication, the longest healing time, and the most severe final scar. Lewisite was the second most potent agent and HN3 the least potent, although the HN3 lesions had the most edema of the three vesicants examined. The results confirmed the previously published studies which followed the development of skin pathogenesis after topical exposure to SM.

Clinical injury by SM has been extensively reviewed and will be summarized here. Sulfur mustard injury to human skin begins almost immediately after exposure when the highly reactive bifunctional SM directly alkylates resident proteins. However, recognizable skin pathology does not usually occur for several hours to a day after exposure. The very first physical sign of SM exposure is usually erythema which may or may not be associated with itching (Papirmeister *et al.*, 1991a). This is often followed later by distinct fluid-filled blisters that break open and become covered with a scab. Many researchers have noted that the blisters resemble those formed by epidermolysis bullosa (EB), a genetic or acquired skin pathology that results in a separation of the epidermis from the dermis (Figure 41.2). In both SM exposure and EB, there may be multiple rounds of blistering and healing in an individual (Balali-Mood and Hefazi, 2005; Pillay, 2008). In fact some of the therapeutic agents for EB are being tested as potential medical countermeasures against SM injury. These will be addressed later.

A. Cytotoxicity of Sulfur Mustard

While stable in lipophilic solvents, SM has a half-life of only 24 min at room temperature in aqueous physiological solutions since it rapidly reacts with water to form thiodiglycol and HCl. This rapid activation of SM in an aqueous environment also allows it to react with small molecules of biological interest, as well as proteins, carbohydrates, lipids, RNA, and DNA (Bartlett and Swain, 1949; Debouzy *et al.*, 2002; Noort *et al.*, 2002; Papirmeister *et al.*, 1991c).

The initial reaction involves the formation of a cyclic ethylene sulfonium ion which readily targets reactive groups on skin components, including sulfhydryls, phosphates, ring nitrogens, and carboxyl groups. As a bifunctional alkylating agent, SM forms monofunctional adducts and intra- and intermolecular crosslinks. Since it is so reactive and indiscriminate in its molecular targets, SM affects many pathways and is cytotoxic on many levels. There are at least three independent mechanisms of cytotoxicity that have been proposed and each will be addressed in separate sections.

1. Alkylation of DNA/Poly(ADP-Ribose) Polymerase (PARP) Activation

One of the major targets of SM alkylation is DNA which it can form both monofunctional adducts and bifunctional crosslinks (Papirmeister *et al.*, 1991c). Complementary DNA strand and intrastrand crosslinks occur after SM exposure (Walker, 1971). The crosslinking of cellular DNA underscores the importance of DNA repair pathways in preventing cytotoxicity of SM-exposed cells. These repair pathways include both the nucleotide and base excision pathways (Matijasevic and Volkert, 2007).

DNA alkylation can also lead to single and double strand DNA breaks. These breaks trigger activation of a family of nuclear repair enzymes called poly(ADP-ribose) polymerases (PARP) (Papirmeister *et al.*, 1985; Shall and de Murcia, 2000). While low levels of PARP activation may signal repair, excessive activity can deplete cells of PARP's major substrate, NAD^+. Depletion of NAD^+ in turn inhibits ATP production, which is essential for metabolism (Martens and Smith, 2008). Apoptosis or necrosis may result, depending upon level of ATP depletion, cell type and other factors (Rosenthal *et al.*, 2001). Preventing the depletion of NAD^+ by interfering with PARP activation has been the rationale for testing PARP inhibitors as therapeutic countermeasures (Debiak *et al.*, 2008). To date, the literature suggests this strategy has been unsuccessful *in vivo* (Casillas *et al.*, 2000b).

2. Reactions with Glutathione/Lipid Peroxidation

Another hypothesis explaining the alkylation effects of SM is that it reacts with the free radical scavenger glutathione (GSH). GSH is able to neutralize free radicals in the cytoplasm that might be harmful to the cytosol of cells, including free radicals that are by-products of oxidative phosphorylation. Glutathione peroxidase catalyzes the reaction of reduced glutathione with hydrogen peroxide. Depletion of intracellular GSH allows the accumulation of oxidants such as H_2O_2 which become abundant and actively contribute to lipid peroxidation and other types of cellular damage. Dermatotoxic agents such as ultraviolet radiation (UVA) and psoralens have been shown to deplete intracellular glutathione, resulting in cellular toxicity (Wheeler *et al.*, 1986). Furthermore, depletion of intracellular reduced glutathione by buthionine sulfoxamine sensitizes cells treated *in vitro* with 10 μM SM (Gross *et al.*, 1993). In other tissues, SM exposure has been shown to reduce glutathione peroxidase and glutathione reductase activity, potentially contributing to the depletion of reduced glutathione (Husain *et al.*, 1996; Jafari, 2007). In the skin, glutathione peroxidase gene expression is increased following SM treatment in the mouse ear vesicant model, suggesting that this enzyme is important in reducing oxidative stress due to SM exposure (Buxton *et al.*, 2001).

3. Reactions with Glutathione/Calcium Homeostasis

Depletion of GSH also affects calcium homeostasis; treatment of primary human epidermal keratinocytes with buthionine sulfoxamine depressed the level of reduced glutathione but increased intracellular Ca^{2+} (Ray *et al.*, 1993). Neuroblastoma cells treated *in vitro* with 0.3 mM SM maintained high cell viability for nearly 9 h, which then decreased with time. The decrease in cell viability was prefaced by an increase in free intracellular calcium that occurred between 2 and 6 h post-exposure (Ray *et al.*, 1995). Intracellular free calcium is a well-recognized marker of cell stress (Ruff and Dillman, 2007). Induction of intracellular calcium is thought to contribute to apoptosis induced by SM exposure in keratinocytes *in vitro* (Rosenthal *et al.*, 2003). Despite these findings, Sawyer's group has shown that the sensitivity of primary human keratinocytes to SM was unaffected when calcium was reduced using chelators or increased using the membrane ionophore ionomycin (Sawyer and Hamilton, 2000). These findings suggest that although calcium levels are significantly altered by SM treatment, modulation of calcium alone is neither necessary nor sufficient for SM-induced apoptosis.

B. Inflammation

Inflammation is likely one of the major driving forces of the skin pathology caused by SM exposure. The contribution of cytokines to the inflammatory events is well established and their signaling pathways are important targets of medical intervention for potential countermeasures of vesicant injury. The literature linking inflammation and wounding is so extensive as to fill a book by itself. This section will therefore only present an overview of the inflammatory response to dermal skin injury. In short, cytokine signaling involves several Janus kinase (Jak)-signal transducer and activator of transcription (Stat) pathways (O'Shea and Murray, 2008). These pathways are the major regulators of all the cell types involved in inflammation and they can be either positive or negative mediators to the inflammatory process. Both pro-inflammatory and anti-inflammatory events are under the influence of the Jak-Stat pathways and hundreds of cytokine receptors are regulated via these pathways including more than 40 type I and type II cytokine receptors, and receptors for interleukins, interferons, growth stimulating factors, leptin, erythropoietin, and many more.

As for vesicant-injured skin, the inflammatory response appears to be biphasic. This is based upon our years of experience in addition to others who reported that inflammation played a minor role in the initial events of SM-induced cutaneous injury, but had much greater importance at later stages (Papirmeister *et al.*, 1991c). In a more recent examination, Cowan and Broomfield (1993) argued that inflammation may be more significantly involved in the vesication event than previously believed, with inflammatory cells and mediators contributing directly to the formation of the primary lesion.

Numerous accounts, from both *in vivo* and *in vitro* studies, have now documented a rise in a number of inflammatory cytokines in response to SM. Applications of SM in the mouse ear vesicant model (MEVM) have resulted in induction of IL-1β, IL-6, TNFα and GM-CSF within 6 h (Sabourin *et al.*, 2000; Wormser *et al.*, 2005). While IL-1α was not detected in these studies, its inducibility by SM vapor was confirmed in experiments in which the backs of hairless mice were exposed (Ricketts *et al.*, 2000). Further, relative mRNA levels of IL-1β, IL-6, IL-8, and TNFα have been demonstrated to significantly rise within 24 h of SM vapor treatment in full thickness skin biopsies from weanling pigs (Sabourin *et al.*, 2002). Studies with cultured human keratinocytes have shown that these cells respond directly to SM with the production of cytokines. Interleukins-1β, -6, -8, and TNFα were detectable in culture media from these cells 24 h after treatment with 100–300 μM SM (Arroyo *et al.*, 2000). Cultured skin fibroblasts have also been shown to express TNFα in response to SM. The chemotactic activity of keratinocyte-derived IL-8 could initiate the transmigration of circulating granulocytes into SM exposed tissues where they could contribute to the primary lesion. Other cytokines may be involved in priming and activation of the recruited immune cells. While cytokine induction may occur via several means, there is now ample evidence that the inflammatory transcription factor NF-κB is one such pathway activated by SM (Atkins *et al.*, 2000; Minsavage and Dillman Iii, 2007; Rebholz *et al.*, 2008). In fact, enhanced synthesis of the aforementioned cyokines in resident skin cells may occur as a result of this NF-κB activation (Ghosh *et al.*, 1998).

Additional inflammatory mediators have been detected in cutaneous tissues as a consequence of SM treatment. These include free arachidonic acid (Lefkowitz and Smith, 2002) and its cyclooxygenase (Dachir *et al.*, 2004; Rikimaru *et al.*, 1991) and lipoxygenase products (Tanaka *et al.*, 1997). Furthermore, the increased capillary permeability observed would allow a variety of circulating inflammatory participants, such as complement components, kininogens, etc., to enter the dermal interstitium (Rikimaru *et al.*, 1991). Clearly, vesicant injury involves a host of inflammatory mediators similar to those seen in other types of wounds, where individual cytokines have been singled out as potential therapeutic targets.

C. Protease Activation

While there may be protease involvement in the initial SM injury, most studies have viewed the involvement of serine and matrix metalloproteases (MMPs) in SM injury as a downstream event since MMPs in particular regulate various inflammatory and repair processes (Parks *et al.*, 2004). The regulatory role confounds the potential use of MMP inhibitors as therapeutic agents because they play a beneficial role in wound repair and skin degradation. Increased protease activity following SM exposure has been reported *in vitro* in human peripheral blood lymphocytes (PBL) (Cowan *et al.*, 1993) and human epidermal keratinocytes (Smith *et al.*, 1991), *ex vivo* in rabbit skin organ cultures (Higuchi *et al.*, 1988; Woessner *et al.*, 1990) and human skin explants (Lindsay and Rice, 1996; Rikimaru *et al.*, 1991), *in vivo* in hairless guinea pig skin (Cowan *et al.*, 1993, 1994; Kam *et al.*, 1997), and *in vivo* in the mouse ear (Powers *et al.*, 2000) and hairless mouse (Casillas *et al.*, 2000a). The continued assessment of proteolytic activity in animal models is useful for characterizing specific proteases important to SM injury and for identifying effective protease inhibitors with therapeutic use in reducing or eliminating tissue injury caused by SM cutaneous exposure. The relationship between SM-increased protease activity and the subsequent vesication (blistering) that occurs in SM lesions remains unclear, but emerging literature implicating protease involvement is consistent with the known ability of proteases to degrade basement membrane components *in vitro* and *in vivo*. Inhibition of these proteases should reduce the extent of the injury, promote a more rapid recovery, and provide a useful adjunct to other therapeutic strategies aimed at preventing SM-induced degenerative pathophysiological events (Cowan and Broomfield, 1993).

D. Immune Response

Vesicant wounds undoubtedly initiate an immune response due to the nature of the wounds. This response begins almost immediately when the initial events promote capillary permeability, and the interstitium becomes inundated with circulatory components. And the wound site itself is subject to secondary infections by pathogens that reach the open wound area. These pathogens may be responsible for the large number of infiltrating cells that are seen in the mouse ear vesicant model 7 days post-SM exposure (Figure 41.3).

E. Apoptosis

Mechanisms underlying SM-induced apoptosis have been carefully explored using primary cultures of human keratinocytes. Treatment of keratinocytes with 100–300 μM SM resulted in activation of both caspase 8, which initiates the Fas-dependent death receptor pathway, and caspase 9,

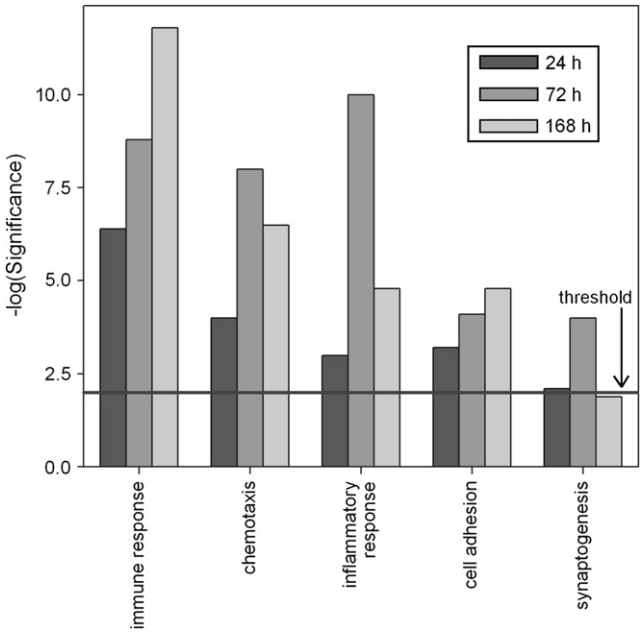

FIGURE 41.3. Results of biological processes sorting for microarray data from three different timepoints after sulfur mustard exposure using the mouse ear vesicant model. The timepoints were 24, 72, and 168 h post-exposure. The bars represent positive fold change increases over the carrier solvent alone samples. The immune response genes were within the top three biological processes activated for all the timepoints studied.

which initiates the mitochondrial apoptotic pathway (Rosenthal *et al.*, 2003). Fas and Fas ligand (FasL) were up-regulated in a concentration-dependent manner by SM leading to activation of caspase 3, the central executioner protease. Transfection of immortalized keratinocytes with a dominant negative Fas activated death domain (FADD) resulted in a blunted caspase response to SM. Microvesication and tissue injury produced *in vivo* by SM exposure of transfected cells after grafting onto athymic nude mice was also reduced by this treatment.

Changes in intracellular calcium levels are known to activate the mitochondrial pathway of apoptosis. A key regulator to Ca^{2+}-dependent proteins is calmodulin. SM has been shown to cause a time-dependent induction of calmodulin in keratinocytes (Simbulan-Rosenthal *et al.*, 2006). Moreover, depletion of calmodulin using antisense probes attenuated SM-induced activation of caspases involved in the mitochondrial pathway of apoptosis. Both antisense and pharmacological inhibition of calmodulin prevented SM-induced nuclear fragmentation in the keratinocytes. Bad, a proapoptotic Bcl-2 family member present in an inactive phosphorylated form in viable cells, was also activated by SM. Furthermore, cyclosporine A, a selective inhibitor of calcineurin, a Bad phosphatase, inhibited SM-induced keratinocyte apoptosis. These results suggest that calcium-dependent activation of Bad may be a mechanism by which SM induces apoptosis in keratinocytes.

One form of cellular demise common to epithelial cells is detachment-initiated apoptosis, also referred to as anoikis (Frisch and Francis, 1994). Epidermal keratinocytes rely on signals derived from the surrounding extracellular matrix (ECM) for survival. It is possible that loss of these signals plays a role in SM-induced epidermal cell injury, and that cell detachment from the basal lamina precedes cytotoxicity. Several lines of evidence support this possibility. First, SM can alter the dynamics of cytosolic proteins that exert control over the attachment of cells to the basement membrane. For example, SM can modify intracellular actin microfilaments and keratin intermediate filaments known to be important in maintaining epithelial cell connections with the basal lamina. Thus, Hinshaw *et al.* (1999) reported that SM causes changes in the actin microfilament architecture and morphology of human keratinocytes within 3 h of exposure. This was associated with a significant decrease in keratinocyte adherence without evidence of cytotoxicity. In addition, Werrlein and Madren-Whalley (2000) found that SM caused rapid, significant decreases in immunodetection of keratins 5 and 14, an intermediate filament pair found in undifferentiated keratinocytes. In both *in vivo* (Gunhan *et al.*, 2004) and *in vitro* studies with human keratinocytes (Dillman *et al.*, 2003), and with purified proteins (Hess and FitzGerald, 2007), keratins 5 and 14 have been found to be alkylated by SM as well as nitrogen mustard (mechlorethamine, HN2) and 2-chloroethyl ethyl sulfide (CEES), the monofunctional analog of SM. Sites of alkylation may be similar to dominantly acting mutations in keratins 5 and 14 that are known to be responsible for the human blistering disorder, epidermolysis bullosa simplex, in which, like SM-induced blistering, basal epidermal cells are targeted (Fuchs, 1997). The keratin cytoskeleton of basal keratinocytes links to the hemidesmosome and makes connections, through plectin, with the β4 cytoplasmic tail of integrin α6β4, thereby strengthening adhesion to the basement membrane via laminin-332 (Giancotti and Tarone, 2003). Alkylation of keratins 5 and 14 could cause aggregation and loss of function of the intermediate filament network and serve as a prelude to basal cell separation from the basement membrane.

In addition to its actions on epidermal cells, SM can directly alkylate extracellular matrix proteins in the skin, a process that can also alter the ability of basal keratinocytes to maintain vital connections with the basement membrane. In support of this idea, Gentilhomme *et al.* (1998) showed that SM treatment of human dermal equivalents reduced the ability of naïve keratinocytes to deposit laminin at the dermal–epidermal interface. In addition, Zhang *et al.* (1995a, b) found that treatment of fibronectin and laminin with SM interfered with the ability of human epidermal keratinocytes to adhere to these matrix proteins. This inhibitory action was determined to be alkylation-dependent, because it could be prevented by co-treatment with SM scavengers. Sulfur mustard and nitrogen mustard also reduce cell and tissue immunoreactivity for laminin-332, as well as integrin α6β4

and collagen XVII (also known as bullous pemphigoid antigen), two hemidesmosomal components that are critical for keratinocyte adherence (Kan *et al.*, 2003; Smith *et al.*, 1997b, 1998; Werrlein and Madren-Whalley, 2000; Zhang and Monteiro-Riviere, 1997). Interestingly, each of these proteins, like keratins, have been implicated in human blistering disorders involving separation of the epidermis at the dermal–epidermal junction (Pulkkinen and Uitto, 1998; Yancey, 2005). These findings suggest that SM can alter the interaction of basal cells with matrix proteins critical for basement membrane detachment. The alteration may occur by reducing protein functionality, decreasing protein expression, or increasing protein degradation. By whichever mechanism, a negative alteration in these critical anchoring components could lead to basal cell detachment and initiate anoikis.

F. Signal Transduction Pathways

Sulfur mustard exposure induces the activation of many molecular signaling pathways (reviewed in Ruff and Dillman, 2007). These pathways mediate many responses including inflammation, cell proliferation, cell differentiation, and apoptosis. Some that involve inflammation include the transcription factor NF-κB and the p38 MAP kinase. NF-κB is a transcription factor that is induced within 2–4 h after SM exposure (Minsavage and Dillman Iii, 2007). Dillman has suggested that this delayed induction is due to a nontraditional pathway of stimulation, whereby p90RSK phosphorylates IκB or the p65 subunit of NF-κB (Ruff and Dillman, 2007). The MAP kinase p38 is activated in response to damaging stimuli including heat, ultraviolet radiation, and pro-inflammatory stimuli. Dillman's group and others have noted an increase in activation of p38 by phosphorylation and demonstrated that inhibition of p38 phosphorylation resulted in a decrease in SM-induced pro-inflammatory cytokine production *in vitro* (Kehe *et al.*, 2008). However, the importance of NF-κB or p38 activation in mediating SM cutaneous injury has not been demonstrated *in vivo*. Also, while important for understanding SM-mediated toxicity, these pathways are difficult to target pharmacologically.

IV. MODELS OF DERMAL SULFUR MUSTARD EXPOSURE

A. Introduction

Although there has been considerable investigation of SM therapies since the publication of Bruno Papirmeister's landmark compilation of *Medical Defense Against Mustard Gas* nearly 20 years ago, no suitable treatment for SM exposure to the skin has been developed (Papirmeister *et al.*, 1991b). Since that time, there has been an increased focus on civilian research as the perceived risk of a terrorist-driven exposure to civilian populations has been recognized. The field has dramatically changed direction from strategies and therapies based on protection from SM exposure to therapies designed to subvert the blistering process and increase the rate of wound healing. New pharmaceutical strategies will be increasingly focused on combination therapies that target multiple processes in blister formation and the wound healing process, together with increased recognition of the importance of pharmaceutics.

Although many advances have been made in the production of skin barrier protection or post-exposure skin decontaminants [such as skin exposure reduction paste against chemical warfare agents (SERPACWA) and reactive skin decontamination lotion (RSDL), respectively], drug countermeasures against vesicants remain a subject of intense investigation. The primary treatment strategy following exposure to vesicants such as mustard gas is decontamination. However, given the high reactivity of SM, there is a very short timeframe (3 to 5 min) in which decontamination can be effectively accomplished (reviewed in Vogt *et al.*, 1984; Wormser, 1991); and some studies suggest that an extractable reservoir persists for much longer. Furthermore, because SM exposure does not cause immediate pain or noticeable effects, exposure is often not recognized until the effective window for decontamination has passed. Therefore, much research has focused on the identification of treatments that can be performed after exposure has occurred. These treatments can be directed at any stage during the progression of injury resulting from vesicant exposure, including before or after blister formation. This chapter focuses on the progress that has occurred since Papirmeister's publication (Papirmeister *et al.*, 1991b).

B. Model Systems for Screening Sulfur Mustard

The lack of effective *in vitro* and *in vivo* models for SM skin injury provides an ongoing challenge. No definitive animal model produces macroblister formation like that which occurs in humans, the major clinical target for SM treatments (extensively reviewed in Papirmeister *et al.*, 1991b). Furthermore, experimental animal models have different skin characteristics, including a reduced barrier for chemical penetration as compared to human skin (Bartek *et al.*, 1972). The reduced barrier results in greater systemic toxicity in animals, complicating other measures of cutaneous injury. Despite these difficulties, animal models have displayed great utility, and surrogate endpoints such as microblister formation or edema are acceptable biomarkers for measuring efficacy of candidate compounds.

A systematic characterization of animal models including the euthymic hairless guinea pig (HGP), weanling pig (WP), the mouse ear vesicant model (MEVM), and the hairless mouse (HM) showed that SM induced subepidermal blister formation and epidermal cell death in all models tested (Smith *et al.*, 1997a). Hairless mice are useful models of

human skin; the absence of hair on the skin and increased skin thickness reduce the rapid penetration of toxicants (Walter and DeQuoy, 1980). First characterized in 1967, the hairless guinea pig has been the most widely used model for vesicant exposure (Cowan *et al.*, 1993, 1994; Graham *et al.*, 1994; Kam *et al.*, 1997; Kim *et al.*, 1996; Marlow *et al.*, 1990a, b; Mershon *et al.*, 1990; Millard *et al.*, 1997; Smith *et al.*, 1995; Yourick *et al.*, 1991, 1992, 1993, 1995). Like human skin, SM-treated hairless guinea pigs experience defects in epithelial cell regeneration, basement membrane modifications, and increased necrosis and apoptosis, making them a good model for therapeutic testing (Dachir *et al.*, 2006; Kan *et al.*, 2003).

The mouse ear vesicant model (MEVM) is performed by application of vesicant to the inner (medial) side of the ear (Casillas *et al.*, 1997). Edema can be quantified by measuring 8 mm diameter ear punch biopsy weights. Microscopic investigation shows clear histopathologic changes that include edema, epidermal–dermal separation, and necrosis. These effects occur in a dose-dependent manner (Figure 41.4). This model has been used to screen many compounds and remains the most cost-effective live animal screen available (Babin *et al.*, 1999, 2003; Casillas *et al.*, 2000b; Inman *et al.*, 1999; Kiser *et al.*, 2005; Sabourin *et al.*, 2004). Furthermore, the benefits of a fully sequenced mouse genome and wide range of antibodies available make this model superior. Systemic effects do occur, as physiological and toxicological effects are detected in the contralateral (untreated) ear of animals (Babin *et al.*, 2000).

Weanling pigs (WP) have also been used extensively for SM-induced skin injury (Graham *et al.*, 1999, 2000; Logan *et al.*, 2000). Erythema was found to peak at 24 h after a 15-min vapor exposure, with maximal edema occurring at 48 h post-exposure (Graham *et al.*, 1999; Smith *et al.*, 1996, 1997a). The dermal–epidermal junction was also damaged at 48 h, with laminin 5 (renamed laminin 332) showing a progressive decrease in protein expression following SM injury (Smith *et al.*, 1997b). Furthermore, inflammatory markers including IL-8, IL-6, IL-1β, and MMP-9 are induced within 72 h of treatment with SM (Sabourin *et al.*, 2002). The weanling pig is also used as a model of wound debridement to enhance repair (Dalton *et al.*, 2008b; Graham *et al.*, 2002a, b, 2006; Reid *et al.*, 2007, 2008b), as discussed in greater detail later in this chapter.

The isolated perfused porcine skin flap (IPPSF) model is an effective *in vitro* model for SM exposure, characterized extensively by Monteiro-Riviere's laboratory (Monteiro-Riviere *et al.*, 1990). Skin flaps consist of isolated, perfused skin with intact dermis and epidermis maintained by microcirculation in a system that mimics normal blood flow. Unlike other animal models, gross blisters are obtained, with blister-induced epidermal–dermal separation occurring at the upper lamina lucida (Monteiro-Riviere and Inman, 1993, 1995, 1997; Riviere *et al.*, 1995). This model has allowed for several interesting experiments which could not have otherwise been performed. For example, the flow rate and composition of perfusing media can be altered: higher flow rate is associated with increased blister formation, whereas increased glucose in the perfusion medium has been shown to block the formation of microvesicles and blisters (Riviere *et al.*, 1997). Whether increased glucose can protect against blister development in live animals has not been tested. No reports using this model have been published since 2004.

In addition to cell lines, artificial human skin has been used to test the effects of SM (Petrali *et al.*, 1993). Human skin equivalent (HSE), commercially available as EpiDerm, is a fully differentiated artificial human skin with both a dermis and an epidermis (Monteiro-Riviere *et al.*, 1997). Full thickness models (EipDerm-FT) have been evaluated for their potential use in SM models as well (Hayden *et al.*, 2005; Paromov *et al.*, 2008). The latter model has been successfully applied for screening of antioxidant molecules in the treatment of SM injury (Paromov *et al.*, 2008). A lack of knowledge regarding the identity of important biochemical

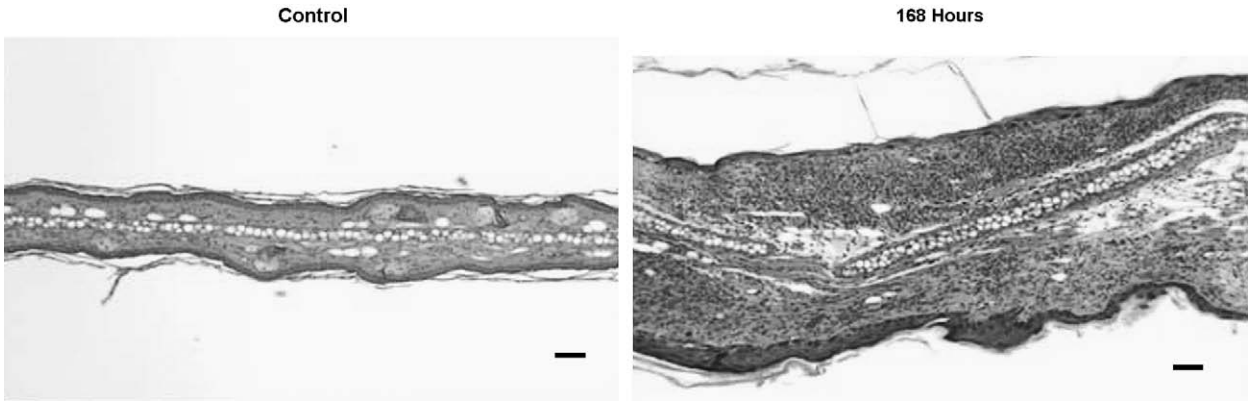

FIGURE 41.4. Biphasic inflammatory response in the MEVM: hematoxylin and eosin stained paraffin sections of mouse ears with (right, 168 h post-exposure) and without (left, carrier solvent, alone). Note the edema in the treated ear. The 168 h post-SM sample had a very large inflammatory cell infiltration (purple nuclei of thousands of infiltrating cells is apparent).

targets of SM has largely prevented the development of *in vitro* biochemical assays that might be used in rapid screening of chemical libraries.

C. Decontamination

If accomplished early, skin decontamination can be an effective means of reducing injury from SM exposure (Sidell *et al.*, 1997). Most SM decontamination strategies focus on its removal with solvents or adsorption of SM to inert substances. Even simple techniques such as washing with soap and water are surprisingly effective (Aasted *et al.*, 1987). Washing with many other substances has been suggested, including kerosene, oil, gasoline, surgical spirits, and neutral sodium hypochlorite (Chiesman, 1944; Gold *et al.*, 1993; Jelenko, 1974; Sollmann, 1919; Wormser *et al.*, 2002). Exposure to mustard liquid can also be treated with the use of binding agents, of which Fuller's earth is the best example. Fuller's earth is clay-rich soil commonly used to purify hydrophobic materials, including oils and greases (Chilcott *et al.*, 2001). In SM injury, it is thought to function by binding in a near-irreversible manner to SM, preventing its absorption, association, and reaction with skin components. Fuller's earth is the standard to which other decontamination agents are tested; modifications of this compound and other related clay-like materials may be more efficacious (Joiner *et al.*, 1987; Lyle *et al.*, 1984, 1986). However, it is difficult to contain and uncomfortable to apply. Other items, including flour and talcum powder, were shown to be effective in reducing the progression of injury (Van Hooidonk *et al.*, 1983). However, decontamination is ineffective in cases of vapor exposures to SM, which occur over a longer time period (McNamara, 1960). These results suggest that nearly anything that could adsorb a hydrophobic product would be effective in reducing SM injury.

Another strategy for decontamination is active chemical neutralization, whereby the SM undergoes a chemical reaction to prevent its reaction with outside components. There have already been successes with this type of approach, with the best example being reactive skin decontamination lotion (RSDL), a product approved for military use by the USA and a number of other nations (FDA, 2003). RSDL has been demonstrated to be as effective as Fuller's earth in its decontamination properties (Taysse *et al.*, 2007). The first generation of this product was composed of a solution of potassium 2,3-butanedione monooximate and its free oxime, diacetyl monooxime, in a mixture of monomethyl esters of polyethylene glycol. The solvent portion of the lotion is designed to solubilize chemical weapons away from the skin, while the oxime component readily reacts with mustards and with nerve agents, producing less toxic products (Sawyer *et al.*, 1991a, b). In domestic pigs, treatment with RSDL 5 min after exposure to SM resulted in significantly less injury observed 3 days post-exposure (Taysse *et al.*, 2007).

Other approaches to chemical neutralization include the use of sodium thiosulfate as a reducing agent to function by reacting with activated SM (Bonadonna and Karnofsky, 1965; Hatiboglu, 1960; Owens and Hatiboglu, 1961), reviewed in McKinley *et al.* (1982). Original studies (WW1-1970) focused on its use as an injectable drug to prevent the bone marrow suppression seen with exposure to SM and related mustard agents. Systemic administration of this and other antioxidant molecules such as *N*-acetyl cysteine is discussed later in this chapter. Another thiol, 2,3-dimercaptopropane sulfonic acid (DMPS), showed protection against injury in mice exposed to SM vapor (Pant *et al.*, 2000).

Decontamination can also be accomplished by the application of creams containing fluorinated crosslinker monomers (Liu *et al.*, 1999). Deactivation occurs when substances within the cream actively react with and decontaminate the agents. Care should be taken with administration of these creams, since they can trap chemical agents on the skin and prevent natural off-gassing. This may result in enhanced injury if inadvertently applied after exposure to a chemical agent. In some cases, perfluorinated creams have caused an 18-fold reduction in the rate of skin absorption (Chilcott *et al.*, 2002).

After exposure to SM, a significant fraction of the agent remains unreacted in the skin, in what is often described as a skin reservoir. This reservoir is thought to contribute to ongoing injury by continually releasing SM, allowing further damage to occur. Indeed, recent studies demonstrated that application of ^{14}C-labeled SM was extractable from an *in vitro* pig skin model for up to 6 h (Dalton *et al.*, 2004; Hattersley *et al.*, 2006). Future work might focus on targeting this reservoir to prevent ongoing damage; no therapies are currently available for this purpose. Although still present in unreacted form, it seems that SM in this reservoir cannot be removed from the skin through the methods discussed above.

D. Treatment of Blisters

The prolonged pathology observed in SM injury suggests two pathological mechanisms: an ongoing toxicity that contributes to a step-wise progression culminating in blister formation, and a healing process that has been subverted. This is quite unlike the wound healing of thermal injuries. Aspiration (removal of the fluid within the blister) and deroofing (removal of the epidermal layer that constitutes the roof of the blister) are the main courses of action taken for larger, coalesced blisters, in order to promote the healing process (reviewed in Graham *et al.*, 2005).

More recently, work has focused on the use of physical debridement of tissues, the surgical removal of tissue beyond the epidermal (roof) layer, to enhance the rate of wound healing (Graham *et al.*, 2005) (Table 41.1). The slow rate of healing suggests that SM-modified proteins or other cellular components are preventing the normal healing process (Eldad *et al.*, 1998). SM-mediated crosslinking of structural

TABLE 41.1. Comparison of dermabrasion (debridement) strategies for enhancing the rate of SM-induced skin injury repair

Therapy	Time of administration	Agent route	Species/system	Efficacy	Reference
Reactive Skin Decontamination Lotion (RSDL)	Pretreatment	Topical	*In vitro,* human skin	18-fold reduction in skin absorption rate, may partially extract SM from the skin reservoir	Chilcott *et al.* (2002)
Dermabrasion	96 h post	Vapor, skin	Yucatan pigs (miniature, larger white)	Accelerated ($\leq$3 $\times$) wound healing	Rice *et al.* (2000)
Debridement, CO_2 laser	6, 24, or 48 h post	Vapor, skin, 15 min	WP	3-fold fewer wounds. Improved histological skin structure	Graham *et al.* (1997)
Debridement, CO_2 laser	48 h post	Topical, liquid, 2 h	WP	Improved histological skin structure	Graham and Braue (2000)
Debridement, xeroform petrolatum	48 h post	Topical, liquid, 2 h	WP	Skin elasticity similar to sham (non-HD-treated) pig skin	Graham *et al.* (2006)
Debridement, Scarlet Red Ointment	48 h post	Topical, liquid, 2 h	WP	Skin elasticity similar to sham (non-HD-treated) pig skin	Graham *et al.* (2006)
Debridement, surgical tangential excision	48 h post	Topical, liquid, 2 h	WP	Mild improvement in healing	Graham and Braue (2000)
Debridement, surgical tangential excision and skin grafting	48 h post	Topical, liquid, 2 h	WP	Improved histological skin structure	Graham and Braue (2000)
Debridement, Versajet	48, 72, and 96 h post	Not specified	WP	No improvement at day 14	Dalton *et al.* (2008)
Debridement, Compound W	48, 72, and 96 h post	Not specified	WP	No improvement at day 14	Dalton *et al.* (2008)
Debridement, Collagenase Santyl	48, 72, and 96 h post	Not specified	WP	No improvement at day 14	Dalton *et al.* (2008)

[a] WP – wearling pig

proteins such as laminins may not be easily repaired and may contribute to a delayed wound healing response (Zhang *et al.*, 1994). This could occur by promoting prolonged inflammation or by preventing the normal wound closure event that occurs as dermal cells migrate across and repair the blister area. Early studies demonstrated that SM-induced lesions in the skin of weanling pigs or Yucatan miniature pigs underwent faster wound healing when treating lesions by debridement after exposure to SM, whether the debridement was performed by CO_2 laser or surgically (Graham *et al.*, 1997, 2002b; Rice *et al.*, 2000). Furthermore, when combined with skin grafting, debridement promotes wound repair (Graham *et al.*, 2002a; Rice, 2003). Further investigations into different types of debridement in conjunction with other therapies are underway (Dalton *et al.*, 2008a; Evison *et al.*, 2006).

V. THERAPEUTICS

A. Antioxidants

Chemical scavengers may be used to inactivate free radical forms of SM or the oxygen or nitrogen radicals thought to be formed as a consequence of SM activation. If given early enough after SM exposure, such scavengers might directly deactivate SM and perhaps reduce the reservoir of SM present in the skin. However, scavengers seem to have efficacy beyond the lifetime of SM itself in the skin, suggesting that other physiological mechanisms such as inflammation and oxidative stress might be reduced by these agents (reviewed in Papirmeister *et al.*, 1991b). Scavengers have mostly been tested for their ability to reduce leukopenia and death due to the systemic effects of mustard exposure, rather than the reduction of skin injury (reviewed in Papirmeister *et al.*, 1991b). Although most work has focused on scavengers as therapeutics in pulmonary exposures where ongoing oxidative stress contributes to toxic outcomes such as pulmonary fibrosis or chronic obstructive pulmonary disease, there has been limited research on their efficacy in treating cutaneous injury.

Sodium thiosulfate, a potent antioxidant and scavenger, has been shown to be effective in reducing leukopenia and platelet depression when given systemically in treatment for nitrogen mustard, particularly when given prior to exposure (Bonadonna and Karnofsky, 1965; McKinley *et al.*, 1982; Owens and Hatiboglu, 1961). In the IPPSF model, perfusion with sodium thiosulfate modestly reduced microvesicle formation and attenuated the vascular response (Zhang *et al.*, 1995b). However, it has limited efficacy against skin injury (Vojvodic *et al.*, 1985; Zhang *et al.*, 1995a, b).

Glutathione depletion has been shown to occur in several tissues and cell lines in response to mustard treatment (Kulkarni *et al.*, 2006; Omaye *et al.*, 1991; Ray *et al.*, 1995). Depletion of glutathione by buthionine sulfoximine treatment of isolated human leukocytes increased their sensitivity to SM toxicity (Gross *et al.*, 1993). Given the critical role of glutathione in maintaining the intracellular reducing state of the cell, restoration or pretreatment with glutathione may protect against SM toxicity. Indeed, pretreatment of the basal epidermal keratinocyte cell line SVK-14, the upper respiratory tract cell line BEAS-2B, or the lower airway type II epithelial cell line A549 with glutathione was shown to provide resistance to SM toxicity (Andrew and Lindsay, 1998; Lindsay and Hambrook, 1998; C.N. Smith *et al.*, 1997). Similar results were seen with other human cell lines, including G361, SVK14, HaCaT, and NCTC human skin cells (Simpson and Lindsay, 2005). Also, stimulation of glutathione concentration by pretreatment with glutathione itself or the cysteine precursor 10 mM L-oxothiazolidine-4-carboxylate was shown to be protective against SM *in vitro* (Amir *et al.*, 1998; Gross *et al.*, 1993). However, these early successes did not translate effectively to animal model systems. Reduced glutathione (400 mg/kg) given once before and twice after SM did not protect mice from SM toxicity (Kumar *et al.*, 2001). Because glutathione would be difficult to administer cutaneously, it is an unlikely therapeutic agent for the skin.

Cysteine is an amino acid with a reduced sulfur group that acts as an antioxidant. Cysteine residues are selectively alkylated in proteins by SM and the bifunctional nature of SM allows chemical crosslinking (Byrne *et al.*, 1996). Early studies with nitrogen mustard in mice demonstrated that pretreatment with cysteine protected against toxicity (Contractor, 1963). However, microvesicle formation and dark basal cell formation were not protected in the IPPSF model (Zhang *et al.*, 1995b). *N*-acetyl-L-cysteine (NAC) acts both as a scavenger and as an inducer of glutathione synthesis, restoring the normal reducing status of the cell. Because SM lowers intracellular-reduced glutathione, its restoration may contribute to increased tissue survival and repair. In addition, pretreatment with NAC may elevate glutathione levels above normal and offer protection against low concentrations of SM (Atkins *et al.*, 2000). *In vitro*, pretreatment with NAC protected peripheral blood lymphocytes from 10 μM SM (Gross *et al.*, 1993). Endothelial cells pretreated with NAC were resistant to loss of cell adherence and rounding following exposure to 250 μM SM (Dabrowska *et al.*, 1996). Liposomes containing NAC increased the viability of HaCaT keratinocytes in an *in vitro* study if given simultaneously with CEES (Paromov *et al.*, 2008). Although antioxidants have proven to be efficacious if given prior to SM exposure, their ability to ameliorate skin damage or enhance wound repair has not been shown.

B. Proteolytic Inhibitors

Proteases play a critical role in wound repair and remodeling, and therefore are likely important targets for the enhancement of wound repair (Mohan *et al.*, 2002). In particular, damage to the basement membrane by MMPs is

thought to be one mechanism responsible for dermal–epidermal separation seen in SM-induced blister formation. This could occur by up-regulation of MMP expression, reduced competition for MMPs by adhesion molecules, or both (Danne *et al.*, 2001; Mol, 1999; Shakarjian *et al.*, 2006). MMP-9 expression is up-regulated in WP skin (Sabourin *et al.*, 2002) and the MEVM following SM exposure (Gerecke *et al.*, 2004). Inhibition of proteases might therefore ameliorate damage caused by SM to structural components of the skin (Table 41.2). Explant cultures of SM-treated human skin cotreated with Ilomastat showed no epidermal–dermal separation (Schultz *et al.*, 2004). Sulfur mustard-induced MMP-9 mRNA in the MEVM was partially inhibited by pretreatment with the MMP-9 inhibitor GM 1489 (Gerecke *et al.*, 2005). The antibiotic doxycycline is also an MMP inhibitor that was shown to attenuate SM-induced pulmonary injury (Guignabert *et al.*, 2005). However, doxycycline does not protect HaCaT viability; cells lose adherence and undergo apoptosis (Lindsay *et al.*, 2007).

Microvesication of human skin *in vitro* was inhibited by treatment with MMP inhibitors such as Illomastat, but HGP skin had no decrease in microvesication or necrosis following repeated treatments with Ilomastat (Mol and Van den Berg, 2006). Mol and Van den Berg suggest that this may be due to lack of delivery of the MMP inhibitor to the site of action. Although MMP inhibitors may reduce the ongoing injury caused by up-regulation of MMP-9, most inhibitors have difficulty penetrating the skin. The application of pharmaceutical concepts may aid in the development of better delivery systems that would enhance the efficacy of this class of drugs.

C. Steroids, Corticosteroids, and Glucocorticoids

Steroids have shown some efficacy in reducing inflammation and blister formation in response to SM or genetic blistering diseases such as bullous pemphigoid (Di Zenzo *et al.*, 2007). Early studies showed that several types of corticosteroids were effective in reducing edema induced by SM (Dannenberg and Vogt, 1981). Glucocorticoids were shown to be effective in reducing edema in the initial phase of injury, but did not affect the overall rate of healing (Vogt *et al.*, 1984). Hydrocortisone given systemically or topically 2 h prior to HD administration resulted in a reduction in ear inflammation in the MEVM (Babin *et al.*, 2000; Casillas *et al.*, 2000b). Steroids given after SM exposure also enhance wound healing in a Yorkshire pig model of SM injury (Reid *et al.*, 2008a). Dexamethasone in combination with the nonsteroidal anti-inflammatory diclofenac produced more than a 60% reduction in edema in mouse ears treated with SM (Dachir *et al.*, 2004). However, reduction of edema, while important, did not necessarily correlate with a reduction in the progression of injury as seen in later in this work. Studies using newer steroids such as clobetasol showed improved healing, lower

TABLE 41.2. Summary of the effects of protease inhibitors on SM toxicity

Therapy	Time of administration	Therapy route	Therapy concentration	Agent route	Species/system	Efficacy	Reference
Doxycycline	Cotreatment, then post-treatment	In media	500 µM	In media	HaCaT cells, *in vitro*	Reduced cellular detachment, but did not prevent apoptosis	Lindsay *et al.* (2007)
Doxycycline	1 h post	In media	100 µM	In media, 200 µM	HEK keratinocytes, *in vitro*	Reduction of SM-induced IL-8 production	Nicholson *et al.* (2004)
Doxycycline	Cotreatment	Topical	90 µM	Topical	*In vitro* human skin explants	No effect on SM-induced dermal–epidermal separation	Schultz *et al.* (2004)
GM 1489[a]	Pretreatment 15 min	Topical	20 µl of 25 mM	Liquid	Mouse	Reduced expression of MMP-9 mRNA	Gerecke *et al.* (2005)
Ilomastat	Pretreatment 15 min	Topical	20 µl of 25 mM	Liquid	Mouse	No effect	Gerecke *et al.* (2004)
Povidone iodine	15 m and 24 h post	Topical	40 mg 10% povidone iodine	HN2, 0.5 mg	Haired guinea pig	>80% reduction in MMP-2 and MMP-9 activity in skin	Wormser *et al.* (2002)
Iodine	20 m post	Topical	1% w/v	Liquid, 1.27 mg	Pig	No effect	Margulis *et al.* (2007)

[a]GM 1489 – N-[(2R)-2,4-methylpentanoyl]-L-tryptophan-(S)-methyl-benzylamide

severity of basal cell necrosis, and less inflammation (Reid *et al.*, 2008a). Co-treatment of steroids with nonsteroidal anti-inflammatory drugs (NSAIDs) shows greater promise: co-treatment with diclofenac and tacrolimus in the hairless guinea pig exposed to SM vapor showed less erythema, reduced lesion area, and fewer lesions (Dachir *et al.*, 2008). A similar combination of steroid (Adexone) and NSAID (Voltaren) applied to mouse ears treated with SM led to reduced inflammation, less edema, reduced area of clinical damage, and reduced damage to epithelial cells (Dachir *et al.*, 2004).

D. Nonsteroidal Anti-Inflammatory Drugs

Several studies have demonstrated that NSAIDs given systemically or topically offer protection against continued SM-mediated toxicity. This suggests that inflammation is a key component of SM-induced injury as it is with other cutaneous injuries, such as those induced by ultraviolet radiation (Yourick *et al.*, 1995). These results suggest that inflammation is involved in the ongoing pathology of SM-induced injury, and that anti-inflammatory drugs should be considered as part of a drug cocktail for treatment of SM injury. Early studies with indomethacin in the HGP model showed that oral pretreatment could attenuate erythema and cutaneous injury (Yourick *et al.*, 1995). Partial protection by indomethacin against microvesicle formation was found in the IPPSF model (Zhang *et al.*, 1995b). Significant reductions in SM-induced early edema were found when indomethacin was administered from 24 h prior to exposure to 24 h after exposure (Babin *et al.*, 2000) or when given 20 min post SM challenge (Kiser *et al.*, 2001). Topical indomethacin given 2 h prior to SM exposure in the MEVM protected against early (24 h) but not late (72 h) edema (Casillas *et al.*, 2000b).

Early studies using the MEVM showed that post-treatment with NSAIDs, particularly in combination with steroids, could diminish SM-induced inflammation at early time points, although later effects were not measured (Dachir *et al.*, 2002). As mentioned above, Voltaren, an NSAID, given in combination with the steroid Adexone, reduced skin injury (Dachir *et al.*, 2004). More recently, bifunctional compounds containing NSAIDs (Ibuprofen or Diclofenac) tethered to pyridostigmine, an acetylcholinesterase inhibitor, were somewhat effective against SM dermal toxicity (Amitai *et al.*, 2005). This combination was effective in the MEVM in reducing subepidermal blistering (Amitai *et al.*, 2006). In fact, subepidermal blistering in the MEVM was reduced by these tethered pharmaceuticals (Amitai *et al.*, 2006).

E. TRPV1 Ligands

An emerging hypothesis suggests a neurological component to SM toxicity in the skin. Nonmyelinated sensory C-fibers arising from the dorsal route ganglion transmit sensory information from the skin to the central nervous system in response to noxious stimuli, such as pain and heat. These fibers function as dual sensory efferents and release nociceptive and inflammatory neuropeptides such as substance P, peripherally (Szallasi and Blumberg, 1999; Szolcsanyi, 2004). Agents such as capsaicin, the active ingredient in hot peppers, produce analgesia by binding as an agonist to the transient receptor potential V1 channel (TRPV1) (Szolcsanyi, 2004). Capsaicin rapidly produces desensitization and interferes with the release of neuropeptides from sensory fibers (Campbell *et al.*, 1993). Moreover, TRPV1 are expressed on cells in a number of nonneuronal cutaneous tissues, including keratinocytes and mast cells (Li *et al.*, 2007). Capsaicin and its structural analogs, known collectively as vanilloids, have been shown to have anti-inflammatory activity, as demonstrated by inhibition of edema, mast cell degranulation, and leukocyte migration (Brand *et al.*, 1990; Bunker *et al.*, 1991). Pretreatment of skin with vanilloids prior to SM exposure was shown to significantly reduce edema formation (Babin *et al.*, 2000, 2003; Casillas *et al.*, 2000b; Sabourin *et al.*, 2003). One such vanilloid, olvanil, is a highly lipophilic analog of capsaicin, and has been shown to reduce SM-induced histological damage and edema as well as cytokine and chemokine mRNA induction (Casillas *et al.*, 2000b; Sabourin *et al.*, 2003). Analogs octyl homovanillamide and heptyl isovanillamide were shown to display similar protective activities against SM (Casbohm *et al.*, 2004). There appears to be much promise in following these leads and more closely examining the role of neurogenic inflammation and neuropeptides in the cutaneous damage induced by SM.

F. Temperature

Anecdotal and scientific evidence has shown that exposure to SM in hot environments causes more extreme damage, but little work had been performed on the effect of cooling in the prevention of injury until recently. Human skin keratinocytes treated with SM and cultured at 25°C had less injury after 24 h than keratinocytes grown at 37°C (Sawyer and Risk, 1999). Similarly, hairless guinea pigs with skin exposed to SM had less injury after 72 h if treated for 4.5 h post-exposure with cold (Sawyer and Risk, 1999). Other studies showed that anesthetized swine skin exposed to mild cooling (15°C) for 2–4 h following SM exposure had significantly less injury progression after 7 days (Sawyer *et al.*, 2002). However, later studies demonstrated that this effect was temporary, slowing the rate of injury progression rather than reducing overall injury. Indeed, tissue and animal studies showed that temperature-mediated inhibition of injury was reversible upon return of the tissue to normal body temperature (37°C) (Risk *et al.*, 2001). Sawyer *et al.* (2002) have suggested that cooling might therefore be used as a temporary measure that ‘‘increases the therapeutic window in which other medical countermeasures are useful (Nelson and Sawyer, 2006; Sawyer and Nelson, 2008).’’

VI. CONCLUDING REMARKS AND FUTURE DIRECTION

Countermeasure research to date has focused primarily on the development of therapeutics, but little attention has been given to the use of advances in drug delivery, or pharmaceutics. Weak efficacy can sometimes be enhanced by the use of better delivery mechanisms. Drug delivery by encapsulation of active moieties in nanoparticles has been increasingly used for chemotherapeutic agents such as doxorubicin (Haley and Frenkel, 2008). However, with the exception of barrier creams, nanoparticle-mediated cutaneous SM detoxification has largely been limited to decontamination (Braue and Hobson, 2005; Hobson *et al.*, 2002a, b; Prasad *et al.*, 2007a, b; Singh *et al.*, 2008; Stengl *et al.*, 2005). Most studies with creams focus on the use of nanoparticles that increase the rate of deactivation of the chemical agent (Koper *et al.*, 1999). Liposomes used as delivery devices for hydrophilic or hydrophobic antioxidants have shown enhanced drug delivery efficacy using *in vitro* models (Paromov *et al.*, 2008). NAC-containing liposomes have been used to treat CEES-induced lung injury, suggesting that encapsulated scavengers may be effective at restoring intracellular reducing agents following SM exposure (Hoesel *et al.*, 2008). Formulations that allow effective dermal delivery may enable the development of scavengers, antioxidants, or protease inhibitors for SM treatment. NAC-containing liposomes tested on an *in vitro* model of the skin (Epiderm) maintained cell viability if given concomitantly with SM; whether post-treatment was efficacious is unknown (Paromov *et al.*, 2008). These studies demonstrate that advances in pharmaceutics may dramatically improve the efficacy of previously discarded therapies.

Effective management of SM-exposed patients is likely to include combination therapies that act at the same stage or at different stages of the SM injury and recovery process to enhance overall efficacy. Dermabrasion has been shown to be effective in conjunction with split-thickness wound grafting (Graham *et al.*, 2002a). Other studies have shown increased efficacy when NSAIDs are given in conjunction with steroids (Dachir *et al.*, 2002, 2004, 2008). It is therefore likely that several therapies with limited efficacy could have an additive or synergistic effect for enhancement of SM-mediated injury healing.

Perhaps the largest problem inhibiting the development of effective preventive and therapy-based countermeasures is our continued lack of understanding of which of SM's many actions are critical events leading to SM injury. The major difficulty of SM is that although a large number of biochemical pathways are altered, the identification of pathways with pharmacological significance has yet to be clearly established. Previous studies suggested that the PARP pathway, calcium mobilization, and intracellular pH are affected in SM-mediated injury, but therapies designed against these pathways have not demonstrated effectiveness beyond *in vitro* approaches or have not shown feasibility for development as drugs. It is likely that these pathways, while important, are not the initiating events of toxicity, and therefore targeting these pathways might have limited effectiveness. Indeed, only anti-inflammatory drugs seem to be moderately effective in the treatment of SM injury. If SM is to be effectively treated, more research into the basic mechanisms of SM injury needs to be performed. As Brimfield suggests, ''the search for the primary biochemical lesion is still underway (Brimfield, 2004)''. Given the complex progression of SM injury, multiple interventions used in combination against various components of the progression of injury are likely to be required to deliver the best result. Recent major advances, such as the discovery that cooling of target tissues can slow the rate of injury, are likely to play an important role in treatment strategies (Risk *et al.*, 2001).

CHAPTER 42

Excitotoxicity, Oxidative Stress, and Neuronal Injury

DEJAN MILATOVIC, RAMESH C. GUPTA, SNJEZANA ZAJA-MILATOVIC, AND MICHAEL ASCHNER

I. INTRODUCTION

Exposure to anticholinesterase agents, organophosphates (OPs), and carbamates in the form of insecticides and chemical warfare agents affects or threatens much of the world's population. At present, more than 100 different OPs are used as insecticides worldwide (Kwong, 2002). The advantage of a lower environmental stability compared to organochlorine pesticides and high effectiveness against different insect species is accompanied by the disadvantage of high mammalian toxicity (Lotti, 2001). The widespread use and easy accessibility to these compounds result in a huge number of intoxications and several hundred thousand fatalities annually (Gunnell and Eddleston, 2003). Other derivatives of phosphoric acid, warfare nerve agents, are considered to be the most toxic compounds among all chemical weapons. Devastating effects of these agents have been demonstrated during the Iraqi conflict with Iranian troops and Kurdish civilians, as well as the terrorist attack on the Tokyo underground train system in 1995, resulting in over 5,500 casualties (Black *et al.*, 1994; Nozaki *et al.*, 1995; Nagao *et al.*, 1997). Terrorist attacks involving warfare nerve agents, weapons of mass destruction, or other industrial chemicals present worldwide security threats and health concerns. Therefore, anticholinesterase agents represent a significant potential threat not only in military arenas, but also to the general civilian population.

The nerve agents were originally synthesized during the 1930s in Germany in attempts to achieve more efficient pesticides based on OP compounds. Tabun (GA; ethyl *N*-dimethyl-phosphoramidocyanidate) was the first compound synthesized, followed by sarin (GB; isopropyl methylphosphonofluoridate), soman (GD; 1,2,2-trimethypropyl-methyl-phosphonofluoride), and VX [*S*-(2-diisopropyl-aminoethyl) *O*-ethyl methyl phosphonothiolate]. They differ from each other by the type of chemical group replacing the [$\cdot OH^-$] radical on the acid–base structure (Figure 42.1).

They also differ from one another in their potency and volatility, as well as in their ability to cross the blood–brain barrier (BBB) and to exert central nervous system (CNS) toxicity.

Pharmacologically, all these compounds are acetylcholinesterase (AChE) inhibitors. Their acute symptoms are attributed to accumulation of acetylcholine (ACh), thus exhibiting cholinergic toxicity. Phosphorylation of the esteratic site of the enzyme (Taylor, 1990) diminishes its capacity to catalyze its endogenous substrate ACh. Most of the OP compounds combine with the AChE only at the esteratic sites and the stability of the bond depends upon the structure of the compound attached. OP compounds containing larger alkyl groups may hinder cleavage, leaving the phosphorylated AChE inactivated almost indefinitely, so that normal activity recurs only upon the synthesis of a new enzyme. This process is known as ''aging'' and its time course varies depending on the nerve agent. Consequently, the hydrolysis of ACh is prevented, leading to accumulation of ACh in the synaptic cleft and overstimulation followed by desensitization of muscarinic and nicotinic ACh receptors. The constantly activated nicotinic cholinergic receptors generate involuntary skeletal muscle contraction, followed by complete depolarization block, the clinical manifestation of which is flaccid paralysis. In a manner similar to the events in the peripheral nervous system, the accumulation of ACh in CNS nerve endings causes anxiety, disorientation and general convulsions, followed by loss of consciousness and respiratory arrest. Anticholinesterase agent-induced ACh accumulation at the muscarinic sites also enhances the activity of various secretory glands, leading to excessive salivation, lacrimation, bronchorrhea, diarrhea, and sweating. The severity of poisoning by nerve agents varies from mild cases (mild dyspnea, blurred vision, and glandular hypersecretion) to more severe poisoning, which is characterized by severe dyspnea, skeletal muscle fasciculation, convulsions, and unconsciousness, which occurs soon after an intense exposure of only a few minutes (Goldfrank *et al.*, 1982; Weinbroum, 2005). Thus, dependent upon the degree of AChE inhibition, cholinergic stimulation may also lead to respiratory failure, coma, and death.

Exposure to these agents can also lead to long-term neurological impairments, including: (1) a delayed intermediate syndrome affecting muscles, which occurs 24–96 h post-exposure; and (2) subtle, long-term neurological

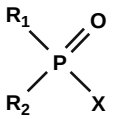

FIGURE 42.1. General structural formula of organophosphates: R1 and R2 are alkyl-, alkoxy-, or amido groups; X is the acyl residue (labile fluorine-, cyano-, substituted, or branched aliphatic, aromatic, or heterocyclic groups).

effects, which may last months or even years. Chronic OP induced neuropsychiatric disorder (COPIND) (Jamal, 1997) with symptoms of anxiety and depression; memory and attention deficit have also been described in workers exposed to OP compounds. In addition, dystonic reactions, schizophrenia, cog-wheel rigidity, choreoathetosis, and electroencephalographical changes have been reported with high-dose exposures. These extrapyramidal symptoms are thought to be due to the inhibition of AChE in the human extrapyramidal area. Psychosis, delirium, aggression, hallucination, and depression may also be seen during recovery from the cholinergic syndrome. Commercial sprayers of insecticides exhibit high level of anxiety (Levin *et al.*, 1976) and other types of delayed neurobehavioral effects are seen among people exposed to low doses of OP compounds for prolonged periods. Notably, clinical features of psychological syndromes occurring after chronic exposure to OP compounds exhibit many similarities to chronic fatigue syndrome (Behan, 1996).

Convulsions are a major sign of OP nerve agent poisoning (Misulis *et al.*, 1987). OP-induced seizures rapidly progress to status epilepticus, which leads to profound structural brain damage (Lemercier *et al.*, 1983; McLeod, 1985). It has been hypothesized that several neurotransmitter systems become involved sequentially in the initiation and maintenance of seizures elicited by OP compounds (McDonough and Shih, 1997). The progression of events includes initial high cholinergic activity followed by a transitional phase of cholinergic and glutamatergic hyperactivity and finally after about 40 min following the onset of seizures a predominantly glutamatergic phase (McDonough and Shih, 1997). Glutamate is therefore a major mediator of central neurotoxicity associated with exposure to OP nerve agents.

II. EXCITOTOXICITY AND NEURODEGENERATION

Previous studies have emphasized the role of glutamate receptors in the propagation and maintenance of OP-induced seizures (Shih *et al.*, 1990; Lallement *et al.*, 1991a, b, 1992; Sparenborg *et al.*, 1992; McDonough and Shih, 1993; De Groot *et al.*, 2001). OP-induced sustained seizure activity is thought to result in the release of excessive amounts of glutamate (Choi, 1998; Danysz *et al.*, 1995; Faden and Salzman, 1992). It has been shown that soman-induced seizures produce an increase in extracellular glutamate in the pyriform cortex (Wade *et al.*, 1987) and cornu ammonis (CA) region of hippocampus (Lallement *et al.*, 1992), followed by activation of *N*-methyl-D-aspartate (NMDA) glutamate receptors in the CA1 region. Moreover, glutamate stimulates the continuous release of ACh (Anderson *et al.*, 1994), contributing to further excitatory stimulation, prolongation of the seizures and thus like a brushfire it perpetuates excitotoxic neurodegeneration in vulnerable brain regions (Wade *et al.*, 1987; Lallement *et al.*, 1991a, 1992). Microdialysis studies reported an immediate increase in extracellular glutamate concentrations in the septum, pyriform cortex, hippocampal regions, and amygdale following soman-triggered seizures (Lallement *et al.*, 1991a, b; Wade *et al.*, 1987). Importantly, blocking specific glutamate receptors reduces neuropathogenic responses, including nerve agent toxicity (Sheardown *et al.*, 1990; Sparenborg *et al.*, 1992; Deshpande *et al.*, 1995).

Excitotoxic injury caused by increased levels of glutamate causes cognitive dysfunction (Phillips *et al.*, 1998; O'Dell *et al.*, 2000; Faden *et al.*, 2001). Interestingly, studies show sublethal nerve agent exposure can lead to memory and attention deficits that are controlled by the hippocampus (Hatta *et al.*, 1996; Nishiwaki *et al.*, 2001; Miyaki *et al.*, 2005). High concentrations of NMDA and alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) glutamate receptors, which play a key role in hippocampal-mediated learning and memory (Izquierdo and Medina, 1997), also make the hippocampus highly vulnerable to glutamate-induced excitotoxic injury following nerve agent poisoning (Shih *et al.*, 1990; Lallement *et al.*, 1991a, b, 1992; Sparenborg *et al.*, 1992; McDonough and Shih, 1993; De Groot *et al.*, 2001). Increased synaptic glutamate concentrations following OP exposure also alter glutamate receptor expression (Piehl *et al.*, 1995; Kreutz *et al.*, 1998; Cebers *et al.*, 2001) and perturb NMDA receptor subunit distribution, thus changing the overall physiology of the receptor and the functionality of the hippocampus (Cebers *et al.*, 1999). Many models of cognitive dysfunction have shown altered glutamate receptor expression (Luthi-Carter *et al.*, 2003; Mishizen-Eberz *et al.*, 2004) and NMDA subunit ratio rearrangement (Mikuni *et al.*, 1999), suggesting these mechanisms may also contribute to cognitive dysfunction following sublethal nerve agent exposure.

The role of glutamate receptors in mediating seizure-induced brain damage was first shown in the 1980s when kainic acid (KA) was found to damage limbic structures by inducing limbic epilepsy in rats (Ben-Ari *et al.*, 1980). Kainate is a rigid analog of glutamate, the principal excitatory neurotransmitter in the central nervous system (CNS), and it is a very potent stimulant of a subset of the ligand-gated ion channel, called KA receptors (Milatovic *et al.*, 2005b). Activation of the KA subtype of ionotropic glutamate receptors results in sustained epileptic activity

in the hippocampus, followed by a selective pattern of neuropathology that is similar to human temporal lobe epilepsy (Ben-Ari, 1985; Ben-Ari and Cossart, 2000; Schwob *et al.*, 1980). Kainate administration and intense seizure activity associated with status epilepticus is sufficient to induce degeneration of hippocampal CA neurons, and hyperexcitability of surviving hippocampal CA neurons (Dudek *et al.*, 1994; Ben-Ari, 1985, 2001; Dong *et al.*, 2003, Zaja-Milatovic *et al.*, 2008) (Figure 42.2).

Results from studies with kainate and other glutamate analogs led to the hypothesis that excessive amounts of glutamate are released during limbic seizures following OP exposure. Cellular events involved in this neurotoxicity are first marked by acute neuronal swelling resulting from Na^+ influx through NMDA receptor ion channel, followed by a secondary influx of Ca^{2+} ions and water into affected neurons. Whereas neurons are rapidly damaged when loaded with Ca^{2+} ions through NMDA receptors, a similar Ca^{2+} load incurred through other non-NMDA receptors (Bouchelouche *et al.*, 1989) and alternative influx pathways, such as voltage-sensitive Ca^{2+} channels, is innocuous (Tymianski *et al.*, 1993; Sattler *et al.*, 1998). In addition, alterations in Ca^{2+} and glutamate induce other biochemical mechanisms, which further compromise cellular viability. For example, increased Ca^{2+} is also induced by activating voltage-dependent Ca^{2+} channels (VDCC) and NMDA activates the syntheses of nitric oxide (NO) (Garthwaite *et al.*, 1989), a molecule believed to be toxic to neurons and to participate in the formation of seizure activity and neurodegeneration following nerve agent intoxication (Lallement *et al.*, 1996). Accordingly, antagonists of NMDA receptors or VDCC are effective in protecting CNS neurons against glutamate-mediated neuronal excitotoxicity (Weiss *et al.*, 1990; Mattson, 2003).

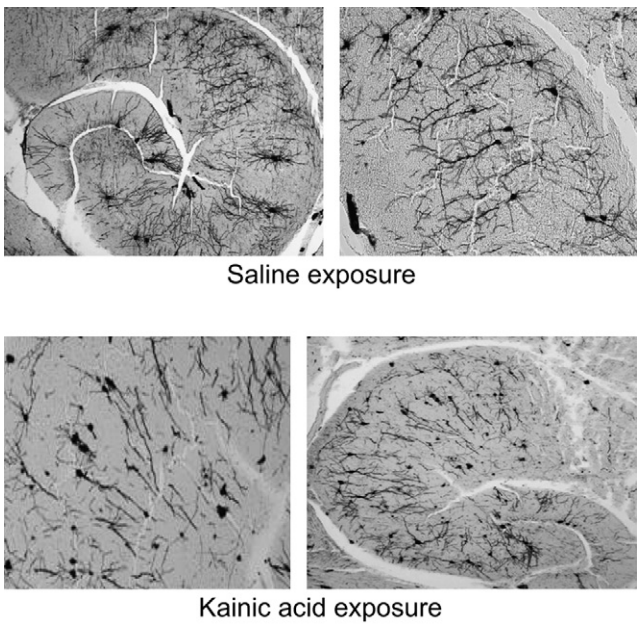

FIGURE 42.2. Photomicrographs of mouse hippocampi with pyramidal neurons from the CA1 hippocampal area of brains 1 h after saline (control) and kainic acid (KA, 1 nmol/5 µl, i.c.v.) injections. Treatment with KA induced degeneration of hippocampal dendritic system and a decrease in total length of dendrite and spine density of hippocampal pyramidal neurons.

III. OXIDATIVE INJURY

The brain is considered to be exceedingly sensitive to oxidative stress because of its: (1) great consumption of O_2, glucose, and energy, (2) large amounts of peroxidizable fatty acids, (3) relatively low levels of antioxidants, and (4) ease of peroxidation of peroxidizable fatty acids (Floyd, 1997; Simonian and Coyle, 1996). During normal physiological conditions, reactive oxygen species (ROS) are generated at a low rate and are efficiently removed by scavenger and antioxidant systems. However, in the pathophysiological conditions, such as seizures, OPs or carbamates, acetylcholinesterase inhibitors (AChEI) induced a high rate of ATP consumption accompanied by increased generation of ROS. Previous studies have supported a role for oxidative stress and excessive generation of ROS and reactive nitrogen species (RNS) in anticholinesterase-induced neurotoxicity (Dettbarn *et al.*, 2001; Gupta *et al.*, 2001a, b, 2007; Milatovic *et al.*, 2005a). During sustained seizures the flow of oxygen to the brain is greatly increased at a time when the use of ATP is greater than the rate of its generation. This metabolic stress results in a markedly increased ROS generation. A greatly increased rate of ROS production, overwhelming the capacity of inherent cellular defense systems, results in attack on the mitochondria and cell membranes, leading to peroxidation of lipids, cell lesions and, in turn, cell death (Sjodin *et al.*, 1990).

Neurons in particular are dependent upon mitochondrial energy production. This high utilization of energy, coupled with the inhibition of oxidative phosphorylation, compromises the cell's ability to maintain its energy and antioxidant levels, causing excessive production of ROS/RNS, which leads to neuronal damage (Dettbarn *et al.*, 2001; Gupta *et al.*, 2001a, b). The most consistent pathological findings in acute experiments with anticholinesterase agents include degeneration and cell death in the pyriform cortex, amygdala, hippocampus (where the CA1 region is preferentially damaged), dorsal thalamus, and cerebral cortex. The early morphological changes in AChEI-induced status epilepticus (SE) include dendritic swelling of pyramidal neurons in the CA1 region of the hippocampus (Carpentier *et al.*, 1991).

Accordingly, the hypothesis concerning OP-induced neuronal oxidative injury is that overstimulation of glutamatergic receptors results in sustained epileptic activity in the hippocampus, followed by a typical pattern of neuropathologic changes predominantly in the pyramidal neurons. Cell damage is thought to result from intense transient influx of calcium leading to mitochondrial

functional impairments characterized by activation of the permeability transition pores in the inner mitochondrial membrane, cytochrome c release, depletion of ATP, and simultaneous formation of ROS (Heinemann *et al.*, 2002; Cadenas and Davies, 2000; Patel, 2002; Nicholls and Ward, 2000; Nicholls *et al.*, 2003). In addition, increase in cytoplasmic calcium ions triggers intracellular cascades through stimulation of enzymes, including proteases, phospholipase A_2, and nitric oxide synthase, which also lead to increased levels of free radical species and oxidative stress (Lafon-Cazal *et al.*, 1993; Farooqui *et al.*, 2001). Since free radicals are direct inhibitors of the mitochondrial respiratory chain, ROS generation perpetuates a reinforcing cycle, leading to extensive lipid peroxidation and oxidative cell damage (Cock *et al.*, 2002; Cadenas and Davies, 2000).

Two radicals that play predominant roles as initiators of lipid peroxidation are the hydroxyl radical (OH^-) and the peroxynitrite radical ($OONO^-$). The superoxide anion radical (O_2^-), which is generated during the electron transport process in mitochondria, is involved in the generation of both OH^- and $OONO^-$. Superoxide dismutase (MnSOD and Cu/ZnSOD) converts O_2 to hydrogen peroxide (H_2O_2), which is then converted to OH^- via the Fenton reaction, catalyzed by Fe^{2+}, Cu^+, or Mn^{2+}. $OONO^-$ is generated from the interaction of NO with O_2^-. A major stimulus for NO production is elevation of intracellular Ca^{2+}, which binds to calmodulin, resulting in the activation of NO synthase. Peroxynitrite is a powerful oxidant exhibiting a wide array of tissue damaging effects ranging from lipid peroxidation, inactivation of enzymes and ion channels via protein oxidation and nitration to inhibition of mitochondrial respiration (Virag *et al.*, 2003). Peroxynitrite, which dissipates during oxidation (Wang *et al.*, 2003), has also been found to nitrate as well as oxidize adenine, guanine, and xantine nucleosides (Sodum and Fiala, 2001). Low concentrations of peroxynitrite trigger apoptotic death, whereas higher concentrations induce necrosis with cellular energetics (ATP and NAD) serving as a switch between the models of cell death. Thus, increased ROS and RNS production has been directly linked to oxidation of proteins, DNA, and lipids, which may cause injury or induce a variety of cellular responses through the generation of secondary metabolic reactive species (Figure 42.3).

IV. LIPID PEROXIDATION AND *IN VIVO* MARKERS OF OXIDATIVE DAMAGE

Due to a high concentration of substrate polyunsaturated fatty acids (PUFAs) in cells, lipid peroxidation is a major outcome of free radical-mediated injury (Montine *et al.*, 2002a, b). A critically important aspect of lipid peroxidation

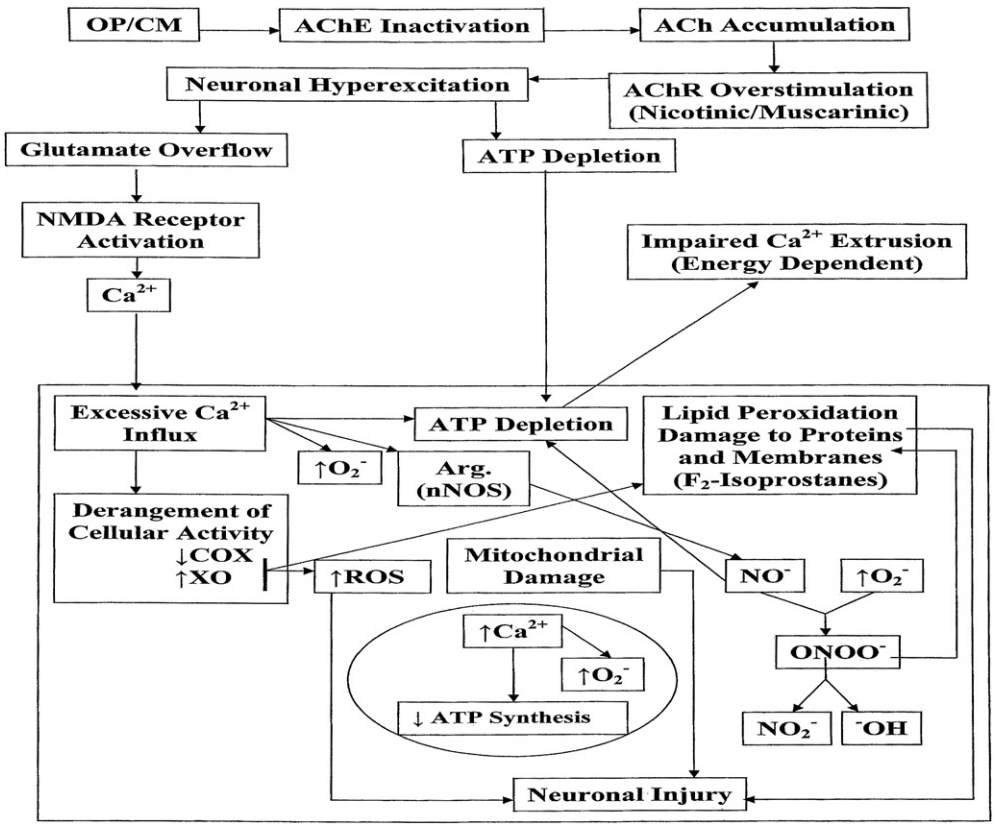

FIGURE 42.3. A schematic diagram showing possible mechanisms involved in an anticholinesterase-induced neuronal injury or death by excessive production of ROS/RNS leading to lipid peroxidation. See text for the details.

is that it will proceed until the oxidizable substrate is consumed or termination occurs, making this fundamentally different from many other forms of free radical injury in that the self-sustaining nature of the process may entail extensive tissue damage (Porter *et al.*, 1995). Decreased membrane fluidity following lipid peroxidation makes it easier for phospholipids to exchange between the two halves of the bilayer, increase the leakiness of the membrane to substances that do not normally cross it other than through specific channels (e.g. K^+, Ca^{2+}), and damage membrane proteins, inactivating receptors, enzymes, and ion channels (Halliwel and Gutteridge, 2006; Halliwell, 2007). Increases in Ca^{2+} induced by oxidative stress can activate phospholipase A_2, which releases arachidonic acid (AA) from membrane phospholipids. The free AA can then both undergo lipid peroxidation (Farooqui *et al.*, 2001) and act as a substrate for eicosanoid synthesis. Increased prostaglandin synthesis is immediately linked to lipid peroxidation, because low levels of peroxides accelerate cyclooxygenase action on PUFAs (Smith, 2005). Phospholipase A_2 can also cleave oxidized AA residues from membranes.

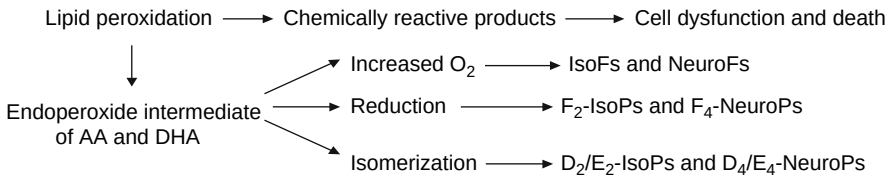
The use of reactive products of lipid peroxidation as *in vivo* biomarkers is limited because of their chemical instability and rapid and extensive metabolism (Gutteridge and Halliwell, 1990; Moore and Roberts, 1998). For these reasons, other more stable lipid products of oxidative damage have generated intense interest in recent years as *in vivo* markers of oxidative damage. These compounds include the F_2-isoprostanes (F_2-IsoPs), isofurans (IsoFs), and F_4-neuroprostanes (F_4-NeuroPs) (Morrow *et al.*, 1990; Fessel *et al.*, 2002). F_2-IsoPs are formed by peroxidation of AA. Three major structural isomers of IsoPs are formed from a common intermediate: F-ring IsoPs formed by reduction and D/E-ring IsoPs formed by isomerization (Morrow *et al.*, 1998). The ratio of F-ring to D/E-ring compounds reflects the reducing environment in which F_2-IsoPs form, with greater reducing equivalents favoring a higher ratio of F- to D/E-ring compounds (Morrow *et al.*, 1998). More recently, it has been shown that in the presence of increased oxygen tension in the microenvironment in which lipid peroxidation occurs, an additional oxygen insertion step may take place (Fessel *et al.*, 2002). This step diverts the IsoP pathway to form tetrahydrofuran ring-containing compounds termed IsoFs, which are functional markers of lipid peroxidation under conditions of increased oxygen tension.

The measurement of F_2-IsoPs is a method that has been extensively replicated as an efficient means of quantifying free radical damage in *in vivo* models associated with neurodegenerative diseases, including Alzheimer's disease (Montine *et al.*, 1999), inflammation (Milatovic *et al.*, 2003, 2004), and excitotoxicity (Milatovic *et al.*, 2005b). Since AA present throughout the brain and in different cells in the brain at roughly equal concentrations, F_2-IsoPs reflects damage to brain tissue but not necessarily to neurons.

Similar studies of lipid peroxidation products have been performed for other substrate lipids. Of particular interest are oxidation products of docosahexaenoic acid (DHA), which have been termed F_4-neuroprostanes (F_4-NeuroPs) (Roberts *et al.*, 1998). In contrast to AA, which is evenly distributed in all cell types in all tissues, DHA is highly concentrated in neuronal membranes (Salem *et al.*, 1986; Montine *et al.*, 2004). Thus, determination of F_4-NeuroPs permits the specific quantification of oxidative damage to neuronal membranes *in vivo* (Montine *et al.*, 2004). In fact, to our knowledge, F_4-NeuroPs are the only quantitative *in vivo* marker of oxidative damage that is selective for neurons.

V. HIGH-ENERGY PHOSPHATES

Inhibition of AChE leads to unremitting stimulation of nervous tissue and muscle, which, in turn, causes depletion of high-energy phosphates (HEP), ATP, and phosphocreatine (PCr) (Dettbarn *et al.*, 2001). If this stimulation is sufficiently low in intensity or brief in duration, cellular recovery will ensue without lasting consequences. If, however, intense cholinergic stimulation is allowed to persist, a self-reinforcing cycle of cellular damage is set into motion. ATP depletion for several hours to approximately 30–40% of normal levels leads to a fall in the mitochondrial membrane potential that is associated with: (1) reduced energy production (due to decrease in complex I and complex IV activities), (2) impaired cellular calcium sequestration, (3) activation of protease/caspases, (4) activation of phospholipases, (5) activation of nitric oxide synthase (NOS), and (6) excessive generation of ROS (Milatovic *et al.*, 2006). Several of these steps are associated with exacerbation and propagation of the initial depletion of ATP; most notable are the decreases in complex I and IV activities, the impairment of mitochondrial calcium



metabolism that regulates ATP production even in the face of a constant supply of substrates, and the generation of nitric oxide, which binds reversibly to cytochrome c oxidase (COx) in competition with oxygen, with subsequent sensitization to hypoxia. COx is the terminal complex in the mitochondrial respiratory chain, which generates ATP by oxidative phosphorylation, involving the reduction of O_2 to H_2O by the sequential addition of four electrons and four H^+. Electron leakage occurs from the electron transport chain, which produces the superoxide anion radical (O_2^-) and H_2O_2. Under normal conditions, COx catalyzes more than 90% of the oxygen consumption in the cells. The chance of intermediate products, such as O_2^- and H_2O_2 and hydroxyl (OH^-) radical, escaping is small under conditions where COx remains active. During the hyperactivity of brain or muscle, the activity of COx is reduced (Milatovic *et al.*, 2001), leading to an increased electron flow within the electron transport chain, thereby increasing ROS generation, oxidative damage to mitochondrial membranes, and vulnerability to excitotoxic impairment (Soussi *et al.*, 1989; Gollnick *et al.*, 1990; Bose *et al.*, 1992; Bondy and Lee, 1993; Yang and Dettbarn, 1998). We have previously established that several of these key events occur within 1 h of anticholinesterase treatment (Gupta *et al.*, 2000). DFP-induced seizures markedly lowered the cellular ATP and PCr levels in discrete brain regions (Gupta *et al.*, 2001a, b, c) and significantly reduced COx activity (Milatovic *et al.*, 2001).

VI. NITRIC OXIDE (NO/NOS)

Another important free radical related to lipid peroxidation is NO. NO is synthesized by neuronal cells from L-arginine by NO synthases (NOS), with the accompanying release of citrulline (Wendland *et al.*, 1994; Burette *et al.*, 2002). There are three different isoenzymes of NOS, neuronal (nNOS), inducible (iNOS), and endothelial (eNOS). A major stimulus for NO production is elevation in intracellular Ca^{2+}, which binds to calmodulin, resulting in the activation of constitutive NOS (nNOS and eNOS). NOS activity increases during anticholinesterase- and KA-induced excitotoxicity (Parathath *et al.*, 2006; Gupta *et al.*, 2007; Zaja-Milatovic *et al.*, 2008). It has been suggested that NO is involved in glutamate receptor-mediated neurotoxicity by decreasing intracellular ATP levels. There are two possible mechanisms responsible for energy depletion caused by NO in neuronal cells: one is the prolonged activation of poly-(ADP ribose) polymerase (PARP), which can be activated by NO (Zhang *et al.*, 1994), leading to depletion of ATP. The other mechanism is the inhibition of the mitochondrial complexes, leading to diminished ATP production. Many reports establish that NO impairs mitochondrial/cellular respiration and other functions by inhibiting the activities of several key enzymes, particularly COx, thereby causing ATP depletion (Yang and Dettbarn, 1998; Milatovic *et al.*, 2001; Gupta *et al.*, 2001a, b; Dettbarn *et al.*, 2001). NO was also reported to inhibit complexes II and III (Bolanos *et al.*, 1994), as well as complex IV (Lizasoain *et al.*, 1996) in neuron-derived mitochondria and neuronal energy production in cultured hippocampal neurons (Brorson *et al.*, 1999), leading to rapid ATP depletion. In addition, increased production of NO in the presence of the superoxide anion radical may generate peroxynitrite radical (Montine *et al.*, 2002c; Milatovic *et al.*, 2002), a potent inducer of lipid peroxidation.

VII. DENDRITIC INJURY

In addition to formation of ROS, RNS and depletion of HEP, seizures may cause brain injury via a number of mechanisms, potentially contributing to neurological and cognitive deficit alterations. The hippocampus and its pyramidal neurons are particularly susceptible to excitotoxicity, resulting in the selective deterioration of synapses and cytoskeletal damage. Although seizures can induce neuronal death, they may also have ‘‘nonlethal’’ pathophysiological effects on neuronal structure and function. Dendritic spines represent the structural sites of contact for the majority of excitatory, glutamatergic synaptic inputs onto neurons and are strongly implicated in mechanisms of synaptic plasticity and learning. NMDA and other glutamate receptor subtypes are clustered in dendritic spines (Rao and Craig, 1997; O’Brien *et al.*, 1998), which serve as integrative units in synaptic circuitry and participate in synaptic plasticity (Yuste and Denk, 1995). The accumulation of glutamate receptor clusters in spines is governed by excitatory synaptic activity, and increases when activity is suppressed (Rao and Craig, 1997; O’Brien *et al.*, 1998). Conversely, excitotoxicity produces a rapid and profound loss of dendritic spines in cultured neurons (Halpain *et al.*, 1998), mimicking the loss in dendritic spine synapses in neurological conditions including epilepsy, aging, and schizophrenia (Jeffrey *et al.*, 1997; Jiang *et al.*, 1998). This suggests that receptor localization at synapses might be critical to excitotoxicity, and govern neuronal vulnerability to excitotoxicity.

A number of studies demonstrate a loss of dendritic spines in pathophysiological specimens from animal seizure models (Olney *et al.*, 1986), suggesting that seizures can cause dendritic injury. It has also been shown that overstimulation and altered expression of glutamate receptor following anticholinesterase exposure are associated with synaptic architecture dysfunction and cellular deterioration in the brain, especially in the hippocampus (Johnson *et al.*, 2008). Thus, excitotoxic levels of glutamate following soman exposure are thought to be involved in the dendritic and synaptic damage as an early toxicological response that leads to neuronal dysfunction and memory impairment (Carpentier *et al.*, 1991).

VIII. ANTICHOLINESTERASE-INDUCED SEIZURES, OXIDATIVE INJURY, AND NEURODEGENERATION

Lipid peroxidation, mitochondrial dysfunction, reduced neuronal energy levels, and reduced COx activity support the contention that anticholinesterases, such as diisopropylphosphorofluoridate (DFP) and carbofuran (CF), cause neuronal injury by excessive formation of ROS (Yang and Dettbarn, 1998; Jeyarasasingam *et al.*, 2000; Gupta *et al.*, 2001a, b; Milatovic *et al.*, 2000a, b, 2001, 2005a). Additionally, our recent studies showed that seizure-induced cerebral oxidative damage in adult animals is accompanied by alterations in integrity of the hippocampal CA1 dendritic system (Gupta *et al.*, 2007; Zaja-Milatovic *et al.*, 2008).

A single injection of DFP (1.5 mg/kg, s.c.) or another AChE inhibitor, carbofuran (CF, 1.5 mg/kg, s.c.), produces toxic signs in rats, including salivation, tremors, wet dog shakes, fasciculations, and mild to moderate seizures with rearing and rolling over, with progression to severe seizures within 7–15 min (Milatovic *et al.*, 2006; Gupta *et al.*, 2007). Signs of maximal intensity such as severe muscle fasciculations, seizures, and convulsions develop within 15–30 min and last for more than 2 h before tapering off. By 24 h, animals are free of toxic signs. The observed signs are typical of anticholinesterase toxicity and reveal the involvement of both the central as well as the peripheral nervous systems (Gupta *et al.*, 2001a, b; Milatovic *et al.*, 2005a). Analysis of brains from saline-treated control rats revealed regional variability in brain AChE activity (cortex, 222.0 ± 10.7; amygdala, 529.2 ± 10.29; and hippocampus 301.2 ± 9.5 µmol/g wet weights). A single acute dose of DFP (1.5 mg/kg, s.c.) suppressed AChE activity to less than 20% in all brain regions compared to control 60 min following the exposure. Similarly, 60 min after a single acute dose of CF (1.5 mg/kg, s.c.), AChE was markedly depressed (% remaining activity: cortex, 10.02 ± 1.04%; amygdala, 18.18 ± 1.48%; and hippocampus, 12.75 ± 0.74%) (Gupta *et al.*, 2007). At the time of high AChE inhibition and resultant severe seizure activity, significant increase in biomarkers of global free radical damage (F_2-IsoPs) and the selective peroxidation biomarker of neuronal membranes

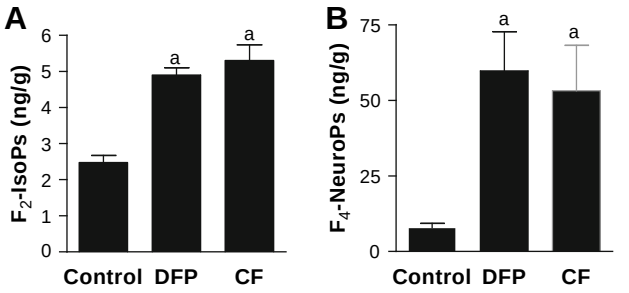


FIGURE 42.4. Effect of DFP (1.5 mg/kg, s.c.) and carbofuran (CF, 1.5 mg/kg, s.c.) on F2-IsoPs (A) and F4-NeuroPs (B) levels in rat brain. Values are mean ± SEM ($n = 4$–6). [a]Significant difference between control and DFP- or CF-treated rats ($p < 0.05$).

(F_4-NeuroPs) were seen in the brain of DFP and carbofuran exposed animals.

While two-fold elevations are seen in F_2-IsoPs levels, F_4-NeuroPs levels are more than five-fold higher compared to controls (Figure 42.4). The results confirm the presence of oxidative damage in cerebrum as a novel aspect of anticholinesterase toxicity. The selective increase in F_4-NeuroPs indicates that neurons are specifically targeted by this mechanism.

DFP and exposure also caused marked elevation in brain citrulline levels (an indicator of NO/NOS activity) (Gupta *et al.*, 2001b, 2007). Control levels of citrulline are similar in the hippocampus (247.90 ± 4.10 nmol/g) and the amygdala (293.20 ± 6.90 nmol/g) (Gupta *et al.*, 2007). Within 5 min of CF injection, the citrulline levels were elevated more than two-fold in the investigated brain areas. Within 15 min of CF treatment, the levels of citrulline were significantly higher in both brain regions and were maximally elevated at 30 min post-injection (three- to four-fold). They remained elevated up to 60 min, but returned to control levels when measured 24 h later (Figure 42.5). Similar response was seen following DFP exposure.

Many reports provide evidence that NO impairs mitochondrial/cellular respiration and other functions by inhibiting the activities of several key enzymes, particularly COx, thereby causing ATP depletion (Yang and Dettbarn, 1998; Milatovic *et al.*, 2001; Gupta *et al.*, 2001a, b; Dettbarn *et al.*, 2001). Results from our experiments also showed that

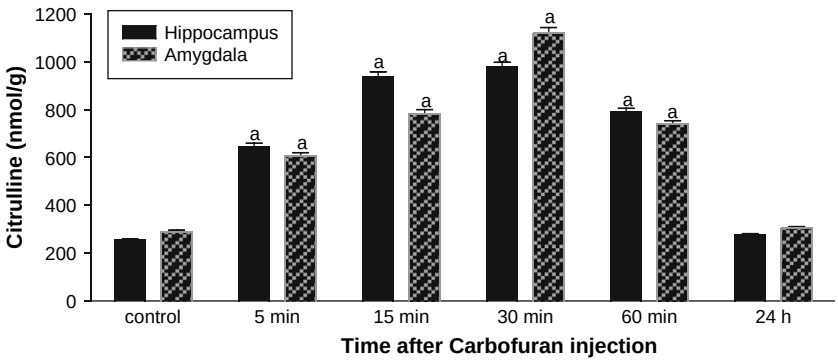

FIGURE 42.5. Citrulline levels in brain regions of rats intoxicated with an acute dose of carbofuran (1.5 mg/kg, s.c.). Values of citrulline are presented as mean ± SEM ($n = 4$–6). [a]Significant difference between values from control and carbofuran-treated rats ($p < 0.05$).

1 h after DFP (1.5 mg/kg, s.c.) or CF (1.5 mg/kg, s.c.) treatment, the levels of ATP and PCr were significantly reduced in the hippocampus and amygdala. (Figure 42.6). With either DFP or CF treatment, the reduction in ATP and PCr levels was similar in the amygdala and hippocampus. During the course of these excitatory processes, a high rate of ATP consumption, coupled with the inhibition of oxidative phosphorylation, compromises the cell's ability to maintain its energy levels, and excessive amounts of ROS and RNS may be generated. Thus, the combination of impaired synthesis of ATP with its greater utilization during brain hyperactivity appears to result in a significant depletion of ATP. Three days after anticholinesterase treatment, significant recovery of ATP and PCr is observed in discrete brain regions (Figure 42.6). The rapid decrease in energy metabolites at the onset of seizures indicates early onset of mitochondrial dysfunction, in turn, further increasing ROS production and neuronal injury.

An important question that emerged from previous studies is whether brain hyperactivity, such as seizures, first generates increases in ROS and then causes a decrease in HEPs. The findings revealed that within 5–15 min after carbofuran injection (the time required for onset and development of clinical signs), NO levels increased more than five- to six-fold in the cortex and more than two- to three-fold in the amygdala and hippocampus. The maximum increase in NO occurred at 30 min post-injection in all three brain regions. The data also revealed that maximum decline in HEPs occurred 1 h after carbofuran injection. This is in agreement with our previous data showing a rapid and significant increase in NO precedes increases in lipid peroxidation, mitochondrial dysfunction, loss of energy metabolites, as well as a reduction of COx activity, and an increase in xanthine oxidase (Dettbarn *et al.*, 2006). Therefore, the findings suggest that in the case of carbofuran, the increase in ROS preceded the decrease in HEPs.

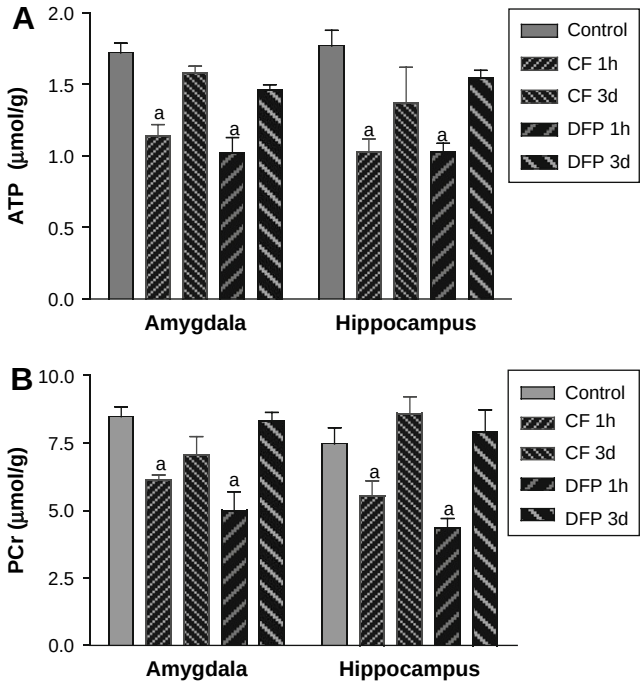

FIGURE 42.6. Levels of high-energy phosphates, ATP (A) and PCr (B) in amygdala and hippocampus of rats intoxicated with an acute dose of carbofuran (CF, 1.25 mg/kg, s.c.) or diisopropyl phosphorofluoridate (DFP, 1.25 mg/kg, s.c.). Rats were sacrificed 1 hour (1 h) or 3 days (3 d) after CF or DFP injection. Values of ATP and PCr are presented as means ± SEM ($n = 4$–6). [a]Significant difference between values from control rats and DFP- or CF-treated rats ($p < 0.05$).

Seizures, convulsions, and CNS lesions are typical results of systemic application of sublethal doses of anticholinesterase agents (Sparenborg *et al.*, 1992). The most consistent pathological findings in acute experiments include degeneration and cell death in the pyriform cortex, amygdala, hippocampus (where the CA1 region is preferentially destroyed), dorsal thalamus, and cerebral cortex. The early morphological changes in AChEI-induced status epilepticus (SE) include dendritic swelling of pyramidal neurons in the CA1 region of the hippocampus (Carpentier *et al.*, 1991). Therefore, we have investigated whether seizure-induced cerebral oxidative damage in adult rats is accompanied by alterations in the integrity of the hippocampal CA1 dendritic system. Our results showed that anticholinesterase-induced early increases in biomarkers of global free radical damage (F_2-IsoPs) and the selective peroxidation biomarker of neuronal membranes (F_4-NeuroPs) was accompanied by dendritic degeneration of pyramidal neurons in the CA1 hippocampal area. Anticholinesterase-induced brain hyperactivity targeted the dendritic system with profound degeneration of spines and regression of dendrites, as evaluated by Golgi impregnation and Neurolucida-assisted morphometry (Figure 42.7).

Rats injected with DFP show a significant decrease in total dendritic length and spine density compared to pyramidal neuron from the hippocampal CA1 area of control rats (Figure 42.7). Taken together with the biochemical data presented above, our results suggest that oxidative damage that selectively targets cerebral neurons is a hitherto unrecognized aspect of anticholinesterase toxicity. Results also revealed that anticholinesterase exposure is associated with oxidative and nitrosative stress, alteration in energy metabolism and consequent degeneration of pyramidal neurons from the CA1 hippocampal region of rat brain. Ultimately, the additive or synergistic mechanisms of cellular disruption caused by anticholinesterase agents lead to cellular dysfunction and neurodegeneration.

IX. OXIDATIVE DAMAGE AND DENDRITIC DEGENERATION FOLLOWING KAINIC ACID-INDUCED EXCITOTOXICITY

Since excessive presynaptic release of glutamate and activation of NMDA and non-NMDA receptors have

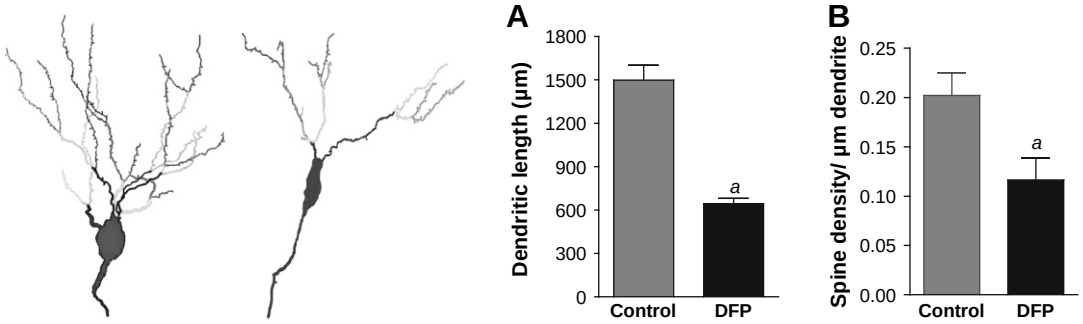

FIGURE 42.7. Morphology and quantitative determination of dendritic length (A) and spine density (B) of hippocampal pyramidal neurons from CA1 sector of rats treated with saline (control) or DFP (1.5 mg/kg, s.c.) and sacrificed 1 h after the treatment. Four to six Golgi-impregnated dorsal hippocampal CA1 neurons were selected and spines counted by using the Neurolucida system. [a]Significant difference between control and DFP-treated rats ($p < 0.05$). Treatment with DFP induced degeneration of the hippocampal dendritic system and a decrease in total length of dendrite and spine density of hippocampal pyramidal neurons. Tracing and counting are done using the Neurolucida system at 100× under oil immersion (MicroBrightField, VT).

a significant role in anticholinesterase-induced neurotoxicity, we have investigated the role of glutamatergic excitation, oxidative injury, and neurodegeneration in the model of KA excitotoxicity. We have used intracerebroventricular (i.c.v.) injection of KA, known as an experimental model for investigation of cerebral vulnerability, particularly during acute brain disorders (Ben-Ari, 1985) and status epilepticus (Ben-Ari and Cossart, 2000; Schwob *et al.*, 1980). The study was designed to investigate whether F_2-IsoPs and F_4-NeuroPs formation correlated with the vulnerability of pyramidal neurons in the CA1 hippocampal area following KA-induced excitotoxicity. Our results showed that i.c.v. KA-induced early increase in biomarkers of oxidative damage, F_2-IsoPs and F_4-NeuroPs was accompanied by dendritic degeneration of pyramidal neurons in the CA1 hippocampal area.

Time-course changes in biomarkers of oxidative damage in the rat model of anticholinesterase-induced seizures showed that the highest increase in F_2-IsoPs was evaluated at 1 h after the injection of anticholinesterase agent or 40 min after the beginning of seizure symptoms (Gupta *et al.*, 2007). In the model of KA-induced excitotoxicity the earliest time point evaluated was 30 min since seizures start immediately after the i.c.v. KA injection. Elevated levels of these *in vivo* markers of oxidative damage are in agreement with our previous findings (Montine *et al.*, 2002c; Milatovic *et al.*, 2005b; Gupta *et al.*, 2007), as well as those of others (Patel *et al.*, 2001), and indicate that KA injection leads to profound cerebral and neuronal oxidative damage in mice.

Our results also showed that the transient rise in F_2-IsoPs and F_4-NeuroPs is accompanied by rapid evolution of dendritic abnormalities, apparent in significant decrease in dendritic length and spine density of pyramidal neurons as early as 30 min post-KA injection. However, the recovery in both oxidative damage biomarkers at 60 min following the injection was not paralleled by the rescue of damaged neurons from the CA1 hippocampal area. Extended seizure activity (60 min) induced the same level of dendritic length and spine density decrease when compared to 30 min following KA injection (Table 42.1). Together, these data suggest that both oxidative stress and neurodegeneration occur as an early response to seizures, but do not establish whether oxidative stress is a cause or

TABLE 42.1. Cerebral concentrations of F2-IsoPs and F4-NeuroPs and dendritic degeneration of hippocampal pyramidal neurons following KA-induced seizures in mice

	F_2-IsoPs (ng/g)	F_4-NeuroPs (ng/g)	Dendritic length (µm)	Spine density (number/100 µm dendrite)
Control	3.07 ± 0.05	13.89 ± 0.58	1032.10 ± 61.41	16.45 ± 0.55
KA 30 min	4.81 ± 0.19[a]	34.27 ± 2.71[a]	363.44 ± 20.78[a]	8.81 ± 0.55[a]
KA 60 min	3.40 ± 0.18	18.55 ± 1.26	425.71 ± 23.04[a]	7.44 ± 0.56[a]

Data from KA-exposed mice were collected 30 or 60 min post-injection

[a]One-way ANOVA showed $p < 0.0001$ for each endpoint. Bonferroni's multiple comparison test showed significant difference ($p < 0.001$) compared to vehicle-injected control

an effect of seizure-induced CA1 cell damage. Neuronal damage processes triggered by sustained seizure activity may occur as a continuum, last longer than formation of oxidative lipids and, although not evident by the markers, may already be in progress when the peak increases in F_2-IsoPs and F_4-NeuroPs occur. Thus, we investigated dynamic changes in lipid peroxidation and dendritic structures immediately after seizures, but future studies over the longer period should be able to determine the long-term time course of these spine and dendritic changes. It is very likely that the spine loss seen in our study is the initial phase of more chronic spine loss and progressive neurodegeneration reported in other studies (Muller *et al.*, 1993; Multani *et al.*, 1994; Isokawa and Levesque, 1991; Jiang *et al.*, 1998; Zeng *et al.*, 2007).

In vivo data have also established that KA induced a significant increase (more than two-fold) in citrulline concentrations 30 min following the injection (Zaja-Milatovic *et al.*, 2008). Although we did not determine whether increased citrulline originated from a combination of NOS isozymes or one in particular, our data are in agreement with the results from the models of anticholinesterase toxicity and activated innate immunity (Gupta *et al.*, 2007; Milatovic *et al.*, 2003, 2004) and indicate that a subset of NOS activity also contributes to cerebral oxidative damage in the model of KA-induced excitotoxicity.

X. SUPPRESSION OF SEIZURE-INDUCED OXIDATIVE INJURY AND NEURODEGENERATION

A. Antioxidants

Antioxidants (e.g. vitamins, glutathione, selenium, zinc, creatine, and arginine) and antioxidant enzymes (e.g. superoxide dismutase, catalase, glutathione reductase, and glutathione peroxidase) exert synergistic actions in scavenging free radicals. A large body of literature supports the notion that antioxidants play an important role in preventing many human diseases (e.g. cancer, atherosclerosis, stroke, rheumatoid arthritis, and neurodegeneration) (Fang *et al.*, 2002). Vitamin E has been recognized as one of the most important antioxidants. Vitamin E inhibits ROS-inducing generation of lipid peroxyl radicals, thereby protecting cells from peroxidation of PUFA in membrane phospholipids, from oxidative damage of cellular proteins and DNA, and from membrane degeneration (Topinka *et al.*, 1989). Vitamin E mainly acts as a chain breaking antioxidant and radical scavenger, protecting cell membranes against oxidative damage (VanAcker *et al.*, 1993). In addition, vitamin E regulates ROS production (Chow *et al.*, 1999), maintains oxidative phosphorylation in mitochondria, and accelerates restitution of high-energy metabolites (Punz *et al.*, 1998; Kotegawa *et al.*, 1993). Decreased levels of vitamin E in response to hyperoxia or treatment with convulsants reported in recent studies (Mori *et al.*, 2004; Onodera *et al.*, 2003; Rauca *et al.*, 2004), suggest that vitamin E in the brain is consumed to prevent oxidative damage. Vitamin E also prevented metasystox (OP insecticide)-induced changes in lipase activity and lipid peroxidation in the brain and spinal cord of rats (Tayyaba and Hasan, 1985).

A synthetic spin trapping agent such as phenyl-*N*-*tert*-butylnitrone (PBN) is also capable of scavenging many types of free radicals. This compound is widely used to trap ROS in a variety of physical, chemical, and biological studies using electron paramagnetic resonance spectrometry. PBN is known to be concentrated in the mitochondria, where it reacts with ROS and forms stable adducts, and thereby maintains normal levels of energy metabolites. Numerous *in vitro* and *in vivo* experiments have shown the beneficial effects of PBN on the prevention of neuronal degeneration. Protective effects are described in experimental models of brain ischemia/reperfusion (Phillis and Clough-Helfman, 1990; Carney and Floyd, 1991; Gido *et al.*, 1997; Fetcher *et al.*, 1997), excitotoxicity (Cheng and Sun, 1994; Lancelot *et al.*, 1997; Milatovic *et al.*, 2002), inhibition of nitric oxide synthase induction (Krishna *et al.*, 1996; Miyajima and Kotake, 1995), and in different models of seizures (He *et al.*, 1997; Thomas *et al.*, 1997). Additional findings also corroborate that PBN effectively prevents neurodegeneration in Parkinson's disease (Fallon *et al.*, 1997; Frederiksson *et al.*, 1997; Sack *et al.*, 1996), Alzheimer's disease and anticholinesterase neurotoxicity (Sack *et al.*, 1996; Gupta *et al.*, 2001a, b). Thus, PBN has been proven to rescue neurons in multiple experimental injury models. Other pharmacological properties of spin trapping agents have been described that could influence the outcome of oxidant injury. These have been described for PBN as reversible Ca^{2+} channel blockade in vascular muscle causing vasodilatation (Anderson *et al.*, 1993), direct effect on striatal function, including inhibition of excitation–contraction coupling (Andersen *et al.*, 1996), and induction of hypothermia (Pazos *et al.*, 1999).

Previous studies have shown that antioxidant pretreatment suppressed DFP- or CF-induced alterations in HEP, their metabolites and citrulline levels, supporting the possibility that increased generation of ROS/RNS contributes to depletion of energy phosphates (Gupta *et al.*, 2001a, b). PBN or vitamin E treatment alone did not alter the levels of high-energy phosphates, their major metabolites, or citrulline in any of the brain regions. Vitamin E pretreatment suppressed the depletion of HEP and their metabolites and increased citrulline levels without preventing seizures (Gupta *et al.*, 2001a). The protective efficacy provided by vitamin E against DFP- or carbofuran-induced changes in energy metabolites was of varying degrees in different brain regions and could partly be due to pharmacokinetic variables involved in attaining different levels of vitamin E in different brain regions. However, PBN pretreatment, 1 h before anticholinesterase agent, protected mitochondria, maintained cellular level of

high-energy metabolites, but also prevented DFP- or CF-induced convulsions and seizures (Gupta *et al.*, 2001a, b). This could primarily be due to a protective interaction of PBN with AChE, sufficient to protect a critical fraction of AChE against phosphorylation by DFP or carbamylation by CF (Zivin *et al.*, 1999; Milatovic *et al.*, 2000a, b). We have also shown that AChE inhibitor-induced increases in NO (citrulline) were significantly prevented by PBN as well as by vitamin E (Gupta *et al.*, 2001a). There is evidence that suggests that PBN inhibits the induction of inducible NOS (iNOS) by reducing the expression of iNOS protein (decrease in mRNA expression), thus preventing the over-production of NO (Miyajima and Kotake, 1995, 1997).

The efficacy of the spin trapping agent PBN and the antioxidant vitamin E was tested to suppress increase in NO and lipid peroxidation and prevent neurodegeneration of pyramidal neurons in the CA1 hippocampal area in the model of KA-induced excitotoxicity. Vitamin E or PBN alone did not alter basal citrulline and F_4-NeuroPs levels or dendritic arborization. However, vitamin E and PBN suppressed KA-induced increases in citrulline and cerebral and neuronal markers of oxidative damage, F_2-IsoPs and F_4-NeuroPs, respectively (Figures 42.8 and 42.9).

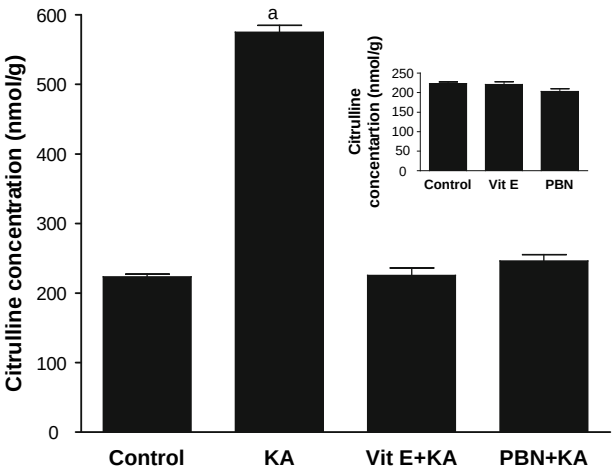

FIGURE 42.9. Ipsilateral cerebral citrulline concentrations following i.c.v. KA with or without vitamin E (Vit E) or *N-tert*-butyl-α-phenylnitrone (PBN) pretreatment. Brains from mice exposed to KA were collected 30 min post-injections ($n \geq 5$ for each group). One-way ANOVA had $p < 0.001$ with Bonferroni's multiple comparison tests significant for KA vs control, Vit E + KA, or PBN + KA treatment.

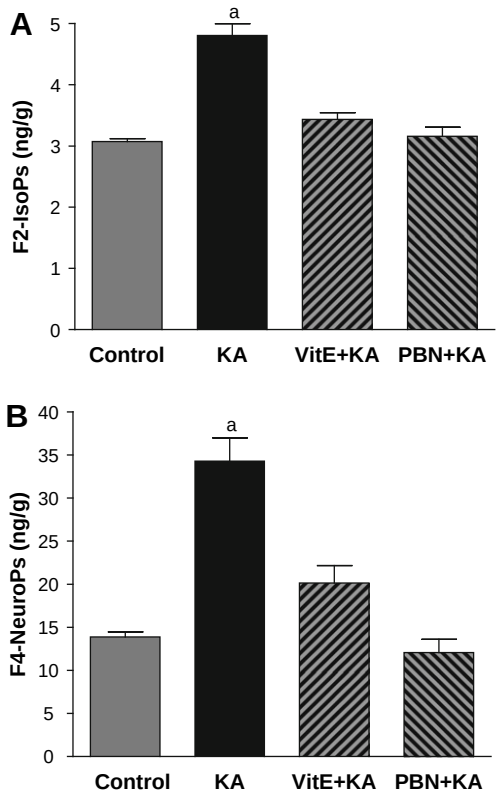

FIGURE 42.8. Ipsilateral cerebral F2-IsoPs (A) and F4-NeuroPs (B) concentrations following i.c.v. KA with or without vitamin E (Vit E) or *N-tert*-butyl-α-phenylnitrone (PBN) pretreatment. Brains from mice exposed to KA were collected 30 min post-injections ($n \geq 5$ for each group). One-way ANOVA had $p < 0.0001$ with Bonferroni's multiple comparison tests significant for KA vs control, Vit E + KA or PBN + KA treatment.

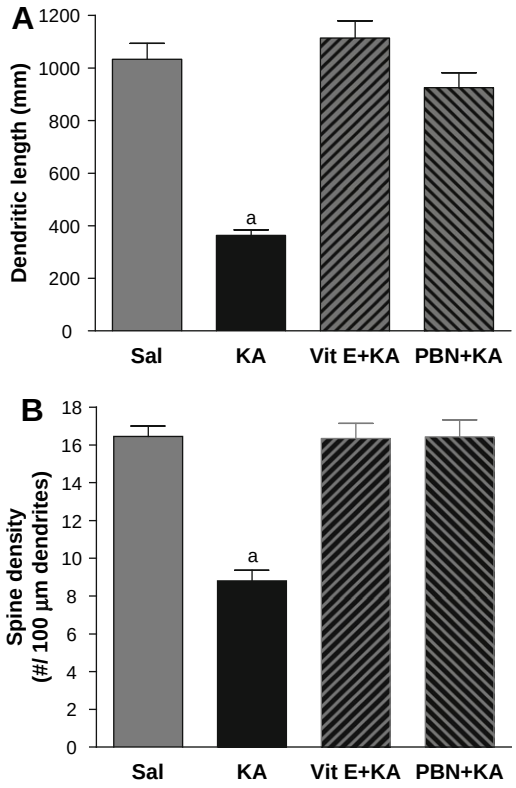

FIGURE 42.10. Dendritic length (A) and spine density (B) of pyramidal neurons from the CA1 hippocampal area of mice following i.c.v. KA with or without vitamin E (Vit E) or *N-tert*-butyl-α-phenylnitrone (PBN) pretreatment. Brains from mice exposed to KA were collected 30 min post-injections ($n \geq 5$ for each group). One-way ANOVA had $p < 0.001$ with Bonferroni's multiple comparison tests significant for KA vs control, Vit E + KA or PBN + KA treatment.

Importantly, vitamin E and PBN completely suppressed both reduction in dendrite length and reduction in spine density of pyramidal neurons from the CA hippocampal area from KA-exposed mice (Figure 42.10).

A close concordance was found between these results showing that protection of the cerebrum from neuronal oxidative damage also protected hippocampal CA1 pyramidal neurons from dendritic degeneration. These agents did not alter kainite-induced seizure severity, indicating that the protective effect of vitamin E and PBN is most likely mediated by scavenging ROS, preventing lipid peroxidation and consequent neuronal damage, and not by a specific effect on seizures *per se*. Furthermore, since antioxidants minimize lipid peroxidation following an increase in α-tocopherol and PBN, then a parallel reduction in neuronal damage provides strong evidence that oxidative stress and lipid peroxidation in a causal way mediate seizures and the corresponding injury. One limitation to the potential therapeutic application is that the drugs, to be effective, need to be administered prophylactically before the onset of seizures. Future research should address the efficacy of these agents when administered at higher concentrations either during or possibly even after seizures, in preventing seizure-induced oxidative and dendritic changes and potentially reducing resultant neurocognitive deficits.

XI. NMDA RECEPTOR ANTAGONIST (MEMANTINE)

As excitotoxicity-induced neuronal damage in the model of anticholinesterase-induced seizures is explained by excessive release of glutamate that activates both NMDA and non-NMDA posynaptic receptors, antagonism of the excitotoxicity mechanism may protect the CNS from the deleterious effects of anticholinesterase agents. Several NMDA receptor antagonists have been shown to exert anticonvulsant effects against nerve agent-induced seizures when administered as a pretreatment or after the seizure has been initiated, usually terminating the convulsions after an initial period of epileptical activity (Shih, 1990; Sparenborg *et al.*, 1992). NMDA receptor antagonists do not modify the events responsible for the early phase of the seizure, but block the subsequent recruitment of glutamate receptor activation and hence the maintenance of seizure activity and irreversible functional and structural brain damage.

Among promising candidates as antidotes against CNS intoxication by OP nerve agents, memantine (MEM) has been shown to pose both anti-excitotoxic and anti-epileptic properties. Memantine is an uncompetitive NMDA receptor antagonist, clinically used for the treatment of Alzheimer's disease, Parkinson's disease and spasticity, in the absence of serious side effects (Ozsuer *et al.*, 2005; Lipton, 2005). From a series of rat *in vivo* experiments, it is evident that pre-administration of memantine significantly protects AChE activity from inhibition caused by AChE inhibitors, including OP and CM insecticides and OP nerve agents (Gupta and Kadel, 1990; Gupta and Dettbarn, 1992; McLean *et al.*, 1992; Gupta and Dekundy, 2005). By now, it is well established that memantine exerts various pharmacological effects by multiple pharmacological mechanisms: (1) blockage of nicotinic acetylcholine receptor–ion channel complex (Masuo *et al.*, 1986), (2) reduced reflex excitability of both flexors and extensors (Wand *et al.*, 1997), (3) prevention of neural hyperexcitability (McLean *et al.*, 1992), (4) central muscle relaxation (Grossman and Jurna, 1997), and (5) prevention of AChE inhibitor-mediated energy loss from muscle cells (Milatovic *et al.*, 2005a). Memantine is also able to prevent the pathogenic calcium influx caused by continuous mild activation by low-level glutamate. On the other hand, memantine allows the physiological activation of the NMDA channels by high concentrations of glutamate, a phenomenon necessary for synaptic plasticity underlying normal learning and memory (Parsons *et al.*, 1999).

In recent studies it has also been demonstrated that memantine treatment significantly reduces lipid peroxidation (Figure 42.11), alterations in citrulline and HEP

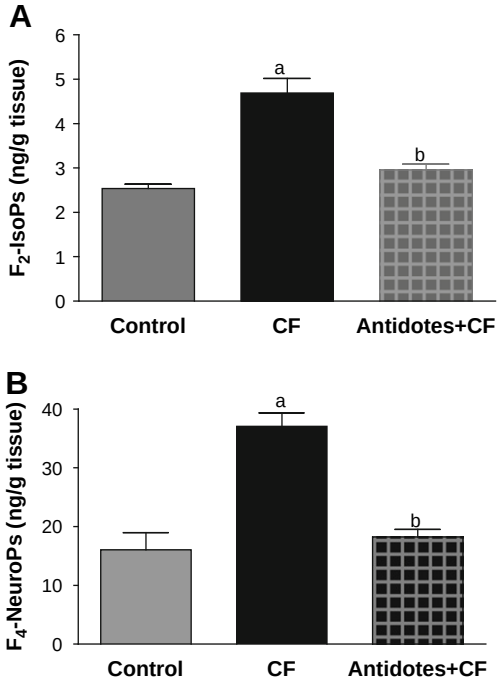

FIGURE 42.11. Cerebral F2-IsoPs (A) and F4-NeuroPs (B) concentrations following carbofuran (CF, 1.5 mg/kg, s.c.) with or without antidote (memantine, 18 mg/kg, and atropine, 16 mg/kg, given prophylactically, 60 min and 15 min, respectively, before CF administration) pretreatment. Brains from rats exposed to CF were collected 60 min post-injections ($n \geq 5$ for each group). One-way ANOVA had $p < 0.0001$ with Bonferroni's multiple comparison tests significant for CF vs control (a), and for CF vs antidote + CF (b).

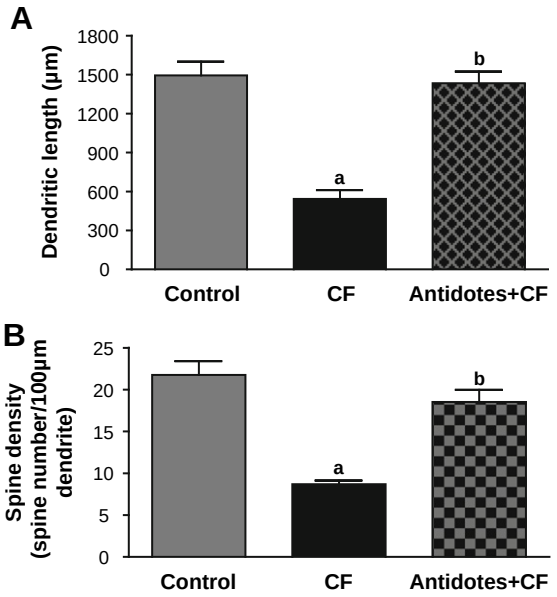

FIGURE 42.12. Dendritic length (A) and spine density (B) of pyramidal neurons from the CA1 hippocampal area of mice following carbofuran (CF, 1.5 mg/kg, s.c.) with or without antidote (memantine, 18 mg/kg and atropine, 16 mg/kg given prophylactically, 60 min and 15 min, respectively, before CF administration) pretreatment. Brains from rats exposed to CF were collected 60 min post-injections ($n \geq 5$ for each group). One-way ANOVA had $p < 0.0001$ with Bonferroni's multiple comparison tests significant for CF vs control (a), and for CF vs antidote + CF (b).

levels in muscles and brain of rats intoxicated with carbofuran (Milatovic *et al.*, 2005a; Gupta *et al.*, 2007).

No significant alterations in biomarkers of neuronal damage, citrulline, HEP, and their metabolite levels were seen in any of the brain regions receiving MEM and atropine. In addition, MEM and ATS exposure did not induce any alteration in neuronal morphometry but when given as pretreatment, provided protection against carbofuran-induced morphometric changes in hippocampal neurons (Figure 42.12). Memantine, in combination with atropine, completely suppressed both reduction in dendrite length and reduction in spine density of pyramidal neurons from the CA hippocampal area from CF-exposed rats (Figure 42.12).

In conclusion, the data demonstrated that synergistic mechanisms of cellular disruption caused by anticholinesterase agents led to cellular dysfunction and neurodegeneration. It has also been demonstrated that preventing CF-induced neuronal hyperactivity by pretreatment with MEM and atropine blocks pathways associated with oxidative damage in rat brain. The documented ability of MEM therapy to reduce free radical generation and lipid peroxidation, prevent HEPs and attenuate the morphological injury provides further support for the role of ROS and RNS in anticholinesterase-induced seizures.

XII. CONCLUDING REMARKS AND FUTURE DIRECTION

Exposure to OP nerve agents induces seizures, rapidly progressing to status epilepticus and profound structural brain damage. The progression of events includes initial high cholinergic activity followed by activation of glutamatergic neurons as a result of release of glutamate. Moreover, glutamate stimulates the continuous release of ACh, contributing to further excitatory stimulation, prolongation of the seizures, and excitotoxic neurodegeneration in vulnerable brain areas. The ensuing neuronal damage is thought to result from intense transient influx of calcium leading to mitochondrial functional impairment, cytochrome c inactivation, depletion of ATP, simultaneous formation of free radical species, and oxidative stress. Therefore, control of excitotoxicity and oxidative stress, better understanding of the mechanisms of noncholinergic mediated activities, and pathways that protect or promote neuronal survival are essential for development of efficacious treatments and preventive therapies associated with OP exposures.

We have explored mechanisms associated with OP-induced neurotoxicity by probing their effects on oxidative stress and associated dendritic degeneration of pyramidal neurons in the CA1 hippocampal area. We have also investigated different pathways to attenuate biomarkers of oxidative damage associated with anticholinesterase exposure and the extent to which such attenuation is accompanied by rescue from neurodegeneration. Results from our studies suggest that vitamin E, PBN, and memantine efficiently suppress oxidative injury. Future studies should be directed at deciphering the mechanisms of protection, addressing the ability of these agents to attenuate OP neurotoxicity via radical scavenging, AChE inhibition, and/or glutamate antagonism. Additional studies should also determine whether a combination of these treatments improve the therapeutic index against OP poisoning (compared to administration of each alone). Complementary studies should also investigate not only the prophylactic, but also therapeutic effects of these neuroprotectants. Successful identification of safe and effective neuroprotectants that suppress noncholinergic activities associated with anticholinesterase exposure will provide new pharmacological modalities to protect and treat both the acute and delayed effects of nerve agent poisoning.

CHAPTER 43

Neuropathologic Effects of Chemical Warfare Agents

RANDALL L. WOLTJER

I. INTRODUCTION

Nerve agents exert their effects through binding and irreversible inactivation of acetylcholinesterase (AChE), the enzyme that hydrolyzes acetylcholine, leading to a toxic accumulation of acetylcholine at nicotinic (skeletal muscle and preganglionic autonomic) receptors, muscarinic (mainly postganglionic parasympathetic) receptors, and central nervous system synapses. Exposure to symptomatic doses of these agents leads to characteristic neuropathologic effects that have been examined in a variety of animal models. In addition, it is becoming increasingly recognized that even lower levels of exposure to these agents, even in the absence of seizures or other severe manifestations of acute toxicity, may be associated with more subtle forms of injury to nervous tissue. Historically, this has been of concern in organophosphate and carbamate insecticide exposure among farm workers; however, it is likely that use of nerve agents in civilian populations or against military personnel would result in a range of exposures that stem from both the proximity of various groups to the site of deployment and the persistence of residues of some agents in the environment. This chapter describes the neuropathologic consequences of exposure to agents, and touches upon underlying mechanisms that may mediate their effects in nervous tissues.

II. BACKGROUND

Common nerve agents developed for chemical warfare purposes include the G-series (so named because they were first developed by German scientists in the mid-1930s) and V-series (a designation of more ambiguous origin) weapons. The G-series includes tabun (GA), sarin (GB), soman (GD), and cyclosarin (GF); the V-series includes VX, first synthesized by the British in 1954, which is approximately an order of magnitude more potent than agents of the G-series. The G-series compounds are volatile liquids at room temperature, are soluble in both fat and water, and are absorbed readily through the eyes, respiratory tract, and skin. V-series agents are viscous and toxic mainly via skin exposure, and therefore pose a lower inhalation hazard than the G-agents. However, their persistence in the environment has implications for chronic exposures, including low-level exposures that may also lead to more subtle toxicities.

Nerve agents are organic esters of phosphorus-based acid derivatives that are potent inhibitors of AChE. A large toxicological and medical literature has been produced since their development, and it has been helpful to classify exposure-associated health effects in terms of four general clinical classifications that have been described elsewhere in the literature (Brown and Brix, 1998), and are summarized as 1 through 4 below. To these, I have added a fifth, for which I have finally presented a brief rationale below, and will deal with in more detail subsequently. These are:

1. Acute cholinergic effects that occur within minutes to hours, which may be lethal or lead to at least some degree of recovery.
2. Long-term neurological and neuropsychological effects that sometimes follow recovery from acute toxicity, and which may persist for years.
3. A delayed peripheral polyneuropathy, known as organophosphate-induced delayed neurotoxicity (OPIDN), from which recovery may be poor.
4. A delayed syndrome of muscle weakness (the so-called ''intermediate syndrome'') that occurs within days of recovery from severe acute effects and is typically reversible.
5. In addition, new literature supports the hypothesis that even asymptomatic exposures to these agents, especially if these occur over a prolonged period of time, may lead to effects on nervous tissue, the clinical consequences of which are as yet poorly understood. This would be an obvious concern in the event that populations would be exposed to nerve agents, as unrecognized exposure and repeated low-dose exposure during the course of inappropriately conducted decontamination procedures could lead to these effects. Furthermore, the possibilities of additional susceptibilities of pregnant women and children to low doses of nerve agents in these circumstances are areas of concern that we know very little about.

Nonneurologic effects of nerve agent exposure have also been reported and include psychiatric and cardiac disease (Brown and Brix, 1998). However, this chapter will focus on known neuropathologic effects, which are highly correlated with the cognitive effects of nerve agent exposure (Myhrer *et al.*, 2005). For the purpose of organization of this chapter, the clinical classification of exposure effects presented above will be used as an approximate scaffold for the description of lesions, predominantly in the central nervous system, that have been encountered in approximately equivalent stages of exposure in animal models. In addition, the limited amount of data regarding lesions encountered in humans who have been exposed to these agents will be described.

III. ACUTE EFFECTS OF SYMPTOMATIC EXPOSURE

A. Ischemic/Hypoxic Injury

A large number of studies using experimental animals, including rodents, cats, and nonhuman primates, have been carried out to characterize the neurobehavioral effects of nerve agent exposure and their histopathologic correlates in brain tissue (Baze, 1993; Carpentier *et al.*, 1990; Churchill *et al.*, 1985; Hymowitz *et al.*, 1990; Kadar *et al.*, 1995; Lemercier *et al.*, 1983; Petras, 1981, 1994; Singer *et al.*, 1987). Acute exposure to nerve agents is associated with a range of clinical symptoms, varying from abnormal movements and salivation, to limb tremor and muscle fasciculations, to convulsions. In general, axonal degeneration was present in the cerebrum of all animals with convulsions and in the majority of animals with tremor and fasciculations. In a variety of animal and especially rodent models, animals that survived seizures tended to manifest extensive bilateral brain neuronal necrosis that affected predominantly the forebrain, thalamus, tegmentum, and spinal cord. In monkeys, the striatum, globus pallidus, substantia nigra, amygdala, hippocampus, and optic pathway including the lateral geniculate bodies, pretectum, and superior colliculi also sustained injury proceeding to necrosis.

Acute injury may be attributable to several mechanisms. Ischemic hypoxia may derive from respiratory insufficiency during prolonged seizures, and evidence of cellular ischemia is present in brains of exposed animals. This consists of shrinkage of the cell soma and proximal dendrites, cytoplasmic microvacuolation due to mitochondrial swelling, dispersion of Nissel substance (cytoplasmic RNA), increased cytoplasmic eosinophilia, nuclear changes including displacement of the nucleus to an eccentric position in the neuron, shrinkage, and darkening. Generally, these nerve agent-associated lesions were described as being indistinguishable from those associated with brain ischemia or anoxia (Brierley *et al.*, 1973; Brown and Brierley, 1966, 1972; McLeod *et al.*, 1984).

Subsequent data argued against the hypothesis that hypoxic injury, at least in isolation, primarily accounts for the patterns of injury observed with acute nerve agent-induced brain injury. Although the presence of prolonged seizure activity is highly correlated with nerve-agent associated brain damage (Carpentier *et al.*, 2000; Lemercier *et al.*, 1983; McDonough and Shih, 1997), the changes in blood or brain oxygenation preceding or during nerve agent-induced seizures are minimal (Carpentier *et al.*, 1990; Clement and Lee, 1980; Goldman *et al.*, 1993; Lynch *et al.*, 1985), and in rat experimental models, increases in regional blood flow and glucose uptake are actually observed (Goldman *et al.*, 1993; Maxwell *et al.*, 1987; McDonough *et al.*, 1983; Miller and Medina, 1986; Pazdernik *et al.*, 1985; Samson *et al.*, 1985; Scremin *et al.*, 1991; Shih and Scremin, 1992). In addition, hippocampal slices exposed in culture to soman at levels that elicited spontaneous epileptiform activity were found to have earliest morphologic changes that recapitulated those seen in soman-treated intact animals; these included nuclear indentations and a decrease in nuclear size (Sikora-VanMeter *et al.*, 1985, 1987). These findings differed from the dilated endoplasmic reticulum and mitochondrial alterations observed in hippocampal slices maintained in hypoxic conditions, and argued that some other aspect of seizure activity, apart from hypoxic injury, contributes mechanistically to at least part of the damage to cerebrum associated with nerve agent exposure.

B. Nerve Agent-Associated Excitotoxic Injury

Within minutes after exposure to nerve agents, there is a marked decrease in AChE activity and associated rise in ACh. Earliest seizure activity begins in the absence of other significant neurotransmitter alterations and is prevented by anticholinergic drugs. These observations suggest that seizure-associated neuropathologic findings that occur upon nerve agent exposure are caused primarily by a mechanism of cholinergic toxicity. However, if seizures progress untreated, other neurotransmitter systems display secondary alterations, and the involvement of these has been invoked in models of injury to cerebrum that involve mechanisms of ‘‘excitotoxic’’ injury. Specifically, these refer to the involvement of the excitatory amino acid transmitter glutamate, which increases intracellular calcium mobilization. In excitotoxicity, overstimulation of glutamatergic synapses leads to marked neuronal calcium dyshomeostasis that in turn leads to neuronal injury (Aarts and Tymianski, 2004; Arundine and Tymianski, 2003; Bittigau and Ikonomidou, 1997; Sattler and Tymianski, 2000). Excitotoxic injury contributes to neuronal pathology in a variety of conditions including epilepsy, stroke, traumatic brain injury, multiple sclerosis, and an assortment of neurodegenerative diseases (Corona *et al.*, 2007; Estrada Sánchez *et al.*, 2008; Fujikawa, 2005; Gonsette, 2008; Hazell, 2007;

Hynd *et al.*, 2004; Jennings *et al.*, 2008; Meldrum, 1991, 1993; Sheldon and Robinson, 2007; Ting *et al.*, 2007).

Protein expression changes support the involvement of glutamate receptors in nerve agent exposure. Hippocampal lysates from soman-exposed guinea pigs were found not to differ in their content of neurofilament or synaptophysin, but showed significant increases in subunits of a variety of glutamate and *N*-methyl-D-aspartate (NMDA) receptors (Johnson *et al.*, 2008) that mediate excitatory neurotransmission. Experiments in which nerve agents were injected directly into various brain sites established that the areas most sensitive to seizure induction lie generally in the ventrolateral aspects of the forebrain that contain high concentrations of AChE and ACh (McDonough *et al.*, 1987, 1993). Following activation of these areas, seizures can propagate to sites distant from the area of injection, and these may also demonstrate morphologic evidence of neuronal injury. Importantly, pretreatment or early post-exposure treatment of experimental animals with anticonvulsants, for example with the benzodiazepine diazepam, blocks nerve agent-associated seizures which in turn prevents or diminishes neuropathologic effects (Clement and Broxup, 1993; Hayward *et al.*, 1990; Martin *et al.*, 1985; McDonough *et al.*, 1989, 1995; Philippens *et al.*, 1992). This occurs in the absence of a direct effect on cholinergic processes. These observations, taken together, suggest strongly that excitotoxic mechanisms contribute largely to the structural changes observed in cerebrum upon nerve agent exposure. Abrogation of these mechanisms by anticholinergic drugs within 20–40 min of the onset of seizures is sufficient in most cases to significantly diminish neuropathologic lesions (McDonough and Shih, 1997). The failure of anticholinergic drugs to prevent nerve agent-associated pathologic changes after this time period has been attributed to the recruitment and dominance of non-cholinergic mechanisms of excitotocity and perhaps to secondary loss of the integrity of the blood–brain barrier (McDonough and Shih, 1997).

C. Additional Acute Effects of Nerve Agents on Brain Tissue

Literature on excitoxicity suggests a variety of subsequent mechanisms by which calcium dyshomeostasis leads to neuronal dysfunction and injury. It is conceivable that pathologic effects of nerve agents could also arise via additional, as yet incompletely characterized, mechanisms that are independent of excitotoxicity, or that involve a variety of self-reinforcing cycles of brain tissue injury. A recent ''toxicogenomic'' study of mRNA expression changes following acute sarin exposure provided evidence for increased free radical stress and neuroinflammation in cerebrum, as well as anticipatable changes in the expression of genes involved in calcium flux and binding, neurotransmission, synaptic activity, and glial activation (Damodaran *et al.*, 2006). Roles for oxidative injury and neuroinflammation have been hypothesized in a host of other neurologic conditions, including neurodegenerative diseases (Carnevale *et al.*, 2007; DeLegge and Smoke, 2008; Klegeris *et al.*, 2007; Reynolds *et al.*, 2007; Shi and Gibson, 2007; Tansey *et al.*, 2008), and the demonstration of their involvement in nerve agent-associated neuropathologic changes in brain may suggest additional prophylactic or therapeutic opportunities that are being explored in other neurologic diseases. Hence, the possibility of modulation of the effects of AChE inhibitors on brain tissue by antioxidant and anti-inflammatory drugs has been the subject of a number of recent investigations (Dettbarn *et al.*, 2001; Gupta *et al.*, 2000, 2001a, b; Klaidman *et al.*, 2003; Milatovic *et al.*, 2006).

The morphologic manifestations of immune activation upon exposure of soman-treated rats include a rapid increase in glial fibrillary acidic protein staining, a marker of gliosis, as well as subsequent (1 to 4 hours post-exposure) microglial activation in susceptible areas including the piriform cortex and hippocampus (Zimmer *et al.*, 1997). This is accompanied by increased expression of central neuroinflammatory genes (Williams *et al.*, 2003; Levy *et al.*, 2004; Chapman *et al.*, 2006; Dhote *et al.*, 2007). These observations have led to the development of a novel class of anti-inflammatory, anticholinergic drugs including AChE reactivators that may have utility in nerve agent poisoning (Amitai *et al.*, 2005). In a rat model of AChE inhibitor intoxication, markers of reactive oxygen species (ROS) and reactive nitrogen species (RNS) were found to be elevated in susceptible regions of brain within 15 min to 1 h of exposure (Gupta *et al.*, 2007); this was accompanied by dendritic damage to the hippocampus, a sensitive morphologic marker of neuronal injury (Gupta *et al.*, 2007; see also Figure 43.1). Consistent with an excitotoxic contribution to neurotoxicity, the NMDA receptor antagonist memantine, in combination with the anticholinergic drug atropine, prevented increases in ROS and RNS as well as dendritic damage (Gupta *et al.*, 2007). These findings, taken together, suggest that novel combination therapies that target a variety of processes of nerve agent toxicity may offer enhanced protection, or at minimum may offer a degree of protection if post-exposure treatment is delayed past the point at which anticholinergic drugs have lost much of their utility.

IV. PROLONGED EFFECTS OF SYMPTOMATIC EXPOSURE

A number of studies describe the long-term effects of nerve agent exposure in cerebrum (Collombet *et al.*, 2005a, 2006; Grauer *et al.*, 2008; Kadar *et al.*, 1992; Lemercier *et al.*, 1983; McDonough *et al.*, 1998). Inflammatory changes are pronounced, and may occur in two phases, namely an initial response to cholinergic cell death, as well as a second, delayed inflammatory process that begins approximately 1 month after exposure and persists for at least several months (Grauer *et al.*, 2008). Morphologically, reactive changes

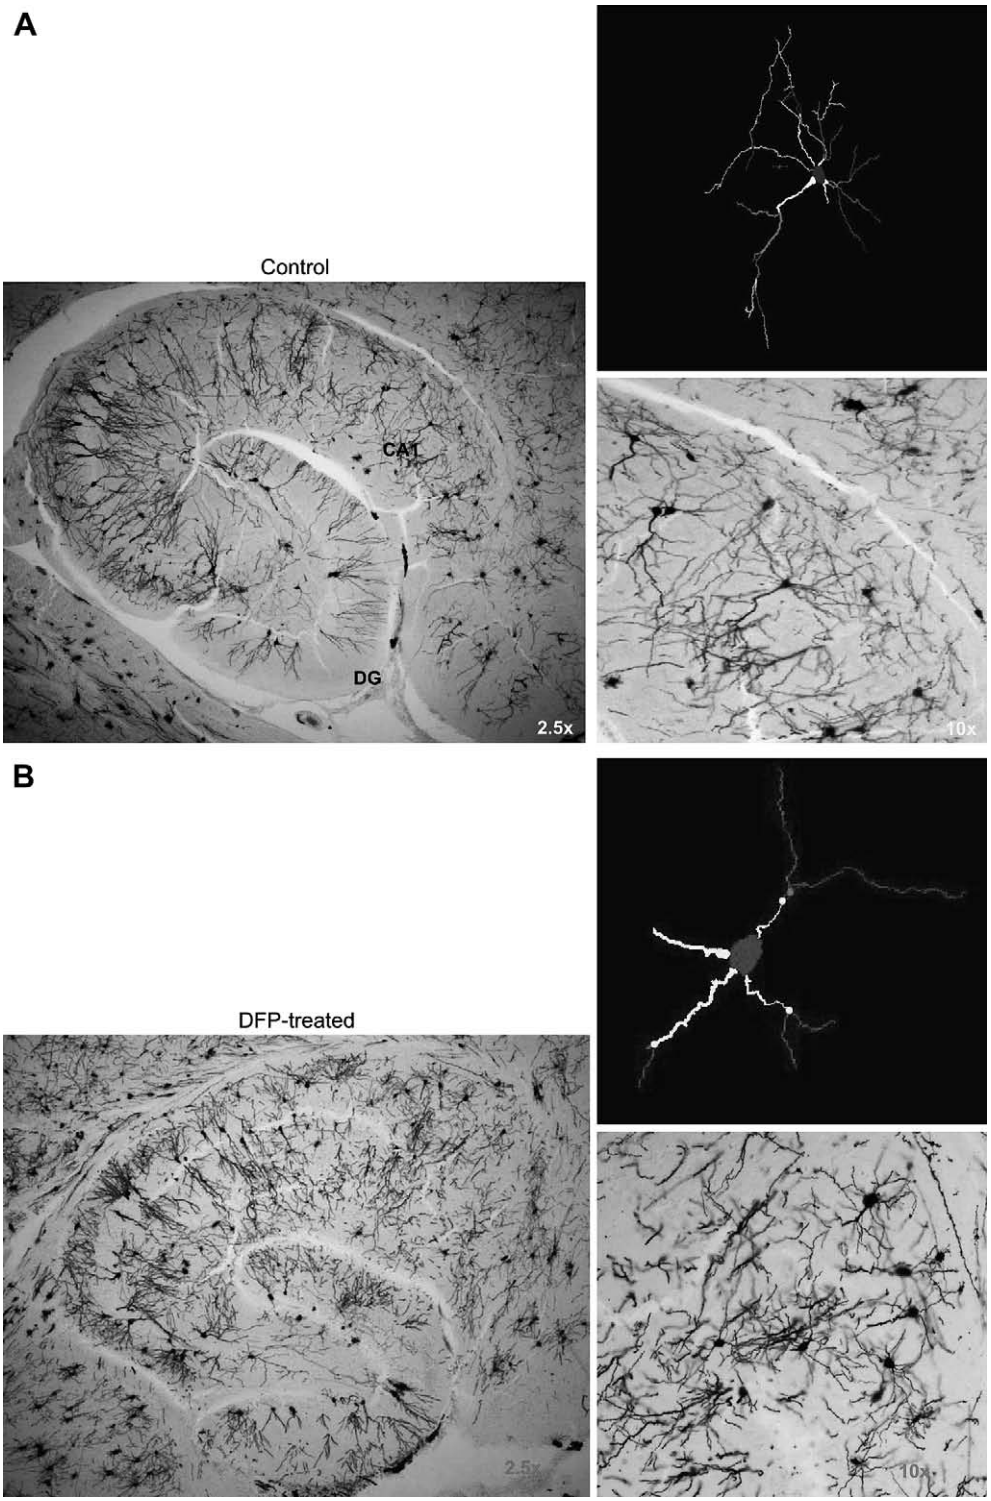

FIGURE 43.1. Photomicrographs of rat hippocampi with pyramidal neurons and their tracings from CA1 hippocampal area (DG, dentate gyrus) of rat brains 1 h after saline (control, panel A) or diisopropyl phosphorofluoridate (DFP, 1.5 mg/kg, s.c.) (panel B) injections. DFP acts as a potent acetylcholinesterase inhibitor with a structure similar to that of organophosphate nerve agents. A single injection of DFP produces toxic signs in rats, including salivation, tremors, fasciculations, and seizures within 15 min that last for more than 2 h before tapering off. The observed signs are typical of anticholinesterase toxicity and reveal the involvement of both the central and the peripheral nervous systems.

Morphological correlates of anticholinesterase exposure were investigated using the structural integrity of the CA1 dendritic system, the neuronal compartment most sensitive to both age-related and disease-related degeneration (Uylings and de Brabander, 2002), as an experimental endpoint. Golgi impregnation of 50 μm thick rat brain sections from paraffin-embedded blocks was carried out according to

that may be seen with many etiologies of brain tissue injury may be observed if survival is sufficiently prolonged after exposure. These include subpial astrogliosis with hyperplastic, swollen astroctyes, as well as reactive microgliosis with microglial lipid accumulation. Focal calcification of brain parenchyma may also be observed, also with localized associated gliosis.

Other long-term changes may be more particular to nerve agent exposure. After acute soman exposure in mice, neuronal degeneration in the hippocampus begins within 1 day. After initial neuronal losses, a subpopulation of degenerating neurons persists for approximately 30 to 90 days before many of these are lost as well (Collombet *et al.*, 2006). These losses are accompanied by a dramatic decline in spatial memory, with a slight recovery at 90 days that may reflect partial neuronal degeneration (Collombet *et al.*, 2006). Similar changes were described in the amygdala (Collombet *et al.*, 2008).

Neurogenesis has also been described in cerebrum in response to focal or global ischemia and epilepsy-associated neurotoxicity (Dong *et al.*, 2003; Nakatomi *et al.*, 2002; Scharfman *et al.*, 2000; Schmidt and Reymann, 2002). After soman-induced toxicity, neural progenitor cells in the subgranular zone of the dentate gyrus and the subventricular zone of the cerebrum expand (Collombet *et al.*, 2005a) and migrate to sites of brain injury (Collombet *et al.*, 2005b), where they engraft and differentiate into neurons and astrocytes within approximately 34 days after exposure (Collombet *et al.*, 2005b). Whether neurotrophic treatments that have been proposed and are under investigation in models of neurodegenerative diseases (Blesch, 2006; Counts and Mufson, 2005; Hennigan *et al.*, 2007; McGeer and McGeer, 2005; Mocchetti *et al.*, 2008; Schulte-Herbrüggen *et al.*, 2008) may have a place in the therapy of nerve agent exposure remains currently a speculative matter, but one that surely warrants investigation.

The only published study of the brain structural effects of nerve agent exposure in a human population focused on long-term changes induced in victims of the 1995 Tokyo subway sarin attack (Yamasue *et al.*, 2007). In this event, which resulted in 12 deaths, approximately 5,500 victims were exposed to sarin, and essentially all patients exhibited typical symptoms of acute intoxication (Lee, 2003; Ohbu *et al.*, 1997). A variety of somatic, ocular, and cognitive symptoms were reported to persist among victims even 5 years after the attack (Kawana *et al.*, 2001). Magnetic resonance imaging revealed decreased regional brain volumes in the insular cortex, neighboring white matter, and hippocampus of victims (Yamasue *et al.*, 2007); reduced regional white matter volume was significantly correlated with decreases in serum cholinesterase levels and with victim symptoms (Yamasue *et al.*, 2007). Although these findings are compatible with sites of susceptibility reported in the nonhuman primate studies cited above, the findings reported were from purely imaging studies, and the precise histopathologic correlates of these findings remain unknown.

V. ORGANOPHOSPHATE-INDUCED DELAYED NEUROTOXICITY (OPIDN)

OPIDN is defined as a delayed onset central and peripheral distal sensorimotor polyneuropathy caused by exposure to nerve agents (Brown and Brix, 1998), typically within 1 to 2 weeks, and less than 4 weeks, after exposure (Johnson, 1980). Symptoms attributable to effects on sensory (numbness, tingling, pain) and motor (fatigue, weakness, and paralysis) targets are present and display a typical axonal length-associated pattern (e.g. predominantly lower extremities, with upper extremities affected at higher agent exposure). No treatment exists, and recovery is slow and rarely complete.

OPIDN has been attributable to inhibition of neuropathy target esterase (NTE), rather than AChE, as inhibition of AChE is not necessary for the development of OPIDN (Jamal, 1997; Pope *et al.*, 1993; Wu and Casida, 1996). Hence, since nerve agents target AChE much more than NTE (Gordon *et al.*, 1983), the degree to which OPIDN would emerge as a significant consequence of nerve agent exposure alone is questionable; rather, doses that could potentially lead to OPIDN would, as a practical matter, cause lethal acute anti-AChE effects first. In fact, unlike many other organophosphates, VX has not been shown to induce OPIDN and is reported to be at least 1,000 times less effective than sarin in inhibiting NTE (Gordon *et al.*, 1983; Vranken *et al.*, 1982). However, several therapies, such

---

the manufacturer's specifications (FD Rapid GolgiStain Kit). Golgi-impregnated pyramidal neurons with no breaks in staining along the dendrites from CA1 sector of the hippocampus were selected and spines counted according to the methods by Leuner *et al.* (2003). Tracing and counting were carried out with a Neurolucida system at ×100 objective magnification under oil immersion (MicroBrightField, VT).

In each panel, the lower left view is a low (2.5× original objective) magnification view of the hippocampus, the lower right view shows dendritic structure at higher magnification (10× original objective), and the upper right view shows a Neurolucida tracing of dendritic structure, in which colors indicate the degree of dendritic branching (yellow = 1°, red = 2°, purple = 3°, green = 4°, turquoise = 5°, gray = 6°).

Anticholinesterase-induced seizure is accompanied by rapid evolution of dendritic abnormalities, apparent in a significant decrease in dendritic length and spine density of pyramidal neurons as early as 1 h post-DFP. Dendritic degeneration seen in this model of DFP-induced seizures is similar to neurodegeneration of pyramidal neurons in CA1 hippocampal area in mouse models of kainic acid-induced excitotoxicity (Zaja-Milatovic *et al.*, 2008) and activated innate immunity (Milatovic *et al.*, 2003). (Courtesy of Dr Dejan Milatovic, Department of Pediatrics, Vanderbilt University School of Medicine)

as the anticonvulsant agent diazepam, that are used to minimize or prevent injury to the central nervous effects of nerve agents have fewer significant effects in the periphery and specifically no effects on the targeting of NTE at peripheral sites. Therefore it is conceivable that OPIDN could be a significant effect in treated survivors of nerve agent exposure. Indeed, exposure of humans to OP insecticides has led in some instances to OPIDN even in the absence of symptoms associated with acute toxicity (Barns, 1975). Experimentally, OPIDN has been induced in hens treated with subsymptomatic doses of OPs, if the time of dose administration is not prolonged (Barns, 1975).

Morphologically, OPIDN is manifested as classic neuropathologic lesions associated with Wallerian-type, or ''dying-back'' degeneration of axons, with secondary demyelination. Briefly, this begins with swelling of the axolemma, the membrane of the axon, and is followed by granular disintegration of intraaxonal organelles and cytoskeleton, including the microtubular network. Schwann cells react rapidly, stopping synthesis of new myelin initially, and clearing degenerating myelin debris; they are aided in this by subsequently recruited macrophages. In the recovery phase, which may be initiated within days after injury, Schwann cells proliferate and release neurotrophic factors which encourage the growth of proximal axonal sprouts from intact axons. This pattern is a nonspecific response to axonal injury and in the absence of a history of exposure to nerve agents, the clinical and neuropathologic differential diagnosis is fairly broad, and includes amyotrophic lateral sclerosis as well as a variety of toxic neuropathies attributable to heavy metal, solvent, and other exposures (Barrett and Oehme, 1985; Longstreth, 1994). Hence, the history of nerve agent exposure is critical in establishing the etiology of clinical neuropathy.

VI. ORGANOPHOSPHATE-ASSOCIATED MUSCLE WEAKNESS

The ''intermediate syndrome'' refers to a delayed syndrome of muscle weakness that occurs shortly after recovery from severe acute effects of OP exposure and is typically associated with full recovery within approximately 4 weeks (Marrs, 1993; De Bleecker, 2006). Although details of the mechanism by which this occurs are not known, it is believed to be attributable to accumulation of ACh at the neuromuscular junction (Karalliedde and Henry, 1993). Consistent with this, morphologically, one finds a necrotizing myopathy that appears somewhat localized to regions of nerve endplate regions (Ariens *et al.*, 1969; Fenichel *et al.*, 1972, 1974; Good *et al.*, 1993; Kawabuchi *et al.*, 1976). Ultrastructural studies reveal vacuolated myofibers in association with nerve terminals containing swollen mitochondria (Hudson *et al.*, 1978; Laskowski *et al.*, 1975, 1977; Meshul *et al.*, 1985; Petras, 1981, 1994). In these studies, a large degree of variability both between experimentally treated animals and within affected muscles was observed; hence, it is clear that unknown additional factors mediate susceptibility. Separation of nerve terminals from the muscle surface was attributable to progressive myofiber vacuolar swelling and insertion of Schwann cell or macrophage processes into the region. This appears likely to be incompatible with effective neurotransmission at this site, and the reversibility of this process may account for the transient nature of OP-associated muscle weakness.

VII. EFFECTS OF SUBSYMPTOMATIC EXPOSURE TO NERVE AGENTS

The classic neuropathologic lesions of nerve agent exposure in cerebrum, as described above, are highly associated with the induction of clinically and electrographically apparent seizure activity. Recently, however, concern has been raised about even low levels of exposure to nerve agents that may not be sufficient to result in symptoms at the time of exposure, but may nevertheless lead to clinical symptoms or neuropathologic effects after long delays, perhaps in the context of chronic or repeated exposures. One scenario in which this might occur invokes an urban exposure to an agent such as VX followed by incomplete decontamination with prolonged evaporative or other contact with persistently contaminated surfaces (Bloch-Shilderman *et al.*, 2008). In addition, practical experience with nerve agent exposure has shown that most episodes involve small or asymptomatic doses, for example to emergency and medical treatment personnel, as opposed to acute symptomatic toxicity (Gray *et al.*, 1999; Levin and Rodnitzky, 1976; Morita *et al.*, 1995).

Concern about the effects of low doses of nerve agents is founded in part on observations in populations, such as agricultural workers, with chronic occupational exposure to OP compounds, such as pesticides. Many reports relate neurologic changes to these exposures (Kamel *et al.*, 2005, 2007; Pilkington *et al.*, 2001; Rohlman *et al.*, 2005; Roldán-Tapia *et al.*, 2005, 2006; Rothlein *et al.*, 2006; Salvi *et al.*, 2003; Wesseling *et al.*, 2002), and relevant biochemical alterations have been described in these subjects, including changes in antioxidant status (López *et al.*, 2007). Other investigators have shown biochemical changes including muscarinic receptor decreases and mRNA cytokine expression changes in affected cerebrum in animal models (Henderson *et al.*, 2002). In a rat model of subsymptomatic exposure, repeated exposure to sarin at a dose that induced a 30% inhibition of erythrocyte AChE led eventually to ataxic gait, increased stereotyped behavior, and increased central nervous system excitability following administration of the convulsive drug pentamethylenetetrazol (Kassa *et al.*, 2001). Repeated low-dose sarin exposure also led to a disrupted electroencephalographic sleep pattern (Shih *et al.*, 2006) and decreased locomotor activity and cognitive performance tests in rats and mice (Baille *et al.*, 2001; Nieminen *et al.*, 1990; Russell *et al.*, 1986; Sirkka *et al.*, 1990).

Interestingly, some endpoints, such as temporal perception, were initially impaired by low-dose soman treatment, but led to tolerance later on, whereas others, such as nociceptive sensory and perceptual thresholds, became and remained elevated throughout the course of treatment (Russell *et al.*, 1986). In nonhuman primates treated with subtoxic doses of sarin (Burchfiel *et al.*, 1976) as well as humans with symptomatic but limited exposure to nerve agents (Duffy *et al.*, 1979; Metcalf and Holmes, 1969; Wadia *et al.*, 1974), electroencephalographic changes were significant and persisted many months after exposure.

In no study of subsymptomatic nerve agent exposure were significant neuropathologic lesions, as determined by standard histopathologic techniques, found to be associated with behavioral or biochemical endpoints. However, it remains to be determined whether more sensitive morphologic endpoints, such as hippocampal dendritic structure as illustrated in Figure 43.1, are altered by exposures of this nature. This having been said, the data reviewed here illustrate the difficulty of determining ''safe'' levels of nerve agent exposure in human populations.

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

The neuropathologic effects of chemical warfare agents, particularly OP nerve agents, have been characterized and related to a variety of central and peripheral clinical syndromes. The most prominent of these are neuronal losses at characteristic sites in cerebrum that follow and correlate with the presence of nerve agent-induced seizure activity, with accompanying glial reaction and a subsequent, incomplete neuroregenerative response. Recent progress in our understanding of excitotoxic, neuroinflammatory, and oxidative processes that may contribute to the development of neurotoxicity provides a conceptual link to other neurologic diseases. Therapies that prove successful in preventing or treating these diseases might also be translated into neuroprotective strategies that might be useful in populations exposed to chemical warfare agents. Conversely, if novel, effective treatments for nerve agent exposure can be developed, we should be mindful of the possible value of their application to a host of neurological illnesses, especially age-related neurodegenerative diseases that are becoming increasingly prevalent in Western societies.

CHAPTER 44

Molecular and Transcriptional Responses to Sarin Exposure

T.V. DAMODARAN

I. INTRODUCTION

Chemical warfare related agents such as cyclosarin, sarin, soman, tabun, VR, and VX have become the focus of attention of both the international scientific community and the public ever since the end of Gulf War in 1991 (Golomb, 2008), followed by the tragic nerve agent exposure-related deaths and sicknesses in Tokyo in 1995. As a result of the September 11, 2001 terrorist attacks on the World Trade Center, and the ensuing possibility of unexpected war and terrorist attack scenarios that may involve chemical agents, there is a general heightened awareness of the necessity for more detailed studies on the nature of biological effects of these agents, and to improve diagnostic, preventive, and treatment aspects of toxic chemical exposure.

Sarin (*O*-isopropyl methylphosphonofluoridate; GB) is an organophosphorus (OP) ester that belongs to a group of highly toxic nerve agents. Many individuals have been suspected of exposure to various levels of sarin during the Gulf War (Golomb, 2008) as well as the Tokyo subway attacks (Miyaki *et al.*, 2005). Clinical symptoms such as arthralgia, weakness, fatigue, headache, memory loss, and increased susceptibility to infections were recorded in these individuals. There have been speculations about the low level of sarin exposure affecting distinct regions of the brain (Damodaran *et al.*, 2002a). High levels of exposure result in seizures, which increase the release of glutamate and cause toxicity to the surrounding cells (Solberg and Belkin, 1997). However, very little is known about the genomic and related nongenomic effects of sarin exposures at different dosage levels leading to pathological outcome.

II. BACKGROUND

One of the major mechanisms known for sarin-induced toxicity is the irreversible inhibition of the enzyme acetylcholinesterase (AChE), resulting in central accumulation of acetylcholine (ACh) and overexcitation of cholinergic neurons in sarin exposure related neurotoxicity. Besides this, a range of noncholinergic effects have been observed (Ray, 1998). Cholinergic components including ACh, choline acetyltransferase (ChAT), AChE, vesicle acetylcholine transporter (VAChT), muscarinic and nicotinic ACh receptors (mAChRs and nAChRs, respectively) have been identified in numerous nonneuronal cell and tissue types (Kawashima and Fujii, 2008) and thus make the biological response to sarin exposure into a very complex phenomenon. Given the complex levels of physiological alterations, one can expect global changes in RNA and protein species of different genes. Hence, gene expression approaches and other relevant molecular assays will help to identify key pathways that are triggered immediately and showed sustained expression over a long period of time, thus giving a mechanistic view on the possible mode of initiation, modification, persistence or disappearance of distinct molecular lesions that may translate into cellular/tissue level pathology leading to clinically and behaviorally observable disease/syndromic features (Damodaran *et al.*, 2006a).

A. Gene Expression as a Tool of Toxicity Testing

The idea of using gene expression as a tool in toxicology is based on the known fact that all toxic responses require modulation of expression of several key genes involved in various biological pathways to some degree and that no gene is regulated in isolation, even in the simplest biological system. Gene expression studies can be useful for the following reasons: (1) the construction of a large database of gene expression information linked to toxic endpoints, (2) more detailed understanding of the molecular mechanisms of compound toxicity, (3) identifying expression signatures that distinguish toxic effects of closely related chemicals, (4) identification and monitoring of different doses of suspected toxic chemical exposures (such as low vs high level), (5) differentiating acute vs chronic exposures and different combinations of both types, (6) identifying different chemicals in scenarios of suspected exposure to unknown chemical mixtures, (7) therapy or antidote response and effectiveness, and (8) long-term monitoring for any unknown biological effects. The strategic application of information

obtained by the above-mentioned approaches should result in the development of both more rapid, mechanism-based diagnostic screens for toxicity and novel therapeutic targets. Thus the development and use of gene expression-based biomarkers in toxicology are becoming widespread, specifically in the areas of exposure monitoring, and the determination of response and susceptibility to toxins.

B. Application of Genomics Technology for Studying Gene Expression

Two general approaches of gene expression related to toxicology and safety assessment have evolved, either of which can be deployed depending on the nature of the investigation being carried out.

The first (candidate gene or deductive) approach is to use either a single gene or arrays with discrete, often limited number of known (candidates for disease pathology or monitoring either one or several clinical and treatment endpoints related to toxic exposure) genes that have been selected on a rational basis as being associated with one or more toxic endpoints. The advantage here is that the methodology is relatively simple, and data analysis is considerably easier and restricted to those genes that are likely to be ''interesting'' and relevant to the toxicological problem in question. A large body of data has been published regarding expression profiles of few candidate genes for many toxic substances such as sarin and similar chemicals. Very often, the data obtained by this approach can be categorized as ''hypothesis testing'' – for example, the hypothesis that a subacute dose (0.5 LD_{50}) of sarin may affect neuronal and astroglial cells was tested by studying the expression of neuron-specific alpha tubulin (Damodaran *et al.*, 2002b), astrocyte-specific glial fibrillary acetic protein (GFAP), and vimentin (Damodaran *et al.*, 2002a). These time course studies confirmed the hypothesis by yielding expression data indicative of differential (various regions of the brain) and temporal (different days after exposure) modulation of all of these genes. Furthermore, another hypothesis that differential and temporal expression of AChE genes may explain the various molecular, cellular, and behavioral aspects of sarin exposure was tested by this approach (Damodaran *et al.*, 2003) in a time course study which also provided valuable data that confirmed biochemical, cell biological, and behavioral data obtained earlier (Jones *et al.*, 2000; Abou-Donia *et al.*, 2002; Abdel-Rahman *et al.*, 2002).

The second (global gene expression profiling or ''inductive'') approach is to use gene arrays with as many genes as possible, both characterized and otherwise, to maximize the amount of information obtainable from a single experiment. This scenario is applicable when novel genetic markers associated with a particular toxicity are sought or when a gene regulation ''fingerprint'' associated with a particular compound or toxic endpoint is to be generated. Moreover, identification of several novel pathways and gene clusters by this approach makes it a much more attractive option. The amount of data obtained by this approach is enormous and very often requires complex statistical and bioinformatics tools. Other disadvantages include situations where the interaction of cells and tissues with certain compounds such as xenobiotics will result in changes in patterns of gene expression, not all of which will be of significance in terms of toxicity. The data obtained by this approach are generally ''hypothesis generating'' for the most part, while they can be used to verify already known facts or hypotheses. For example, the hypothesis that early molecular events after sarin exposure define long-term pathology was studied by global gene expression approaches (Damodaran *et al.*, 2006a, b). Enormous amounts of data obtained by this study not only verified already known facts and verified the above-mentioned hypothesis, but also generated more hypotheses for future testing. For example, in a recent study, it was shown that signature expression profiles found in lung cancer patients with and without long-term exposure to pesticides were significantly different, thus paving the way to develop novel approaches to classify the patients based on this molecular profile, identify therapeutic targets, and monitor efficacy of treatment (Potti *et al.*, 2005). Hence, ultimately the decision to select an approach depends on the short- and long-term objectives in the effort to elucidate the toxicity of chemicals under study. Very often, both approaches are used simultaneously for better and faster understanding of the biological phenomena associated with toxicity of the chemical being studied.

1. Current Methodologies Available for Studying Gene Expression

Several methods have been developed to screen cells/tissues for differentially expressed genes, such as screening of differential cDNA libraries (Dworkin and David, 1980), screening of subtractive cDNA libraries (Sargentg, 1998), screening by differential display by PCR (Liang and Pardee, 1992), and sequence-based serial analysis of gene expression (SAGE) (Velculescu *et al.*, 1995). While these procedures are suitable for identifying few-fold or greater changes in gene expression (i.e. when genes are either turned off or on), they are inadequate for detecting subtle changes in gene expression. High-density cDNA arrays allow one to rapidly screen cells/tissues for differential gene expression as well as quantify changes as small as 0.5-fold or less with statistically significant levels of accuracy (Damodaran *et al.*, 2006b). Recent assessment of the relative impact of experimental treatment and platform on measured expression found that biological treatment had a far greater impact on measured expression than did platform for more than 90% of genes, and thus confirmed that global approaches in gene expression studies are reliable and promising (Larkin *et al.*, 2005).

2. Latest Genomic Technologies that Hold Promise for Future Investigations

Although most of the gene expression studies on sarin and related compounds address the changes in transcriptomes,

there have been recent developments in microarray technology such as: (1) global analysis of changes at DNA level such as deletions, inversions, duplications, and translocations in monogenic diseases, complex diseases, and various types of cancers, possibly due to exposure to chemical and physical agents, using comparative genomic hybridization (CGH) methodology, (2) genotyping single nucleotide polymorphism (SNP) or other point mutations as a factor in susceptibility to certain disease development and/or as an adverse or protective effect against certain chemical exposures or drug treatment, (3) level of methylation changes due to chemical exposure or other disease states using global epigenetic profiling, and (4) microRNA expression profiling as an adjunct technology to address specific effects of chemical exposure on molecular regulation of differentiation and proliferation-related changes in various target tissues. It is noteworthy to mention here that there are studies using sister chromatid exchange (SCE) analysis of peripheral blood lymphocytes from victims of sarin exposure from the Tokyo train terrorist attack (Li *et al.*, 2000) and scoring of various cytogenetic anomalies such as mitotic chromosome and chromatid breaks, gaps, and other anomalies of anaphase such as lagging of chromosomes have been employed in studies of *in vitro* peripheral blood culture from humans exposed to pesticides (Das *et al.*, 2006) to assess genomic effects on somatic cells. Furthermore, the use of multicolor fluorescence *in situ* hybridization (FISH) on germ cells (sperms) of individuals exposed to OPs was also attempted (Recio *et al.*, 2001). There is an excellent Prospectus for identifying subtle DNA level changes which could be either megabase deletions of large contiguous regions of genome or minor deletions of a few kilobases of genomic regions of instability and/or recombination due to exposure to warfare chemicals by CGH technology. This also corresponds to the identification of the modifying effect of inherited and acquired interactions between AChE and paraoxonase1 (PON1) polymorphisms modulating AChE and plasma paraoxonase enzyme activities both within and between genotypes on the susceptibility of individuals, in their response to OPs exposure warrants, such as genotype studies and other SNP-based screenings at population level (Bryk *et al.*, 2005; Sirivarasai *et al.*, 2007). This kind of population data will be of great advantage in situations where there is a need to screen soldiers, medical personnel, and members of other support organizations during warfare or a terrorist attack for assessing their increased or decreased susceptibilities to warfare agents. The modifying effects of methylation and its importance in transmitting abnormally methylated alleles to future generations are also gaining widespread attention. Besides these latest developments, other established and emerging technologies such as proteomics and global analysis of post-translation changes (such as phosphorylation), respectively, may address several biological end points relevant to sarin-induced toxicity, its treatment and management as well as long-term monitoring. Tissue arrays and high throughput validation (such as high content confocal analysis) methodologies related to genomic technologies make it a very promising future for prompt and precise detection of toxic exposure that can lead to better treatment options, thus reducing overall mortality and morbidity associated with any such scenarios.

III. SARIN-INDUCED CLINICAL CHANGES AS A FUNCTION OF CELLULAR AND MOLECULAR ALTERATIONS

A. Acute Sarin Exposure and Clinical and Molecular Symptoms

A high dose of acute exposure results in marked muscle fasciculation, tachycardia, high blood pressure (nicotinic responses), sneezing, rhinorrhea, miosis, reduced consciousness, respiratory compromise, seizures, and flaccid paralysis (Yokoyama *et al.*, 1998). High-dose acute exposure targets several pathways such as cholinergic, cyclic nucleotide signaling, catecholaminergic signaling, GABAergic signaling, glutamate and aspartate signaling, nitric oxide signaling, and purinergic, serotogenic, as well as cholinergic signaling, within the first 15 min to 2 h of sarin exposure (Damodaran *et al.*, 2006a, b). Other signal transduction pathways such as calcium channels and binding proteins, ligand-gated ion channels, neurotransmission and neurotransmitter transporters, neuropeptides, and their receptors are also altered. Inflammation-related pathways such as TNF pathways, chemokines and their receptors, and cytokines are also altered within 15 min to 2 h after sarin exposure (Damodaran *et al.*, 2006a).

B. Sarin-Induced Delayed Neurotoxicity

High doses of sarin exposure can lead to delayed onset of ataxia, accompanied by wallerian-type degeneration of the axon and myelin of the central nervous system (CNS) and peripheral nervous system (PNS), also known as both organophosphorus ester-induced delayed neurotoxicity and OPIDN (Smith *et al.*, 1930; Abou-Donia, 1990). After the Tokyo subway incident, a 51-year-old man who survived the initial acute toxicity later died (after 15 months), with neurological deficits and histopathological lesions consistent with OPIDN (Himura *et al.*, 1998). This observation strongly suggests that humans are more sensitive to OPIDN caused by sarin than the hen (a commonly used experimental model organism to study OPIDN), as it required 26–28 daily doses of sarin LD_{50} (25 μg/kg, i.m.) to produce OPIDN in this species (Davies and Holland, 1972). It has been shown that the anomalous increase in phosphorylation and altered expression of mRNA and proteins of cytoskeletal genes is the central mechanism in the pathogenesis of OPIDN in model systems (Abou-Donia, 1995; Gupta *et al.*,

1998, 1999, 2000a, b, 2001; Gupta and Abou-Donia, 1999; Damodaran and Abou-Donia, 2000; Xie *et al.*, 2001). Sustained hyperphosphorylation of cytoskeletal proteins is not only a feature of OPIDN, but also a mediator of axonal dysfunction that perturbs the dynamics of the cytoskeleton. There are several kinases [such as protein kinase A (PKA)] associated with cytoskeletal proteins [such as neural filaments (NFs), tau, tubulin] shown to be altered in OPIDN (Gupta and Abou-Donia, 1999). Abnormal axonal transport is one of the main reasons for the degeneration of axons in OPIDN. Microtubules form the base for transport of axonal constituents, which are essential for the maintenance of axons. Microtubules interact with microfilaments, neurofilaments, kinesin, dynein, and microtubule-associated proteins (e.g. MAP-1, MAP-2, tau). Altered mRNA expression of several major cytoskeletal genes such as beta tubulin (Tubb1), Nestin (Nes) at immediate early (15 min), and neurofilament heavy (NEFH), GFAP at early (2 h), as well as MAP2 (microtubule associated protein 2) at late (3 months) time points after sarin exposure in rats indicates the existence of OPIDN-related molecular changes (Damodaran *et al.*, 2006a, b). Similar changes were noted in studies on hens showing clinical and histopathological features typical of OPIDN (Gupta *et al.*, 1999; Damodaran and Abou-Donia, 2000).

C. Sarin-Induced Chronic Neurotoxicity

The category is postulated as organophosphorus-induced chronic neurotoxicity (OPICN) which is characterized as long-term neurological deficits accompanied by brain neuronal cell death (Abou-Donia, 2003). Exposure to large toxic or small subclinical doses of OPs can result in such syndrome. Some of the Tokyo subway incident's victims developed long-term, chronic neurotoxicity characterized by central nervous system deficits and neurobehavioral impairments (Masuda *et al.*, 1995). Rescue workers and some victims who failed to show any early symptoms of neurotoxicity exhibited a chronic decline in memory 3 years and 9 months after the Tokyo incident (Yokoyama *et al.*,1998). Several genes (Bax, Bok, Bcl2l1, Casp6, Bcl-X, Dedd) related to cell death phenomena showed alterations at various time points after sarin exposure (Damodaran *et al.*, 2006a, b). Differential alteration of mRNA expression of AChE in rat brain regions exposed to sarin has been reported (Damodaran *et al.*, 2003) and is postulated to be related to the cell death observed in earlier studies on the brain of sarin-treated rats (Kadar *et al.*, 1995; Abdel-Rahman *et al.*, 2002).

D. Sarin-Induced Molecular Changes

Because of the complexity of the nervous system and the multiplicity of neurotoxic effects (sensory, motor, cognitive, etc.), it is apparent that several mechanisms of neurotoxicity exist; some may be specific to the nervous system, while others may be specific to other target organs and represent general cytotoxicity processes. Some of the major mechanisms include:

1. direct effect on a particular step in cell signaling and associated gene expression (e.g. protein kinases)
2. effect on second messenger responses activated by an endogenous compound (e.g. a neurotransmitter-induced activation of phospholipid hydrolysis) and related gene expression
3. indirect effect due to other toxic actions (e.g. induction of oxidative stress) and related gene expression.

The complexity of the pathways altered by sarin can be very well understood by the schematic pathway diagram (Figures 44.1–44.3).

1. Sarin-Induced Changes in Cell Signaling

Cell signaling is the fundamental process by which specific information is transferred from the cell surface to the cytosol and ultimately to the nucleus, leading to changes in gene expression. Since these chains of biochemical and molecular steps control the normal function of each cell, any disruption of these processes will have a significant impact on cell physiology. The phosphoinositide/calcium/PKC system, with a focus on the cholinergic system, plays a prominent role in several CNS- and PNS-related functions. ACh, by activating muscarinic receptors, may play a fundamental role in the regulation of synaptogenesis, neurocytomorphogensis, and glial cell proliferation (Costa, 1993) and exposure to sarin may alter its effect on the above-mentioned biological aspects. In astrocytes, ACh stimulates the metabolism of phosphoinositides and the hydrolysis of phosphatidylcholine increases intracellular calcium levels. These effects linked to muscarinic receptor stimulation may be modulated by sarin exposure. Other pathways important for glial cell proliferation (e.g. the phosphoinositide 3-kinase, MAP kinase, etc.) may be activated by ACh in these cells and may represent significant targets for sarin's action.

Neurotransmitters, hormones, and growth factors serve as first messengers to transfer information from one cell to another by binding to specific cell membrane receptors. This interaction results in activation or inhibition of specific enzymes and/or opening of ion channels, which leads to changes in intracellular metabolism and, in turn, to a variety of effects, including activation of protein kinases and transcription factors. These intracellular pathways can be activated by totally different receptors and are very interactive, or crosstalking, so they can control and modulate each other. The principal systems that link membrane receptors to second-messenger systems are represented by G-protein coupled receptors (GPCRs) and by receptors that possess intrinsic tyrosine kinase activity (Costa, 1998).

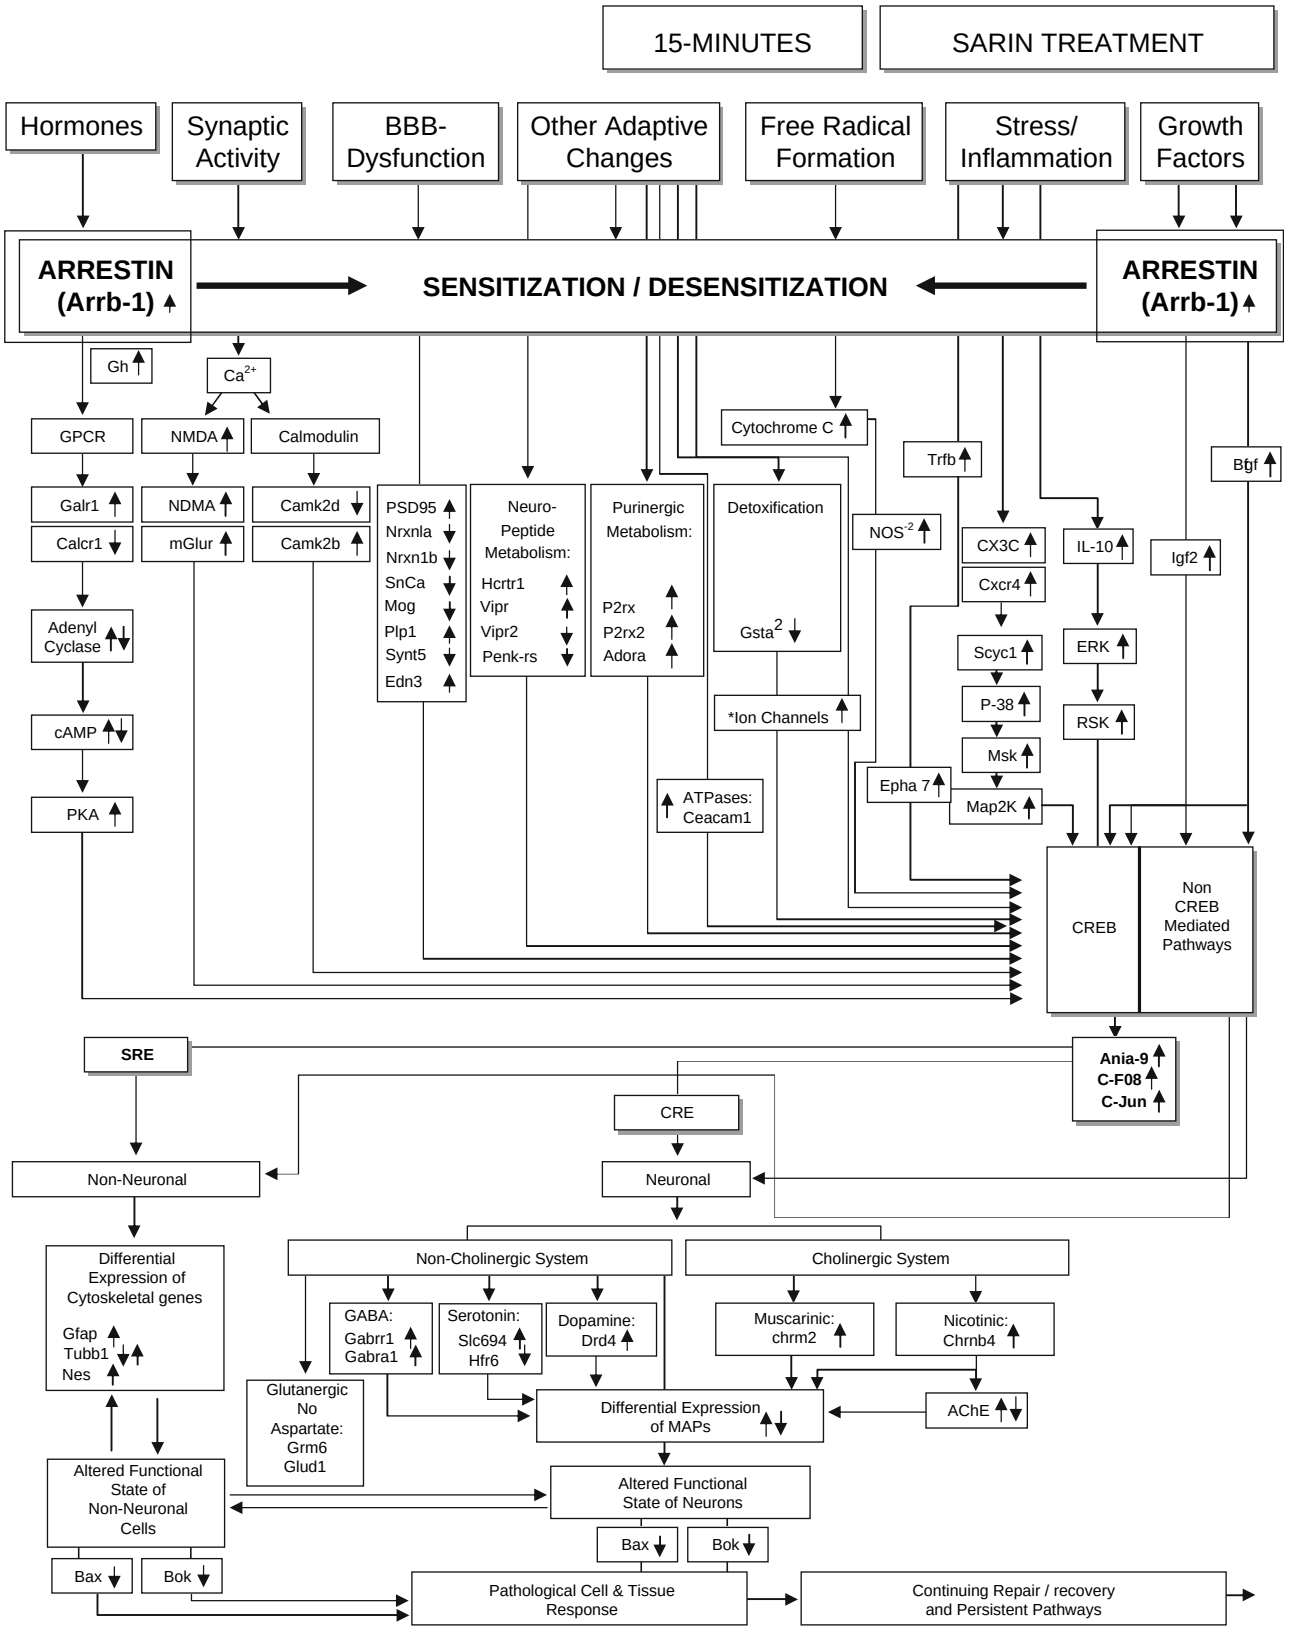

FIGURE 44.1. Similar phenomena as shown in Figure 44.1, at 2 h post-sarin exposure (0.5 LD_{50}) in rat brain, to much lesser complexity, as indicated by the fewer number of genes (pathways) altered. Major upstream events include beta arrestin/GPCR pathways followed by CREB/non-CREB pathways. In spite of the same dose (0.5 LD_{50}) used in both, 15 min (Figure 44.1) and 2 h (Figure 44.2), there are far fewer genes altered at 2 h, which strongly suggests initiation of prompt and effective recovery, repair, and adaptive processes early on. This figure is reproduced with permission from Springer Pvt Ltd.

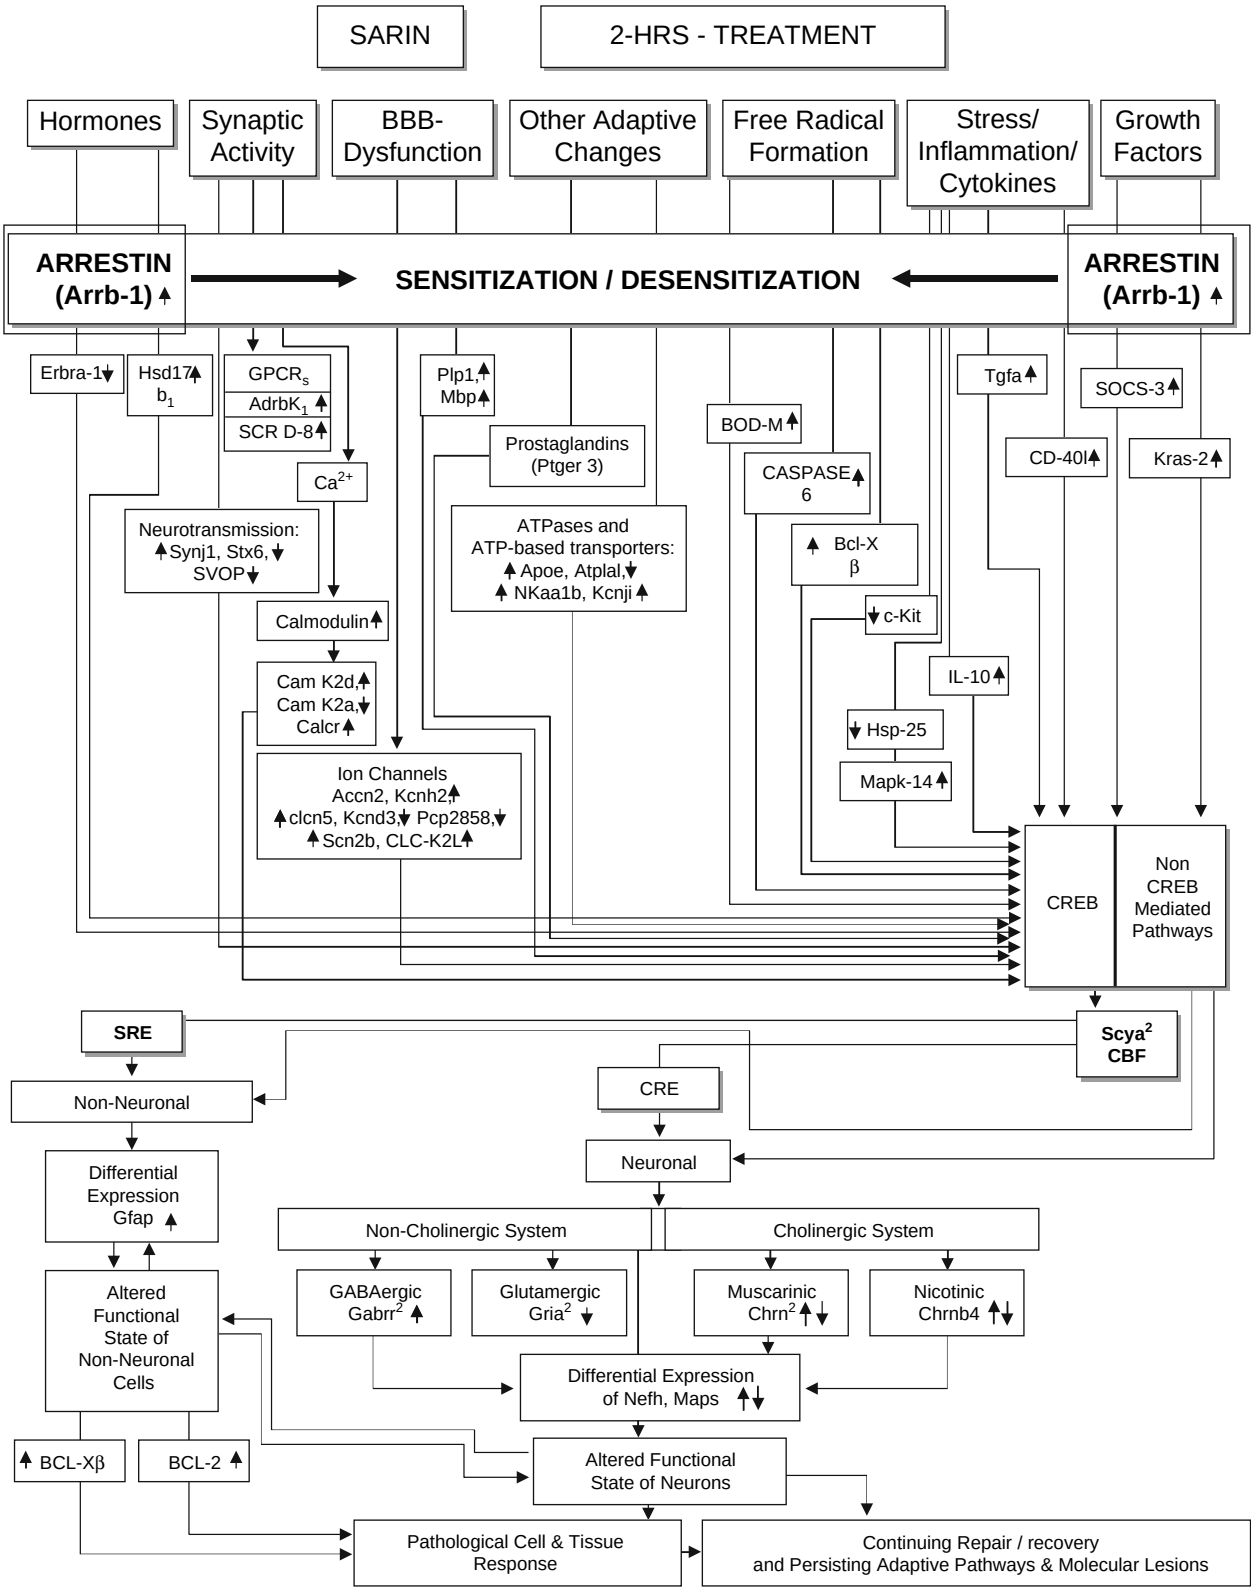

FIGURE 44.2. The complex gene expression changes initiated by sarin exposure (0.5 LD_{50}) in rat brain. Various factors such as hormones, altered synaptic activity, BBB dysfunction, free radical formation, stress/inflammation, alteration in the level of growth factors, and other adaptive pathways are found to be triggered by these changes. Major upstream events are all mediated through altered sensitization/desensitization mechanisms of beta arrestin/GPCR pathways. Another major upstream event which is downstream to beta arrestin/GPCR is the CREB (phosphorylated and/or unphosphorylated) and non-CREB mediated pathways. The signals processed at these two levels cause further changes in cholinergic and noncholinergic pathways in neuronal and nonneuronal cells. Thus, there are alterations in several mechanisms related to cell and tissue homeostasis, repair, and recovery pathways, thus leading to several adaptive changes. This figure is reproduced with permission from Elsevier Pvt Ltd.

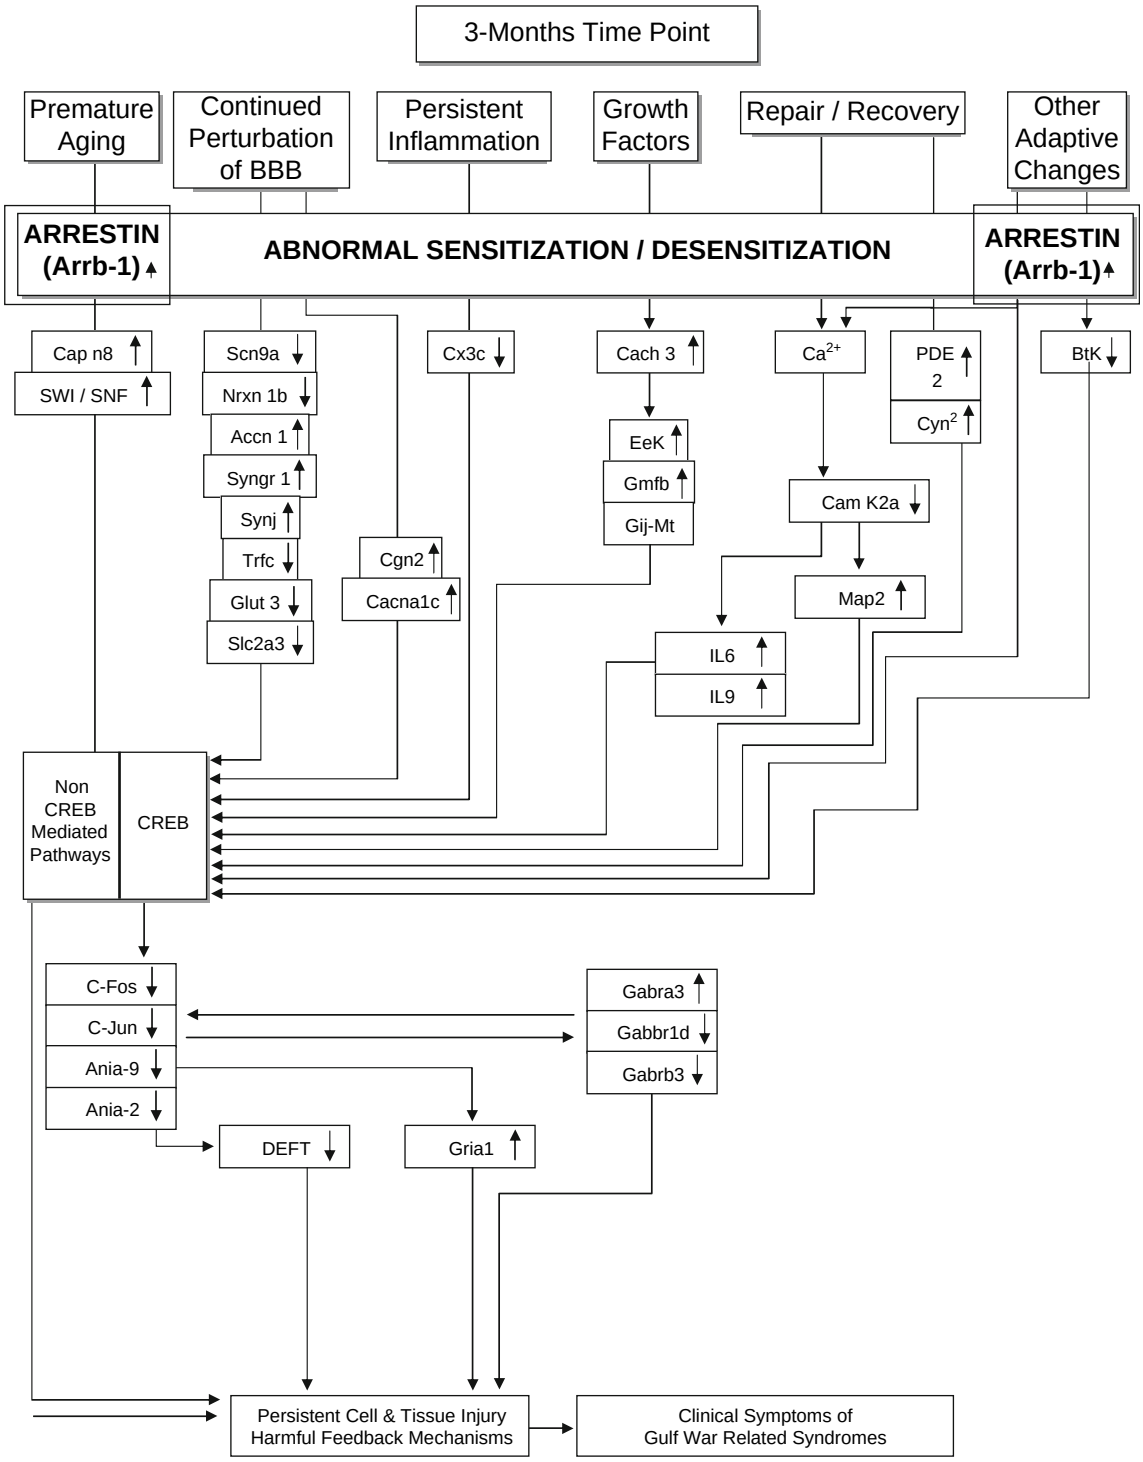

FIGURE 44.3. Pathways (genes) triggered at 3 months post-sarin exposure ($1 \times LD_{50}$) in rat brain. Various factors such as abnormal or premature aging process, continued BBB perturbations, persistent inflammation, and other adaptive, repair, and recovery pathways are found to be altered by upstream events such as beta arrestin/GPCR. This is followed by CREB/non-CREB pathways leading to changes in other downstream mechanisms of cell and tissue damage which lead to observable clinical symptoms as noted in Gulf War Syndrome patients and Japan subway terrorist incident-related victims. This figure is reproduced with permission from Elsevier Pvt Ltd.

2. Sarin-Induced Changes in G-Protein Coupled Receptors (GPCR) and Arrestin Mediated Pathways

G-protein coupled receptors (GPCRs) are one of the largest gene families of signaling proteins. Residing in the plasma membrane with seven transmembrane domains, GPCRs respond to extracellular stimuli that include catecholamine neurotransmitters, neuropeptides, larger protein hormones, lipids, nucleotides, and other biological molecules. They activate cellular responses through a variety of second messenger cascades (such as PKA and PKC signaling pathways). These receptors provide rapid responses to a variety of stimuli, and are often rapidly attenuated in their signaling. Failure to attenuate GPCR signaling can have dramatic consequences. One method to attenuate GPCR signaling is by removal of the stimulus from the extracellular fluid. At the synapse, removal of neurotransmitter or peptide signaling molecules is accomplished by either reuptake or degradation. ACh is removed from synapses through degradation by the enzyme AChE. Inhibition of AChE results in prolonged signaling at the neuromuscular junction (NMJ), and uncontrollable spasms in humans caused by sarin and other OPs. Transporters for serotonin, dopamine, GABA, and noradrenaline remove these neurotransmitters from the synapse to terminate signaling. The attenuation of GPCR signaling is receptor desensitization, in which receptors are modified to terminate signal transduction, even if the stimulus is still present.

The overexpression of either arrestin 1 or arrestin 2 has been demonstrated to augment the desensitization and internalization of several GPCRs (Pippig *et al.*, 1993; Oakley *et al.*, 1999). Thus, overexpression of arrestin at 15 min, 2 h, and 3 months post-sarin exposure, along with continued overexpression of several other genes belonging to several classes (Camk Ib, Camk2d, SCR D-8, M2-AchR; GALR1; CRLR) at 15 min, 2 h or 3 months, clearly indicate that sarin-induced hyperphosphorylation and related molecular changes persist until a later time point, thus causing defects in the tissue repair process (Damodaran *et al.*, 2006a, b).

3. Sarin-Induced Immediate Early Genes (IEGs)

In sarin-induced Ania-9 (activity and neurotransmitter-induced early gene 9) at 15 min post-exposure, the levels were down-regulated to 42% of the control value at 3 months post-exposure. Other genes such as c-fos, c-jun, and Ania-2 were also severely down-regulated at 3 months (Damodaran *et al.*, 2006a). Scya2 (immediate early serum responsive JE) was the only gene induced (285% of control levels) at 2 h post-sarin exposure (Damodaran *et al.*, 2006b). It is a well-known fact that ITFs (immediately induced transcription factors) and IEGs are among the most rapidly degraded of all proteins suggesting breakdown by the calpain and ubiquitin systems operating through lysosomes and proteosomes (Jariel-Encontre, 1997). Thus, down-regulation of these IEGs at a late time point can be caused by (1) successful regeneration, or, if this cannot be achieved, (2) a resting atrophic state, or (3) cell death (Damodaran *et al.*, 2006a, b).

4. Cholinergic System as the Primary Target of Sarin-Induced Toxicity

Sarin, like other OPs, elicit its toxic effects by irreversibly inhibiting AChE in the central cholinergic system, and excessive stimulation of postsynaptic cholinergic receptors. The overstimulation of the central cholinergic system is followed by the activation of other neurotransmitter systems including glutamate receptors leading to an increase in extracellular levels of the excitatory amino acid glutamate (McDonough and Shih, 1997). Numerous studies have shown that excessive accumulation of ACh leads to activation of ligand-gated ion channels, nicotinic ACh receptors (nAChRs), and muscarinic ACh receptors (mAChRs), which activate diverse kinds of cellular response by distinct signaling mechanisms (Abou-Donia *et al.*, 2002; Damodaran *et al.*, 2006a). Immediate and overexpression of the M2 receptor (214%) of the control value (100%) confirms biochemical data from several studies, showing consistent alterations in receptor density at 1, 3, 6, 15, and 20 h post-treatment (Abou-Donia *et al.*, 2002; Damodaran *et al.*, 2006a, b). nAChRs are essential for neuromuscular signaling, apoptotic signaling, neuroprotection, and synapse formation. The induced levels of nAChRs (150%) probably indicate its role in all of the above-mentioned capacities (Damodaran *et al.*, 2006a).

It is a well-known phenomenon that the cholinergic system interacts with various CNS neurotransmitters including serotonin (Quirion *et al.*, 1985), dopamine (Lehmann and Langer, 1982), catecholamines (Mason and Fibiger, 1979), GABA (Scatton and Bartholini, 1980), and neuropeptides (Lamour and Epelbaum, 1988). The cholinergic neurotransmitter system also controls cerebral vasculature (Armstrong, 1986). Modified gene expression of genes belonging to various systems such as serotonin [Slc6a4 (141%), Htr6 (47%)], dopamine [Drd4 (225%)], GABA [Gabbr-1 (179%), Gabra1 (130%)], and neuropeptides [Vipr (219%), Edn3 (236%), Hcrtr1 (139%)] from the control value (100%) confirms such an active interaction (Damodaran *et al.*, 2006a, b).

In addition, neurons express two pools of AChE: active and inactive (Choi *et al.*, 1998). It is not known how these two pools of AChE are regulated post-translationally.

Moreover, Kaufer *et al.* (1999) suggested that in addition to ACh, an autologous feedback response could regulate transcriptional elevation from the AChE gene through AChE-antiChE complexes on signaling intracellular pathways. Excess muscarinic activation induced either by agonist application or by inhibition of the AChE results in long-lasting modifications of gene expression and protein levels of key cholinergic proteins (Meshorer and Soreq, 2006). Specifically, such changes involve transcriptional accentuation as well as shifted alternative splicing of AChE

pre-mRNA transcripts. This yields elevated levels of the stress-induced ''readthrough'' AChE-R mRNA transcript, translated into soluble AChE-R monomers rather than the primary ''synaptic'' AChE-S membrane-altered tetramers (Meshorer and Soreq, 2006). These two AChE variants can both hydrolyze ACh with similar efficiency, yet their different C-terminal sequences affect their subcellular localization as well as their protein partners (Meshorer and Soreq, 2006). Thus, multilevel changes initiated by sarin exposure on the cholinergic system have a major effect on several downstream processes of cell metabolism.

5. Sarin-Induced Changes in Protein Kinase C (PKC) Pathway

The protein kinase C (PKC) signaling pathway has been associated with modulation of *N*-methyl-D-aspartate (NMDA) receptor activity, motor behavior, learning, and memory, all of which are severely impaired in intoxication with sarin and similar OPs. There was a reduction in the immunoreactivity levels of betaII-PKC and Zeta-PKC in the frontal cortex (up to 24 h), and in the striatum (up to 5 days) post-sarin exposure, in contrast to the increase in the immunoreactivity of both enzymes in the hippocampus or thalamus, following a $1\times LD_{50}$ exposure to sarin. These observations suggest a role for both conventional and atypical PKC isozymes in OP-induced neuropathy in the rat and further support their role in cell death (Bloch-Shilderman *et al.*, 2005).

6. Sarin-Induced Alterations in Gene Expression Related to Electrophysiological Activities of CNS

Abnormal electrophysiological recordings following a single large dose or repeated subclinical dose of sarin in rhesus monkeys (Burchfiel *et al.*, 1976; Burchfiel and Duffy, 1982) and neuropathy in rats (Kadar *et al.*, 1995) have been reported. High concentrations of OPs have been reported to affect excitable membranes directly, by blocking peripheral nerve conduction (Woodin and Wieneke, 1970). A very large group of ion channel-related genes, belonging to almost every possible type (sodium, potassium, chloride, and proton-gated) such as Scn4a (338%), Kcnma1 (331%), Kcnj3 (199%), Clns1a (177%), Clcn5 (146%), Kcnd (138%), and Accn1 (129%), were induced to various degrees from the control levels (100%) as well as down-regulation of Kcnn2 to 64%, and clearly support severely altered electrophysiology at 15 min post-exposure (Damodaran *et al.*, 2006a). Similarly, several genes encoding mRNA for ion channels remained induced although to a lesser extent at 2 h after sarin exposure (Damodaran *et al.*, 2006b). The list includes Clcn5 (155%), Scn2b (138%), Cncg (136%), Clc-k21 (130%), Accn2 (122%), Kcnh2 (113%). However, the overall trend seems to be that of returning to control levels. Two genes, namely Kcnd3 (76%) and Pcp2858 (72%), showed down-regulation. On the other hand, there were only two genes (Accn1: 130% and Scn9a: 47%) showing altered expression at 3 months (Damodaran *et al.*, 2006a). The fact that two genes such as voltage-gated sodium channel (Scn9a) and neuronal degenerin channel MDEG (Accn1) showed persisting alterations at 3 months clearly indicates that sarin-induced alterations in the electrophysiological changes initiated at an early time point were minimized, but not completely normalized in rat animal models. Some degeneration and other problems related to memory and other defects in sarin-exposed GWS-related clinical features could be due to such a phenomenon. In a similar way, the highest expression of Ecto-ATPase at 15 min (Damodaran *et al.*, 2006a) and the persistence of altered levels of several other ATPases and ATP-based transporters at a 2 h time point (Damodaran *et al.*, 2006b) as well as at 3 months (other transporters like transferrin and neuron glucose transporter) clearly support the idea that perturbations in electrophysiological parameters of CNS persisted for a long time after the initial acute sarin exposure event (Damodaran *et al.*, 2006a, b).

7. Sarin-Induced Calcium Channels and Binding Proteins

Ca^{2+} is involved in the control of neuronal membrane excitability, neurosecretion, synaptic plasticity, gene expression, and programmed cell death. In physiological conditions, neuronal stimulation induces transient increases in the $[Ca^{2+}]$. Basal Ca^{2+} levels in the cytoplasm are principally maintained by efflux of Ca^{2+} through a membrane-associated Ca^{2+}-ATPase and also through a membrane Na/Ca^{2+} exchanger. In addition, cytosolic Ca^{2+} concentration is controlled by active Ca^{2+} sequestration into intracellular stores (endoplasmic reticulum and mitochondria) and by Ca^{2+} binding to intracellular proteins. An increase in the cytosolic concentration of Ca^{2+} can be the result of either influx of extracellular Ca^{2+} or the release of Ca^{2+} from internal stores. Ca^{2+} can enter the neuron through two major classes of Ca^{2+} channels, such as voltage-sensitive Ca^{2+} channels (VSCCs), which are sensitive to alteration in membrane potential and receptor-operated Ca^{2+} channels (ROCCs).

A sustained increase in cytosolic Ca^{2+} concentration, different from the rapid and transient changes occurring in physiological conditions, is invariably associated with neural damage (Nicotera, 1992). Sarin may induce alterations in the physical integrity of the plasma membrane, mitochondrial impairment, and consequent ATP depletion (Komulainen and Bondy, 1988). In addition, $[Ca^{2+}]$ overload is postulated to play an important role in hypoxic–ischemic brain damage, as a consequence of excitatory amino acid excessive stimulation and enhanced Ca^{2+} influx through membrane channels (Kristian and Siesjo, 1996). Moderate induction of CamK1b, Cacna1g, and down-regulation of Cacna1d and Camk2d were noted at 15 min post-sarin exposure (Damodaran *et al.*, 2006a). Induction of several genes (Calcr: 207%; Camk2d: 159%;

Calm: 132%; S100b, calcium binding protein: 130%) and down-regulation of CamK2a (56%) was found at 2 h post-sarin exposure (Damodaran *et al.*, 2006b). Induction of CaCh3 (neuroendocrine calcium channel alpha 1) to 220% and Cacna1c (L-type VDCC alpha unit) to 149%, accompanied by down-regulation of Camk2a (21% of the control levels) and Atp2a3 (Ca^{2+} transport ATPase 2) to 79%, suggest expression changes persisted at 3 months post-sarin exposure (Damodaran *et al.*, 2006a).

8. CaMKII as the Key Molecule in the Development of Neurotoxicity

The processing of a Ca^{2+} signal requires its union with specific intracellular proteins. Calmodulin is a major Ca^{2+} binding protein in the brain, where it modulates numerous Ca^{2+}-dependent enzymes and participates in relevant cellular functions. Among the different calmodulin-binding proteins, the Ca^{2+}/calmodulin-dependent protein kinase II and the phosphatase calcineurin are especially important in the brain because of their abundance and their participation in numerous neuronal functions. Studies on the acute effects of sarin on microsomal and cytosolic components of the calmodulin system in the rat striatum indicated CaM/calmodulin levels in both cell fractions were significantly increased by sarin (Hoskins *et al.*, 1986). Decreased cyclic AMP-PDE and adenylate cyclase activities and cyclic GMP-PDE and guanylate cyclase activities were noted after sarin exposure. Sarin administration caused significant increases in microsomal protein kinase activity (Hoskins *et al.*, 1986). Recent gene expression studies also confirmed the prominent role of the CAMK system by the altered mRNA levels of CaMK 2 alpha, CaMK 2 delta, calmodulin, and CaMK1. Persistent down-regulation of CamK2a at early (2 h) and late (3 months) time points clearly indicates its important role in sarin-induced neurotoxicity (Damodaran *et al.*, 2006a, b).

9. Sarin-Induced Blood–Brain Barrier (BBB) Damage and Related Alterations in Gene Expression

The entry of molecules to the CNS is regulated by the BBB, which is the interface between blood and the CNS, and this entry is based on the size, charge, hydrophobicity, and/or affinity to carriers. MOG (myelin oligodendrocyte glycoprotein), PSD-95, and neurexin were also altered, indicating disturbances to the BBB-related function. Large doses of sarin caused BBB damage and BBB disruption plays an important role in sarin-induced cell death (Abdel-Rahman *et al.*, 2002; Damodaran *et al.*, 2003). Kinase cascades such as CaMKII and MAP kinase kinase are altered in cell types with compromised BBB, within 15 min, which probably received transducing signals due to changes seen in several upstream molecules (Damodaran *et al.*, 2006a, b). Tyrosine phosphorylation is the next logical step, which may increase tight junction permeability (Staddon *et al.*, 1995). Up-regulation of tyrosine kinase receptor EHK-3, altered levels of transporters such as sodium-dependent neurotransmitter transporter, and ATP-based transporters were suggested to support such a possibility (Damodaran *et al.*, 2006a). A primary mediator of injury-induced BBB disruption is nitric oxide (NO). Induction of nitric oxide synthase along with changes in EDN 3 expression clearly support such a scenario (Damodaran *et al.*, 2006a). Agents that regulate vasoactive processes, such as vasoactive intestinal receptor-1 (Vipr 1) and 2 (Vipr 2), may be involved in the biochemical opening of the BBB (Damodaran *et al.*, 2006a), as other vasoactive genes such as bradykinin and angiostensin have been shown to (Black, 1995).

Other changes noted in the NMDA receptor function-related genes such as PSD-95 as well as PSD-95/SAP-90-associated protein were up-regulated at 15 min post-sarin exposure, along with NMDA and NO synthase levels (Damodaran *et al.*, 2006a). PSD-95 participates in the anchoring of the NMDA receptor and interacts with neuronal NO synthase at the postsynaptic membrane, and thereby plays a fundamental role in synaptic transmission and memory formation (Kim *et al.*, 2002) about the role of NOS/NMDA mediated apoptosis in DFP (a structural analog of sarin)-treated rat CNS. Altered levels may explain an early abnormal event that may initiate a complex process leading to memory loss observed in sarin-exposed rats (Kassa *et al.*, 2001). Besides, persistence of altered expression of BBB-related molecules such as neurrein-1 adds support to the important role of BBB damage in initiating and amplifying neurotoxicity-related phenomena.

10. Effect of Sarin on Hormones and Growth Factors

Hormones play an important role in the cholinergic neurotransmission at pre- and postsynaptic levels in the basal forebrain. The neurobiological mechanisms that underlie these effects are not fully understood, but most likely reflect effects of hormones on the survival, connectivity, and function of specific neural systems in the hippocampus and may trigger a variety of intracellular signals (Foster, 2005). All of the growth factor-related genes such as rat growth hormone, basic fibroblast growth factor, and insulin-like growth factor-II were found to be induced at 15 min, while at 3 months growth factors related to glial function (Gmfb) were induced along with eek (eph and elk-related kinase) and growth inhibitory factor-metallothionein homolog (Gif-Mt) (Damodaran *et al.*, 2006a, b). C-erb-A-Thyroid hormone receptor and 17 betahydroxysteroid dehydrogenase showed down- and up-regulation, respectively, 2 h after sarin exposure (Damodaran *et al.*, 2006b). DFP (structural analog to sarin) has been shown to reduce serum prolactin, thyropton, luteinizing hormone, and growth hormone, and increase adenocorticotropin and corticosterone in rats and it was concluded that cholinesterase inhibition evokes a multiplicity of effects on anterior pituitary function (Smallridge *et al.*, 1991). A similar mechanism of action can be expected for the effect of sarin exposure on

endocrine systems. A statistically significant correlation between body weight loss, plasma cholinesterase levels, and hormonal control of hydration levels in sarin-dosed animals established that the satiety center controlling the hypothalamus and CNS might be affected by sarin treatment (Young *et al.*, 2001).

It is known that cells that are stimulated by bFGF also showed robust expression of nestin, which plays a role in the neuronal glial differentiation of bipotential cells (Cameron *et al.*, 1998). Both nestin and bFGF are induced in the sarin-treated CNS at 15 min, thus confirming their protective role either inducing the proliferation or increasing the differentiation of bipotential cells into neurons or glia as and when required at distinct regions of damaged CNS (Damodaran *et al.*, 2006a, b).

11. Effect of Sarin on CREB Pathway

CAMP-response element binding protein (CREB) is a member of a large family of structurally related transcription factors which has the transcriptional control of numerous genes, many of which are rapidly expressed in response to an elevation of cytoplasmic cAMP or Ca^{2+} levels. The persistent phosphorylation of CREB in the CNS, in response to OPs like diisopropyl-phosphorofluoridate (DFP), has been shown to be involved in the initiation of delayed neurotoxicity (Damodaran *et al.*, 2002c). There are numerous adaptive changes that can be broadly divided into (a) cell survival and (b) cell death that may be mediated through CREB pathways. Altered gene expression for several genes (Camk2, Pka, c-Fos, c-Jun) was shown in DFP-treated hen CNS (Gupta *et al.*, 1997, 1998, 2000a, b; Gupta and Abou-Donia, 1999; Damodaran *et al.*, 2003). Similarly, expression profiles for several genes (Cam2a, Camk2d, Calm, Cbf-C, and Scya2) were also shown to be altered in sarin-treated rats (Damodaran *et al.*, 2006a, b). Transducing signals of several other kinases also converge on the CREB pathway leading to the activation of several downstream processes. Activation of c-Jun N-terminal kinase (JNK) and slight activation of mitogen-activated protein kinase (MAPK) in the cytosol fraction of the brain homogenate was observed after exposure to sarin-like organophosphate BIMP (bis isopropylmethyl phosphonate), which increased tyrosine phosphorylation of several proteins in the cytosol fraction (Niijima *et al.*, 2000). Altered expression of Camk2a, Camk2d, Calm, JNKs, and MAPKs by sarin exposure clearly supports such a phenomenon mediated through CREB pathways.

12. Sarin-Induced Alterations in Gene Expressions Related to Astroglial Marker Genes

Astrocyte activation or reactive gliosis involves proliferation, recruitment to the site of injury (Walton *et al.*, 1999), and release of numerous cytotoxic agents including proteolytic enzymes, cytokines, complement proteins, reactive oxygen intermediates, NMDA-like toxins, and nitric oxide (Weldon *et al.*, 1998). Sarin exposure activated astrocytes and resulted in the altered mRNA expression profile of GFAP and vimentin in a time course study (Damodaran *et al.*, 2002b). Global gene expression studies showed an alteration in the expression levels of S-100 beta, an astrocyte-specific Ca^{2+}-binding protein (neurotropic factor), at 2 h post-treatment, thereby confirming the fact that sarin-induced calcium changes resulted in alterations in several downstream molecules. The alteration in S-100 levels also indicates changes taking place in Schwann cells of the CNS. In rats, S-100 beta has been shown to present in about 35% of the neurons (Landgrebe *et al.*, 2000). Hence up-regulation at 2 h probably indicates that both neurons and glial cells are affected by sarin treatment. Another gene of special interest induced by sarin is apolipoprotein E (apoE), which may play a role in various CNS disorders, and its altered levels indicate modified astrocyte and/or neuronal response and functions (Damodaran *et al.*, 2006b). Altered expression of apoE has been associated with chronic reactive gliosis (Martins *et al.*, 2001) and is also suggested to be neuroprotective (Boschert *et al.*, 1999). ApoE has been shown to stimulate the transcriptional activity of CREB by activating the extracellular signal-regulated kinase (ERK) cascade in rat primary hippocampal neurons (Ohkubo *et al.*, 2001).

13. Gender-Based Differences in Gene Transcript Expression

Overall, female rats were more sensitive to sarin vapor toxicity than male rats over the range of exposure concentration and duration studied (Mioduszewski *et al.*, 2002). In a recent global gene expression study, male and female Sprague-Dawley rats exposed to low-level doses (0.010 to 0.033 mg/m^3) of the aerosolized sarin via whole body inhalation for 4 h showed differential gene expression response between male and female rats (Sekowski *et al.*, 2002). Many of the altered genes participate in cellular processes critical to detoxification pathways and neurological homeostasis which may reflect the difference in the sensitivities as demonstrated by the differences in the miosis EC_{50} levels. Transcripts of UDG glycolase (Uracil DNA glycosylase) were shown to be significantly up-regulated at the highest dose point (0.033 mg/m^3) for females but not for males. UDG glycolase is involved in base excision repair (Scharer and Jiricny, 2001). The transcripts for the gene Cyp2A and other Cyp2 family members also showed differential expression pattern. While the expression pattern of all Cyp2 family members in females was not altered by any of the doses of sarin tested, the Cyp2A family of enzymes is variably, but significantly influenced by the doses of sarin tested in males. Furthermore, it appears that the constitutive levels of these enzymes are higher in males than in females. It is well known that the Cyp2 family of enzymes is involved with primary metabolism and bioconversation of many toxicants (Sekowski *et al.*, 2002).

DNA polymerase alpha was up-regulated following low-level sarin exposure. Since mammalian DNA replication (and possibly DNA repair) mechanisms utilize DNA

polymerase alpha, the DNA replication machinery may be turned on or up-regulated to synthesize DNA and/or repair lesions in the DNA (Sekowski *et al.*, 2002). Sarin exposure also down-regulated endothelin-1, which plays a critical role in vascular tension, as it interacts with the sympathetic nervous system and the renin–angiotensin system (Sekowski *et al.*, 2002).

14. Sarin-Induced Changes in Cytokine Profile

Sarin exposure resulted in prolonged central neuro-inflammatory processes in rat brain tissues (Damodaran *et al.*, 2006a, b; Chapman *et al.*, 2006). Gene expression analysis at various time points (15 min, 2 h, and 3 months) in sarin-treated rats indicated up-regulation of 1L-10 at early time points, while IL6 and IL9 were noted at late (3 months) time points (Damodaran *et al.*, 2006a, b). Biochemical evaluation of rat brain tissues revealed a significant increase in the level of the proinflammatory peptides starting at 2 h and peaking at 2–24 h following sarin exposure (Chapman *et al.*, 2006). Hippocampal values of IL1-beta increased one-fold at 2 h and nine-fold at 8 h. PGE2 (prostagladin E2) levels in the hippocampus increased up to four-fold to six-fold at 2 and 8 h. In addition, a second increase in inflammatory markers was observed 30 days following sarin exposure only in the rats with 30 min of prolonged seizures. Marked histological damage to the brain was demonstrated following 30 min of seizure activity, consisting of severe damage to the hippocampus, piriform cortex, and some thalamic nuclei as compared to rats with 5 min seizures.

Subacute doses of sarin on wistar rats led to suppression of cellular and humoral immune reactions and to a decrease in blood concentrations of cytokines (IL-2, IL-4, IFN-gamma), with a reduction of the IFN-gamma/IL-4 and IL-2/IL-4 ratios, which attests to a more pronounced decrease in Thy1 lymphocyte function in comparison with Th2 cells (Zabrodskii *et al.*, 2007). Grauer *et al.* (2008) studied the long-term neuronal and behavioral deficits after a single whole body exposure to sarin vapor. Neuronal inflammation was demonstrated by a 20-fold increase in prostaglandin (PGE2) levels 24 h following exposure that markedly decreased 6 days later. An additional, delayed increase in PGE2 was detected at 1 month and continued to increase for up to 6 months post-exposure. Glial activation following neural damage was demonstrated by an elevated level of peripheral benzodiazepine receptors (PBR) seen in the brain 4 and 6 months after exposure. Six week, 4 and 6 month post-exposure behavioral evaluations were performed. In the open field, sarin-exposed rats showed a significant increase in overall activity with no habituation over days. In the working memory paradigm in the water maze, these same rats showed impaired working and reference memory processes with no recovery. Thus, the data suggest long-lasting impairment of brain functions in sarin-exposed animals. The PGE2-dependent, ERK (extracellular signal-regulated kinase), 1/2-regulated, microglia–neuron signaling pathway may mediate the interaction between microglia and neurons in pain maintenance after injury (Zhao *et al.*, 2007) in sarin-exposed animals.

15. Sarin-Induced Oxidative Stress and Cell Death/Neuroprotection-Related Gene Expression

Oxidative stress mediated free radical generation and alterations in the anti-oxidative scavenging system have been implicated in OP-induced neurotoxicity (Abu-Qare and Abou-Donia, 2001; Abu-Qare *et al.*, 2001). Alteration in the levels of brain Acyl-CoA synthetase and leptin accompanied by alterations in the mRNA levels of key mitochondria associated proteins such as Bax (apoptosis inducer) and BOK (BCL-2-related ovarian killer protein) in sarin-exposed rats clearly supports oxidative stress-induced cell death (Damodaran *et al.*, 2006a). Induction of both proapoptotic (Bcl2l11, caspase 6) and antiapoptotic (Bcl-X) genes, besides suppression of p21, suggests complex cell death/protection-related mechanisms operating early on. Moreover, persistent alteration in the cell death-related molecule DEFT at 3 months adds support to the notion that oxidative stress-related changes can cause long-term complications in cell physiology and pathology (Damodaran *et al.*, 2006a, b).

Reactive oxygen species (ROS) have been shown to initiate a number of signaling events that lead to endothelial cell ‘‘activation’’ and up-regulation of cell adhesion molecules and chemoattractants. Strong induction of tumor necrosis factor (TNF)-beta along with down-regulation of CX3C at 15 min and further down-regulation at 3 months post-sarin exposure strongly suggest such a mechanism (Damodaran *et al.*, 2006a). Many cell adhesion and cytoskeleton and BBB-related molecules (neurexin 1-beta; neurexin 1-alpha, PSD-95/SAP90-associated protein 4), and cytoskeletal genes (nestin, beta tubulin) showed prominent alterations in mRNA expression (Damodaran *et al.*, 2006a, b).

Lipid peroxidation has been shown to be present in the CNS of rats treated with sarin (Abou-Donia *et al.*, 2002). Altered expression levels of lipophilin supports to the notion of sarin exposure initiated lipid peroxidation as an important by-product of oxidative stress. The glutathione system is an important protective mechanism responsible for removing H_2O_2 and maintaining protein thiols in their appropriate redox state in the cytosol and mitochondria for minimizing oxidative damage. Altered expression of glutathione, dopamine (Drd4), and GABA (Gabbr-1, Gabra1, Gabra3, Gabbr-1d, Gabrb3)-related genes may potentiate the cell death and injury to these populations (Damodaran *et al.*, 2006a).

16. Effect of Sarin on DNA and Protein Content

Kassa *et al.* (2000) showed that not only symptomatic level 3 but also asymptomatic levels 1 and 2 of sarin were able to significantly decrease the incorporation of radiolabeled thymidine without changing total concentrations of DNA or

protein at 3 months following exposure. On the other hand, the significant decrease in total contents of DNA and protein in liver without the changes in the incorporation of tritiated thymidine was noted in liver 6 months following sarin exposure. No significant changes in the metabolism of DNA and protein were observed at 12 months following sarin exposure. Thus, not only clinically manifested intoxication but also low-level, asymptomatic exposure to sarin altered nucleic acids and protein metabolism, several months following exposure.

Repeated low-dose exposure to sarin produced a dose-dependent response in leukocytes at 0 and 3 days post-exposure. There was a significant increase in all measures of DNA fragmentation at 0.2 and 0.4 LD_{50}, but not at 0.1 LD_{50}. There was no significant increase in DNA fragmentation in any of the groups at 17 days post-exposure. Sarin did not produce systematic dose-dependent response in parietal cortex at any of the time points. However, significant increases in DNA fragmentation at 0.1 and 0.4 LD_{50} were observed at 0 and 3 days post-exposure and levels were back at control level by day 17 (Dave *et al.*, 2007). Analysis of phosphor-carrying metabolites of sarin and its by-products by Li *et al.* (2000) in urine samples from the victims of the Tokyo train terrorist attack suggested that they were exposed not only to sarin, but also to by-products generated during sarin synthesis, i.e. diisopropyl methylphosphonate (DIMP) and diethyl methylphosphonate (DEMP). Sister chromatid exchange (SCE) was significantly higher in the victims than in a control group. Both DIMP and DEMP significantly inhibited NK and CTL activity in a dose-dependent manner. The inhibition induced by DIMP was stronger than that by DEMP. The effect of DIMP and DEMP on the splenic NK activity of mice was stronger than on the splenic CTL activity, and the human lymphocyte is more sensitive to DIMP and DEMP than the splenocytes of mice.

17. Effect of Sarin on Immune System

There is increasing evidence that the immune, endocrine, and nervous systems communicate with each other through hormones, neurotransmitters, and cytokines (Tracey, 2005). Immune function is not only regulated by the cytokine system, it is also under the control of an independent lymphoid cholinergic system (Kawashima and Fujii, 2008). Immunosuppressive effects of sarin are mediated through the central and peripheral mechanisms (Sopori *et al.*, 1998). Interestingly, serum corticosterone levels of the sarin-treated animals were dramatically lower than the control animals (Kalra *et al.*, 2002). Subclinical doses (0.2 and 0.4 mg/m^3) inhibited the anti-sheep red blood cell antibody-forming cell (AFC) response of spleen cells without affecting the distribution of lymphocyte subpopulations in the spleen (Kalra *et al.*, 2002). Moreover, sarin suppressed T cell receptor (TCR) antibody-induced T cell proliferation and the rise in the intracellular calcium following TCR ligation. These concentrations of sarin altered regional but not total brain acetylcholinesterase activity (Kalra *et al.*, 2002). Pretreatment of animals with the ganglionic blocker chlorisondamine abrogated the inhibitory effects of sarin on spleen cell proliferation in response to Con A and anti-TCR antibodies. These results suggest that effects of sarin on T cell responsiveness are mediated via the autonomic nervous system and are independent of the HPA (hypothalamus–pituitary–adrenal axis). Furthermore, sarin-induced inhibition of T cell dependent functions such as the AFC response and the TCR mediated rise in intracellular Ca^{2+} is lost 2 weeks after sarin exposure. Low-level (single or repeated) inhalation exposure of sarin on inbred BALB/c mice to evaluate the effect of sarin on immune functions indicated that sarin is able to alter the reaction of the immune system at 1 week after exposure to sarin (Kassa *et al.*, 2004). While the number of CD3 cells in the lung was significantly decreased, a slight increase in CD19 cells was observed especially in the lungs after a single sarin inhalation exposure. Lymphoproliferation was significantly decreased regardless of the mitogen and sarin concentration used and the number of low-level sarin exposures. The ability of peritoneal and alveolar macrophages to phagocytose the microbes was also decreased regardless of the number of low-level sarin exposures. The production of N-oxides by peritoneal macrophages was decreased following a single low-level sarin exposure but increased following repeated low-level sarin exposure. However, the change in the production of N-oxides that reflects a bactericidal activity of peritoneal macrophages was not significant. The natural killer activity was significantly higher in the case of inhalation exposure of mice to low concentrations of sarin regardless of the number of exposures. Generally, repeated exposure to low concentrations of sarin does not increase alteration of immune functions compared to the single low-level sarin exposure, with the exception of phagocyte activity of alveolar macrophages and natural killer cell activity.

Sarin exposure also up-regulated the mRNA expression of proinflammatory cytokines in the lung, which is associated with the activation of NFκB in bronchoalveolar lavage cells (Pena-Philippides *et al.*, 2007). These effects were lost within 2 weeks of sarin inhalation. While the effects of sarin on T cell function were on the autonomic nervous system (ANS), the decreased corticosterone levels by sarin might result from its effect on the HPA axis. Sarin induces lung inflammation resulting from neutrophilic and eosinophilic infiltration (Levy *et al.*, 2004; Pant *et al.*, 1993). Subclinical doses of sarin did not cause signs of lung inflammation, but left molecular imprints of lung inflammation. Sarin promotes the nuclear translocation of NFκB in BAL cells. Therefore, increased gene expression of IL-1, TNF-alpha, and IL-6 observed in BAL cells from sarin-treated animals may result through activation of NFκB. In higher doses, sarin may elevate the transcription, as observed by others (Levy *et al.*, 2004; Pant *et al.*, 1993; Damodaran *et al.*, 2006a).

18. Studies on the Long-Term Effect of Sarin Exposure to Human Subjects Support Data from Animal Models

Golomb (2008) summarized the findings from several epidemiological studies, and suggested that AChE inhibition by various OP nerve agents and other OP and carbamate pesticides could be linked to Gulf War Syndrome-related illness. Thirty-eight victims of the Tokyo subway sarin attack exhibited smaller than normal regional brain volumes (of the matched controls) in the insular cortex and neighboring white matter, as well as in the hippocampus, all of whom had been treated in an emergency department for sarin exposure in a long-term study, using T1-weighted and diffusion tensor magnetic resonance imaging (DTT), the voxel-based morphometry.

Furthermore, an extensively lower than normal fractional anisotropy was also noted in the victims. The reduced regional white matter volume correlated with decreased serum cholinesterase levels and with the severity of chronic somatic complaints related to interoceptive awareness (Yamasue *et al.*, 2007). Similarly, another study of Gulf War veterans showed subtle but persistent central nervous pathology such as reduced white matter and increased right and left lateral ventricle with higher levels of exposure to sarin and cyclosarin (Heaton *et al.*, 2007). Moreover, electrophysiological deficits of controlled attention, accompanied by lower P300 amplitude and smaller anterior cingulated cortex volume, were observed in patients (victims of the Tokyo subway sarin attack), and suggested a link to brain morphological changes (Araki *et al.*, 2005). Similarly, the patients from subway sarin attack also performed significantly less well in the psychomotor function test (tapping) than the referent group. There were dose-dependent effects for these observations and thus these results indicate a chronic decline of psychomotor function and memory function 7 years after sarin exposure (Miyaki *et a*l., 2005). Investigations on the neurobehavioral task performance of Gulf War veterans categorized as having received high, moderate, or low-to-no exposure dose levels to sarin and cyclosarin indicated that sarin and cyclosarin exposure was significantly associated with less proficient neurobehavioral functioning on tasks involving the psychomotor dexterity and visuospatial abilities 4–5 years after exposure (Proctor *et al.*, 2006). All these observations from human studies strongly correlate with the data from gene expression and other molecular studies in animal models.

19. Sarin-Induced Altered Expression Profile Provides Biomarker Panels and Therapeutic Targets

Molecules that show persistent altered expression over a period of several time points strongly suggest that they play important roles in preserving, amplifying, and transmitting the altered expression as and when needed, which could be either degenerative or regenerative in nature. There are several molecules such as Arrb-1, Nrxn-1b, Nos-2a, Ania-9, PDE2, Gabab-1d, CX3C, CamK2a, Camk2d, Clcn5, IL-10, c-Kit, and Plp1 that showed such a pattern (Damodaran *et al.*, 2006a, b). Beta-arrestin (Arrb-1) maintained its altered state at three different time points such as immediate early (15 min), early (2 h), and late (3 months), thus confirming persistent pathological changes due to altered signal transduction pathways mediated through beta arrestin. Continued down-regulated mRNA levels of neurexin (Nrxn-1b) and persistent up-regulation of Nos2a clearly support an idea that BBB-related perturbations were still persistent at 3 months after the treatment, and might lead to persistent cell death in susceptible brain regions. Immediate early up-regulation of Ania-9 at 15 min followed by significant down-regulation at 3 months strongly indicates either successful regeneration or a continuing cell death/atropic state. Initial down-regulation at 15 min, followed by up-regulation of PDE 2 at 3 months, probably indicates recovering cyclic nucleotide metabolism at 3 months from its sarin-induced suppression. Initial up-regulation (15 min) followed by severe down-regulation of GABAB-1d (3 months) confirms the persistent defective GABAerginic metabolism. Induction at early time points followed by down-regulation at late time points makes CX3C one of the potential biomarker molecules. Clcn5 showed persistent alterations at both immediate early (15 min) and early (2 h) suggesting altered ion-channel-related functions. Persistent overexpression of IL-10 at early time points may indicate an underlying anti-inflammatory response. Continued alteration of kinase pathways was suggested by the persistent alterations in the levels of Camk2a, Camk2d, and c-Kit. Hence early events such as BBB damage (neurein 1-beta, Plp1, Nos2a), IEGs alteration (Ania-9, probably c-Fos and cJun and other Ania members), modified GPCR mediated signaling pathways (mediated by beta arrestin), altered cyclic nucleotide metabolism (PDE 2), and inflammation and injury-related changes (CX3C), probably play major roles along with other known mechanisms as shown in Figures 44.1–44.3. These persistently altered genes can become candidate biomarkers to monitor sarin exposure as well as to develop therapeutic targets. For example, the Camk2 family of genes can be a good therapeutic target of intervention, as it seems to be central to the upstream and downstream signal transduction processes. Large amounts of data are already available for Camk2 regarding its structure, expression, inhibitors, and potential target genes (pathways). Similarly, AChE is a good candidate for such intervention, as already several studies attempted for that purpose show promising results at least at the level of ''proof of hypothesis'' (Curtis *et al.*, 2005, 2008; Li *et al.*, 2006). Time course studies on both Camk2 and AChE have shown that they are differentially altered in various regions of the brain (Gupta *et al.*, 1998; Damodaran *et al.*, 2003, 2006a). Beta arrestin can be a good candidate for monitoring any interventions, as its expression was consistently up-regulated. Different doses of sarin exposure can be identified by monitoring abundant yet

dose-dependent expression of selected genes, representative of various subregions (such as cerebellum, hippocampus, etc.) and cell types (neuronal, astroglial, microglial, oligodendrocytes, endothelial, etc.) which can be identified by further testing on several published genes (Damodaran *et al.*, 2006a, b). Other approaches include measuring the levels of tyrosine adducts which are relatively long-lived and are not degraded by oxime therapy, after exposure to sarin and other warfare chemicals (Williams *et al.*, 2007).

IV. CONCLUDING REMARKS AND FUTURE DIRECTION

Sarin exposure results in significant levels of transcriptional changes (either activation or suppression) of several genes (pathways) in the brain of animal models like the rat, mouse, and, potentially, humans. Global and candidate gene expression studies in model systems yielded data that confirm the toxic effect of sarin exposure on different cell types of the central nervous system such as neuronal, astroglial, microglial, and endothelial as well as oligodendrocytes. Sarin exposure also causes damage to structural components of the brain such as BBB at gross level as well as to the cytoskeletal framework at the molecular level as indicated by the altered expression data and histopathological data specific to such structures. There seem to be gender-specific gene expression profiles as a response to sarin exposure in rats, suggesting higher susceptibility in females than in males. The changes indicate that persistence of both altered degenerative and regenerative-related gene expression patterns activated early on may contribute to the level of neurodegeneration and neuropathology at a later time point. Sarin exposure also affected the molecular profiles of immune and endocrine systems besides the nervous system, as it is a well-known fact that they communicate with each other through cytokines, hormones, and neurotransmitters. Exposure to sarin can initiate (1) acute response-related clinical changes, (2) OPIDN, and (3) OPICN. Altered profiles of gene expression, protein expression, hormonal and other biochemical parameters in response to sarin exposure confirm the highly toxic nature of the nerve agent leading to significant amounts of nervous system pathology and end organ system pathology. Various neurological abnormalities observed in the victims of sarin exposures may be due to the above-mentioned molecular changes. These data thus provide a wealth of novel insights into the mechanisms of toxicity, so that newer approaches can be initiated in the diagnosis, prevention, and treatment aspects of toxic exposures to warfare chemicals like sarin.

CHAPTER 45

The Effects of Organophosphates in the Early Stages of Human Muscle Regeneration

TOMAZ MARS, KATARINA MIS, SERGEJ PIRKMAJER, AND ZORAN GRUBIC

I. INTRODUCTION

The clinical condition of organophosphate (OP) poisoning is complex. Increased acetylcholine (ACh) concentration in the cholinergic synapses due to acetylcholinesterase (AChE) inhibition leads to altered signaling in these synapses causing various pathological effects. Particularly threatening among these effects is hypoxia which develops as a result of impaired exchange of gases in the lungs combined with bradycardia. In addition, cholinesterases are not the only targets of OPs, and various intracellular mechanisms are modified due to direct or indirect OP actions (Jett and Lein, 2006). DNA microarray analysis of cells treated with OP diazinon disclosed overwhelming modulation (up- or down-regulation) of a wide range of genes (Mankame *et al.*, 2006). Although still poorly understood, these noncholinergic OP actions may directly or indirectly modify the functioning of the complex intracellular mechanisms and in this way contribute to the effects of OP poisoning.

Typical of OP poisoning are myopathies (Preusser, 1967; Wecker *et al.*, 1978). Their pathophysiology is complex and is a combination of muscular hyperactivity and consequent alterations in oxidative processes in the muscle fibers. During sustained seizures and fasciculations, the flow of oxygen through the muscle is greatly increased at a time when the use of ATP is greater than the rate of its generation. Under such conditions production of reactive oxygen species (ROS) is greatly increased and exceeds the protective capacity of the cellular defense system so that their damaging effects result in muscle injury (Dettbarn *et al.*, 2001, 2006; Gupta *et al.*, 2002).

Skeletal muscle responds to injury by the activation of a regeneration process (Bischoff, 1979). As described in more detail below, muscle regeneration is a repeated embryonic development of the skeletal muscle only that in this case it starts from the dormant mononucleated satellite cells located between the basal lamina and cell membrane of the adult skeletal muscle fiber. The final outcome after the muscle damage therefore depends not only on the extent of the damage itself but also on the efficiency of the regeneration process that begins in the injured muscle. Especially at high OP intakes, typically found in suicide attempts, poisoning is often complicated by respiratory failure combined with metabolic and respiratory acidosis (Emerson *et al.*, 1999). These patients must be treated in intensive care units and often require mechanical ventilation. Such critically ill patients frequently develop skeletal muscle dysfunction (de Letter *et al.*, 2001; Bolton, 2005), which often persists even after hospital discharge. Insufficient muscle regeneration might be an important contributing factor in such myopathies (Prelovsek *et al.*, 2006) and it is therefore important to know whether OPs in anyway interfere with the mechanisms involved in this process. This aspect of OP poisoning has not been approached yet in human muscle and in this chapter we provide evidence that the mechanisms underlying early stages of human muscle regeneration are indeed affected by OPs.

The most important step in the process of muscle regeneration is myoblast proliferation which decisively determines the mass of regenerated muscle material. Our investigations on the effects of OPs on muscle regeneration were therefore focused on these early precursors of muscle fibers. All experiments were carried out on the *in vitro* model in which the process of human muscle regeneration is genuinely reproduced. We describe various OP influences on the early precursors of muscle development and discuss their potential effects on muscle regeneration. Since AChE is the best established target of OPs we also approached the question of role and expression of this enzyme in the mononuclear myoblasts and studied the effects of OPs on its expression. Diisopropylphosphorofluoridate (DFP) was used throughout our studies.

II. REGENERATION PROCESS IN THE HUMAN SKELETAL MUSCLE

The process of human muscle regeneration is just a repeated process of muscle embryonic development (Figure 45.1A). The earliest myogenic precursors in this development are mononuclear myoblasts. These still monunucleated but

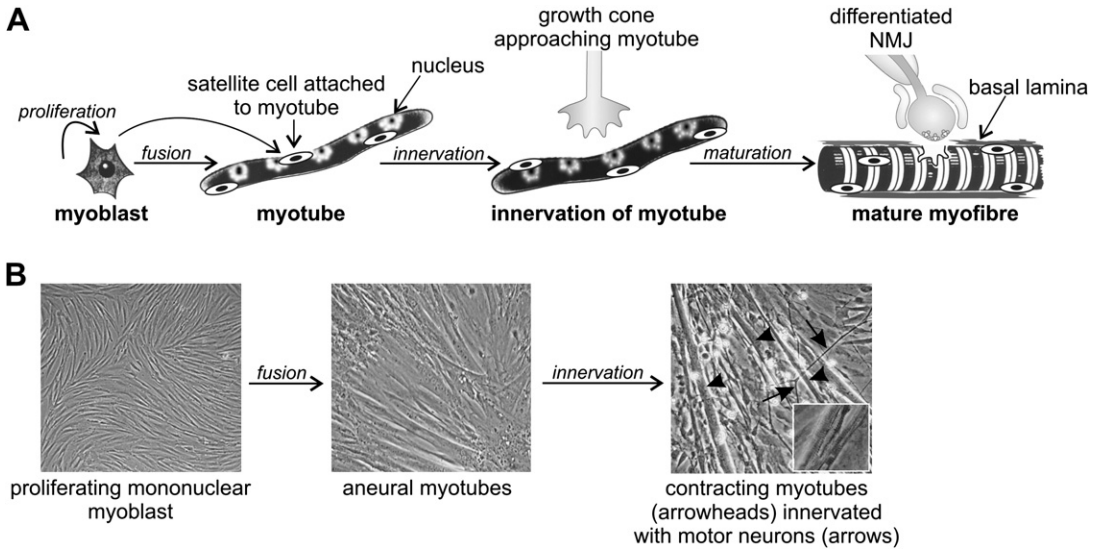

FIGURE 45.1. (A) Schematic presentation of the stages of muscle development and (B) reproduction of these stages under *in vitro* conditions. A: Stages of muscle development from mononuclear myoblast to the mature innervated myofiber. Nuclei, which are still centrally located in myotubes, move to the periphery in the mature fiber as a result of the synthesis of contractile elements in the sarcoplasm. Mature fibers contract and exhibit cross-striations. Only mononuclear myoblasts still have the capacity to divide and proliferate. Some of them do not fuse and become entrapped as mononuclear satellite cells under the basal lamina of the mature fiber. B: Reproduction of this process in the experimental model of the *in vitro* innervated human muscle; axons are labeled by arrows and functionally innervated myotubes by arrowheads. Cross-striations could be seen in the innervated myotubes at higher magnification (insert).

already committed cells proliferate several times in order to reach sufficient density before they fuse into multinucleated myotubes. Once formed, myotubes enter into the long-term and complex process of muscle differentiation which results in the development of fully functional mature myofibers. An important step in the transition from myotube to myofiber is its innervation and formation of the complex structure of the neuromuscular junction (Emerson and Hauschka, 2004).

All these steps are repeated in the regeneration process except that mononuclear myoblasts are derived from the satellite cells. These primordial cells failed to enter the developmental and differentiation process during the embryonic myogenesis but retained the capacity to enter the myogenetic process when activated by the muscle damage. As such they serve as mononuclear muscle precursors of the *de novo* formed muscle fibers during muscle regeneration (Figure 45.1A).

All stages of muscle regeneration can be reproduced in the experimental model of the *in vitro* innervated human muscle (Figure 45.1B). This system was first described in the 1980s (Kobayashi and Askanas, 1985; Askanas *et al.*, 1987) and then further characterized in studies in various laboratories, including ours. In this experimental model satellite cells are released by trypsinization from small pieces of adult human muscle routinely removed at the orthopedic operations of the equinovarus. These cells are the source of mononucleated myoblasts which then proliferate and at certain density start to fuse and form multinucleated myotubes. At that stage an explant of the rat embryonic spinal cord is placed on a monolayer of muscle cells. After 6 to 10 days in co-cultures motor neurons functionally innervate myotubes which then start contracting. These co-cultures are long-lived and contract for up to 6 months. Morphology of the neuromuscular junctions does not differ from that observed *in vivo* (Askanas *et al.*, 1987) and glial cells in the embryonic spinal cord explant also recapitulate temporally regulated developmental steps as reported in the *in vivo* studies (Mars *et al.*, 2001). For the details of the preparation and various applications of this model see also Grubic *et al.* (1995), Mars *et al.*, (2003) and Jevsek *et al.* (2004).

III. THE EFFECTS OF DFP ON THE REGENERATION PROCESS IN THE HUMAN SKELETAL MUSCLE

A. The Effect of DFP on the IL-6 Secretion from the Mononuclear Myoblasts and Myotubes

In our previous study we found that cultured human myoblasts, fusing myoblasts and myotubes constitutively secrete interleukin-6 (IL-6) (Prelovsek *et al.*, 2006). This cytokine is known as the major cytokine released from the skeletal muscle under various conditions (Febbraio and Pedersen, 2005). We also found that IL-6 secretion is stimulated by the major proinflammatory agents like tumor necrosis factor (TNF)-α and endotoxin lipopolysaccharide (LPS). Since IL-6 is a potent stimulator of myoblast

proliferation (Austin *et al.*, 1991; Austin and Burgess, 1992; Cantini *et al.*, 1995; de Letter *et al.*, 2001; Baeza-Raja and Munoz-Canoves, 2004; Serrano *et al.*, 2008) it is assumed that the physiological meaning of this response is a promotion of muscle regeneration so that the myopathy due to septic conditions is at least to some extent compensated by the muscle regeneration.

As mentioned above severe OP poisoning is often complicated by the critical illness which is very often accompanied by the so-called critical illness myopathy. Such a condition is even more likely after OP poisoning which specifically causes myopathy (Dettbarn *et al.*, 2006). It is therefore important to find out whether OP intoxication affects IL-6 signaling and consequently muscle regeneration. The effects of OP on the IL-6 secretion from human myoblasts can be expected since it has already been reported that OPs drastically interfere with cytokine signaling in mouse immune system (Alluwaimi and Hussein, 2007).

Here we show that IL-6 secretion from the human myoblasts is indeed significantly inhibited by DFP (Figure 45.2). The decrease in IL-6 secretion of about 50% in myoblasts might be important in reducing the efficiency of the muscle regeneration process in the damaged muscle. The mechanism underlying this effect of DFP remains to be established and is probably complex. In our culture medium DFP is hydrolyzed quickly and becomes practically inactive in less than an hour (Worek *et al.*, 2004). Its effects are therefore not continuous; they are probably induced shortly after DFP addition and then last beyond the period during which DFP is still active.

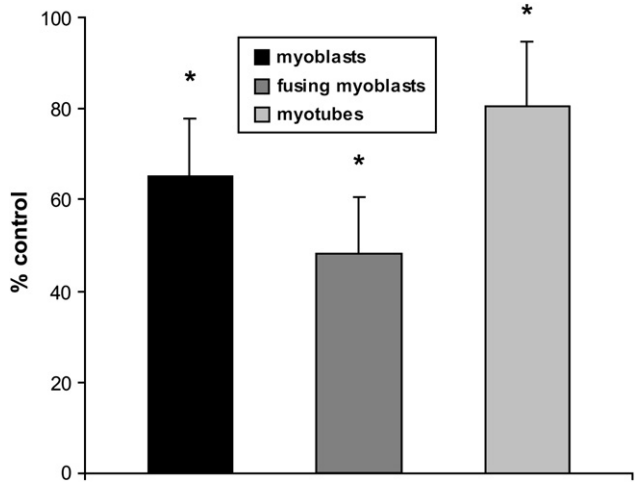

FIGURE 45.2. IL-6 secretion from myoblasts, fusing myoblasts, and myotubes. Cultured human myoblasts, fusing myoblasts, and myotubes were added DFP at the 10^{-5} M concentration. The secreted IL-6, calculated per 100,000 nuclei, was determined 24 h later with ELISA kit (Endogen, Rockford, IL, USA). *Significant difference (Student *t*-test, $p < 0.05$; $n = 3$) between control and treated cultures was observed at all stages studied but was most prominent in the myoblasts.

B. Heat-Shock Proteins in the Human Myoblasts and Myotubes after Treatment with DFP

One of the most prominent cellular responses to stress is a rapid change in gene expression to yield a family of highly conserved proteins known as heat shock proteins (HSPs) (Welch, 1992; Morimoto, 1993; Kiang and Tsokos, 1998; Kregel, 2002). They are cytoprotective due to their chaperone functions in protein folding and protein degradation. Various physical, chemical, biological and environmental stress factors including xenobiotics can induce this response (Wu and Tanguay, 2006). As it was reported that OP pesticides are among inductors of HSP response *in vivo* and *in vitro* (Bagchi *et al.*, 1996) we tested whether DFP can induce such cytoprotection in the precursors of muscle regeneration. We studied the levels of two HSPs: HSP 27 and HSP 70, which are typically induced by stress factors. The level of stress factor of HSP 27 but not of HSP 70 was slightly but significantly increased in the DFP-treated human myoblasts (Figure 45.3), which is in accord with the reported selectivity of HSP induction in various tissues (Wu and Tanguay, 2006). The HSP response to DFP becomes more prominent in the later, myotube stages, when HSP 70 also becomes significantly increased (Figure 45.3). This pattern of effects is just the opposite of that observed for the decrease in IL-6 secretion (Figure 45.2) suggesting that these two effects are not related. From the standpoint of muscle regeneration it remains to be investigated whether the observed HSP response to DFP in any way protects proliferative myoblast potential which is hampered by DFP-induced reduced IL-6 secretion. These results are again indicative for the wide spectrum of effects that OPs induce by direct action on muscle tissue.

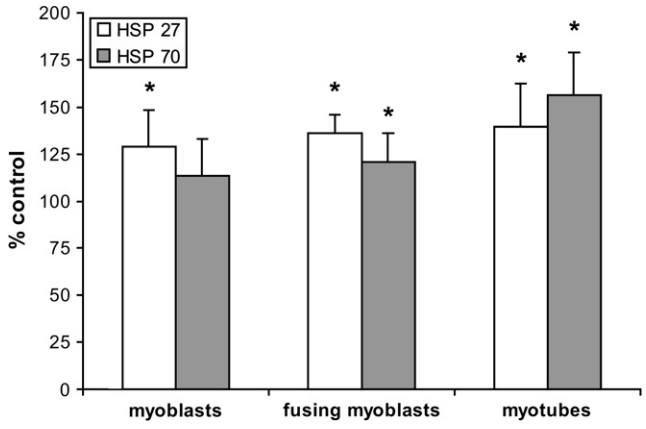

FIGURE 45.3. The effects of DFP on the HSP 27 and HSP 70 levels in myoblast, myoblasts in fusion, and myotube cultures. Levels of HSP 27 and 70 were determined 24 h after addition of DFP at the 10^{-5} M concentration. They were quantitated by Western blot with Chemi Genius BioImaging System (Syngen, Cambridge, UK). *Significant difference (Student *t*-test, $p < 0.05$; $n = 4$) between control and DFP-treated cultures was observed in all determinations except for HSP 70 in myoblasts.

C. Response of Human Myoblasts to Hypoxia

Severe OP poisoning can result in respiratory failure with arterial oxygen partial pressures below 50–60 mm Hg (6.65–7.99 kPa) (Tsao *et al.*, 1990). In such circumstances peripheral tissues, including skeletal muscle, become extremely hypoxic which might have an important effect on the cellular precursors of human muscle regeneration. As known from the extensive studies in other systems, central to the cellular response to hypoxia is hypoxia-inducible factor-1 (HIF-1), a heterodimeric transcription factor, consisting of an oxygen-regulated α-subunit (HIF-1α) and an oxygen-independent β-subunit (HIF-1β). HIF-1α, which is normally almost undetectable due to its continuous degradation in the ubiquitin–proteosome pathway, rapidly accumulates in hypoxia and translocates to the nucleus where it dimerizes with HIF-1β to form a functional transcription factor that controls expression of hundreds of genes (Manalo *et al.*, 2005; Semenza, 2007a). Through its effects on gene expression HIF-1 not only increases oxygen delivery to hypoxic tissues by stimulating erythropoiesis and angiogenesis but also promotes cell survival by redirecting cellular energy metabolism towards glycolysis (Pasteur effect) (Seagroves *et al.*, 2001; Semenza, 2007b). Due to its central role in response to hypoxia, we tested whether such adaptation also takes place in human myoblasts *in vitro*. We exposed human myoblasts to acute hypoxia (1% O_2, 4 h) and found a 6.2-fold increase in HIF-1α level compared to normoxic control (Figure 45.4). This means that human myoblasts respond to hypoxia in a similar fashion to other cell types. Investigations are under way in our laboratory with the aim of finding out whether myoblast response by increased HIF-1α leads to modifications in IL-6 secretion and in this way also in muscle regeneration.

D. AChE Expression in the Normal and DFP-Treated Myoblasts, Myotubes, and Innervated Myotubes

Unlike most of the contractile and synaptic muscle proteins which could first be detected in muscle after fusion, AChE is expressed already at the myoblast stage (Tennyson *et al.*, 1971; Grubic *et al.*, 1995). Its role at this earliest stage of muscle ontogenesis is not known. Since no other component of the cholinergic system is present in myoblasts, only some noncholinergic or noncatalytic AChE role(s) (Meshorer and Soreq, 2006) can be considered. We approached this question by selective elimination of AChE expression in cultured human myoblasts by siRNA. Although the AChE level (determined on the basis of catalytic activity) fell to about 50% of control after siRNA treatment (Figure 45.5), we could not detect any functional or morphological changes in myoblast cultures in comparison to control. The addition of DFP to the siRNA-treated myoblasts, which practically blocked all AChE catalytic activity, also resulted in no visible changes in myoblast cultures. Obviously, binding of DFP to AChE does not change or modify the function (if any) of AChE in the human myoblasts.

Since *de novo* AChE synthesis is an important contributor to the recovery of this enzyme in the skeletal muscle after OP poisoning (Grubic *et al.*, 1981) we wanted a more detailed insight into this process in our experimental model of human muscle. We followed and compared the levels of AChE mRNA and AChE activity in the siRNA-treated myoblasts and in this way estimated the temporal relationship between AChE expression at the mRNA and mature protein level. We then followed AChE mRNA expression at the various developmental stages of muscle ontogenesis. We also tested whether, due to diverse DFP effects, AChE mRNA levels are in any way influenced by DFP treatment at these stages. Since AChE is polymorphic and alternative splicing of primary transcript gives rise to three AChE mRNA species: tailed (T), hydrophobic (H), and read-through (R), which encode differently targeted AChE catalytic subunits (Massoulie, 2002), we followed these mRNA species separately in these experiments.

Three stages could be distinguished in a 6-day period in which we followed AChE activity/AChE mRNA ratio in the siRNA-treated myoblasts. In the first 10 h after siRNA treatment AChE mRNA already fell to about 60% of control level, while AChE activity remained practically unchanged. In the second stage (hours 10 to 50) AChE mRNA fell to

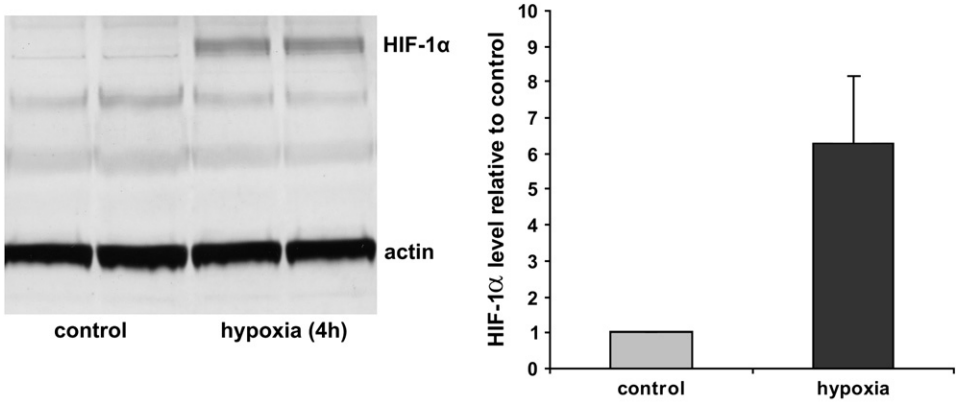

FIGURE 45.4. The effect of acute hypoxia on HIF-1α expression in human myoblasts. Human myoblasts were exposed to 1% O_2 for 4 h. A representative Western blot is shown on the left. Relative expression level of HIF-1α (three independent experiments) is shown on the right (arbitrary units, control = 1) (Student *t*-test, $p = 0.004$). Quantification was performed with Chemi Genius Bio-Imaging System (Syngen, Cambridge, UK).

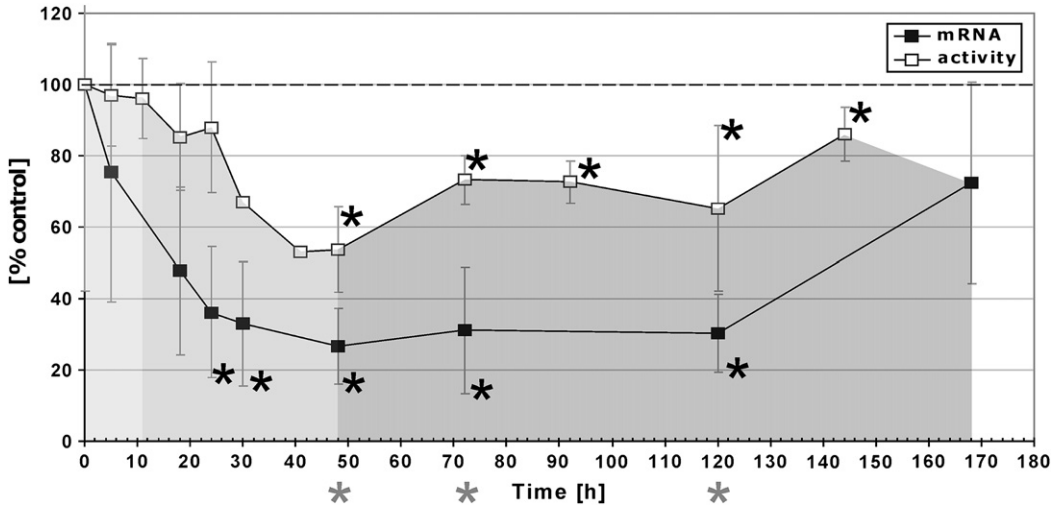

FIGURE 45.5. Relative changes of AChE-T mRNA and AChE activity in lysates of human myoblasts during the first week following siRNA application. Cultures of control and treated myoblasts were prepared from the satellite cells of the same donor and were processed in parallel. Gene silencing was achieved by lipofection of siRNA (Dharmacon); for details see Mis *et al.* (2006). Q-PCR with TaqMan chemistry was employed. AChE mRNA levels were standardized to GAPDH mRNA. AChE activity was expressed per 10,000 cells the number of which was determined with the help of Hoechst 33258 nuclear staining. Each point represents mean of three to seven measurements in each of which we determined the AChE-T mRNA or AChE activity ratio between control and siRNA-treated levels (% control). The statistically significant (Student *t*-test, $p < 0.05$) differences relative to the starting point are marked by black *. The statistically significant (Student *t*-test, $p < 0.05$) % differences between AChE activity levels determined by Ellman technique and mRNA levels at the same time point are marked by gray *. Three shades of gray correspond to the three stages discussed in the text.

about 30% of control. AChE activity followed this fall and reached its lowest level of about 50% of control 50 h after siRNA treatment reflecting AChE turnover. From hour 50 onward a new, more or less constant relationship between AChE and its mRNA was established.

Of the three mRNA species, AChE-H and AChE-T mRNA followed practically the same pattern of expression after siRNA treatment, while AChE-R mRNA behaved in a completely different and less reproducible manner (Figure 45.6). In comparison to the other two mRNA

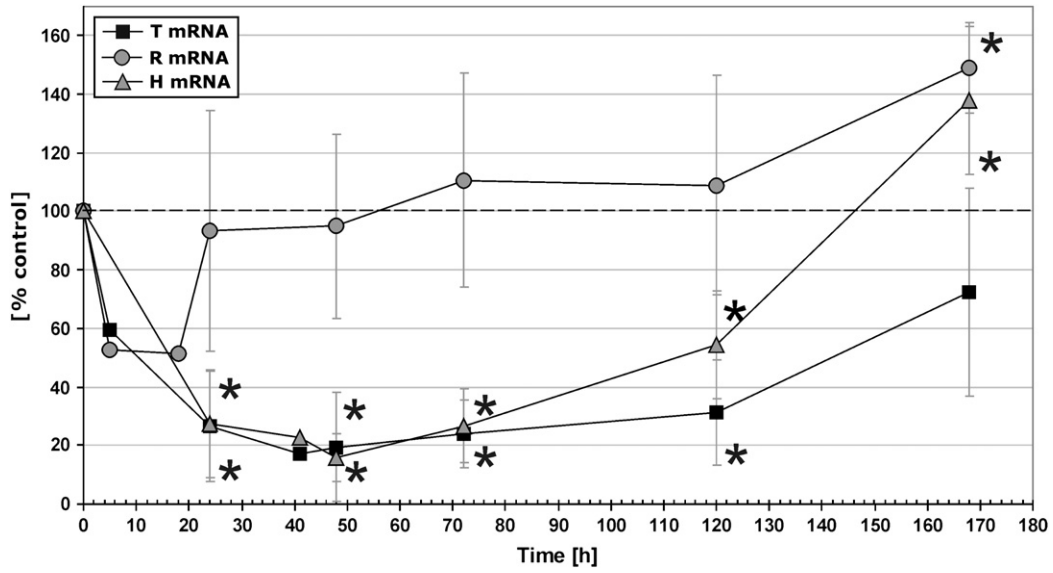

FIGURE 45.6. Relative changes of AChE-H, -R and -T mRNAs in human myoblasts during the first week following siRNA application. Q-PCR with TaqMan chemistry was employed (standardized to GAPDH mRNA). Each point represents the mean of five separate siRNA experiments. In absolute terms the levels of AChE-T mRNA were about 50 times higher than the levels of H and R (see Figure 45.7). The differences regarding starting point (*) were statistically significant (Student *t*-test, $p < 0.05$).

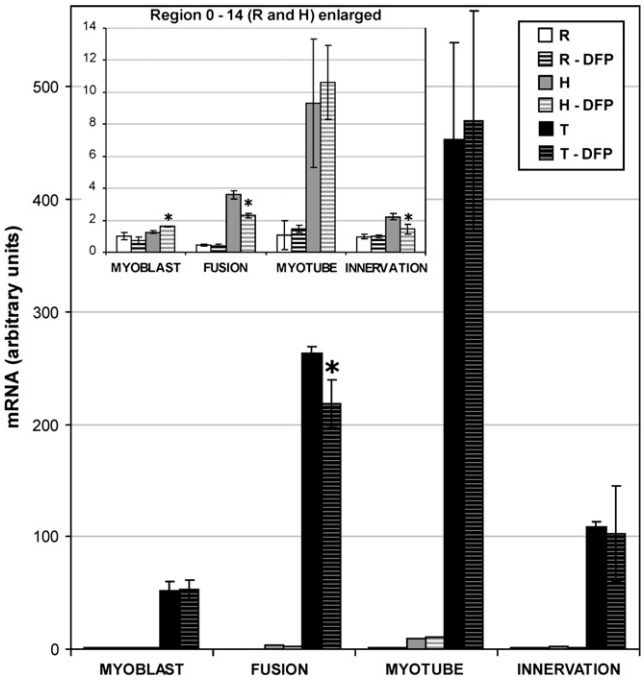

FIGURE 45.7. The levels of R, H, and T AChE mRNA species at four differentiation stages of cultured human muscle in the control and DFP-treated cultures. AChE mRNA levels were measured 24 h after addition of 10^{-5} M DFP by Q-PCR with TaqMan chemistry and GAPDH mRNA as a standard. Top left: Enlarged 0–14 region of the *y* axis showing R and H AChE mRNA species. Each bar represents mean of three measurements. *Significant difference (Student *t*-test, $p < 0.05$) between control and DFP-treated cultures.

species, which fell to about 20% of control after siRNA treatment, AChE-R mRNA never fell below 50% of control. It quickly recovered and then increased so that 7 days after siRNA treatment its level was almost 1.5 times higher than in control. On the 7th day but not earlier we observed similar overshoot also for AChE-H but never for AChE-T. At present we have no explanation for the different expression pattern of R-mRNA species in comparison to the other two. Increased AChE-R mRNA levels have been reported in mouse brain after exposure to stress (Nijholt *et al.*, 2004) but under *in vivo* conditions external factors not present in our culture could be responsible for changed expression of this mRNA. There have been several reports from the H. Soreq group in which the AChE-R variant was specifically induced by various stressors (Cohen *et al.*, 2003; Grisaru *et al.*, 2006; Ofek *et al.*, 2007; Evron *et al.*, 2007; Shapira-Lichter *et al.*, 2008) but we do not know whether our results are related to these findings. In any case R-species represent only a very small fraction of AChE mRNA (Figure 45.7) and it is not known whether it is translated.

All three AChE mRNA species could be detected at all developmental stages. Patterns of their expression were developmental stage dependent, but at all stages T-species was highly predominant (Figure 45.7). No significant changes in the levels of any of the three AChE mRNA species could be observed at any of the developmental stages of human muscle after treatment with DFP (Figure 45.7), suggesting that OPs have no direct influence on AChE expression in human muscle during the regeneration process.

IV. CONCLUDING REMARKS AND FUTURE DIRECTION

It has been known for some time that myopathies are one of the typical consequences of OP poisoning (Dettbarn *et al.*, 2001, 2006) which might be additionally complicated by reduced efficiency of muscle regeneration. According to the present studies various intracellular mechanisms are involved in the response to DFP in the precursors of muscle regeneration. The findings revealed significantly reduced IL-6 secretion, increased levels of HSPs and also increased levels of HIF-1α as a response to secondary hypoxia. Future research will be devoted to the better understanding of molecular mechanisms, which will be reflected in the observed changes and their relationships with OP poisoning.

CHAPTER 46

Organophosphate Intoxication: Molecular Consequences, Mechanisms and Solutions

BRIAN C. GEYER, TAMA EVRON, HERMONA SOREQ, AND TSAFRIR S. MOR

I. INTRODUCTION

Our understanding of the essential role of acetylcholinesterase (AChE) in the neuromuscular junction (NMJ) predicts severe consequences following loss of function by its irreversible inhibition (Silman and Sussman, 2005; Soreq and Seidman, 2001). Through the use and misuse of nerve agents, pesticides, and therapeutic anticholinesterases we learned about the acute and life-threatening manifestations of organophosphate (OP) toxicity observed at all levels, from dysregulated molecular interactions to severe and potentially fatal clinical presentations. The immediate negative physiological consequences associated with critical deficiency in acetylcholine (ACh) hydrolysis in the NMJ and central nervous system are readily explained by the well-characterized role of AChE in cholinergic signal termination. Yet loss of homeostasis can likewise be a result of overcompensation and overproduction of AChE associated with many disease states and indeed with long-term outcomes of sublethal OP exposure. Supporting this notion are the delineated manifestations with span motor, inflammatory, and cognitive effects (Meshorer and Soreq, 2006). Importantly, biological monitoring of cholinergic homeostasis depends on appropriate substrate release, ACh receptor function, AChE isoform selection, and localization.

II. HUMAN CHOLINESTERASES: THE COMMON CORE

The vital role of the acetylcholine-hydrolyzing enzyme AChE in terminating cholinergic neurotransmission has been recognized for almost as many years as ACh has been recognized as a neurotransmitter (Dale, 1914a, b). For nearly as long, AChE research was intimately linked to the study of its inhibitors [Loewi *et al.*, 1926, cited in Loewi's Nobel lecture (http://nobelprize.org/nobel_prizes/medicine/laureates/1936/loewi-lecture.html) and by Dale, 1962]. The vulnerability of cholinesterases to certain natural compounds promoted the discovery and synthesis of new inhibitors for use as pesticides, therapeutics, and, unfortunately, as chemical warfare agents (Gupta, 2006). These inhibitors helped to elucidate the enzymatic mechanism of action and this knowledge, in turn, was used to design even more potent or more specific anticholinesterases.

Seven decades of research led to a widely accepted view of cholinesterases as ''a family of enzymes that hydrolyze choline esters'' (Small *et al.*, 1996). Uncertainty existed, perhaps, only for the mammalian AChE paralog butyrylcholinesterase (BChE): ''the function of [BChE] is unknown, while the function of AChE is to terminate nerve impulse transmission at cholinergic synapses'' (McTiernan *et al.*, 1987). By the early 1990s, this functional definition of AChE and BChE was well complemented by a molecular one of serine hydrolases belonging to the α/β fold superfamily. This resulted from cloning of cholinesterase genes from invertebrates (e.g. Hall and Spierer, 1986) and vertebrates including humans (e.g. McTiernan *et al.*, 1987; Prody *et al.*, 1987; Schumacher *et al.*, 1986; Soreq *et al.*, 1990) and the consequent elucidation of the three-dimensional structure of cholinesterases (Sussman *et al.*, 1991).

The three-dimensional crystal structure of human synaptic AChE (Kryger *et al.*, 2000) reveals a globular core, penetrated by a narrow groove (the ''gorge'') at the bottom of which lies the active site. Several functional subsites in the active site gorge were identified (numbering according to the human AChE sequence – see Soreq *et al.*, 1990). These include (a) the ''catalytic triad'', Ser-203, Glu-334 and His-447, which transiently binds the acyl moiety of the substrate, (b) the ''acyl pocket'', and (c) the ''hydrophobic subsite'', which accommodates the alcohol moiety of the tetrahedral transition state. Another important component is (d) the ''oxyanion hole'', which stabilizes the transition state by accommodation of the negatively charged carbonyl oxygen. In addition to the invariant catalytic triad, there exists (e) a secondary substrate-binding site, referred to as the ''peripheral anionic site'' (PAS). This site is involved in both modifying catalytic activity (substrate inhibition) and mediating many inhibitor interactions of AChE. In addition, this site is involved in some nonhydrolytic functions of AChE (Inestrosa *et al.*, 1996). At the enzymatic level, AChE has

been characterized by its substrate specificity, which is essentially limited to ACh (Radic *et al.*, 1997), and its mode of interaction with selective inhibitors (Ariel *et al.*, 1998). The broader catalytic spectrum of BChE and its preference for longer chain substrates (Kaplan *et al.*, 2001; Loewenstein *et al.*, 1993) can be explained by its acyl binding pocket that is significantly bigger than that of AChE (Ngamelue *et al.*, 2007; Nicolet *et al.*, 2003).

Cholinesterases are heavily glycosylated. The three glycosylation sites on human AChE are all occupied (Kronman *et al.*, 2000) and at least eight of the nine potential sites on human BChE are occupied as well (Kolarich *et al.*, 2008). Glycosylation is variable and depends on (among other factors) cell type (Moral-Naranjo *et al.*, 1997; Saxena *et al.*, 1997b) and physiological state (e.g. Saez-Valero *et al.*, 2003; Silveyra *et al.*, 2006). Additional, isoform-dependent, post-translational modifications include oligomerization, proteolytic processing, and (for one of the C-terminal variants) attachment to a glycosylphosphatidylinositol (GPI) anchor.

The ''classic'' view of choinesterases as ~70 kDa cholinolytic glycoproteins whose sole function is to terminate cholinergic signals at the synapse has been repeatedly challenged by observations that were incongruent with it and suggested a far more interestingly complex picture of multiple molecular forms with distinct temporal and spatial expression patterns. Moreover, the various protein products of the *ACHE* locus (and BChE) play surprisingly diverse cholinergic and noncholinergic functions in health and disease (Appleyard, 1992; Greenfield, 1984, 1996; Layer, 1996; Silman and Sussman, 2005; Small *et al.*, 1996; Soreq and Seidman, 2001).

III. HUMAN CHOLINESTERASES: MYRIAD OF MOLECULAR FORMS

Humans possess two cholinesterase genes at two separate loci: *BCHE* (3q26, Allderdice *et al.*, 1991) and *ACHE* (7q22, Ehrlich *et al.*, 1992), respectively, encoding BChE and the plethora of AChE protein isoforms. The latter are translated from several mRNA variants arising, as described below, through highly regulated transcriptional and post-transcriptional processes.

Alternative splicing at the 3′-end of the *ACHE* pre-mRNA yields three different mRNA transcripts (Figure 46.1), which encode proteins with distinct carboxyl termini (Soreq and Seidman, 2001). The synaptic form, AChE-S (also known as T for ''tailed''), is generated by splicing of exon 4 to exon 6. This is the dominant transcript in most tissues. AChE-S mRNA translation gives rise to a 40 amino acid C-terminal extension of the core AChE. This C-terminal peptide contains cysteine, which allows the formation of dimers and tetramers. These are able to further bind a cholinesterase-specific collagen tail (ColQ) unique to AChE in the NMJ (Massoulie, 2002) or a proline-rich membrane anchor (PRiMA) in the central nervous system (Perrier *et al.*, 2002). Within the NMJ, interactions between the ColQ tails of two or three different tetrameric units and the two structural subunits generate an ''asymmetric'' AChE form and anchor it to the synapse (Massoulie, 2002).

A second transcript, AChE-E (also known as H for ''hydrophobic''), includes exon 5. Dimerization of AChE-E occurs through a cysteine residue in position 8 of the 43 residue-long C-terminal domain, which is cleaved after amino acid 14 (557 from the N-terminus). The newly

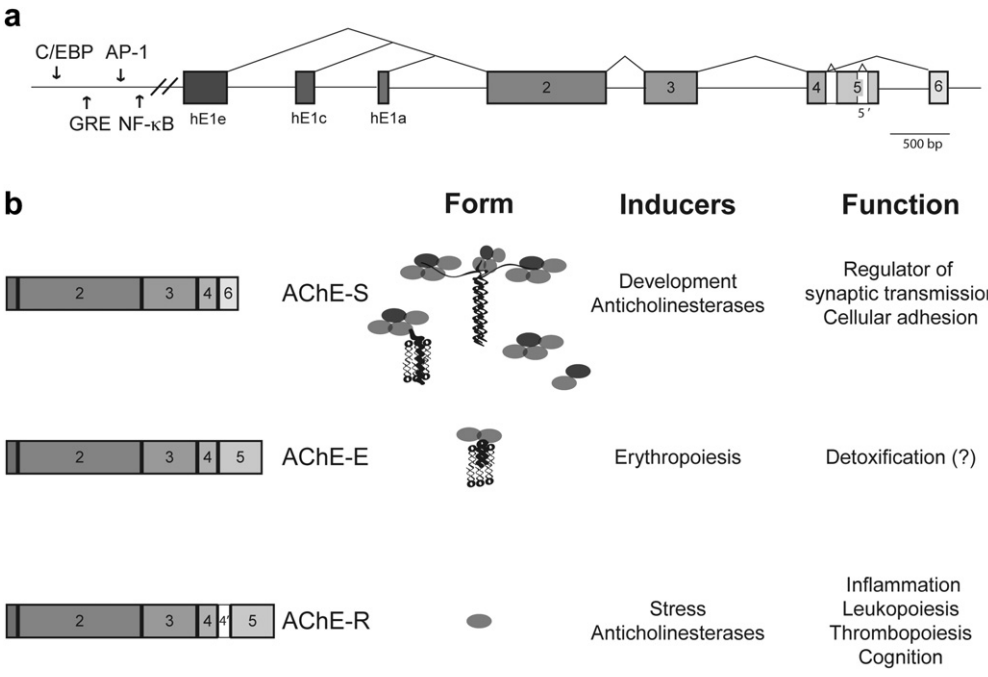

FIGURE 46.1. Regulation at the human AChE locus. (a) The human AChE gene contains several putative upstream enhancers, including the inflammation-associated C/EBP, AP-1 and NF-κB, and the stress-associated glucocorticoid response element (GRE). (b) Diverse cellular mechanisms regulate alternative splicing, yielding three C-terminal isoforms with diverse physiological activities.

generated C-terminus is GPI-anchored to the erythrocytic membrane.

A third form, the ''readthrough'' AChE-R, is encoded by a transcript containing pseudointron 4. This variant accumulates under various stressful insults through a feedback response that activates AChE mRNA transcription and shifts splicing in brain (Kaufer *et al.*, 1998; Meshorer *et al.*, 2002; Meshorer and Soreq, 2006), muscle (Lev-Lehman *et al.*, 2000), spermatocytes (Mor *et al.*, 2001a, 2008), hematopoietic cells (Gilboa-Geffen *et al.*, 2007; Grisaru *et al.*, 2006), and intestine (Shapira *et al.*, 2000). AChE-R has a shorter C-terminal peptide: 26 and 30 amino acids long in human and mouse, respectively. This C-terminus lacks a cysteine residue and hence AChE-R remains monomeric and soluble (Soreq and Seidman, 2001). Although the protein products of these mRNAs differ in their C-terminal peptide sequence and capacity to oligomerize, all of the molecular forms of AChE carry an identical active site and display similar catalytic properties (Schwarz *et al.*, 1995). Importantly, the distinct C-termini dictate dissimilar biological roles and noncatalytic properties.

The 5′-end of the AChE pre-mRNA is subject to alternate promoter usage, together yielding five and three alternative transcripts in mice and humans, respectively (Figure 46.1; Meshorer *et al.*, 2004). The alternative 5′- and 3′-end significantly increase the combinatorial complexity of AChE. Most of the identified 5′ exons produce alternative untranslated regions. However, at least one of those exons in humans is translated to a protein, with an extended N-terminus (N-AChE; Meshorer *et al.*, 2004). Based on the combinations of the 3′ and 5′ alternative transcripts, N-AChE-E, N-AChE-R, N-AChE-S might all exist (Meshorer and Soreq, 2006). Since N-AChE was shown to associate with the plasma membrane of blood cells (Meshorer *et al.*, 2004), it might have the capacity to dock the soluble AChE-R to synaptic membranes, without ColQ or PRiMA.

IV. REGULATION OF AChE GENE EXPRESSION

Regulation of AChE is primarily at the transcriptional and post-transcriptional levels (Soreq and Seidman, 2001). Transcriptional control of the *ACHE* gene is principally regulated by two proximal promoters, one that is clearly dominant and the other an alternative promoter (Atanasova *et al.*, 1999; Li *et al.*, 1993). Additionally, enhancers are present distally and within the first intron (Camp *et al.*, 2008; Chan *et al.*, 1999; Shapira *et al.*, 2000) as well as proximally to the four alternative first exons (Meshorer and Soreq, 2006). The upstream region of the *ACHE* locus contains numerous putative transcription-factor binding sites, including those which potentially bind NF-κB, AP-1 as well as a glucocorticoid response element (GRE) binding site. An increase in *ACHE* transcription is noted as a consequence of various stimuli as diverse as differentiation (Rotundo, 1990), vitamin D exposure (Grisaru *et al.*, 1999a), anticholinesterase exposure (Darreh-Shori *et al.*, 2004; Kaufer *et al.*, 1998), and transiently reduced levels of AChE (Galyam *et al.*, 2001). Decreases in AChE transcription are seen in mice deficient in the neural growth factor TrkA (Schober *et al.*, 1997). Additionally, the effects of AChE overproduction can be attenuated by activity dependent, secondary feedback responses in the nervous system (Soreq and Seidman, 2001). This can be seen in AChE overexpressing transgenic mice where increased hydrolysis of ACh is at least partially counterbalanced by a parallel increase in ACh synthesis (Erb *et al.*, 2001).

In vertebrate skeletal muscle, the collagen-tailed AChE-S variant is primarily detectable under normal physiological conditions (Li *et al.*, 1991, 1993). Muscle-specific expression of AChE is believed to be controlled by the transcription factors MyoD and myocyte enhancer factor-2 acting on the regulatory region located within the first intron (Camp *et al.*, 2008). This region is exceptionally well conserved between higher vertebrates, suggesting a generalization of this phenomenon. Negative regulation of AChE expression has been shown via a calcitonin-related gene polypeptide (CGRP)-dependent mechanism. CGRP is secreted from motor neurons and binds to the calcitonin receptor located on the skeletal muscle membrane (Rossi *et al.*, 2003). Receptor activation results in increased intracellular cAMP, and subsequent attenuation of AChE transcription through a cAMP-response element in the AChE promoter. It has more recently been shown that CGRP also reduces synthesis of the proline-rich membrane anchor region (PRiMA) of skeletal muscle AChE, and that overexpression of PRiMA itself can drive AChE transcription (Xie *et al.*, 2007).

V. LOCATION AND FUNCTION OF AChE IN THE NEUROMUSCULAR JUNCTION

AChE is found in the neuromuscular junction (NMJ) anchored to the cell membrane and is spatially related to the nicotinic ACh receptor (nAChR; Jasmin *et al.*, 1993). This specific localization is conferred by an N-box motif located within a 500nt region of the first intron (Chan *et al.*, 1999). Within the muscle, axons branch to innervate multiple muscle fibers, each fiber receiving a single synaptic input. The post-synaptic membrane of the skeletal muscle forms deep invaginations which are called junctional folds. nAChR molecules are concentrated in the peaks of the folds ($\sim$104/μm^2), close to the neuronal pre-synaptic active zone enriched in ACh-releasing vesicles (Sanes, 1997). nAChRs belong to the superfamily of ligand-gated ion channels. Each AChR molecule is a pentamer composed of four different subunits with the stoichiometry of $\alpha 2\beta\delta\gamma$ (in the adult) or $\alpha 2\beta\delta\varepsilon$ (in embryos). The synaptic cleft is filled by

the basal lamina of the NMJ, highly enriched in AChE (~2,500 sites/μm^2; Anglister, 1991; Anglister *et al.*, 1998; Massoulie *et al.*, 1993). Depolarization of the nerve terminal by nerve impulse is followed by an influx of calcium ions into the terminal via voltage-gated calcium channels. This influx results in exocytosis of many synaptic vesicles and the release of a corresponding number of ACh quanta into the synaptic space. Binding of two ACh molecules to the nAChR multisubunit complex opens the AChR channel, allowing the inward flux of cations along their electrochemical gradient and producing endplate potential (EPP). If this depolarization exceeds the threshold required to open the voltage-gated sodium channels at the depths of the folds, an action potential is generated, leading to muscle contraction. The evoked responses that can be recorded from the surface of the muscle following nerve stimulation are called a compound muscle action potential (CMAP). The CMAP represents the cumulative action potentials of all muscle fibers activated by nerve stimulation. Hydrolysis of ACh by AChE prevents free diffusion of the transmitter within the synapse and additional binding events. Part of the resulting choline pool is recycled with the aid of a high affinity transporter. These molecules enter the pre-synaptic nerve terminal and are being used as substrate by choline acetyltransferase (ChAT) to generate ACh.

VI. BUTYRYLCHOLINESTERASE AS THE INHERENT PROTECTOR OF AChE

When examining OP effects on the NMJ, one must first consider the various layers of inherent protection afforded by other OP-scavenging molecules. Like AChE, BChE can hydrolyze ACh, albeit with considerably slower kinetics. BChE binds most anticholinesterases that threaten synaptic AChE, making it a natural scavenger of OP nerve agents and pesticides (Ashani, 2000). The natural role of BChE is believed to be detoxification due to its ability to hydrolyze many naturally occurring and synthetic compounds such as succinylcholine, cocaine, and aspirin (Masson *et al.*, 1998). Providing an evolutionary justification, many plant alkaloids can inhibit both AChE and BChE (Fletcher *et al.*, 2004; Mukherjee *et al.*, 2007). Interestingly, increases in serum BChE are seen in such hypertriglyceridemic conditions as diabetes and obesity, and insulin or bacterial endotoxin are both sufficient to induce BChE production (Ofek *et al.*, 2007; Randell *et al.*, 2005). While BChE is a promiscuous enzyme with multiple functions, those subjects carrying mutations rendering BChE inactive possess a normal phenotype in the absence of anticholinesterase or succinylcholine challenge (Chatonnet and Lockridge, 1989). Additionally, BChE is highly polymorphic, further underscoring the dispensable nature of this protein in humans (Primo-Parmo *et al.*, 1996). Parallel roles can be ascribed to erythrocytic AChE-E (Salmon *et al.*, 1999; Simone *et al.*, 1994).

VII. ACUTE TOXICITY PRODUCES SHORT-TERM LOSS OF FUNCTION

A. Introduction

Anticholinesterases can be commonly encountered as industrial pesticides, weapons of war, Alzheimer's medications as well as the natural toxins of many organisms including fungi, plants, and animals. Exposure to clinically relevant doses of anticholinesterases results in immediate and multisystem physiological disturbances that underscore the broad anatomical distribution of the mammalian cholinergic system. The body adapts to the insult and attempts to compensate for the cholinergic dysregulation by inhibitor–enzyme interactions, NMJ remodeling, and changes in circulating cytokine profiles. This is the acute phase of anticholinesterase intoxication, encompassing the vast majority of the work in this field, which has resulted in a nearly complete and predictable clinical picture. One area of recent research intensity involves the delineation of a mechanism for immunosuppression in the context of excessive cholinergic stimulation (Nizri *et al.*, 2006; Oke and Tracey, 2008; Pavlov *et al.*, 2003; Van Westerloo *et al.*, 2005). We now possess a framework for understanding the immunomodulation that has been periodically reported in the literature and which enhances our understanding of cholinergic biology and suggests novel therapeutic interventions that may yield positive outcomes in the clinic.

B. Gross Clinical Presentation

Unregulated overstimulation of nicotinic and muscarinic ACh receptors through inhibition of AChE and subsequent ACh accumulation initiates a variety of detrimental processes that can culminate in severe consequences for the exposed patient (Brown and Brix, 1998; Marrs, 1993; Weinbroum, 2005; Yanagisawa *et al.*, 2006). These range, acutely, from excessive glandular secretions and headache to respiratory depression and death. Chronic manifestations in patients include NMJ dysmorphology, inflammation, and behavioral and cognitive deficits. Clinically, cholinergic dysregulation is most often found secondary to accidental or intentional ingestion of a variety of agents from anticholinesterase pesticides, nerve agents, and Alzheimer's therapeutics to cholinergic agonists like nicotine. The resulting pathology is referred to as a ''cholinergic crisis''. Diagnosis of anticholinesterase toxicity is made by patient history and clinical presentation, with confirmation by measurement of the degree of inhibition of erythrocyte AChE activity (Nozaki *et al.*, 1997).

Existing treatment protocols emphasize three complementary approaches: antagonize the muscarinic ACh receptor, reactivate endogenous AChE with oxime therapy, and manage the severe toxicity symptomatically (Lee, 2003). Atropine is the drug of choice for mitigating the synaptic ACh accumulation, and is titrated until the patient

is breathing comfortably. Airway management may require endotracheal intubation; however, succinylcholine is contraindicated as it is metabolized by BChE (Li *et al.*, 2008). Diazepam is used to manage the seizures that are seen with anticholinesterase toxicity. While these approaches have proven value in reducing mortality, they are unable to prevent the debilitating acute morbidity or long-term consequences that are associated with anticholinesterase poisoning (Huang *et al.*, 2007).

In 1877 (Taylor, 1996), prior to the discovery of ACh as a neurotransmitter in the brain in 1914 (Dale, 1914a, b), physostigmine (eserine) – a carbamate extracted from the seeds of *Physostigma venenosum* – became the first cholinesterase inhibitor used therapeutically to control increased ocular pressure, caused by wide angle glaucoma. In 1993, tacrine became the first ChE inhibitor approved in the USA for the treatment of Alzheimer's disease (Giacobini, 1998). More recently, second generation anti-ChEs such as rivastigmine, donepezil, and eptastigmine have shown higher efficacy, lower toxicity, and easier administration (Ringman and Cummings, 2006). In the Far East, plant-originated anti-ChEs such as Huperzine have been used for thousands of years in the treatment of aging-induced memory impairments (Haviv *et al.*, 2007).

In the peripheral nervous system, anti-ChEs elevate ACh levels at the NMJ, ameliorating the damaged cholinergic balance and transmission. Neostigmine and physostigmine were also the first effective treatments for myasthenia gravis (MG). Since physostigmine is capable of crossing the blood–brain barrier (BBB), neostigmine was the preferred theraputic. Pyridostigmine bromide (Mestinon™) became available in the 1950s as a longer-lasing agent, active for 3–6 h with fewer side effects and the ease of oral administration. Longer-lasting agents were not used since they accumulated to overdose levels. A similar problem was reported when OP inhibitors were tested. Importantly, anti-ChE therapy can cause a variety of side effects, including gastrointestinal problems, salivation, sweating, and cardiac and hypotension effects (Fisher, 2000).

C. Molecular Mechanisms of Cholinesterase Inhibition

The therapeutic/toxic action of AChE inhibitors is targeted at the well-known hydrolytic activity of AChE. Such inhibitors can bind to the catalytic site at the bottom of the gorge (Sussman *et al.*, 1991), the peripheral site (Silman and Sussman, 2005), or both. AChE inhibition leads to the accumulation of free ACh, which further leads to uncontrolled cholinergic neurotransmission. Since the cholinergic balance depends on well-regulated release and hydrolysis of ACh, excessive inhibition of AChE may lead to overstimulation and damaged cholinergic neurotransmission (Soreq and Seidman, 2001), which in high doses may be fatal.

Different types of AChE inhibitors exist. The carbamate group of anti-AChEs includes physostigmine (which can penetrate the BBB) and pyridostigmine (unable to cross the BBB under normal conditions); both harbor a reactive carbamate group. Similar to ACh, they undergo acylation (carbamylation) to form a carbamyl–enzyme intermediate, but the subsequent hydrolysis rate of this hemi-substrate is very slow, occupying the enzyme carbamylated for a considerably long time and competing with the natural substrate (Conner *et al.*, 1996). Carbamylation of AChE with this type of carbamate is often termed irreversible inhibition, but since some carbamylated ChEs can undergo rapid reactivation, carbamates have been incorrectly considered as reversible inhibitors for many years (Feldman, 1999b). A second group of irreversible inhibitors includes the OPs. OPs are esters of phosphoric, phosphonic, and phosphinic acids, with no free hydroxyl group on the phosphorus atom (Feldman, 1999a). Similar to carbamates, they react with ChEs and other serine esterases due to the structural resemblance of their substrates. However, phosphorylated enzyme is reactivated considerably slower than the carbamylated enzyme and certain OPs can further undergo dealkylation following their interaction with the enzyme and completely block its reactivation (''aging''; Feldman, 1999a; Taylor, 1996). Both carbamates and OPs are used in agriculture as pesticides and therapeutically to elevate ACh levels. The high toxicity of OPs further led to their use as chemical warfare agents (e.g. OP nerve agents, soman, sarin, cyclosarin, tabun, and VX), calling for development of therapeutic agents to prevent their lethal effects (Cowan *et al.*, 2004; Newmark, 2004; Raveh *et al.*, 1993).

D. AChE Dynamics at the NMJ

Inhibition of AChE at the NMJ results in persistent cholinergic transmission that must be rapidly corrected by modifications in the signaling environment. This occurs primarily by rapid internalization of the AChR with homeostasis being restored through the simultaneous process of AChE replacement (Krejci *et al.*, 2006). OP treatment has been shown to inactivate the AChR within seconds of application, validating the concept of receptor-level compensations (Katz *et al.*, 1997). In an elegant experimental series, a one-time blockade of AChE resulted in a 54% internalization of the AChR at the NMJ within 3 days, presumably in an attempt to mitigate the increased synaptic ACh. The degree of AChE inhibition appears to be tightly linked to AChE replacement and remodeling, with chronic blockade producing a $t_{1/2}$ of 12 h. One-time inhibition of NMJ AChE results in a biphasic $t_{1/2}$, which is increased initially to 3 days and subsequently to 12 days. Interestingly, one-time inhibition of AChE results in a 1:1 ratio of replaced:internalized AChE. However, chronic exposure decreases this ratio significantly, presumably due to cellular toxicity. Importantly, almost one-third of the initially inhibited AChE may be present weeks later, implying that there may be two pools of AChE at the

NMJ, with the remaining pool possibly representing ColQ-linked AChE.

AChE-S location in the NMJ basal lamina has been well established (Anglister *et al.*, 1994). AChE-S, but not AChE-R, accumulates and adheres to the active zone at the NMJ (Harlow *et al.*, 2001; Seidman *et al.*, 1995) and is an essential component of functional NMJs. Compatible with this notion, the loss of the ColQ collagen-like structural subunit linking AChE-S to the NMJ leads to congenital myasthenia (Donger *et al.*, 1998; Ohno *et al.*, 2000), and modified AChE levels were associated with muscle dystrophy in chickens (Silman *et al.*, 1979). However, the inhibitory action of small molecule anti-ChEs exerts complex consequences. For example, AChE inhibitors induce AChE-R overproduction in muscle, have deleterious effects on muscle and NMJ morphology (Lev-Lehman *et al.*, 2000), and modify ACh levels, affecting the inflammatory status (Pollak *et al.*, 2005). When up-regulated, AChE-R is capable of reaching the synaptic cleft and changing the ACh balance there, as well as in the circulation. Together, this implies that AChE-R might participate in acquired or inherited myopathies and that it should serve as a preferred target for therapeutic agents.

E. The Cholinergic Anti-Inflammatory Pathway

The term ''cholinergic anti-inflammatory pathway'' was coined in recognition of the ability of excessive stimulation of nAChRs to prevent the secretion of the pro-inflammatory cytokines TNFα, interleukin (IL)-1β, IL-6, and IL-18, but not the anti-inflammatory cytokine IL-10, from macrophage (Czura and Tracey, 2005; Gallowitsch-Puerta and Tracey, 2005; Tracey, 2002; Tracey *et al.*, 2001). In lipopolysaccharide (LPS)-stimulated human macrophage cultures, nAChR stimulation impairs positive stimulation by pattern-associated molecular patterns (PAMPs) such as bacterial LPS (Borovikova *et al.*, 2000a, b). Vagus nerve secretion of ACh inside the spleen is the principal site of *in vivo* anti-inflammatory action, as splenectomized mice show profoundly reduced pro-inflammatory cytokine levels following LPS administration (Huston *et al.*, 2006). This neuroregulated anti-inflammatory pathway using ACh has been shown to operate through the suppression of NF-κB, much like HPA axis-induced immunosuppression utilizing glucocorticoids (Pavlov *et al.*, 2003). Long ago the deleterious effects of OPs on immune function were demonstrated, most notably affecting humoral immunity (Beaman *et al.*, 1999; Casale *et al.*, 1983, 1984). More recently, OP-mediated suppression of TNF-α, IL-1β, and iNOS has been shown, as well as a confirmation of decreased humoral immunity through suppression of IL-4 (Singh and Jiang, 2003). This, in turn, has led to investigation of OP-mediated suppression of the HPA axis (Pena-Philippides *et al.*, 2007). In addition to OPs, therapeutic anti-cholinesterases have also been shown to exert anti-inflammatory properties (Tyagi *et al.*, 2007). Thus it can be seen that anti-ChEs are valid inducers of the cholinergic anti-inflammatory pathway, presumably through their role in increasing ACh levels.

A reciprocal role to that of ACh is implicated for the soluble AChE-R protein, which should principally reduce ACh levels while inducing pro-inflammatory properties. Indeed, the response to chemical warfare agents such as OP inhibitors of AChE shows interesting parallels with those symptoms caused by the release of cytokines. Accordingly, the nerve agent soman and other anti-AChEs initiate immune responses as well. Soman induces an increase in the pro-inflammatory cytokine IL-1β in rats, including brain where IL-1β is thought to contribute to irreversible brain damage following exposure (Svensson *et al.*, 2001). Moreover, immune stimulation by LPS influences AChE activity in human serum (Cohen *et al.*, 2003; Ofek *et al.*, 2007) and in pro-megakaryocytes (Pick *et al.*, 2006). In light of these reports, and due to the fact that IL-1 causes AChE overproduction in PC12 cells and in the rat cortex (Y. Li *et al.*, 2000a, b), the following relationships can be postulated: IL-1 induction of AChE overexpression suppresses ACh levels, ablating ACh's capacity to attenuate IL-1 production, a cycle that may explain the prolonged anti-AChE effects. Conversely, AChE suppression was shown to suppress IL-1 production in brain and blood, presumably by increasing ACh levels (Pollak *et al.*, 2005). Hence, AChE inhibitors will initially block the inflammatory response due to their capacity to increase ACh levels, but in the long term they will not be able to prevent AChE's noncatalytic effects, such as NMJ proliferation, especially since AChE inhibition induces AChE-R overproduction. Increased inflammatory response is hence predicted to follow the feedback response of AChE-R accumulation (Figure 46.2).

The cholinergic anti-inflammatory pathway has profound implications for excessive nAChR stimulation in the context of an infected host by increasing susceptibility to initial infection or therapeutically reducing the host overreaction seen in sepsis. Because OP levels inducing immunosuppression appear to be lower than those inducing acute cholinergic crisis, it is important to consider treating OP-exposed patients not exhibiting acute cholinergic symptoms in order to reduce the likelihood of opportunistic infections following survivable OP intoxication. A bioscavenger like AChE-R that enhances host immunity may be useful in this situation.

VIII. LONG-TERM EFFECTS OF AChE-R OVERPRODUCTION

A. Introduction

Loss of synaptic cholinergic regulation by AChE inhibition has immediate negative consequences for mammalian physiology. The severe multisystem clinical presentation of anti-ChE intoxication demonstrates the essential and

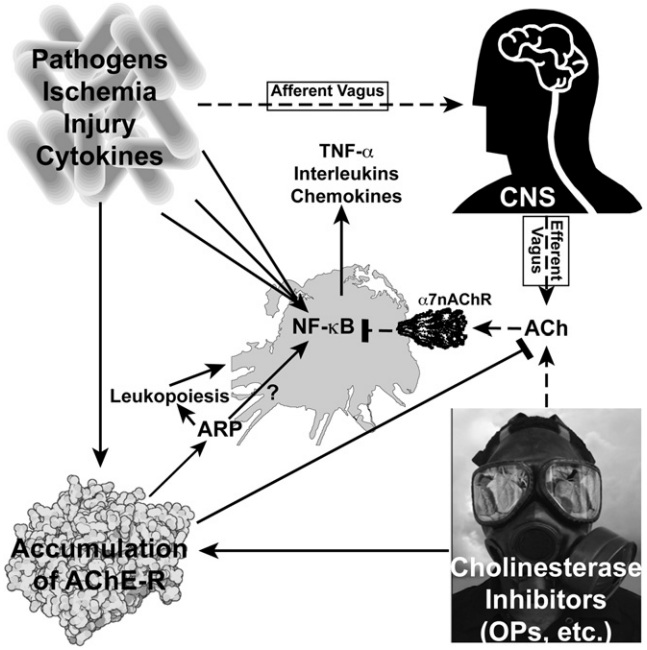

FIGURE 46.2. Cholinergic regulation of inflammation. Upper left corner: Diverse physiological insults converging on the cell are initially attenuated by the cholinergic anti-inflammatory pathway (dashed lines). Long-term cholinergic regulation of inflammation adopts a decidedly pro-inflammatory character constituting a cholinergic pro-inflammatory pathway, principally mediated by AChE-R and the peptide derivative ARP (solid lines). This bivalent perpetuation of inflammation operates through suppression of anti-inflammatory pathways (flat heads) and activation of novel pro-inflammatory pathways (arrow heads). Lower right corner: Anticholinesterases, such as OPs, have similar short- and long-term effects on the immune system.

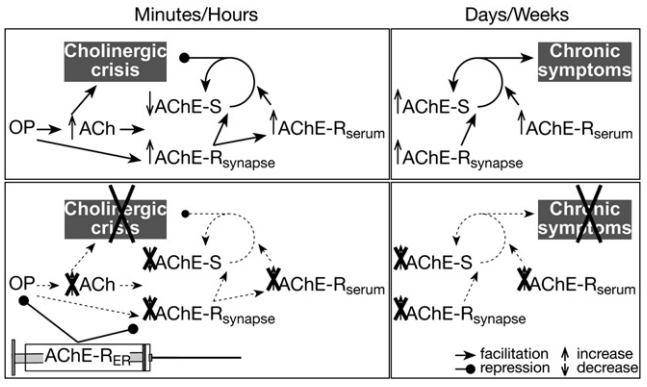

FIGURE 46.3. Model for mechanism of protection from acute and chronic consequences of OP intoxication afforded by plant-derived AChE-R.

ubiquitous nature of the mammalian cholinergic system. Conventional wisdom holds that surviving the acute phase confers a positive prognosis. While this is certainly true for the immediately life-threatening complications of OP intoxication, this dogmatic and historically practiced approach ignores many new advances in the understanding of AChE physiology and molecular biology.

Exposure to anti-ChEs affects both nicotinic and muscarinic cholinergic pathways and results in cholinergic hyperexcitation (e.g. excessive salivation) and neuromuscular malfunctioning (e.g. shortness of breath). Such intoxication, when surviving the acute exposure, has long-term consequences, including OP-induced delayed neuropathy, social/behavioral effects, and delayed muscle weakness (Brown and Brix, 1998). In the brain, effects of OP exposure, like many other stressful insults, are mediated by the accumulation of the early immediate protein c-Fos followed by up-regulation of AChE gene expression (Friedman *et al.*, 1996) and a 3′ alternative splicing shift from AChE-S to AChE-R (Kaufer *et al.*, 1998; Meshorer *et al.*, 2002). This prolonged overexpression of AChE-R causes dramatic deleterious consequences, manifested as degenerated synaptic folds in NMJs, enlarged motor endplates, disorganized muscle fibers and branded terminal nerves (Lev-Lehman *et al.*, 2000), accompanied by physiological malfunctioning (Farchi *et al.*, 2003). Finally, mice overexpressing AChE-R display significant deficits in both normal social behavior and memory (Cohen *et al.*, 2002; Farchi *et al.*, 2007b; Nijholt *et al.*, 2004), compatible with the assumption that AChE-R excess is causally involved with these consequences of anti-ChE exposure.

B. "Non-Classical" Roles of Cholinesterases

In addition to the traditional roles of regulators of cholinergic transmission in the serum and at the synapse, many novel roles have been proposed for ChEs (Soreq and Seidman, 2001). For example, BChE has recently been shown to attenuate amyloid plaque formation and also be involved in neurogenesis (Diamant *et al.*, 2006; Mack and Robitzki, 2000). AChE-E has been shown to degrade heroin into 6-amino morphine, a function that AChE-S cannot perform (Salmon *et al.*, 1999).

The first discovered noncatalytic role of AChE-S was the enhancement of embryonic neurite extension, both in cell cultures (Bigbee *et al.*, 2000; Layer *et al.*, 1993; Small *et al.*, 1995) and in *Xenopus* motor neurons that express human AChE-S (Sternfeld *et al.*, 1998). Lately, many additional roles have been proposed for AChE, apart from its traditional role of terminating cholinergic transmission at the synapse (Silman and Sussman, 2005; Soreq and Seidman, 2001). For example, AChE was suggested to function as an adhesion molecule, due to its sequence homology to ChE-like adhesion molecules such as neuroligin. In that way, it was argued that AChE may be involved in synaptogenesis and synaptic maintenance (Silman and Sussman, 2005). Other noncatalytic roles include accentuation of amyloid plaque formation by AChE-S (Inestrosa *et al.*, 1996; Rees *et al.*, 2003, 2005; Rees and Brimijoin, 2003) and the inverse attenuation of plaque formation by AChE-R (Berson *et al.*, 2008).

Perhaps the most significant advances in understanding nontraditional roles of ChEs have come through the study of AChE-R (Meshorer *et al.*, 2002). First recognized as a stress-induced soluble AChE variant, it was quickly noticed that AChE-R maintained a role as a contributor to numerous important processes from fear to hematopoiesis and inflammation. Specifically, AChE-R has been shown to enhance fear memory and long-term fear potentiation (Birikh *et al.*, 2003; Nijholt *et al.*, 2004). A proliferation function of AChE-R has recently been recognized in hematopoiesis (Pick *et al.*, 2006) and osteogenesis (Grisaru *et al.*, 1999a), while AChE-S was inversely shown to interfere with lymphopoiesis (Perry *et al.*, 2007). Importantly, the cleavable C-terminus peptide of AChE-R, acetylcholinesterase readthrough peptide (ARP), was shown to have a role in hematopietic proliferation and pro-inflammatory cytokine production (Gilboa-Geffen *et al.*, 2007; Deutsch *et al.*, 2002; Grisaru *et al.*, 2006), contextual fear and LTP enhancement (Farchi *et al.*, 2007b; Nijholt *et al.*, 2004), neuronal development, plasticity (Dori and Soreq, 2006), and inflammation-associated neuropathies (Dori *et al.*, 2007).

C. Cholinergic Hyperexcitation and Induction of AChE-R Production

Acute psychological stress and sublethal intoxication with AChE inhibitors both induce cholinergic stimulation, yielding neuronal hyperexcitability (Ennis *et al.*, 1992; Imperato *et al.*, 1991). Immediate reactions to such cholinergic stimulation include a dramatic increase in neuronal c-Fos mRNA (Kaufer *et al.*, 1998; Lev-Lehman *et al.*, 2000). The c-Fos protein further binds and activates the promoters of the ChAT (Bausero *et al.*, 1993), VChAT (Cervini *et al.*, 1995), and ACHE (Meshorer *et al.*, 2004) genes. A consequent decrease in ChAT and VChAT then suppresses ACh synthesis and packaging, while enhanced AChE mRNA synthesis and translation facilitates ACh hydrolysis, together yielding an effective restraint of the hypercholinergic response. The larger AChE activity observed in both brain and NMJ following AChE blockade reflects the induction of a soluble AChE variant, AChE-R (Kaufer *et al.*, 1998). This profound feedback response is largely controlled by the splice factor SC35 (Meshorer *et al.*, 2005a). It serves well in the short term to quickly reduce the cholinergic hyperactivity following an acute insult (Kaufer and Soreq, 1999), but may entail long-term damage. Thus, AChE-R mRNA levels remain elevated for several weeks following a days-long exposure, even to exceedingly low doses of the OP AChE inhibitor diisopropyl fluorophosphate (DFP; Lev-Lehman *et al.*, 2000; Meshorer *et al.*, 2002). In the striatum, exposure to AChE inhibitors predictably increased AChE-R mRNA by three-fold but did not affect AChE activity or total AChE mRNA, possibly suggesting arrested translation or production of inactive AChE-R (Perrier *et al.*, 2005). In the hippocampus, exposure to AChE inhibitors could not be rebalanced by subsequent cholinergic stimulation due to limited ability for additional AChE-R induction (Meshorer *et al.*, 2002). Therefore, repeated cholinergic stimulation by AChE blockade induces long-term hypersensitization with potentially damaging consequences. Supporting this notion, transgenic mice overexpressing AChE-S in the central nervous system possess delayed cognitive and neuroanatomical pathologies (Cohen *et al.*, 2002; Farchi *et al.*, 2003). In humans, traumatic stress with a severe stress response is often followed by long-term pathological changes (McEwen, 1999; Sapolsky *et al.*, 2000). Under extreme conditions, such changes are clinically referred to as the anxiety-associated post-traumatic stress disorder (PTSD; Mezey and Robbins, 2001). Physiological relevance of AChE-R to these increases was reported in healthy human volunteers, where higher blood AChE-R levels occurred in association with the subjects' anxiety (Sklan *et al.*, 2004). It is still unknown whether this stress-induced alternative splicing of AChE occurs as a cause or an outcome of anxiety, or both. However, in either case this phenotype may reflect physiological relevance of the overexpressed AChE-R in reaction to stress. Apart from this apparent association, AChE-R may mediate at least some of the adverse cellular changes associated with delayed stress responses (e.g. spine loss or glial hyperactivation, see Sternfeld *et al.*, 2000). Intriguingly, AChE-R mRNA was found in apical dendrites of neurons from all cortical layers following exposure to cholinesterase inhibitors (Kaufer *et al.*, 1998; Meshorer *et al.*, 2002), suggesting possible local regulation and translation of AChE in the synapse also in noncholinergic neurons.

D. AChE-R Accumulation in NMJs Under Cholinergic Imbalances

Similar to the case in the brain, AChE-R accumulates in neuromuscular tissues under diseases and stress conditions. AChE-R levels rise both in the serum and muscles of experimental autoimmune myasthenia gravis (EAMG) rats and in the serum of MG patients (Brenner *et al.*, 2003; Euron *et al.*, 2005). In the primate spinal cord, AChE-R accumulated under handling stress in a cell size-dependent manner, suggesting that the characteristic response of shift in the alternative splicing of AChE pre-mRNA spans different cell types and is pivotal for controlling motor functions. In the spinal cord, cholinergic interneurons that innervate large motor neurons, but not the motor neurons themselves, respond to stress conditions by elevating AChE-R and by reducing the translocation of AChE-S mRNA into neurites, similarly to AChE-R elevation in mouse tongue muscles following exposure to AChE inhibitors (Lev-Lehman *et al.*, 2000) and compatible with the shift in alternative splicing toward AChE-R and its transport to neural extensions, where it replaces the normally expressed transcript, AChE-S (Farchi *et al.*, 2007a; Meshorer *et al.*, 2002). A rapid and transient elevation in serum AChE-R following stress responses further suggests a mechanism for suppressing

ACh mediated excitation after stress. However, prolonged elevation in AChE-R, for example, following stress and anti-ChE intoxication, may damage cholinergic signaling and exert noncholinergic effects.

E. Noncholinergic Effects of AChE-R Excess in NMJs

A direct role for AChE-R in MG symptoms likely involves several functional levels. The first is the clear cholinergic function of AChE-R in controlling ACh levels at the NMJ. The second is interference with the anti-inflammatory role of ACh, exacerbating the outcome of the autoimmune origin of the disease. Finally, secondary signaling effects that further change the disease progression may involve AChE-R protein–protein interaction with the scaffold protein RACK1 and its target, protein kinase C βII (PKCβII; Birikh *et al.*, 2003; Sklan *et al.*, 2006). These interactions have already been identified within brain neurons with an association to fear-induced behavior (Nijholt *et al.*, 2004) and in hematopoietic cells (Pick *et al.*, 2006) and may be relevant to more tissues, including muscles. Another potential mechanism is based on AChE's sequence homology to cell surface adhesion molecules such as neuroligin (Silman and Sussman, 2005). In brain synapses, AChE-R might compete with neuroligin on interaction with its partners (i.e. neurexin), interfering with and even modifying the post-synaptic signaling pathway. Such interference may serve as a potential mediator of cytoarchitectural changes (Grifman *et al.*, 1998) in central nervous system synapses. Both neuroligin and neurexin are also expressed and function at the NMJ (Johnson *et al.*, 1995; Sons *et al.*, 2006), suggesting parallel relevance to NMJ architecture. Within the NMJ, synaptic differentiation is induced by axon-derived agrin and muscle-derived laminin (Fox and Umemori, 2006). Laminin 1 was suggested as a potential partner for AChE (Johnson and Moore, 2003, 2004; Paraoanu and Layer, 2004) and for AChE-R's C-terminal peptide, ARP (Johnson and Moore, 2007). This may further explain the increase in NMJ density and area following OP intoxication associated with elevated AChE-R (Evron *et al.*, 2007a, b; Lev-Lehman *et al.*, 2000). Furthermore, this morphological effect was partially preventable by either EN101/Monarsen (Lev-Lehman *et al.*, 2000) or by the plant-derived AChE-R_{ER} (Evron *et al.*, 2007a, b). Further experiments are required to elucidate the mechanisms underlying AChE's noncatalytic roles in general and within neuromuscular tissues in particular.

Compatible with previous findings (Perry *et al.*, 2004; Perry and Soreq, 2004; Sklan *et al.*, 2004), AChE-R appears to contribute to the maintenance of cholinergic homeostasis while accentuating neuronal inflammatory reactions. Because AChE-R accumulation reduces ACh levels, suppression of AChE-R overproduction can retrieve the blockade over pro-inflammatory cytokine production, suppressing the inflammatory status in treated subjects.

F. mARP as a Physiological Mediator of Recovery

Exposure to OP inhibitors of AChE leads to short-term severe symptoms, followed by longer-term effects such as memory impairments and muscle fatigue (Rosenstock *et al.*, 1991), and accompanied by AChE-R up-regulation (Kaufer *et al.*, 1998; Lev-Lehman *et al.*, 2000; Salmon *et al.*, 2005). In farmers, exposure to OP insecticides correlates to a higher risk of leukemia (Brown *et al.*, 1990), which was tentatively correlated to AChE-R accumulation (Perry and Soreq, 2004). However, immune stimulation by LPS also influences AChE levels (Cohen *et al.*, 2003; Ofek *et al.*, 2007; Pick *et al.*, 2006). In CD34+ hematopoietic progenitors in culture, cortisol treatment also induced AChE-R accumulation (Grisaru *et al.*, 2001). The up-regulated AChE-R can further induce hematopoietic cellular processes through its noncatalytic properties and the enhanced interaction with RACK1 (Pick *et al.*, 2006). Moreover, AChE-R elevation in the serum of stressed mice was associated with an apparent cleavage of the AChE-R C-terminal peptide, human (h) ARP (Grisaru *et al.*, 2001). A parallel cleavage also occurred in the serum of human volunteers following exposure to LPS (Cohen *et al.*, 2003). Mimicking this phenomenon by *ex vivo* administration of a synthetic human ARP, promoted expansion and differentiation of hematopietic stem cells (Deutsch *et al.*, 2002; Grisaru *et al.*, 2006), accentuated neuronal plasticity (Dori *et al.*, 2005; Dori and Soreq, 2006), facilitated LTP enhancement (Farchi *et al.*, 2007b; Nijholt *et al.*, 2004), and induced inflammation-associated neuropathies (Dori *et al.*, 2007), all known as pivotal elements of organismal reactions to acute stress and exposure to poisonous substances. Intriguingly, RNA-targeted suppression of AChE-R prevented at least some of the described effects of the mouse administered mARP (Deutsch *et al.*, 2002; Grisaru *et al.*, 2001; Nijholt *et al.*, 2004). In cultured CD34+ cells, administered human ARP enhanced AChE gene expression (Grisaru *et al.*, 2006). Importantly, human and mouse ARP differ in their primary amino acid sequences, but share common immunogenic features and cell proliferative function(s) (Dori *et al.*, 2007).

In the brain, mARP is capable of undergoing endocytosis and retrograde transport through a mechanism which was reported to involve the recruitment of RACK1 and PKCβII (Nijholt *et al.*, 2004). In blood cell progenitors, human ARP promoted megakaryocytopoiesis with similar involvement of RACK1 and PKCε (Pick *et al.*, 2006). Systemic administration of mARP to mice following paraoxon and LPS exposures affected multiple levels of body defense. Those included both organismal responses such as changes in body temperature and arrested motor activity and molecular reactions such as modified corticosterone levels and muscle AChE gene expression; and led to a longer-term dramatic increase in motor activities, high above normal values. In contrast to the rapid effect following paraoxon exposure,

mARP administration increased light- and dark-phase motor activities several days post-LPS exposure. This is compatible with the symptoms recorded for AChE-R overexpressing transgenic mice, which presented dramatic activity changes following a circadian shift (Cohen *et al.*, 2002). It is also consistent with the tissue-specific effect on endogenous AChE mRNA and protein production. While in the plasma AChE activity was elevated, mARP reduced total AChE and AChE-S mRNA levels within the muscle. This was compatible with the decrease observed in the muscle AChE protein following treatment with plant-produced recombinant AChE-R_{ER} (Evron *et al.*, 2007a), supporting the hypothesis of auto-regulatory effects of mARP on AChE gene expression in the *in vivo* context as well. Importantly, reduced levels of muscle AChE were associated with mitigated damage in diaphragm NMJs. Altogether, our findings hence raise the possibility of using synthetic ARP as a regulatory element, capable of facilitating recovery and minimizing exposure-induced damage, following chemical stresses.

G. Modified Alternative Splicing Patterns by Spinal Cord Cholinergic Signaling

Modified and aberrant alternative splicing in the nervous system is associated with diseases, aging, and stress (Meshorer and Soreq, 2002; Nissim-Rafinia and Kerem, 2005; Stamm *et al.*, 2005). For example, aberrant splicing of the glutamate transporter gene EAAT2 is associated with ALS (Lin *et al.*, 1998). The detailed mechanisms by which missplicing or modified splicing patterns lead to human diseases are not clear yet, but probably involve multiple factors that participate both in basic splicing (e.g. serine–arginine (SR)-rich proteins, small nuclear ribonucleoproteins (snRNPs); reviewed in Stamm *et al.*, 2005) and in alternative splicing processes. Cholinergic stress responses include a transient increase in ACh levels in the mammalian brain (Masuda *et al.*, 2004), similar to the outcome of exposure to the small molecule inhibitors of AChE. Additionally, AChE alternative splicing following stress leads to a shift from AChE-S transcripts to AChE-R ones. The consequent accumulation of AChE-R then mediates at least part of the cellular changes of delayed stress responses (Meshorer and Soreq, 2006). In the mouse prefrontal cortex, AChE-R accumulation was further associated with parallel increases of the splicing factor SC35 (Meshorer *et al.*, 2005b). SC35 is a member of the serine-arginine (SR) proteins, involved in both constitutive and alternative splicing (Tacke and Manley, 1999). In cell cultures, SC35 shifted the splicing toward the AChE-R variant when cotransfected with the AChE minigene (Meshorer *et al.*, 2005b). In the hematopoietic system, SC35 is essential for the normal development of T lymphocytes (Wang *et al.*, 2001), a process subjected to stress-induced modulation (Gilboa-Geffen *et al.*, 2007; Pick *et al.*, 2004, 2006). Also, cultured cells overexpressing either AChE-R or AChE-S inversely show reduced SC35 levels (Ben-Ari *et al.*, 2006), indicating network contributions to this effect. A direct association between the levels of nuclear SC35 and cytoplasmic AChE-R mRNA was found in interneurons, but not in large motor neurons, further reflecting a cell-size dependent effect for this association (Evron *et al.*, 2005). Together, our observations support the notion of a reciprocal control of the spliceosome function by cholinergic signaling. SC35 is required for the formation of the earliest ATP-dependent splicing complex (Kramer, 1996). It also binds the 5′ and 3′ splice sites during spliceosome assembly. Our findings therefore suggest that cholinergic signaling regulates the splicing and alternative splicing patterns in the spinal cord.

H. AChE-R in Neuromuscular Pathologies

Two weeks following DFP exposure for 4 days, the mouse tongue muscles show a significant increase in AChE catalytic activity (Lev-Lehman *et al.*, 2000). The punctuated expression pattern of NMJ-related AChE-S mRNA remains unchanged, but AChE-R mRNA is significantly induced and exhibits a diffuse, extrajunctional distribution. TgS mice, which also show host AChE-R mRNA overexpression, presented a similar expression pattern (Lev-Lehman *et al.*, 2000). Furthermore, in control animals, histochemical activity staining localized the signal to motor endplates, whereas in TgS mice, the soluble AChE-R presented dispersed staining in muscle fibers, not restricted to the endplate region.

In both TgS mice and strain-matched controls chronically treated with DFP, AChE-R overexpression was accompanied by neuromuscular pathology. This neuropathology was exhibited as a chaotic fiber disorder with severe atrophy and vacuolization, compared to control mice where fiber organization was conspicuous (Lev-Lehman *et al.*, 2000). A significant increase was observed by silver staining in small unbundled neurites, but not in large nerve bundle fibers, both in TgS mice and following chronic DFP treatment compared to strain-matched controls. Corresponding to the previously reported neurite-promoting activity of AChE (Grifman *et al.*, 1998; Sternfeld *et al.*, 1998), these findings indicate axon branching under the influence of AChE-R overexpression and suggest that the affected muscles were subjected to denervation–reinnervation processes. Importantly, nontransgenic mice treated with DFP and TgS mice exhibited a significant increase in the number of endplates in their diaphragm muscle compared to FVB/N controls (Lev-Lehman *et al.*, 2000). These endplates were smaller in diameter; compatible with the assumption that reinnervation occurred. Intact TgS muscles stimulated directly via the phrenic nerve examined *ex vivo* demonstrated rapid fatigue following initial stimulation, accompanied by enlarged decrements and delayed recovery compared to strain-matched controls, which was attributed to both neuronal and muscle impairments (Farchi *et al.*, 2003).

Inherited (Donger *et al.*, 1998; Lindstrom, 1998) or acquired (Engelhardt *et al.*, 1997; Livneh *et al.*, 1988; Schonbeck *et al.*, 1990) interference with ACh mediated neurotransmission in the NMJ causes a variety of myasthenic syndromes, i.e. progressive muscle weakness and fatigue. These impairments of cholinergic neurotransmission further induce neuroanatomical NMJ pathologies characterized by co-deterioration of muscle structure and function. Interestingly, sepsis-mediated critical illness polyneuropathy (CIP; Hund, 2001a) and critical illness myopathy (Hund, 1999) were also shown to be responsible for muscle weakness and atrophy in intensively treated patients. This weakness is mediated by neuropathy and disturbance of neuromuscular transmission as well as disturbance in the function and/or structure of the muscle (Hund, 2001b), suggesting that neuromuscular impairments may also be induced by inflammatory signals.

Ample information suggests the involvement of AChE-R overexpression in neuromuscular failure (Table 46.1). Additionally, TgS transgenic mice overexpressing the AChE-S ''synaptic'' form of human AChE in spinal cord motor neurons displayed progressive neuromotor impairments that were associated with changes both in NMJ ultrastructure (Andres *et al.*, 1997) and in spinal cord synapses (Andres *et al.*, 1998). Among the delayed effects of anti-ChE intoxication are degeneration of synaptic folds, terminal nerve branching, enlargement of motor endplates, and disorganization of muscle fibers (Kawabuchi *et al.*, 1976; Laskowski *et al.*, 1975). The morphogenic effects of transgenic AChE were largely attributed to the deposition and accumulation of neuronal AChE in NMJs (Andres *et al.*, 1998).

IX. PREVENTION OF ANTICHOLINESTERASE TOXICITY: THE ''NEXT GENERATION''

A. Stoichiometric Bioscavengers

Current medical intervention in the case of acute exposure to anticholinesterase agents includes use of the muscarinic receptor antagonist atropine to block overstimulation, and oximes to reactivate the OP-modified AChE (Dunn and Sidell, 1989; Gunderson *et al.*, 1992; Millard and Broomfield, 1995; Schwarz *et al.*, 1995; Taylor, 1996). The reversible carbamate inhibitor, pyridostigmine bromide, is also used for prophylaxis. However, these conventional treatments have limited effectiveness and may have serious short- and long-term side effects (Dunn and Sidell, 1989; Friedman *et al.*, 1996; Maxwell *et al.*, 1993; Schwarz *et al.*, 1995). In fact, the routine treatments, while successfully decreasing anticholinesterase-induced lethality, rarely alleviate post-exposure toxicity and result in significant performance deficits and even permanent brain damage (Castro *et al.*, 1992; Dunn and Sidell, 1989; Leadbeater *et al.*, 1985; Maxwell *et al.*, 1993).

The shortcomings of the pharmacological approach to the problem prompted the development of an alternative approach that makes use of the OP-binding potential of soluble isoforms of AChE and the related enzyme BChE (Ashani, 2000; Saxena *et al.*, 1997a). Administration of exogenous cholinesterases can provide protection against nerve agents, as was demonstrated in a variety of rodent models (Allon *et al.*, 1998; Ashani *et al.*, 1991; Brandeis *et al.*, 1993; Genovese and Doctor, 1995; Maxwell *et al.*, 1993) and in primates (Maxwell *et al.*, 1992; Raveh *et al.*, 1997). The considerable success with plasma-purified butyrylcholinesterase (BChE) as an OP bioscavenger (Ashani, 2000; Doctor and Saxena, 2005) brings to the foreground, nonetheless, the question of the practicality of this therapeutic approach as it depends on the availability of large amounts of these human enzymes, which are required in stoichiometric rather than catalytic quantities. Indeed the 1:1 stoichiometry necessary for OP bioscavenging by ChEs, stemming from the virtual irreversibility of the interaction of the enzymes with the inhibitors, is one of the major limitations of this approach. Co-administration of oximes to enhance regeneration of the bioscavengers is only partially effective (and not effective at all against some nerve agents such as tabun and soman) and the chemistry involved in the process results in highly reactive and toxic phosphyloximes (Caranto *et al.*, 1994; Herkenhoff *et al.*, 2004).

B. Catalytic Bioscavengers

An ideal bioscavenger should be broad-acting, avoid aging, and have sufficient reactivation kinetics, i.e. it should be catalytically active. Several enzymes from diverse organisms [ranging from bacteria (Benning *et al.*, 1994) through invertebrates (Hartleib and Ruterjans, 2001) to vertebrates (Harel *et al.*, 2004)] are known to hydrolyze anti-ChE compounds and despite their genetic and structural diversity are lumped together as OP hydrolases or as phosphotriesterases. Their utility as catalytic bioscavengers of nerve agents and pesticides did not go unnoticed (Masson *et al.*, 1998; Sogorb *et al.*, 2004). The most broadly active members of this artificial grouping are the enzymes from *Pseudomonas diminuta* and *Flavobacterium* sp. (Masson *et al.*, 1998), and their study yielded valuable structural and functional insights (Benning *et al.*, 1994; Gopal *et al.*, 2000; Grimsley *et al.*, 2005), but their utility for treating humans is questionable because of their bacterial origin. On the other hand, mammals have several serum enzymes that reveal low, but significant, hydrolyzing activity toward OPs. These include not only paraoxonase but also members of the α/β fold hydrolase family, particularly BChE and carboxylesterase (CarbE; Li *et al.*, 2005).

Of the three members of the paraoxonase (PON) family, the most studied and hence best known is PON1 (Van Himbergen *et al.*, 2006). The genes encoding for the various PONs are >60% identical and all three are mapped to nearby loci on the long arm of chromosome 7 (Primo-Parmo

TABLE 46.1. AChE-R associated pathologies

Pathology	Cell/animal model	AChE-R involvement/ suggested role	References
CNS			
Alzheimer's disease	*In vitro* SH-SY5Y cells APPsw/AChE-R mice	Suppresses amyloid-beta fibrils formation and toxicity (neuroprotective)	Berson *et al.* (2008)
Alzheimer's disease	Human	Reduced in Alzheimer's brains and CSF. Elevated levels following tacrine and rivastigmine treatments are correlated to improved cognition	Darreh-Shori *et al.* (2004)
Parkinsonism	AChE-R mice	Attenuates disease progression following MPTP exposure (neuroprotective)	Ben-Shaul *et al.* (2006)
Photoreceptor damage	Albino rats	Overexpressed and involved in light-induced photoreceptor damage	Kehat *et al.* (2007)
Anxiety	Human	Inversely correlated with trait anxiety	Sklan *et al.* (2004)
Blood–brain barrier (BBB) disruption	Human	Elevated levels in CSF associated with BBB impairments	Tomkins *et al.* (2001)
PTSD	Mice	Key molecule, elevated in the Ca^{2+}-dependent feedback response to cholinergic insult	Kaufer *et al.* (1998) Zimmerman and Soreq (2006)
Synaptic plasticity (stress associated behaviors)	Mice	Interacts with RACK1 and PKCβ2 and promotes contextual fear, fear-induced conflict behavior, and PKC-augmented LTP in CA1 region	Nijholt *et al.* (2004) Birikh *et al.* (2003)
Neuronal hypersensitivity	PC12 cells Primary cerebellar mouse neurons	AChE-R translocation to neurites under stress modulates hypersensitivity to both anticholinesterases and atropine	Meshorer *et al.* (2002)

Closed head injury	Traumatized mice	Overexpressed in somatosensory cortex following injury. CA3 hippocampal neuron death	Shohami *et al.* (2000)
Stress-related neurodegeneration	AChE-R mice	Protects the hippocampus from stress-related morphologies (neuroprotective)	Sternfeld *et al.* (2000)
Glioblastoma	Human U87MG glioblastoma cells	PKCε-mediated cell proliferation	Perry *et al.* (2004)
Periphery			
Myasthenia gravis (MG)	EAMG rats Human patients	Overexpressed and involved in muscle malfunctioning and disease progression	Brenner *et al.* (2003); Argov *et al*., (2007)
Myopathies	AChE-S mice; OP-treated mice	Promote excessive neurite outgrowth and disorganized muscle fibers	Lev-Lehman *et al.* (2000)
MG-related thymic hyperplasia	Human AChE-R mice	Interferes with thymic differentiation mechanisms toward positive selection of CD4(+)CD8(+) cells	Gilboa-Geffen *et al.* (2007)
Thrombocytopenia	AChE-R mice human CD34+ cells	Promotes thrombopoietic recovery by elevating thrombopoietin levels and platelet counts.	Pick *et al.* (2006)
Impaired sperm quality	AChE-R mice; Human patients with impaired sperm qualities	Interacts with RACK1 and enolase-α and affects both sperm differentiation and motility	Mor *et al.* (2008) Mor *et al.* (2001)

et al., 1996), and, interestingly, only 5.5 Mb away from the *AChE* locus (Sklan *et al.*, 2004). Of the three, PON1 and PON3 are serum enzymes associated with high-density lipoprotein (HDL) (Mackness *et al.*, 1998a; Reddy *et al.*, 2001), whereas PON2 is expressed in many tissues (Mochizuki *et al.*, 1998). The three PONs can hydrolyze a variety of esters and lactones (Jakubowski, 2000), but despite their name, weak OP hydrolyzing activity is associated only with PON1 (Aharoni *et al.*, 2004; Harel *et al.*, 2004). Although the precise physiological roles of PONs remain elusive, epidemio-genomic studies (e.g. Carlson *et al.*, 2006), *in vitro* biochemical experiments (Rosenblat *et al.*, 2006), and *in vivo* experiments with knockout mice (Shih *et al.*, 1998, 2000) build a compelling case for the involvement of at least PON1 in protection from atherosclerosis (Lusis, 2000; Mackness *et al.*, 1998b). At the same time, similar lines of evidence point to a much broader role in protection, especially neuroprotection. PON1, true to its name, is an OP hydrolase, but its hydrolytic capacity is quite promiscuous (La Du *et al.*, 1999). Levels of serum PON activity, on the one hand, correlate well with polymorphisms in the PON1 locus and, on the other hand, correlate with sensitivity to anticholinesterase pesticides (Costa *et al.*, 2003; Furlong *et al.*, 2005, 2006, 2000). Revealingly similar correlation between the PON1 status and susceptibility for disease exists with the incidence of several neurodegenerative diseases such as Alzheimer's disease (Dantoine *et al.*, 2002; Erlich *et al.*, 2006; Janka *et al.*, 2002; Pola *et al.*, 2005), Parkinson's disease (Akhmedova *et al.*, 1999; Benmoyal-Segal *et al.*, 2005; Kondo and Yamamoto, 1998; Taylor *et al.*, 2000), psychiatric disorders (e.g. anxiety), and neurodevelopmental disorders, such as autism (Berkowitz *et al.*, 2004; D'Amelio *et al.*, 2005; Pasca *et al.*, 2006; Serajee *et al.*, 2004). The relevance of AChE (and related proteins) and of AChE inhibitors to these pathologies is well known for some and suspected for others (Birikh *et al.*, 2003; De Jaco *et al.*, 2006; Greenfield and Vaux, 2002; Nijholt *et al.*, 2004; Perry *et al.*, 2001; Toiber and Soreq, 2005). The most compelling evidence for the potential role of PON1 as xenobiotic scavenger comes from the studies conducted with PON1 knockout mice (W.F. Li *et al.*, 2000; Shih *et al.*, 1998).

Based on biochemical data (Aharoni *et al.*, 2004; Josse *et al.*, 1999a, b, c, 2001) but mainly on their 2.2 Å-resolution crystal structure of a recombinant PON1 variant (Harel *et al.*, 2004), Tawfik and co-workers recently offered a model for the architecture and function of the lactonase active site(s) of the PON enzymes (Khersonsky and Tawfik, 2006; Rosenblat *et al.*, 2006). According to the crystal structure (Harel *et al.*, 2004), PON is a six-bladed β-propeller, with two calcium ions located in the central tunnel – the structural Ca^{2+} is buried while the catalytic Ca^{2+} was solvent exposed. Two His residues, the so-called His^{115}-His^{134} dyad, mediate the lactonase (and esterase) activity of PON enzymes: the former acts as general base to activate a water molecule attacking the carbonyl oxygen of the substrate, the latter is a proton relay and the calcium is stabilizing the negatively charged intermediate (Khersonsky and Tawfik, 2006).

While the His dyad model is consistent with other data and nicely explains both lactonase activity and consequently PON1's anti-atherosclerotic function (Rosenblat *et al.*, 2006), it fails to describe the phosphotriesterase activity of the enzyme. Nonetheless, molecular evolution experiments from the Tawfik laboratory (Aharoni *et al.*, 2004), together with site-directed mutagenesis by that group and others (Khersonsky and Tawfik, 2006; Yeung *et al.*, 2004, 2005), indicate that while the lactonase and OP hydrolase active sites are partially overlapping, substrates are oriented differently so as to face different chemically active residues. Several mutations specifically increase the OP hydrolase activity. For example, H134Q increases it three to six-fold relative to WT (Harel *et al.*, 2004; Khersonsky and Tawfik, 2006), the same mutation reduces the lactonase activity to 11% (Khersonsky and Tawfik, 2006) and two other mutations, H134W and H134F, abolish both activities (Yeung *et al.*, 2004). Even more dramatic is the >40-fold increase compared to WT in the OP hydrolysis activity of either V346A or L69V obtained through *in vitro* evolution of the gene (Aharoni *et al.*, 2004). Further work is obviously needed to develop PON1 into a more efficient OP hydrolase.

It is noteworthy that the two enzymes that thus far were shown to provide the best protection, AChE and BChE, belong to the α/β fold hydrolase family. These bind OP anticholinesterases very efficiently but the phosphorylated enzymes fail to reactivate as was described above. However, certain mutants of BChE were shown to reactivate much less slowly, effectively making them OP hydrolases (Broomfield *et al.*, 1999; Lockridge *et al.*, 1997; Millard *et al.*, 1995, 1998). Unfortunately, the process is still very inefficient, especially with the soman-inhibited enzyme, which is rapidly undergoing aging. Mutations that reduce the rate of the dealkylation aging process were reported in both BChE (Millard *et al.*, 1998) and AChE (Maxwell *et al.*, 1999). Although significant improvements were achieved, they are still not sufficient. In this context it is interesting to note that murine BChE, but not its human counterpart, can spontaneously reactivate (Kaliste-Korhonen *et al.*, 1996; Li *et al.*, 2005). Carboxylesterase, CarbE, is another member of the same family, with broader catalytic activities, and sensitive to OPs. CarbE can self-activate, and it is speculated that a naturally occurring His residue within the sequence WI**H**GGGL plays a role in this process. The corresponding sequence of BChE (and AChE) is WI**Y**GGGF. One of the OP-hydrolase enhancing mutations, G117H of BChE, is in the same region (WIYGG**H**F). But, unlike PON1 and the ChE enzymes, CarbE *is not* normally found in human serum (Li *et al.*, 2005). The OP-hydrolyzing activities associated with native CarbEs, murine BChE, and recombinant human BChE raise the option of evolving these enzymes into more efficient phosphortriesterases.

C. Production Systems for OP Bioscavengers

Stoichiometric or catalytic human enzymes intended for use as bioscavengers have to be produced in a eukaryotic system. This is demonstrated by the difficulties of producing human PONs in *Escherichia coli* (Aharoni *et al.*, 2004) which may lead to unfortunate artifacts (see Corrigendum for Harel *et al.*, 2004). Of the candidate bioscavengers, human BChE is the most explored. Several strategies for production of BChE have recently been evaluated, including purification from outdated blood-banked human plasma (Doctor and Saxena, 2005; Grunwald *et al.*, 1997; Lenz *et al.*, 2005) and milk of transgenic goats (Cerasoli *et al.*, 2005). BChE purification from serum (Grunwald *et al.*, 1997) is supply-limited, extremely costly, and carries the risk of human-pathogen contamination in the final product. Similarly, production of recombinant cholinesterases in mammalian cell cultures (e.g. Kronman *et al.*, 1992; Velan *et al.*, 1991) is also confronted with limited scalability, high costs, and risk of pathogen contamination. For AChE-R, mammalian-based production systems seem less promising for large-scale production because of the natural low levels and relative instability of the protein and its cognate mRNA in such systems (Chan *et al.*, 1998; Cohen *et al.*, 2003). Recent reports (Cerasoli *et al.*, 2005) describe the use of transgenic goats expressing human BChE in their milk. The limitations of this technique include low efficiency, high cost, and current lack of a regulatory framework for the production of pharmaceuticals in lower mammalian species (Baldassarre *et al.*, 2004). Additionally, transgenic animals must be consistently maintained, and production and purification should occur continuously.

In the 16 years since the first tentative report of expression of pharmaceutically relevant human proteins in plants (albumin; Sijmons *et al.*, 1990) to the recent USDA approval of the first plant-derived vaccine (Vermij, 2006), the use of plants as a means to produce protein pharmaceuticals (so called ‘‘molecular pharming’’) is slowly coming of age with major scientific strides enabling this novel technology to challenge the conventional fermentation-based technologies. As an alternative to other available technologies for the production of recombinant proteins, transgenic plants and cultured cells thereof offer several unique advantages such as low costs of production and scale-up (and equivalent costs for purification) as well as biosafety (Fischer and Emans, 2000; Mason *et al.*, 2002).

Transgenic plants have been shown by us to be capable of producing AChE functionally equivalent to other sources (Evron *et al.*, 2007a; Fletcher *et al.*, 2004; Geyer *et al.*, 2005, 2007; Mor and Soreq, 2004; Mor *et al.*, 2001b). Plant-produced bioscavengers have key advantages including equivalent quality and improved safety of the product (plants do not contain human pathogens or agents such as prions) as well as significant savings on production costs. We conservatively estimate costs of raw materials containing the target protein to be $20/g of target protein, with purification and regulatory costs which are comparable to other production systems used. Of major importance to pharmacoeconomics, however, is that the increased production of more plant material is scalable by simply planting more seed, and does not require a ‘‘before the market’’ capital investment decision on construction of fermentation facilities. This is particularly relevant for some products such as bioscavengers for which a strategic reserve must be created with the capacity to scale up production if/when an emergency occurs; in the plant-production scenario, advanced research can create the seed supply which can be processed as needed for a drug supply and replenished as needed by simply growing more of the crop. But, the single most important aspect of plant-derived enzyme is the scalable expansion of production that will be suitable for establishment of an industrial scale supply.

D. AChE-R_{ER} Amelioration of Chronic OP Toxicity Effects: Interference with AChE Gene Expression

The long-term effects of sublethal exposure to OPs are muscle fatigue and cognitive decline, including cardiac failure and memory impairments (Rosenstock *et al.*, 1991). Recently, an association was reported between exposure to sublethal doses of sarin and anatomical brain damage, including reduced white matter volume and increased lateral ventricle volumes (Heaton *et al.*, 2007). In a seminal series of experiments recently reported by our groups we have tested the effects of treating mice with plant-derived AChE-R in conjecture with their exposure to OPs (Evron *et al.*, 2007a). Interestingly, by 10 days post-exposure, AChE-R prophylaxis ameliorated the chronic effects of OP toxicity by mitigating the long-term up-regulation of AChE gene expression: it mitigated plasma murine AChE-R levels as well as the NMJ dismorphology. However, in addition to its capacity to restore the cholinergic balance immediately after the acute intoxication, prolonged overproduction of AChE-R associates with overproduction of pro-inflammatory cytokines (Grisaru *et al.*, 2006), behavioral impairments (Birikh *et al.*, 2003), declarative memory loss (Farchi *et al.*, 2007b; Nijholt *et al.*, 2004), muscle malfunctioning (Brenner *et al.*, 2003), and excessive myelopoiesis (Gilboa-Geffen *et al.*, 2007; Pick *et al.*, 2006). Pretreatment with the enzyme would likely cause a transient elevation of inflammation markers (Grisaru *et al.*, 2006). Nevertheless, the relatively rapid clearance of the plant-derived AChE-R_{ER}, which makes it transient, would limit the duration of such effects. Moreover, interference with the overproduction of endogenous AChE-R in the circulation should further limit the duration of such symptoms, avoiding much of the delayed post-poisoning phenotype which is due to exposure-induced AChE-R accumulation. These findings highlight the advantages of plant-produced AChE-R_{ER} for both short- and long-term protection.

By utilizing AChE-R, a known positive modulator of inflammation, we have demonstrated a means for counteracting the immunosuppressive actions of nicotinic AChR stimulation. AChE-R has been shown to induce a pro-inflammatory cytokine response as well as an enhanced cellular response. We demonstrated that the effects of OP-induced immunosupression in skeletal muscle are reversed following treatment with AChE-R. Thus in AChE-R we have produced a therapeutic protein that is capable of preventing both the acute presentation and chronic dysmorphology and immunosuppression of OP toxicity.

The result of the inherent comparison of AChE and BChE that was completed in our laboratory revealed two very adept OP bioscavengers. The major difference noted in this study was an ineffectiveness of oxime-mediated reactivation of BChE relative to the accelerated rates seen with AChE (Geyer, Cerasoli, Lenz, and Mor, unpublished results). In the case of both enzymes, by utilizing purification protocols that were only mildly adapted from those used to purify serum BChE or recombinant ChEs we can assume that any associated purification costs will be similar to those incurred in other systems. Before this project is ready to transition into a clinical study, a further refinement of the PEGylation and other modifications that have been shown to enhance the circulatory profile of these plant-derived ChEs must be undertaken.

E. Selective RNA-Targeted Suppression of AChE Gene Expression

That AChE-R overexpression leads to muscle weakening (e.g. in myasthenic animals; Brenner *et al.*, 2003) tentatively attributed these symptoms to AChE-R accumulation. The effects of excess AChE-R in neuromuscular pathologies could be alleviated by small molecule inhibitors, but their effects were short-lasting. This could be due to the failure of the small molecule inhibitors to distinguish between the different AChE variants. Thus, indiscriminate inhibition of both AChE-S and AChE-R would induce general increases in ACh and subsequent feedback overproduction of yet more AChE-R, exacerbating muscle weakness. Supporting this notion, the effect of such small molecule inhibitors to improve muscle functioning in human MG patients has also been known as short-lasting, to the extent that patients typically require oral drug administration every 4–6 h, and up to every 3 h in more refractory cases (Drachman, 1994; Ropper and Brown, 2005). Antisense oligonucleotide suppression of nascent AChE-R mRNA transcripts emerged as an effective means for challenging the hypothesis that AChE-R was causally involved with these symptoms, as well as a promising therapeutic alternative. Designated AS3 (Galyam *et al.*, 2001; Grifman and Soreq, 1997; Grisaru *et al.*, 1999b), EN101 (Dori *et al.*, 2005), or Monarsen (Argov *et al.*, 2007; Kehat *et al.*, 2007), the AChE mRNA-targeted agent is a 20 residue long antisense molecule, 2′-oxymethylated at its three 3′-terminal positions. It is targeted at exon 2 of AChE mRNA, which is common to the different AChE mRNA splice variants (Meshorer and Soreq, 2006; Soreq and Seidman, 2001). Mouse, rat, and human EN101/Monarsen are each complementary to the corresponding exon 2 sequence in AChE mRNA. Nevertheless, the nascent, relatively unstable AChE-R transcripts (Chan *et al.*, 1998) demonstrated particular sensitivity to the antisense treatment compared to AChE-S mRNA. This was the case in cultured primary brain cells (Meshorer *et al.*, 2002), live mice (Birikh *et al.*, 2003; Cohen *et al.*, 2002; Nijholt *et al.*, 2004), and human-originated cell lines (Grisaru *et al.*, 2001; Perry *et al.*, 2004).

In muscle, AChE's catalytic activity was increased 2 weeks following repeated DFP exposure for 4 consecutive days. This increase reflected the overexpressed AChE-R and could be significantly reduced by systemic antisense treatment. EN101/Monarsen treatment brought down AChE's catalytic activity to the range of control animals (Lev-Lehman *et al.*, 2000). Importantly, this treatment further prevented the increase in NMJ endplate density, supporting the notion that these plastic changes were also attributed to AChE-R. The muscle weakness characteristic of AChE-R excess resembles the reported weakness syndrome that follows continuous or repeated exposure to agricultural anti-AChE pesticides, such as the OP paraoxon (Ray and Richards, 2001) or warfare agents such as those associated with the Gulf War Syndrome (Haley *et al.*, 1999). Thus, excess AChE-R may be pivotal for rapid regaining of homeostasis following OP exposure, but its long-term accumulation entails multiple delayed damages.

The success of EN101/Monarsen treatment in animal models led recently to clinical trials in human myasthenic patients, which are simultaneously run in Israel and the UK. EN101/Monarsen is provided at a daily single orally delivered dose followed by measurable improvement in muscle functioning (Argov *et al.*, 2007). The reported effect lasts over 24 h, with a 100-fold lower required molar dose than that of pyridostigmine.

F. RNA-Targeted Suppression vs Small Molecule AChE Inhibitors

Small molecule AChE inhibitors that are currently used in therapy are unable to distinguish between the different AChE variants, since the different variants all harbor identical active and peripheral anionic sites. In principle, EN101/Monarsen is also designed to bind a common sequence of all of the AChE mRNA variants; however, it was experimentally demonstrated that the nascent transcript of AChE-R is more sensitive to EN101/Monarsen suppression (Grisaru *et al.*, 2001). EN101/Monarsen suppressed AChE-R in EAMG rat muscles as well as in monkey spinal cord neurons, leaving AChE-S almost unaffected (Brenner *et al.*, 2003; Evron *et al.*, 2005). Moreover, anti-AChEs induce a feedback response and up-regulation of the AChE-R variant, suggesting that they would actually exacerbate

AChE-R overexpression in myasthenic muscles, and perhaps explaining their short-lasting effect. In contrast, EN101/Monarsen should not activate this feedback loop, providing yet another added value to its use.

Based on the above considerations, using EN101/Monarsen to enhance NMJ functioning may also be relevant for gaining effective recovery from neuromuscular blockade (NMB), used in the clinic to achieve surgical relaxation or facilitate mechanical ventilation in critically ill patients (Bom *et al.*, 2007). The majority of neuromuscular blocking agents (NBAs) in the clinical practice are competitive antagonists of the post-synaptic nAChR. These mimic the structure of ACh and thus operate as blockers of the corresponding AChR. After terminating the infusion of an NBA, a large portion of the post-synaptic AChR remains bound to the NBA, hence being unavailable for neuromuscular transmission for a long period of time. This results in residual NMB, which may be seen in over 40% of patients following general anesthesia (Debaene *et al.*, 2003). Recovery from NMB is achieved when ACh quanta levels at the synaptic cleft overcome the blocking effect of the NBA. EN101/Monarsen may possibly be used for reversal of NMB; due to its prolonged effect, it may also prevent residual NMB in anesthetized and paralyzed patients. This could be an advantage over current AChE inhibitors in clinical use such as neostigmine or edrophonium, which have relatively short-lived action that can produce recurrence of NMB with hazardous effects on respiration. EN101/Monarsen could potentially become a ''cleaner'' drug with precise effects.

G. Modified Cytokine Expression under RNA-Targeted Suppression of AChE-R

In EAMG animals and MG patients, EN101/Monarsen treatment promoted an improved clinical status (and improved survival of EAMG rats). In Cynomolgus monkeys, systemic EN101/Monarsen administration (either oral or intravenous) caused a reduction in pro-inflammatory cytokines within spinal cord interneurons (Brenner *et al.*, 2003; Euron *et al.*, 2005). These neurons are known to carry the α7 nicotinic ACh receptor (Hellstrom-Lindahl *et al.*, 1998), which in macrophages controls the levels of neuronal pro-inflammatory cytokines such as IL-1β and IL-6 (Wang *et al.*, 2003). Since oligonucleotides are usually unable to cross the BBB (Jaeger and Banks, 2004), it has been considered that the observed anti-inflammatory effects were initiated in the periphery (either in the digestive tract or in the circulation). Importantly, cumulative data show peripheral transduction of altered inflammatory cytokines also beyond the BBB. For example, induction of inflammation by systemic administration of LPS was shown to up-regulate pro-inflammatory cytokines, such as IL-1β within the rodent brain without LPS penetration of the BBB (Pitossi *et al.*, 1997; Quan *et al.*, 1994; Turrin *et al.*, 2001). Furthermore, systemic administration of LPS or IL-1β regulates CNS neuronal function by stimulating the vagal sensory pathways (Ek *et al.*, 1998). Compatible with this hypothesis, systemic EN101/Monarsen suppression of AChE activity in plasma (as was shown in the plasma of treated monkeys) can elevate ACh levels in the periphery, which can reduce the levels of peripheral pro-inflammatory cytokines. This would subsequently reduce the cytokine effects on brain neurons, suppressing the reciprocal production of yet more cytokines in these neurons. This self-propagating pathway may explain the increase of pro-inflammatory cytokines under cholinergic imbalances (e.g. exposure to OPs; Svensson *et al.*, 2001) and points at the neuronal inflammatory response as a body ''self-defense'' machinery protecting it from excessive cholinergic load.

X. CONCLUDING REMARKS AND FUTURE DIRECTION

Throughout this chapter we have explored current thinking and experimental data in their support of the principal roles that cholinesterases play in maintaining synaptic and systemic cholinergic homeostasis. This view puts the various protein members of the cholinesterase family, especially the readthrough variant of AChE, at a crucial and therefore vulnerable intersection between the central and peripheral nervous systems and other body networks such as the hematopoietic and immune systems. We presented an intricate balancing act consisting of transcriptional, post-transcriptional, and post-translational regulation aiming at mitigating the short- and long-term consequences of exposure to chemical stressors that interfere with cholinergic neurotransmission and have system-wide repercussions. Through gain and loss of function experimental approaches and the use of various *in vivo*, *ex vivo* and *in vitro* systems, a more coherent picture is beginning to emerge, a picture that is also suggestive of novel therapeutic strategies relying on enzyme supplementation in combination with RNAi agents to restore a healthy cholinergic status by carefully manipulating AChE levels to ameliorate the chronic effects of OP toxicity.

Acknowledgments

This work was funded in part by a DARPA research contract #N66001-01-C-8015 (to TSM & HS) and by the National Institute of Health CounterACT Program through the National Institute of Neurological Disorders and Stroke under the U-54-NSO58183-01 award – a consortium grant awarded to USAMRICD and contracted to TSM under the research cooperative agreement number W81XWH-07-2-0023. CHAPTER 47

Chemical Warfare Agents and Risks to Animal Health

TINA WISMER

I. INTRODUCTION

Animals are susceptible to all four basic types of military agents: choking (chlorine, phosgene), blister (mustard, lewisite, phosgene oxime), blood (cyanide, hydrogen cyanide), and nerve agents (tabun, sarin, soman, VX). They can also be affected by incapacitating agent BZ (3-quinuclidinyl benzylate), riot control agents, ricin, and abrin. Since chemical warfare agents can be deployed by a variety of inexact methods (bomb, spray tanks, rockets, missiles, land mines, and artillery projectiles), domestic and wild animals living in proximity to human populations will be affected (USACHPPM, 2001a). Americans own 62 million dogs and 68 million cats and more than half of American households own at least one pet (Wise *et al.*, 2003). Due to the expansion of suburbia, human–wildlife interactions are also increasing (Daszak *et al.*, 2004). Livestock are very important potential targets of attack as they have secondary ramifications for human health and disruption of the food chain.

The CDC Strategic Planning Working Group, as part of their preparedness plan for possible terrorist attacks using biological or chemical weapons, has called for ''prompt diagnosis of unusual or suspicious health problems in animals'' (Anonymous, 2000a). The CDC recommended establishing ''criteria for investigation and evaluation of suspicious clusters of human and animal disease or injury and triggers for notifying law enforcement of suspected acts of chemical terrorism''. With many of the military agents, there are few initial indicators of a chemical attack. It has been proposed that animals could serve as sentinels for chemical terrorism. These animals would be similar to the canaries used by coal miners in the UK and USA to provide early warning of deadly mine gases (Burrell and Seibert, 1914).

Throughout history, it has been noted that during chemical warfare attacks, animals may also be affected. A newspaper article from World War I gives details of the effects on animals during an unspecified type of gas attack (Anonymous, 1918):

> Results show that horses suffer much from the noxious fumes, and are subsequently thrown into a state of nervous terror on again scenting them. Mules are more inclined to stand their ground, and appear as if trying not to breathe … cats quickly scent the gas, and run about howling. Guinea pigs are first to succumb … Rats and mice emerge from their holds, and are found dead in quantities, which as the soldiers say, is the only advantage of a gas attack by the enemy.

The same account discusses how much these animals meant to the soldiers as they even managed to fashion gas masks for several of these species to protect them during gas attacks (Anonymous, 1918). The soldiers believed that different species of animals may have been more sensitive to certain types of gas attacks than humans:

> … Poultry of all kinds are useful for giving warning, ducks and fowl becoming agitated 10 min or so before the oncoming gas clouds. Many kinds of wild birds are greatly excited, and the usually unruffled owl becomes, as it were, half demented. Only the sparrow seems to disregard the poisonous vapor, and sparrows chirp on where horses are asphyxiated, and bees, butterflies, caterpillars, ants and beetles die off in great numbers. The gas at once kills snakes, and earthworms are found dead in their holes many inches below the ground.

Not much has changed in using animals for sentinels over the years. Crates of rabbits were placed on the cargo deck of ships transporting nerve gases during World War II and crewmen were instructed to watch for sudden animal deaths that could signal a gas release (Brankowitz, 1987). Even today with the development of sophisticated biosensor technology the use of animals as sentinels continues to be explored (Paddle, 1996). After the Aum Shinrikyo sarin attack in Tokyo, Japanese policemen used canaries to serve as a warning of poison gas release (Biema, 1995). The USA also planned to use chickens during the initial invasion of Iraq in 2003 (Ember, 2003). The chickens were to be used as early warnings of nerve gas agents. It was thought that if caged chickens remained alive following a warning alert, it would be safe for soldiers to remove their gas masks. Using live animals would help avoid possible false alarms with ion-mobility spectrometry biosensors. The plan was never implemented as there were no controlled studies showing that chickens were likely to show effects of nerve agents before humans (Garamone, 2003). The EPA is now

considering evidence regarding the use of animals as sentinels for chemical threats (EPA, 2006).

Some of the important chemical warfare agents that may pose risks to animal health are described below. For the information on their mechanism of action, readers are referred to Section II of this book.

II. CHEMICAL WARFARE AGENTS

A. Chlorine Gas

1. Clinical Signs

Chlorine gas is very irritating, or in concentrated amounts, even corrosive. Eyes, skin, nose, throat, and mucous membranes can all be affected. When inhaled or ingested, chlorine combines with tissue water and forms hydrochloric acid, and reactive oxygen species. Oxidation of respiratory epithelium leads to alveolar capillary congestion and accumulation of edematous fluid (Noe, 1963). Death is due to cardiac arrest from hypoxemia secondary to atelectasis, emphysema, and membrane formation (Decker, 1988).

Ocular exposure can result in severe pain and blindness. Erythema and pain are also common after dermal exposure. Both liquid and high concentrations of chlorine gas can cause dermal burns (Raffle *et al.*, 1994). Inhaled chlorine gas causes rhinorrhea, ataxia, syncope, muscle weakness, dyspnea, tachypnea, bronchospasm, and acute lung injury. Inhalation of high concentrations can cause laryngospasm, tachycardia, and hypoxia (Noe, 1963). Cardiovascular collapse and respiratory arrest may develop and lead to rapid death.

Chlorine is teratogenic. One hundred ppm when given to pregnant rats caused both biochemical and metabolic effects in the newborns, while 565 mg/kg given prior to mating was embryotoxic (RTECS, 2008). Carcinogenicity can be seen with chronic exposures (Morris *et al.*, 1992; RTECS, 2008).

2. Kinetics

Respiratory, dermal, and ocular irritation starts immediately. The speed of onset and severity of signs is directly related to the concentration (Bingham *et al.*, 2001). The water solubility of chlorine allows it to have a greater effect on the lower respiratory tract as a large percentage bypasses the upper airways. Acute lung injury peaks in 12 to 24 h. Death usually occurs within 48 h (Decker, 1988).

With mild exposures, signs disappear within 6 h, but can continue for more than 24 h with severe exposures. Exposure to moderate or severe concentrations can result in chronic respiratory dysfunction (Decker, 1988; Schwartz *et al.*, 1990). This can be career or life ending if the affected animal is an equine athlete or a working dog.

3. Decontamination and Treatment

Move animals into fresh air and onto higher ground. Monitor respiratory rates and oxygenation status (SpO_2). If coughing or dyspnea develops, provide supplemental oxygen and ventilation. Bronchodilators should be used to counteract bronchospasm (Guloglu *et al.*, 2002). Sedation and pain control may be needed so the animal can be handled safely.

Corticosteroid use is controversial. Animal models have shown positive results in hastening recovery from severe chlorine gas poisoning; however, administration to humans has not been shown to provide any significant change (Traub *et al.*, 2002). Wang *et al.* (2004) demonstrated that pigs exposed to chlorine gas responded better to a combination of aerosolized bronchodilators and corticosteroids (terbutaline, budesonide) than to either therapy alone. Sheep nebulized with 4% sodium bicarbonate had decreased mortality and improved oxygenation after inhalation of chlorine gas (Chisholm *et al.*, 1989).

For ocular exposures, eyes should be flushed with generous amounts of tepid 0.9% saline or tap water for at least 15 min. After flushing, fluorescein should be used to stain the eyes and check for corneal ulcers (Grant and Schuman, 1993). Bathing with dish soap and water will remove chlorine from the skin and fur/feathers.

Chlorine does not leave an environmental residue, so animals may be returned to affected pastures within hours to days (more quickly in warm environments) (Munro *et al.*, 1999). When entering the area contaminated with chlorine gas, rescuers should wear self-contained breathing apparatus (SCBA) and protective clothing (gloves, gowns, masks) until the gas dissipates. The risk for secondary contamination of rescuers is low. Chlorine gas does not bind to leather or fabrics.

4. Species Susceptibility

Chlorine gas is heavier than air and will settle in low areas. Pets and smaller livestock may be more at risk than humans due to their proximity to the ground. There are no controlled studies that show animals are more sensitive to chlorine gas or that they will develop signs sooner than humans.

B. Phosgene

1. Clinical Signs

Most animal exposures to phosgene are from inhalation, but there can also be dermal exposures to the liquefied material. The severity of pulmonary injury correlates with the concentration and length of exposure, and initial symptoms are not always a good indicator of prognosis (Diller, 1985; Bingham *et al.*, 2001). Due to low water solubility phosgene is able to penetrate deeply into the lungs where it irritates the lower respiratory tract (Franch and Hatch, 1986). When phosgene gas contacts water in the lungs, it forms hydrochloric acid causing cellular injury (Murdoch, 1993). Phosgene also causes protein and lipid denaturation and changes in membrane structure, leading to increased pulmonary vascular permeability (Borak and Diller, 2001). This fluid accumulation in the lung interstitium and alveolae results in gas diffusion abnormalities and pulmonary edema

(Diller, 1985; Ghio *et al.*, 1991). Pulmonary injury is exacerbated by elevated levels of leukotrienes and neutrophil chemotactic agents. The neutrophils release cytokines and other reactive mediators worsening pulmonary injury (Ghio *et al.*, 1991; Sciuto *et al.*, 1995). Localized emphysema and partial atelectasis occur. Death is from anoxia secondary to pulmonary edema (Borak and Diller, 2001; Proctor and Hughes, 2004).

Dyspnea, cough, cyanosis, and hemoptysis can progress to hypoxemia and hypoventilation (Borak and Diller, 2001). Animals may develop secondary organ damage from anoxia. Dogs experience bradycardia followed by tachycardia and progressive hypotension with severe phosgene poisoning (Patt *et al.*, 1946). With concentrations >200 ppm, phosgene can enter the blood and cause hemolysis and coagulopathies (Sciuto *et al.*, 2001). Direct contact with liquid phosgene can cause dermal burns (Proctor and Hughes, 2004). Ocular exposure to both liquid phosgene and highly concentrated phosgene gas can cause severe eye irritation and corneal opacification (Grant and Schumann, 1993; Proctor and Hughes, 2004).

Prognosis is directly related to the severity of pulmonary injury. Animals that survive the first 24 to 48 h still have a guarded prognosis. These animals are more susceptible to infectious agents as they have suppressed natural killer cell activity. Infections may become evident 3 to 5 days after exposure. Animals may develop chronic exercise intolerance and abnormal pulmonary function (Borak and Diller, 2001). Working dogs and equines may no longer be able to fulfill their functions.

2. Kinetics

Respiratory signs develop 2 to 6 h post-exposure in most patients, but can be delayed up to 15 h with exposures to lower concentrations (<3 ppm) (Borak and Diller, 2001). Concentrations of 3 to 5 ppm cause immediate conjunctivitis, rhinitis, pharyngitis, bronchitis, lacrimation, blepharospasm, and upper respiratory tract irritation. Extended (170 min) exposure was fatal (Diller 1985; Proctor and Hughes, 2004). Fifty ppm for 5 min or longer will cause pulmonary edema and rapid death (Borak and Diller, 2001; Chemstar, 1996; RTECS, 2008). If the animal survives, pulmonary edema begins to resolve in 2 to 3 days.

3. Decontamination and Treatment

Move animals to fresh air and higher ground. Bathe animals with soap and water and flush eyes for 15 min with tepid water or 0.9% saline. Animals should be monitored for 24 h for the development of pulmonary edema (Borak and Diller, 2001). If coughing or dyspneic, administer 100% oxygen. Animals may need to be intubated and ventilated. Animals can be nebulized with beta adrenergic agonists to combat bronchospasm. Patients with pulmonary edema should be managed the same as an ARDS (acute respiratory distress syndrome) patient (mechanical ventilation with oxygen and positive end-expiratory pressure).

Rabbits exposed to toxic levels of inhaled phosgene, did not develop noncardiogenic pulmonary edema if given intravenous aminophylline and subcutaneous terbutaline within 10 min of exposure (Kennedy *et al.*, 1989). Intertracheal *N*-acetylcysteine (Mucomyst®) administered to rabbits 45 to 60 min after inhalation of phosgene (1,500 ppm/min) decreased pulmonary edema, production of leukotrienes, and lipid peroxidation, and maintained normal glutathione levels as compared to rabbits exposed to phosgene only (Sciuto *et al.*, 1995). Rat and rabbit studies have shown that ibuprofen also protects against acute lung injury from phosgene (Guo *et al.*, 1990). Oxygen, sodium bicarbonate, and aerosolized surfactant have all been shown to be beneficial in dog experiments (Mautone *et al.*, 1985). Corticosteroids, prostaglandin E1, and atropine may be helpful in reducing phosgene-induced pulmonary edema (Chemstar, 1996). Intravenous fluids should be used for cardiovascular support, but monitor for overhydration. Colloids are preferred over crystalloids as they will remain in the vascular space for a longer period of time. Oxygen supplementation will resolve most of the arrhythmias.

Phosgene is nonpersistent in the environment. Moisture reduces air concentrations (Borak and Diller, 2001). The potential for secondary contamination of rescue personnel is low, but rescuers should wear proper protective clothing. Phosgene gas does not persist in fabric or leather.

4. Species Susceptibility

Phosgene is heavier than air and will settle close to the ground. This can affect species that are low to the ground or that are pastured in low-lying areas. There is no indication that animals are affected before or at lower levels than their human counterparts.

C. Mustard Gas

1. Clinical Signs

Mustard gas is a vesicant that is toxic by all routes of exposure (oral, inhaled, dermal, and ocular) (EPA, 1985b; Lewis, 2000; Pohanish, 2002; Sidell *et al.*, 1997). Mustard causes both localized and systemic cellular damage and tissues with high cell turnover are the most affected (NATO, 1973). Mustard gas can produce erythema, severe pruritus, blistering, ulceration, and necrosis of exposed skin (Borak and Sidell, 1992; Budavari, 2000; Dacre and Goldman, 1996; Pohanish, 2002). Skin lesions are most severe at warm and moist sites (genitalia, perineal regions, groin, skin folds, and axillae), due to the high number of sweat glands in these areas. Amounts as low as 0.02 mg of mustard will cause blisters (Smith *et al.*, 1997).

Ocular exposure can cause pain, lacrimation, corneal ulceration, swelling, blepharospasm, and blindness as the eyes are very sensitive to the effects of mustard gas (Borak and Sidell, 1992; Dacre and Goldman, 1996; Garigan, 1996; NATO, 1973). Pathognomonic signs of mustard gas poisoning include porcelain-white areas in the episcleral

tissues and formation of large, varicose veins (Grant and Schuman, 1993). Conjunctivitis and keratopathy can be seen chronically after exposure (Blodi, 1971).

Inhalation of small amounts of mustard gas produces nasal discharge, sneezing, epistaxis, and coughing within 12 to 24 h of exposure. Higher concentrations or longer exposures can cause pulmonary damage, hypoxia, and respiratory acidosis. Seizures may be seen with extremely acute, high doses (Sidell *et al.*, 1997).

Mustard gas is also a radiomimetic (Sidell *et al.*, 1997). It destroys precursor cells in the bone marrow leading to leukopenia, thrombocytopenia, pancytopenia, and anemia (Borak and Sidell, 1992; Dacre and Goldman, 1996). Infection can be seen secondary to bone marrow damage (Sidell *et al.*, 1997). Bone marrow aplasia and death can be seen in severe cases.

Mustard gas is a possible animal teratogen. Some rat studies show abnormalities of the musculoskeletal system in the offspring of rats orally dosed with mustard gas, but only at doses high enough to be toxic to the dams, while other rat and rabbit studies showed no correlation (Dacre and Goldman, 1996; RTECS, 2008). Injection of mustards both IV and IP into male mice caused inhibition of spermatogenesis, but full recovery was seen within 4 weeks (Dacre and Goldman, 1996). Mustard gas is both a human and animal carcinogen (NTP, 2005). It has been linked to carcinomas in the skin, limbs, lungs, thorax, and leukemia in rats and mice after inhalation and IV exposure (RTECS, 2008).

2. Kinetics

Both liquid and vaporized mustard have rapid skin penetration. The higher the dose, temperature and humidity, the quicker the absorption (NATO, 1973). Mustard is dermally absorbed through hair follicles and sweat glands within minutes. Cellular reactions begin within 1 to 2 min of contact of mustard to skin or mucous membranes, but clinical effects are delayed between 2 and 24 h (Grant and Schuman, 1993; Sidell *et al.*, 1997).

The skin initially pales and then becomes erythematous within a few hours of exposure (Requena *et al.*, 1988). Erythema, blisters, bulla, and small vesicles form over 2 to 24 h. The blisters can progress for several more days. Erythema resolves over 3 to 7 days, while ulcers take 6 to 8 weeks to heal (Garigan, 1996; Sidell *et al.*, 1997). Discoloration (brown or black hyperpigmentation) commonly occurs after resolution of the burns, especially in areas with thinner skin (Requena *et al.*, 1988).

Ocular absorption happens within minutes. With mild ocular exposures, conjunctivitis and lacrimation begin about 4 to 12 h after exposure. Moderate ocular exposures produce conjunctivitis, blepharospasm, lid inflammation, corneal damage, and eyelid edema about 3 to 6 h post-exposure. Severe ocular exposures will lead to marked swelling of lids, corneal ulceration, corneal opacification, severe pain, and miosis in 1 to 2 h (Requena *et al.*, 1988).

Inhalation produces respiratory signs (rhinorrhea, sneezing, epistaxis, and coughing) within 12 to 24 h of exposure. A severe exposure produces a productive cough, tachypnea, pulmonary edema (rare), and pulmonary hemorrhage within 2 to 4 h. Studies in dogs indicate that equilibrium between blood and tissues was achieved within 5 min after inhalation (IARC, 1975). Ingestion of small amounts can cause hypersalivation and vomiting within 24 h, while larger amounts can cause gastrointestinal bleeding (rare) and bloody diarrhea within 3 to 5 days.

Mustard preferentially accumulates in fatty tissue (in decreasing concentration: fat, skin with subcutaneous tissue, brain, kidney, muscle, liver, cerebrospinal fluid, spleen, and lung) (Somani and Babu, 1989). Excretion is through the urine in rabbits, mice, and rats (IARC, 1975). Mustard is excreted over 72 to 96 h after IV administration in rats and mice (Dacre and Goldman, 1996; Maisonneuve *et al.*, 1993). Complete blood count (CBC) changes are not evident for 3 to 5 days post-exposure. Leukopenia usually occurs at day 7 to 10 (Garigan, 1996).

3. Decontamination and Treatment

Animals should be moved into fresh air. Emesis is not recommended and activated charcoal administration after oral ingestion is controversial. Activated charcoal appears to have some beneficial effects if administered within 1 h of ingestion. Sodium thiosulfate (2% solution) given orally may help in cases with oral exposures (Borak and Sidell, 1992; Dacre and Goldman, 1996). Perforation and stricture formation can follow esophageal burns.

For ocular exposures, flush eyes with tepid water for at least 15 min. Follow with 2.5% sodium thiosulfate ophthalmic to help neutralize the mustard. The eyes need to be decontaminated quickly as mustard disappears from the eye very rapidly, and late flushing of the eye generally provides no benefit (Sidell *et al.*, 1997). Topical ophthalmic antibiotics and pain control should be used if corneal lesions are present (Sidell *et al.*, 1997). Corneal transplants may be considered for valuable animals (Blodi, 1971).

Animals need to be bathed with copious amounts of soap and water. If dermal decontamination is not implemented quickly, mustard will react with the skin and cannot be easily removed (Sidell *et al.*, 1997). Sodium thiosulfate (2.5% solution) can be used dermally to neutralize mustard exposures (Garigan, 1996). Animals may also be bathed with dilute (0.5%) hypochlorite solutions (Borak and Sidell, 1992). Monitor for dermal burns. Secondary infection is common. Topical silver sulfadiazine can be applied to all burns and an Elizabethan collar placed to decrease ingestion of the ointment and self trauma. Topically applied dexamethasone and diclofenac reduced inflammation in a mouse model when applied within 4 h (Dachir *et al.*, 2004). All equine and ovine patients should be inoculated with tetanus toxoid. Vaccination of other species should be determined on a case by case basis.

Monitor for respiratory irritation (coughing, dyspnea). If seen, monitor arterial blood gases, and pulse oximetry. Thoracic radiographs may be taken but there can be a lag time of up to 2 days before infiltrates are seen radiographically (Smith, 1999). Nebulization with 2.5% sodium thiosulfate or *N*-acetylcysteine may help neutralize the mustard gas. *N*-acetylcysteine may also be given intravenously as a potential mustard gas antagonist (Garigan, 1996). A loading dose of 140 mg/kg should be given, followed by 40 mg/kg every 4 h for a total of 17 doses (Garigan, 1996). Provide oxygen, ventilation, and inhaled beta agonists if needed. Dexamethasone, promethazine, vitamin E, and heparin have all shown protective effects against mustard gas poisoning in laboratory animals (Requena *et al.*, 1988; Vojvodic *et al.*, 1985).

Serial CBCs with platelets should be monitored for 2 weeks after exposure. Antibiotics should be given if leukopenia develops (Sidell *et al.*, 1997). Mustard can be detected in urine and body tissues for up to 1 week post-exposure using gas chromatography–mass spectrometry (Vycudilik, 1985). This can confirm diagnosis, but is not likely to be of value in the management of the patient.

Mustard is persistent in the environment. Mustard may remain in the environment for up to 1 week in temperate areas. It disappears more quickly in hot climates and in desert conditions; persistence is reduced to about 1 day. Since mustard binds to vegetation for days to weeks, grazing animals need to be kept away from these areas (USACHPPM, 2001b).

Rescue personnel must wear protective clothing, eye protection, and a respirator as the potential for secondary contamination is high (HSDB, 2008). Mustard gas will penetrate wood, leather, rubber, and paints.

4. Species Susceptibility

Animal model studies of skin exposure to nitrogen and sulfur mustard show that these agents cause more severe skin lesions in hairless animals and less in fur-covered species (Smith *et al.*, 1997). Dermal absorption of mustard varies greatly by species. Rats absorb about 75% of a dermal dose through their skin, while only 20% is absorbed through human skin (Hambrook *et al.*, 1992; Smith, 1999). The rat dermal LD_{50} is only 5 mg/kg while the mouse and human dermal LD_{50}s are 92 and 100 mg/kg, respectively (Lewis, 2000; RTECS, 2008). However, with oral dosing, humans appear to be much more susceptible (LD_{50} oral 0.7 mg/kg for humans, 17 mg/kg for rats). Due to these variable results, more studies are needed to determine if rats or mice would make good sentinel animals.

D. Lewisite

1. Clinical Signs

Lewisite is an arsenical compound that acts locally as a vesicant, but also causes systemic effects (HSDB, 2008; Sidell *et al.*, 1997). Lewisite directly affects enzyme systems, resulting in decreased ATP production. Lewisite also causes increased capillary permeability, leading to a significant loss of blood plasma into the extravascular space (''lewisite shock'') and hypotension (Sidell *et al.*, 1997). Lung capillaries are affected not only by inhalation but also by first pass through the lungs following dermal exposure. Pulmonary edema or ARDS can develop (Sidell *et al.*, 1997).

Signs can be seen when lewisite is contacted dermally, orally, ocularly, inhaled, or ingested. Dermal and respiratory exposures are seen most frequently. Lewisite causes dermal, ocular, and respiratory lesions similar to mustard gas. Lewisite is about ten times more volatile than mustard gas (Budavari, 2000).

Exposure to lewisite is very painful. Both the vapor and liquid lewisite can penetrate skin. Reddening of the skin is followed by tissue destruction (EPA, 1985a; Goldman and Dacre, 1989; Pohanish, 2002; Sidell *et al.*, 1997). Amounts as small as 0.5 ml may cause severe systemic effects and 2 ml may be lethal. Severe edema develops secondary to increased capillary permeability. Dermal burns are deeper than those seen with mustard gas and are quicker to appear (Goldman and Dacre, 1989; Sidell *et al.*, 1997).

Ocular exposure causes immediate pain, lacrimation, and blepharospasm. Without rapid decontamination, within 1 min, permanent blindness may occur (EPA, 1985a; Pohanish, 2002). In livestock this is a death sentence as they cannot survive on the range when blind. Droplets as small as 0.001 ml can cause corneal perforation and blindness (Sidell *et al.*, 1997).

Inhalation of vapor causes irritation to the nasal passages, rhinorrhea, and violent sneezing (HSDB, 2008). Coughing and hemoptysis commonly occur (HSDB, 2008; Sidell *et al.*, 1997). After inhalation, dogs developed necrotizing pseudomembranous laryngotracheobronchitis (Goldman and Dacre, 1989). Death can occur within 10 min after inhalation of high concentrations (EPA, 1985a).

Lewisite does not cause damage to the bone marrow or immunosuppression (Sidell *et al.*, 1997). Arrhythmias and renal dysfunction are due to hypovolemia from fluid loss. Lewisite was fetotoxic to rats and rabbits and is a suspected carcinogen (Goldman and Dacre, 1989; RTECS, 2008).

2. Kinetics

Immediate pain occurs upon inhalation, dermal, or ocular contact with lewisite. Skin penetration occurs within 3 to 5 min, especially following liquid exposures (Sidell *et al.*, 1997). The skin becomes red, then gray, within 15 to 30 min after exposure (EPA, 1985a; Goldman and Dacre, 1989; Pohanish, 2002; Sidell *et al.*, 1997). Severe blisters develop within 12 h. The blisters rupture about 48 h after occurrence, with large amounts of fluid seeping from the site. Healing is generally complete within 4 weeks (much faster than with sulfur mustard-induced lesions).

Lewisite has extensive tissue distribution (HSDB, 2008). The highest concentrations were found in the liver, lungs,

and kidneys in rabbits (greater than seven times blood concentration). Arsenic crosses the placenta and is excreted in the milk. Nursing animals may be at risk (Barlow and Sullivan, 1982). Elimination half-life of arsenic in rabbits is 55 to 75 h (HSDB, 2008).

3. Decontamination and Treatment

Remove animal from affected areas. If any coughing or respiratory distress, monitor blood gases and SpO_2. Provide oxygen and assisted ventilation as needed. Nebulized beta agonists and possibly corticosteroids can be used to treat bronchospasm. Monitor electrolytes and PCV as there can be fluid shifts out of the vasculature (Goldfrank *et al.*, 2002). Urine arsenic levels may be measured, but are not clinically useful due to the lag time before results are obtained. Watch for liver and kidney failure.

As lewisite is a vesicant, emesis is not recommended in those species that can vomit (dogs, cats, swine, and ferrets). Dilution with milk or water is recommended. Activated charcoal is not recommended as severe irritation/vesication of the esophagus or gastrointestinal tract is likely to occur. Endoscopy can be performed very carefully to determine the extent of injury. Esophageal perforation and/or stricture formation may occur.

Eyes should be flushed with copious amounts of tepid water for at least 15 min. If 5% BAL (dimercaprol, British Anti-Lewisite) ophthalmic ointment can be applied within 2 min this may prevent a significant reaction. Application up to 30 min after exposure will lessen the ocular reaction but will not prevent all damage (Goldfrank *et al.*, 2002).

Animals should be washed with water and dilute household bleach (5% sodium hypochlorite) as soon as possible. Application of a 5% BAL ointment within 15 min can be effective in diminishing the blistering effects of lewisite (Smith, 1999). Remove BAL ointment with soap and water after 5 min. Leaving the ointment on can cause stinging, itching, or urticaria. Burns should be managed with pain control, antibiotics, and debriding as needed.

A chelator should be given if there is dyspnea, pulmonary edema, or skin burns larger than palm size (Goldfrank *et al.*, 2002). BAL is the traditional arsenic chelator, but it has numerous side effects. The deep intramuscular injections are very painful and BAL can cause hypertension, tachycardia, and vomiting. 2,3-Dimercaptosuccinic acid (DMSA, Succimer®) can also be used to chelate arsenic (Graziano *et al.*, 1978). 2,3-Dimercapto-1-propanesulfonic acid (DMPS) is used in Europe and has been effective in protecting rabbits from the lethal effects of lewisite (Aposhian *et al.*, 1982).

Lewisite remains in the environment for about 24 h and it can react with water to form a solid arsenoxide that also has vesicant properties. Affected areas can be treated with strong alkalis to form less harmful substances. Rescue personnel need to wear protective clothing and masks as the risk for secondary contamination is high. Carcasses should be disposed of properly, either buried deeply (away from water supplies), rendered, or incinerated to insure safety of the food supply.

4. Species Susceptibility

Lewisite has the potential to cause skin lesions in any species but the risk is greatest in hairless animals such as pigs, and decreases in fur-covered species (Smith, 1997). Mice and rats appear to be almost twice as susceptible to dermal lewisite exposures than humans (LD_{50} equals 12, 15, and 30 mg/kg, respectively) (DeRosa *et al.*, 2002; RTECS, 2008; Sidell *et al.*, 1997). More studies are needed to determine if rodents would be good sentinel animals.

E. Phosgene Oxime

1. Clinical Signs

Phosgene oxime in both its liquid and vapor forms causes severe pain and local tissue destruction on contact with skin, eyes, and mucous membranes (Sidell *et al.*, 1997). Signs depend on its route of entry, as phosgene oxime exerts its greatest effects in the first capillary bed it encounters.

Dermal, ocular, and respiratory lesions are similar to those caused by mustard gas. Inhalation and oral absorption may cause respiratory tract irritation, dyspnea, and pulmonary edema. Dermal lesions are erythematous and extremely painful. With ocular exposure to phosgene oxime, very low concentrations can cause lacrimation, inflammation, and temporary blindness, while high concentrations can cause permanent corneal lesions and blindness (Sidell *et al.*, 1997; NATO, 1996; USACHPPM, 2001c). Death is generally due to respiratory arrest.

2. Kinetics

Complete absorption occurs in both dermal and inhalational exposures within seconds (Sidell *et al.*, 1997). Dermal lesions begin to form within seconds; grayish tissue damage may be seen within several minutes and within 1 h the area becomes edematous. Phosgene will spread in sweat and move to other nonexposed areas of the body (DeRosa *et al.*, 2002). Pulmonary edema can be seen on thoracic radiographs within 2 h of high-dose exposure, 4 to 6 h of moderate exposure, and approximately 8 to 24 h after low dose exposure (Sidell *et al.*, 1997). The skin turns brown and blistering occurs the next day. It takes about 3 weeks for desquamation, necrosis, crust formation, and purulent exudate to occur (NATO, 1996; Sidell *et al.*, 1997). Pain can last for several days and healing of dermal lesions can take from 1 month to over a year.

3. Decontamination and Treatment

Animals should be moved into fresh air. Emesis is not recommended due to the irritant and corrosive effects of phosgene oxime. Dilution with milk or water is recommended for oral ingestions. Activated charcoal is not recommended as the primary toxicity is a local corrosive

injury. Sedation and pain control (opioids) may be needed to allow safe decontamination.

Irrigate eyes with tepid water until pH returns to neutral and remains so for 30 min after irrigation is discontinued (Brodovsky *et al.*, 2000). Time until decontamination after ocular exposure is important since phosgene oxime is absorbed within seconds. Corneal ulcers should be treated with atropine ophthalmics to prevent synechiae formation and other ophthalmics to aid in re-epithelialization (Brodovsky *et al.*, 2000; Grant and Schuman, 1993).

The animal should be bathed with copious amounts of water and a mild soap. Phosgene oxime reacts quickly with tissue and decontamination is not expected to be entirely effective after pain has been produced. Sodium hypochlorite (0.5%) or isotonic sodium bicarbonate can help neutralize phosgene oxime that has not yet reacted with tissue. Burns should be managed with topical silver sulfadiazine and systemic antibiotics as needed (Roberts, 1988). Horses and sheep should receive tetanus prophylaxis. Other species should be vaccinated on a case by case basis.

Monitor oxygenation and thoracic radiographs in patients following significant exposures. Administer oxygen, perform endotracheal intubation, and provide assisted ventilation if needed. Nebulized beta adrenergic agonists can help if bronchospasm develops. Administer IV fluids but monitor for overhydration (Goldfrank *et al.*, 2002).

Phosgene oxime is nonpersistent in the environment and it hydrolyzes rapidly in aqueous alkaline solutions. Veterinary personnel and rescuers should wear aprons, rubber gloves, and masks when treating patients to avoid secondary contamination.

4. Species Susceptibility

There are no controlled studies showing that any species of animal would make a good sentinel for phosgene oxime exposure.

F. Cyanide and Hydrogen Cyanide

1. Clinical Signs

Cyanide and hydrogen cyanide (HCN) are classified as blood agents. They cause toxicity by forming a stable complex with ferric iron (Fe^{3+}) in cytochrome oxidase enzymes. This inhibits cellular respiration, oxygen utilization, and ATP production, causing deprivation of oxygen to the body at the cellular level (Way *et al.*, 1988). Both arterial and venous blood appears cherry red due to the accumulation of oxyhemoglobin (Bingham *et al.*, 2001; Lewis, 2000). Unhaired skin may also appear bright pink due to the high concentration of oxyhemoglobin in the venous return (HSDB, 2008). HCN and cyanogen chloride are the volatile, water-soluble, liquid forms of cyanide and are the most likely to be used for terrorism purposes.

Cyanide exposure can cause transient CNS stimulation, followed by syncope, ataxia, dyspnea, seizures, paralysis, apnea, and coma (Hall and Rumack, 1986; Vogel *et al.*, 1981). The odor of bitter almonds may be noted in gastric or ruminal contents and expired breath. Initial tachypnea is followed by respiratory depression. Dyspnea without cyanosis can help with the diagnosis. Chickens develop tachypnea, have rapid eye blinking, hypersalivation, and lethargy (Wiemeyer *et al.*, 1986). Blindness may occur from cyanide-induced damage to the optic nerve and retina (Grant and Schuman, 1993; Vogel *et al.*, 1981). Hypersalivation, vomiting, and abdominal pain may occur after ingestion (Hall and Rumack, 1986; Singh *et al.*, 1989; Vogel *et al.*, 1981). Metabolic and lactic acidosis is commonly seen. Death can occur within minutes.

2. Kinetics

Cyanide and HCN can be absorbed by all routes (inhalation, oral, ocular, and dermal) (Hall and Rumack, 1986). There is rapid diffusion into tissues and cyanide irreversibly binds to its target sites. Cyanide has a wide volume of distribution and will concentrate in red blood cells two to three times greater than in plasma (HSDB, 2008). Cyanide preferentially accumulates in the hypothalamus, with levels about 40% higher compared to other areas of the brain (Borowitz *et al.*, 1994).

Cyanide is metabolized by rhodanese in the liver to thiocyanate (Hall and Rumack, 1986). Thiocyanate is excreted mainly in the urine. Without administration of an antidote, the half-life for the metabolism of cyanide to thiocyanate is 20 min to 1 h (Feldstein and Klendshoj, 1954). Cyanide can be excreted in breast milk (Soto-Blancoand Gorniak, 2003).

3. Decontamination and Treatment

Remove animal from the affected area. Do not induce vomiting due to the rapid progression of the clinical signs and potential for seizures, coma, or apnea. One gram of activated charcoal will bind 35 mg of cyanide and activated charcoal may be beneficial if administered immediately after ingestion (Lambert *et al.*, 1988). Irrigate eyes for at least 15 to 20 min with tepid water. Bathe animals thoroughly with soap and water.

Blood gases and serum electrolytes should be monitored and corrected as needed (Hall and Rumack, 1986; Vogel *et al.*, 1981). Blood cyanide levels can confirm exposure, but due to the time needed to get the results, they are not clinically useful. Provide supplemental oxygen with assisted ventilation as indicated. Animal study results for hyperbaric oxygen therapy have been questionable (Way *et al.*, 1972). Acidosis (pH <7.1) should be corrected with intravenous sodium bicarbonate, but acidosis may not resolve until after the administration of antidotes (Hall and Rumack, 1986). Benzodiazepines or barbiturates can be used to control seizures.

Cyanide toxicosis progresses so rapidly that treatment is rarely administered to animals in time. If the animal is still alive but in respiratory distress or a coma, antidotal agents may still be life saving. The classic treatment for cyanide

intoxication includes several steps. Sodium nitrite is given intravenously over 15 to 20 min (fast administration causes hypotension). Sodium nitrite reacts with hemoglobin in the red blood cells to form methemoglobin. Methemoglobin combines with free cyanide to form cyanomethemoglobin. Sodium thiosulfate is given after sodium nitrite. Sodium thiosulfate supplies sulfur for the rhodanese reaction (Hall and Rumack, 1987). The sulfur reacts with cyanomethemoglobin to form hydrogen thiocyanate which is excreted in the urine.

Hydroxocobalamin (Cyanokit®) has been the chelator of choice in Europe and Australia, and was just approved for use in the USA in 2007. It works by combining with cyanide to form cyanocobalamin (vitamin B_{12}) (Hall and Rumack, 1987). Hydroxocobalamin has been shown to reduce mortality in rats, mice, and Beagle dogs and has the advantage of producing neither methemoglobinemia nor hypotension, as sodium nitrite does (Borron *et al.*, 2006; Hall and Rumack, 1987). Dicobalt-EDTA (Kelocyanor®) and 4-dimethylaminophenol hydrochloride (4-DMAP) are other chelators available in Europe, Israel, and Australia, but not in the USA (Hillman *et al.*, 1974; Weger, 1990).

Other substances that have been tested in the lab on animals include: stroma-free methemoglobin solutions, alpha-ketoglutaric acid, chlorpromazine, hydroxylamine, phenoxybenzamine, centrophenoxine, naloxone, etomidate, para-aminopropiophenone, and calcium channel blockers (Amery *et al.*, 1981; Ashton *et al.*, 1980; Bright and Marrs, 1987; Budavari, 2000; Dubinsky *et al.*, 1984; Johnson *et al.*, 1986; Leung *et al.*, 1984; Ten Eyck *et al.*, 1985; Yamamoto, 1990). The use of these substances has shown positive results, but they have not been tried during actual poisoning situations.

HCN is lighter than air and has a long half-life in air. However, in open spaces, HCN is rapidly dispersed and is diluted to nontoxic concentrations. Cyanide does not bind to soil or plant material, but can mix with water. Contaminated water can be treated with ozone, hydrogen peroxide, or calcium/sodium hypochlorite bleach. Rescue personnel should wear boots, gloves, goggles, full protective clothes, and a self-contained positive pressure breathing apparatus as the potential for secondary contamination is high (AAR, 2000).

4. Species Susceptibility

There are significant interspecies differences in the toxicity of hydrogen cyanide (Sousa, 2003). Dogs appear to be more susceptible than humans to cyanide poisoning. This is thought to be due to lower levels of endogenous rhodanese (hepatic enzyme that catalyzes the sulfuration of cyanide to thiocyanate) (Aminlari and Gilanpour, 1991). Barcroft (1931) exposed both a man and a dog simultaneously to hydrogen cyanide gas. The 70 kg man and 12 kg dog were exposed to HCN concentrations between 500 and 625 ppm in an airtight chamber. The dog became ataxic at 50 s, unconscious at 74 s, and began to seizure at 90 s. At 91 s, the man walked out of the exposure chamber with no symptoms, although over the next 10 min he developed transient nausea and difficulty concentrating (Barcroft, 1931). As HCN is lighter than air, it is probably not that the small dog experienced a higher exposure than the human.

Cats are more resistant to subcutaneous HCN than humans. The LDLo (SQ) for humans is 1 mg/kg, as compared to 11 mg/kg for cats (Sax and Lewis, 1989). The LDLo (oral) for HCN in humans, dogs, and rabbits is comparable (5.7, 4, and 4 mg/kg, respectively) (Sax and Lewis, 1989).

Dogs may be good sentinel animals as they appear to have increased susceptibility relative to humans based on physiological differences. More controlled studies are required, however.

G. Military Nerve Agents

1. Clinical Signs

Military nerve agents are probably the most toxic of the known chemical warfare agents. Military nerve agents are divided into ''G'' (for Germany) agents (sarin, soman, tabun) and ''V'' (for venomous) agents (VX). Nerve agents are extremely dangerous as they are absorbed without producing any irritation or other sensation on the part of the exposed person or animal (HSDB, 2008).

Nerve agents are organophosphates (OPs). Acute exposure to OPs can cause muscarinic, nicotinic, and CNS signs. Muscarinic effects include salivation, lacrimation, urination, dyspnea, diarrhea, emesis (SLUDDE) along with miosis, bradycardia, hypotension, and bronchoconstriction. Nicotinic effects include muscle fasciculations and weakness (including the diaphragm), tachycardia, hypertension, and mydriasis. CNS effects include restlessness, anxiety, seizures, and coma (Garigan, 1996). VX has CNS effects that are unrelated to AChE activity and prolonged effects may be seen following convulsive doses (Young *et al.*, 1999). Death is due to paralysis of the diaphragm, airway obstruction from increased bronchial secretions, or depression of the CNS respiratory center (Garigan, 1996).

The ''G'' agents present a vapor hazard as they are very volatile. VX has a high dermal toxicity, even through intact skin, as the liquid does not evaporate quickly (Berkenstadt *et al.*, 1991; Sidell *et al.*, 1997). VX is 300 times more toxic than tabun on skin. A very small drop on the skin may cause sweating and fasciculations at the site. A larger dermal drop may cause loss of consciousness, seizures, apnea, and flaccid paralysis. Toxicity in descending order, on a per weight basis, is: VX > soman > sarin > tabun (HSDB, 2008).

Delayed peripheral neurotoxicity has been reported in animal studies. Soman produced severe delayed neuropathy in the atropinized hen assay at 1.5 mg/kg (Willems *et al.*,

1984). Sarin, tabun, and VX cause post-implantation mortality and fetotoxicity (HSDB, 2008; RTECS, 2008).

2. Kinetics

Nerve agents can be absorbed by any route (ocular, oral, inhalation, dermal) (RTECS, 2008; HSDB, 2008). Onset of signs and duration of effects depend on the form of nerve gas (vapor, liquid) and the route of exposure. With a vapor exposure and inhalation, local signs of nasal discharge and respiratory noise begin within one to several minutes and signs can last for a few hours (mild exposure) up to 1 to 2 days (severe exposure) (Pfaff, 1998). Inhalation of a large amount of the vapor will result in sudden loss of consciousness, apnea, flaccid paralysis, and seizures within seconds to 2 to 3 min (Sidell *et al.*, 1997). Peak effects are seen within 20 to 30 min and death is usually due to respiratory failure (Berkenstadt *et al.*, 1991).

Liquid nerve agents applied dermally cause local sweating and muscular twitching starting 3 min to 2 h after exposure. Signs last for 3 to 5 days. Following dermal exposure to a large drop clinical effects start within 30 min but with small drops a delay of up to 18 h can be seen (Sidell *et al.*, 1997).

Ocular exposure to vapor causes miosis, conjunctival hyperemia, and eye pain within one to several minutes. Signs can last 2 to 3 days. Liquid tabun penetrates the eye quickly and can result in death nearly as rapidly as an inhalational lethal dose (1 to 10 min) (EPA, 1985c). Ingestion of the liquid causes muscarinic, nicotinic, and CNS signs about 30 min after mild exposures. The signs can last several hours up to 2 to 5 days depending on the amount of exposure.

Volume of distribution is slightly different for each of the nerve agents. Sarin is distributed to the brain, liver, kidney, and plasma of mice (Little *et al.*, 1986). Soman is distributed throughout the mouse brain, with the highest levels found in the hypothalamus (Wolthuis *et al.*, 1986). Tabun is also found in high concentrations in the hypothalamus after IV administration in mice (Hoskins *et al.*, 1986). Soman is unique in that it has apparent storage in body ''depots'' and is released over time. This release can result in eventual death in animals who survive the initial dose of soman (Wolthuis *et al.*, 1986).

Most military nerve agents have rapid ''aging'' of the OP–enzyme complex. After aging the inhibitor–enzyme complex becomes resistant to reactivation (Young *et al.*, 1999). VX and tabun are exceptions to this rule with aging half-lives ($t_{1/2}$) of greater than 40 h (Garigan, 1996). The aging $t_{1/2}$ is only a few minutes for soman and about 5 h for sarin (Garigan, 1996).

Sarin is metabolized to isopropyl methylphosphonic acid (IMPA) and excreted by the kidneys (Little *et al.*, 1986). Approximately 50% of soman is converted to free pinacolyl-methylphosphonic acid within 1 min in mice. The half-life of this metabolite is less than 1 h (Reynolds *et al.*, 1985).

Cholinesterase levels can take weeks to return to normal (Rengstorff, 1985). RBC AChE recovers even more slowly (several days to 4 months) depending on the severity of the depression (Grob, 1956). Pupillary reflexes also remain suppressed for weeks to 1.5 months (Rengstorff, 1985).

3. Decontamination and Treatment

Administer oxygen and remove the animal from the toxic environment. For ocular exposures, flush eyes with copious amounts of tepid 0.9% saline or water for at least 15 min. Wash all animals three times with either soap and water, dilute bleach solution (1:10 with water), ethanol, or a tincture of green soap (Cancio, 1993). Towelettes impregnated with alkaline chloramine and phenol are used by the military (M291 Skin Decontaminating Kit, Rohm and Haas).

Due to the rapid development of signs, emesis is not recommended in oral ingestion. Activated charcoal can be used in both oral and dermal exposures. Seizures can be controlled with diazepam, methocarbamol, or barbiturates as needed. Assisted ventilation may be necessary if signs progress.

Atropine is an antidotal treatment. It is used to reverse the muscarinic signs, but it will not reverse the nicotinic effects (muscular weakness, diaphragmatic weakness, etc.). Atropine blocks the effects of accumulated acetylcholine (ACh) at the synapse and should be continued until the nerve agent is metabolized (Midtling *et al.*, 1985). Overatropinization can cause hyperthermia, tachycardia, agitation, mydriasis, and ileus, which can be life threatening in the horse (Meerstadt, 1982).

Oximes are used to treat the nicotinic signs. Pralidoxime (2-PAM) is the oxime of choice in the USA and it is most effective when administered in the first 1 to 3 h. Due to the quick aging of soman, pralidoxime is rarely given soon enough to be effective (Sidell *et al.*, 1997). 2-PAM can be given up to 48 h after exposure to VX and tabun, due to slow aging (Sidell and Groff, 1974). Other oximes, such as obidoxime dichloride (Toxogonin, LüH-6), are used in other countries (Belgium, Israel, The Netherlands, Scandinavia, Portugal, and Germany). HI-6 is another alternative oxime that has excellent acetylcholinesterase regenerating action with VX, very good action with sarin, good response to soman, but a poor or no response following tabun exposures (Hoffman, 1999).

Autoinjectors (AtroPen®, Mark I®, Combopen MC®) are atropine or atropine and pralidoxime combinations available for human use. They are not used in veterinary medicine as they are not adjustable for different sized patients. Experimental vaccines against nerve agent VX, and monoclonal antibodies which protect against soman, sarin, and tabun toxicity have been produced and are being tested (Dunn and Sidell, 1989; Somani *et al.*, 1992).

AChE activity can be tested in plasma, serum, or whole blood. In most animal species, 80% or more of the total blood AChE activity is in the RBC (as compared to 50% in humans); therefore, whole blood is the preferred sample for

most veterinary diagnostic labs. In general, in the context of OP poisoning, whole blood AChE activity <50% of normal is generally associated with severe symptoms (Midtling *et al.*, 1985). Furthermore, inhibition of RBC AChE is interpreted as: 10–20%, no reliable evidence of exposure; 30–50%, mild poisoning; 50–70%, medium or moderate; and 70–90%, severe intoxication. This decrease is in good agreement with results on humans and animals (Bajgar, 1992).

The ''G'' agents are volatile and evaporate over several hours. They are nonpersistent in the environment (Garigan, 1996). Environmental persistence is estimated to be 0.5 to 1 day for tabun, 1 to 2 days for soman, and 5 days for sarin. VX is an oily liquid that remains in the environment for weeks or longer after being dispersed (Budavari, 2000; Garigan, 1996; Munro *et al.*, 1999; Sidell *et al.*, 1997). Contaminated soil should be treated with alkaline substances (sodium carbonate, sodium bicarbonate, calcium hydroxide, calcium hydroxide, or calcium carbonate) or chlorine compounds (sodium hypochlorite or calcium hypochlorite) (EPA, 1975).

Protective equipment (rubber gowns, aprons, and gloves), along with respiratory protection, must be worn by rescuers and veterinary personnel. Leather and fabrics absorb organophosphates and are extremely difficult to decontaminate. Collars, muzzles, and other items should be incinerated.

4. Species Susceptibility

Nerve agent susceptibility varies widely between species. Animals may be more at risk for greater exposures than nearby human populations. Both the ''G'' and the ''V'' nerve agents are heavier than air, and animals with a lower breathing zone will be more affected (Rabinowitz *et al.*, 2008). Some species differences can make animals more sensitive than humans, while others will make them more resistant. Rats may be less susceptible than humans, since they possess aliesterases (enzymes) that can reduce the toxicity of certain nerve agents such as GA (Fonnum and Sterri, 1981). These enzymes are not present in humans. Nasal breathers, such as rodents, are capable of partially detoxifying nerve agents in the nasal pathways, presumably by hydroxylation and other mechanisms (Garamone, 2003). Carboxylesterase activity in guinea pigs and rabbits may provide protection from soman, when compared to humans (Maxwell *et al.*, 1987).

RBC AChE activity also varies among species. In humans, low RBC AChE activity has been associated with increased susceptibility to nerve agents (Leng and Lewalter, 1999). Pigs, sheep, dogs, rabbits, and cats have less RBC cholinesterase activity than humans (Anonymous, 2000b; Ellin, 1982). This would make these species more sensitive to nerve agents unless they have an alternative system to combat cholinesterase inhibition.

The LCt_{50} (50% lethal concentration via inhalation route) for military personnel for different nerve agents has been estimated from animal studies. Humans appear to be more sensitive to tabun than other animals. The LCt_{50} for tabun is 70 mg.min/m^3 for humans, 320 mg.min/m^3 for dogs, 450 mg.min/m^3 for rats, and 960 mg.min/m^3 for rabbits (Anonymous, 2000a; NRC, 2003; Sidell *et al.*, 1998). Goats are more sensitive than humans to VX. The LCt_{50} for goats is 9.2 mg.min/m^3, while the human LCt_{50} is 15 mg.min/m^3 (Anonymous, 2000a; NRC, 2003; Sidell *et al.*, 1998).

Even though the lethal nerve agent exposure level for animals may be higher than that for humans, it is still possible that animals could exhibit other nonlethal effects sooner and more noticeably than humans. Rabbits develop 90% miosis at a lower inhaled concentration of cyclohexyl sarin when compared to humans (2.71 mg.min/m^3 versus 13.85 mg.min/m^3) (NRC, 2003).

Another way that animals could provide an early warning is via their sense of smell. Most animals have much more sensitive olfactory systems when compared to humans. Animals may be able to be trained to sense low nerve gas concentrations (Dalton, 2003).

It is unknown if animals may have decreased dermal absorption compared to humans due to protective fur or feathers. Comparing dermal exposures in humans and other species also shows differences for the various nerve agents. Mice appear to be more sensitive to dermal sarin than humans, LD_{50}s are 1.08 and 28 mg/kg, respectively (RTECS, 2008; Sidell *et al.*, 1997). The mouse may also be a good sentinel animal for tabun. The dermal LD_{50} for mice is 1 mg/kg, rats 18 mg/kg, and humans 14 mg/kg. Mice may be slightly more resistant to dermal soman, with LD_{50}s of 7.8 mg/kg for mice and 5 mg/kg for humans.

There are a few cases where shared exposures to nerve agents have been reported for both animals and humans. In 1968, there was an accidental release of two different nerve agents (one is thought to have been VX) in Utah. A flock of sheep that was grazing near the base was noted to be acting ''crazy in the head'', and thousands died less than 24 h later (Boffey, 1968). Nearby humans, cattle, dogs, and horses did not develop symptoms. The sheep had severely depressed cholinesterase levels, as did the cattle and horses. Cholinesterase testing of dogs and humans was normal. The sheep may have been more affected due to higher exposures through ingestion of contaminated pasture, or by spending more time in the vicinity of the chemical release.

H. 3-Quinuclidinyl Benzilate (BZ)

1. Clinical Signs

3-Quinuclidinyl benzilate (BZ) is a centrally acting synthetic anticholinergic agent. BZ is used as a hallucinogenic and incapacitating chemical warfare agent. It is about 25 times more potent than atropine and has a very long duration of action. BZ is disseminated as an aerosol, with the primary route of absorption through the respiratory system.

BZ affects both peripheral and central nervous systems. Peripheral anticholinergic effects can be summarized by the mnemonic ''dry as a bone, red as a beet, hotter than Hades and blind as a bat''. BZ inhibits glandular secretions (''dry as a bone'') leading to a dry mouth and foul breath (Holstege, 2006). Cutaneous vasodilation and skin flushing may be noted (''red as a beet'') due to decreased capillary tone. Hyperthermia (''hotter than Hades'') is due to elevated body temperature secondary to inhibition of sweating and inability to dissipate heat. Vision loss (''blind as a bat'') is from a loss of accommodation reflexes and decreased depth of field secondary to ciliary muscle paralysis and mydriasis (Anonymous, 1998; Holstege, 2006). Paralytic ileus is commonly seen as a result of anticholinergic toxicity (Holstege, 2006; Ketchum and Sidell, 1997). This can lead to fatal colic in equids. Urinary retention is also a common anticholinergic effect following exposure to BZ (Holstege, 2006; Ketchum and Sidell, 1997).

CNS signs of disorientation, agitation, tremor, ataxia, stupor, coma, and seizures may occur from inhibition of central muscarinic receptors (Holstege, 2006; Ketchum and Sidell, 1997). It is unknown if animals hallucinate like people, but they do appear distressed. Rhabdomyolysis can be seen secondary to seizures and agitation. If severe, myoglobinuric renal failure could develop (Holstege, 2006).

Other systemic signs may also occur. Sinus tachycardia is common (Anonymous, 1998; Holstege, 2006; Ketchum and Sidell, 1997). Moderate hypertension may occur and tachypnea may be expected following an acute exposure. Nausea and vomiting may also occur.

2. Kinetics

BZ easily crosses the blood–brain barrier leading to mostly CNS effects. Signs are dependent on the dose and time post-exposure. Prolonged effects may occur depending on the dose of BZ absorbed. Tachycardia and dry mouth develop within 15 min to 4 h after exposure (Anonymous, 1998). Peak effects occur at 8 to 10 h (Anonymous, 2001).

BZ accumulates in the cerebrum following an intravenous injection in rats (Sawada *et al.*, 1990). It is highly lipophilic and has a high degree of plasma protein and red cell binding. Steady state was reached in the cortex and caudate within 1 to 5 min. Binding to high-affinity m-AChRs is essentially irreversible for the first 6 h.

BZ is excreted via the kidneys (Holstege, 2006). Only about 3% is excreted unchanged in rat urine (Byrd *et al.*, 1992). The two major metabolites are 3-quinuclidinol and benzilic acid. Without treatment following an incapacitating dose, recovery is gradual, requiring 72 to 96 h (Anonymous, 2001; Ketchum and Sidell, 1997).

3. Decontamination and Treatment

Move into fresh air. Monitor animals for respiratory distress. If cough or dyspnea develops, administer supplemental oxygen. Assisted ventilation may be required. Nebulized beta-adrenergic agonists should be used if bronchospasm develops.

Due to the method of distribution (aerosol) most exposures are expected to be inhalational. However, with animals' tendency to groom, dermal exposures can also become oral exposures. Emesis is not recommended due to potential seizures and coma. Activated charcoal or gastric lavage can be helpful after oral exposures. These procedures can be successful even if delayed, as anticholinergics slow gastrointestinal motility.

Flush eyes with copious amounts of tepid water for at least 15 min. Animals should be bathed with soap and water. Bathing will not only remove the BZ but will also provide external cooling to combat hyperthermia. BZ may be detected in urine, serum, or blood, but there are no rapid tests to diagnose exposure to BZ, so clinical use is minimal.

Benzodiazepines can be used to control agitation. Avoid phenothiazines due to possible hypotension. Animals may need to be heavily sedated so they do not injure themselves or others. Control seizures with a benzodiazepine, phenobarbital, or propofol. Rhabdomyolysis can occur if agitation or seizures are not controlled.

Treat arrhythmias symptomatically (lidocaine, propranolol, etc.). Physostigmine can be used to treat severe arrhythmias but long lasting reversal of anticholinergic toxicity does not occur. Physostigmine is ineffective if given during the first 4 to 6 h following the onset of BZ effects. If physostigmine is discontinued, recovery from BZ may be slightly prolonged (Ketchum and Sidell, 1997).

Monitor electrolytes and renal function tests in symptomatic patients. Administer intravenous fluids to maintain urine output and to protect the kidneys from myoglobinuria. The prognosis is good if animals do not develop rhabdomyolysis or secondary infection. No chronic problems are expected from BZ itself (Holstege, 2006).

BZ is stable and environmentally persistent. ''Off gassing'' may occur from contaminated patients. Goggles and masks should be worn by all personnel until the animal is decontaminated (Anonymous, 1998; Holstege, 2006). Remove contaminated collars, leashes, harnesses, halters, etc., and discard as leather and fabrics absorb BZ.

4. Species Susceptibility

There are no studies demonstrating that animals are more sensitive than humans.

I. Riot Control Agents (Lacrimators)

1. Clinical Signs

Chloroacetophenone (CN, mace, tear gas), chlorobenzylidene malonitrile (CS, Paralyzer®, super tear gas), and oleoresin capsicum (OC, pepper-mace) are lacrimators used in riot control. They are solid chemicals administered as a fine dust or aerosol spray, and not true gases. Exposure to lacrimators causes immediate pain, blepharospasm, lacrimation, rhinorrhea, coughing, and sneezing but usually

no permanent tissue damage (Blain, 2003; Grant and Schuman, 1993). With higher ocular concentrations, chemical burns with keratitis and loss of the corneal epithelium may occur (Hoffman, 1967). A 4% w/v CN product has caused permanent corneal injury and ocular necrosis in animals, but no such injury was seen in a 10% w/v CS product (Gaskins *et al.*, 1972; Grant and Schuman, 1993). Oral ingestion will also cause eye irritation, lacrimation, vomiting, and diarrhea (Blain, 2003). Laryngospasm may occur in some cases due to the irritant effects; it can progress to pulmonary edema, bronchospasm, and bronchopneumonia.

Dermal contact with lacrimators is very painful (Pinkus, 1978). Erythema and blisters are common. The extent of dermal effects depends on the thickness of the stratum corneum, and the extent of exposure (Blain, 2003). High concentrations can cause first and second degree burns of the skin (Hu *et al.*, 1989; Stein and Kirwan, 1964). No teratogenicity or carcinogenicity has been demonstrated in humans or animals (Blain, 2003; Folb and Talmud, 1989; Himsworth *et al.*, 1971; Upshall, 1973).

2. Kinetics

The effects of lacrimators occur very quickly (Beswick, 1983). Pain, salivation, coughing, rhinorrhea, sneezing, and erythema begin within seconds of exposure and can last approximately for an hour (Blain, 2003). Delayed effects may also be seen. Conjunctivitis and ocular edema may be noted from 1 to 2 days following exposure. Laryngospasm and pulmonary edema may occur up to 48 h (usually 12 to 24 h) post-exposure. Bronchospasm may also be delayed up to 48 h post-exposure and become chronic (Folb and Talmud, 1989).

One of the CS metabolites is cyanide, but cyanide toxicosis does not appear to happen with routine use (Cucinell *et al.*, 1971). Gastrointestinal signs resolve over 24 h (Solomon *et al.*, 2003). Erythema disappears over 48 h and coughing may persist for weeks after exposure (Blain, 2003).

3. Decontamination and Treatment

Animals may need to be sedated to be able to treat them safely. Move animals into fresh air and monitor for respiratory distress. If cough or dyspnea develops, monitoring is necessary for oxygenation status. Supplemental oxygen may be needed. Laryngospasm may require intubation to permit adequate ventilation. Inhaled beta-2 agonists (albuterol, salbutamol), corticosteroids, and aminophylline may help reduce bronchospasm (Ballantyne and Swanston, 1978; Folb and Talmud, 1989). Thoracic radiographs should be monitored if pulmonary edema is expected (Stein and Kirwan, 1964).

Flush eyes with copious amounts of tepid 0.9% saline or water for at least 15 min. Diphoterine® solution can be used for decontamination of both eyes and skin after exposure to lacrimators (Viala *et al.*, 2005). Ocular signs resolve approximately 3 to 7 min after decontamination with Diphoterine®.

Animals should be bathed with soap and copious amounts of cold water. Using small amounts of water can actually increase irritation (Lee *et al.*, 1984). Topically applied magnesium hydroxide–aluminum hydroxide–simethicone suspension (Maalox Max®) caused resolution signs within 2 min after application after exposure to OC. If chemical burns develop, clean wounds with a mild disinfectant soap and water. Pain control and antibiotics may be needed. Tetanus toxoid should be given if burns are present. With oral ingestions, antacids may help decrease gastrointestinal signs.

Secondary contamination is common and personnel should wear aprons, rubber gloves, and masks as needed. Contaminated items can be washed in cold water (hot water will cause residual gas to vaporize) with soap or allow nonwashable items to air out for a few days. Most lacrimators dissipate quickly, but CS may be micronized and mixed with an antiagglomerant agent (CS1) which remains active for up to 5 days. A similar formulation mixed with silicone (CS2) remains in the environment for up to 45 days (Hu *et al.*, 1989).

4. Species Susceptibility

There are no controlled studies showing that animals are more sensitive to lacrimators than humans.

J. Ricin and Abrin (Toxalbumins)

1. Clinical Signs

Ricin and abrin are toxalbumins. Toxalbumins are plant lectins with a specific affinity for animal cell receptors. *Ricinus communis* (castor bean plant, castor oil plant, koll, mole bean, moy bean, palma christi) contains ricin. The castor bean plant is grown throughout the USA as an ornamental. The brown and white seeds, which resemble large ticks, contain the ricin. Most animals are exposed to ricin by eating the seeds, but ricin has been used as a chemical warfare agent, a reagent for pepsin and trypsin, an experimental antitumor and immunosuppressive agent, and a commercial mole killer (Budavari, 2000; Hayes, 1982; HSDB, 2008; Sax and Lewis, 1989). Abrin is found in the *Abrus precatorius* plant (Buddhist rosary bead, crab's eyes, Indian bead, Indian licorice seed, jequirity bean, jungle bead, love bean, lucky bean, mienie-mienie, ojo de pajaro, prayer bead, rosary pea, seminole bead, weather plant). This tropical ornamental vine produces colored seeds that are popular for use in jewelry and other decorative items. The seeds come in three different colors: red with a black eye, black with a white eye, and white with a black eye (Niyogi, 1969).

Variable toxicity is seen in cases of oral ingestion. Seeds that are chewed are much more likely to cause clinical signs. Seeds swallowed whole may not cause any problems at all (Kinamore *et al.*, 1980). The amount of toxalbumins in the

seeds will vary by size, weight, moisture content, region, season, and the period of plant growth at the time of harvesting (Audi *et al.*, 2005). The ricin content of castor beans can vary from 1 to 10% (Balint, 1974; Waller and Negi, 1958). The abrin content in *Abrus precatorius* seeds is estimated at 0.15% (Lin *et al.*, 1971). Toxicity and death have occurred with ingestions of one to two chewed beans of either plant. Ricin levels can be measured in plasma and urine but are not clinically useful (Kopferschmitt *et al.*, 1983).

Vomiting, abdominal pain, and bloody diarrhea are the most common signs seen after ingestion (Kopferschmitt *et al.*, 1983; Malizia *et al.*, 1977; Pillay *et al.*, 2005). Toxalbumins cause severe gastrointestinal lesions of the oropharynx, esophagus, and stomach. The lesions are clinically similar to alkaline burns. Fluid losses can lead to dehydration, electrolyte disturbances, hypotension, and tachycardia (Ingle *et al.*, 1966).

Liver damage occurs in toxalbumin toxicosis. Histopathology reveals injury to the smooth endoplasmic reticulum and depletion of liver glycogen (Balint, 1978). The liver enzyme values for ALT, total bilirubin, AST, alkaline phosphatase, and GGT can all be elevated (Niyogi, 1977). Glucose metabolism is affected by ricin. Not only do glycogen stores decrease, but gastrointestinal absorption of glucose decreases and glucose concentrations fall (Lampe, 1976; Malizia *et al.*, 1977). Hypoglycemia is a common finding.

Mild to moderate CNS depression is commonly observed. Seizures are reported more frequently in animals than in people (Frohne and Pfander, 1984; Hart, 1963). While hematuria is commonly reported, the hemagglutination that is seen in animal and laboratory work is almost never seen in actual toxicities (Corwin, 1961; Jelinikova and Vesely, 1960; Malizia *et al.*, 1977; Waller *et al.*, 1966).

Ricin is among the most toxic compounds known when given parenterally. Parenteral toxicity is much greater than oral toxicity. The oral lethal dose of ricin is estimated to be 1 mg/kg (Kopferschmitt *et al.*, 1983). When given by injection, the lethal dose of ricin drops to about 1 µg/kg (Budavari, 2000). With an inhalation exposure, signs seen are cough, dyspnea, arthralgias, fever, and death (Griffiths *et al.*, 2007). Other organ system dysfunctions may not occur (Audi *et al.*, 2005).

2. Kinetics

Gastrointestinal effects usually develop in under 6 h, but vomiting can begin in 1 to 3 h post-ingestion of castor beans (Kopferschmitt *et al.*, 1983; Spyker *et al.*, 1982). In some cases, signs may be delayed for several days. The cytotoxic effects on the liver, CNS, kidney, and adrenal glands may not occur for 2 to 5 days post-exposure. With an inhalation exposure symptoms begin within 8 h. Death occurs about 48 h after a parenteral or oral exposure (Budavari, 2000).

Glycoproteins are large molecules and are poorly absorbed from the gastrointestinal tract. Many cell surfaces contain receptors specific for ricin and the toxin is taken up by active transport. The primary site of distribution of ricin is the liver, spleen, and adrenal cortex in the mouse. A high concentration was also found in the bone marrow (Godal *et al.*, 1984). In rats, abrin is distributed primarily to the liver (12%) and spleen (Lin *et al.*, 1970, 1971).

The metabolism and elimination of toxalbumins is poorly understood. Ricin is eliminated by first order kinetics when injected IV into mice and human cancer patients (Godal *et al.*, 1984). The plasma half-life in humans is about 2 days (Kopferschmitt, 1983).

3. Decontamination and Treatment

There are no specific treatments for toxalbumin exposure. Aggressive decontamination is recommended. With ingestions, emesis should be induced in species that can vomit (dogs, cats, ferrets, and swine), if the animal is not already vomiting. Activated charcoal can bind orally ingested toxalbumins. Monitor asymptomatic animals for 8 h following any exposure to toxalbumins. Monitor for dehydration, electrolyte disturbances, elevated liver enzymes, and hypoglycemia.

Intravenous fluids are very important to maintain normovolemia and urine output. If hematuria is present, consider alkalinization of the urine. A goat anti-ricin polyclonal and a mouse anti-ricin A-chain monoclonal antibody have been tested and shown to neutralize ricin in castor bean extract, but they are not clinically available (Lemley and Wright, 1991; Wannemacher *et al.*, 1991).

If the toxalbumin was distributed by air, move the animal into fresh air and monitor for respiratory distress. If cough or dyspnea develops, administer supplemental oxygen. Wash animals thoroughly with soap and water. Eyes should be flushed with copious amounts of tepid 0.9% saline or water for at least 15 min. Other treatments are the same as for an oral exposure.

4. Species Susceptibility

There are no controlled studies demonstrating that animals are more susceptible to developing acute effects than humans.

III. CONCLUDING REMARKS AND FUTURE DIRECTION

The lack of controlled studies comparing animals and humans needs to be addressed if animals are to be used as sentinels. The existing studies and anecdotal reports do not provide enough convincing evidence (Rabinowitz, 2008). Sentinels would need to demonstrate easily recognizable signs before the emergence of human illness. A good sentinel could have either greater susceptibility to

a particular toxin relative to humans or a shorter latency time from exposure to onset of signs (Cottrell and Morgan, 2003).

With any suspicious outbreaks, the local health department, poison center, law enforcement agency, and US Federal Bureau of Investigations (FBI) should be contacted immediately. Due to the absence of a nationwide surveillance system for animal diseases, the responsibility for detecting possible outbreaks of unusual symptoms in animals will fall over several different groups of people. Farmers, agriculture officials, veterinarians, animal control officers, wildlife rehabilitators, (animal) poison control centers and the lay public (animal owners) may all be involved in detecting outbreaks.

During a chemical warfare incident, the human casualities should be addressed first, followed by the animal casualities. Situations in which herds of livestock or flocks of poultry are affected are going to be much more complex to manage than exposures to house pets. The simple logistics in getting the personnel and equipment to the site of exposure can be daunting, if not impossible. Handling livestock can be dangerous, especially to untrained personnel. The use of antidotes and other pharmaceuticals must be documented in food-producing animals and withdrawal times for meat and milk followed. In many herd situations, humane euthanasia may be the best solution.

CHAPTER 48

Potential Agents that Can Cause Contamination of Animal Feedstuffs and Terror

R.W. COPPOCK

I. INTRODUCTION

A. Terror Objectives

Terrorism has long been recorded in the chronicles of history. Terror is not new in terms of its objectives. The objective of any act of terrorism, though dangerous or lethal to human and animal life, is to intimidate or coerce a civilian population (Crutchley *et al.*, 2007). Acts of terrorism can create fear and anger among the public, influence the policy of and affect the conduct of a government, and topple political leaders. A key message to the public is that their government(s) is powerless to protect them. New technologies have produced a whole new arsenal of weapons for terrorists.

Feedstuffs and foodstuffs (foodstuffs and food refer to substances consumed by humans and feedstuffs and feeds refer to substances consumed by nonhuman animals) are vulnerable to terrorist attack. A terrorist attack targeted at feedstuffs could have a remarkable impact on the feed and livestock industries. The World Health Organization (WHO, 2002) considers that a local terrorist attack on food could have global impacts. These impacts can largely be due to the public losing faith in the ability of governments to detect harmful adulterants in foodstuffs and feedstuffs and thereby protect health. Specific industries can be targeted with significant economic losses (Crutchley *et al.*, 2007). Terrorist attacks can indirectly affect feedstuffs. For example, fallout from a dirty bomb can contaminate forages, cereals, and other feedstuffs. Humans are exposed by consuming contaminated edible animal products. Companion animals can be exposed through contaminated animal products being incorporated into pet foods. Attacks on companion animal feedstuffs can have a considerable emotional impact on a community.

B. Agricultural Food Ecosystem and Terror

A brief review of the agri-food ecosystem is important in the discussion of terrorist-linked toxicology of animal feedstuffs. Generally, the activities and technologies in the agro-ecosystem are maximized for human control and economic gain. All aspects of food production in the agro-ecosystem, including input chemicals and fertilizers, can be the target for terrorists. Harmful agents and organisms can be added directly or indirectly to feedstuffs. Tragic incidents of food-borne intoxication can occur without malicious intent. The scientific literature has examples wherein xenobiotics in feedstuffs were relayed to humans via contaminated animal products, and resulted in human illness (Curley *et al.*, 1971; Gerstner and Huff, 1977). For example, humans have been poisoned by consumption of methyl mercury-contaminated grain donated for use as seed (Gerstner and Huff, 1977; Al-Damluji, 1976).

1. Upsetting the Margins Between Safe and Unsafe Practices

The production of cereal grains, oilseeds, other commodities, and forage occurs essentially in an artificial ecosystem (Sinha, 1995; Dorea, 2006). Activities in this agro-ecosystem include seeding, growing, harvesting, storing, and transportation of cereal grains, oilseeds, forages, nuts, fruits, raw materials for beverages, and animal bedding (Balazs and Schepers, 2007). The agronomic ecosystem is driven by economic decisions that generally maximize profitability and minimize labor and input costs. This ecosystem is dependent on management that ensures activities are done in a timely manner, and in a manner that ensures the safety of foodstuffs and feedstuffs. The margin between safe and unsafe practices is generally close. The decision-dependent activities include fertilization, weed and other pest control, harvest methods, preservation, and enhancements. Management of the agro-ecosystem is important to prevent feedstuffs being damaged by pests and spoilage while minimizing exposure of animals and humans to toxic substances.

The agro-ecosystem is vulnerable to attacks by terrorists which can narrow the margins between safe and unsafe practices. For example, the tactics used by terrorists can have huge impacts on foodstuffs and feedstuffs and can be as simple as, for example, disrupting the distribution of electrical and fossil fuel energy. For example,

a remarkable reduction in available and affordable energy can immediately alter practices traditionally used to harvest and preserve feedstuffs and increase the risk of growth of toxigenic fungi. Manufacturing of feedstuffs and foodstuffs also occurs within this ecosystem. This agroecosystem is especially vulnerable to persistent toxigenic organisms, and persistent chemicals that are recycled and bioconcentrated.

2. Economics of Chemical Incidents

Examples exist where large outbreaks of animal to human contamination not linked to terror can have a distinct economic impact (Kojima and Fujita, 1973; Kay, 1977; Fries, 1985; Dorea, 2006; Burns, 2007). These incidents have long-term impacts on human health (Kojima and Fujita, 1973; Sweeney and Symanski, 2007). Chemical-induced illness at the local level can have a significant impact on the health system and government agencies (Kojima and Fujita, 1973; Green *et al.*, 1987).

II. MYCOTOXINS AND TOXIGENIC FUNGI

A. Background

The use of mycotoxins as a chemical weapon has a controversial history (Tucker, 2001; Katz and Singer, 2007). Mycotoxins and toxigenic fungi can be used for terrorist attack on both feedstuffs and foodstuffs (Tucker, 2003; Shannon, 2004). Mycotoxicosis as disease entities are not commonly considered in a differential diagnosis by medical professionals in the USA. In addition to low consideration as the etiology of disease, the clinical presentation caused by mycotoxins can easily be diagnosed as being caused by other etiologies (Paterson, 2006). Thus, the delay in the identification of mycotoxins as the causal agent(s) could occur over a considerable period of time. Delay in recognition can increase the numbers of animals and humans exposed.

B. Applications of Biotechnology

It should be assumed that the effective use of mycotoxins as terrorist weapons can be increased with the use of biotechnology. Development of fungi for bioterrorism has been reported to share technologies with the forensic development of fungi for use as weapons (Paterson, 2006). The genetics of mycotoxin production are better understood (Bhatnagar *et al.*, 2006). It is well known that the conditions for mycotoxin production are the presence of toxigenic fungi having favorable growing conditions which include temperature and substrate moisture content. It is possible that aggressive strains of toxigenic fungi can be developed that produce mycotoxins at lower temperatures and moisture levels than would be considered the usual limits for a particular species. Also, fungal varieties can be genetically modified (GM) in a manner that would enhance toxin production by removing the ''restrictors'' of toxin production. The use of toxigenic fungi and mycotoxins in terrorist activities may likely follow the developments in genetic research and biotechnology.

C. Potential Use of Fungal Biocontrol Agents

Fungal biocontrol agents (FBCAs) could be used in terrorist activities. Some FBCAs have been developed using bioselection and some have been developed using genetic modification technologies (Paterson, 2006). A number of the FBCAs produce mycotoxins and known toxigenic fungi have been used to control unwanted vegetation. These actions have occurred, for example, to control the plants in the Erythroxylaceae family (cocca) of plants. If the target had been a crop used for production of substances other than an illicit drug, the act may have been considered bioterrorism or use as a biological weapon.

D. Economics of Mycotoxins as Weapons

The use of toxigenic fungi and mycotoxins for bioterrorism can have economic consequences. Increasing the environmental prevalence of aggressive strains of toxigenic fungi could increase the losses due to mycotoxins from ~$2.5 billion to some substantially higher number (CAST, 2003). These losses may be underestimated because Robens and Cardwell (2003, 2005) projected the loss due to aflatoxins at $1.5 billion/year without including secondary industry and trade losses. International commodity trading can be used as a method of disseminating the spores of GM aggressive toxigenic strains of a particular fungus. Once released into the environment, the GM fungi would be difficult to control.

E. Use of Mycotoxin Contaminated Feedstuffs

Mycotoxin contaminated feedstuffs could be purchased and used as a terrorist tactic in manufacture of a completed feed. For example, horse or swine feeds could be formulated to contain a high level of screenings which are known to contain mycotoxins. Field incidences of mycotoxicoses not linked to terrorist activities have been reported from the use of fumonisin contaminated screenings in formulating horse and swine feeds (Wilson *et al.*, 1990; Osweiler *et al.*, 1992).

F. Residues in Edible Tissues

Food-producing animals can ingest mycotoxin contaminated feedstuffs and mycotoxin residues can be present in edible animal products. The concern for residues of mycotoxins in edible animal products has primarily been focused on residues of aflatoxins (Coppock and Christian, 2007). Residues of some mycotoxins in animal products can be

regulated. Incidents of aflatoxin contaminated feedstuffs being fed to milk-producing animals and subsequent contamination of foodstuffs are a public concern. Bioterrorism using aflatoxins could contaminate a large volume of dairy products with aflatoxin M_1.

G. Mycotoxicology

A discussion of mycotoxicology is beyond the scope of this chapter. For further details on mycotoxicology, the reader is referred to recent publications elsewhere (CAST, 2003; Plumlee, 2004; Gupta, 2007).

III. MICROBIAL TOXINS

A. Botulism Toxin

1. Background

Botulism toxins can be used as a terrorist weapon (Osborne *et al.*, 2007; Adler *et al.*, 2008). This group of toxins can easily be produced at low cost. Exposures to botulism toxins are oral, and these toxins have been formed in feedstuffs, or *in vivo* from toxin production by *Clostridium botulinum* growing in the gut or wounds (Critchley, 1991; Bohnel *et al.*, 2001). The production of botulism toxin is considered to be inexpensive and requires a low level of technology.

Clinical reports have shown that botulism occurs in livestock and some outbreaks can be associated with feedstuff containing animal carcasses (Bienvenu *et al.*, 1990; Kinde *et al.*, 1991; Braun *et al.*, 2005; Otter *et al.*, 2006). Type D botulism has been identified in cattle fed chicken litter, type C has been associated with ensiled chicken litter, and type B has been associated with forages (Long and Tauscher, 2006).

2. Mechanism of Action

Botulism neurotoxins bind with synaptic vesicular proteins and block the release of acetylcholine from the presynaptic membrane (Osborne *et al.*, 2007). Clinical signs of botulism are weakness, tremors, recumbency, laryngeal paresis, and other signs of nervous system dysfunction (Braun *et al.*, 2005). Botulism toxins do not appear to be excreted in milk (Galey *et al.*, 2000).

3. Potential Production and Use

Botulism toxins can be produced and incorporated into ingredients used in feedstuffs. The use of dead rodents or other animals can serve as a substrate for *Clostridium botulinum*, providing anaerobic conditions. Contamination of feedstuffs with the carcasses of dead mice or other small animals could be a method of disseminating botulism toxins. For further details of botulism toxins, readers are referred to in Chapter 30.

IV. PLANT TOXINS

A. Background

Poisonous plants and their seeds could be used to adulterate feedstuffs. Seeds of poisonous plants have been incorporated into animal rations and have resulted in animal intoxication (Burrows and Tyrl, 2001). Poison seeds can be used to intentionally adulterate feedstuffs. For example, grain screenings that contain high levels of toxic plant seeds could be used as a terrorist tactic to manufacture a pelleted feed. Pasture lands can be seeded with poisonous plants to increase the presence of poisonous plants in rangelands. Overgrazed pasture lands could be more susceptible to this type of terrorist attack. The genes required for production of poisonous plant proteins could be used to produce selected plant toxins by biotechnology. These terrorist tactics would also undermine the trust in governments to control biotechnologies.

B. Castor Beans (Ricin)

1. Background

Castor beans are grown commercially for castor oil. Castor oil has sought-after industrial and automotive applications. The annual production of castor bean waste mash exceeds 1 million tons (Doan, 2004). Castor bean cake is also sold as fertilizer. Ricin is easy to extract from castor bean meal.

2. Ricin as a Weapon

Ricin (ricin-D) from castor beans (*Ricinus communis*) is considered a potential bioterrorist weapon and has been considered as a chemical weapon since 1918. The ricin content of castor bean varies with the growing conditions and genetics of the plant (Millard and LeClaire, 2008). A general guide is 1 to 2 mg of ricin/g of ground castor seed. Ricin can be 5% of the total protein in castor beans, and is present in the waste mash after the oil has been extracted. The ricin content of the waste mash generally is 1 to 5% (w/w). Ricin is considered to be relatively heat stable at temperatures used for food processing (Audi *et al.*, 2005; Jackson *et al.*, 2006). Ricin is soluble in water over a wide range of pH values.

3. Toxicity

The seed coat of the castor bean needs to be fractured for the ricin to be released. Ricin in waste mash is biologically available. Most animal species including birds are sensitive to castor bean poisoning (Jensen and Allen, 1981; Burrows and Tyrl, 2001; Mouser *et al.*, 2007). The degree of toxicity depends on the dose (number of seeds) ingested and liberation of ricin by degradation of the seed coat by some form of mastication. The liberated ricin is absorbed from the gastrointestinal tract. The estimated lethal dose of castor bean seeds by species is given in Table 48.1 (Burrows and Tyrl, 2001).

TABLE 48.1. Sensitivity of different species to castor bean intoxication

Species	Lethal castor bean mass/kg of body mass	Comment
Human	225 mg	Seed considered to require mastication
Horse	100 mg	Considered the most sensitive species
Duck	255 mg	1 in 8 ducks died at 16 days after treatment. Grinding of the seeds by the proventriculus can be a variable in toxicity
Chicken	400 mg	Grinding of the seeds by the proventriculus can be variable in toxicity
Goose	400 mg	Grinding of the seeds by the proventriculus can be variable in toxicity
Rabbit	1.2 g	Mastication considered required
Pig	1.2 g	Mastication likely required
Goat	5 g	Age of ruminant can be a factor as the rumen may inactivate ricin
Sheep	14 g	Age of ruminant can be a factor as the rumen may inactivate ricin
Cattle	*a*	See text

[a]Cattle have been fed castor bean meal at ingredient levels (Albin *et al.*, 1968)

Ruminants are considered to be more resistant to ricin (Table 48.1) (Albin *et al.*, 1968; Burrows and Tyrl, 2001). The most likely reason is degradation of ricin by microbes in the rumen. This phenomenon also suggests that young ruminants would likely have the same sensitivity to ricin as monogastric animals.

4. Analytical Methods

Analytical methods include immune methods (ELISA) and liquid chromatography/mass spectrometry (LC/MS). Gastric contents can be assayed and ricin can be detected in blood and body fluids by radioimmunoassay and LC/MS (Darby *et al.*, 2001; Mouser *et al.*, 2007).

5. Mechanism of Action

Ricin is a lectin-type globular glycoprotein and consists of A and B chains (Doan, 2004; Li and Pestka, 2008). Ricin is considered a Type 2 ribosome-inactivating protein (RIP) (Millard and LeClaire, 2008). The ricin B chain attaches to the plasma membrane at the galactose receptors, pits are formed and the ricin is internalized by clathrin-dependent and clathrin-independent endocytosis and forms an intracellular vesicle. The cellular uptake of ricin is a slow process and this can explain the lag time between exposure and onset of clinical signs. The vesicles containing ricin coalesce and form endosomes. The internalized ricin can dissociate from the endosomes and be transported to lysosomes for degradation. Ricin can bleb off the endosome and return to the cell surface by vesicular and tubular structures, or be transported to the Golgi apparatus. In the Golgi apparatus, the A chain undergoes retrograde transport to the endoplasmic reticulum (Audi *et al.*, 2005). Cleavage of the A and B chains occurs in the endoplasmic reticulum. From the endoplasmic reticulum, the ricin A chain is translocated to the cytosol. The ricin A chain catalytically inactivates ribosomes. The A chain is an enzymic polypeptide that catalyzes the N-glycosidic cleavage of adenine from position 4324 of the 28S rRNA in the ribosome (Lord *et al.*, 1994; Doan, 2004; Li and Pestka, 2008). The removal of adenine from 28S rRNA in the ribosome destroys its functionality and thereby blocks protein synthesis. One A chain can enzymatically inactivate ~1,500 ribosomes/min.

6. Clinical and Pathological Findings

Clinical signs of ricin intoxication are high morbidity, abdominal pain, emesis, diarrhea, and lethargy. Hematemesis and melena may be observed. Clinicopathology includes elevated hepatic enzymes in serum, hyperphosphatemia, and sometimes hypoglycemia. Electrolyte imbalance can occur due to diarrhea and emesis. Pathological findings in a dog were hepatocellular necrosis, fibrosis of central veins and sinusoids, and lymphocytic infiltrate. Jejunal mucosa can be eroded, infiltrated with leukocytes, and the tunica muscularis can also be affected. Hemorrhage can be observed in the mucosal and muscular layers. Necrosis can be seen in the spleen. Renal pathology is also noted.

7. Other Plant Source Type 2 RIPs

Abrin is a plant source Type 2 RIP. It is found in *Abrus precatorius* (rosary pea, Indian licorice, jequirity bean). The toxicology of abrin is considered to be very similar to ricin. A similar *Abrus* toxin is pulchellin, produced by *A. pulchellus* (Millard and LeClaire, 2008). The rosary pea has been reported to be more toxic than castor beans (Griffiths *et al.*, 1994). Species sensitivity is variable and horses are considered to be the most sensitive. The mature goat is considered to be a more resistant species and 2 g of seed/kg body weight is reported as a lethal dose. The lethal dose for cattle is reported at 600 mg of seed/kg body weight. It is likely that abrin is denatured in the rumen (Burrows and Tyrl, 2001).

There is limited commercial production of the jequirity bean. The rosary pea is grown as an ornamental plant and has escaped into the wild in the warmer climate in the USA.

Abrus sp. is not grown as an oilseed or for other large-scale commercial use.

For further details on ricin, readers are referred to in Chapter 25.

V. RAPIDLY ACTING AND EASILY AVAILABLE SUBSTANCES

A. Cyanide

Cyanide is considered a terrorist weapon (Wismer, 2007; Ballantyne and Salem, 2008). Cyanide has a history of use in controlling problem wildlife and unwanted farrow animals (Westergaard, 1982; Wiemeyer *et al.*, 1986). Cyanide in a solid form could be used to adulterate feedstuffs. Two common forms of cyanide salts are sodium cyanide and potassium cyanide. Cyanide could be incorporated into animal feedstuffs, especially concentrate and mineral mixes.

1. Mechanism of Action

The toxicology of cyanide (CN^-) is complex (Wismer, 2007; Ballantyne and Salem, 2008). The lethal effect of cyanide is blockage of cytochrome C oxidase, which results in loss of electron transfer and where molecular oxygen is unused. In addition to cytochrome C, other cytochromes are adversely affected by forming complexes with the cytochrome iron. The oxidized cytochrome–CN complexes are stable, but the complex is relatively unstable in a reductive environment. The instability of the cytochrome-CN^- complex in a reductive environment is the focus of the majority of treatment regimens.

2. Plant Sources – Ruminants

Certain plants contain cyanogenic glycosides (Nicholson, 2007). Cyanogenic plants and trees are common in some geographical regions, and could be placed in pastures. Plant parts containing cyanogenic glycosides, precursors that form hydrogen cyanide (HCN) in the rumen, could be placed in ruminant rations.

3. Treatment of Cyanide Poisoning

Treatment of cyanide poisoning has been discussed in detail by Wismer (2007) and Nicholson (2007), and in Chapter 19.

B. Insecticides

Large numbers of cattle and other domestic livestock have been poisoned with insecticides that were inadvertently incorporated into feedstuffs. There have been instances where the same transport vessels have been used to transport/store insecticides, seeding crops, and silage, resulting in cross-contamination. Insecticides could be used by terrorists to adulterate animal feedstuffs. The toxicology and treatment of insecticides have been discussed in detail by Plumlee (2004) and Gupta (2006, 2007).

VI. PERSISTENT ORGANIC COMPOUNDS

A. Background

Persistent organic compounds (POCs), also known as persistent organic pollutants (POPs), could be candidates for a terrorist attack on livestock. The majority of the POCs are bioconcentrated in body lipids. Most of these compounds require high doses to cause acute illness in livestock, poultry, and fish. At low doses the resultant illness is generally is less evident. The lack of overt clinical signs increases the risk of edible animals passing inspection and their products being consumed by humans (Fries, 1985; Hayward *et al.*, 1999; Dorea, 2006). The issues of the relay of POCs from feedstuffs to food-producing animals and from animal-source foods to humans are known (Kay, 1977; Fries, 1985; Huwe and Smith, 2005; Dorea, 2006). Environmental sources of POCs are also important in the agro-ecosystem (Stevens and Gerbec, 1988). The widespread flame retardant (polybrominated biphenyls) contaminated feedstuffs found in an incident in Michigan [ball clay contaminated with polychlorinated dibenzodioxins (PCDDs) and dibenzofurans (PCDFs) in animal mineral mixes] and other incidents clearly show that these events can occur over a substantial period of time before low-level contamination is recognized. Recognition of these incidents requires substantial resources consisting of highly trained personnel, sophisticated laboratory procedures and laboratory safety requirements.

B. Economics of a Terrorist Attack Using POCs

The history of incidents clearly shows that feedstuffs contaminated with POCs have caused remarkable economic loss. If the feedstuffs have a wide distribution, the economic impacts can be great. For example, with the ball clay incident, it was estimated that 1.7 million eggs/day and 35% of the catfish were contaminated with PCDDs/DFs (Hayward *et al.*, 1999). Animal-source foodstuffs contaminated with PCDDs/DFs were consumed by humans (Fiedler *et al.*, 1997; Rappe *et al.*, 1998). The polybrominated biphenyl (PBB) retardant incident in Michigan contaminated feedstuffs and large numbers of livestock and poultry were destroyed (Fries, 1985). More than 400 upright silos were coated with a polychlorinated biphenyl (PCB) containing resin (Willett *et al.*, 1987). Subsequently, milk was contaminated with PCBs.

C. Clinical Findings

Clinical signs of a mixture of PCBs and PCDDs/DFs in poultry feed have been reported (Bernard *et al.*, 2002).

A sudden drop in egg production occurred followed by a reduction in hatchability. Ascites and edema were observed along with ataxia. Pathology included degenerative changes in skeletal and cardiac muscle. The source of the contamination was PCB oil that had accidentally been emptied into a tank of recycled fat. The toxicology of PCBs and PBBs in cattle is controversial (Jackson and Halbert, 1974; Cook *et al.*, 1978; Willett *et al.*, 1987). My review of dairy records in herds fed silage from silos sealed with a PCB-containing sealant and accounts from clients who were feeding dairy cattle from PCB-contaminated silos showed that there were signs of intoxication. The observations were an increase in the rebreeding interval due to anestrus and reduced conception. Some cattle had signs of abomasitis. Calf mortality was increased due to failure to thrive syndrome. The occurrence of infections in calves was also increased, suggestive of immune suppression. The calves had decreased weight gains. Milk production was also decreased after feeding from the bottom of upright silos.

D. Human Exposure

Human populations have been exposed to POPs by consuming contaminated animal-source foodstuffs. The incidents have shown that feedstuffs can be contaminated by toxic substances that resembled mineral supplements, and mineral and fat supplements are vehicles for POPs. Contamination of feedstuffs also caused dissemination of POPs in the agro-ecosystem. Past experiences have shown that delays can occur before the contamination is recognized.

VII. HEAVY METALS

A. Background

There are several incidents of heavy metal intoxication and contamination of livestock feedstuffs. The source of the heavy metals was from smelters being deposited on forage or heavy metals as contaminants being incorporated into feedstuffs (Curley *et al.*, 1971; Rice *et al.*, 1987; Coppock *et al.*, 1988; Galey *et al.*, 1990; Swarup *et al.*, 2005). The risk for translocation of lead to milk appears to increase with blood lead levels above 0.20 μg/ml. Human poisoning has occurred when meat from pigs fed methyl mercury was consumed.

B. Deposition in Tissues

Heavy metals are deposited in liver, kidney, and bone. Organ meats (liver and kidney) can contain heavy metals and methyl mercury is deposited in skeletal muscle.

C. Use as Terrorist Weapons

Heavy metals can be used as terrorist weapons by incorporation into animal feeds. There are reports of zinc sulfate imported as a fertilizer supplement being contaminated with cadmium. This raises concerns because zinc sulfate is incorporated into animal feeds.

D. Toxicology

Readers are referred to other books for discussions on the toxicology of heavy metals (Plumlee, 2004; Gupta, 2007).

VIII. CONTAMINATED TRANSPORT VESSELS

Historically, occurrences of feedstuffs becoming contaminated in transport vessels were primarily because of the failure to clean the vessels after use. Increasing energy costs most likely will discourage dedicated use of transportation vessels for feedstuffs. Contamination of transport vessels could be a terrorist activity. Likely chemicals would be pesticides, POPs, heavy metals, and cyanide salts. Contamination of transport vessels used for ingredients such as salt and mineral would ensure wide dissemination.

IX. CONCLUDING REMARKS AND FUTURE DIRECTION

The agro-ecosystem is vulnerable to terrorist activity. Protection of the agro-ecosystem from chemical contamination is a challenge. Farm gate biosecurity protocols are becoming more common, but many of these programs do not include protection from chemical threats. Identification of contaminated feedstuffs and foodstuffs generally occurs after animals and humans have been contaminated. The use of acutely toxic chemicals by terrorists would most likely result in the deaths of a large number of livestock and poultry. The contamination of edible animal-source foodstuffs would be less likely because the animals are dead, sick, recumbent, or debilitated, and would not pass inspection. Few intoxicating substances produce pathognomonic signs, clinicopathologic profiles, and lesions. For toxic substances that cause chronic illness and increase the risk of cancer and endocrine disruption, considerable time is generally required for the pattern of disease occurrences and the etiology associated with feedstuffs and animal-source foodstuffs to be identified. Additional time is required to track and remove the suspect feedstuffs or foodstuffs from storage and commerce. The load demand on laboratories and personnel can be substantial when widespread contamination of feedstuffs/foodstuffs has occurred and the toxic substance is known. The workload can be overwhelming when laboratory personnel are required to identify unknown chemical(s) and develop analytical methods.

Examples exist where interactions of chemicals used as adulterants are required to produce toxicity (Brown *et al.*, 2007; Puschner *et al.*, 2007). Clever use of chemical

mixtures for a terrorist attack on food can delay identification of the etiology. This would help the terrorists to achieve their objective of maximizing psychological, sociological, economic, and political impacts, preventing governments and corporations from ensuring the public that food is safe.

CHAPTER 49

Threats to Wildlife by Chemical Warfare Agents

R.W. COPPOCK

I. INTRODUCTION

Wildlife as a target of terrorist activity is a relatively new concept. Wildlife has value as a source of food, materials for garments, and other necessities and luxuries. There is also a desire to view wildlife in its natural habitat. Ecotourism is a growing industry especially if a country has unique or rare wildlife species or spectacular habitats. Wildlife is also important for sport and trophy hunting. The role of government is to protect wildlife from overkilling, and to protect the environment necessary for wildlife to feed and breed – this role is enforced by using a variety of laws and regulations. Additional laws and enforcement measures can be used to protect wildlife from human disturbances. Terrorist activities against wildlife can be undertaken to disrupt or destroy income and to remove a food source from aboriginal peoples that depend on wildlife for subsistence and culture preservation. Terrorist activities by their nature are generally carried out to destabilize society.

II. BACKGROUND

Wildlife can be an indirect target for terrorist attack and generally has a similar spectrum of sensitivity to terrorist agents as humans and domestic animals. Terrorist attacks against commercial operations could occur in more remote areas and such attacks could have an immense impact on wildlife including fish and other aquatic organisms. Impoundments of toxic water could be a target for terrorists for the primary purpose of contaminating potable water sources. Not linked to terrorism, there are recent examples of toxic water being released, with subsequent public outcry and economic impact, in several countries. Release of toxic water into the headwaters of large river systems was reported to have devastating impact on wildlife (Cunningham, 2005). One can only imagine the public and political reaction that would have occurred if such an incident was proven to be an act of terrorism.

Fish and other aquatic organisms can be impacted by run-off water from terrorist-linked fire fighting. This water could contain toxic substances and these substances could have negative impacts on wildlife. Run-off waters from burnt-over lands draining into waterways also are high in toxic substances.

III. WILDLIFE PROBLEMS OCCURRING AFTER A TERRORIST ATTACK

Wildlife problems can occur after a terrorist attack. For example, gulls (*Larus* spp.), crows (*Corvus* spp.), rats (*Rattus* spp.), and mice (*Mus* spp.) can become a nuisance in areas used for crime scene investigations (Chipman *et al.*, 2002). Such a problem occurred after the September 11, 2001 attacks on the World Trade Center. Control measures are required to enable investigations to be conducted without the danger of attacks on humans and the destruction of evidence. The need for wildlife control in an emergency could be unforeseen in emergency planning.

IV. ILLICIT AND RESTRICTED SUBSTANCES

A. Background

There are concerns regarding illicit pesticides being used for clandestine activities (Whitlow *et al.*, 2005). Because of their extreme toxicity, over time the use of certain substances was limited and in some cases they were even deregistered. These compounds are especially dangerous to wildlife because residual levels in carcasses can also kill animals that feed on them.

1. Tetramethylenedisulfotetramine

Tetramethylenedisulfotetramine (TETS, tetramine, CAS No. 80-12-6, 2,6-dithia-1,3,5,7-tetraazatricyclo[3.3.1.13,7]-decane,2,2,6,6-tetraoxide) is emerging as an illicit neurotoxin (Barrueto *et al.*, 2003; Whitlow *et al.*, 2005). Tetramine is an odorless white crystalline power that is radially soluble in water, mixes with feedstuffs, and is generally considered to be tasteless. The mechanism of action for TETS is that it selectively and irreversibly binds

with the chloride channel on the γ-aminobutyric acid receptor and disrupts regulation of chloride in the neuron. Inhibitory activity in the central nervous system (CNS) is decreased and clinical manifestations are seizures with onset occurring shortly after TETS ingestion. Tetramethylenedisulfotetramine is considered to be more potent than sodium monofluoroacetate (SMFA, Compound 1080). The oral LD_{50} of TETS for most species is 0.1 to 0.3 mg/kg of body weight, and the total lethal dose for a human is considered to be ∼10 mg. Rabbits dosed with 0.4 mg of tetramine/kg body weight and killed 1 h later had detectable levels (0.07 to 0.238 μg/g) of tetramine in the liver, kidney, heart, and lung (Xiang *et al.*, 2001). Tetramine is excreted in urine and urine can be used for forensic investigations (Zeng *et al.*, 2006). Tetramethylenedisulfotetramine is stable in tissues and relay or secondary poisoning can occur. Scavenging animals and birds can be poisoned with TETS because of the stability of TETS in tissues and body fluids.

The pathology of TETS in humans has been reported (Zhou *et al.*, 1998). Pathology observations in poisoned humans were edema of the brain, hemorrhages in the brain stem, and myocardial degeneration in the papillary muscles. Human tissues and urine can be assayed for TETS (Xiang *et al.*, 2001; Zeng *et al.*, 2006). A reasonable assumption is that similar pathology would occur in other species.

2. Sodium Monofluoroacetate (Compound 1080)

Sodium monofluoroacetate had common use as a poison until the early 1970s (Proudfoot *et al.*, 2006). In addition to being synthetic, SMFA and closely related compounds are found in *Dichapetulum* spp. of plants. The use of SMFA as a poison to eliminate unwanted animals and birds is restricted in many countries. Countries with limited indigenous mammal populations use SMFA to control imported animal species that disrupt and endanger indigenous wildlife (Eason, 2002). The use of SMFA can be limited to kill problem predators. For example, SMFA in some jurisdictions has been limited to sheep collars containing SMFA. In these applications, the SMFA is contained within bladders that are punctured during a predator attack (Burns and Connolly, 1995). The toxicology of fluoroacetamide is similar to SMFA (Osweiler *et al.*, 1976).

Sodium monofluoroacetate essentially is not detected by the sense organs. It is a white powder that has the appearance of flour or sugar, and is stable in storage over a long period of time. SMFA is heat stable to 200°C. It is soluble in water and insoluble in ethanol and lipids. In water, it can be degraded by microorganisms.

Compound 1080 is absorbed from the gastrointestinal tract, respiratory tract, mucous membranes, and wounds (Holstege *et al.*, 2007). Different routes of exposure do not have a remarkable effect on toxicity. The mechanism of action for SMFA is blockage of the Krebs cycle. Metabolic activation by the formation of fluorocitrate is required; a process known as lethal synthesis. Fluoroacetate is converted to fluoroacetyl-CoA and then converted by the enzyme citrate synthase to fluorocitrate. Aconitase catalyzes the conversion of citrate to isocitrate and aconitase is inhibited by fluorocitrate. Inactivation of aconitase blocks the Krebs cycle. Fluorocitrate also blocks the transport of citrate through the mitochondrial membrane. The heart and CNS are simultaneous targets for SMFA. Animals poisoned by SMFA are a hazard to scavengers, opportunists, and carnivores.

Clinical signs of SMFA toxicity (see Chapter 19) are due to the effects on the CNS and heart (Osweiler *et al.*, 1976; Proudfoot *et al.*, 2006). Herbivores can show more cardiac signs. The sequence of cardiac events is arrhythmias, tachycardia, inefficient pumping (weak pulse), and death when the heart fibrillates. Clinical signs observed are ataxia, collapse, and a short interval of agonal struggling (Robinson, 1979). Field observations are usually the discovery of a dead animal with the appearance of sudden collapse and limited evidence of agonal struggling. Carnivores generally have neurological signs of hyperesthesia, aimless wandering, frenzied running, vocalization, incoordination, emesis, opisthotonus, coma, and death. Death occurs from 1 to 24 h after ingestion of SMFA. Birds fall from the sky and die shortly after hitting the ground, or show nervous system signs and an inability to fly. Relay poisoning can be observed wherein animals poisoned by SMFA are consumed by other vertebrates.

Pathological findings in SMFA poisoning are those of acute heart failure and hypoxia. Hypocalcemia can be observed in SMFA intoxication (Proudfoot *et al.*, 2006). Tissues can be assayed for SMFA by gas chromatography methods (Okuno *et al.*, 1984).

V. CYANIDE

A. Background

Cyanide is poisonous to essentially all animal species. Cyanide can be placed in baits including water bait. Sodium and potassium cyanide and other forms of cyanide can be used. Breaching the impoundment can release tons of cyanide into streams, rivers, and lakes. Impoundments of toxic water containing cyanide could be a target of terrorism.

Cyanide is used in the extraction of gold and silver ores. The cyanide used in the process is recycled, but some cyanide escapes into the tailing pond. Bats and other animals drinking from these tailing ponds have been poisoned. There is a historical record of a dam holding a tailing pond being breached by a weather event, and subsequently releasing tons of cyanide into river systems causing an ecological disaster (Cunningham, 2005).

B. Toxicology

Cyanide has a history of being used to control unwanted wildlife and is toxic in the marine environment (Wiemeyer

TABLE 49.1. Estimated LD_{50} of cyanide

Identification	LD_{50} (mg/kg body wt)
Black vulture	4.8
American kestrel	4
Eastern screech owl	8.6
European starling	17
Chicken	21
Japanese quail	10
Coyote	4.1

Sterner (1979); Wiemeyer *et al.* (1986)

et al., 1986). Clinical signs of cyanide intoxication in birds have been described (Wiemeyer *et al.*, 1986). The progression of clinical signs of cyanide poisoning in vultures is ataxia, eye blinking, head bowing, wing droop, increased ataxia, seizures with tail fanning, opisthotonos gasping, and death. The progression of clinical signs in kestrels, owls, and quail is more violent. Time from ingestion to death is dose dependent. The lethal dose 50 (LD_{50}) for some species is given in Table 49.1.

A cyanide disaster can have long-term consequences on a freshwater system (Lakatos *et al.*, 2003). Cyanide can be in run-off water from fire fighting and in run-off from burnt-over lands (Barber *et al.*, 2003). Freshwater fish are highly sensitive to free cyanide. Fish mortality can occur at <20 µg/l (Eisler and Wiemeyer, 2004). The lethal level of cyanide in rainbow trout is changed by water temperature and exercise (McGeachy and Leduc, 1988). Young fish can also be sensitive to the effects of cyanide on the thyroid gland (Brown *et al.*, 2004). Cyanide can reduce the number of viable eggs produced by sexually maturing rainbow trout (Lesniak and Ruby, 1982). The toxicology of cyanide has recently been reviewed (Wismer, 2007; Coppock, 2009).

VI. RICIN (CASTOR BEAN)

A. Background

Castor beans (*Ricinus communis*) and ricin have been identified as potential terror agents of terrorism (Coppock, 2009). Castor beans do not give unique clinical signs of intoxication and in waterfowl can be confused with other acute causes of death (Jensen and Allen, 1981). There are inconclusive reports of Canada geese being killed due to castor bean. In Texas, castor bean intoxication could have been the cause of deaths of 10,000 ducks in 1967, and 2,000 ducks in 1969 to 1970 (Jensen and Allen, 1981). The death of 1,673 ducks occurred again in Texas in 1971. A castor bean was found in the examination of one duck. Castor beans were known to have been grown in the area. Although inconclusive, this report does incriminate castor bean ingestion as the cause of death in ducks and geese.

B. Toxicology

Ducks, taken from the area where 2,000 ducks had died in 1969–1970, were examined by diagnostic procedures (Jensen and Allen, 1981). The toxins of *Clostridium botulinum* and pathogenic bacteria were not identified. Catarrhal enteritis was identified with hemorrhage into the intestine. Seed parts suggestive of *Ricinus communis* were found in scrapings of the wall of the proventriculus. Fatty degeneration of hepatocytes was observed.

Ducks were force-fed whole castor beans (Jensen and Allen, 1981). Progressive signs of acute intoxication were passage of blood-streaked mucus, leg paresis, loss of mobility with wings, sitting, prone recumbency, and death. Necropsy findings were whole and fragments of castor beans, and congestion of the liver. Histopathology changes were severe fatty degeneration of hepatocytes, granulocytic infiltration into portal areas, pulmonary congestion and peribronchial hemorrhage; necrosis and hemorrhage were observed in the spleen. These findings suggest that some waterfowl consume castor beans which can result in castor bean intoxication.

The observation that the duck is the most likely to ingest castor beans provides evidence that castor beans could be used by terrorists against wild ducks.

VII. PESTICIDES

A. Background

Birds and other wildlife are nontarget species for insecticides (Schafer *et al.*, 1983). Observations from the registered and illegal uses of insecticides show that insecticides could be used in acts of terrorism against a targeted wildlife population.

Vertebrates can be nontarget species when insecticides are applied according to the registered label (Marian, 1983; Hunt *et al.*, 1995; Allen *et al.*, 1996; Poppenga, 2007). Vertebrate deaths have been reported from illegal and off-label use of insecticides. Models can estimate the probability of bird deaths resulting from field application of pesticides (Mineau, 2002). Birds, mammals, fish, and other aquatic organisms can be nontarget species from pesticides that enter water systems from surface water.

1. Pesticides

Waterways and flood areas can be contaminated with pesticides, especially insecticides, and result in bird deaths (Hunt *et al.*, 1995; Elliott *et al.*, 1996). Granules of carbofuran in flooded fields have been incriminated as the cause of duck deaths and the cause of death in raptors scavenging dead or debilitated ducks. Illegal use of insecticides resulting in the death of wildlife has also been reported (Allen *et al.*, 1996). The toxicology of insecticides has recently been reviewed (Gupta, 2006, 2007; Poppenga, 2007).

VIII. CONCLUDING REMARKS AND FUTURE DIRECTION

Wildlife generally has not been considered in the emergency management of terrorist events using chemical agents. The need to manage problem wildlife at the remote investigation site for wreckage from the World Trade Center brought attention to this aspect of emergency management planning. Regardless of the cause, wildlife can be intoxicated when chemicals and physical agents are released into the environment. Disruption of ecotourism can be an objective of terrorists. Emergency planning needs to include terrorist attacks on wildlife especially in areas where wildlife is concentrated during breeding and migration, and where wildlife congregates during the nonbreeding season. Shooting of the mountain gorillas hopefully is not an indication that these events will become more common (Jenkins, 2008).

CHAPTER 50

Toxicokinetics of Chemical Warfare Agents: Nerve Agents and Vesicants

HARALD JOHN, FRANK BALSZUWEIT, KAI KEHE, FRANZ WOREK, AND HORST THIERMANN

I. INTRODUCTION

Despite the long lasting history of chemical warfare agents (CWAs) first used in large quantities during World War I at the beginning of the 20th century, vesicants and nerve agents especially still represent a commonly admitted threat for military and civilian communities. Therefore, effective medical countermeasures and state-of-the-art medical care are mandatory prerequisites to take the threat of poison attacks seriously. Rising interest in effective treatment of sulfur mustard and especially nerve agent poisoning leads national and governmental authorities to continue programs of medical defense against toxicants. The development and continuous improvement of therapy relies on intensified knowledge of provoked pathophysiological effects, toxicology, and toxicokinetics. The latter is important when understanding the reactivity of poisons in organisms at the molecular level. Awareness of predominant metabolism and efficient elimination processes is essential for the design of a therapeutic regimen of poisoning. For example, the development of protective scavengers is a current challenge in nerve agent defense research.

The toxicokinetic profile of a chemical warfare agent in mammalian organisms depends on numerous factors, including the nature of the poison, route of exposure, and species differences. Sophisticated study design, modern technical and analytical monitoring tools as well as reliable data from literature are indispensable quality criteria which should be met when performing toxicokinetic studies. The present chapter is focused on this topic. For guidance, we will comment on the structure of this chapter to provide the reader with an impression of the content.

We will first introduce the reader to typical invasion processes of exogenous poison. The anatomy of exposed areas of the body is discussed emphasizing interactions with nerve agents and vesicants invading on similar routes following common absorption principles. Afterwards both classes of chemical warfare agents are discussed individually in two subsequent main sections. Organophosphorus (OP) nerve agents are distinguished in terms of their physicochemical properties and toxicity as well as invasion and distribution processes *in vivo* which are of relevance for toxicokinetic characteristics. Subsequently, special focus is given to the basics of elimination and metabolism describing the phenomena of detoxification and concentration decrease at the molecular level. Enzymatic hydrolysis as well as binding to proteins and enzymes is discussed in comprehensive detail. A few comments on excretion will finish this ''journey through the poisoned body''. The last sections are dedicated to concentration–time profiles exemplarily selected for typical routes of nerve agent exposure followed by short introductions to predictive mathematical toxicokinetic models as well as to most modern bioanalytical methods allowing poison quantification and metabolite identification.

Vesicants including sulfur mustard and lewisite are the subject of the second main part of this contribution. Coherences of invasion and distribution are presented and the major processes of metabolism and elimination caused by binding to proteins and more prominently to DNA are discussed. The part closes with comments on current bioanalytical approaches.

This chapter provides readers with a comprehensive overview of the toxicokinetics of OP nerve agents and vesicants.

II. OVERVIEW OF INVASION PROCESSES OF CHEMICAL WARFARE AGENTS

Toxicokinetics is a subfield of toxicology which studies how, how fast, and to what extent toxicants are absorbed by, distributed in, metabolized by, and eliminated from the bodies of living organisms. These processes are dependent on multifaceted conditions, such as the species and gender of intoxicated organism, the physicochemical properties of the toxicant (e.g. hydrophobicity, charge, and molecular weight), its dose and concentration as well as chemical reactivity and stability. Furthermore, the route of exposure is a crucial parameter impacting the effectiveness of incorporation and time for distribution within the organism.

Elaboration of toxicokinetic data of chemical warfare agents is essential for designing effective antidotes, improving first aid, and optimizing therapeutic regimen and medical care. It has to be considered that data obtained from *in vitro* or *in vivo* animal studies need careful extrapolation to humans which, at least, requires sophisticated mathematical models to consider basic interspecies differences (Langenberg *et al.*, 1997; Levy *et al.*, 2007; Sweeney *et al.*, 2006; Worek *et al.*, 2007).

For controlled toxicological studies the poison is most often administered subcutaneously (s.c.), intravenously (i.v.), or intramuscularly (i.m.) whereas more realistic scenarios of chemical warfare agent uptake are percutaneous (p.c.) through unprotected skin, by inhalation of aerosols and vapor (inhal.), or by ingestion (p.o.) of contaminated food and drinks.

Such exposure events that lead to poison uptake and its distribution in the organism are part of the invasion process whereas all steps causing poison decrease, e.g. elimination by degradation, metabolism, or excretion, are part of the evasion process. For a better understanding of the pathophysiology and toxicokinetics of chemical warfare agents, an overview of the routes of poison incorporation follows in the next section with a special emphasis on OP nerve agents and vesicants.

A. Percutaneous Uptake by Contact with Skin

The total skin surface of an adult human is approximately 1.8 m^2 which is quite small when compared to the adsorptive surface of the lungs (100 m^2) and the gastrointestinal tract (GIT, 200 m^2) (Marquardt *et al.*, 1999). The primary function of the skin is to protect the organism against exogenous compounds present in the external environment. Nevertheless, percutaneous uptake is the predominant route of poisoning by nonvolatile and rather lipophilic agents, e.g. VX, which exhibits low vapor pressures thus making respiratory incorporation quite unlikely except the inhalation of aerosols (Czerwinski *et al.*, 2006). In the case of vesicant agents, such as sulfur mustard and lewisite, the skin is both a target organ, susceptible to severe local effects, and a pathway for absorption of the agent, leading to its distribution and subsequent systemic effects. The protective skin architecture is provided by a sophisticated and effective barrier built of two main components, the outer epidermis and the underlying inner dermis.

1. Epidermis

The epidermis is composed of various consecutive complex layers including stratum corneum (horny layer), stratum ludicum (clear layer), stratum granulosum (granular layer), and stratum germinativum (germinative layer), which itself is subdivided into stratum spinosum (spinous or prickle layer) and stratum basale (basal layer) (Marquardt *et al.*, 1999). For a general overview of percutaneous poison uptake we will now restrict the introduction to the horny and germinative layer which are in this sense the most significant epidermal strata.

The stratum corneum is the upper stratum of the epidermis which consists of several avascular, stratified cellular layers of dead keratinocytes characterized by a quite low water content (5–10%) thus making the surface hydrophobic and reducing its permeability for polar compounds. This layer, which exhibits the character of a multilayer lipid membrane, is the major barrier hindering hydrophilic substances from invading the organism. Penetration through the horny layer is most often a passive diffusion-controlled process following Fick's law in a good approximation. Because of their lipophilic nature liquid nerve agents as well as vesicants can readily penetrate the horny layer and absorption is much more effective than for their corresponding vapors (Blank *et al.*, 1957). To estimate the capability of nerve agents for skin penetration the octanol:water partition coefficient (listed as dimensionless log P, Table 50.1) can be used which correlates to the lipophilicity of the agent (Czerwinski *et al.*, 1998, 2006). This parameter can also be used to predict the distribution of OP agents in other tissues and blood (Langenberg *et al.*, 1997; Sweeney *et al.*, 2006).

TABLE 50.1. Physicochemical properties of VX and G-type OP nerve agents

Agent	CASNo.	NATO code	MW (g/mol)	Boiling point (°C)	Vapor pressure (mbar)	Water solubility (g/l)	Hydrolysis rate, $\tau_{1/2}$ (h)	log P(–)
Cyclosarin	329-99-7	GF	180.2	239	0.059 (25°C)[a]	3.7 (20°C)	n.a.	1.04[b]
Sarin	107-44-8	GB	140.1	158	2.8 (20°C)	Miscible	39 (pH 7.0)	0.30[b]
Soman	96-64-0	GD	182.2	190	0.53 (25°C)	21 (20°C)	45 (pH 6.6)	1.82[b]
Tabun	77-81-6	GA	162.1	237–240	0.049 (20°C)	98 (25°C)	8.5 (pH 7.0)	0.38[b]
VX	50782-69-9	VX	267.4	298	$9*10^{-4}$ (20°C)	30 (20°C)	1000 (pH 7.0)	2.09/0.68[b]

log P – octanol:water partition coefficient; MW – molecular weight; n.a. – not available; $\tau_{1/2}$ – period of half-change for hydrolysis. Data are taken from Munro *et al.* (1999) unless otherwise noted,

[a] Committee on Gulf War and Health (2004)

[b] Czerwinski *et al.* (2006)

Skin permeation velocity of toxic substances increases with (1) decreasing molecular weight, (2) increasing lipophilicity, (3) increasing area of contaminated skin, and (4) decreasing thickness of contaminated horny layer. Thickness of the stratum corneum varies depending on the area of the body and the species. Heavily strained areas, e.g. sole of foot, palm of the hand and insides of the fingers, are protected by a 400–600 µm horny layer in humans whereas arms, legs, and body are covered by a barrier of 8–15 µm thickness. Since the first incidents of chemical warfare in World War I, it was observed that skin areas with a very thin horny layer, in particular the axillae and the scrotum, were most susceptible to the effects of sulfur mustard. Effects in these regions, even though they were rarely exposed to the liquid agent, were severe.

Considering thickness and structural composition of the skin (e.g. diameter and density of hair follicles as well as number of cell layers) is essential for choosing appropriate *in vitro* models for skin penetration. Pig skin exhibiting a stratum corneum thickness in the ear of 8.6–28 µm is similar to human abdominal skin (5.5–40 µm) thus representing a good model to study the agent's permeation as recently shown for VX (Vallet *et al.*, 2008). The best model for p.c. *in vivo* exposure studies is thought to be the pig after inner ear-skin application of the agent (Chilcott *et al.*, 2003). In contrast to persistent VX, the major fraction (98%) of a small amount of liquid sarin, which was applied p.c. to six human subjects, evaporated quite rapidly without passing the skin as caused by its high volatility (Marrs *et al.*, 2007). In the presence of organic carrier solutes skin penetration may be enhanced as shown for VX dissolved in isopropanol thus doubling permeation velocity for animal and human skin *in vitro* (Dalton *et al.*, 2006). At the least, experimental conditions should also consider that moisture, heat, and abrasions force transfer and uptake of permeable chemical warfare agents (Blank *et al.*, 1957).

The germinative layer located under the stratum corneum consists of living keratinocytes responsible for the regeneration and proliferation of the skin. It exhibits the highest metabolic activity of all strata towards endogenous and exogenous substances initiating binding to carboxylesterases (CaE or CarbE). Nevertheless, sorption to cutaneous tissue may form a depot as demonstrated for sarin (Fredriksson, 1958; Satoh and Hosokawa, 2006), which explains the delayed local fasciculation of muscles observed after s.c. administration of nerve agents (Czerwinski *et al.*, 2006).

2. Dermis

The dermis (corium) consists of connective vascularized tissue composed of collagen, elastic and reticular fibres anchoring sweat and sebaceous glands, and hair follicles. Capillaries pervading the dermis and hypodermis (subcutis, located beneath the dermis) allow systemic distribution of toxic compounds once they have passed the epidermis. Therefore, percutaneously incorporated poison may be directly transported by the circulation to any compartment of the organism or it may be temporarily retained within the skin layers. In addition, it might penetrate with first-order kinetics into subcutaneous tissues and muscles thus creating a poison depot for delayed release (Chilcott *et al.*, 2005; Wolthuis *et al.*, 1981). If nerve agents are kept in fat tissue metabolic degradation appears rather unlikely thus maintaining an active release system (Sweeney *et al.*, 2006). Correspondingly, Van der Schans and colleagues (2003) reported that it took more than 3 h to reach a maximum concentration in blood of the rather lipophilic VX after percutaneous administration of $1 \times LD_{50}$ to hairless guinea pigs (see Percutaneous uptake, below).

B. Respiratory Uptake by Inhalation

1. Airways and Absorption

Gaseous poison or aerosols of toxic substances are incorporated following inhalation and contact with the respiratory tract. This appears to be the predominant route of poison intake for volatile G-type nerve agents, e.g. tabun, sarin, and soman exhibiting relatively high vapor pressures (Table 50.1). The respiratory tract is composed of three main compartments distinguishable by the areas and organs involved in the breathing process: (1) the extrathoracic or nasopharyngeal compartment comprising mouth, nose, and throat (pharynx), (2) the tracheobronchial compartment containing the voice box (larynx), windpipe (trachea), and right and left bronchi to convey air to the (3) alveolar or pulmonary compartment of the lung, which includes the bronchioles connecting the bronchi with the lobes of the lung and the alveoli. The sacs and cavities of the alveoli allow diffusion-controlled oxygen and carbon dioxide exchange in the blood of pulmonary capillaries (blood–air barrier). This diffusion process follows Fick's law whereupon the diffusion layer exhibits a thickness of 0.4–2.5 µm composed of surfactant and alveolocapillary membranes. The lung of a healthy adult person possesses 300–400 million alveoli spread over a surface of approximately 100 m^2 (Marquardt *et al.*, 1999).

Depending on the physicochemical nature of the toxic gas or aerosol, absorption will take place at different areas of the respiratory tract. Apart from the chemical properties the size of particles and aerosols will also affect the targeted area. Materials with diameters less than 2 µm will reach the alveoli whereas larger ones (about 20 µm in diameter) are retained in the upper respiratory areas of throat and bronchi thus protecting gas exchange in the lung.

a. Absorption in the Upper Respiratory Tract

In contrast to highly lipophilic compounds, hydrophilic toxicants characterized by higher water solubility, e.g. hydrogen chloride and fluorine, are primarily adsorbed by the wet mucosa membranes of the throat and trachea in the upper respiratory tract. This is also the primary area for G-agent first-order absorption according to higher water

solubility (Marrs *et al.*, 2007; Sweeney *et al.*, 2006). Early studies have shown that 80–90% of inhaled nerve agent sarin was readily absorbed by humans when exposed to concentrations ranging from 7 to 43 $mg \cdot min/m^3$ (Oberst *et al.*, 1959, 1968). Slightly lower rates (approximately 70%) were obtained for sarin applied to guinea pigs, dogs, and monkeys (Benschop and de Jong, 2001). More aggressive and reactive agents, e.g. vesicants or pulmonary agents, may harm by chemical burn provoking time delayed inflammation and scarring in these areas. Langenberg and colleagues (1998b) found significant effects of sulfur mustard in the upper respiratory tract of guinea pigs caused by a large fraction of the inhaled agent.

The nasal system of guinea pigs is more complex than that of other mammalian species, including humans. In those species the fraction of agent absorbed or deposited in the upper respiratory system may be smaller. Consequently, the middle and lower respiratory systems are likely to be exposed to a larger portion of the agent.

b. Absorption in the Middle Respiratory Tract

Toxic agents with medium water solubility, e.g. chlorine and sulfur dioxide, reach further into the middle respiratory tract being absorbed in the bronchi and its junctions. As a result, elevated excretion of mucus, coughing, and bronchoconstriction will lead to heavy dyspnea. The respiratory tube system from the nose to the bronchioles is lined with ciliated epithelium allowing transportation of the mucous layer produced by cells of the bronchial system from the lung into the oral cavity. This mechanism, which may be supported by coughing, allows the binding and removal of dust particles thus protecting the alveoli from deterioration. However, once the mucus has reached the oral cavity spontaneous swallowing might provoke poison transport into the digestive tract of the stomach and gut (gastrointestinal tract, GIT).

It is the middle respiratory tract that apparently is the most significant target in the case of respiratory exposure to sulfur mustard. Local effects, such as the formation of pseudomembranes, may both be life-threatening in the acute phase of illness after poisoning and cause long-term disability. The systemic absorption from the middle respiratory tract has never been investigated separately. However, findings from Langenberg's guinea pig model (Langenberg *et al.*, 1998b) suggest that the largest fraction of inhaled sulfur mustard is deposited in that particular area.

c. Absorption in the Alveoli

Several toxic compounds particularly gases of low water solubility or increased lipophilicity, e.g. carbon monoxide, hydrocyanic acid, nitrogen oxides, phosgene and further inorganic and organic irritants, reach the alveoli and are absorbed by the blood. Aggressive and reactive compounds inhaled may damage the epithelial cells of the alveoli causing the liberation of edema fluid which fatally prolongs the diffusion layer and minimizes the permeability for oxygen and carbon dioxide, finally leading to unconsciousness or death by asphyxia (toxic lung edema). Only very few hints exist for OP-induced lung edema following a yet unraveled mechanism of action (Lainee *et al.*, 1991; Delaunois *et al.*, 1992; Niven and Roop, 2004). Similarly, in the case of sulfur mustard exposure the alveoli are only of minor importance in terms of target organ for both local effects and systemic absorption (Langenberg *et al.*, 1998b).

2. Nose-Only Exposure Model for Controlled Respiratory Uptake in Animal Studies *in Vivo*

To elucidate the velocity of nerve agent absorption via the respiratory tract, which may take seconds to hours, Langenberg and colleagues (1998a) designed an apparatus that challenged guinea pigs by nose-only exposure with a constant stream of nerve agent vapor in air held for several minutes. As guinea pigs were not ventilated artificially sublethal doses of soman and sarin (0.4–0.8 LCt_{50}) were applied thus enabling the affected respiratory frequency and minute volume to be monitored. A typical concentration–time profile detected for C(–)P(+)-soman after administration of C(±)P(±)-soman is characterized by a discontinuous curvature reflecting concentration increase during absorption and concentration decrease by elimination (see Respiratory uptake (nose-only model), below). For more detailed technical data on the nose-only apparatus the reader is referred to Langenberg *et al.* (1998a, b) and Benschop and de Jong (2001). The same group also used this apparatus in subsequent experiments to investigate the respiratory uptake of vesicant agents, results of which will be discussed in Respiratory uptake, below.

C. Gastrointestinal Uptake by Ingestion

When drinking poisoned liquids or ingesting contaminated food, toxicants will be incorporated and directly transferred from the mouth, through the gullet (esophagus) into the stomach and bowels (intestine) representing the GIT where transfer into the circulation occurs. The physiological function of the digestive tract includes intake, breakdown, transport, and digestion of food and creation of waste (excrement). Food ingredients as well as toxicants and their digested (metabolized) forms are either absorbed through the walls of the intestine for entering the circulation or eliminated by feces. The surface of the small intestine of an adult human covers more than 200 m^2 and is made up of a huge number of 4–5 million, tiny, finger-like projections (villi and microvilli) covering the surface of the mucous membrane. In contrast the resorbing areas of large intestine (0.5–1 m^2), stomach (0.1–0.2 m^2), rectum (0.04–0.07 m^2), and oral cavity (0.02 m^2) are explicitly smaller due to the lack of villi and are thus of minor importance for poison uptake. Uptake by diffusion through the lipid layers (hydrophobic molecules) and pores (small hydrophilic molecules) of the intestinal mucosa following Fick's law are the most common processes. Nevertheless, facilitated

diffusion and active transport based on affinity binding of the toxicant to carrier molecules might also occur (Marquardt *et al.*, 1999). The processes of pinocytosis and phagocytosis are unlikely for small chemical warfare agents. Following intestinal uptake into the circulation, toxicants are directly transported to the liver, where further metabolism by cytochrome P450 enzymes may happen. This is of essential relevance for toxification of OP pesticides, including parathion, chlorpyrifos, diazinon, and dimethoate, which are transferred into their more toxic oxon derivatives (Butler and Murray, 1997; Furlong, 2007). Liver and intestine are supposed to play very important roles in the elimination of free soman as deduced from rabbit studies at high soman dosing (Li *et al.*, 2002).

In contrast, for sarin it has been shown that the kidney is more important for detoxification than the liver (Little *et al.*, 1986). However, only very limited research efforts have been undertaken to characterize this route of poison uptake for nerve agents (Sidell and Groff, 1974; Sim *et al.*, 1971). Quite high lethal oral doses were reported for tabun (rabbit: 16,300 μg/kg; rat: 3,700 μg/kg; dog: 200 μg/kg) and sarin (rat: 550 μg/kg) indicating extensive hydrolysis in the GIT (Marrs *et al.*, 2007). Very few investigations of toxicokinetics of vesicants after ingestion have been conducted. Nevertheless, this route of exposure is supposed to result in a significant systemic absorption of the agent. The rationale behind this apparent ''blind spot'' of toxicokinetic investigation might be the rarity of gastrointestinal exposure under conditions of military operations. Moreover, should a GIT exposure occur, the local rather than the systemic effects would be life-threatening. See Invasion, below, for an in-depth discussion.

In contrast, ample work has been done with OP pesticides meeting the concerns of more than 500,000 deaths worldwide per year caused by accidental and suicidal ingestion (Eddleston *et al.*, 2005, 2008a, b).

D. Uptake by Intravenous Injection

Intravenous (i.v.) uptake of chemical warfare agents is highly unlikely for realistic exposure scenarios except perhaps for the contamination of open and bleeding wounds. Nevertheless, numerous scientific studies investigating the toxicity and therapeutic treatment of CWA made use of this route of administration. The rationale behind this design is to constitute a defined amount of poison in the blood which is immediately systemically distributed by the circulation to the target compartments under conditions of 100% bioavailability. Therefore, i.v. studies are of undoubted relevance to elaborate systemic toxicity and to characterize the impact on the whole organism. It was shown that sarin was distributed in the central nervous system within 20–30 s after i.v. administration to mice (Waser and Streichenberg, 1988). Therefore, poison acts without delayed uptake caused by diffusion or permeation through skin, tissue, and organs which would increase the extent of metabolic degradation and hydrolysis. The latter processes reduce the amount of toxic agents and hamper direct correlation to poison concentrations in the blood. As demonstrated by Van der Schans and colleagues (2003) only 2.5% bioavailabilty was observed in guinea pigs resulting from a 7 h permeation period after percutaneous adminstration of VX.

As outlined in the sections above, the amount of incorporated poison and its fraction interacting with target molecules to induce more or less specific toxicological effects may vary drastically even under controlled conditions of administration. However, monitoring of quantitative concentration–time profiles of original poison and its metabolites is needed to elucidate the kinetic behavior and to unravel pathophysiological mechanisms. Due to the broad range of such essential variations causing a number of uncertainties, many *in vivo* and *in vitro* studies have been performed during the last 30 years of sophisticated research on protection against OP compounds (OPC) and blister agents. The following sections will summarize the most important consolidated findings underlining the current status of toxicokinetics of the most prominent CWAs: nerve agents and vesicants.

III. NERVE AGENTS

A. OP Compounds as Nerve Agents

For important background information addressing the history, synthesis, basic chemical data, decontamination, toxicity, military use, and political relevance of nerve agents we refer readers to a number of textbooks, reports, and monographs which go beyond the scope of this toxicokinetic contribution (Augerson, 2000; Committee on Gulf War and Health, 2004; Franke, 1977; Koelle, 1963; Langford, 2004; Marrs *et al.*, 2007; Munro *et al.*, 1999; Richardt and Blum, 2008). Nevertheless, in the following section selected chemical and physicochemical properties are considered which are of importance for understanding the toxicokinetic behavior of OP compounds.

Well-known representatives of nerve agents are cyclosarin (*o*-cyclohexyl methylphosphonofluoridate, GF), sarin (isopropyl methylphosphonofluoridate, GB), soman (1,2,2-trimethylpropyl methylphosphonofluoridate, GD), tabun (ethyl dimethylphosphoramidocyanidate, GA), VX (*S*-2-diisopropylaminoethyl *o*-ethyl methylphosphonothioate), and Russian VX [*o*-isobutyl *S*-(*N*,*N*-diethylaminoethyl)methyl phosphonothioate, RVX, RV] (Table 50.1; Figure 50.1). Apart from these substances a large number of additional OP toxicants with high structural similarity are known on the experimental and laboratory level especially when including pesticides for civilian use. However, the above-mentioned compounds are the most prominent nerve agents in the literature. This fact is obviously due to political instructions for national security and defense programs considering historical development, large-scale production, and intended

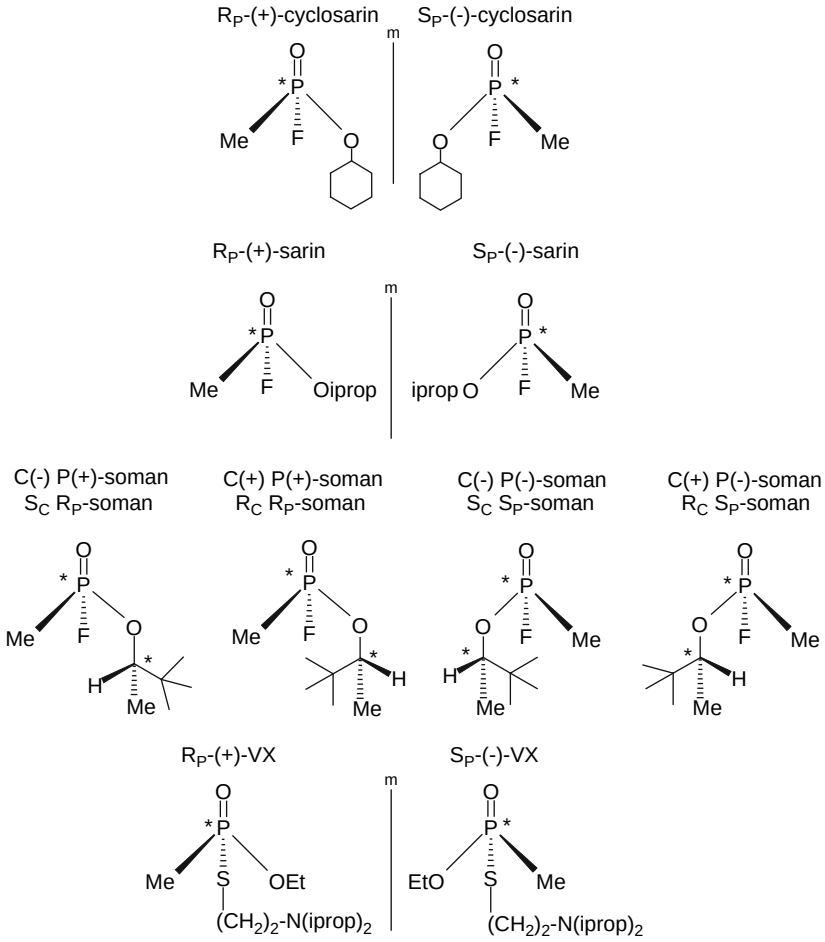

FIGURE 50.1. Structures of stereoisomeric OP nerve agents. Chirality was assigned according to the rules of Cahn, Ingold and Prelog (Cahn *et al.*, 1966; Prelog and Helmchen, 1982) considering oxygen of the P=O bond with minor priority compared to alkoxy substituents (Quin, 2000). Empirically found opticity is, according to Benschop and de Jong (1988), correlated to compounds obtained from stereoselective synthesis (Li *et al.*, 2001). Chirality emerged as a crucial parameter for toxicokinetic properties. S_P-isomers (P(−)-forms) of illustrated G-agents (cyclosarin, GF; sarin, GB; soman, GD) are characterized by higher toxicity combined with higher stability against hydrolyzing mammalian wild-type enzymes as their corresponding R_P-isomers, P(+)-forms (Table 50.3).

military use focusing on the agents most likely relevant for chemical threat. Soman, for example, was produced in large amounts especially by the former Soviet Union thus menacing the Western world during the Cold War period. Therefore, toxicokinetic studies on nerve agents are mainly restricted to sarin, soman, and VX. In addition, following United Nations inspections in Iraq in the 1990s, which revealed the weaponizing of cyclosarin, some studies on the toxicokinetic properties of this agent were also conducted.

1. Physicochemical Properties

If present in high purity all nerve agents are colorless and odorless liquids characterized by different vapor pressures thus causing either quite rapid evaporation with increasing inhalational risk (e.g. G-type agents) or relative high resistance abating p.c. absorption (e.g. V-type agents and cyclosarin) (Table 50.1). Therefore, visual or sensory recognition by smell or taste is nearly impossible.

a. Water Solubility

Water solubility is a crucial parameter affecting the toxicological potency of a compound. Solubility of non-hydrolyzed nerve agents is fundamentally determined by the hydrophobicity and extent of organic substituents. On the one hand, hydrophilic compounds exhibiting high water solubility are less effectively absorbed by skin in the absence of organic carrier solutes but they are easily distributed once they have reached aqueous biological fluids. Therefore, skin penetration of less lipophilic sarin (miscible in water) is not favored whereas nerve agents of significant lipophilicity with low water solubility (VX: 30 g/l; GF: 3.7 g/l, Table 50.1) penetrate the skin and other hydrophobic biological membranes and mucosa quite unhampered (Winkenwerder, 2002). Nerve agent transfer into blood and its systemic distribution are limited thus potentially provoking accumulation in fatty tissue. Nevertheless, noncovalent binding to carrier proteins of the circulation, e.g. γ-globulin and albumin, may support the systemic transport of hardly water-soluble compounds in blood as expected for VX (Vallet *et al.*, 2008) and as commonly known for endogenous fatty acids or exogenous drugs (John and Schlegel, 1999; Weiss *et al.*, 2008; Li *et al.*, 2007). Table 50.1 denotes the corresponding measures of solubility in water.

b. Octanol:Water Partition Coefficient

The lipophilicity of nerve agents and their expected partition behavior are characterized by the octanol:water

partition coefficient (log P). This parameter is often used as an estimate for the tendency of the toxicant to bioaccumulate in the organism. Furthermore, it is helpful to predict penetration of skin and distribution between tissue and blood (Czerwinski *et al.*, 1998, 2006; Poulin and Krishnan, 1995). The log P for the more polar sarin was determined to be 0.30 whereas this measure for lipophilic VX is 2.09 documenting a 50 times increased lipid solubility. However, this ratio might be slightly different when considering inconsistency of data from the literature (Table 50.1). Table 50.1 summarizes log P values of selected nerve agents.

c. Hydrolysis

In aqueous media, nerve agents undergo nonenzymatic hydrolysis which is accelerated by quite acidic and basic pH values (Franke, 1977). Hydrolysis substitutes primarily the reactive leaving group of the OP compound by a hydroxy group thus making the molecule more soluble (Figure 50.2). After cleavage of diisopropyl ethyl mercaptoamine (DESH) from the phosphorus atom of VX (Figure 50.1) the remaining ethyl methylphosphonic acid exhibits a water solubility of 180 g/l: six times higher than VX itself (Munro *et al.*, 1999). Depending on the pH, the alkoxy-group of VX might also be cleaved from the phosphorus atom. Hydrolysis of the reactive electronegative leaving group, which is essential for the primary toxicity (inhibition of acetylcholinesterase), deactivates the molecule thus reducing its toxicity dramatically. The major hydrolysis product of sarin is isopropylmethyl phosphonic acid (IMPA) which is about 10,000 times less toxic than its precursor when administered orally to rats (Munro *et al.*, 1999). IMPA is also the most prominent metabolite of sarin produced *in vivo* (Little *et al.*, 1986). Dramatically increased rates of hydrolysis under acidic conditions are presumably the most important reason for extraordinarily high LD_{50} values found in laboratory animals after oral administration of nerve agents (Marrs *et al.*, 2007). Table 50.1 summarizes hydrolysis rates expressed as periods of half-change in aqueous solutions of nerve agents near neutral pH.

d. Chirality

Typical production batches of nerve agents formerly intended for military use are mixtures of enantiomers obtained from nonchiral synthesis (Figure 50.1). Sarin, cyclosarin, tabun, and VX consist of mixtures of two enantiomers each of which differs in the chirality at the central phosphorus atom thus enabling rotation of linearly polarized light clockwise [P(+)-enantiomers] or anticlockwise [P(−)-enantiomers] (Figure 50.1). In contrast, chirality of soman appears more complex based on two chiral centers, which reside at the phosphorus atom, P(+) and P(−), and additionally in the pinacolyl moiety, C(+) and C(−). Hence, soman occurs in four stereoisomeric conformations as two pairs of diastereomers: P(+)C(+), P(+)C(−), P(−)C(+), and P(−)C(−) (Figure 50.1). To denominate stereoisomers of nerve agents the experimentally found rotational direction of light is typically provided whereas assignments according to the R and S nomenclature are rare. Therefore, Figure 50.1 summarizes both absolute configurations and related optical activities of these most common nerve agents. Chirality was assigned according to the established rules of Cahn, Ingold, and Prelog (Cahn *et al.*, 1966; Prelog and Helmchen, 1982) considering oxygen of the P=O bond with minor priority to alkoxy substituents (Quin, 2000). Empirically found opticity is, according to Benschop and de Jong (1988), correlated to compounds obtained from stereoselective synthesis (Li *et al.*, 2001).

It is well known that chirality of OP nerve agents causes significantly differing toxicological properties determining poison elimination by hydrolysis and kinetics of enzyme inhibition (Benschop and de Jong, 1988). Therefore, special attention should be paid to the corresponding stereoisomers when elaborating toxicokinetics. A number of studies took care of these conformational differences by administration of pure stereoisomers (Benschop and de Jong, 2001) or by enantioselective detection and quantification of poison molecules (Li *et al.*, 2003a, b; Reiter *et al.*, 2007; Spruit *et al.*, 2001; Van der Schans *et al.*, 2003; Yeung *et al.*, 2007). Different techniques were established to produce pure or at least enriched enantiomers of nerve agents, e.g. (1) synthesis by use of chiral adducts subjected to reactions of defined strereochemical outcome, (2) fractional crystallization, chromatographic separation, and isolation of mixed enantiomers, (3) stereoselective binding to serine-esterases, e.g. α-chymotrypsin, and (4) stereoselective enzymatic hydrolysis by phosphorylphosphatases (chemoenzymatic preparation) (Benschop and de Jong, 2001; Li *et al.*, 2001).

Stereoselective enzymatic degradation of nerve agents is also a current issue in developing both novel noncorrosive decontamination systems and new therapeutics making use of recombinant mutated enzymes optimized for fast and exhaustive hydrolysis of most toxic isomers (Blum and Richardt, 2008; Furlong, 2007; Ghanem and Raushel, 2005; Li *et al.*, 2001; Tsugawa *et al.*, 2000).

2. Toxicity

OP compounds, especially nerve agents, represent a class of highly reactive compounds undergoing nucleophilic substitution of their leaving group [e.g. F, CN, S-$(CH_2)_2$-N(^{i}prop)$_2$] (Figure 50.1) by nearly irreversible coupling to nucleophiles, e.g. strongly polarized hydroxyl groups in amino acid side chains or OH functions in aqueous media (Figure 50.2). Toxic effects are mainly due to derivatized enzymes which were subjected to this reaction.

Although most toxicological studies were performed as animal studies a few data for humans exist obtained from (1) military volunteers exposed to nonlethal doses of sarin (NRC, 1982, 1985), (2) accidentally intoxicated industrial

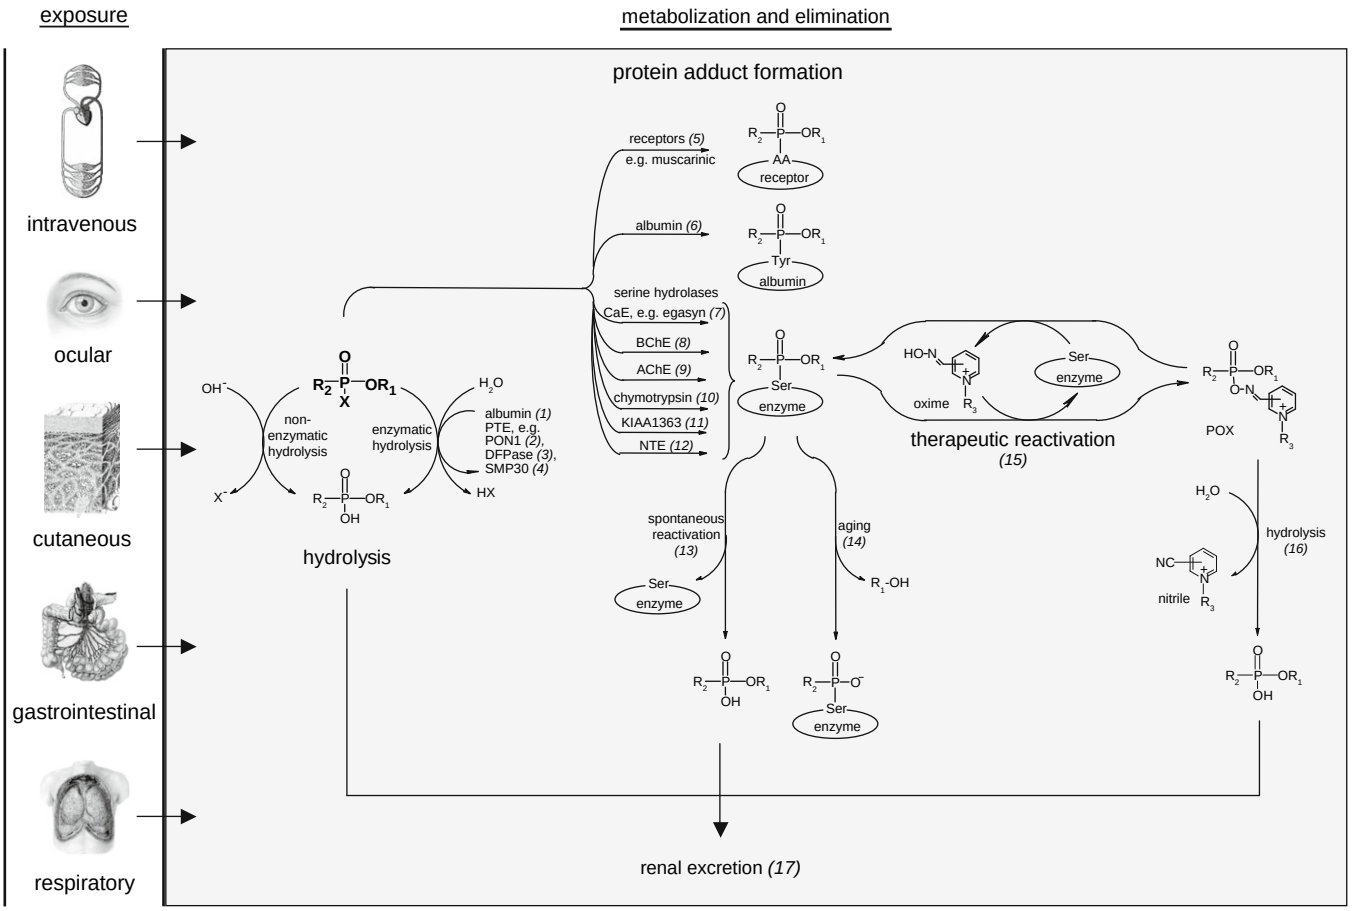

FIGURE 50.2. Elemental steps of toxicokinetics of OP nerve agents in mammalian organisms. OP nerve agents are incorporated following different routes of exposure. Whereas G-agents are predominantly uptaken by the respiratory tract via inhalation the V-agents follow mainly percutaneous invasion. Once the poison has reached the circulation it is distributed systemically causing poisoning of the central and peripheral nervous system by inhibition of acetylcholinesterase. Several processes of metabolism (e.g. enzymatic and nonenzymatic hydrolysis) and elimination (e.g. formation of adducts by binding to proteins and multiple serine esterases followed by marginal spontaneous reactivation and more prominent aging) reduce the amount of circulating poison. Therapeutic causal intervention by oximes reactivates cholinesterases under liberation of a toxic phosphoryloxime intermediate (POX) which itself undergoes immediate hydrolysis. Hydrolyzed nerve agents emanating from these chemical conversions are excreted by kidney more prominantly than by the liver. AA, amino acid; AChE, acetylcholinesterase; BChE, butyrylcholinesterase; CarbE, carboxylesterase; DFPase, diisopropyl fluorophosphatase; KIAA1363, acetyl monoalkylglycerol ether hydrolase; NTE, neuropathy target esterase; PON1, paraoxonase 1; POX, phophoryloxime; PTE, phosphotriesterases; $R_{1/2}$, organic substituents, e.g. methyl, cyclohexyl, isopropyl; Ser, serine; SMP30, senescence marker protein 30; Tyr, tyrosine; X, nucleophilic leaving group, e.g. F, CN, $(CH_2)_2$-N(^{i}prop)$_2$. workers (Duffy *et al.*, 1979), and (3) poisoned civilians affected by the terrorist attacks in Tokyo in 1995, Matsumoto in 1994, and Osaka (Morita *et al.*, 1995; Okumura *et al.*, 1996; Tsuchihashi *et al.*, 1998). For detailed data on these events readers are referred to the reports of the Committee on Health Effects Associated with Exposures During the Gulf War (2000).

a. Inhibition of Acetylcholinesterase

Phosphylation of the OH moiety of the serine residue, being part of the catalytic triad in the esteratic center of acetylcholinesterase (AChE), represents the pathophysiologically most important reaction resulting in enzyme deactivation. Inhibition of AChE was proven to be the predominant major reaction *in vivo* that causes death

within minutes in mammals, insects, and other species depending on acetylcholine (ACh) mediated signal transduction. Maxwell *et al.* (2006) found compelling arguments that inhibition of AChE by nerve agents is the primary mechanism of OP toxicity. They correlated the median lethal doses (LD_{50}) of highly toxic nerve agents determined from rats after s.c. administration with the corresponding bimolecular rate constants of AChE inhibition determined *in vitro* using a probit model for interpreting the mathematical relationship.

AChE is present in the nervous system, where it is most important for toxic effects, and on the surface of red blood cells (RBC) where its biological function is still unknown. Inactivation of AChE hinders the degradation of the neurotransmitter ACh in the synaptic cleft which is of major importance for the regulation of pre- and especially postsynaptic effects. Rising ACh concentrations cause permanent overstimulation of muscarinic (subtypes m1–m5) and nicotinic receptors of effector cells leading to cholinergic crisis and ultimately to death. Clinical symptoms of poison-induced AChE inhibition include (1) muscarinic effects (e.g. miosis, bradycardia, increased secretion of urine, saliva, tears and sweat, bronchoconstriction, and increased gastrointestinal motility) as well as (2) nicotinic effects (e.g. muscular weakness, twitching and tremors, elevated blood pressure, and tachycardia), and (3) central effects (e.g. headache, impaired memory and alertness, anxiety, insomnia, and most importantly respiratory depression and paralysis). Death is caused by respiratory failure as elicited by flaccid paralysis of respiratory muscles, and bronchoconstriction together with increased bronchial secretion and central respiratory depression (Costa, 2006). Liquids or vapors from these agents can cause death within minutes after exposure. Table 50.2 summarizes LD_{50} values for different species and routes of administration for the most common nerve agents. The relative lethality found in animal studies is as follows: VX > soman > cyclosarin > tabun (Sidell and Borak, 1992).

Local irritations do not occur except fasciculation of underlying muscles after percutaneous uptake or miosis caused by excessive stimulation of muscarinic receptors on papillary sphincter muscles resulting from ocular exposure (Dabisch *et al.*, 2008; Sidell and Borak, 1992). However, clinical symptoms related to massive restraints in the motoric and respiratory abilities require the reduction of AChE activity by more than 70% as deduced by Thiermann and colleagues (2005) from murine diaphragm experiments. Accordingly, acute cholinergic syndromes in humans were observed not until the red blood cell AChE activity was inhibited by 75–80% (Sidell and Borak, 1992). Clinical symptoms may depend on the gender of species as recently documented for the extent of miosis after vapor exposure to soman, cyclosarin, and VX (Dabisch *et al.*, 2008). Male rats were approximately three times less sensitive than female rats whereas minipigs show the reversed effect. This phenomenon is referred to different activities of ocular AChE and butyrylcholinesterase (BChE) (Dabisch *et al.*, 2008).

b. Additional Targets with Potential Clinical Relevance

As binding to proteins others than AChE reduces the amount of free OP poison these alternative targets are to be considered when discussing toxicokinetic behavior. Albumin (Black *et al.*, 1997a, b; Williams *et al.*, 2007; Li *et al.*, 2007, 2008), receptor/channel complexes (Pope, 1999), the muscarinic and nicotinic ACh receptors (Bakry *et al.*, 1988; Silveira *et al.*, 1990), and other secondary serine-hydrolase targets were shown to be chemically modified by OPCs thus changing their functionality into potential pathophysiological situations by affecting noncholinergic mechanisms (Casida and Quistad, 2005; Duysen *et al.*, 2001). In general, chemical modification of those proteins and enzymes requires quite high OPC concentrations which are far beyond the lethal dose of nerve agents thus being of minor relevance for acute poisoning scenarios (Pope, 1999). In contrast, elaboration of the toxicity of the much less toxic OP pesticides is more and more focused on these additional targets investigating, for example, genetic susceptibility, developmental toxicity and neurotoxicity, delayed neurotoxicity, and organophosphate-induced delayed polyneuropathy (OPIDP, a distal sensorimotor axonopathy) (Balali-Mood and Balali-Mood, 2008; Costa, 2006). OPIDP is associated with the OP-inhibited enzyme neuropathy target esterase (NTE) that undergoes an essential aging process of phosphylated NTE (elimination of an organic substituent from the central phosphorus atom, Figure 50.2) (Costa, 2006). However, Gordon and colleagues (1983) demonstrated that despite NTE inhibitory potency of the nerve agents tabun, soman, and VX no OPIDP was induced. Nerve agent concentrations inhibiting half of the NTE activity were about three orders of magnitude higher (micromolar range) than for AChE (nanomolar range).

B. Elemental Steps of Nerve Agent Toxicokinetics

Although toxicological characterization in terms of mean acute lethal doses for different species is available for all nerve agents, detailed and extensive toxicokinetic data are rare in the literature for most of them with the exception of soman and sarin (Benschop and de Jong, 2001). For VX and in particular GF only a very limited extent of data is obtainable (Reiter *et al.*, 2007; Van der Schans *et al.*, 2003).

1. Invasion

Supplementary to the more common discussion on invasion processes given in the introductory overview (Section II) we now present some recent findings on skin penetration models. Nerve agents are readily absorbed through skin, eyes, lung, and the gastrointestinal tract. Depending on the individual vapor pressures of nerve agents different routes

of poison uptake are preferred. G-agents, e.g. sarin, soman, and tabun, are quite volatile thus limiting percutaneous uptake due to significant evaporation from the skin (approximately 98% for sarin). In contrast VX exhibits high persistency because of its vapor pressure being 3,000 times lower than that of sarin (Marrs *et al.*, 2007) (Table 50.1). Therefore, percutaneous uptake is most prominent for V-agents characterized by an absorption rate of at least 600 µg/cm^2 per hour as shown for VX after inner ear-skin droplet application of 2 LD_{50} (Figure 50.2) (Chilcott *et al.*, 2005). Nevertheless, VX penetration through skin is characterized *in vitro* by a significant lag time of at least 1 h and a moderate penetration rate of about 1–2%/h (Vallet *et al.*, 2008). These data are in accordance with early studies on human subjects demonstrating that 3 h after percutaneous exposure of VX only 0.4–0.6% was incorporated (Vallet *et al.*, 2008). *In vitro* studies using guinea pig and human skin as well as dermatomed, abdominal skin from domestic pig revealed significant differences for VX permeability. Highest permeability was observed for the skin of the guinea pig whereas no significant differences in the penetration kinetics were found for human and pig skin taken from the animal's flank (Dalton *et al.*, 2006). Therefore, pig skin may serve as an appropriate *in vitro* model for human skin (Vallet *et al.*, 2008) as already established in pharmaceutical research making use of the Franz-type diffusion cell (Franz, 1975; Simonsen and Fullerton, 2006). To predict *in vivo* human VX absorption via skin the human full-thickness abdominal skin was demonstrated to be appropriate also (Vallet *et al.*, 2008).

2. Distribution

Once nerve agents have penetrated into the blood, systemic distribution including crossing of the blood–brain barrier causes toxicity within the central and peripheral nervous system. In mouse and rat studies it has been shown that within 1 min after sublethal single dose i.v. administration of sarin the nerve agent was present in many other compartments, e.g. diaphragm, heart, lung, and brain, and in much higher concentrations in plasma, liver, and kidney (Little *et al.*, 1986; Waser and Streichenberg, 1988). Similar results were observed for VX (Chilcott *et al.*, 2005) and soman, which was also found in cerebrospinal fluid with 100% bioavailability after i.v. bolus injection to pigs (Göransson-Nyberg *et al.*, 1998; Augerson, 2000). For mathematical description Langenberg and colleagues (1997) calculated related tissue/blood partition coefficients for the distribution of soman in guinea pigs revealing approximately a measure of 2 for liver and 1.1 for kidney whereas lung and brain were calculated to be 0.5. Nevertheless sarin present in the brain did not severely inhibit AChE activity in cortex (60%), striatum (40%), and hippocampus (56%) within 24 h (Whalley and Shih, 1989). In contrast soman has caused more severe inhibition in these three areas (83–99%) lowering the synaptosomal sodium-dependent, high affinity choline uptake (SDHACU) within the first 4 h in the hippocampus, whereas from 2–24 h after exposure SDHACU increased in the striatum (Whalley and Shih, 1989). The differences are thought to be due to, e.g. different aging rates and different AChE-inhibiting potencies. However, brainstem and midbrain were influenced neither by sarin nor by soman. It is assumed that active sites of the brain are affected primarily according to increased metabolic action, vasodilation, and increased blood flow in these regions (Scremin and Jenden, 1996). In contrast, 50% inhibition of AChE activity in brain was associated with death or serious signs of toxicity in mice after subcutaneous exposure (Duysen *et al.*, 2001).

The presence of sarin, soman, and VX in the brain demonstrates the necessity for antidotes, especially AChE reactivators, to be capable of passing the blood–brain barrier, representing a current scientific challenge (Lorke *et al.*, 2008; Okuno *et al.*, 2008).

Concentrations of sarin found in the different tissues were decreased by 85% within 15 min after exposure (Committee on Gulf War and Health, 2004). Apart from the active sarin its inactivated metabolite IMPA was found in these tissues in a predominant ratio indicating rapid *in vivo* metabolism as discussed in the next section. Soman was mainly accumulated in the lung after s.c. challenge of rats (Shih *et al.*, 1994) and disappeared from blood and liver largely 2 min after i.p. administration of $0.75 \times LD_{50}$ to mouse (Nordgren *et al.*, 1984). In contrast, VX is more persistent *in vivo* than sarin or soman causing delayed systemic distribution after s.c or p.c. administration. This fact provoked maximum concentrations of VX in blood several hours after p.c. exposure of guinea pigs (Van der Schans *et al.*, 2003).

As outlined in the toxicity section above the toxicological mechanism of action of nerve agents is based on the chemical reactivity of the nucleophilic leaving group. Therefore, metabolism in terms of degradation by hydrolysis and binding to proteins determines bioavailability and elimination processes thus regulating toxicity.

3. Metabolism and Elimination

Enzymes from plasma and tissue are mainly responsible for hydrolysis of OP compounds producing derivatives of phosphoric and phosphonic acids characterized by high water solubility and nearly no toxicity. *In vivo* studies in mice have shown that within 1 min after injection 50% of sarin was rapidly metabolized generating both free hydrolyzed IMPA and bound IMPA attached to esterases by phosphylation as predominant in plasma (Little *et al.*, 1986). In contrast, V-type agents are more stable against enzymatic hydrolysis but may undergo additional metabolism pathways including oxidation of nitrogen and/or sulfur (Van der Schans *et al.*, 2003). Due to the slow reaction velocity of nonenzymatic hydrolysis this process is of minor importance for the elimination kinetics of nerve agents under physiological conditions near neutral pH. As listed in Table 50.1 periods of half-change for nerve agent hydrolysis range from approximately 9 h for tabun to 6 weeks for VX. In contrast, the velocity of enzymatic hydrolysis in blood is much faster thus defining the rate-determining step for poison elimination.

a. Enzymatic Hydrolysis

Enzymes which hydrolyze OP compounds cleave the reactive leaving group of OP compounds, e.g. F or CN, from the central phosphorus atom thus initiating nucleophilic substitution by a hydroxyl group. Hydrolyzing enzyme activity is present in plasma and to a much higher specific extent in kidney and liver thus enabling removal of toxicants from the circulation (Sweeney *et al.*, 2006). Early studies using an isolated hydrolyzing rat liver enzyme demonstrated degradation efficacy for nerve agents in the following order: sarin > soman > tabun (Little *et al.*, 1989). Metabolites deactivated by hydrolysis are nearly nontoxic and easily eliminated from the organism via renal excretion (Munro *et al.*, 1999). Despite this capability to hydrolyze OP compounds the original physiological functions and substrates of the different enzymes vary significantly not allowing assignment to a specific uniform class of enzymes (Figure 50.2). The following section presents the most important enzyme systems relevant for nerve agent metabolism.

i. Phosphotriesterases (PTE)

Based on historical development, different, sometimes inconsistent, nomenclatures were used to assign enzymes that lead to the degradation of OPs. Meanwhile, the

International Union of Biochemistry has introduced systematic rules and numbering classifying the relevant enzymes in the following way: hydrolases (group 3), which cleave ester links (group 3.1) which may represent carboxylester hydrolases (group 3.1.1) or phosphoric triester hydrolases, PTE (group 3.1.8). The latter group contains aryldialkylphosphatase (EC 3.1.8.1) and diisopropyl fluorophosphatase (EC 3.1.8.2) (Vilanova and Sogorb, 1999). As these enzymes catalyze substrate cleavage without self-inhibition they are representatives of A-esterases.

- *Paraoxonase 1 (PON1)*

Paraoxonase (PON1, EC 3.1.8.1, formerly EC 3.1.1.2) is a calcium-dependent liver-expressed P450 phosphotriesterase belonging to the class of A-esterases with broad substrate specificity towards various lactones and esters, which is present in liver and in plasma associated with high-density lipoprotein particles (Vilanova and Sogorb, 1999). P450 isozymes and variants are well known for their dual role in organophophorus metabolism. On the one hand, they bioactivate less toxic phosphorothioates to their highly toxic oxon derivatives via monooxygenase activity. On the other hand, they hydrolyze and detoxify OP insecticides, such as paraoxon, chlorpyrifos, and diazinon by dearylation, as well as nerve agents, e.g. sarin and soman, by defluorination (Davies *et al.*, 1996; Furlong, 2007; Kiderlen *et al.*, 2005) (Figure 50.2).

The original physiological function of PON1 is involved in inactivation of toxic products produced by lipid oxidation (Draganov and La Du, 2004). In addition, PON1 hydrolyzes OP compounds, such as sarin, cyclosarin, tabun, and soman, thus accomplishing enzymatic protection against nerve agents in the circulation (Amitai *et al.*, 2006; Billecke *et al.*, 2000) (Figure 50.2). Levels and genetic variability of PON1 influence sensitivity to these specific substrates caused by Glu/Arg point mutation at position 192 of the human wild-type enzyme (Billecke *et al.*, 2000; Dragonov and La Du, 2004). The Glu^{192} mutant is about three times more active than the Arg^{192} variant (Draganov and La Du, 2004). Despite these differentiations rather low catalytic activity of recombinant human PON1 expressed in HEK cells occurred as a moderate stereoselective process characterized by preferred cleavage of the less toxic P(+)C(+)-enantiomer of soman (k_{cat} 1,030 min^{-1}) which happens twice as fast as for the other three stereoisomers (Yeung *et al.*, 2007, 2008) (Table 50.3). In accordance, Nordgren *et al.* (1984) used an enzyme isolated from swine kidney they called phosphoryl phosphatase to incubate purified enantiomers of soman *in vitro*. Whereas the less toxic P(+)-isomers (R_PS_C- and R_PR_C-soman) were hydrolyzed quite rapidly ($\tau_{1/2} = 2$ min under experimental conditions) both highly toxic P(−)-forms (S_PS_C- and S_PR_C-soman) showed much higher stability ($\tau_{1/2}$ 60–120 min). It appears likely that the predominant enzyme isolated was PON1. In contrast, no stereoselective effects in the catalytic PON1 mediated hydrolysis of cyclosarin and soman using recombinant mammalian material from *E. coli* were detected by Amitai *et al.* (2006). Nevertheless, no (+)-cyclosarin was detected in hemolyzed blood samples taken from swine after i.v. administration of racemic (±)-cyclosarin whereas the (−)-cyclosarin enantiomer was present for at least 20 min after exposure (Reiter *et al.*, 2007). However, the authors suppose that this phenomenon was due to rapid enzymatic and nonenzymatic hydrolysis in blood *in vivo* but do not discuss the potential role of PON1 explicitly. Yeung *et al.* (2007) conclude that variations in the catalytic efficiency of hPON1 towards soman enantiomers are due to differing Michaelis-Menten constants (K_M) characterizing the stability of the enzyme–substrate complex. Consequently, site-directed mutagenesis of recombinant enzymes could cause reduction of K_M for the more toxic enantiomers improving its hydrolyzing capacity. A 10–100-fold increase in catalytic activity of wild-type hPON1 is expected to allow effective protection against incorporated nerve agents (Amitai *et al.*, 2006; Rochu *et al.*, 2007; Masson and Rochu, contribution to this handbook). Accordingly, engineering efficient recombinant human PON1 is a current challenge in medical defense research intending to yield an effective and biocompatible therapeutic applicable for a wide range of nerve agents exhibiting sufficient activity towards all relevant isomers (Amitai *et al.*, 2006). Figure 50.2 displays its role in metabolism and elimination.

- *Senescence Marker Protein-30 (SMP30)*

The human senescence marker protein-30 (SMP30 or regucalcin, primary Swiss-Prot accession No. Q15493) is expressed by hepatocytes and plays a role in the regulation of plasma membrane Ca^{2+}-pumping activity with the potential to rescue cells from high calcium level-induced apoptosis (Kondo *et al.*, 2004). The expression of this liver enzyme decreases with aging. SMP30 was originally identified in rat liver and exhibits a 65% amino acid similarity to PON1 in rat species but does not show catalytic PON1 activity towards the hydrolysis of paraoxon (Billecke *et al.*, 1999). In contrast, mouse and rat SMP30 hydrolyze diisopropyl phosphorofluoridate (DFP), an OP compound related to nerve agents (Kondo *et al.*, 2004). Therefore, it may be speculated that this enzyme is also involved in nerve agent metabolism in the liver. This assumption is supported by the findings of Little *et al.* (1989) who observed hydrolysis of sarin, soman, and tabun by an enzyme derived from rat liver homogenate.

- *Diisopropyl Fluorophosphatase (DFPase)*

Some enzymes were isolated but not unambiguously identified from swine kidney which exhibit diisopropyl fluorophosphate (DFP)-cleaving activity and were thus denominated diisopropyl fluorophosphatase (DFPase) in the older literature (Nordgren *et al.*, 1984). This DFPase belongs to the class of A-esterases acting on DFP, tabun, and organofluorophosphates, e.g. cyclosarin, sarin, and soman. Nowadays, most recent studies define DFPase (EC 3.1.8.2, formerly assigned as EC 3.8.2.1) as a calcium-dependent phosphotriesterase identified in squid *Loligo vulgaris* exhibiting

Rate constants for inhibition of most prominent serine esterases by nerve agents differ significantly depending on the nature of enzyme, its originating species and stereoisomers of the agent. It appears obvious that for the depicted G-agents and VX the P(−)-isomers are much more effective inhibitors than their corresponding P(+)-forms. In contrast hydrolysis of the latter isomers happens faster than of the toxic P(−)-variants. Hydrolytic stability is determined by PON1 activity characterized by its catalytic constant k_{cat} (last column). Both properties (inhibition and hydrolysis) cause higher toxicity for P(−)-agents *in vivo* selectively (Table 50.4)

AChE – acetylcholinesterase; BChE – butyrylcholinesterase; CarbE – carboxylesterase; CVX – Chinese VX; hr wt – human recombinant wild-type; k_{cat} – catalytic constant for hydrolysis; PON1 – paraoxonase 1; VR – Russian VX

unique structural properties (Blum *et al.*, 2006). This squid-type DFPase has not yet been identified in mammalian organisms.

ii. Non-Mammalian Enzymes

Several other enzymes from bacteria (e.g. phosphotriesterases or OP hydrolases, OPH, from *Pseudomonas diminuta* or *Flavobacterium* sp. and OP acid anhydrolase, OPAA, from *Alteromonas* sp.) or squid (diisopropyl fluorophosphatase, DFPase) are also known to detoxify nerve agents thus being of interesting relevance for novel noncorrosive decontamination approaches (Blum and Richardt, 2008) but do not play a role in the toxicokinetics of OP compounds in mammalian species so far (Amitai *et al.*, 2006; Rochu *et al.*, 2007; Masson and Rochu, contribution to this handbook). However, potential application as detoxifying antidotes remains a future challenge.

b. Formation of Protein Adducts

Besides direct enzymatic hydrolysis of nerve agent substrates numerous additional proteins are present in the

organism that allow covalent binding to OP compounds thus contributing to detoxification of the poison load (Figure 50.2). Serine esterases are especially predominant targets of nerve agents mostly undergoing irreversible adduct formation. Nevertheless, more than 75% of the serine hydrolases (B-esterases) present in plasma and tissues are essentially unknown with respect to their interaction with OPCs (Casida and Quistad, 2005).

i. Carboxylesterase

Ubiquitous glycosylated carboxylesterases (CarbE, EC 3.1.1.1), formerly named ali-esterases, are B-esterases belonging to the multigene enzyme superfamily of α/β hydrolases (Hosokawa and Satoh, 2006; Satoh and Hosokawa, 2006). In principle this class of isozymes plays a major role in pharmacokinetics by hydrolytic biotransformation of exogenous ester-drugs and ester-prodrugs. However, their physiological function still remains unclear (Satoh and Hosokawa, 2006).

Carboxylesterases are very important serine-esterases in plasma of nonhuman species that bind nerve agents with broad specificity thus representing the major determinant for *in vivo* detoxification especially in mice and rats (Maxwell and Brecht, 1991) (Figure 50.2). Apart from catalytic CarbE activity in plasma it is also found in several tissues and organs including brain, lung, kidney, and liver thus realizing poison decrease not only in the circulation (Satoh *et al.*, 2002). Microsomal liver carboxylesterase 1, which is also referred to as egasyn, is loosely associated with a β-glucuronidase (BG) complex (Fujikawa *et al.*, 2005). Organophosphate-inhibited egasyn causes cleavage of this complex liberating elevated quantitites of BG into the circulation. Thus BG plasma activity may serve as a sensitive biomarker for OP poisoning (Inayat-Hussain *et al.*, 2007).

Interaction of CarbE with nerve agents follows a kinetic of first order characterized by inhibition of CarbE at the active site serine residue described by a bimolecular rate constant, k_i (Maxwell and Brecht, 2001). For noncharged nerve agents (e.g. sarin and soman) the k_i of rat serum CarbE was found to be $>10^6\,M^{-1}min^{-1}$ whereas cationic substrates (e.g. VX) are converted with poor reactivity ($k_i < 10^4\,M^{-1}min^{-1}$). This specificity is explained by the electrostatic characteristics of the large active site containing only a few cation-Π bonding and anionic residues (Maxwell and Brecht, 2001; Satoh and Hosokawa, 2006).

Covalent binding of OP compounds to CarbE is considered as an irreversible reaction of 1:1 stoichiometry resulting in adducts that do not age (Maxwell and Brecht, 2001). In contrast, spontaneous pH-dependent reactivation liberates the enzyme thus being accessible for additional detoxification although only to a very limited extent. At physiological pH *in vitro* spontaneous reactivation (specified by the rate constant k_r) is a poison-dependent process showing significantly different velocities depending on the size of the inhibitor (steric demand). Whereas reactivation of VX- and sarin-inhibited rat serum CarbE was faster (k_r $4.2*10^{-3}$ min^{-1} and $3.8*10^{-3}$ min^{-1}) reactivation for soman and VR was about ten times slower (k_r $0.44*10^{-3}$ min^{-1} and $0.52*10^{-3}$ min^{-1}) (Maxwell and Brecht 2001). In addition to these differences CarbE exhibits stereoselective properties. Nordgren and colleagues (1984) have demonstrated that CaE from swine liver bound to the less toxic P(+)C(+)-enantiomer of soman (R_CR_P) most efficiently whereas conversion of highly toxic P(−)C(+)-soman (R_CS_P) happens much more slowly (Table 50.3). This fact indicates that degradation of incorporated nerve agents is primarily targeted on less toxic enantiomers thus minimizing the protective effect of CaE. In contrast to G-agents no prominent enantiomeric selectivity was evident for sequestration of VX after p.c. administration (Van der Schans *et al.*, 2003).

Consequently, striking species-dependent differences in the LD_{50} values of OP compounds are mainly due to the variable concentrations of endogenous CarbE acting as a bioscavenger in blood (Table 50.2). Whereas mice and rats exhibit high CarbE activities, activity in rabbits and guinea pigs appears moderate. In contrast, dogs and primates as well as humans possess only little or no CarbE (Benschop and de Jong, 2001). These relations are obvious from s.c. soman LD_{50} values obtained from mice and guinea pigs after inhibition of CarbE (10.2 and 12.2 μg/kg) which were very similar to those obtained for dogs and primates without inhibition (9.1 μg/kg and 13.0 μg/kg) (Maxwell and Brecht, 1991). In contrast, the corresponding soman s.c. LD_{50} values for untreated CarbE are much higher for mice (113 μg/kg) and guinea pigs (28.2 μg/kg) (Maxwell and Brecht, 1991). For these reasons guinea pigs are most often used today for *in vivo* toxicity and toxicokinetic studies intending to examine a small laboratory animal model predictive for humans. Missing CarbE activity in humans hinders efficient detoxification *in vivo* thus keeping the toxic effect of nerve agents (Due *et al.*, 1993). Consequently, the value of CarbE as a bioscavenger for effective clearance of OP poison from the circulation has led to therapeutic concepts which were applied successfully to rodents and nonhuman primates (Maxwell and Brecht, 2001). Feasibility for human organisms has still to be demonstrated.

ii. Acetyl Monoalkylglycerol Ether Hydrolase (AcMAGE)

KIAA1363 (primary Swiss-Prot accession No. Q6PIU2) is a human serine hydrolase derived from acetyl monoalkylglycerol ether hydrolase (AcMAGE, EC 3.1.1.) present in brain, lung, heart, and kidney which is involved in tumor cell invasiveness and lipid metabolism but can also detoxify OP compounds by hydrolysis of the reactive leaving group following transient binding to the active site serine residue (Nomura *et al.*, 2008) (Figure 50.2). This capability has been demonstrated for the pesticide chlorpyrifos and its more toxic oxon derivative. Therefore, activity towards nerve agent hydrolysis is expected but has not been shown so far.

iii. Acetylcholinesterase (AChE)

Acetylcholinesterase (AChE, EC 3.1.1.7) from vertebrates is deduced from a single gene (Massoulie, 2002) expressing identical enzyme primary structures on the surface of red blood cells (RBC), in synapses and different organs. Inhibition of this serine-esterase causes the most prominent pathophysiological effects determining severity of poisoning. Nevertheless, covalent binding to AChE can also be considered as a step in poison elimination (Figure 50.2) which reduces the amount of incorporated poison even though only to a small extent.

AChE activity in whole blood differs significantly among mammalian species thus being of relevance for toxicokinetic consideration. Humans exhibit a quite high AChE activity in blood (651 mU/µmol hemoglobin, Hb) in contrast to smaller values for minipigs (297 mU/µmol Hb) and pigs (190 mU/µmol Hb) (Worek *et al.*, 2008). Furthermore, the bimolecular rate constants (k_i) for nerve agent-induced inhibition of AChE vary among different species. Table 50.3 gives an overview of corresponding inhibition kinetics. The k_i for inhibition of human AChE by VX, for example, is about twice as high as for pig AChE (Aurbek *et al.*, 2006). These differences have to be considered when assessing interspecies toxicokinetic data.

Nerve agents show enantioselective inhibition kinetics when reacting with AChE. Chirality at the central phosphorus atom plays the predominant role affecting higher rates of inhibition for the P(−)-isomers (S_P) than for the P(+)-forms (R_P) (Nordgren *et al.*, 1984). Benschop and de Jong (2001) made great efforts on this stereoselectivity topic and determined the corresponding inhibition rate constants (k_i) for electric eel AChE *in vitro* (Table 50.3). Both P(−)-diastereomers of soman (SpS_C- and S_PR_C-soman) exhibit very high k_i-values ranging from 1.8–2.8*10^8 $M^{-1}min^{-1}$ thus documenting their high toxicity. In contrast, the less toxic P(+)-diastereomers (RpR_C- and R_PS_C-soman) are characterized by k_i-values being 100,000 times smaller (<5*10^3 $M^{-1}min^{-1}$) (Benschop and de Jong, 2001). Similar results were obtained for the sarin enantiomers which differ by a factor of 5,000 revealing a k_i of 1.4*10^7 $M^{-1}min^{-1}$ for the S_P-(−)-form (Table 50.3). In contrast, VX-enantiomers exhibit the smallest differences as obvious from the k_i of the more toxic S_P-(−)-VX (4*10^8 $M^{-1}min^{-1}$) being 200 times higher than for the R_P-(+)-enantiomer (Table 50.3) (Benschop and de Jong, 2001). These k_i data correspond to the order of experimentally determined LD_{50} values in mouse although not considering the impact of hydrolyzing enzymes *in vivo* which also exhibit stereoselective kinetics for hydrolysis (Table 50.4) (Benschop and de Jong, 2001).

AChE on the surface of RBC shows a turnover rate of about 1% per day thus enabling complete exchange within approximately 100 days after exposure (Sidell and Borak, 1992). In contrast, regeneration of synaptic AChE is assumed to be faster reaching 7–10% turnover rates, an estimation that results from animal experiments (Brank *et al.*, 1998; Eddleston, 2008b; Grubić *et al.*, 1981). Both are of importance for the therapeutic monitoring of poisoning as well as for the verification of exposure following bioanalytical methods.

TABLE 50.4. Acute lethality in mice caused by stereoisomers of OP nerve agents

Nerve agent stereoisomers	LD_{50} (µg/kg) mouse
Soman	
C(±)P(±)-soman	156 (s.c.)[a]
C(+)P(+)-soman	<5,000 (s.c.)[b]
C(−)P(+)-soman	<5,000 (s.c.)[b]
C(+)P(−)-soman	99 (s.c.)[a]
C(−)P(−)-soman	38 (s.c.)[a]
Sarin	
(±)-sarin	83 (i.v.)[b]
(+)-sarin	
(−)-sarin	41 (i.v.)[b]
VX	
(±)-VX	20.1 (i.v.)[b]
(+)-VX	165 (i.v.)[b]
(−)-VX	12.6 (i.v.)[b]

Higher rate constants of P(−)-isomers for inhibition of AChE in combination with their minor susceptibility to enzymatic hydrolysis by mammalian phosphotriesterases cause eminently different lethal doses *in vivo*

[a]Benschop *et al.* (1984)

[b]Benschop and de Jong (2001)

- *Spontaneous Reactivation of AChE*

Although inhibition of AChE is mainly discussed as an irreversible reaction, detailed kinetic investigations consider the process of spontaneous reactivation rereleasing an active enzyme and a hydrolyzed detoxified agent (Figure 50.2). Accordingly, rate constants for spontaneous reactivation (k_S) of human AChE adducts are very small as measured for some sarin analogs (0.01–0.052 h^{-1}) whereas the k_S for sarin, cyclosarin, and VX was too small to provoke an experimentally detectable effect (Bartling *et al.*, 2007). Sidell and Groff (1974) demonstrated that spontaneous reactivation of RBC AChE inhibited by VX happens much faster than for sarin which is in accordance with recent human k_s data on V-agents: VX 0.021 h^{-1}; VR 0.039 h^{-1}; and Chinese VX (CVX) 0.171 h^{-1} (Aurbek *et al.*, 2006). However, the toxicokinetic relevance of spontaneous reactivation is obvious from the liberation of free esterase accessible for reinhibition with 1:1 stoichiometry.

- *Aging of AChE*

The cleavage of an organic substituent from the phosphorus atom which is bound to the side chain of an amino acid residue from a protein is described by the aging process

(Figure 50.2). Promoted by specific ionic interactions of neighboring amino acid residues in AChE (and BChE) the remaining P-OH function will undergo deprotonation thus leaving a negatively charged phosphorus moiety (Figure 50.2). Whereas esterase adducts of sarin and soman age by cleaving alkoxy moieties from the central phosphorus atom, tabun loses its dimethylamine moiety (P-N scission) instead of its ethoxy group (Elhanany *et al.*, 2001).

These aged enzyme adducts are not accessible for reactivation by common antidotal oximes thus limiting the success of therapeutic treatment of poisoning with OP compounds. The soman–AChE adduct is known for very rapid aging ($\tau_{1/2} \approx 2$ min) causing severe problems in clinical treatment (Worek *et al.*, 2005). Aging half-lives of phosphylated AChE as well as phosphylated BChE depend on the nature of the inhibiting OP compound. Whereas GF-inhibited AChE exhibits a half-life of 8.7 h the corresponding BChE derivative ages much more rapidly (2.2 h) (Worek *et al.*, 1998). The order of $\tau_{1/2}$ for aging of human AChE–nerve agent adducts was found to be: soman (2 min) < sarin (3 h) < cyclosarin (7 h) < tabun (19 h) < VX (36.5 h) (Worek *et al.*, 2005). Therefore, V-agent-inhibited RBC-AChE ages quite slowly in humans thus allowing therapeutic intervention with oximes for a longer period lasting several days (Sidell and Groff, 1974; Thiermann *et al.*, 2007).

iv. Butyrylcholinesterase (BChE)

Butyrylcholinesterase (BChE, EC 3.1.1.8), formerly named pseudocholinesterase, is synthezised in the liver and present in blood (5 μg/ml), the synapse of neuromuscular junctions, and glia cells and axons of white matter in the brain in numerous allelic variants (Massoulie, 2002). Although BChE has long been considered a nonfunctional vestigial analog of AChE, recent findings point out a possibly more prominent role especially in mouse where the total amount of BChE in the body is ten times as high as AChE (Duysen *et al.*, 2001). Correspondingly, it was observed that the activity of BChE in human whole blood was significantly higher than of AChE (Worek *et al.*, 2008). This led to speculation that BChE may play a backup role for insufficient AChE activity in neurotransmission as deduced from the physiology of AChE knockout mice (Duysen *et al.*, 2001) and may serve as a safeguard against diffusion of ACh into the bloodstream (Massoulie, 2002). However, mandatory experimental evidence is still missing.

Highly glycosylated BChE is a prominent target of OP compounds thus acting as a protective biological stoichiometric scavenger averting damage to neuronal AChE (Kolarich *et al.*, 2008). However, common nerve agents may exhibit significantly differing inhibition rate constants (k_i) for AChE and BChE being approximately in the range from 10^7 to $10^9\,M^{-1}min^{-1}$ (Bartling *et al.*, 2007). Table 50.3 allows comparison of inhibitory potency of nerve agents against AChE and BChE. *In vivo* studies in humans suggest that VX preferentially inhibits RBC AChE much more effectively than BChE resulting in 70% and 20% inhibition, respectively (Sidell and Groff, 1974). In addition to agent-dependent k_i values there is a striking stereoselective dependency in BChE inhibition. The more toxic soman P(−)-enantiomers (S_P) inhibit with preference when compared to their corresponding P(+)-forms (R_P) (Table 50.3) (Nordgren *et al.*, 1984). However, differences are not as pronounced as for AChE but point out effective detoxification properties of endogenous BChE.

Interestingly, no clinical features result from inhibited BChE *in vivo* (Eddleston *et al.*, 2008b). The status of plasma BChE activity is, despite all concerns, a commonly recommended measure to monitor the progress of chemical injury (Eddleston *et al.*, 2008a).

In contrast to all studies on VX toxicokinetics and toxicodynamics published so far, Dorandeu and colleagues (2008) reported an unexpected and not yet clarified phenomenon which emerged after i.v. administration of VX to isoflurane-anesthetized and ventilated swine without oxime therapy. Time-resolved measurement of esterase activities during the experimental period of poison application revealed very fast rebound of BChE activity (from 70% inhibition to 30% within 1 h) while retaining nearly complete inhibition of whole blood cholinesterase. Design and control experiments allowed the following explanations to be excluded: (1) spontaneous reactivation which should happen much more slowly, (2) induced hypoalbuminemia liberating albumin as scavenger competing with BChE, and (3) stimulated release of hydrolyzing enzymes like paraoxonase (PON1). More probably, this observation is explained by an increased biosynthesis of BChE in the liver and/or an elevated release of BChE from other organs (e.g. heart, lung, or pancreas). Future studies will possibly shed more light on this curious and interesting phenomenon.

As total replacement of BChE by synthesis in the liver happens within a couple of weeks, this rather long period allows experimental verification of OP poisoning even when blood samples from poisoned humans are collected with significant delay to the time of exposure (Sidell and Borak, 1992). Therefore, detection of BChE adducts by means of modern mass spectrometric methods is the state of the art technique to prove exposure to OP nerve agents (Carol-Visser *et al.*, 2008; Noort *et al.*, 2006; John *et al.*, 2008).

Nevertheless, the relevant enzyme adducts may undergo the previously described consecutive reactions: spontaneous reactivation and aging. Aging of BChE nerve agent adducts occurs with highly different agent-dependent periods of half-change ($\tau_{1/2}$) as determined *in vitro* by Worek *et al.* (2005). Whereas the soman adduct exhibits typically by far the shortest $\tau_{1/2}$ of less than 1 min, cyclosarin appears much more stable ($\tau_{1/2}$ 2.2 h), followed by tabun ($\tau_{1/2}$ 7 h) and sarin ($\tau_{1/2}$ 12 h). The adduct of VX was the most stable BChE derivative characterized by a $\tau_{1/2}$ of 77 h. Spontaneous reactivation by simple hydrolysis of the serine—phosphorus bond was observed for cyclosarin with a period of half-change of 20 h and much longer times for VX (63 h) and sarin (63 h)

(Worek *et al.*, 2005). These data demonstrate that inhibition of wild-type BChE is nearly irreversible thus lowering the amount of incorporated toxic OP compounds significantly in a stoichiometric manner. Therefore, protection against nerve agent doses of up to $5.5 \times LD_{50}$ (soman and VX) was achieved with exogenous BChE from different species applied prophylactically i.m. to guinea pig, rhesus monkey, and cynomolgus (Lenz *et al.*, 2007). It is supposed that a dose of 200 mg BChE/70 kg will be sufficiently protective in humans against $2 \times LD_{50}$ of soman (Saxena *et al.*, 2008). Based on this valuable protective capacity current efforts are under investigation to use BChE from recombinant (milk of transgenic animals) or natural sources for therapeutic, mainly prophylactic, treatment of nerve agent poisoning (Chilukuri *et al.*, 2005; Huang *et al.*, 2007; Lenz *et al.*, 2007; Lockridge *et al.*, 2005). Plasma half-life of recombinant preparations is significantly prolonged by fusion to albumin (Huang *et al.*, 2008) or pegylation (attachment of polyethyleneglycol) (Chilukuri *et al.*, 2005). In addition, enhanced rapid spontaneous reactivation will deblock the enzyme thus being accessible for subsequent binding to another OP molecule. This strategy is followed by site-directed mutagenesis of BChE leading to a 10^5-fold increase of dephosphorylating activity (Casida and Quistad, 2005). However, feasibility for the human organism has to be shown.

v. Albumin

Although albumin is present in blood in high concentrations (0.6 mM; 41 g/l; 50–60% of total plasma protein) it does not represent an effective scavenger for nerve agent detoxification *in vivo*, hampered by its slow reaction velocity (Li *et al.*, 2008). Nevertheless, sarin and soman bind to albumin at active site tyrosine residue 411 as shown in neat buffered solution and crude human plasma thus inhibiting the enzymatic acylamidase and esterase activity of albumin (Black *et al.*, 1999; Li *et al.*, 2007, 2008) (Figure 50.2). Albumin also exhibits slight hydrolyzing catalytic activity against OP compounds (Vilanova and Sogorb, 1999). Concerning the enantioselectivity in phosphonylation of albumin by soman contradictory results are presented in the recent literature. Whereas Li *et al.* (2008) did not find any enantiomeric preference, Yeung *et al.* (2008) demonstrated that human serum albumin preferentially binds to the less toxic C(±)P(+)-enantiomer. However, the albumin adduct is quite stable in terms of spontaneous reactivation exhibiting extended periods of half-change (6.5 days at 25°C, pH 8.0 and 20 days at 22°C, pH 7.4) and, in addition, does not show any aging phenomena (Li *et al.*, 2007, 2008). Derivatized albumin may thus serve as a biomarker for nerve agent exposure detectable by modern mass spectrometric techniques (Black *et al.*, 1999; Li *et al.*, 2007, 2008; Peeples *et al.*, 2005; Williams *et al.*, 2007).

vi. Muscarinic Receptors

It was shown that tabun, sarin, soman, and VX bind to the muscarinic receptor subtype m_2, leading to the assumption that the ACh binding site is deactivated thus causing potential additional vulnerability (Figure 50.2) (Silveira *et al.*, 1990). Despite the high affinity of nerve agents, pathophysiological effects seem to be of minor relevance when compared to AChE inhibition. However, binding to the receptors will lower the concentration of toxic and reactive OPCs.

4. Excretion

Sarin and its corresponding nontoxic hydrolysis products (IMPA, and additional methyl phosphonic acids) are predominantly eliminated via the kidneys which are thus more important for detoxification than the liver (Little *et al.*, 1986; Waser and Streichenberg, 1988). Urinary excretion happens quite rapidly as demonstrated for single dose s.c. application of sarin, cyclosarin, and soman to rats (Shih *et al.*, 1994). The terminal elimination half-life was found to be 3.7 ± 0.1 h for sarin and 9.9 ± 0.8 h for cyclosarin. In contrast soman showed a biphasic elimination with terminal half-lives of about 18.5 h and 3.6 h (Shih *et al.*, 1994). Maximum peak levels of sarin metabolites in urine were detected 10–18 h after exposure (Minami *et al.*, 1997) and after 2 days hydrolyzed sarin metabolites had been excreted nearly quantitatively (Shih *et al.*, 1994). In contrast, even at 5 days post-exposure soman metabolite recovery was only 62% (Shih *et al.*, 1994). Excretion of soman from blood, liver, and kidney compartments following chemical and enzymatic hydrolysis is considered a first-order elimination process (Sweeney *et al.*, 2006).

5. Concentration–Time Profiles of Nerve Agents in Blood After Various Routes of Administration

Extensive toxicokinetic studies in animal models using rats, marmosets, and guinea pigs were performed for sarin and most often for soman thereby considering individual concentration–time profiles of the different enantiomers (Benschop and de Jong, 2001). The resulting concentration curvatures reflect the combination of the toxicokinetic factors of distribution and elimination by hydrolysis and protein binding as described above in detail. The following section will briefly summarize the most prominent findings considering stereoselectivity and related blood concentration–time profiles. In contrast to lots of OP pesticides, detailed toxicokinetic data on oral uptake of nerve agents are not available. Therefore, we restrict this section to i.v., s.c., p.c., and respiratory exposure. For more details readers are referred to a concise and extensive overview given by Benschop and de Jong (2001).

a. Intravenous Uptake

Direct poison injection into the circulation allows immediate distribution in the organism but also enables undelayed elimination provoked by plasma components. To illustrate these impacts we introduce some fundamental results obtained for some G-agents as depicted in Figure 50.3A (Benschop and de Jong, 2001).

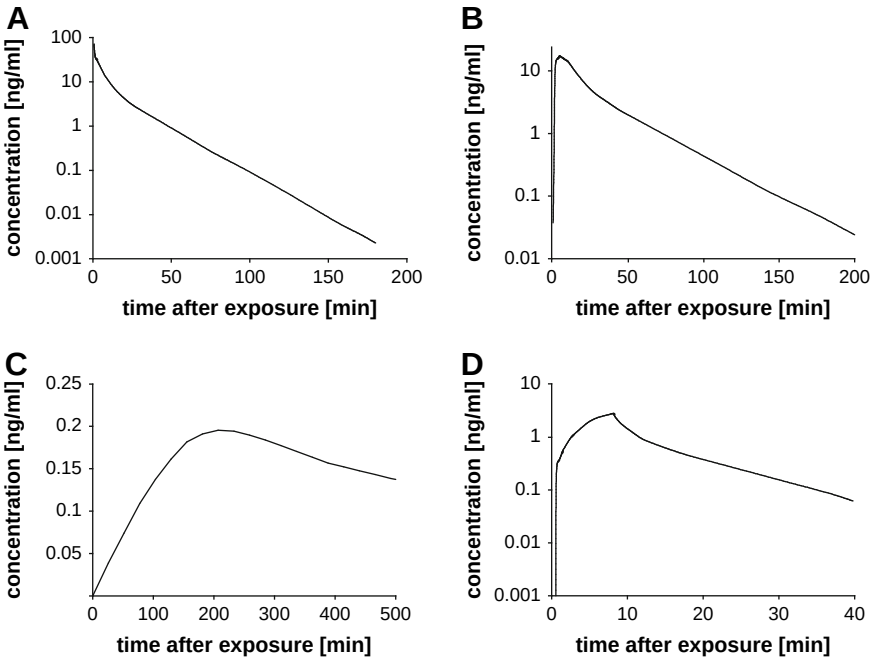

FIGURE 50.3. Concentration–time profiles of highly toxic C(−)P(−)-soman and (±)-VX in guinea pig blood after administration of nerve agents via different routes of exposure. Guinea pigs were challenged with C(±)P(±)-soman (A, B, D) or (±)-VX (C). A: intravenous, 6×LD_{50} (165 µg/kg); B: subcutaneous bolus, 6×LD_{50} (148 µg/kg); C: percutaneous bolus, 1×LD_{50} (125 µg/kg); D: nose-only for soman vapor in air at 0.8×LCt_{50} (48 mg/m^3 for 8 min). Nerve agents were applied to anesthetized, atropinized, and mechanically ventilated animals. Data fits are according to basic studies presented by Benschop and de Jong (2001) (A, B, D) and by Van der Schans *et al.* (2003) (C).

As soon as 0.3 min after i.v. administration of C(±)P(±)-soman to rats, guinea pigs, and marmosets (3–6 LD_{50}) the less toxic C(+)P(+)-enantiomer had been degraded to nondetectable concentration, whereas its diastereomer C(−)P(+)-soman was detectable for a few minutes longer. This rapid decrease of P(+)-enantiomers is caused by fast enantioselective catalytic hydrolysis (Table 50.3). In contrast, the highly toxic P(−)-diastereomers were detected for up to 1 h or longer showing a steep initial concentration decrease caused by systemic diastribution, protein binding, and hydrolysis followed by a more moderate concentration decline during the later elimination phase (Figure 50.3A). CarbE is expected to be the most important scavenger in laboratory animals being essential for nerve agent elimination and causing high species-dependent variations in LD_{50} values (rat > guinea pig > marmoset) which correlate to individual CarbE concentrations (Table 50.2). Resulting concentration curvatures were fitted best by a three-exponential equation (Benschop and de Jong, 2001). Table 50.3A gives a representative example of the concentration–time profile of C(−)P(−)-soman in guinea pig. Corresponding experiments performed with (±)-sarin applied to guinea pigs demonstrated that initial distribution of (−)-sarin happened an order of magnitude faster than P(−)-soman whereas elimination was one order of magnitude slower (Benschop and de Jong, 2001). Reasons for these differences are not clarified yet but are expected to be due to different kinetics of hydrolysis and protein binding causing higher persistence of (−)-sarin.

b. Subcutaneous Uptake

Subcutaneous exposure is often used as a substitute for respiratory exposure due to experimental difficulties in performing controlled inhalational poisoning (Benschop and de Jong, 2001). Exemplarily, we will note a typical study illustrating the s.c. behavior of soman (Figure 50.3B). A C(±)P(±)-soman bolus injection in the scruff of a guinea pig neck resulted in a discontinuous C(−)P(−)-soman concentration–time profile following a mono-exponential equation for the absorption phase and a bi-exponential fit for the distribution phase (Figure 50.3B) (Benschop and de Jong, 2001). The steep initial concentration increase in blood indicated the rapid penetration through capillary vessel walls. Maximum concentration was reached not until 7 min after soman injection yielding in an absorption half-life of about 3.5 min. Despite some certain diastereomer-specific differences [decreased bioavailability of C(+)P(−)-soman] both P(−)-forms exhibited comparable kinetic behavior. Bioavailability was found to be 70–80% when comparing the corresponding area under the curve (AUC) to that of i.v. injection. Very similar to the i.v. characteristics mentioned above, the toxic, more stable, P(−)-isomers were detectable in blood for more than 3 h after exposure whereas the less toxic P(+)-forms of soman could not be determined at any time point. This is attributed to the high hydrolyzing catalytic activity of phosphotriesterases in blood, skin, and other affected tissue (Table 50.3).

c. Percutaneous Uptake

(±)-VX dissolved in isopropanol (1 LD_{50}) was applied p.c. to hairless guinea pigs (Figure 50.3C) (Van der Schans *et al.*, 2003). Typically for p.c. exposure, concentration in blood increased quite slowly reaching its maximum between 3 and 4 h after challenge followed by slight decrease within the next 4 h. However, despite that longer period of monitoring the illustrated concentration–time profile only reflects the distribution and early elimination phase. This slow release is due to the formation of a depot under and in the skin as well as to

reduced hydrolytic degradation of VX *in vivo*. No prominent effects of stereoselective toxicokinetics were observed, therefore depicted curvature reflects the racemic mixture of analytes. Bioavailability of VX at 7 h was found to be quite small when compared to i.v. data, not exceeding 3%. However, the long lasting elimination phase demonstrated high VX persistence in the organism thus resulting in threatening concentrations with acute toxicological relevance for a longer period. Such information is important for therapeutic treatment, pointing out the necessity of long time oxime infusion.

d. Respiratory Uptake (Nose-Only Model)

As pointed out above (see Respiratory uptake by inhalation) respiratory uptake is the most likely route of exposure for G-agents causing 70–80% absorption in the upper respiratory tract. The sophisticated exposure model of the nose-only design applied to guinea pigs challenged the laboratory animals free from potential distortions derived from simultaneous ocular or p.c. uptake as occurring in vapor chambers (Langenberg *et al.*, 1998a).

The toxicokinetics caused by administration of C(±)P(±)-soman to guinea pigs documented a discontinuous process of mono-exponential function for the absorption phase followed by a bi-exponential fit for distribution and elimination (Figure 50.3D). C(−)P(−)-soman was detected in blood as early as 30 s after challenge and a short-term maximum was reached immediately after terminating the 8 min exposure period (Figure 50.3D) (Benschop and de Jong, 2001). Nevertheless, some depot formation might also occur when applying higher doses thus causing maximum levels after completion of exposure. The concentration curvature of C(+)P(−)-soman showed a similar profile but with consistently smaller concentrations which is again due to a higher degree of enzymatic hydrolysis (Table 50.3). In contrast, the less toxic C(−)P(+)-soman was detected in very small concentrations during the exposure phase exclusively whereas C(+)P(+)-soman was not detected at all. Curvatures for S_P-(−)-sarin appeared to be very similar in terms of time for first appearance in blood and for reaching maximum concentration.

These selected representative examples indicate that concentration–time profiles are variable despite common underlying basic chemical reactions of hydrolysis and adduct formation. Despite improving medical treatment of nerve agent poisoning the concurrence of numerous physiological and pathophysiological parameters should be understood. Therefore, establishment of a descriptive and predictive model is of importance for the medical defense of OP compounds.

C. Mathematical Simulation for Prediction of Nerve Agent Toxicokinetics

As is obvious from the huge number of parameters affecting the toxicokinetic behavior, e.g. route of administration, nature of OP compounds, hydrolyzing and bioscavenging enzymes and proteins as well as distinct compartments for distribution and species specificities, mathematical modeling of this complex situation is a big challenge. Nevertheless, based on numerous experimental data on soman toxicokinetics Sweeney *et al.* (2006) introduced a model described by mathematical algorithms that allows the prediction of concentration–time profiles evoked by i.v., s.c., or inhalational soman uptake ($\geq$1 LD_{50}) in common laboratory animals (rat, guinea pig, and marmoset). This physiologically based pharmacokinetic model (PB/PK) benefits from the combination of relevant pharmacokinetic basics and soman-specific experiences realizing both an excellent degree of confidence for theory and laboratory data as well as extrapolation to other species. This concept is a further development of an initial model from the same working group introduced by Langenberg *et al.* (1997). A more detailed description of these models would go beyond the scope of this contribution. Therefore, readers are referred to cited literature.

D. Bioanalytical Techniques Relevant to Toxicokinetics

Elaboration of nerve agent toxicokinetics requires sophisticated analytical tools to detect and, if possible, to quantify the free toxicants as well as adducts with proteins and enzymes. Analysis of OP nerve agents has been performed by capillary electrophoresis (CE), biosensors, matrix-assisted laser desorption/ionization (MALDI) MS, desorption electrospray ionization MS (DESI MS), ion mobility time-of-flight MS (IM-TOF MS), nuclear magnetic resonance spectroscopy (NMR), LC-UV, gas chromatography (GC), and many more techniques (Hooijschuur *et al.*, 2002; John *et al.*, 2008).

1. Determination of Nerve Agents

In contrast to those rather unusual methods, GC coupled to diverse detection systems, e.g. flame ionization detector (FID), nitrogen-phosphorus detector (NPD), flame photometric detector or mass spectrometer, as well as liquid chromatographic (LC) methods, represent the most common techniques for OP determination especially for biological samples. These methods offer high resolution, sufficient limits of detection, good reproducibility, and robust hardware devices. For more detailed information readers are referred to recent review articles (Hooijschuur *et al.*, 2002; John *et al.*, 2008).

However, analysis becomes much more complex when stereoisomers are quantified separately (Figure 50.1). Enantiomers cause identical detector responses in NPD, FID, or MS. Therefore, chiral separation systems are required to overcome these detector limitations. Despite enormous progress in separation media and detector systems within the last two decades the number of reports on chiral analysis of nerve agents valuable for toxicokinetic studies is

still quite small. Chiral separations make use of special chromatographic columns modified with chiral ligands.

Isomers of soman were separated by GC on a Chirasil-L-Val column but lacked baseline separation (Benschop *et al.*, 1981, 1985; Li *et al.*, 2003). In contrast, (+)-sarin and (−)-sarin could be completely separated by the same column (Benschop and de Jong, 2001). A recent study presented a modified method using a Chiraldex γ-cyclodextrin trifluoroacetyl GC-column coupled to an electron impact (EI)-MS which enabled sufficient baseline separation of all four stereoisomers of soman (Smith and Schlager, 1996; Yeung *et al.*, 2008).

Apart from the Chirasil-L-Val method, sarin enantiomers were also separated by a 2D-GC technique on chiral Cyclodex B material prior to NPD monitoring (Spruit *et al.*, 2000, 2001). An additional GC-based approach allowed baseline separation of cyclosarin enantiomers on a GAMMA DEX column monitored by EI-MS (Reiter *et al.*, 2007). VX enantiomers were chromatographed on a Chiracel OD column by LC coupled to an electrochemical detector yielding a lower limit of quantification of about 10 ng/ml blood (Van der Schans *et al.*, 2003). To our knowledge no chiral HPLC-MS separation of OPCs has been described so far although mobile phases are compatible with MS detection.

2. Detection of Enzyme and Protein Adducts of Nerve Agents

In contrast to the measurement of free agent the qualitative detection of protein adducts is a quite novel approach that came about by the overwhelming technical progress in bioanalytical mass spectrometry. Electrospray ionization (ESI) and MALDI as soft ionization methods for mass spectrometric detection are highly valuable for the detection of biomacromolecules like DNA, peptides, and proteins (John *et al.*, 2004, 2005; Schulz-Knappe *et al.*, 2001). Therefore, these technologies are also favorable for the analysis of proteins interacting with nerve agents. Consequently, a number of approaches have been published identifying and characterizing these adducts. Typically, protein and enzyme adducts are first isolated from complex biological matrices (e.g. blood) using affinity chromatographic methods and subsequently they are subjected to enzymatic cleavage by adding selected proteases. Resulting internal peptide cleavage products containing the derivatized (phosphylated) residues are chromatographically separated and analyzed by modern mass spectrometry. Using sophisticated MALDI-MS techniques this general procedure allowed the identification of the albumin adducts of soman (Li *et al.*, 2008) and sarin (Li *et al.*, 2007) as well as the adducts of AChE and tabun, respectively, their aged products (Elhanany *et al.*, 2001). LC-ESI MS was applied to analyze albumin adducts of cyclosarin, sarin, tabun, and soman (Williams *et al.*, 2007) and some OP pesticides (Peeples *et al.*, 2005), BChE adducts of sarin, soman, and VX (Noort *et al.*, 2006; Tsuge and Seto, 2006), and CarbE adducts of OP pesticides (Peeples *et al.*, 2005). For a more detailed description readers are referred to John *et al.* (2008).

This short summary underlines the great importance of modern analytical techniques to unravel pathophysiological situations at the molecular level and to support toxicokinetic studies by enlightening most relevant protein-binding elimination processes.

IV. VESICANTS

A. Sulfur Mustard

1. Overview of Sulfur Mustard

Sulfur mustard is a blistering or vesicating agent that primarily incurs damage at the organs that come into immediate contact with either its liquid or vaporous form. However, severe dermal and respiratory exposure to the agent may also result in the absorption of sulfur mustard that subsequently causes additional systemic damage (Kehe and Szinicz, 2005).

Unfortunately, sulfur mustard has been used in acts of chemical warfare throughout the 20th century, from World War I to the attacks of the former Iraqi regime against Iran and even Kurdish civilians. The simplicity of the agent and its synthesis, combined with devastating medical, psychological, and socioeconomic effects, along with the fact that to the present day, no causative therapy has been established, may convince future aggressors, state and in particular nonstate parties, to use this agent in their attacks. This, in turn, necessitates medical research efforts, including toxicodynamic and toxicokinetic studies, to develop countermeasures against the effects of sulfur mustard. Table 50.5 displays the basic physicochemical properties for sulfur mustard which constitute the fundamental reason for many of its toxicokinetic properties. Data for lewisite, another vesicant agent described in Section IVB, are also shown.

2. Toxicity of Sulfur Mustard

Figure 50.4 depicts the basic chemical mechanism by which sulfur mustard incurs the primary damage to biological molecules which results in subsequent damage to cells, tissues, and organs.

Sulfur mustard forms an intermediate sulfonium ion that further transforms into a carbenium ion, a strong electrophile capable of reacting with nucleophile targets, primarily in DNA and RNA, such as the N7 in guanine (61%) (Ludlum *et al.*, 1994), the N3 in adenine (16%), and the O6 in guanine (0.1%). Even though the latter is considerably less frequent, it is the reason for significant concern as the repair enzyme (O6-alkylguanine-DNA-alkyltransferase) is not capable of reversing this reaction. Therefore, DNA mutation due to mispairing may occur during DNA replication, which is proposed to be the origin of subsequent cancer formation (Ludlum *et al.*, 1986). Because of its bifunctional character, sulfur mustard also forms interstrand

TABLE 50.5. Physicochemical properties of most common vesicant agents

Agent	CAS-No.	NATO code	MW (g/mol)	Melting point (°C)	Boiling point (°C)	Vapor pressure (mbar)	Water solubility (mg/l)	Hydrolysis rate, $\tau_{1/2}$ (h)	log P (–)
Sulfur mustard	505-60-2	HD	159.1	14	217	0.147 (25°C)	0.684[a]	14.7 (20°C)	1.37

log P – octanol:water partition coefficient; MW – molecular weight; n.a. – not available; $\tau_{1/2}$ – period of half-change for hydrolysis. Data are taken from Munro *et al.* (1999) unless otherwise noted

[a]Seidell (1941)

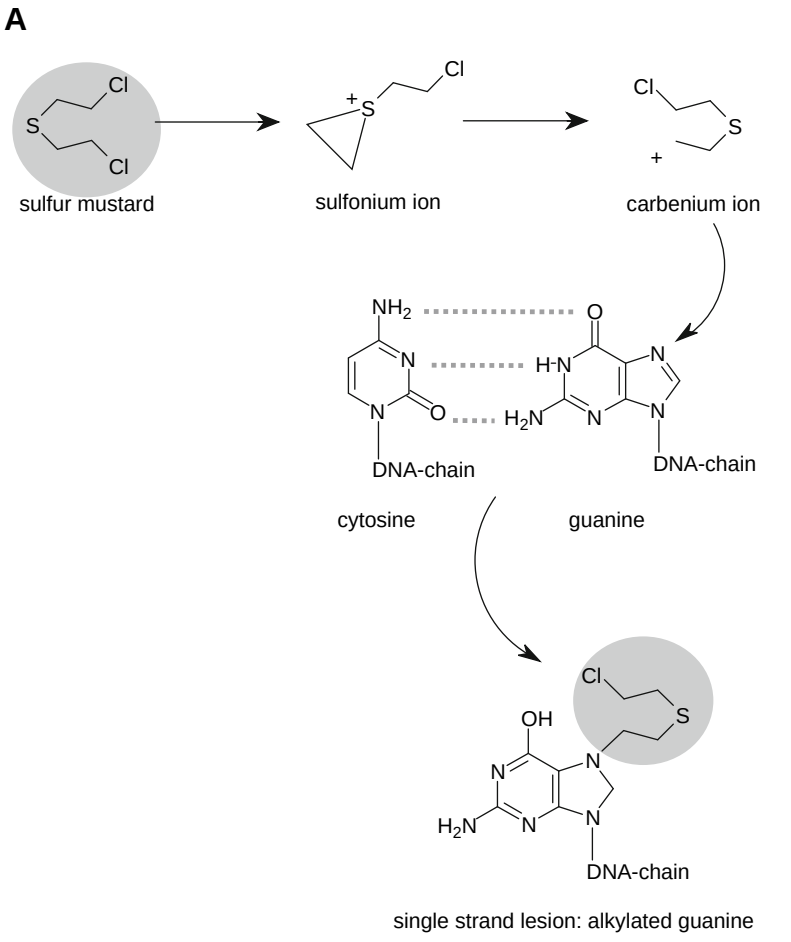

FIGURE 50.4. Sulfur mustard, its structure, mechanism of action, and targets of adduct formation. A: Mechanism of reaction of sulfur mustard and nucleotide guanine. B: Sites of alkylation by sulfur mustard. Arrows mark identified targets in nucleotides and amino acid histidine.

DNA crosslinks, in particular from one guanine to another (17%). It is estimated that a 100 μM concentration of sulfur mustard accounts for 0.28 crosslinks per 10,000 DNA bases (Shahin *et al.*, 2001).

Membrane-bound proteins and enzymes may undergo alkylation in the presence of sulfur mustard (Kehe and Szinicz, 2005). Figure 50.4 depicts targets of alkylation in both DNA bases and amino acids. However, as sulfur mustard-induced DNA damage has the most significant impact on the cell's short- and long-term survivability, it is DNA alkylation that produces the most significant toxic effects, whereas effects from protein alkylation are usually visible only in the presence of high concentrations of sulfur mustard (Lodhi *et al.*, 2001; Peters, 1947). As systemic concentrations will always be several orders of magnitude below local concentrations at the site of immediate contact, the systemic toxic effects of sulfur mustard are also most likely to result from DNA alkylation. DNA alkylation produces the most evident effects in proliferating cells and thus tissues with rapidly proliferating cells such as bone marrow suffer the most obvious damage. Toxic effects are similar to side effects from alkylating antineoplastic drugs (Dacre and Goldman, 1996). (Actually, the first antineoplastic drug had been developed from a structural analog of sulfur mustard, i.e. nitrogen mustard; Goodman *et al.*, 1984.) Those effects include nausea, vomiting, fever, fatigue, apathy, and loss of appetite. Bone marrow toxicity results in an initial leukocytosis, which is soon followed by leukopenia, thrombopenia, eosinopenia, and subsequently anemia (Dacre and Goldman, 1996).

Specific toxic effects of sulfur mustard have also been reported in the central nervous system and may range from agitation to seizures (Balali-Mood and Navaeian, 1986).

3. Invasion

Significant amounts of sulfur mustard may be absorbed from skin that has been in direct contact with sulfur mustard. Vapors of sulfur mustard may also be absorbed from the respiratory system.

In theory, there are two additional pathways for systemic uptake of sulfur mustard: the surface of the eyes and the gastrointestinal system. They have, however, never been investigated for the following reasons: gastrointestinal exposure to sulfur mustard is a rare phenomenon and may only occur in cases of sabotage (deliberate food poisoning) or a considerable lack of basic chemical defense measures, i.e. food consumption in a contaminated area. If occurring, the local effects of exposing the gastrointestinal system to sulfur mustard are severe and life-threatening and include strong abdominal pain, bloody diarrhea and vomiting, and rupture of stomach or duodenum. Subsequent peritonitis is often fatal (Dacre and Goldman, 1996). In comparison to the life-threatening local effects of gastrointestinal exposure, any related systemic effect would be of secondary importance.

Contrary to the rarity of gastrointestinal exposure, ocular exposure is unfortunately frequent among the victims of sulfur mustard attacks and local symptoms of varying severity are likely to occur whenever the individual was not protected by a respirator (mask) at the time of attack (Solberg *et al.*, 1997). As the eye is a very sensitive organ, ocular symptoms are often among the first signs of sulfur mustard exposure. Due to the close proximity of a large number of capillary vessels and as the eye constitutes a relatively weak barrier, xenobiotic substances are often rapidly absorbed (Lama, 2005). However, as the surface of the eye is small in comparison to the skin and the respiratory tract, the total amount of sulfur mustard that may be absorbed from the eye's surface is low. Self-protective effects of the eye such as blepharospasm and pronounced lacrimation may further reduce the amount of the agent that may be absorbed through this pathway. Again, the local effects of exposure appear very severe and are a primary reason for concern in victims of sulfur mustard effects. Whereas blepharospasm and lid edema cause transitory loss of vision – already resulting in immense distress for victims – heavy exposure may result in permanently opaque cornea and blindness. In general early effects in eyes are accessible by therapy with relatively good outcome after several weeks of treatment. In comparison, any systemic effects from transocular absorption alone would be of minor concern. It has to be emphasized that isolated ocular exposure on the battlefield or due to terrorist attacks utilizing sulfur mustard is exceedingly unlikely. Ocular exposure would inevitably be accompanied by cutaneous and respiratory exposure. The specific rate of absorption (i.e. the amount absorbed through a given surface over a specified time) may be lower, in particular in the case of initially intact skin. However, the larger total surface of the skin (and possibly the respiratory tract) would result in an amount that constitutes the major fraction of sulfur mustard absorbed which would subsequently determine the occurrence and severity of systemic effects. Therefore, research regarding the absorption of sulfur mustard has focused on two major pathways which are described in further detail in the subsequent sections.

a. Percutaneous Absorption

Penetration rates of liquid sulfur mustard were determined *in vitro* (71–294 μg/cm^2/h) on human skin with a Franz-type glass diffusion cell and correspond quite well to *in vivo* data derived from human skin (60–240 μg/cm^2/h) (Chilcott *et al.*, 2000). Significant effort has been dedicated to confirm the validity of animal models by comparing data derived from these models with findings from *in vitro* human skin experiments. Chilcott *et al.* (2001) investigated absorption in *in vitro* models of pig ear and heat-separated human skin. Absorption was determined at 411 ± 175 μg/cm^2/h for pig ear skin and 157 ± 66 μg/cm^2/h for human skin, respectively. These data were considered in agreement with earlier *in vivo* findings, even though the authors cautioned that data

on the effectiveness of decontaminants were in complete disparity when comparing human to pig ear skin. Logan *et al.* (1999) determined the sulfur mustard exposure through the skin of the hairless guinea pig at 120 µg/cm^2/h.

Occlusion of the skin, i.e. covering the skin with a material that is impenetrable to air and moisture, can result in a dramatic increase in p.c. absorption. For example, in a study by Chilcott *et al.* (2002) using various *in vitro* models of human skin, absorption rates in unoccluded controls (4.41 ± 1.90 µg/cm^2/h) increased to 538 ± 193 µg/cm^2/h under occluded conditions.

b. Respiratory Absorption

Langenberg *et al.* (1997) conducted inhalation exposure experiments in hairless guinea pigs. LCt_{50} was determined at 800 mg·min/m^3. Following application of one LCt_{50} over 5 min, no unchanged sulfur mustard in blood was found (limit of detection 5 pg/ml). Low concentrations (0.7 adducts per 10^7 nucleotides) of N7-guanine adducts of sulfur mustard were found in the lung. Concentration of N7-guanine adducts was also determined from various tissues along the respiratory tract. Actually, concentrations found were much larger, peaking at approximately 90 adducts per 10^7 nucleotides in the larynx and trachea. Concentration in the carina was lower (approximately 50 per 10^7 nucleotides), but still substantially higher than the above-mentioned value in the lungs. The authors concluded that most of the sulfur mustard inhaled reacts in the upper airways, rather than being absorbed. In animals with complex nasal systems (such as guinea pigs), only very minor fractions would reach the lung. However, they also pointed out that in humans (along with other species with a less complex nasal system), the proportion of sulfur mustard reaching the lung may be larger.

Following inhalation of 3×LCt_{50} (300 mg/m^3 over a period of 8 min), sulfur mustard was found in blood. Its peak concentration during the inhalation period was found to be approximately 5 ng/ml. This concentration soon declined. However, a mean value of 2 ng/ml was found even after 4 h. Nevertheless, a mathematical model explaining the data during the distribution and elimination phase could not be developed. Findings were further complicated by the fact that in two of 12 animals, no sulfur mustard was found in any of the samples. Moreover, no sulfur mustard was detected in any of the animals at 15 and 20 min (7 and 12 min post-exposure, respectively) before reappearing in most of the animals at the above-mentioned concentration of 2 ng/ml. The latter finding may possibly be explained by the hypothesis that the early peak in sulfur mustard concentration is due to direct inhalation (afterwards, concentration declines to levels below the limit of detection), whereas the second, long-term increase in sulfur mustard concentration may be attributed to sulfur mustard absorbed from depots in the upper airways. Figure 50.5 depicts the concentration over time, following the respiratory exposure to 3×LCt$_{50}$ of sulfur mustard. For comparison, concentration over time after i.v. application is also depicted. In summary, the authors concluded that toxicity from sulfur mustard inhalation was due to its local, rather than systemic, effects.

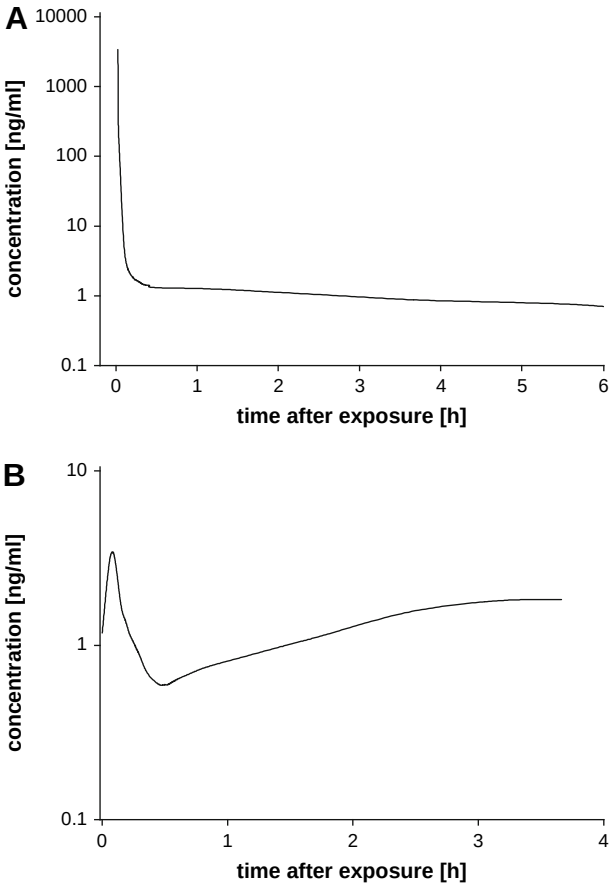

FIGURE 50.5. Concentration over time, following i.v. and respiratory exposure to sulfur mustard in the guinea pig model. A: Decline of sulfur mustard exposure after intravenous injection. B: Concentration over time after respiratory exposure: initial increase in the inhalation phase, followed by a decline and a secondary increase, concentration of approximately 2 ng/ml is sustained for 4 h.

4. Distribution

Sulfur mustard is a strongly lipophilic substance that may accumulate in fatty tissues and has actually been detected at autopsy in a patient who had died 7 days post-exposure. Detailed data, as published by Drasch and colleagues (1987), are displayed in Table 50.6.

Obviously, these findings confirm the theoretical assumption that the lipophilic properties of sulfur mustard result in a distribution, primarily in lipophilic tissues. High concentrations found in the brain may also explain why the central nervous system is one of the organs exhibiting systemic effects of sulfur mustard poisoning, even though it is not a site of rapidly proliferating cells.

TABLE 50.6. Content of sulfur mustard in the tissues of a deceased victim

Tissue/organ	Concentration (mg/kg)
Fat	15.1
Skin with subcutaneous fatty tissue	11.8
Brain	10.7
Skin	8.4
Kidney	5.6
Liver	2.4
Cerebrospinal fluid	1.9
Muscle	3.9
Spleen	1.5
Blood	1.1
Lung	0.8
Urine	Not detected
Blister fluid	Not detected

Data are according to Drasch and colleagues (1987)

It should be noted that some authors have questioned the findings by Drasch and colleagues, considering the absolute concentrations excessively high and therefore unlikely. However, as high-dose sulfur mustard poisoning is fortunately a rare event, it is nearly impossible to verify or falsify these data. One might argue that the amounts of sulfur mustard described may not even permit short-term survival. However, if most of the agent had entered the organism via p.c. absorption, there is a possibility that large amounts of the agent actually had been absorbed and formed a depot without resulting in an instant fatality, but ultimately leading to the death of the patient 7 days later. Whether or not the absolute values are accurate, they at least give an impression of the distribution of sulfur mustard within the organism that correlates with the agent's lipophilic properties.

More recent *in vitro* experiments, using human skin, have confirmed the presence of unhydrolyzed sulfur mustard in the lipophilic stratum corneum and the upper epidermis. Twenty-four hours post-exposure, the distribution ratio between the epidermis and the dermis has been determined at 62 to 38%. Chilcott and colleagues (2000) also suggested that efforts to remove or neutralize the agent from these deposits might have a clinical benefit for the patient.

In summary, these findings suggest that despite the presumably brief half-life calculated (see Elimination, below), sulfur mustard may be present in the organism for a significantly longer period of time necessitating protective measures for the medical personnel providing therapy and an awareness for the possibility of secondary blister formation, even 30 days post-exposure (Balali-Mood and Hefazi, 2005) as well as efforts to remove these deposits. In particular, the use of laser debridement (Graham *et al.*, 2008) and mechanical dermabrasio (Rice, 2008) has been recommended to facilitate the healing process after dermal exposure to sulfur mustard. The effects may at least partly be attributed to the removal of epidermal depots of sulfur mustard.

5. Metabolism

While the previously discussed findings demonstrate the stability of sulfur mustard in lipophilic tissues, the agent is rapidly hydrolyzed whenever situated in an aqueous compartment (Vycudilik, 1987). Thiodiglycol is the primary hydrolysis product, in which the chlorine atoms have been replaced by hydroxyl groups. Thiodiglycol may undergo oxidation to thiodiglycol sulfoxide, which is being conjugated with glutathione to form 1,1′-sulfonylbis [2-*S*-(*N*-acetylcysteinyl)ethane]. Following the β-lyase pathway, the 1,1-sulphonylbis[2-(methylsulfinyl)ethane] and 1-methylsulfinyl-2-[2-(methylthio)ethylsulfonyl]ethane can be formed (Black and Read, 1995). Figure 50.6 summarizes the pathways of sulfur mustard metabolism. No sulfo- or glucuronyl-conjugates were detected in urine after i.v. administration of sulfur mustard (Maisonneuve *et al.*, 1993).

Within cells, sulfur mustard forms adducts with DNA, primarily those described in Toxicity of sulfur mustard, above. Adducts can also be formed with nucleophilic sites of amino acids and proteins. Contrary to DNA adducts, there is no specific mechanism to reverse protein adduct formation. For this reason, there is a strong forensic interest in the detection of protein adducts of sulfur mustard as these may provide evidence of sulfur mustard exposure for prolonged periods after the incident.

A number of adducts to amino acid residues have been identified by Noort and colleagues (1996) and Black *et al.* (1997a, b). Six different histidine residues, three glutamic acid residues, and both of the N-terminal valines were found. Alkylated cysteine, aspartic acid, lysine, and tryptophan were also detected. While the N1 and N3 histidine adducts were found to be most abundant, it was the alkylated N-terminal valine adducts that were most useful for subsequent quantification. See Detection of DNA and protein adducts of vesicants, below, for analytical details.

Noort and colleagues (2008) investigated the persistence of sulfur mustard adducts to albumin and hemoglobin in rats. The albumin adduct (*S*-2-hydroxyethylthioethyl)-Cys-Pro-Tyr was detectable up to 7 days after the exposure, while the adduct to the N-terminal valine in hemoglobin was still detected after 28 days. The decrease of adduct concentration corresponded with albumin half-life and the lifetime of the rat erythrocyte, respectively.

Following two simultaneous cases of accidental human exposure to sulfur mustard, Smith *et al.* (2008) investigated the concentration of the cysteine-34 adduct to albumin and adducts to glutamic and aspartic acids of plasma proteins. In the case of a more severely exposed patient who required hospitalization, both adducts were detected over a 42 day period, though decreasing by approximately 75% towards

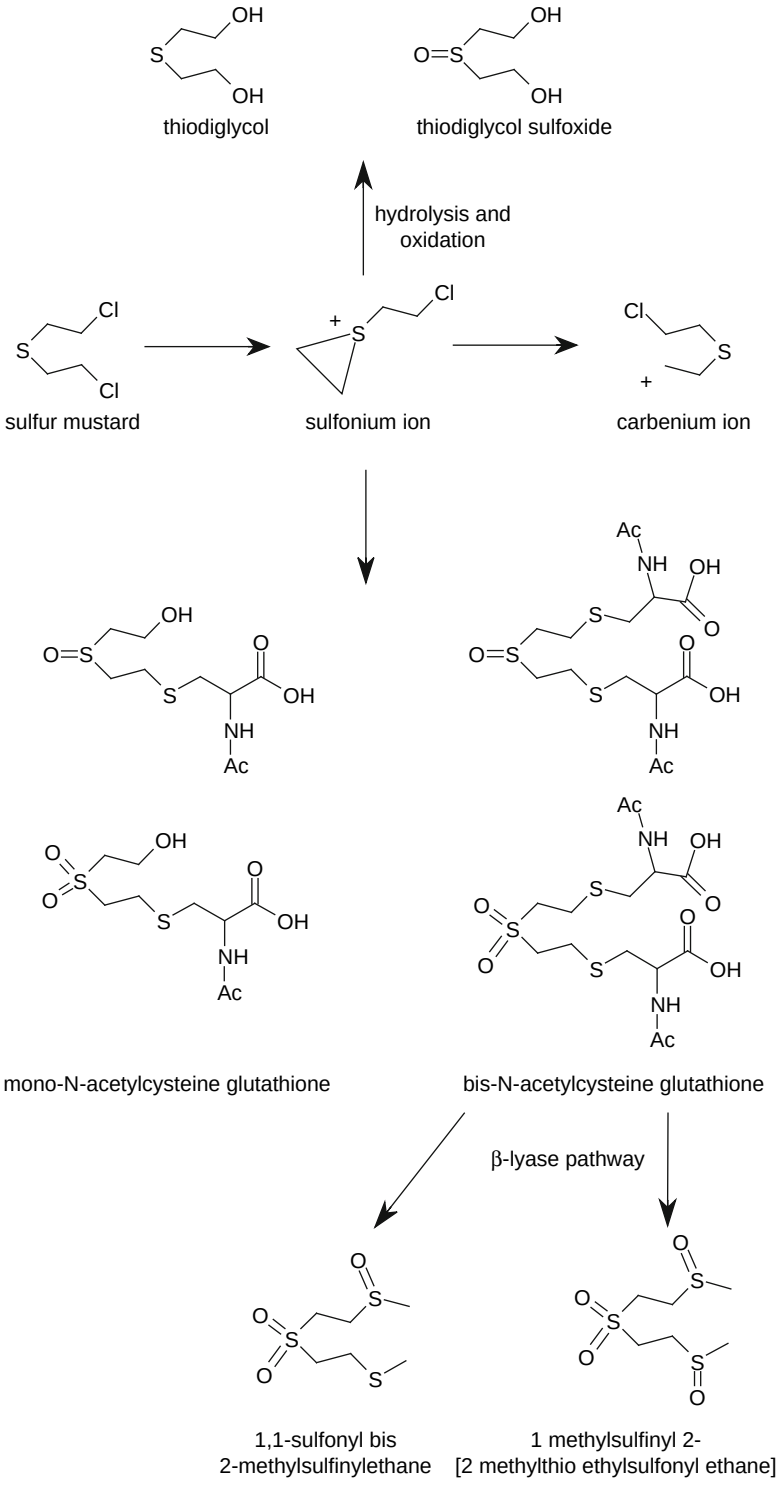

FIGURE 50.6. Metabolism of sulfur mustard.

the end of that period. In a second patient who had developed a single, small blister the albumin adduct was found during a 6 day period post-exposure.

6. Elimination

Following i.v. application of ^{14}C-labeled sulfur mustard in rats, 80% of the radioactivity administered was excreted via the renal pathway. Fecal excretion amounted to less than 3% (Maisonneuve *et al.*, 1993). Metabolites excreted in the urine after accidental human exposure included thiodiglycol, thiodiglycol-sulfoxide and the bis-mercapturate of mustard sulfone (Barr *et al.*, 2008). Comparing the concentrations of thiodiglycol and its sulfoxide, the latter was found in concentrations twice as high. When p.c. exposing weanling

pigs to sulfur mustard, Graham *et al.* (2000) found peak levels of thiodiglycol either in the samples drawn after 6 to 8 h or in other cases after 24 to 48 h. Findings were considered to be in agreement with earlier data from rodent species and cases of accidental human exposure.

It is worth noting that background levels of thioglycol and thiodiglycol sulfoxide have been found in the urine of healthy individuals never exposed to sulfur mustard. For this reason their validity as unambiguous markers for sulfur mustard exposure has been questioned. Black and Read (1995) suggested the determination of β-lyase pathway metabolites which in the urine of exposed patients were found at concentrations similar to those of thiodiglycol sulfoxide, but were not found in unexposed individuals.

B. Lewisite

1. Overview of Lewisite

Lewisite (2-chlorvinyldichlorarsin) is another vesicant agent. Unlike sulfur mustard, there has never been a documented use in armed conflict. It was first synthesized and described by the Belgian priest and chemist Julius Arthur Nieuwland (Nieuwland, 1904). During World War I, the US military chemist Winford Lee Lewis suggested and initiated its development into a chemical weapon, which due to the 1918 armistice in Europe was not used on the battlefield (Vilensky and Redman, 2003).

Lewisite remains a reason for concern because its physical properties, in particular a melting point of −18°C (Table 50.5), might facilitate its use in cold climates. Thus, a belligerent willing to use chemical weapons might feel convinced that lewisite would provide a ''unique'' capability to wage chemical warfare even in winter and/or in mountainous regions. Moreover, large stockpiles of the agent had been abandoned by the Imperial Japanese Army during their retreat from China in the latter stages of World War II, creating a chemical hazard that persists even decades after the war (Hanaoka *et al.*, 2006). Table 50.5 summarizes the physicochemical properties of lewisite.

2. Toxicity of Lewisite

The dominant element in the lewisite structure is arsenic, which is able to react with the sulfhydryl groups of various enzymes, disabling the enzyme in the process (Goldman and Dacre, 1989). Figure 50.7 depicts the structure of lewisite and its toxic mechanism.

Lipoic acid is particularly susceptible to this reaction and one of the most evident consequences is the inhibition of the enzyme pyruvate dehydrogenase (PDH), rapidly disabling the cell's metabolism of glucose and fatty acids. The resulting energy deficiency may lead to swift necrotic cell death. In comparison to sulfur mustard, the latency period (from exposure to first signs and symptoms) is significantly shorter and lewisite injuries have been described as extremely painful from an early stage. Moreover, it is a much more lethal agent and has a large systemic toxicity; 0.5 ml of the agent may produce systemic effects, whereas 2 ml (approximately 3.6 g) can be fatal (Marrs *et al.*, 1996).

3. Invasion

a. Percutaneous Absorption

Precise data, i.e. a diffusion coefficient expressing the p.c. absorption of lewisite (amount absorbed per area and time), are not available. However, Inns and Rice (1993) conducted p.c. toxicity studies in rabbits and determined the LD_{50} at 5.3 mg/kg (3.5–8.5 mg/kg, 95% confidence interval). The exposed area was 2 cm^2 and exposure lasted for 6 h.

Inns *et al.* (1990) had also determined the LD_{50} of i.v. lewisite administration at 1.8 mg/kg (1.6–2.1 mg/kg 95% confidence interval). Thus, it can be concluded that by exposing 2 cm^2 of rabbit skin to a dose of 5.3 mg/kg for 6 h, a dose producing the equivalent effect of 1.8 mg/kg is absorbed. No further calculations that might exaggerate the reliability of available data shall be conducted here.

b. Respiratory Absorption

The LCt_{50} of lewisite in humans has been estimated at 1,500 mg·min/m^3 (ATSDR, 2007), although no experimental

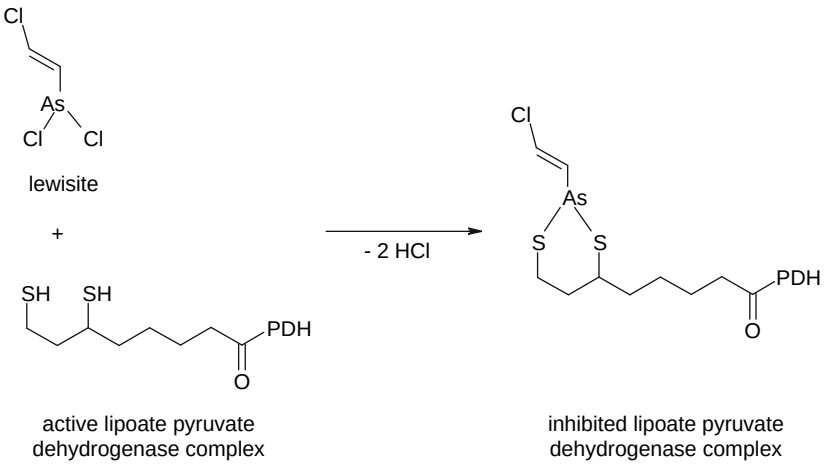

FIGURE 50.7. Lewisite, its structure and mechanism of action. Lewisite forms covalent bonds with lipoic acid, inactivating the enzyme pyruvate dehydrogenase (PDH).

data were cited. Considering its pronounced local effects, however, lethality can at least partly be attributed to the local effects of lewisite on the respiratory tract.

4. Distribution

High distribution volumes per kilogram indicate extensive distribution in tissues, due to the lipophilicity of the substance. In a rabbit model more than seven-fold values, compared to blood concentrations, were found in some tissues, e.g. liver, lung, and kidneys. That ratio was maintained over the sampling period, i.e. for at least 96 h (Snider *et al.*, 1990).

5. Metabolism

Once incorporated, unbound lewisite is quickly hydrolyzed. Its predominant metabolite is 2-chlorovinylarsonous acid, CVAA (Figure 50.8). Analytical methods to confirm lewisite exposure have, at least in the past, focused on the detection and quantification of CVAA. However, Noort *et al.* (2002) also pointed out that due to the high affinity of arsenic towards sulfhydryl groups, adducts of lewisite/CVAA and cysteine residues of proteins are formed. In an *in vitro* study, incubating ^{14}C-labeled lewisite with human blood samples, 90% of lewisite was found in erythrocytes, whereas 25 to 50% of arsenic was bound to globin. From these protein adducts, CVAA can be released to form an adduct with the antidote British Anti-Lewisite (BAL) (Fidder *et al.*, 2000). The authors were also able to identify a specific protein adduct of lewisite formed with the cysteine residues 93 and 112 of β-globin. See Detection of DNA and protein adducts of vesicants, below, for analytical details. Figure 50.8 summarizes the metabolism and reversal of adduct formation by BAL.

6. Elimination

Snider *et al.* (1990) determined the elimination of lewisite from rabbits after p.c. injection. Half-life was determined, ranging from 55 to 75 h. A clearance of 120 ml/h/kg was found. However, these findings only describe the overall elimination of arsenic from the organism, following a lewisite exposure.

In vivo, unbound CVAA is quickly excreted via the renal pathway and cannot be detected in urine samples taken later than 12 h post-exposure. However, the biological half-life of protein adducts is much longer: in blood samples taken 10 days post-exposure and treated with BAL, Fidder *et al.* (2000) were still able to release 10% of the CVAA-BAL concentration found on day 1. Thus, protein adducts of CVAA have an important role in the verification of potential lewisite exposure.

C. Bioanalytical Techniques for Quantification of Vesicants

1. Determination of Vesicants and Direct Metabolites

When Drasch and colleagues (1987) determined the concentration of sulfur mustard in tissues of a deceased victim, they had to employ a combination of dichloromethane extraction, a thin layer chromatography cleanup on silica plates, followed by derivatization with gold chloride,

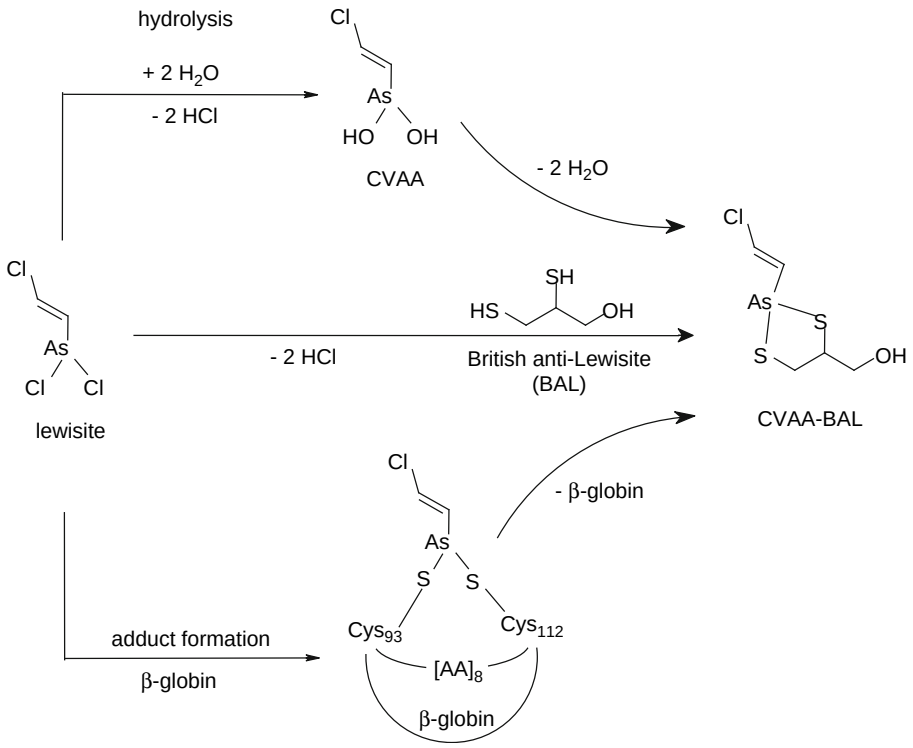

FIGURE 50.8. Lewisite metabolism, adduct formation, and its reversal.

and quantification by electrothermal atom absorption spectroscopy.

Vycudilik (1985) had already used gas chromatography–mass spectrometry (GC–MS) to confirm the presence of sulfur mustard in urine samples. Sodium chloride was added to the sample to facilitate extraction and slow down the hydrolysis in the aqueous sample, and the analyte was then extracted with diethylether. The solvent was evaporated and the residue dissolved in methylene chloride. After purification – by shaking the sample solution for 1 h with silicagel – the solvent was again evaporated. The residue was again dissolved in methylene chloride and used for chromatography.

To detect thiodiglycol, thiodiglycol sulfoxide, and their acid-labile esters, Black and Read (1991) used $TiCl_3$ reduction, converting these metabolites into the single analyte thiodiglycol. Thiodiglycol was then converted to its bis(-pentafluorobenzoyl) derivative and quantified by GC–MS using negative ion chemical ionization. Thiodiglycol sulfoxide could also be extracted directly, using solid phase extraction, followed by a Florisil cleanup. Derivatization and quantification were conducted as described above. $TiCl_3$ was also used by Daly and O'Hehir (2007) to reduce the β-lyase pathway metabolite 1,1-sulphonylbis[2-(methylsulfinyl)ethane] to 1,1′-sulfonylbis[2-(methylthio)ethane] (SBMTE). This was followed by automated solid-phase extraction and liquid chromatography–positive ion-electrospray ionization–tandem mass spectrometry. Methods to detect lewisite exposure have been focused on its main metabolite 2-chlorovinylarsonous acid (CVAA). Initial methods were developed for environmental samples (Bossle *et al.*, 1989). Methods for CVAA quantification in serum were described by Fowler *et al.* (1991) as well as Jakubowski *et al.* (1993). CVAA was derivatized with 1,2-ethanedithiol and quantified using GC–MS. Logan *et al.* (1996) employed a similar method to detect CVAA in the urine of guinea pigs exposed to lewisite.

2. Detection of DNA and Protein Adducts of Vesicants

Adducts of sulfur mustard can be hydrolyzed to release thiodiglycol. Lawrence *et al.* (2008) used this procedure, followed by extraction, derivatization, and gas chromatography–negative ion chemical ionization–mass spectrometry. However, a number of methods have been developed to directly detect and quantify the adducts of sulfur mustard. The most prevalent DNA adduct, N7-(2-hydroxyethylthioethyl)-guanine, was directly detected and quantified by Fidder *et al.* (1994, 1996a), using electrospray LC–tandem MS with multiple reaction monitoring.

Initial efforts by Noort *et al.* (1996, 1997) to detect protein adducts of sulfur mustard focused on the 4-(2-hydroxyethylthioethyl)-L-aspartate, 5-(2-hydroxyethylthioethyl)L-glutamate, the cysteine and the N-terminal valine adduct and two histidine adducts, N1- and N3-(2-hydroxyethylthioethyl)-L-histidine, respectively. Acidic hydrolysis and pronase digestion were used to release these adducts from globin. Pronase is a mixture of proteinases isolated from the extracellular fluid of *Streptomyces griseus*. Adducts were derivatized with 9-fluorenylmethyl chloroformate, followed by identification and quantification, using GC–MS.

The N-terminal valine adducts, even though they constitute only 1–2% of alkylated amino acids, were useful for subsequent quantification efforts. N-alkylated N-terminal valine could be selectively cleaved, using pentafluorophenyl isothiocyanate as reagent in a modified Edman procedure. The product of this reaction, pentafluorophenyl thiohydantoin, was derivatized with heptafluorobutyric anhydride and quantified by negative ion GC–MS–MS. This method was sensitive enough to confirm an *in vivo* exposure of guinea pigs, 48 h after intravenous administration of 0.5 mg/kg, i.e. 6% of the LD_{50} (Fidder *et al*, 1996b).

Noort *et al.* (1999) again used pronase to digest human serum albumin that had been incubated with sulfur mustard. The cleavage product, *S*-[2-[(hydroxyethyl)thio]ethyl]-Cys-Pro-Phe, was analyzed by micro LC-tandem mass spectroscopy.

Incubation of lewisite–protein adducts with BAL is capable of transferring its metabolite 2-chlorovinylarsonous acid (CVAA) into a BAL-CVAA derivative. This derivative can be quantified using GC–MS. The method is able to detect a 1 nM lewisite exposure of human blood *in vitro* (Fidder *et al.*, 2000).

A specific β-globin adduct to Cys93 and Cys112 was identified by the use of electrospray tandem mass spectrometry as well as by chemical transformation with the cysteine-selective reagent vinylpyridine and derivatization by S-carbamylation (Fidder *et al.*, 2000). No method for quantification of this adduct was described. As of mid-2008, no specific adducts other than the above mentioned have been described in the literature.

Despite 90 years of research on the effects of vesicant agents and on medical countermeasures only very limited data on toxicokinetics are available. However, technological advances in analytical chemistry have, in particular in the last two decades, contributed to a better understanding of the toxicokinetic properties of both sulfur mustard and lewisite. Knowledge gaps do exist, but research efforts continue. The Chemical Weapons Convention constitutes enormous progress in the efforts to completely rule out future incidents of chemical warfare, and the risk of chemical weapons being used by state parties is probably lower than in any decade since the 1910s. On the other hand, there is a worldwide asymmetric threat and the risk of terrorist attacks using chemical weapons cannot be ruled out. Defense experts, including medical chemical defense researchers, will be concerned with these issues for the foreseeable future. It is to be hoped that the more comprehensive knowledge on both toxicodynamics and toxicokinetics will contribute to the development of more effective, possibly causative therapies of vesicant poisoning. At the same time, the capability to unanimously prove vesicant exposure, even long after the incident, does certainly increase the possibility that any use

of these chemical warfare agents will ultimately be detected and sanctioned. Thus, state-of-the-art analytical methods may have an important role in deterring and preventing acts of chemical warfare.

V. CONCLUDING REMARKS AND FUTURE DIRECTION

Measurement of toxicokinetic profiles is primarily motivated to improve in-depth understanding of the poison's fate in the organism and thus of pathophysiological consequences. Both are important to optimize antidote treatment and therapy regimens for poisoned humans intending to boost poison elimination and reverse toxic effects or at least minimize harm by causal and symptomatic approaches. As outlined in the sections above, the fate of poison is regulated by multifactorial processes characterized by degradation and enzymatic metabolism as well as elimination by protein or DNA binding. With respect to state-of-the-art techniques and study design only a few animal models are being investigated comprehensively for nerve agents whereas nearly no data on sulfur mustard and lewisite are available in the literature. To make matters worse, almost no human toxicity or toxicokinetic data for chemical warfare agents are available due to ethical reasons, thus hindering specific and tailored medical approaches. Therefore, data are to be obtained from animal studies requiring extrapolation of relevant characteristics to human conditions. As obvious from the tabular compilations on acute lethal doses of nerve agents in different laboratory animals and different routes of exposure (Table 50.2), especially under consideration of stereoisomeric differences (Table 50.4) and underlying kinetic characteristics in terms of rate constants for serine esterase inhibition and catalytic constants for phosphotriesterase mediated hydrolysis (Table 50.3), such data are still incomplete. In addition, inter- and intraspecies variations are enormous, thus limiting comparability and transferability of experimental results. Furthermore, there are only a few data considering specific differences between lethal and sublethal exposure scenarios. Data on tissue distribution in animals are rare and correlation to human organisms is not clarified conclusively to explain, for example, the larger persistence of nerve agents in the human body. This lack of information indicates future demands of medical defense research. Accordingly, there is also a rising need for combined toxicokinetic and pharmacokinetic data obtained from poisoned organisms under therapeutic treatment. This will help to find the most valuable reactivators of OP-inhibited cholinesterases which differ dramatically in efficacy in a poison- and species-dependent manner. Taken together, results of future studies should (1) support the development of mathematical models to describe and predict poison and antidote behavior *in vivo* in humans, (2) unravel novel targets of poison on the molecular or compartmental level, which are useful as biomarkers or to identify additional pathophysiological situations, and (3) establish novel bioanalytical methods and techniques which allow very low quantification limits and sufficient selectivity for stereoisomers in various tissues and compartments. Whereas a number of studies have been performed using the commonly known nerve agents there remains a much higher demand for elaborative work with respect to vesicants.

CHAPTER 51

Physiologically Based Pharmacokinetic Modeling of Chemical Warfare Agents

JEFFERY M. GEARHART, PETER J. ROBINSON, AND EDWARD M. JAKUBOWSKI

I. INTRODUCTION

Pharmacokinetics (PK) is the quantitative determination of drug or chemical movement (time-course concentration) throughout the body. One of the basic principles of pharmacology and toxicology is that the effect of a drug or chemical is directly related to its concentration at some target site or receptor in the different tissues of the body. This premise is the critical reason and continued justification for the development of improved PK descriptions of chemical warfare agents. Mathematical models are applied to this type of data to simplify or reduce the description of the basic chemical–biological processes of absorption, distribution, metabolism, and excretion (ADME). These model types are driven by the basic premise that significant pharmacological or toxicological understandings are gained by knowing the internal drug/chemical concentration at the target site. Most often termed ''classical'' PK models, they reduce the entire body mass to either one or two mathematical compartments which represent the volume of blood, plasma, and/or readily accessible extracellular spaces, and a deep compartment storage representing other tissues. The advantage of this analytical approach is the determination of a simple global description of a chemical's behavior in the body and potentially the concentration at major target receptor sites. The major disadvantage is that these empirical models are poor at interspecies extrapolation, since the parameters do not have a physiological interpretation, and it is difficult to predict how they change when the underlying physiology changes.

Physiologically based pharmacokinetic (PBPK) models are a special type of PK model that attempts to provide more definition to the model analysis by incorporating physiological factors into the model design, like tissue volumes, blood flow rates, and species-specific enzyme characteristics that can more accurately differentiate the dose–response relationship for a chemical or drug in one species from that of another species. The power of this approach is to be able to perform laboratory studies, both *in vitro* and *in vivo*, in common experimental species to develop a complete PBPK model and then extrapolate these results to predictions in humans based on *in silico* experimentation.

Physiologically based pharmacokinetic (PBPK) models have become useful analytical tools to interpret pharmacokinetic data and to interpret data from complex chemical exposure scenarios. These models are mathematical constructs that allow the coordination of species-specific physiology, chemical-specific information, and the experimental protocol for the chemical or chemicals of concern. The power of PBPK models lies in aiding the ability of scientists and decision makers to simulate the time-course concentration of chemicals in experimental animals and humans, to better determine estimates of actual chemical doses delivered to the target tissue, and thereby provide a better prediction of response. Due to the physiologically based nature of these models, simulations of experimental data can be performed by one exposure route, to validate the PBPK model, and then this model can be used to simulate and predict the kinetics and pharmacodynamics in the human by one or multiple exposure routes. This provides decision makers with a fairly rapid method of comparing results from *in vitro* and *in vivo* laboratory studies, to potentially real world exposure scenarios. Perhaps the most useful application of these models lies in a strongly animal data-based PBPK-PD (PD – pharmacodynamic) model being used to make predictions about human responses to chemical warfare agents (CWAs), across a broad range of doses and CWA types, in light of not being able to actually conduct human exposure studies.

CWAs are represented by any one of a number of chemicals exhibiting a very high toxicity by various mechanisms. The present Handbook exhibits CWAs with structures as simple as carbon monoxide (CO) and as complex as botulinum toxin or ricin proteins. While this chapter could address the development of PBPK models of CWAs in general, the focus will primarily be on the organophosphate (OP)-based nerve agents typically represented by sarin (GB – isopropyl methylfluorophosphonate).

II. DEVELOPMENT OF PHYSIOLOGICALLY BASED PHARMACOKINETIC MODELS

Most attempts at describing CWA PK and PD have used classical kinetic models that often fit one set of animal experimental data, at lethal doses, with extrapolation to low-dose or repeated exposure scenarios having limited confidence. This is due to the inherent nonlinearity in high-dose to low-dose extrapolations. Also, the classical approach is less adept at addressing multidose and multiroute exposure scenarios, as occurs with agents like VX, where there is pulmonary absorption of agent, as well as dermal absorption. PBPK models of chemical warfare nerve agents (CWNAs) provide an analytical approach to address many of these limitations.

There are only a few PBPK models that have been developed to describe the pharmacokinetics and pharmacodynamics of CWNAs. Maxwell *et al.* (1988) developed a pharmacodynamic model for soman in the rat describing the inhibition of acetylcholinesterase (AChE) in different tissues, with mass balance equations including parameters for blood flow, tissue volumes, soman metabolism, and tissue/plasma partition coefficients. This effort resulted in an accurate prediction of AChE activity in eight different tissues after intramuscular soman dosing and was able to reproduce dose–response inhibition from 10% up to 100% of the brain AChE activity. Gearhart *et al.* (1990) used diisopropylfluorophosphate (DFP) as a model compound for CWNAs, to develop a PBPK-PD model describing the pharmacokinetics of DFP and the inhibition of AChE and butyrylcholinesterase (BuChE) in all the pertinent tissues of the body. This model construct was able to predict the pharmacokinetics of DFP and inhibition of AChE and BuChE after acute and repeated doses by three different routes. Recently, the PBPK-PD model for DFP was reparameterized to predict GB kinetics, inhibition of AChE, and regenerated GB from bound AChE sites on the red blood cells (RBCs) (Gearhart *et al.*, 2005).

There are three basic critical components to PBPK models: (1) species-specific physiological parameters, (2) chemical-specific parameters, and (3) specific experimental details for the studies to be simulated. Species-specific physiological parameters are the organ weights and blood flow rates for the defined compartments in the PBPK model. These values are most often available in the published literature and when lacking, are derived from the closest like species. Chemical-specific parameters that are unique for each chemical are the tissue solubility (partition coefficient), metabolism of the parent compound, and plasma and tissue binding characteristics. Tissue solubility is most often measured experimentally for the volatile CWNAs by the vial equilibration method (Gargas *et al.*, 1989). Existing models for the physiological distribution of CWNAs are based on a limited number of data sets for each agent and typically rely on single exposures at relatively high doses, often in the supralethal range (Van der Schans *et al.*, 2003). Mathematical models of these data have been developed but extrapolation to low-level exposures has proven problematic (Sweeney and Maxwell, 1999). Further, there are very few experimental data and essentially no modeling efforts for repeated low-level exposures (Benschop and de Jong, 1991). Thus, new experimental data at the appropriate dose ranges appear to be required for further refinement and extension of existing physiologically based pharmacokinetic (PBPK) models.

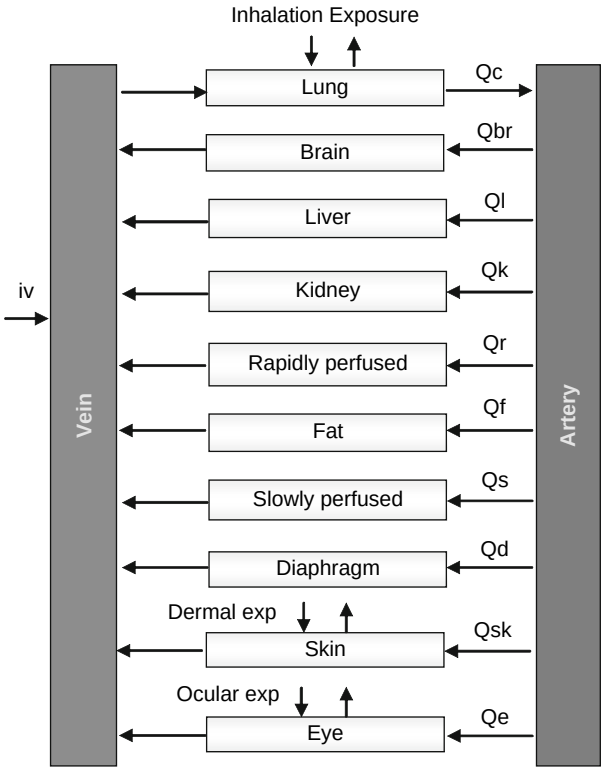

FIGURE 51.1. PBPK-PD model schematic of sarin in Hartley guinea pig. This model structure allows for the simulation of experimental studies with dosing by intravenous or subcutaneous dosing, and inhalation exposure. This model design was after Gearhart *et al.* (1990) and was adapted to simulate the pharmacokinetics and pharmacodynamics of sarin in the guinea pig.

Much of the animal data on the biological effects of low-level exposure to GB and other nerve agents has been collected via the subcutaneous or intramuscular route, particularly in guinea pigs, because of their lack of carboxylesterase. A good deal of data has also been collected by this dosing route or intramuscular dosing in rats, minipigs, and nonhuman primates. The primary exposure route of interest for human exposure is almost exclusively inhalation or dermal contact, so the quantitative implications of these laboratory exposure data for human health risk assessment are not straightforward. The most reliable tool for extrapolating across both species and exposure routes is

PBPK modeling, in which species differences in physiology are taken directly into account, and equivalent systemic and tissue doses for different routes of exposure can be calculated. Such extrapolation procedures, exemplifying the integration of diverse datasets in both animals and humans, are illustrated in Figure 51.2. Here the lower pentagon represents the dermal (or SC dosing) exposure route for different species, while the upper pentagon represents inhalation exposure. The green arrow represents specifically the extrapolation of subcutaneous exposure data in the guinea pig to apply to human inhalation exposure situations. In this example, the relevant biological effects observed in the guinea pig at specific subcutaneous exposures are noted. The guinea pig PBPK model then allows blood and tissue concentration time-courses corresponding to these doses to be calculated. Assuming that similar biological effects occur at similar target-site concentrations across species, the necessary inhalation exposure corresponding to the same blood and/or tissue concentrations in the humans can then be back-calculated using the human PBPK model for the agent. By using PBPK models in this way, human inhalation exposures are thereby quantitatively linked to the rich animal response and health effects databases.

III. NEED FOR IMPROVED MEASURES OF CWNA EXPOSURES – USE OF PBPK ANALYSIS OF DATA

Historically, cholinesterase activity has been used to evaluate exposure of humans and animals to nerve agents. Unfortunately, circulating cholinesterase activity is a relatively insensitive and imprecise marker of nerve agent exposure. By contrast, regeneration of nerve agents from inhibited enzymes using a high fluoride concentration (fluoride regeneration) is well suited to monitoring absorbed doses resulting from low-level exposures to sarin (GB), soman (GD), and other CWNA (Polhuijs *et al.*, 1997; Jakubowski *et al.*, 2001, 2003; Adams *et al.*, 2004). This technique has not yet been applied systematically for kinetic modeling of CWNA exposures in guinea pigs. Recently, a method for regeneration of GB from blood/tissue has been developed and validated in rat, guinea pig, and pig models and provides a sensitive and quantitative means for estimating the kinetics of GB in blood (Jakubowski *et al.*, 2004). This method is based on fluoride ion regeneration of the protein-bound agent. Fluoride ion regenerated sarin (R-GB) was found in blood and tissues of minipigs exposed to sarin vapor levels ranging from miosis to lethality. The R-GB in these samples was analyzed by gas chromatography mass spectrometry (GC-MS) after a C18 solid-phase extraction sample preparation that included fluoride ion addition and pH adjustment. Serial blood samples taken before and during miosis-level GB inhalation exposures resulted in red blood cell R-GB levels that steadily rose during the exposure. This demonstrated the ability of the R-GB assay as a biometric of exposure. The slopes of the lines created by plotting R-GB versus time closely correlated to the experimental exposure level. Therefore, the rates of GB absorption in these animals were proportional to the GB exposure concentration. In contrast to R-GB, monitoring AChE activity was an ineffective indicator of exposure at miosis levels in these experiments.

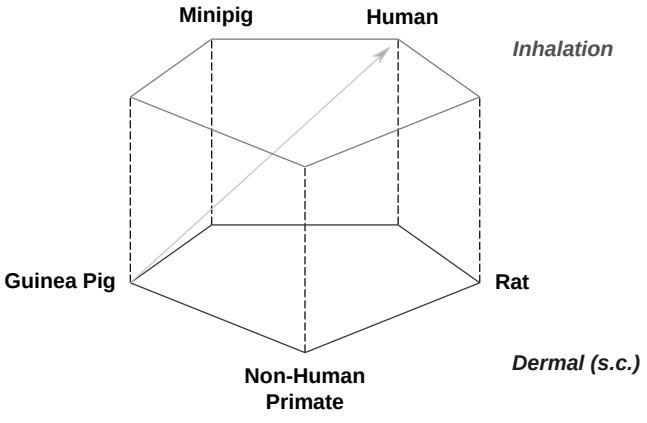

FIGURE 51.2. Schematic illustration of combined interspecies and route-to-route extrapolation. The arrow represents the extrapolation of guinea pig subcutaneous exposure data to human inhalation exposure situations.

A. Relationship Between Regenerated Sarin and AChE Activity and its Use as a Dose Surrogate

Regenerated sarin S_R from red blood cells is experimentally related to AChE activity A in Figure 51.3. It is apparent that the relationship can be adequately described in terms of a Michaelis–Menten equation as follows:

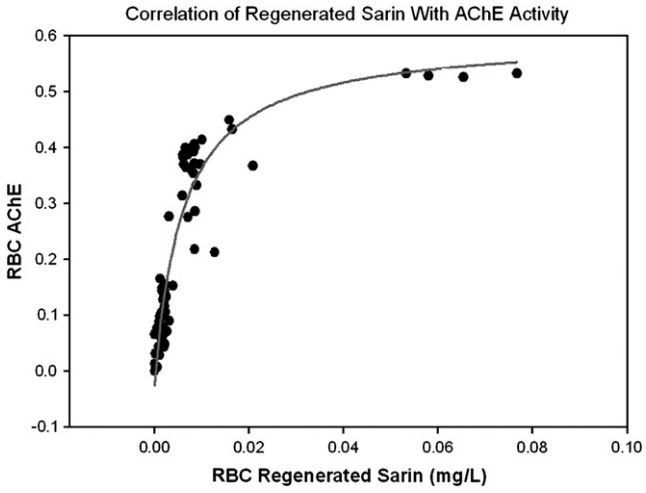

FIGURE 51.3. Plot of red blood cell acetylcholinesterase activity as a function of regenerated RBC sarin.

$$A = A_{\max}\left[1 - \frac{S_R}{S_R + K_m^{eff}}\right] \qquad (51.1)$$

where $A_{\max} = 0.623$, and $K_m^{eff} = 0.006$. Note that K_m^{eff} is not the true K_m for sarin binding to AChE, which is the concentration of sarin needed to fill half the AChE receptors, since we do not know that the regenerated sarin is the same as the original exposure concentration. (If there are additional sarin-binding sites than AChE, for example, the regenerated sarin would underestimate the exposure concentration, and the true K_m would be larger than K_m^{eff} by a certain factor.) The fact that these data fit so well to an M–M-type equation strongly suggests that there is a simple proportionality between K_m^{eff} and the ''true'' K_m, and that sarin regenerated from RBCs is a suitable surrogate for the original exposure to sarin in blood (Figure 51.3).

Regenerated sarin from RBCs at high doses may exceed the total available binding capacity of the AChE receptors associated with the RBCs. There are therefore additional sarin-binding sites proposed to be associated with RBCs that continue to bind sarin well after the AChE receptors are filled, and therefore may comprise the bulk of the regenerated sarin at high concentrations. We thus have proposed two competing binding processes: one high-affinity, low-capacity site that dominates binding of sarin at low concentrations, and which normally releases sarin very slowly if at all (the AChE receptors); and one relatively low-affinity, high-capacity site that releases sarin rapidly compared with the circulation time of the blood (Figure 51.4). This latter site would dominate at higher concentrations, and in the absence of any evidence for its saturation even at these high concentrations, we approximate it as a first-order process described with simple association and dissociation rate constants k_{on} and k_{off}.

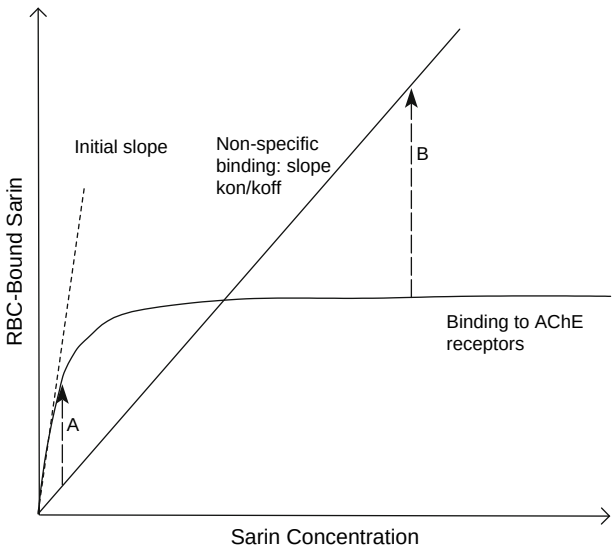

FIGURE 51.4. Hypothetical bound GB vs free sarin concentrations for saturable AChE binding, and linear nonspecific binding. The AChE binding has a higher initial slope, so it will dominate in a competitive situation at low doses (A), but is saturable and so will eventually be swamped by the nonspecific binding at higher doses (B).

B. General PBPK Model Structure

The basic structure of the PBPK model used to describe GB pharmacokinetics and pharmacodynamics (PD) followed that of the PBPK-PD model for DFP (Gearhart *et al.*, 1990). Tissue compartments (Figure 51.1) were added to the previous model structure describing the eye and the skin, where previously these compartments were lumped together in the rapidly perfused or slowly perfused tissues. The eye was added to provide the means of predicting miosis during CW agent exposure, from both the systemic absorption of chemicals, but more importantly, the amount of chemical absorbed directly to the eye structures via the ocular surface via absorption and diffusion. Adding this compartment also provided a mechanism of addressing the pharmacodynamic effects of sarin on the eye, by correlating inhibition of AChE enzyme levels in the iris with levels of miosis. The skin was added primarily to provide an exposure route for those agents that have a significant dermal absorption potential. Decreases in absorption due to upper respiratory tract deposition were accommodated by refining the model as shown in Figure 51.5.

PBPK parameters for individual organ weights were obtained from Breazile and Brown (1976), Altman and Katz (1979) and Peeters *et al.* (1980). Blood flows for most organs were obtained from Peeters *et al.* (1980) or were scaled from other rodent species. The partition coefficients were based on the values used for DFP and soman (Gearhart *et al.*, 1990), as well as the cholinesterase and sarinase values for tissue and blood. The description of the interaction of GB with the mammalian system of the guinea pig followed that as described by Gearhart *et al.* (1990) for the CWA simulant diisopropylfluorophosphate (DFP) in rodents and Gearhart *et al.* (2005) in the Göttingen minipig. The description of sarin binding to AChE is shown in Figure 51.6. Sarin interaction with AChE is described by a bimolecular rate constant, causing loss of AChE activity.

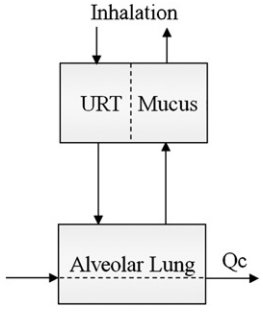

FIGURE 51.5. Detailed schematic for upper respiratory tract (URT) interactions for inhalation exposures.

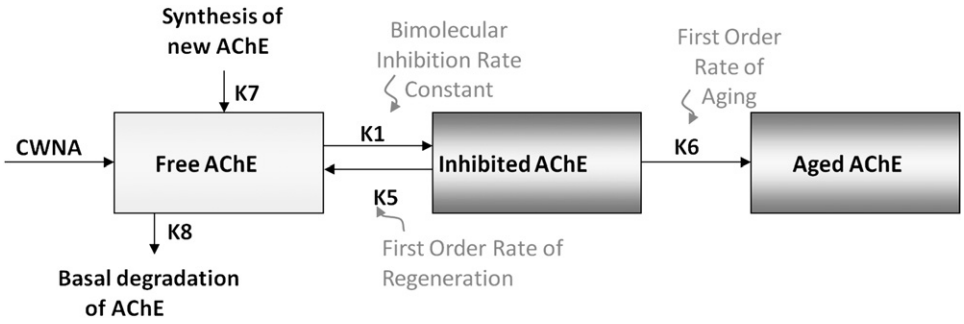

FIGURE 51.6. Schematic for acetycholinesterase inhibition by sarin.

The inhibited AChE sites represent the amount of sarin which can be regenerated from the red blood cells.

IV. PBPK SIMULATION OF CHOLINESTERASE INHIBITION AND REGENERATED GB

The main focus of this effort was to develop and validate methods to relate and integrate CWNA toxicity data across routes of exposure in a common species. The specific goal is to compare uptake and clearance kinetics of similar sublethal doses of GB in the blood of guinea pigs exposed to the agent by acute intravenous (IV), inhalation (IH), or subcutaneous (SC) injection. GB regenerated from blood was used as the dose metric to compare the uptake and clearance kinetics of similar doses of GB administered to guinea pigs by IV, SC, or IH routes of exposure. The resulting database will be used to derive a quantitative ratio (SC/IH) of systemically absorbed agent that will allow predictions of the atmospheric GB concentration relevant to a second species based upon SC injection exposures.

Guinea pigs were exposed to sublethal levels of GB by IV, IH, and SC routes. Serial blood samples were collected in order to determine simple uptake and clearance kinetics using regenerated agent as a dose metric in a single dose (IV, SC, and IH). The resulting database was used to derive the PBPK model. This model will be used to determine a quantitative ratio (SC/IH) of systemically absorbed agent that will allow predictions of the atmospheric GB concentration relevant to the increased guinea pig data sets based upon subcutaneous injection exposures.

Simulations of inhibited cholinesterase and regenerated GB versus the plotted data are exhibited in Figures 51.7 through 51.13. The methods of GB exposures or dosing shown are for either intravenous, subcutaneous, or inhalation. In most cases the experimental data were well represented by the PBPK-PD model simulations. Those instances where the greatest deviation occurred between the model and the data were most likely due to data variability, such that the trend of the data would not follow a reproducible model behavior (Figure 51.11), or cases where there is still some question about the strength of the model parameters being used. Figures 51.7 through 51.10 show the model simulation of some of the key data used to determine model behavior. In each of these cases, the simulations provide a good representation of the overall magnitude and tread of

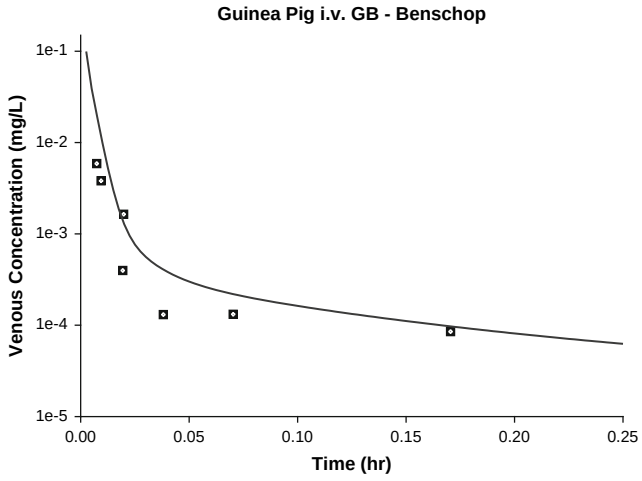

FIGURE 51.7. PBPK-PD simulation of AChE inhibition in the guinea pig after an intravenous GB dose of 0.8 LD_{50} (0.0042 mg/kg body weight) (Benschop and De Jong, 2001 – 19.2 µg/kg).

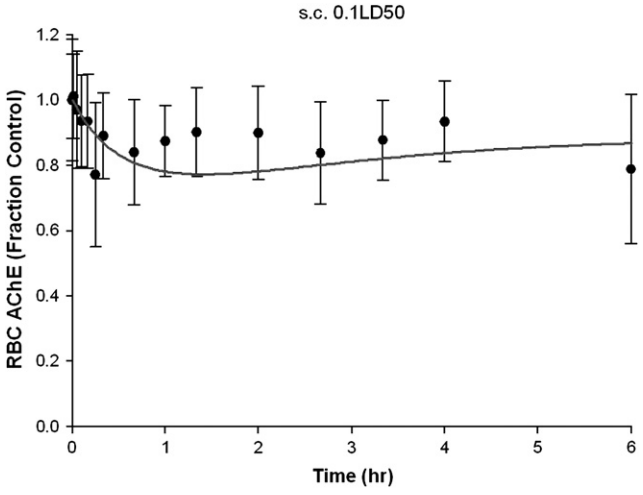

FIGURE 51.8. PBPK-PD simulation of AChE inhibition in the guinea pig after an SC dose of 0.1 LD_{50} (0.0042 mg/kg body weight).

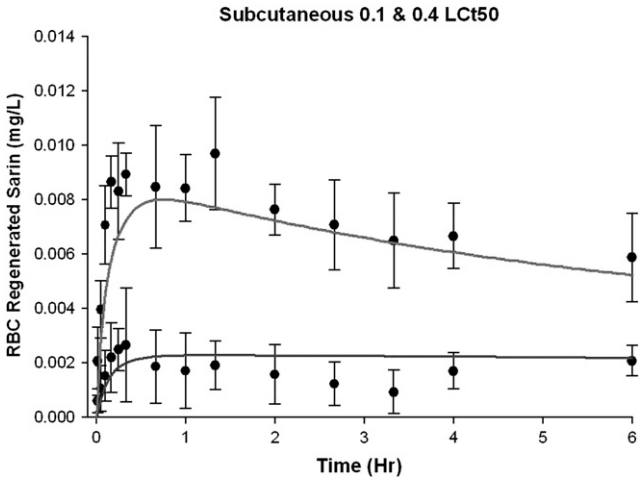

FIGURE 51.9. PBPK-PD simulation of regenerated sarin in the guinea pig after an SC dose of 0.1 LD_{50} (0.0042 mg/kg body weight) and 0.4 LD_{50} (0.0168 mg/kg body weight).

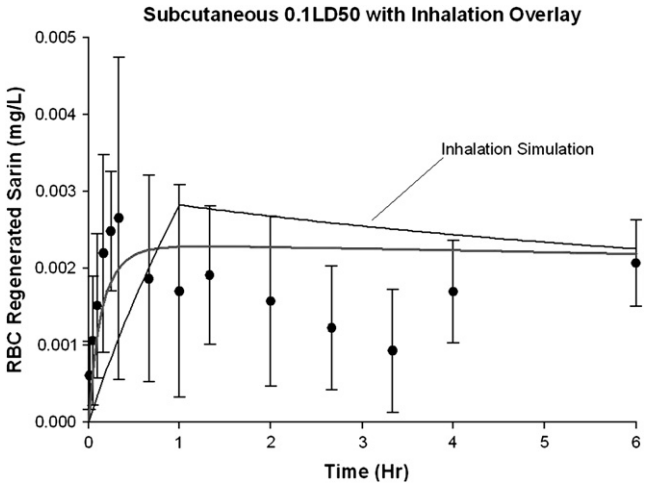

FIGURE 51.11. Overlay of the simulation of regenerated RBC sarin after a 0.1 LD_{50} SC dose of sarin vs IH dosing simulation at the inhalation concentration required to reproduce the SC data.

the data. In some cases, as in Figures 51.7 and 51.9, there are points during the simulation when there is either an over- or underestimation of the data. This type of variation between PBPK-PD simulations and data is a common occurrence whenever there is an attempt to exactly simulate time-course kinetic data for such toxicologically active a compound as GB. If it appears that significant decreases or increases in the actual experimental values are indications of real mechanisms and not just animal to animal variability, then that may only be simulated using more sophisticated methods, as with stochastic processes where actual fluctuations in blood flows or shunting of blood could, for example, cause changes in represented concentrations out of the normal trend of the data. Certainly one major issue not addressed in this chapter is the effects of GB on its own pharmacokinetics which in turn has a significant impact on key PBPK parameters such as blood flow or respiratory ventilation parameters. A well-known response to severe CWNA exposure is a suppression of the cardiac output and respiratory ventilation, both of which could alter measured PK and PD endpoints and if not modulated in the PBPK-PD model, lead to over- or underestimation of data.

V. CONCLUDING REMARKS AND FUTURE DIRECTION

The overall performance of the PBPK-PD model in predicting both the concentration of regenerated GB and the inhibition of RBC AChE was very successful for both the subcutaneous and inhalation routes of exposure, at these doses. Previously published studies showing the significant

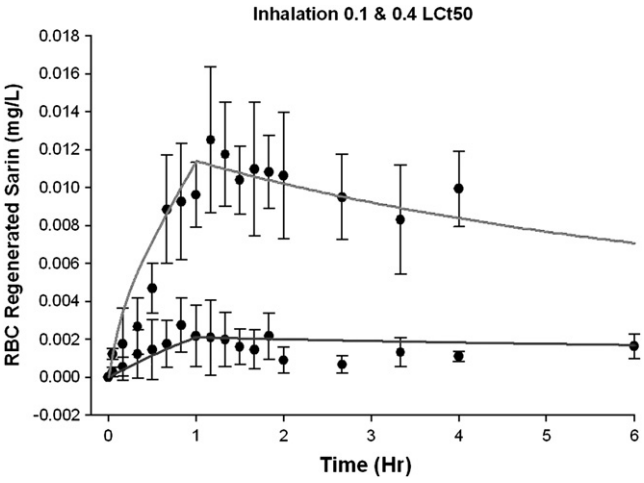

FIGURE 51.10. PBPK-PD simulation of regenerated sarin in the guinea pig after a 1 h inhalation exposure to sarin vapor at 0.1 LC_{50} (0.4 mg/m^3) or 0.4 LC_{50} (1.6 mg/m^3).

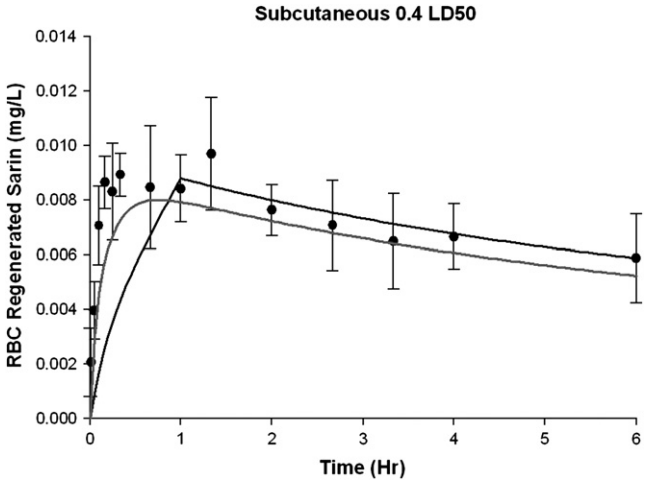

FIGURE 51.12. PBPK-PD simulation of an exposure of guinea pigs to the SC concentration equaling 0.4 of the lethal concentration affecting 50% of the exposure population (LCt_{50}).

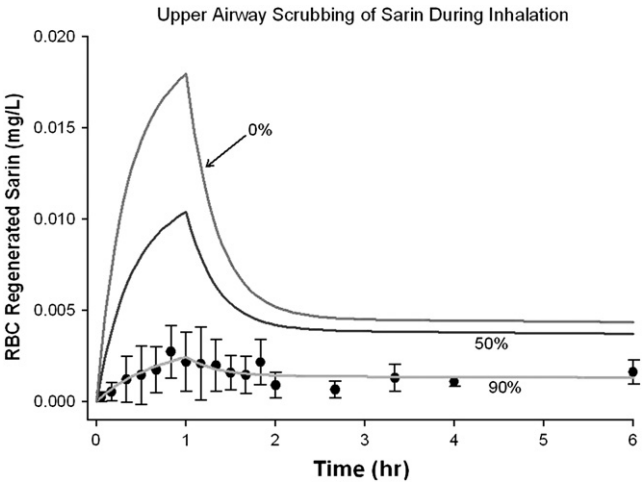

FIGURE 51.13. Upper airway scrubbing simulations. As was previously seen with the simulation of minipig inhalation exposures, a significant percentage of the inhaled dose was scrubbed by the upper respiratory tract, with the best fit to the data requiring the loss of 90% of the inhaled dose.

deposition of GB in the upper respiratory tract were confirmed in this analysis of the inhalation of GB in the guinea pig at 0.1 and 0.4 times the LC_{50} for this species. The PBPK-PD model was utilized to equate the delivered dose of sarin by subcutaneous exposure, with what would be obtained after inhalation. In this analysis, it was determined that at lower GB inhalation concentrations, there is a significant amount of deposition of the agent on the upper respiratory tract (Figure 51.13), material which is both hydrolyzed and resultantly inactivated, or is bound in by such a mechanism that it presently is hypothesized to have limited activity. This is one aspect of this analysis which requires further study. To determine the actual inhalation concentration that would correlate with a particular subcutaneous dose, the PBPK-PD model was exercised repeatedly, and the simulation output was overlaid on the subcutaneous simulations. This process is shown in Figures 51.5–51.11 and 51.12 for the 0.1 and 0.4 SC LD_{50}s. This calculation showed that to reproduce the SC 0.1 LD_{50} of 0.0042 mg/kg (Figures 51.11) required an inhalation concentration of 0.08 ppm for a 1 h inhalation exposure. This value is very close to the experimentally determined value for the inhalation 0.1 LC_{50} of 0.05 ppm. The SC 0.4 LD_{50} of 0.0168 mg/kg required an inhalation concentration of 0.28 ppm for a 1 h inhalation exposure (Figure 51.12). Further simulations will need to be exercised to confirm these apparent relationships.

A previously developed PBPK-PD model for the CWNA surrogate DFP was parameterized to simulate the concentration and effects of low-level chemical warfare agents (CWAs) in the guinea pig after exposure by inhalation and subcutaneous injection. The model code was written to account for absorption of CWAs from multiple sites (respiratory tract – lower and upper, dermal, ocular) after vapor or subcutaneous exposure. Literature references to guinea pig physiology were used for the majority of organ volumes and blood flows, while some parameter values were scaled from other species. Unique features of this PBPK-PD model structure were physiological compartments for the eyes, as a source of external CWA absorption and internally as a site of cholinesterase binding, and skin as a dermal absorption pathway. One initial pharmacodynamic endpoint developed in this model was CWA inhibition of cholinesterases (AChE, BuChE). Covalent binding of sarin to cholinesterases and other proteins was also estimated by a novel parameter based on fluoride ion regeneration of the agent. The PBPK-PD model was used to simulate AChE inhibition after inhalation and subcutaneous injection of CWAs and to predict potential pharmacodynamic effects at different tissue target sites. This preliminary model will provide a quantitative tool to predict the physiological consequences of low-level, nonlethal exposure after CWNA exposure.

CHAPTER 52

Metabolism of Warfare Nerve Agents

MILAN JOKANOVIĆ

I. INTRODUCTION

The first organophosphorus (OP) nerve agents, tabun (GA) and sarin (GB), were developed in the 1930s by Gerhard Schrader. These, and the even more toxic soman (GD), developed in 1944, are members of the so-called G-agents. Together with VX, developed after World War II in the United Kingdom, these compounds have emerged as the major nerve agents known to have been produced and weaponized. The nerve agents are alkylphosphonic acid esters. Tabun contains a cyanide group. Sarin and soman, which contain a fluorine substituent group, are methylphosphonofluoridate esters. These nerve agents contain a C—P bond that is almost unique in that it is not found in organophosphate pesticides. This C—P bond is very resistant to hydrolysis. VX contains a sulfur and is an alkylphosphonothiolate.

The very high toxicity of these agents can be attributed to the excessive cholinergic stimulation caused by inhibition of acetylcholinesterase (AChE) at neuromuscular junctions and in the central nervous system. Nerve agents react rapidly with a serine hydroxyl group in the active site of AChE with the formation of a phosphate or phosphonate ester. The phosphorylated enzyme regenerates very slowly rendering the enzyme inaccessible for its physiological substrate acetylcholine. The chirality around the phosphorus atom largely influences the toxicity of these agents as documented in the case of soman whose P(−)-isomers are much more toxic than the P(+)-isomers (Van der Schans *et al.*, 2007).

In the case of G-agents the intact agent is present in the organism for only several hours. The dominant metabolic pathway of G-agents is hydrolysis, a process mainly mediated by so-called A-esterases, and the metabolic products formed are corresponding *O*-alkyl methylphosphonic acids in the case of sarin and soman (Figure 52.1). VX is a less suitable substrate for A-esterases. In addition to hydrolysis, binding reactions of nerve agents to esterases such as AChE, serum cholinesterase (ChE), carboxylesterase (CarbE), and other proteins occur. Both OP pesticides and nerve agents lose their acyl moieties when they react with AChE, ChE, and CarbE. After binding to AChE and ChE the phosphoryl residues of soman, sarin, tabun, and VX undergo an intramolecular rearrangement with subsequent loss of one phosphoryl group. This process is called aging and the reaction is further discussed in Chapter 65.

In addition, due to the reversibility of the binding reaction of sarin and soman to CarbE, it appears that CarbEs are involved in metabolic detoxification of these agents to their corresponding nontoxic metabolites isopropyl methylphosphonic acid (IMPA) and pinacolyl methylphosphonic acid (PMPA) (Jokanović *et al.*, 1996).

One of the important proofs which support the significance of detoxification reactions of nerve agents in the body was presented by Fonnum and Sterri (1981) who reported that only 5% of LD_{50} of soman in rats or about 5 μg/kg reacts with AChE causing acute toxic effects, while the remaining 95% undergoes various metabolic reactions.

In this chapter the mechanisms involved in metabolism of warfare nerve agents are discussed. Mechanisms of biotransformation of OP pesticides are beyond the scope of this chapter and interested readers are referred to other publications (Jokanović, 2001; Chambers *et al.*, 2001; Tang *et al.*, 2006).

II. CHEMICAL ASPECTS OF METABOLISM OF NERVE AGENTS

The G-agents are anticholinesterase OP nerve agents which at sufficient concentrations can be toxic or fatal by any route of exposure. Differences in volatility and water solubility result in varying degrees of persistence and variations in the likelihood of exposure by certain routes. Of the G-agents, tabun gives rise to the greatest number of degradation products. The main metabolic product of tabun is EDMPA (Figure 52.1). Toxicity data are available only for a limited subset of the tabun degradation products. Hydrolysis gives rise to dimethylamine, among other substances. Dimethylamine is moderately toxic in terms of acute lethality but causes irritation of the human respiratory tract (Munro *et al.*, 1999).

Sarin is metabolized to IMPA, which slowly undergoes further hydrolysis to the very stable MPA. IMPA also forms in the course of spontaneous reactivation of sarin-inhibited CarbEs and ChEs. IMPA has low oral toxicity in rats and mice, but it produces mild skin irritation in rabbits.

In the study of Little *et al.* (1986) a single sublethal dose (80 μg/kg) of radiolabeled sarin was administered intravenously to mice and the tissue distribution was studied for 24 h. Within 1 min, sarin was distributed to the brain, lungs,

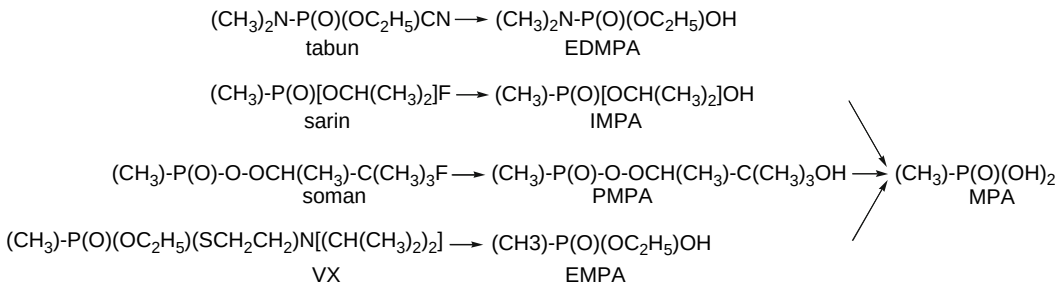

FIGURE 52.1. Metabolic detoxification of warfare nerve agents tabun, sarin, soman, and VX in mammals *in vivo*. Chemical names of metabolites are: EDMPA – ethyl dimethylaminophosphoric acid, IMPA – isopropyl methylphosphonic acid, PMPA – pinacolyl methylphosphonic acid, EMPA – ethyl methylphosphonic acid, and MPA – methylphosphonic acid.

heart, and diaphragm, but the highest concentrations were found in kidneys, liver, and plasma. Thereafter, the concentrations in all tissues rapidly declined and within 15 min only trace quantities of [^{3}H]sarin were found in brain. Within the first minute, about half of the labeled sarin was associated with the major sarin metabolite IMPA. The kidneys contained the highest concentrations of sarin and its metabolites, whereas much lower concentrations of metabolites were detected in the liver suggesting a minor role for the liver in detoxification of sarin.

Shih and colleagues (1994) injected rats subcutaneously with a single dose of sarin (75 μg/kg) and measured excretion of the hydrolyzed metabolites, the alkylmethylphosphonic acids, including IMPA and other methylphosphonic acids. Urinary elimination was found to be quite rapid and the terminal elimination half-life of sarin metabolites in urine was 3.7 h. Most of the administered dose of sarin was retrieved from the urine in metabolite form after 2 days.

Distribution, metabolism, and elimination of sarin in humans appear to resemble findings in animals. Minami and colleagues (1997, 1998) detected the sarin metabolite IMPA in urine of humans after the terrorist attack in Tokyo in 1995. They found peak levels of IMPA or methylphosphonic acid in urine 10–18 h after exposure. The levels of IMPA in urine correlated with the clinical symptoms. They also found evidence of distribution of sarin to the human brain in four of the 12 people who died after exposure. IMPA and MPA were detected in patients from the Matsumoto sarin exposure (Nakajima *et al.*, 1998).

Hydrolysis products of soman include pinacolyl methylphosphonic acid (PMPA) and MPA. No biologic data were found for PMPA. It has been shown that the toxic C(±)P(−)-isomers of soman react rapidly with covalent binding sites. The less toxic C(±)P(+)-isomers are hydrolyzed several orders of magnitude faster than the C(±)P(−)-isomers. The low toxicity of the C(±)P(+)-isomers is primarily due to a low intrinsic reactivity toward AChE and rapid hydrolysis (Van der Schans *et al.*, 2007). The levels of C(±)P(−)-isomers remain toxicologically relevant for periods of 50–100 min in rats, guinea pigs, and marmosets at doses of 2–3 LD_{50} (Benschop and de Jong, 1991).

The organophosphate nerve agent VX is a potent anticholinesterase agent that can act by dermal, oral, or inhalation routes of exposure. The anticholinesterase mechanism of action of VX is due to the oxo (=O) group, but is also influenced by the presence of alkyl substituents. There are some characteristics of VX which make the agent different from G-agents. VX is present in blood as protonated amine, it is hydolyzed at a much slower rate than G-agents, it reacts more slowly with CarbEs and A-esterases, and it can be metabolized by other routes such as oxidation reactions at nitrogen and/or sulfur. Initial metabolic and degradation products may retain some anticholinesterase activity, but hydrolysis of one or more alkyl ester bonds of organophosphonic acids results in the generally nontoxic alkyl methylphosphonic acids. MPA is resistant to further hydrolysis. Limited data for MPA suggest low oral toxicity in the rat and mouse, and irritant effects on human eye and skin. Munro *et al.* (1999) discussed the metabolic degradation products of VX in mammals and found that there are about 25 such products and each had shown different levels of toxicity. Among those only *S*-(diisopropylaminoethyl) methyl phosphonothionate (EA 2192) has anticholinesterase activity and somewhat lower toxicity compared to VX.

Benschop *et al.* (2000) and Van der Schans *et al.* (2003) studied the toxicokinetics of VX stereoisomers in hairless guinea pigs and marmosets. Following an intravenous dose of 28 μg/kg (marmosets) or 56 μg/kg (guinea pigs), VX was found in the blood at toxicologically relevant levels even after 6 h. Detoxification proceeded at a slower rate in marmosets than in guinea pigs. The VX metabolite EMPA was found in the blood of the exposed animals; however, the metabolite contributed only 5% to the recovery of the phosphonyl moieties related to the VX dose. Metabolites of VX were also evaluated in *in vitro* studies by treating liver homogenates and plasma from hairless guinea pigs, marmosets, and humans with the radiolabeled compounds ^{35}S-VX. The potential toxic metabolite VX-N-oxide was not found. Desethyl-VX was found after incubation of VX in plasma of all three species; however, because of its slow rate of formation, Benschop *et al.* (2000) concluded that it would be unlikely that VX would be present at toxicologically

relevant levels after administration of VX *in vivo*. *In vitro* studies with ^{35}S-VX revealed that a significant part of the thiol-containing leaving group (*S*-2-/*N*,*N*-diisopropylamino/ethane thiol) was bound to proteins such as albumin.

Tsuchihashi *et al.* (1998) have developed a method for identification of VX metabolites in serum collected from a victim of the Osaka VX incident. In the serum sample, both EMPA and 2-(diisopropylamino-ethyl)methyl sulfide were detected. The techniques using GC-MS and GC-MS-MS were applicable to biological samples such as serum. These results provided the first documented identification of the specific metabolites of VX in victims' serum and clarified a part of the metabolic pathway of VX in the human body. In addition, methods have been developed for measuring the VX-inhibited AChE hydrolytic product EMPA (Noort *et al.*, 1998; 2002).

III. ESTERASES INVOLVED IN METABOLISM OF WARFARE NERVE AGENTS AND OTHER OPs

Numerous esterases can react with OPs but in a different way. The first classification was given by the late Professor Aldridge (1953). In the first group there were esterases that hydrolyze OPs as substrates, and among them particularly their uncharged esters, which are not inhibited by these compounds. This group of enzymes was named *A-esterases* although in the literature there are many other names for the same group of enzymes given according to the substrate hydrolyzed (paraoxonase, somanase, DFPase, etc.) or their chemical structure (phosphotriesterases, phosphorylphosphatases, anhydrases of organophosphorus compounds). In the second group of enzymes interacting with OPs were *B-esterases* which are inhibited with OPs in the progressive reaction which is time and temperature dependent. This group of enzymes comprises AChE, ChE, CarbE, trypsin, chymotrypsin, and other enzymes. In the third group were *C-esterases* that do not interact with OP. It is paradoxical, but basically true, that OPs can be substrates for both A- and B-esterases because their concentration in blood and tissues is decreased in the presence of these enzymes.

The mechanism of interaction of A- and B-esterases with OP is similar. B-esterases initially form Michaelis complex with an OP inhibitor producing phosphorylated or inhibited enzyme that either reactivates very slowly or does not reactivate at all (see Figure 69.1 in Chapter 65). However, after formation of Michaelis complex with OP A-esterases perform hydrolysis of OP and their catalytic activity and turnover rate are very high. It was already shown that CarbE, as a typical B-esterase, can hydrolyze carboxylic esters that serve as functional groups in OP such as malathion thus performing detoxification of the compound (WHO, 1986; Fukuto, 1990).

A. A-Esterases

In a classification from 1992 (International Union of Biochemistry, 1992) hydrolases of OP were described as a special entity as ''phosphoric triester hydrolases'' which comprise three groups of enzymes: phosphoric monoester hydrolases (EC 3.1.3), phosphoric diester hydrolases (EC 3.1.4), and phosphoric triester hydrolases (phosphotriesterases) (EC 3.1.8). Phosphoric triester hydrolases are further divided in two similar subgroups: aryldialkylphosphatases (EC 3.1.8.1) and diisopropylfluorophosphatases (EC 3.1.8.2).

Aryldialkylphosphatases take part in hydrolysis of aryldialkylphosphates producing dialkylphosphate and aryl alcohol. These enzymes react with substrates such as paraoxon (Figure 52.2a), but also with phosphonates and phosphinates. Other names for this group of enzymes are hydrolases of organophosphate compounds (OPCs), A-esterases, paraoxonases, PON1, aryltriphosphatase, and aryltriphosphate dialkylphosphohydrolase. They are inhibited with compounds that form chelates like EDTA since they require the presence of divalent ions, mainly Ca^{2+} (Walker, 1993). Some fractions of the enzyme purified from human serum were able to hydrolyze both paraoxon and phenylacetate and it was thought for a long time that the same enzyme is responsible for both. However, enzymes hydrolyzing aryl esters are classified as arylesterases (EC 3.1.1.2).

Diisopropylfluorophosphatases take part in hydrolysis of diisopropylfluorophosphate (DFP) and similar compounds producing diisopropylfluorophosphoric acid and fluoride ion (Figure 52.2b). These enzymes react with phosphorus anhydride bonds such as those between phosphorus and acyl radical (F^-, Cl^-, CN^-) in highly toxic OPCs such as soman, sarin, tabun, and DFP, and they were accordingly named somanase, sarinase, tabunase, DFPase, diisopropylfluorophosphate fluorohydrolase and anhydrases of organophosphorus acids. They are also inhibited by chelating agents, and their activity requires the presence of divalent ions such as Ca^{2+}, Mg^{2+}, and Mn^{2+} (Walker, 1993). They exist in several forms, even in different tissues of the same species, which react differently with substrates. However, in the literature published during the last 15 years the term PON1 apparently covers both phosphoric triester hydrolases. In a further text, in order to avoid eventual confusion, the term A-esterase will be generally used for enzymes
