Microtubules are formed by polymerization of α- and β-tubulin. They are intrinsically in dynamic turnover state, subject to treadmilling and dynamic instability. Microtubule-associated proteins (MAPs) are a heterogeneous group of proteins that have microtubule-binding domains. MAPs are abundantly expressed in the brain, and historically MAPs (e.g., MAP1, MAP2, and tau) derived from the brain have been studied extensively. MAP4 is ubiquitously expressed. These classical MAPs are filamentous proteins of various lengths, ranging from 50 to 185 nm. They have microtubule-binding domain and the projection domain that extends as filamentous structure. By binding along the side of microtubules, they stabilize microtubules. In addition, by extending the projection domain from the microtubule surface, they produce microtubule bundles of various densities. Tau and MAP2C predominantly expressed in the axon produce microtubule bundles of ~20 nm distances. MAP2 predominantly expressed in the dendrite produces microtubule bundles of ~65 nm distances. The microtubule bundles produced by tau/MAP2C and MAP2 resemble microtubule domains in axons and dendrites, respectively. These microtubule bundles are extended from the cell as axon- or dendrite-like processes. Therefore, MAPs serve as determinants of microtubule organization within the cell, particularly in neurons. There are some other groups of newly identified MAPs, and some of them destabilize microtubules. Binding of MAPs to microtubules is regulated by phosphorylation. In some neurodegenerative diseases including Alzheimer's disease, hyperphosphorylated tau precipitates as filaments on its own and may be one of the important factors to determine the progress of the disease.

Classical Microtubule-Associated Proteins

Microtubules are formed by polymerization of α- and β-tubulin. Microtubules play important roles in organizing and maintaining the shape of the cell, and also act as tracks for the transport of membranous organelles and macromolecules. So-called motor proteins (kinesin superfamily proteins and dynein superfamily proteins) are involved in the transport processes and they use the energy derived from the hydrolysis of ATP. Microtubule-associated proteins (MAPs) bind to microtubules without a requirement for nucleotide involvement, and organize the spatial arrangement of microtubules within the cell; they also regulate the polymerization of microtubules. Historically, MAPs have been isolated from the mammalian brain by their property that they remain bound to microtubules through repeated cycle of polymerization and depolymerization. The quick-freeze, deep-etch microscopy reveals that in neurons, there are abundant filamentous structures of various length associated with microtubules. These filamentous structures were proven to be mainly composed of MAPs (Figures 1 and 2). These MAPs have been studied extensively, and we term these well-characterized MAPs as classical MAPs. The major part of this article will be spent on these classical MAPs. Some other MAPs have been known and some new MAPs have been identified recently. These will be dealt with in relevant places. Classical MAPs include MAP1A, MAP1B, MAP2A, MAP2B, MAP2C, and tau (from mammalian brains) and MAP4 (found ubiquitously) (Table I). All these MAPs are fibrous molecules of different lengths, ranging from 50 to 185 nm, and form filamentous projections from the microtubule surface. First, the basic biochemical properties and their expression patterns will be described for each of the classical MAPs.

MAP1A and MAP1B

MAP1A and MAP1B are high-molecular-weight, heat-labile, filamentous proteins of ~350 and 320 kDa on SDS-PAGE. MAP1A and MAP1B are transcribed from the separate genes. MAP1B has also been called MAP1x or MAP5. The protein originally called MAP1C turned out to be cytoplasmic dynein. Therefore, it is not usually included in MAPs. MAP1A encodes protein of 2774 amino acid residues, and MAP1B encodes protein of

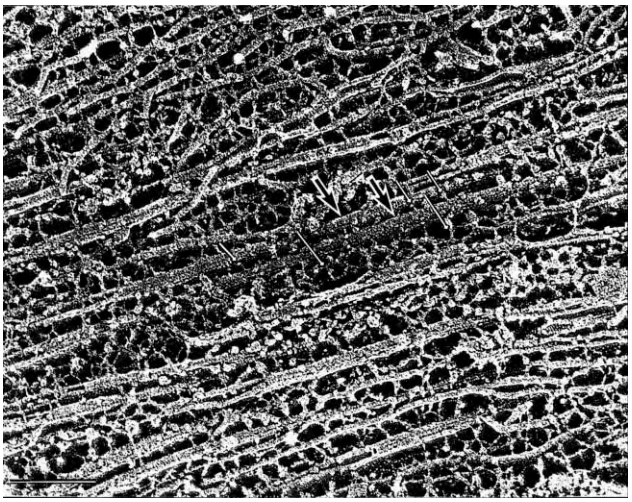

FIGURE 1 Axonal cytoskeleton observed by quick-freeze, deep-etch electron microscopy. Between microtubules (thick black arrows), short crosslinkers (short arrows) and longer crosslinkers are found. Reproduced from Hirokawa, N. (1991). Molecular architecture and dynamics of the neuronal cytoskeleton. In *Neuronal Cytoskeleton* (R. D. Burgoyne, ed.) pp. 5–74. 2464 amino acid residues. Rotary-shadowing electron microscopy reveals that MAP1A and MAP1B are highly elongated, flexible molecule of ~150–185 nm in length. Both MAP1A and MAP1B have associated light chains. Interestingly, the light chains, LC2 and LC1, are encoded at the C-terminal portion of MAP1A and MAP1B molecules, respectively. At the N-terminal portion of both MAP1A and MAP1B molecules, there is a domain

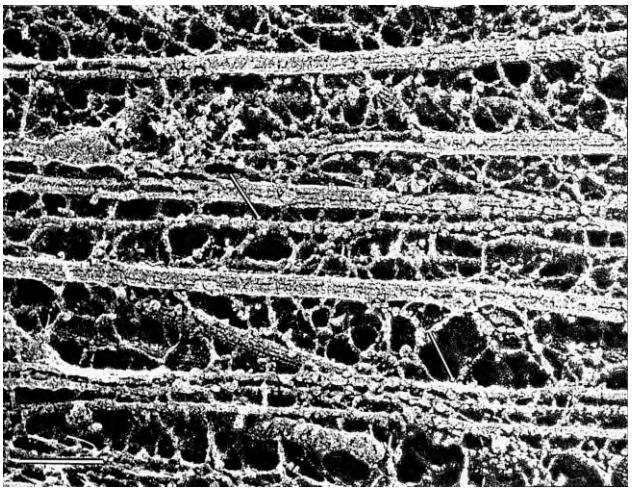

FIGURE 2 Dendritic cytoskeleton observed by quick-freeze, deep-etch electron microscopy. Between microtubules, and between microtubules and neurofilaments (arrows), long crosslinkers are found. Reproduced from Hirokawa, N. (1991). Molecular architecture and dynamics of the neuronal cytoskeleton. In *Neuronal Cytoskeleton* (R. D. Burgoyne, ed.) pp. 5–74. enriched in the positively charged amino acids and contains the short motif (KKEX), repeated 11 and 21 times in MAP1A and MAP1B (Table I and Figure 3). This domain serves as microtubule-binding domain, and interacts with C terminus of tubulin, which has a large number of acidic residues. Both MAP1A and MAP1B form filamentous structures associated with microtubules in neurons.

MAP1A and MAP1B are predominantly expressed in neuron, although a smaller amount may be expressed in other tissues as well. There is a developmental regulation in the expression of MAP1. MAP1A is more abundantly expressed in the adult, and MAP1B is more abundantly expressed in the developing nervous system. In fact, the expression of these two proteins appears to be complementary to each other. In the rat brain development, the level of MAP1B expression is highest at the first few postnatal days, when many neurons are extending their axons. Thereafter, the expression of MAP1B declines. In contrast, the expression of MAP1A is very low at this period, but the level of its expression increases thereafter, and reaches its maximal level in adults. There is a spatial difference in the expression of MAP1B and MAP1A. MAP1B is predominantly expressed in the developing axon, although smaller amount is found in the dendrite of juvenile and mature neurons. In contrast, MAP1A is abundantly expressed in the mature dendrites, with the smaller amount of expression at the axons.

MAP2A, MAP2B, AND MAP2C

MAP2A and MAP2B were identified as high-molecular-weight, filamentous protein of ~280 and 270 kDa on SDS-PAGE. MAP2A and MAP2B have been known to be heat stable, which is rather unique considering the high molecular weight of these proteins. MAP2B encodes proteins of 1828 amino acid residues; MAP2A is a splice variant having additional exon of 83 amino acid residues in the middle of the molecule. Rotary-shadowing electron microscopy revealed that MAP2A and MAP2B are highly elongated, flexible molecules of ~100 nm in length. Subsequent study revealed that there is additional low-molecular-weight form, MAP2C, which is ~70 kDa on SDS-PAGE. In MAP2C, the N- and C-terminal ends are joined, resulting in the protein of 467 amino acid residues. The unique characteristic of MAP2 is that they have binding domain for the regulatory subunit of type II cyclic AMP-dependent kinase on the N terminus. The C-terminal portion of the MAP2 forms the microtubule-binding domain (Table I and Figure 3). The sequence of this region does not have homology to MAP1, but it has unique imperfect tandem repeats of 31–32 amino acids; similar repeats of 18 amino acids joined by less-conserved, variable "spacers" of

TABLE I

Characteristics of Classical MAPs

MAPs	App. mol. weight on SDS-PAGE (KDa)	# of amino acids	Length of isolated molecule (nm)	Distance in microtubule bundles (nm)	Microtubule-binding domain	Developmental and topological expression pattern
MAP1A[a]	350	2774	150–185		N-terminal KKEX repeats	Abundant in mature dendrite
MAP1B[a]	320	2464	150–185		Same as above	Abundant in developing axon
MAP2A[b]	280	1911	~100	~65	C-terminal tandem repeats	Specific to developing dendrite
MAP2B[b]	270	1828	~100	~65	Same as above	Specific to developing and mature dendrite
MAP2C[b]	70	467		~20	Same as above	Abundant in developing axon and dendrite
tau[c]	55–65	352–441	~50	~20	Same as above	Abundant in developing and mature axon
MAP4	210	1072			Same as above	Ubiquitously expressed

[a] MAP1A and MAP1B are transcribed from separate genes.
[b] MAP2A, MAP2B, MAP2C are splice variants.
[c] Six isoforms of tau are splice variants.

13–14 amino acids. These repeats bind to the C-terminal ends of tubulin. These imperfect tandem repeats are also used in the microtubule-binding domain of tau and MAP4, which also reside in the C-terminal part of the molecule. Each molecule has three or four repeats. The central portion of the MAP2A and MAP2B molecule corresponds to the extended arm. Lacking this arm portion, MAP2C is revealed as

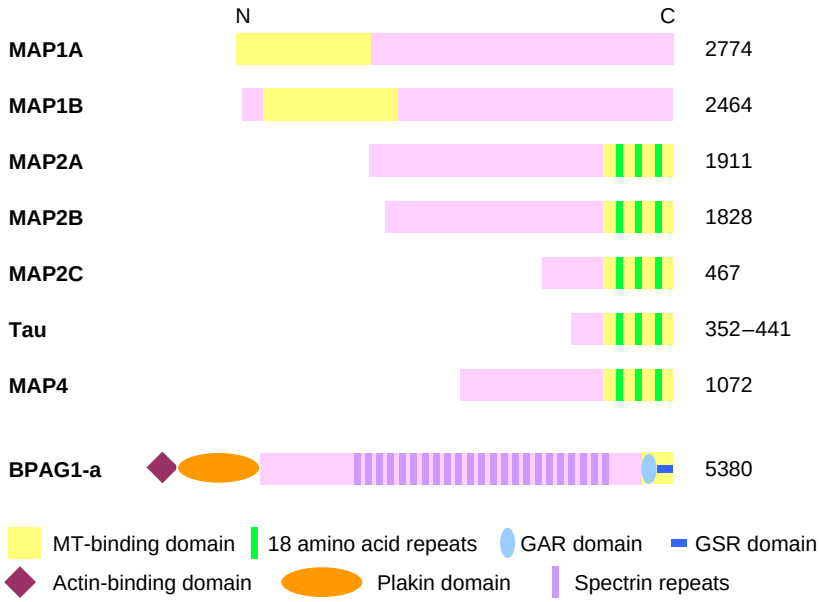

FIGURE 3 Schematic diagram of representative MAPs. Domain structures of MAP1A, MAP1B, MAP2A, MAP2B, MAP2C, tau, MAP4, and BPAG1-a are shown. Numbers of amino acids of representative molecules are shown on the right. MAP1A and MAP1B have a microtubule-binding domain on the N-terminal portion, which is a domain enriched in the positively charged amino acids and contains the short motif (KKEX), repeated 11 and 21 times in MAP1A and MAP1B, respectively. C-terminal portion serves as a projection domain. MAP2A, MAP2B, MAP2C, tau, and MAP4 have a microtubule-binding domain on the C-terminal portion, which is a unique imperfect tandem of three or four basic repeats of 31–32 amino acids, similar repeats of 18 amino acids joined by less conserved, variable "spacer" of 13–14 amino acids, and is quite well preserved among these MAPs. Molecules with three repeats are depicted in the drawing. BPAG-1a, one of the new MAPs, has actin-binding domain, plakin domain, spectrin-repeat-containing rod domain, GAR domain, and GSR domain. The GAR and the GSR domain together constitute the microtubule-binding domain in BPAG1-a as well as in MCAF. In plakin, which is not depicted here, GAR domain is missing and GSR domain at the C-terminal portion can associate with microtubules. Not drawn to scale.

filamentous molecule ~50 nm in length by the rotary-shadowing electron microscopy.

MAP2 is almost exclusively expressed in neurons. Importantly, MAP2A and MAP2B are specifically localized to the dendrites. It is often used as markers for dendrites. There is a developmental regulation of MAP2 expression. MAP2C is expressed in juvenile neuron; it is found in cell bodies, dendrites, and axons. MAP2A is expressed in the adult, and MAP2B is expressed throughout the developmental stage.

Tau

Tau was the first MAP purified from the brain. It is heat stable, consists of several bands of 55–65 kDa on SDS-PAGE. It is now known that tau consists of six isoforms (ranging from 352 to 441 amino acid residues), which are splice variants of single tau gene. In the C-terminal half of the molecule, tau has three or four tandem repeats of 31 or 32 amino acids, as described above, which serves as the microtubule-binding domain (Table I and Figure 3). In rotary-shadowing electron microscopy, tau forms filaments of ~50 nm in length. Tau forms ~20 nm short filamentous structures associated with microtubules. It is known that in the peripheral nervous system, additional isoform of 110 kDa is expressed. However, this isoform is less well characterized.

There is a developmental regulation of expression of tau isoforms. In the juvenile brain, only the three repeat isoforms are expressed, and in the adult brain, tau isoforms with both three and four repeats are expressed. Tau is posttranslationally modified by phosphorylation. A part of the heterogeneity of the tau bands on the SDS-PAGE results from phosphorylation. When antibodies that recognize all tau isoforms are used, tau is predominantly localized in the axon, with some expression in cell bodies and dendrites.

MAP4

Although MAP1, MAP2, and tau are rather abundantly expressed in the nervous system, their expression outside the nervous system is limited. MAP4 is a major MAP found outside the nervous system. It is a protein of 210 kDa on SDS-PAGE. MAP4 encodes protein of 1072 amino acid residues. It is composed of an N-terminal projection domain and a C-terminal microtubule-binding region, which has homology to the microtubule-binding domain of tau and MAP2 (Table I and Figure 3).

Control of Microtubule Dynamics

Microtubules are dynamic and unstable. By binding along the sides of the microtubules, MAPs control microtubule dynamics *in vitro* and *in vivo*. Many MAPs, including classical MAPs, stabilize microtubules. Classical MAPs were usually expressed predominantly in the nervous system. Microtubules in the neuron are usually much more stable than those in most interphase cells. Therefore, it is not surprising that one important function of classical MAPs is the stabilization of microtubules against disassembly. As described above, tau, MAP2, and MAP4 share conserved C-terminal three or four pseudorepeats, which serves as microtubule-binding domain. In tau, it is shown that one of these repeats bind to the tubulin C-terminal end, and other repeats bind to another internal site of tubulin. Therefore, these tandem repeats are likely to bind to microtubule in such a way to crosslink adjacent tubulin subunits and stabilize microtubules against disassembly. These bindings are controlled by phosphorylation. Both tau and MAP2 have many residues, which can be phosphorylated.

There are other modes of regulation of microtubule dynamics by MAPs. Microtubule is usually disassembled in the cold temperature. Stable tubule-only polypeptide

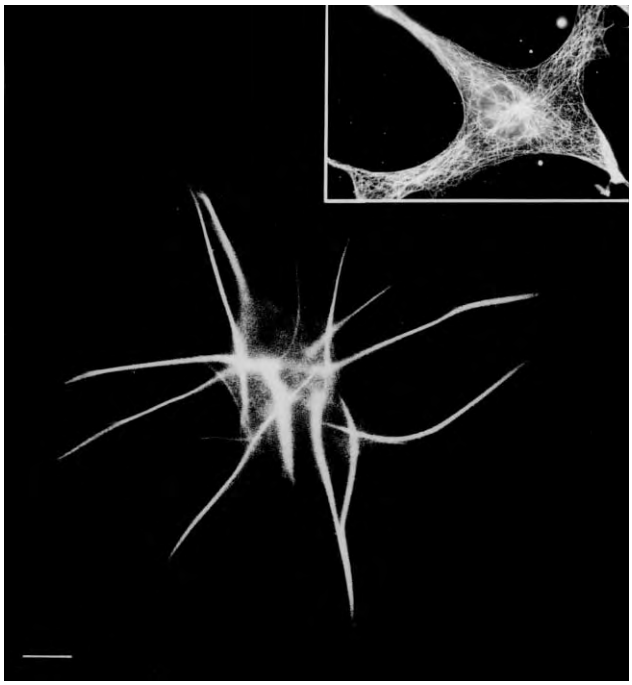

FIGURE 4 Microtubule bundle formation in fibroblasts transfected with tau cDNA. Immunofluorescence using anti-tubulin antibody. Long processes are formed and microtubule bundles extend into the processes. Upper right corner is the immunofluorescence of nontransfected control fibroblasts stained with antitubulin antibody. Microtubules radiate in various direction from the microtubule-organizing center near the nucleus. Reproduced from Kanai, Y., Takemura, R., Oshima, T., Mon, H., Ihara, Y., Yanagisawa, M., Masaki, T., and Hirokawa, N. (1989). Expression of multiple tau iso-forms and microtubule bundle formation in fibroblasts transfected with a single tau cDNA. *J. Cell Biol.* **109**, 1173–1184 with permission of The Rockefeller University Press.

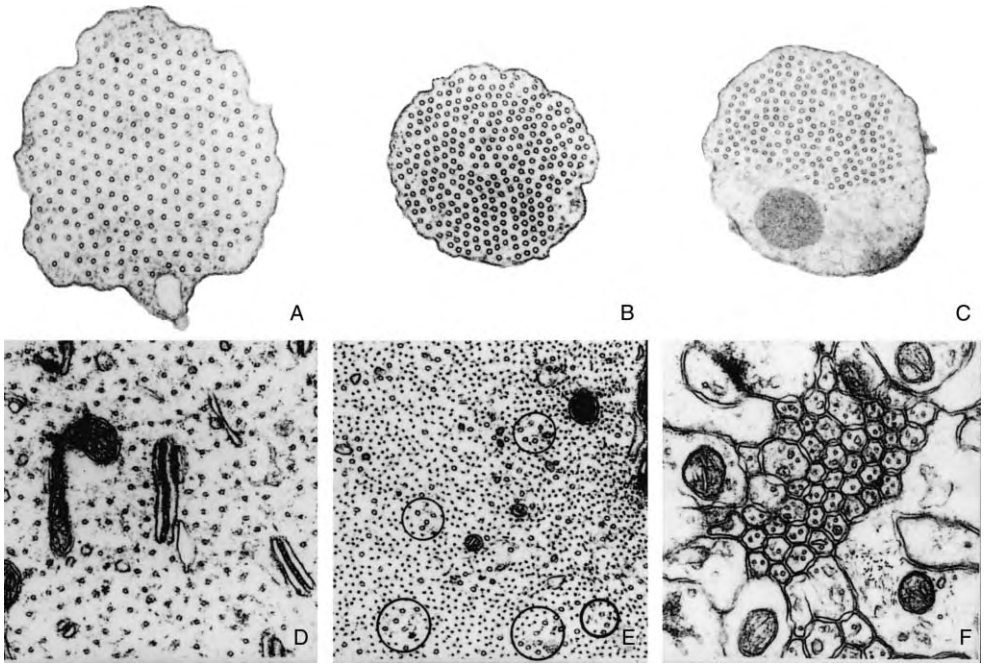

FIGURE 5 Cross-section electron micrographs of processes induced by transfection of MAP2 (A), MAP2C (B), and tau (C) into Sf 9 cells. Each MAP2 forms microtubule bundles, but the organization is different. When MAP2 is transfected, wall-to-wall distance between nearest adjacent microtubules is ~65 nm, which is similar to the microtubule organization of Purkinje cell dendrite in the cerebellum (D). In contrast, when MAP2C or tau are transfected, the distance between microtubules is ~20 nm, which is similar to the microtubule organization of large myelinated axons in the spinal cord (inside the circle in (E)) or parallel fiber axons in the cerebellum (F). Reproduced from Chen, J., Kanai, Y., Cowan, N. J., and Hirokawa, N. (1992). Projection domains of MAP2 and tau determine spacings between microtubules in dendrites and axons. *Nature* **360**, 674–677 with permission of Nature.

(STOP) is a MAP known to stabilize microtubules against cold temperature. A few MAPs are also known to destabilize microtubules, including katanin, Op18, and stathmin. In addition to structural MAPs, some of the kinesin superfamily proteins belonging to KIF2 class also destabilize microtubules.

Bundling of Microtubules: MAPs and Neurite Outgrowth

Neuron extends axon and dendrites from the cell body. In the axon and dendrites, microtubules run in parallel, in longitudinal array. In the quick-freeze, deep-etch electron microscopy, it can be shown that microtubules are highly crosslinked by meshwork of fine filamentous structures in axons and dendrites (Figures 1 and 2). MAPs form these crosslinkers. Moreover, MAPs induce microtubule bundle formation and outgrowth of processes from the cell. When classical MAPs are transfected and overexpressed in the cells, such as fibroblast or Sf9 cells, unusual microtubule bundles are formed, and long processes very much like neurites can be induced (Figures 4 and 5).

In addition, MAPs determine the spacing between neighboring microtubules to be axon like or dendrite like. Namely, MAPs expressed in the axon, such as tau and MAP2C, produce microtubule bundles similar to those seen in the axon (wall-to-wall distance of neighboring microtubules, ~20 nm), and MAPs expressed in the dendrites, such as MAP2A and MAP2B, produce microtubule bundles similar to those seen in the dendrites (wall-to-wall distance of neighboring microtubules, ~65 nm) (Figure 5). Therefore, in addition to the stabilization of microtubules, projection domains of MAPs induce microtubule bundle formation, induce process outgrowth, and determine the spacing between microtubules.

Analysis of Transgenic and Knockout Mice: Relation of MAPs to Neurodegenerative Diseases

Recently, genetically altered mice gave some insights to the role of individual MAPs *in vivo*. In general, lack of MAP produces the expected effect, but the overall effect is rather limited. This implies that there is certain

overlap in the function of MAPs. In fact, when the double knockout mice were formed in the combination of two MAPs, the expected effect is much more severely observed. For example, in *tau* $^{-/-}$ mice, an effect on the microtubule stabilization and bundle formation in the axon was observed, but the effect is evident mainly in the small caliber axon. Likewise, in *MAP2* $^{-/-}$ mice, an effect on microtubule organization in dendrite is evident, but the effect is somewhat limited. However, when both tau and MAP1B, or both MAP1B and MAP2 are deleted, impaired microtubule bundle formation and outgrowth of axon or dendrite was markedly observed.

Tau has been implicated in the pathogenesis of certain cognitive neurodegenerative diseases. The diseases are sometimes grouped as tauopathies, which comprise a heterogeneous group of age-dependent cognitive disorders, including Alzheimer's disease. In these diseases, abnormally hyperphosphorylated tau forms filamentous aggregates within the cell. The aggregates do not contain microtubules, and the formation of aggregates is independent of microtubules. There is a loss of neurons in the affected brain area. In 1998, tau gene mutations were identified in patients with dementia and parkinsonism linked to chromosome 17 (FTDP-17). Transgenic mice with these mutations have been developed for an analysis.

New MAPs

Recently, a family of proteins of a very high molecular weight, plakin family, has been identified as crosslinker proteins that connect different cytoskeletal filaments. Some of the members, such as plectin, Bullous pemphigoid antigen 1 (BPAG1), and microtubule-actin crosslinking factor (MACF), have microtubule-binding domain, and they are likely to crosslink microtubule to intermediate filaments, or actin filaments. Microtubule-binding domain used in the plakin family proteins are of two kinds: Gas2-related (GAR) domain in BPAG1 and MACF; and glycine-serine-arginine (GSR) domain in plakin, BPAG1, and MACF (Figure 3). That these new crosslinkers play an important physiological role is suggested by the fact that mutations in these proteins cause neurological defects *in vivo*. For example, mutations in BPAG1 cause degeneration of sensory neurons, and mutation in MCAF cause deficits in axon outgrowth and dendritic sprouting.

Glossary

axon Structure that transmits the signal from the cell body to the synaptic terminal. Single axon extends from the cell body. Microtubules and neurofilaments are major components of the axonal cytoskeleton. Microtubules in the axons are organized more densely than in the dendrites.

dendrite Structures that receive signals and transmit them to the direction of the cell body. Usually, multiple dendrites emanate from the cell body in "dendritic" shape. Microtubules are the major components of the dendritic cytoskeleton, and microtubules in the dendrites are organized more loosely than in the axon.

microtubule Filament of 25 nm diameter. Assembled from α- and β-tubulin subunits (55 kDa), it is actually a hollow cylinder (hence tubule) composed of 13 protofilaments. During mitosis, it forms a mitotic spindle. Compared to intermediate filaments (10 nm diameter), microtubules turn over much more dynamically. New subunits are added at the "plus" end, while subunits dissociate from the "minus" end (treadmilling). In addition, microtubules show the property called "dynamic instability," in which individual microtubules are either growing or shrinking and they stochastically switch between the two states.

Biography

Nobutaka Hirokawa is Professor and Chair of Department of Cell Biology and Anatomy, and Dean of the School of Medicine, University of Tokyo. His principal research interests are organization of cytoskeletal structures in neurons and molecular motors involved in the intracellular transport. He holds an M.D. and Ph.D. from University of Tokyo. He developed the quick-freeze, deep-etch electron microscopy with Dr. John Heuser, and did pioneering work in elucidating the neuronal cytoskeleton in molecular detail, including the analysis of MAPs. He was also one of the first to tackle the analysis of kinesin motor molecules, and the first to clone multiple kinesin superfamily proteins from mammalian brain and to point out the importance of this motor protein family in mammalian intracellular transport.

Mitochondrial Auto-Antibodies

Harold Baum
King's College London, London, UK

Auto-antibodies are antibodies that bind specifically to self-constituents, and so would seem to be an anomaly of a system geared to respond to foreign molecules and be tolerant to self. The antigens that they may recognize encompass the spectrum from tissue specific to being common to all cell types. They may be pathogenic, disease-specific, and diagnostic, or of no clear significance. Auto-antibodies against mitochondrial components are illustrative of this range of characteristics, even to the extent that diseases characterized by them may be very specifically tissue localized. They have been extensively studied, and in the case of primary biliary cirrhosis (PBC) they have become a paradigm in the study of autoimmune diseases. A consideration of the mitochondrial auto-antibodies (AMA) characteristic of PBC is the major focus of this article.

Detection of Mitochondrial Auto-antibodies

Auto-antibodies (AMAs) have been detected by immunofluorescence (IFL) (where they are visualized as bright granular staining in cell types with high mitochondrial content), or by applying complement fixation tests (CFTs), enzyme-linked immunosorbant assays (ELISAs) or Western immunoblotting (IB) to tissue extracts, purified subcellular constituents or specific, recombinant mitochondrial species. Proof that mitochondria were the target of antibodies detected by such methods was provided in early studies, such as the landmark paper of Walker *et al.*, by the specific absorption of serum reactivity using preparations of mitochondria. It was subsequently recognized that AMAs recognizing different mitochondrial antigens might characterize different clinical conditions. The molecular identity of many, but not all, of these antigens is now established. Not all of these AMAs are detectable by all of the above methodologies. The preferred test in general diagnostic laboratories is IFL on a composite substrate of rodent tissues. In the research laboratory however, and where specific AMAs are under investigation, the preferred assays are ELISAs and IB, using purified or recombinant antigens, or synthetic peptides.

The M-Classification of AMAs

In the early 1980s an arbitrary classification of AMAs, as anti-M1-9, was developed, mainly by Berg's group in Tübingen, on the basis of patterns of IFL and/or properties of target antigens as determined by various assay procedures. It is noteworthy that in all these cases the AMAs are not species specific. Whilst this M-classification is now somewhat obsolete, and does not include all known mitochondrial targets for AMAs, it is still sufficiently in common use for it to be helpful in listing reactivities (Table I).

Anti-M1 AMAs and Cardiolipin

The M1 pattern of IFL is exhibited exclusively with sera of patients with untreated secondary syphilis. The reaction is abolished completely by absorption of sera with cardiolipin, the characteristic phospholipid of the mitochondrial inner membrane. However, the simple conclusion that anti-M1 antibodies are specific for cardiolipin is complicated by another observation. The earlier diagnostic test for syphilis, the Wasserman reaction, is based on CFTs against cardiolipin. However, not all sera positive in this test show an M1 pattern of IFL. Moreover, Wasserman-positive sera that are negative for M1 give a strongly positive ELISA reaction against purified cardiolipin, whereas anti-M1 AMAs are scarcely detectable by ELISAs using purified cardiolipin, whilst they react strongly in ELISAs against sub-mitochondrial particles. Interestingly, M1-negative, Wasserman positive sera are frequently false positives for syphilis and may instead reflect collagen disorders such as systemic lupus erythmatosus (SLE). It seems likely that these anomalies reflect antibodies to different epitopes in cardiolipin, the different assay systems exposing different conformations of the same molecule. (Indeed some of the anti-cardiolipin antibodies in M1-negative sera of SLE patients may be detected as antibodies against nucleic acids, cross-reactivity arising by virtue of the similarity between the glycerol phosphate arrays in cardiolipin arrays and the ribose phosphate backbone of nucleic acids.) Anti-M1 AMAs probably recognize a more native form of the

TABLE I

The M-Classification of Specificities of Mitochondrial Auto-Antibodies

Antigen	Occurrence of auto-antibodies
M1	Secondary syphilis
M2	PBC
M3	Phenopyrazone-induced pseudolupus syndrome
M4	PBC (prognostic indicator? "mixed form"?)
M5	Subgroup of systemic lupus; anti-phospholipid syndrome
M6	Iproniazid-induced hepatitis
M7	Cardiomyopathies
M8	PBC (prognostic indicator?)
M9[a]	PBC (prognostic indicator?)

[a] NB. In fact this antigenic specificity is not mitochondrial (see text).

lipid, as it exists in the intact mitochondrial membrane (and may arise from immunological cross-reactivity with a membrane constituent of the agent of syphilis, *Treponema pallidum*).

Anti-M2 AMAs

The most important mitochondrial auto-antibodies, anti-M2 AMAs, exhibit a characteristic pattern of IFL and were initially defined both by their disease specificity and by properties of the antigen that they recognized. This was shown to be trypsin sensitive and associated with (but detachable from) the inner surface of the inner membrane of all mitochondria tested, from human to fungal. Anti-M2 antibodies were also shown to cross-react with several bacteria, anti-mitochondrial activity, for example, being absorbed out of PBC sera by *E. coli*.

Association with Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a chronic, cholestatic liver disease, predominantly affecting middle-aged women. It is characterized by spontaneous inflammatory damage to the epithelial cells of the bile duct (BEC). Whilst the clinical presentation and disease progression are variable, and the disease may be virtually asymptomatic for many years, the end stage is cirrhotic liver failure, and the disease is the second most frequent reason for liver transplantation in the developed World. Although the most clinically significant pathology relates to the liver, PBC is actually a multi-system disorder, and may feature lachrymal salivary and pancreatic hyposecretion. The paper by Walker, referred to earlier, and many subsequent studies, demonstrated clearly that PBC is characterized by high and persistent titers of AMAs of a kind not seen in normal subjects or other diseases. Since the description of this close association, the detection of this class of AMAs, designated as anti-M2, has acted as a powerful diagnostic tool. Anti-M2 antibodies (both IgG and IgM) are found in up to 98% of PBC patients, the precise figure depending on the sensitivity of the assay used. Interestingly, these AMAs are not restricted to serum, being found in the bile, saliva, and urine of patients with PBC. Moreover anti-M2 AMAs have turned out to be predictors for the disease; asymptomatic subjects, accidentally having been identified as being positive for anti-M2 AMAs, are frequently found to develop the disease subsequently.

Identity of M2 Antigens

Western IB soon revealed that M2 actually consists of a "family" of up to seven co-purifying peptides of differing molecular weight, encompassing a spectrum from around 75 to 36 kDa. Different PBC sera demonstrated different patterns of reactivity against these (see Table II), but virtually all recognized a predominant peptide that was eventually identified as being the E2 component (dihydrolipoamide acetyltransferase) of the pyruvate dehydrogenase complex. Thereafter, it soon became clear that the other M2 antigens were also constituents of one or other of the 2-oxo-acid dehydrogenase multienzyme complexes (OADCs): pyruvate, 2-oxoglutarate and branched-chain 2-oxo acid dehydrogenase complexes (PDC, OGDC, and BCOADC, respectively). Each of the three complexes occupies a key position in energy metabolism in aerobic cells. Each consists of multiple copies of at least three enzymes (E1, E2, and E3), which are encoded by genes in the nucleus and separately imported into mitochondria for assembly into high molecular weight multimers localized to the matrix aspect of the inner membrane. The structural core of these complexes is provided by E2 (the acyltranferase), to which multiple copies of E1

TABLE II

Frequency of Occurrence of Anti-M2 AMA to Specific Antigens in PBC

Complex	Subunit	Apparent M_r (kD[a])	AMA-positive (%)[a]
PDC	E1α	41	53
PDC	E1β	34–36	4
PDC	E2	70–74	96
PDC	E3BP (X)	50–56	96
OGDC	E2	48–50	74
BCOADC	E1α	46	50
BCOADC	E2	50–52	56
All	E2's		50
At least one	E2		98

[a] Approximate average of published data using defined antigens.

(the decarboxylating dehydrogenase) and E3 (dihydrolipoamide dehydrogenase) are noncovalently bound. The E2 enzymes are notably homologous in structure as between different complexes and different species (e.g., there is 52% similarity in sequence as between rat PDC-E2 and OGDC-E2 of *E. coli*). E3 is common to all three complexes, whereas E1 and E2 are unique to each complex. PDC contains a fourth polypeptide with a structural role, the E3-binding protein (E3BP), once termed protein X. This contains a lysine-linked lipoate moiety, located in a domain that is strongly homologous to corresponding domains in PDC-E2.

In view of this latter homology, it is not surprising that all sera recognizing PDC-E2 also bind E3BP, and that the antibodies to the two peptides are cross-reactive. The other members of the M2 "family" were shown to include the E2's of OGDC and BCOADC. However, notwithstanding the general similarity between the respective E2's, there seems only to be a limited degree of antibody cross-reactivity between them and only about 50% of PBC sera recognize all three. (On the other hand AMA against a particular E2 recognize that peptide in mitochondria of all species tested.) About half of all PBC sera also recognize the α-subunit of PDH-E1, (with the β-subunit being rarely recognized). Additionally, human auto-antibodies, specific for BCOADC-E1α, were found, in a more recent study, in the sera of almost half of the PBC patients tested. A summary of frequency of occurrence of AMAs to individual members of the M2 "family" is given in Table II. The E3 component, a common subunit of all three complexes, is not listed in this table. This is because, whilst specifically anti-mammalian E3 antibodies are found in PBC, these are in relatively low amount and are not totally disease specific.

Enzyme Inhibition by Anti-M2 AMAs

A notable characteristic of AMAs in PBC sera is their capacity to block the catalytic function of the 2-OAD multienzyme complexes *in vitro*. For example, sera with AMAs recognizing PDC-E2 rapidly inhibit PDC at dilutions of 1/500–1/5000, much of this inhibitory activity being removed by pre-absorption of the sera with recombinant PDC-E2. Similarly, affinity-purified antibody against PDC-E1α also specifically inhibits PDC reactivity.

Possible Target for Anti-M2 AMAs on Bile Duct Cells

What may be a key fact relating to the occurrence and disease association of AMAs in PBC is the reactivity that has been observed of anti-M2 AMAs (and of selected monoclonal antibodies against PDC-E2) with some component at the surface of a subset of BEC in livers of PBC patients. Conflicting views are that this antigen is an inappropriately localized component of PDC, or that it is a different molecule with a sequence similarity to a dominant B-cell epitope. In view of the potentially fundamental significance of the presence of a disease specific antigen at the site of tissue damage, it is regrettable that no definitive identification has yet been made.

Cross-Reactivity of Anti-M2 AMAs Against Bacteria

Early reports of cross-reactivity of PBC-specific AMAs against a variety of bacterial species were confirmed in studies of reactivity against individual microbial E2's of the three OADC complexes. (There is no homology between microbial and corresponding mitochondrial E1's; neither is there reactivity of E1-specific AMAs against bacteria.) Further evidence of cross-reactivity is that antibodies raised in rabbits, against bacterial mutants having fragile cell walls, were reported to react with a typical M2 pattern on IB against mitochondria. However, detailed absorption/elution and other studies have led to a current view that, whilst there is indeed some cross-reactivity between corresponding enzymes, PBC sera contain distinct sets of antibodies against mitochondrial and microbial OADCs respectively.

Anti-M2 AMAs and Chronic Bacterial Infection

In a study of women with asymptomatic recurrent bacteriuria, a majority of the patients were found to be weakly positive for antibodies to PDC-E2 by immunoblot, in the absence of evidence of liver disease. AMAs were also detected by ELISAs and IB in 43% of patients with active pulmonary tuberculosis and in patients with leprosy. However, it is not clear whether what is being detected in these cases are "true" AMAs or antibodies against corresponding microbial enzymes that are partially cross-reactive against mitochondrial peptides.

Epitopes Recognized by Anti-M2 AMAs

Most studies on B-cell epitopes in PBC have focused on the E2 antigens. Here it is clear that the main immunogenic regions are the lipoyl domains. Short peptides (e.g., of around 20 residues in length) encompassing the lipoyl-binding site are rather weakly antigenic, and full immunological reactivity is only seen for much longer peptides. Thus, for PDC-E2, the 93-residue sequence, 128–221, of the inner lipoyl domain is required for maximal antibody binding. The outer lipoyl domain, although containing a highly homologous region around the lysine residue that is bound to lipoate, is only weakly antigenic. These and other findings suggest that the overall epitopes are conformational

ones, but centered on the lipoyl-binding sites. The strong homologies between these domains among the three OADCs, and between mitochondrial and microbial enzymes, may account for partial cross-reactivities, with extended flanking regions being responsible for specificity and full reactivity. There is some disagreement as to whether lipoyl residues themselves are necessary for full reactivity, but corresponding peptides not containing lipoate are undoubtedly antigenic.

Stimulus for Anti-M2 AMAs Production in PBC

There is good evidence that B-cell clones producing AMAs are maximally stimulated, and it is noteworthy that the dominant epitopes of the $CD4^+$ T-cells, that provide the help for antibody production, are short peptides of the lipoyl-binding domain. (Similar peptides are also the dominant epitopes of the cytotoxic $CD8^+$ T-cells that infiltrate the bile ducts in this disease.) What then is the antigenic drive in PBC? It cannot be a secondary response to tissue damage, since M2 AMAs are not detectable in many other destructive diseases of the liver.

As mentioned earlier, chronic microbial infection may be characterized by low titers of anti-M2 AMAs. There is also epidemiological evidence of association between recurrent urinary tract infection (UTI) and PBC. Moreover, UTI is particularly common in middle-aged women, the group in which PBC most commonly occurs. So it is suggested that the initial stimulus for an immune reaction directed specifically at the E2's of the OADCs, (and E3BP of PDC), is chronic exposure, in the context of co-stimulatory signals (and perhaps a particular genetic background), to microbial peptides that share strong sequence similarities with the lipoyl-binding domains at the core of the dominant epitopes. Expansion of reactivity and specificity to incorporate the entire domain, and then also to recognize E1 subunits, would be by epitope-spreading. Such "microbial mimics" might not necessarily be the homologous OADCs. A number of other bacterial and viral peptides have been identified with strong sequence similarities to the "core" peptidyl epitope of PDC-E2, and have been shown, by ELISAs, to react specifically with PBC sera, the antibodies being cross-reactive with that "core peptide."

One other important fact needs bearing in mind in any speculation about antigenic drive. Once it is established, it persists. Even after liver transplantation high titers of anti-M2 AMAs are still found.

Role of AMAs in the Pathogenesis of PBC

Anti-M2 AMAs are so focused in specificity and so disease specific that it has to be assumed that they are relevant to disease pathogenesis, but most workers have concluded that it is T-cells rather than the antibodies themselves that are the direct cause of tissue damage. For example, high titers of AMAs can be raised in experimental animals, e.g., by immunization with recombinant human PDC-E2, with no evidence of liver damage even after a prolonged period, and only a minority of patients exhibit unambiguous recurrence of PBC following liver transplantation, despite the persistence of AMAs. However in the former case, fine specificities of the AMAs may not be identical to those of the PBC-specific antibodies, and in the latter immunosuppressive drugs may be protective. If the AMAs were to be directly cytotoxic, it might be by inhibition of mitochondrial function following uptake into BEC. Such uptake might be mediated by binding to the elusive antigen that might be the primary recognition target at the surface of BEC.

Anti-M3 AMAs and Pseudolupus Syndrome

Some time ago it was recognized that there was an association between the taking of the drug phenopyrazone, for cardiovascular disease, and a disorder designated as pseudolupus syndrome (PLE). This syndrome was characterized by AMAs that could be demonstrated by IFL, CFTs, and ELISAs, but not by IB. The antigen, classified as M3, was shown to be associated with the outer mitochondrial membrane, and was not organ specific. High titers of anti-M3 were detectable during the acute phase of the disease, but they declined on cessation of treatment with phenopyrazone, a drug that has since been withdrawn. No further cases of PLE have been reported, and the M3 antigen has not been further characterized. However, it has been speculated that it might be a drug-metabolizing enzyme such as monoamine oxidase (MAO), rendered immunogenic through tight binding to the drug.

Anti-M4 AMAs and Sulfite Oxidase

In addition to anti-M2, another complement-fixing antibody has been shown to be closely associated with PBC. The target antigen in this case, designated as M4, was found to co-purify with the outer mitochondrial membrane and be insensitive to trypsin. It was identified as being sulfite oxidase, an enzyme of the intermembrane space, a precursor of which binds to the outer membrane. Sulfite oxidase in an evolutionarily highly conserved enzyme, also found in bacteria, but enzyme activity does not seem to be inhibited by M4-positive PBC sera and the identity of the antigen is now in some doubt. The clinical significance of the detection of anti-M4 in addition to anti-M2 AMA is controversial. There have been claims that anti-M4 AMAs reflect a "mixed form" pathology of PBC with histological

features of chronic active hepatitis, and/or that their detection is an indicator of poorer prognosis towards the end stage of the disease. However, other workers have questioned their specificity in relation to PBC, suggesting that these, and anti-M8/M9, are nonspecific indicators of high serum levels of IgG.

Anti-M5 AMAs and Phospholipid

Mention has been made that false Wasserman-positive tests may reflect a different conformation of cardiolipin than that recognized by the M1-positive, syphilis-specific pattern of IFL, and are frequently associated with SLE. Such false-positive reactions often correlate with a characteristic IFL pattern, designated as M5. This pattern is seen both with a subset of SLE and patients with antiphospholipid syndrome, characterized by thrombocytopenia and recurrent fetal loss. Whilst anti-M5 reactivity may be absorbed out by inner mitochondrial membranes, no specific reactivities have been detected against any mitochondrial proteins, and it is concluded that M5 is some form of phospholipid, although the reactivity is not absorbed out by cardiolipin liposomes or cardiolipin–glycoprotein complexes.

Anti-M6 AMAs and Immuno-Allergic Hepatitis

Anti-M6 AMAs have been detected, by a characteristic pattern of IFL, in sera of patients who had developed acute hepatitis associated with taking the anti-depressive drug iproniazid. The M6 antigen could be detected by CFTs and ELISAs, was partially tissue specific (liver–kidney), and was associated with the inner membrane. The antigen has now been identified as MAO-B and the activity of this enzyme against substrates such as tyramine is inhibited by these AMAs. As MAO-B is irreversibly inhibited by iproniazid, the stimulus for AMA production may arise from metabolite/enzyme haptenization as also suggested, above, in the case of anti-M3.

Anti-M7 AMAs and Flavoenzymes

Around 60% of patients with acute myocarditits and 30% of patients with cardiopathy of unknown etiology exhibit a class of AMAs designated as anti-M7. The antibodies in acute myocarditis are predominantly of the IgM class and disappear on recovery, whilst in chronic disease they are IgG and persist. Such antibodies are not seen in coronary artery conditions and have been considered as reflecting infective disease. The target antigen was originally reported as being heart specific and tightly associated with the inner mitochondrial membrane, but it is now recognized that this class of AMA is directed generally against flavoenzymes. Hence, in heart mitochondria a dominant target is the flavoprotein of succinate dehydrogenase, whilst in liver it includes sarcosine dehydrogenase and dimethylglycine dehydrogenase.

Anti-M8 AMAs and Anti-M9 "AMAs" in PBC

Two other sets of AMAs have been claimed to be specific to PBC, and like anti-M4, important in prognosis of disease progression. One of these recognizes a mitochondrial target categorized as M8. This is an outer membrane, nonorgan-specific, trypsin-sensitive antigen, detectable by CFTs and ELISAs but not by IB. To date M8 is defined only by the protocol for its preparation. The other specificity, categorized as M9, was defined in terms of a trypsin-insensitive constituent of the inner membrane of liver mitochondria. However, it has since been identified as the nonmitochondrial, cytoplasmic enzyme, glycogen phosphorylase, which presumably co-purifies with inner-membrane fragments on ultracentrifugation. Hence, anti-M9 antibodies can no longer be considered as AMAs.

Other AMAs

Naturally Occurring Anti-Mitochondrial Antibodies

Sensitive detection methods reveal that sera of healthy individuals exhibit a spectrum of naturally occurring anti-mitochondrial antibodies (NOMAs), perhaps reflecting an arm of the normal immunoregulatory network, and/or a history of exposure to microbial antigens with structures that "mimic" those of mitochondrial constituents. Where NOMA reactivities against particular antigens have been studied, their fine specificities have been shown to differ from those of disease-associated AMAs recognizing the same molecular species. Interestingly, it has been reported that there is a relative lack of NOMA in patients with PBC, which might be a clue to their normal role in immune regulation.

AMAs Arising from Tissue Damage

Following acute myocardial infarction, many patients demonstrate the short-term production of AMAs against human heart mitochondria. These cross-react against mitochondria from human skeletal muscle, but not with heart mitochondria of other species. Similarly, synovial B-cells in rheumatoid arthritis have been reported as producing AMAs, the finding being interpreted as reflecting local tissue destruction. Such an interpretation

may also apply to the demonstration, in insulin-dependent diabetes, of auto-antibodies against the mitochondrial enzyme of pancreatic β-islet cells, glycerophosphate dehydrogenase.

Pathogenetic AMAs against the Adenine Nucleotide Transporter

Myocarditis and dilated myocarditis are diseases related to viral infection, and (independently of the anti-M7 AMAs described above) are characterized by the production of organ-specific AMAs directed at the mitochondrial ADP/ATP carrier. These antibodies are cytotoxic when tested against guinea pig ventricular myocytes, and in mouse heart, where the transport activity of the carrier has been shown to decline in a manner related to the decrease of cardiac function. The production of these AMAs declines over a period of 2–3 months, and it has been speculated that the underlying mechanism might involve "molecular mimicry" with a viral constituent. However, they may arise as a secondary response to virally induced tissue injury.

Biography

Harold Baum is Emeritus Professor of Biochemistry and visiting professor in Immunology at King's College London, where he was previously Head of the School of Life, Basic Medical and Health Sciences. His current research is on mechanisms of autoimmune disease, but much of his earlier research was on mitochondrial bioenergetics. His Ph.D. was in chemistry from the University of Birmingham, United Kingdom, but he moved into Biochemistry following a postdoctoral year at the Institute for Enzyme Research in Madison, Wisconsin, where he was subsequently a visiting professor. In addition to his normal research output he is also known for having set metabolic pathways to traditional melodies in "The Biochemists' Songbook."

Mitochondrial Channels

M. Catia Sorgato and Alessandro Bertoli
University of Padova, Padova, Italy

Eukaryotic cells are living organisms surrounded by a surface membrane, which also house other membranes that define intracellular organelles. Membranes are lipidic structures impermeable to hydrophilic molecules (polar or charged); that is why they harbor proteins, called ion channels and carriers, catalyzing the life-requiring exchange of material between a cell and the external space, and between organelles and the cytoplasm. At variance from carriers, ion channels form aqueous pores crossing the lipid bilayer that allow the highly selective transmembrane passage of charged species, namely inorganic ions (e.g., Na^+, K^+, Ca^{2+}, Cl^-), with high potency (10^5–10^8 ions per second are transported by a single molecule); they also possess regulatory domains that open and close the pore upon specific stimuli (electric or chemical). Mitochondria are organelles composed of two membranes; channels may be present in either of the membranes. However, while channels in the outer membrane are justified by their overall high permeability, the presence of these entities in the inner membrane was unexpected in view of its implication in the process of oxidative phosphorylation that imposes an extremely controlled permeability to ions. After the initial phenomenological description, substantial advances in the functional (if not molecular) identification of several mitochondrial channels, disclose the possibility that they take part in crucial schemes of mitochondrial functionality, as well as in dramatic cell events.

Channels and Carriers in Mitochondrial Bioenergetics

According to the chemiosmotic principles, the energy-requiring synthesis of ATP, indispensable for the life of the cell, is driven by the inner membrane (IM)-spanning ATP-synthase complex that utilizes a high electrochemical proton gradient generated by the active proton translocation (from the inner compartment (matrix) outwardly) of other IM-enzyme complexes during substrates oxidation. As intuitively expected, mitochondria need to avoid dissipation of the proton gradient by uncontrolled fluxes of protons, and ions in general, toward the negatively charged matrix. Accordingly, such movements have been restricted to tightly regulated processes proceeding at a much lower rate than ions through channels, i.e., catalyzed by enzymes or carriers such as (1) the ATP-synthase; (2) the H^+-carrier that physiologically dissipates energy as heat in brown fat; and (3) carriers driving the accumulation of metabolic anion substrates, or aimed at counterbalancing the influx of positive charges, for example, carried by Ca^{2+} and K^+. A different reasoning applies to the outer membrane (OM) that houses no energy transducing apparatus, and hence develops no proton gradient. This excludes conceptual barriers for its ion permeability properties, and indeed the electric features of OM channels, the first to be identified in mitochondria, have led to assume that, rather than classical ion conducting elements, they act as principal regulated pathways for the intense exchange of molecules (with molecular mass up to 6–8 kDa) connecting the IM with the rest of the cell.

Functional and Molecular Aspects of Mitochondrial Channels

OM Channels

The voltage-dependent anion channel (VDAC, or mitochondrial porin) is one of the few mitochondrial channels with known primary structure. Its presence in all eukaryotes examined so far speaks in favor of a key role pertaining to this protein, and a single case of human pathology, plausibly linked to VDAC malfunction, has been reported. Extensive electrophysiologic studies (carried out by incorporating the purified protein in planar bilayers) have revealed that VDACs from different species have amazingly conserved biophysical properties. Paradigmatic is the symmetrical closure upon raising the transmembrane electric field, in that the large conductive (maximally open) state adopted by VDAC at low applied voltages (roughly between ± 10 mV) (Table I) is drastically reduced (albeit not nullified) as voltage is increased on both directions (positive and negative). Attainment of the lower conducting states, nicknamed "closed," parallels the change of the ionic selectivity from slightly anionic to cationic.

TABLE I

Main Mitochondrial Channels

Location	Maximal conductance (pS) (150 mM salt)	Putative role
Outer membrane		
VDAC	600–750 (1)[a]	Transport of metabolites
		Apoptosis
Unknown	~100–300 (2,3)	Transport of metabolites (?)
Tom40	1000 (1,2)	Protein import
MAC	2500 (2)	Apoptosis
Inner membrane		
K_{ATP}	9.7 (4)	Matrix volume regulation
mCS	107 (4)	
MCC (TIM)	1000 (2)	Protein import

[a] Used techniques: (1) lipid bilayers; (2) patch clamping of proteoliposomes; (3) patch clamping of intact mitochondria; and (4) patch clamping of mitoplasts.

Note. Table I does not include the PTP complex of the IM, likely to be involved in apoptosis, has not yet been conclusively identified neither electrophysiologically nor at the molecular level. However, from the permeability properties detected in intact mitochondria, PTP open state allows the translocation of molecules with mass up to 1.5 kDa.

Such features, in particular the voltage-dependent permeability, and other biochemical, and genetically based findings, have thus frequently suggested that, by acting as a molecular sieve, the protein regulates the cell metabolism, if not the process of oxidative phosphorylation.

Intriguingly, VDACs from different organisms show little conservation of the amino acid sequence. The almost overlapping electric picture has thus suggested that all VDACs acquire similar secondary structures. Indeed, prediction algorithms have proposed a general feature of the pore's wall formed by antiparallel β-sheets, with the hydrophilic amino acids expectedly facing the internal aqueous ion conducting space. A large body of electron microscopic data of fungal, and mammalian, VDAC crystals have also suggested that the channel crosses the membrane as a hollow cylinder, or with an oval structure, respectively, with an internal (lumen) 1.7–2.8 nm diameter that correlates well with the high conductances described in reconstituted systems. Yet, there are instances that may contradict the above hypothesis. For example, the yeast VDAC2 isoform (in yeast, as in other organisms, there is a VDAC-related multigene family), which can functionally replace VDAC1 in VDAC1-knockout cells, is apparently unable to form channels in planar bilayers.

Because VDAC is the most abundant OM protein, its conserved electric pattern in planar membranes was surprisingly never detected when applying a patch clamp electrode to intact mitochondria. Instead of the typical bell-shaped curve, the response of the macroscopic current (i.e., of the entire membrane) to positive and negative voltages was asymmetrical, while in no case was the behavior of analyzed single channels reminiscent of VDAC properties (Table I). Clearly, the picture emerging from *in situ* experiments suggests that either channels different from VDAC are the major contributors to the OM electric behavior, or that VDAC in native membranes is under the control of OM or intermembrane regulators that get lost in reconstitution experiments. As yet, the physiology and molecular structure of most of such channels are still missing, although, consistent with the OM concept, they are most likely to transport metabolites rather than only small ions. Finally, the only attempt to analyze mitochondria in its cellular context (at the presynaptic terminals of large neurons) has demonstrated that, especially during synapse activation, the OM displays intense electrical activities, which, however, do not resemble that of VDAC.

The electrophysiologic analysis of OM- (or IM-) containing proteoliposomes, and of some membrane components (in planar bilayers), has eventually proven the long-lasting hypothesis that most (~99%) mitochondrial proteins, nuclear-encoded and cytosolic-synthesized, reach their final destination by passing through large permeation pathways of mitochondrial membranes. Specifically, it has been found that both the purified multisubunit translocase of the OM (TOM) (which does not include VDAC), and the TOM component putatively involved in translocation, Tom40, form a pore with a large full open state (of around 1000 pS) and a slight preference for cations (Table I). These features, which are *per se* consistent with a role of TOM pore in allowing permeation of unfolded polypeptides, have been further substantiated by the disturbance provoked by cationic peptides mimicking the mitochondrial targeting domain of several proteins, possibly reflecting transient occlusions of the pore during the peptide translocation.

IM Channels

The *in situ* electric recording of the IM of isolated, intact mitochondria demands that the OM be removed first; this allows the expansion of the IM invaginations, and the formation of a vesicle (mitoplast) sufficiently large to be patch clamped. Except for one type of conductance (called mitochondrial mega (MMC) or multiconductance channel (MCC)) showing huge and unselective fluxes of ions, this strategy has been instrumental for the description of two main kinds of channels, distinguishable by several criteria, not the least by discrete conductance values (Table I). One channel, of around 10 pS, with no clear voltage dependence, translocates only K^+ (K_{ATP}), and is

modulated by physiologic effectors (it is active only at low matrix ATP). The other channel, of around 100 pS (named mitochondrial Centum pico-Siemens, mCS), is preferentially permeated by anions. Although several molecules apparently modulate the channel (nucleotides, Ca^{2+}, etc.), its most prominent feature is the voltage dependence that opens the channel at nonphysiologic (positive) matrix voltages, while it renders it inoperative (closed) at those high negative potentials normally sustained by mitochondria. Parenthetically, it is the powerful activity of mCS channels (found in many mammalian tissues), which accounts for the electric pattern of the entire IM, while most of the other described conductances, in the 15–130 pS range, may be rather safely attributed to mCS substates, or to experimentally induced variations of the K_{ATP} channel conductance.

To search for the role of IM channels, much experimentation has followed the concept that the IM transport of small ions may guarantee fundamental aspects of mitochondrial physiology, such as osmotic stability. Insight into such routes has been provided particularly by monitoring the osmotic swelling of isolated mitochondria that, under the used conditions, is the direct consequence of the ability of a specific solute to cross the IM. Several carrier-mediated pathways have been described, two of which are of interest in the context of ion channels' theme: the selective pathway for K^+ (K^+ uniport), and the pathway allowing the permeation of anions different from metabolites, adenine nucleotides, or phosphate (inner membrane anion channel, IMAC). The extensive biochemical and pharmacological characterization of these proteins (initially denominated channels for their high translocation rate, not because of their, as yet unknown, molecular nature) has led to the proposition that both are implicated in maintaining mitochondrial volume homeostasis. In fact, the similar action of physiologic (ATP) and drug molecules has sustained the functional identity between the K^+ uniport and K_{ATP} channels. With regard to their physiology, the enhancement of K^+ influx under the stressed condition of low-matrix ATP content renders the channel suitable at serving in the K^+ cycle-based volume regulatory mechanism, especially within the proposed control of mitochondrial oxidation rate by matrix volume changes. In addition, it has been shown that the same drugs, opening (cromakalin, diazoxide) or closing (glibenclamide, 5-hydroxydecanoate) mitochondrial K_{ATP} channels, enhance or abolish, respectively, the beneficial effects of ischemic preconditioning, a phase that protects the heart from ischemic injuries. These findings thus point to a cardioprotective role of K_{ATP} channels, although the actual means by which this is achieved have not yet been clarified.

Also in the case of IM anion permeation, accurate electrophysiological reinvestigations of mCS single channels, and of the entire IM, have provided substantial evidence for the functional homology of IMAC and mCS channels; both conduct anions of different valence, are active at alkaline internal (matrix) pH (i.e., such pH renders mCS channels operative also at negative matrix potentials), and are equally blocked by specific drugs. The particular conditions of IMAC activation in intact mitochondria have suggested that it mediates efflux of matrix anions, as part of the mechanism designed to protect against excessive swelling. However, more recently, by relying on pharmacological tests on isolated intact cardiomyocytes, it has been proposed that the opening of IMAC/mCS channels may trigger metabolic oscillations, observed when cells are deprived of substrates, which, at the mitochondrial level, give rise to periodic, redox-state transitions, and a continuous switching between dissipation and re-establishment of the proton gradient. As this phenomenon (if uncontrolled) is likely to provoke a whole set of excitability disturbances in the heart, including arrhythmias, mCS channels may thus become important targets of pharmacological heart treatments.

Similar to the TOM machinery, the reconstituted translocase of the IM (TIM) forms pores with that large conductance (of ~1000 pS) expected for protein transport (Table I). Complemented by immunologic approaches, this study has also suggested the functional (and molecular) identity of the MCC, originally described by patch clamping mitoplasts, with the TIM pore.

Involvement of Mitochondrial Channels in Cell Death Mechanisms

In the recent years, there have been increasing suggestions for a mitochondrial implication in regulating the life and death of the cell through the apoptotic process. Apoptosis is a naturally occurring programmed cell death essential for normal embryonic development and tissue homeostasis in adults. Expectedly, the process is controlled by a variety of factors, including members of the Bcl-2 family (e.g., the pro- and anti-apoptotic Bax and Bcl-2, respectively), and mitochondrial proteins of the intermembrane space (cytochrome *c*, endonuclease G, and others) released in the cytosol. By necessity, passage of these high mass molecules across the OM calls for a further increase of the already large membrane permeability. Accordingly, data have been presented involving either an enhancement of VDAC permeability by Bax, for example, or the capacity of Bax itself to form autonomous protein translocating pores. The latter may be identifiable with extremely large single-channel conductances (named mitochondrial apoptosis-induced channel, MAC) (Table I), recently observed by patch

clamping OM-containing proteoliposomes, especially because such activities are dependent on Bax presence, while rendered silent by Bcl-2 overexpression. However, several other observations point to a direct involvement of the mitochondrial IM, in that a dramatic increase of its permeability leads to loss of mitochondrial osmotic stability by excessive ions intake; in turn, this event provokes matrix swelling, OM disruption by the expanded IM, and release of intermembrane proteins. Such process, reported in isolated organelles and in cells challenged with apoptotic stimuli, is apparently caused by the opening of a huge and unselective IM pathway, known as the permeability transition pore (PTP), formed by a multisubunit complex that may include proteins located in both the IM and OM, e.g., cyclophilin D and the adenine nucleotide translocator, and VDAC, respectively. MMC (or MCC) has also been proposed as a PTP subunit, but its recent identification as a TIM component renders such candidacy unlikely.

Glossary

conductance G Expressed in siemens (S = ampere/volt (A/V)) is the ratio between the electric current and the applied voltage. At 100 mV (10^{-1} V), a G of 10 pS (10^{-11} S) corresponds to a current of 1 pA (10^{-12} A) generated by about six million monovalent ions per second.

electrochemical proton gradient Generated by the H^+-pump activity of mitochondrial inner membrane (IM) enzyme complexes, it is commonly expressed in millivolts (mV) as proton motive force ($\Delta p = \Delta\mu_{H^+}/F = \Delta\psi - 60\Delta pH$). $\Delta\psi$ defines the difference in charges, and ΔpH that in H^+ concentrations, between the matrix and the aqueous phase external to the IM. A Δp of 180–200 mV (matrix negative) is normally found, with $\Delta\psi$ contributing for 150–180 mV.

lipid bilayer Allows the recording of electric activities from artificial planar membranes fused with vesicles obtained from native membranes, or reconstituted with purified proteins.

mitochondria Organelles composed of an outer membrane (OM), an intermembrane space, and an invaginated IM delimiting a matrix space that houses crucial metabolic routes.

patch clamp By means of fine electrodes, it records ionic currents directly from the membrane of isolated cells or organelles, as well as from large lipid vesicles reconstituted with channel-containing membrane fractions (proteoliposomes).

Biography

M. Catia Sorgato is a Professor of Medical Chemistry at the Faculty of Veterinary Medicine, University of Padova. After graduating in biology, she worked at the Biochemistry Department, Oxford University (UK) on energy transduction processes, and then at the Max-Planck-Institute, Göttingen (Germany), where she accomplished the first electrophysiologic analysis of mitochondrial inner membranes. Her actual research interest is the physiopathology of prion proteins.

Alessandro Bertoli graduated in physics and holds a Ph.D. in biochemistry and biophysics. He is currently a research fellow at the Department of Biological Chemistry, University of Padova. His past experience dealt with the electrophysiology of mammalian cell, and yeast mitochondrial channels, while his actual interest is the biology of neurodegenerative disorders.

Mitochondrial DNA

Gottfried Schatz
Swiss Science and Technology Council, Bern, Switzerland

Mitochondria, the eukaryotic organelles of oxidative phosphorylation, contain their own DNA genome. This genome is much smaller than that in the nucleus and encodes only ~1% of the mitochondrial proteins. Yet it is essential for the formation of fully functional mitochondria.

Discovery of Mitochondrial DNA

Some concepts take the scientific world by storm, but others conquer it only after many skirmishes. The discovery of mitochondrial DNA (mtDNA) belongs to this second category. Biochemists, histologists, and electron microscopists had seen DNA in mitochondria for years, but most of them were not ready for the idea that the DNA really belonged there. This may explain why textbook accounts of mtDNA almost never tell how this DNA was discovered.

After the basic building plan of the eukaryotic cell had been revealed in the early 1950s by the electron micrographs of Palade, Sjöstrand, and others, biochemists embraced de Duve's dogma that every macromolecule had one, and only one, intracellular location. In the analysis of cell fractions, cytochrome oxidase was taken as a marker for the mitochondria, NADPH–cytochrome *c* reductase for the endoplasmic reticulum, and DNA for the nucleus. Given this frame of mind, it is easy to understand why the presence of DNA in mitochondrial fractions was generally attributed to contamination by nuclear fragments. Histochemical DNA stains, such as the Feulgen reaction, also stained the kinetoplasts of *Trypanosomes* and the "*Nebenkern*" of insect spermatozoa, but at that time it was not yet recognized that these structures were, in fact, unusual mitochondria. Massive amounts of extranuclear DNA were also detected in the cytoplasm of amphibian oocytes, but it took many years to realize that this DNA was, in fact, mtDNA whose abundance reflected the enormous amount of mitochondria in these large cells. In 1961, at the Fifth Annual Meeting of the American Society of Cell Biology in Chicago, Hans Ris showed electron micrographs of mitochondria with inclusions resembling the DNA-containing nucleoids of bacteria and made the heretical proposal that mitochondria (and also chloroplasts) contain their own DNA. In a paper that appeared in the following year, Ris and Walter S. Plaut further documented and expanded these observations. Soon thereafter, biochemical and morphological evidence from several groups confirmed the presence of DNA in chloroplasts.

The discovery of chloroplast DNA made biochemists take a fresh look at early findings by Margaret Mitchell and Boris Ephrussi that certain mutations affecting mitochondrial function in the mold *Neurospora crassa* and the yeast *Saccharomyces cerevisiae* were not inherited according to Mendel's laws. It seemed tempting to speculate that the unknown "extrachromosomal factors" implicated in these mutations were, in fact, mtDNA.

By 1962, the ground for the concept of mtDNA was thus well prepared, but the concept itself was not generally accepted. In retrospect it seems that the scientific community was waiting for convincing studies that documented the existence of mtDNA by several diverse methods.

One of these studies came from the electron microscopists Margit M. K. Nass and Sylvan Nass, who were then working at the Wenner Gren Institute of the University of Stockholm. They showed that the matrix of osmium-fixed chick embryo mitochondria contained thread-like inclusions whose appearance after different fixation procedures closely paralleled that of the histone-free DNA nucleoid of bacteria: after fixation with osmium tetroxide, the inclusions appeared clumped and as bars with a diameter of ~400Å; fixation of the tissues with osmium tetroxide followed by treatment with uranyl acetate before dehydration made them appear as 15–30Å thin fibers. Even more convincing evidence for the presence of DNA in these inclusions was the observation that the inclusions could be removed by treating the lightly fixed embryonic tissue with DNase. Treatment with pepsin, with RNase, or with DNase-free buffer controls was ineffective. The clarity of these electron micrographs and the careful controls that were included had a compelling impact on cell biologists. M. M. K. Nass and S. Nass published their work in two back-to-back papers in a 1963 issue of the *Journal of Cell Biology*. At that time, however, cell biology and biochemistry were still rather

different disciplines and most biochemists did not peruse journals devoted to cell biology. It therefore took a while before the findings by M. M. K. Nass and S. Nass entered the consciousness of the biochemical community.

At about the same time, Ellen Haslbrunner, Hans Tuppy, and Schatz at the Biochemistry Institute of the University of Vienna were trying to find a biochemical basis for the extrachromosomal mutations that abolished respiratory function in the yeast *S. cerevisiae*. In the early 1960s, many biochemists were still reluctant to consider the "respiratory granules" of yeast as *bona fide* mitochondria, which placed the research by Haslbrunner *et al.* well outside the mainstream of mitochondrial biochemistry in the United States and elsewhere.

To look for DNA in mitochondria, a biochemical approach was chosen. Yeast mitochondria were purified by the best methods available, and their DNA content was measured by the time-honored "Diesche" color reaction. A few years before, de Duve and co-workers had shown that centrifuging subcellular fractions to equilibrium in a density gradient often gave a clean separation of different organelles. Surprisingly, the usual sucrose gradients did not separate yeast mitochondria from nuclear fragments, but when sucrose was replaced with the X-ray contrasting agent "Urografin," the mitochondria formed an extremely sharp band, and DNA was present in only two fractions: most was at the bottom of the centrifuge tube, and a very small amount, but discrete peak coincided exactly with that of the mitochondria. The DNA in the bottom fraction was easily digested by DNase and apparently represented nuclear DNA. The DNA in the mitochondrial fraction was not readily digested by DNase unless the organelles were first disrupted with trichloroacetic acid; presumably, it represented DNA enclosed by the mitochondrial membranes. Its concentration was very constant between different experiments – between 1 and 4 μg per mg mitochondrial protein. Urografin – purified mitochondria from rat liver, rat kidney, and bovine heart – contained almost 10 times less DNA, between 0.2 and 0.6 μg DNA per mg protein. The typical mammalian mitochondrion was calculated to contain 3×10^{-17} g DNA. Assuming that the DNA was double-stranded, it could encode no more than 1.2 MDa of polypeptide chains. This result was considered important, because it firmly excluded the possibility that mtDNA encoded all of the mitochondrial proteins. Today, this early calculation by Haslbrunner *et al.* could be challenged on several grounds, yet it came remarkably close to reality: the 13 polypeptides encoded by mammalian mtDNA have a total mass of 0.423 MDa, and the remainder of the coding potential is largely accounted for by genes for ribosomal – and transfer RNAs, as well as the by fact that mitochondria usually have more than one copy of their DNA genome.

Properties of mtDNA

Soon thereafter, several laboratories showed that mtDNA from several organisms had a different base composition and sometimes also a different buoyant density in cesium chloride gradients than the corresponding nuclear DNA. Particularly, striking was the observation that mtDNA from mammals was a small double-stranded circle. Late in 1964, the existence of DNA in mitochondria was generally accepted, and efforts focused on its function. Its identity with the "extrachromosomal factors" affecting respiratory function in *S. cerevisiae* was established by the observations that mtDNA was either altered or missing in the corresponding mutants. Several laboratories then showed that mitochondria from yeast and *N. crassa* synthesized the three large subunits of cytochrome oxidase, the heme-carrying subunit of the cytochrome bc_1 complex, and at least one membrane-bound subunit of the ATP synthase complex.

Sequence and Gene Content

In 1981, Fred Sanger and co-workers published the complete sequence of the 16,569 nucleotides of human mtDNA. This seminal paper provided the first complete sequence of a eukaryotic genome and identified the mitochondrial genes. Subsequent work by others then showed that the size of mtDNA can vary dramatically between different species (Table I). There are also considerable differences in gene content. Whereas mtDNA from humans and most mammals encodes 13 proteins and 24 RNAs (Figure 1 and Table II), that from the freshwater protozoon *Reclinomonas americana*

TABLE II

Genes on Human mtDNA

Function	Molecule(s)	Number
Protein synthesis	rRNAs	2
	tRNAs	22
Electron transport	Cytochrome oxidase	3
	NADH dehydrogenase	7
	Cytochrome bc_1 complex	1

carries no fewer than 97 genes. Sequence comparisons between some of the genes and the corresponding polypeptide products also uncovered the astounding fact that the genetic code of mtDNA differs slightly but significantly from that of nuclear DNA (Table III). For example, the codon UGA defines "stop" in the nucleus, but "tryptophan" in mtDNA from mammals, yeast, and many other species. This unexpected finding explained why so many earlier attempts to identify the protein products of mtDNA by coupled transcription/translation in *Escherichia coli* or reticulocyte lysates had failed.

Outlook

There is no end to the fascinating properties of the mitochondrial genome, and many of these properties still beg an explanation. Why is the mitochondrial genome of mammals one of the most compact genomes known, whereas that of plants and yeast spreads its genes luxuriously over five, ten, or even hundreds of times more DNA? Why has the genetic code diverged from the "standard" one that is used in the nucleus? Why does mtDNA mutate ~10 times faster than the corresponding nuclear DNA? Why have some mitochondria dozens of copies of their genome? Most importantly, why does mtDNA exist at all? Maintaining its few protein-coding genes from one generation to the next keeps hundreds of nuclear genes occupied, which

TABLE III

Unusual Codon Usage in mtDNAs

Codon	"Universal" usage	Mitochondrial usage	Species
CUA	Leucine	Threonine	Yeast
UGA	Stop	Tryptophan	Most species, not plants
AUA	Isoleucine	Methionine	Most species, not plants
AG(A,G)	Arginine	Stop	Mammals
		Serine	Insects
		Arginine	Yeast

seems highly uneconomical. Evolution provides the answer: it is now generally accepted that today's mitochondria are descendants of free-living prokaryotes that entered into symbiosis with other cells and transferred most of their genome to the nucleus of their host. The mtDNA is the small remnant of the genome of these endosymbionts.

Since a typical somatic cell has only two copies of a nuclear gene, but as many as a thousand copies of each mitochondrial gene, mtDNA has become a favorite tool for genetic fingerprinting and evolutionary studies. Also, it is now well established that mutations in mtDNA can cause a host of devastating maternally-inherited diseases, such as blindness, deafness, muscular degeneration, diabetes, and severe neuro-degenerative syndromes. A possible involvement of mtDNA in aging and cancer is under intense investigation. There is also mounting evidence that mutations of mtDNA may impair mammalian fertility and the success of *in vitro* fertilization experiments. Indeed, many of the most exciting functions of mtDNA may yet await discovery.

Biography

Gottfried Schatz obtained his Ph.D. in biochemistry in 1961 in Austria. He then worked as an Assistant Professor at the University of Vienna, as postdoctoral fellow with Efraim Racker at New York, and as a Professor of Biochemistry at Cornell University in Ithaca. In 1974 he joined the Biozentrum at the University of Basel. Upon retiring as a Professor in 1999, he was elected President of the Swiss Science and Technology Council.

Mitochondrial Genes and their Expression: Yeast

Piotr P. Slonimski
Centre de Génétique Moléculaire du Centre National de la Recherche Scientifique (CNRS), Gif-sur-Yvette, France

Giovanna Carignani
University of Padova, Padova, Italy

Mitochondria possess their own genome, which encodes a small part of the proteins that make up the organelle. The remaining proteins, i.e. the majority, are encoded by the nuclear genome. Mitochondrial life thus depends on the coordinated expression and interaction of nuclear genes and genes present on the organellar genome (mtDNA) itself. Although mtDNA encodes very few subunits of the energy-transducing complexes of the inner mitochondrial membrane, these subunits constitute the key elements of the overall process: cytochrome *b* for the reductase activity, cytochrome *c* oxidase subunit 1 for the oxidative activity, and Atp6 for the synthetase activity. The genes coding for these three subunits are always located in the mtDNA in all eukaryotes, whether fungi, protists, animals, or plants. The mtDNA is supposed to be a remnant of a prokaryotic genome that would have originated from a symbiotic event between different cellular species. As the majority of the prokaryotic genes would, however, in the course of evolution, have migrated to the nucleus of the new cell, it is surprising that even today a mitochondrial genome exists. A plausible reason might reside in the compulsory evolution of the formation mechanism of the enzymatic complexes of the inner mitochondrial membrane. This might depend on a topological constraint of the expression and assembly of the different subunits, some of which are very hydrophobic and have to be transcribed, translated, inserted, and assembled from inside the organelle. It follows then that these key genes are present inside the mitochondrion. This would also explain the persistence of mtDNA and its complex machinery of expression for a billion years since the original symbiotic event.

The knowledge of the conjoint expression of both the mitochondrial and nuclear genes involved in energy transduction is best advanced in the study of baker's yeast, essentially due to the extraordinary power of molecular genetics both *in vivo* and *in vitro*.

Yeast as a Model Organism for the Study of Mitochondrial Biogenesis and Function

The facultative anaerobic yeast *Saccharomyces cerevisiae* has provided the main information about mitochondrial biogenesis, from the discovery of petite mutants by Boris Ephrussi and Piotr Slonimski and their collaborators in the 1950s. This was followed by the exhaustive analysis of mitochondrial genetics in the 1970s in the laboratory of Gif-sur-Yvette and by the identification of mtDNA by Gottfried Schatz, and still remains an excellent experimental organism, owing to its capacity of surviving in the absence of competent mitochondria, to the facility of isolation or construction of mutants (several thousand have already been characterized) and to the possibility of mitochondrial transformation. The search for nuclear genes involved in mitochondrial biogenesis and function is constantly carried out in this organism and the results continually lead to the isolation of functionally homologous human genes. In particular, many mitochondrial disease genes have been identified in this way.

Mitochondrial life depends on the coordinated expression and interaction of nuclear genes and genes present on the organellar genome (mtDNA) itself. The mitochondrial genetic system is required for the synthesis of a limited number of proteins, in particular in yeast of seven highly hydrophobic subunits of the energy-transducing complexes of the inner membrane (Figure 1).

All the processes necessary to the expression of these genes (i.e., transcription, RNA processing, and translation), as well as those required for mtDNA maintenance and integrity, take place in the same

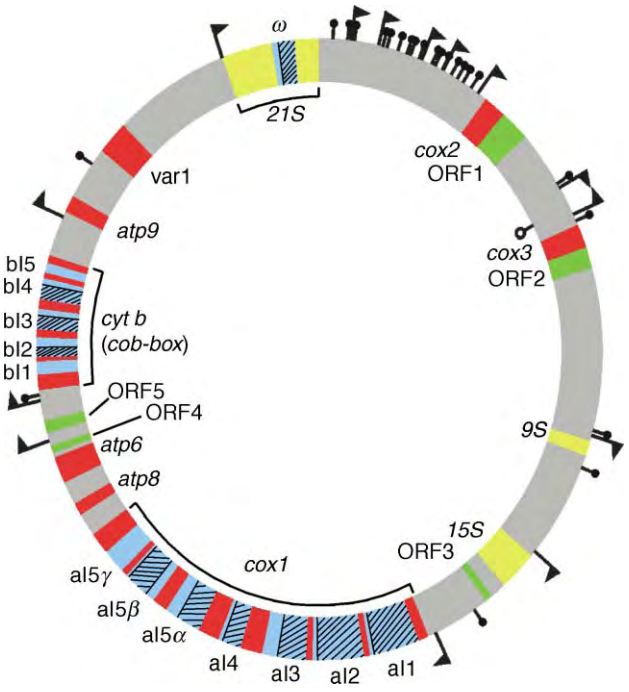

FIGURE 1 The mitochondrial genome of *Saccharomyces cerevisiae*. The circular map is in agreement with the genetic results and with the observation that mtDNA replicates by the rolling-circle mode. Different yeast strains contain mtDNA molecules of different lengths (comprised between 70 and 85 bp). These differences are essentially due to the presence/absence of introns and hypothetical open reading frames (ORFs 1–5 in this representation). Yeast mtDNA encodes seven highly hydrophobic subunits of the energy-transducing complexes of the inner membrane, i.e., apocytochrome *b* (encoded by the *cyt b*, or *cob-box*, gene), three subunits of cytochrome c oxidase (encoded by the *cox1*, *cox2*, and *cox3* genes) and three subunits of ATP synthase (encoded by the *atp6*, *atp8*, and *atp9* genes). The *cytb*, *cox1*, and *21S rRNA* genes contain introns, some of which are translated, independently or in frame with their upstream exons, to produce maturases (e.g., the bI2 intron of the *cytb* gene, see Figure 3) or site-specific endonucleases (the *ω* intron of the *21S rRNA* gene); others encode complex proteins with multiple functions, i.e., maturases, reverse transcriptases, endonucleases (e.g., the aI1 intron of the *cox1* gene). Red: exons of protein-coding genes; blue: introns (aI1–aI5; bI1–bI5; *ω*); hatched blue: intron-encoded ORFs; green: hypothetical ORFs; yellow: 9S, 15S, and 21S RNAs; solid circles: tRNAs. Flags indicate the transcription initiation sites and their orientation. The orientation of all the transcription units is clock-wise, with the exception of the $tRNA^{thr1}$ gene (open circle), which is transcribed from the opposite strand.

compartment, the mitochondrion itself, as they occur in a bacterium, the hypothetical mitochondrial ancestor. Also, the different processes are functionally linked, frequently through the activity of proteins exhibiting multiple roles.

Expression of Mitochondrial Genes

Mitochondrial gene expression requires the coordinated interaction of mitochondrial and nuclear encoded factors: the mitochondrial genome (Figure 1) participates in the process with the genes encoding the RNA-subunit of mitochondrial RNase P (9S RNA), the 21S and 15S rRNAs, a complete set of tRNAs, and one protein of the small mitoribosomal subunit, Var1; in addition some introns encode proteins necessary for RNA splicing (RNA maturases). The nuclear genome encodes all other factors necessary for mitochondrial genome maintenance and expression, as well as all other mitochondrial proteins (~500 yeast proteins located in the organelle were currently listed in the Yeast Proteome Database, YPD, in 2001, but predictions indicate about 700). These are translated in the cytoplasm, and then imported into different compartments of mitochondria using protein-specific import mechanisms. A mitochondrial targeting sequence, often present at the amino terminus of translated precursors, allows their interaction with the mitochondrial receptor–translocator TOM–TIM, followed by maturation of the precursor and its localization in mitochondria. Also, recent results point out that nuclear-encoded mitochondrial proteins of bacterial origin are synthesized on polysomes associated with the mitochondrion, while those of eukaryotic origin are generally translated on free cytosolic polysomes, thus promoting speculations about organelle origins.

General Features of Simple and Mosaic Genes

(To describe the expression of yeast mitochondrial genes, we distinguish between simple genes and mosaic genes, i.e., genes containing introns and thus subject to a more complicated expression pathway.)

Transcription

The yeast mitochondrial genome is ~4 times larger than mammalian mitochondrial genomes, although they contain approximately the same number of genes. The difference is due to the lengths of intergenic regions and to the presence of introns in some of the yeast genes. Whereas the 16,000 base-pair mammalian mitochondrial genome is transcribed by two opposite promoters (one for each strand), genes on the 80,000 base-pair yeast mtDNA are transcribed, singly or in clusters, from several promoters (14 active promoters have been identified, see Figure 1). The consensus sequence of mitochondrial promoters is a nonanucleotide 5′ATATAAGTA 3′, whose last A is the +1 position of the transcript, and termination of transcription is indicated by the dodecanucleotide consensus 5′AAUAAUAUUCUU3′ (see Figure 2).

As in the case of bacterial transcription, all mitochondrial genes are transcribed by the same RNA

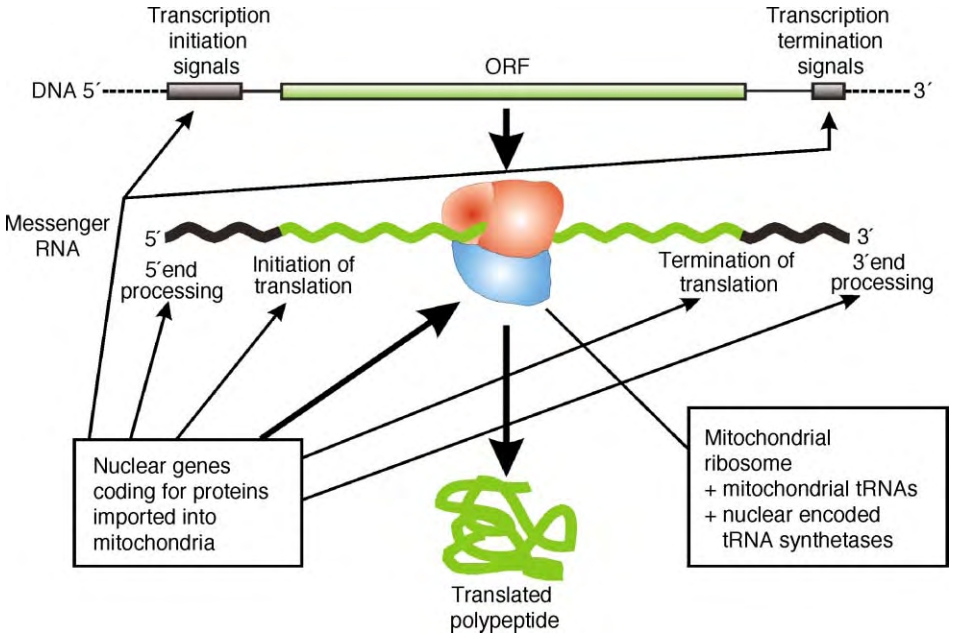

FIGURE 2 Main features of the expression of a "simple" mitochondrial protein-coding gene. The open reading frame (ORF) of the gene located in the mtDNA is transcribed into messenger RNA and translated into a polypeptide chain according to the general principles of molecular biology. However, most of the elements of these two machines derive their information from a different cellular compartment than the one where these processes take place. The genes coding for the transcriptional machinery as well as those involved in the processing or stability of mRNA are located in the nucleus, the proteins synthesized in the cytoplasm and imported inside the mitochondrion where they recognize specific signals, i.e., mtDNA or mtRNA sequences or structures indicating the beginning and the end of DNA transcription or RNA processing (e.g., Mtf1, Nam1). The next step of gene expression is even more complex, since in addition to numerous nuclear genes coding for proteins involved in initiation/termination of translation, as well as the translation process itself (more than seventy ribosomal proteins, e.g., Nam9, all translation factors, e.g., Cbp1, and all specific mitochondrially located tRNA synthetases), a number of genes located in the mitochondrial genome participate in the process. They encode essentially the catalytic RNAs: the two, large and small, rRNAs, the complete set of tRNAs and a subunit of RNAse P. As a result of this double inheritance scenario, a mutational lesion in any one of the elements (e.g., the nuclear encoded leucine tRNA synthetase by gene NAM2 or a mtDNA encoded tRNA) will ineluctably and irreversibly abolish the expression of all the genes located in mtDNA.

polymerase. This is composed of only two nuclear encoded subunits, a core RNA polymerase, Rpo41, which is similar to the very simple T-odd phages RNA polymerases, and the mitochondrial transcription factor, Mtf1, which is required for the recognition of the promoter by the holoenzyme and is released when Rpo41 enters into the elongation mode, as happens for sigma factors of bacterial RNA polymerases. Mtf1 in fact shares sequence similarity with regions 2 and 3 of bacterial sigma factors, but, unexpectedly, crystal structure of Mtf1 has revealed clear similarity to the family of RNA and DNA methyltransferases and one of the two human homologues of Mtf1 has been proved to methylate a conserved stem-loop in bacterial 16S rRNA and human mitochondrial 12S RNA. This is one of the several evidences (the incessant definition of protein crystal structures is currently revealing novel cases) where the structure/function relationship of a present day protein indicates that it might have evolved from a multifunctional ancestor or from a protein with a different function.

RNA Processing: 5′ and 3′ Processing

Mitochondrial transcription units are unusual as they are characterized by the presence of mRNAs interspersed with tRNA and rRNAs. In human mtDNA tRNAs genes "punctuate" the very long principal transcription unit and their processing at both ends "release" the majority of other RNAs. In yeast the mitochondrial transcription units are shorter but also contain various combinations of RNAs. tRNAs precursors are processed at 5′ end by mitochondrial RNAse P and at 3′ end by a specific endonuclease (successively tRNAs are matured by CCA addition and nucleotide modifications). The processing of mRNAs at their 5′ end, assisted by nuclear encoded factors (e.g., Cbp1 for the cytochrome *b* transcript) consists in a cleavage to generate mature mRNA at a position specific for each transcript. In some transcription units the transcript is first released by the 3′ end processing of a preceding tRNA or mRNA. Processing at 3′ end of mRNAs is done near the conserved dodecamer sequence 5′AAUAAUAUUCUU3′, which is protected by a

complex of three proteins before cleavage by a probably specific endonuclease. All these processes are assisted by several nuclear encoded proteins with a gene-specific or a more general role (see Figure 2).

Processing of Mosaic Genes is More Complex: RNA Splicing

A typical feature of yeast mtDNA, which is not shared by human mtDNA (but is common to many mtDNA from plants, fungi, and protists), is that some of its genes are split by introns. In *S. cerevisiae* these are the *21S rRNA*, *cytb* (*cob-box*) and *cox1* genes. Splicing of these introns is catalyzed by the intron itself (catalytic RNA), and depends on the formation of a conserved RNA three-dimensional structure, which enables them to undergo self-splicing *in vitro*, albeit inefficiently and under non-physiological conditions. *In vivo*, however, splicing requires the presence of specific proteins that function to promote a stable and active RNA conformation. Furthermore, some yeast mitochondrial introns behave as mobile genetic elements, as they can be inserted into an intronless version of the gene at the same position it already occupies in the intron-containing version (intron homing) or to a novel location (intron transposition). Mitochondrial introns belong to two classes, group I and II, based on the secondary and tertiary structure of the intron transcript and on the mechanism of splicing. The mechanism of splicing of group II introns has suggested that they might be progenitors of nuclear pre-messenger introns and of the spliceosome-catalyzed splicing process, with group II intron domains having evolved into small nuclear RNAs (snRNAs).

Several features of mitochondrial introns have been uncovered in the laboratory at Gif-sur-Yvette in the late 1970s, among these some encode proteins, i.e., RNA maturases, which assist the splicing of the intron itself and sometimes also of a different intron (see Figure 3), and also promote intron mobility. Intron encoded proteins also belong to two groups. Group I proteins are members of the LAGLI-DADG family of DNA endonucleases and, besides the endonuclease activitiy required for intron mobility via DNA (as happens for prokaryotic transposons), some of them have high-affinity RNA-binding properties necessary for their role in splicing. Mobile group II introns (e.g., intron aI1 of the *cox1* gene) encode multifunctional proteins, endowed with maturase and DNA endonuclease activity, but also encode reverse transcriptases that bind specifically to the intron RNAs to promote both intron mobility and RNA splicing. In the case of group II introns, transposition occurs via RNA, the procedure adopted by eukaryotic nuclear retrotransposons and retroviruses. Some of the mitochondrial intron encoded proteins are translated in-frame with the upstream exon and subsequently processed to mature proteins by various proteases. This process shows how the different events of mitochondrial gene expression (in this case splicing and translation) are strictly interconnected and also enlightens a peculiarity of mitochondrial translation, that it starts immediately after transcription, as in prokaryotes, however before RNA processing, an occurrence unique to this system.

In vivo self-splicing of yeast mitochondrial introns is thus assisted by proteins that, in general, have the role to promote the folding of the catalytic core of the intron, inducing the formation of nucleotide interactions required for catalytic activity. These proteins are the maturases encoded by the intron itself and other proteins, encoded in the nuclear genome, that concur in assisting the splicing event. Numerous of these proteins have been identified as suppressors of splicing-defective mitochondrial mutations and most of them are proteins that, besides their role in mitochondrial splicing, have also other functions. An example is the mitochondrial enzyme leucyl-tRNA synthetase, Nam2, which is also necessary for the splicing of the group I intron bI4. Actually, recent interesting results indicate that the tyrosyl-tRNA synthetase of *Neurospora crassa* interacts with group I introns by recognizing conserved tRNA-like structural features of the intron RNA, thus suggesting that this might be the case for other tRNA synthetases as well. Also the Mrs2 protein, which assists splicing of group II introns, seems to be implicated in a more general function, as a mitochondrial Mg^{2+} transporter. A particularly interesting protein is Nam1, that is involved in the removal of introns from the *cytb* and *cox1* transcripts and in overall translation capacity, and is also responsible of coupling these processes to transcription, through direct interaction with the amino terminus of mitochondrial RNA polymerase, Rpo41.

Translation

Translation of mitochondrial mRNAs resembles more closely its prokaryotic than eukaryotic counterpart with respect to the spectrum of antibiotics inhibiting mitochondrial translation. Also, mitochondrial mRNAs are uncapped and lack the poly(A) tail, as prokaryotic mRNAs. However mitochondrial translation has unique features, e.g., the use of an alternative genetic code and the composition of mitochondrial ribosomes. These are made up of nuclearly encoded proteins (with the exception of Var1), the majority of which have no recognizable homology to known proteins, i.e., are unique. It has been suggested that these proteins have more specialized functions connected with the coupling of the translation process to the inner mitochondrial membrane, where the seven hydrophobic mtDNA-encoded proteins have to be assembled.

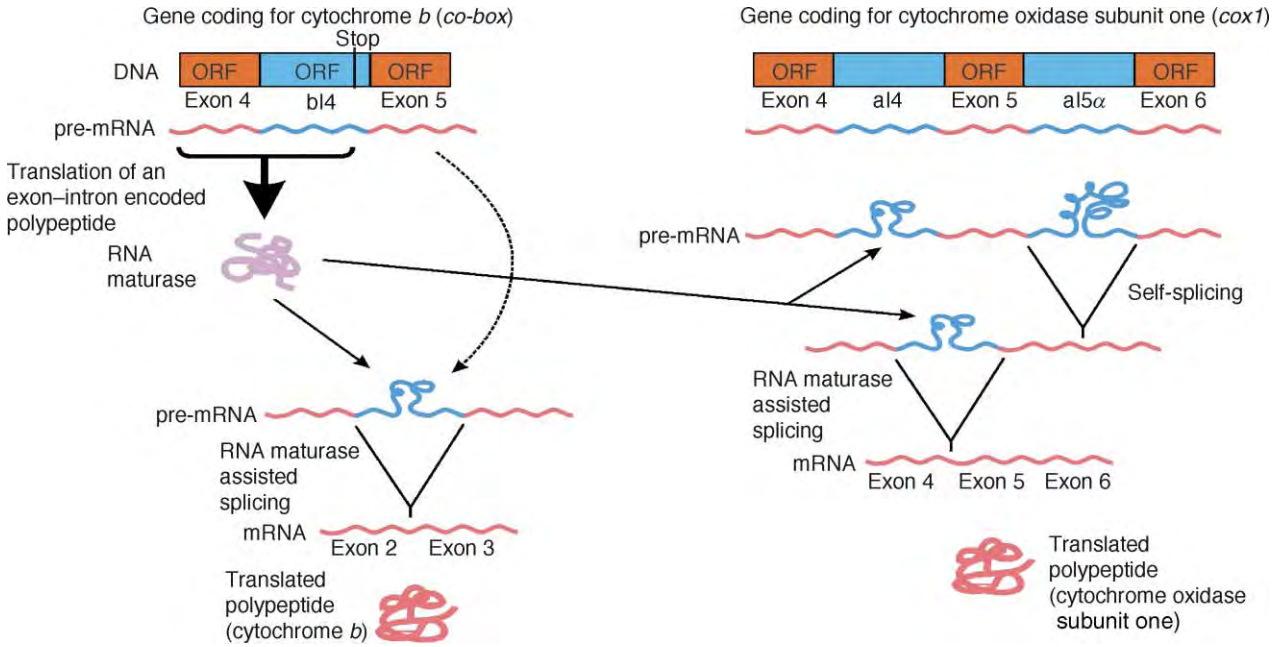

FIGURE 3 Specific features of the expression of a "mosaic" mitochondrial protein-coding gene. Several yeast mitochondrial genes contain introns and some of these introns contain ORFs (see Figure 1). The expression of such "mosaic" genes occurs in two successive steps supplementary to the general features of expression of "simple" genes (see Figure 2). The primary, unspliced RNA transcript (pre-mRNA) for apocytochome *b* acts as a messenger for a protein translated from the upstream exon ORF of cytochrome *b* and the ORF of the successive intron. This fusion protein, mRNA maturase (in the example shown referred to as the bI4 RNA maturase) promotes catalytically the excision of the intervening sequence from the pre-mRNA and ligation of cytochrome *b* exonic RNA leading to the formation of cytochrome *b* mRNA. The maturase recognizes specific structures of the intervening sequence, helps the productive folding and facilitates the activity of the ribozyme. At the same time the maturase activity destroys the RNA which codes for itself and thus exerts a negative feedback for its own biosynthesis. In consequence the amount of maturase in the organelle is very low, and the protein can be detected only when its splicing function is impaired. Generally, the maturases act selectively on the introns which encode them. A notable exception is the maturase shown in the example, i.e., the maturase encoded by the fourth intron of the cytochrome *b* gene (bI4): its activity is essential also for the splicing of the fourth intron (aI4) of a different gene, *cox1*, which encodes the subunit one of cytochrome *c* oxidase. In this manner the expression of the key catalysts of the electron transfer cascade may be coordinated.

The 5′-untranslated leader sequences (UTLs) of mitochondrial mRNAs contain sequence or structural signals that indicate the translation initiation site and that are recognized by mRNA-specific activator proteins (e.g., Cbs1, Cbs2, and Cbp1 for *cytb*, Pet309 for *cox1*, Pet 111 for *cox2* mRNA). Some of the translational activators, that mediate mRNA interactions with mitochondrial ribosomes, are organized on the surface of the inner mitochondrial membrane in a way that facilitates assembly of the inner membrane complexes. Assembly of these complexes necessitates also other proteins, e.g., Oxa1 is necessary for the correct assembly of cytochrome *c* oxidase and the ATP synthase complex.

The recent observed interaction of some membrane-bound specific activators with two proteins, Nam1 and Sls1, that, besides being involved in posttranscriptional events and in translation, are able to bind the amino-terminal domain of mitochondrial RNA polymerase, suggests that expression of mtDNA-encoded genes involves a complex series of interactions that localize active transcription complexes to the inner membrane, in order to coordinate translation with transcription.

In this way synthesis of the mitochondrially encoded proteins is coordinated with their assembly into multimeric respiratory complexes. On the other hand, the posttranslational targeting mechanism of nuclear encoded subunits seems to be preceded by mRNA localization in cytoplasmic ribosomes tightly associated with the organelles, thus facilitating the localization of proteins. This suggests a topological coordination between translation of the mitochondrial and nuclear-encoded subunits and their assembly into higher order complexes.

Giovanna Carignani obtained her degree in pharmacy in 1960 at the University of Trieste (Italy). She is an Assistant Professor of Molecular Biology of the Faculty of Medicine of the University of Padova (Italy).

Piotr P. Slonimski obtained his M.D. degree in 1947 at the University of Cracow (Poland) and soon after he joined the Centre National de la Recherche Scientifique (CNRS), Laboratory of Boris Ephrussi, in Paris. He became Director of the CNRS Laboratory of Physiological Genetics in 1960, then Director of the CNRS Center of Molecular Genetics of Gif-sur-Yvette until 1992. He was Professor of Molecular Genetics at the Sorbonne, at the University Pierre et Marie Curie (Paris VI) and Guest Professor at several American and European universities. He was in charge of the first French government Genome Project (Groupement de Recherches et d'Etudes sur les Genomes, GREG) and is active now, as Emeritus Professor, in the field of genome bioinformatics.

Mitochondrial Genome, Evolution

B. Franz Lang, Dennis V. Lavrov and Gertraud Burger
Université de Montréal, Montréal, Québec, Canada

Mitochondria, the energy-producing organelles of the eukaryotic cells, evolved from an endosymbiotic α-Proteobacterium, more than one billion years ago. These organelles contain their own genetic system, which is a remnant of the endosymbiont's genome. Mitochondrial DNA (mtDNA) varies considerably in size, structure, and coding capacity throughout eukaryotes. The ~5–100 genes contained in mtDNA code for mitochondrial components with functions in oxidative phosphorylation, protein synthesis, protein transport and maturation, RNA processing, and, in rare instances, transcription. Mitochondrion-encoded proteins make up only a small fraction of the mitochondrial proteome. The majority of mitochondrial proteins is encoded by nuclear genes, most of which are thought to have originally resided in mtDNA, and migrated to the nucleus in the course of eukaryotic evolution.

Origin and Evolution of Mitochondria

Eubacterial Ancestry of Mitochondria

Two decades of research in mitochondrial biogenesis and genomics unequivocally confirms the eubacterial ancestry of mitochondria (Figure 1). This ancestry is strikingly obvious in mitochondrial genomes of minimally derived eukaryotes, such as the recently described bacterivorous freshwater flagellate *Reclinomonas americana* (Table I). Among other eubacteria-like features, the mtDNA of this jakobid protist and its relatives has putative ribosome-binding motifs (Shine–Dalgarno sequences) upstream of protein-coding genes typical for bacterial systems, and codes for a eubacteria-like multisubunit RNA polymerase not found in mtDNA of other eukaryotic groups.

Phylogenetic analyses based on mitochondrial protein sequences show that mitochondria originated only once from within α-Proteobacteria, a bacterial assembly that includes free-living species such as *Magnetospirillum* and *Rhodobacter*, facultative symbionts/pathogens of plants like *Rhizobium* and *Agrobacter*, and intracellular, obligatory animal pathogens of the *Rickettsia* group including the causative agents of typhus and spotted fever. The closest living relatives of mitochondria appear to be within the *Rickettsiae*. However, this conjecture needs to be considered with caution, because available phylogenetic methods tend to group together species with highly accelerated evolutionary rates (such as mitochondria and *Rickettsia*), irrespective of their true evolutionary relationships. Whether or not they are sister groups, mitochondria and rickettsial bacteria are most likely the product of independent reductive evolution from a common (most likely free-living) bacterial ancestor, as indicated by differences in energy metabolism, and the lack of shared derived traits (e.g., gene order).

Nature of the Host Cell

A most controversial issue is, whether the host of the endosymbiotic symbiont that gave rise to the mitochondrion was a nucleus-containing amitochondriate eukaryote resembling extant anaerobic protists, or rather an archaebacterium; i.e., it is unclear whether the distinctive features of eukaryotic cells existed before this endosymbiotic event, or arose subsequently. Although accumulating molecular evidence suggests that all known amitochondriate eukaryotes once harbored mitochondria that were lost secondarily, the question remains whether primitively amitochondriate eukaryotes ever existed; and if so, to what extent their cellular organization featured the characteristics of present-day eukaryotes. The inference of the nature of eukaryotic ancestors (e.g., presence or absence of a cytoskeleton and a nucleus), and of the contribution of mitochondrial endosymbiosis to the evolution of the eukaryotic cell, will require additional massive genomic information, particularly from minimally derived eukaryotes.

Genome Size Reduction and Accelerated Evolution in Early Mitochondrial History

Early steps in the evolutionary history of mitochondria were likely governed by similar principles as those observed in present-day intracellular bacterial pathogens and symbionts, as briefly discussed in the following.

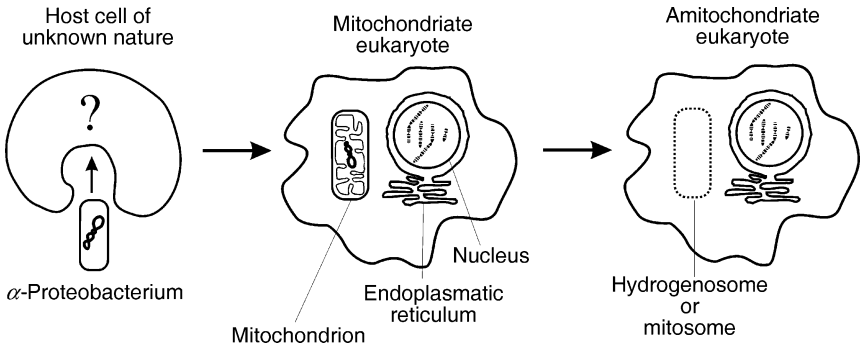

FIGURE 1 Evolution of the mitochondrion. Hypothesis describing the origin of the mitochondrion via endosymbiosis of an α-Proteobacterium with a host cell of undefined nature. Amitochondriate eukaryotes are believed to have lost mitochondria secondarily, often leaving behind relict organelles, such as hydrogenomes or mitosomes.

Bacteria that reside inside eukaryotic cells benefit from an environment rich in nutrients, which renders a large set of their biosynthetic and metabolic genes obsolete. These superfluous genes are usually lost in obligate intracellular bacteria, together with genes involved in DNA repair, recombination, lateral gene transfer among bacteria, and propagation of phages and other mobile sequence elements. Loss of these genes, in conjunction with a radically different selective pressure within the host cell, are likely responsible for the accelerated sequence evolution and changes in nucleotide composition (decrease of G + C content), observed in strictly intracellular bacteria. The gene loss is massive and progressive. For example, the obligate intracellular leprosy bacillus *Mycobacterium leprae* possesses a relatively large genome for a pathogen (3.27 mbp) with 1604 identifiable protein coding genes, 1116 pseudogenes, ~50% noncoding sequence, and a G + C content of 57.7%. In contrast, the genomes of the more derived, obligate endosymbiotic/endoparasitic bacteria *Rickettsia*, *Wigglesworthia* and *Buchnera* (symbionts of insects), and *Wolbachia* (parasite of arthropods and nematods) have genomes sizes of ~1 mbp only, and code for as few as 583 protein coding genes with an overall G + C content as low as 26.3%.

Transition from an Autonomous Bacterium to a Subcellular Organelle

Gene migration from the mtDNA to the nucleus, and the acquisition of a unique mitochondrial protein import machinery, were pivotal steps in the transformation of the proto-mitochondrion into an integrated, subcellular organelle. However, not all genes lost from mtDNA have necessarily moved to the nucleus; mitochondrial genes may have also been substituted by either genuinely nuclear genes, or genes from other (unknown) sources. An example for the latter case is the replacement of the original multisubunit bacteria-like RNA polymerase (inherited from the proto-mitochondrial ancestor) by a bacteriophage T3/T7-like RNA polymerase. This secondarily acquired RNA polymerase directs mitochondrial transcription in all contemporary eukaryotes, except in the minimally derived jakobid flagellates.

There is currently much controversy about the proportion of mitochondrial genes that reside in the nuclear genome. In yeast, some 400–630 nuclear genes (close to 10% of the genome) are considered to code for mitochondrial proteins. However, only a minority of these proteins can be traced to an α-proteobacterial origin on the basis of phylogenetic analysis. We would argue that yeast, with its highly accelerated rate of gene evolution and a considerably reduced gene set, is not an appropriate organism for such estimations. We expect that nuclear genomes of little-derived protists harbor a substantially higher number of genes of clearly identifiable mitochondrial origin.

Ongoing Gene Transfer to the Nucleus

Mitochondrion-to-nucleus gene migration is an ongoing process. For example, in leguminous plants, the active gene specifying cytochrome oxidase subunit 2 (*cox2*) resides in the nucleus in some species, but in the mitochondrion in others (as in all nonleguminous plants). Even more intriguingly, in soybean, an inactive mitochondrial *cox2* gene copy exists in addition to an active nuclear one. In this particular example, there is strong evidence that the transfer to the nucleus proceeded via an mRNA → cDNA intermediate. Nevertheless, direct transfer of genomic DNA appears to be an alternative avenue: nuclear genomes of plants and animals (including human) often contain large insertions of mtDNA, some even of full length. Finally, a surprisingly high rate of gene transfer from the

TABLE I

Features of Mitochondrial Genomes from Representative Eukaryotes

Organismal group	Genome size and structure[a]	Protein genes[b]	RNA genes[c]	Translation code[d]	Introns[e]
Metazoa (animals)					
Homo sapiens (human)	16.6 (circular)	13	24	**UGA(W), AUA(M)**[f]

Reclinomonas americana (jakobid flagellate)	69.0 (circular)	64	31	Standard	1

[a] Size in kbp, rounded values; "circular" stands for "circular mapping," i.e., the major portion of these mtDNAs occurs as long linear concatamers, not as monomeric circles. "Linear" stands for "monomeric linear."

[b] The number of identified genes is indicated. The basic set of protein-coding genes typically found in animals and fungi are, *cob* (apocytochome b), *cox1,2,3* (cytochrome oxidase subunits), *atp6,8,9* (ATPase subunits), and *nad1,2,3,4,4L, 5, 6* (NADH dehydrogenase subunits). The *M. senile* mtDNA contains an additional gene with similarity to bacterial *mutS*, and protists, fungi and plants contain additional hypothetical protein genes (ORFs).

[c] Genes for *rns, rnl* (small and large subunit rRNAs) occur in all mtDNAs, whereas genes coding for *rrn5* (5S rRNA), and RNase P RNA, might be absent. The number of mtDNA-encoded tRNAs varies. Duplicated genes are counted only once.

[d] Deviations from the standard bacterial translation code are indicated in bold.

[e] Total number of introns, the two mitochondrial intron classes "I" and "II" are not distinguished.

[f] Further codon reassignments include the use of AGA and AGG as stop codons, and additional translation initiation codons other than AUG and GUG.

[g] In *S. pombe*, one UGA(Trp) is present in *rps3*, and two in intronic ORFs.

[h] *Prototheca* belongs to green algae, but has secondarily lost its capacity for photosynthesis.

mtDNA to the nucleus ($\sim 10^{-5}$ per generation) has been experimentally determined in yeast.

Limitation of Gene Transfer to the Nucleus

Not a single eukaryote is known in which all genes have been relocated to the nucleus. All eukaryotes that lack mtDNA are unable to produce ATP via oxidative phosphorylation, and frequently contain degenerated mitochondria (hydrogenosomes or mitosomes).

Two major hypotheses have been proposed to explain why certain mitochondrial genes are much more rarely transferred to the nucleus than others. It has been reasoned that import of gene products into mitochondria may be hampered if these are highly hydrophobic (e.g., Cox1 and Cob), or very large (ribosomal RNAs), and thus counteract the transfer of the corresponding genes to the nucleus. Another theory invokes control of transcription initiation of mitochondrial genes by changes in redox potential inside mitochondria. This would require sensor genes to reside on

mtDNA, a mechanism described for chloroplasts. Both interpretations are consistent with the observed hierarchy of mitochondrial gene loss in different eukaryotic lineages, and may well apply in concert.

Mitochondrial Genome Diversity in Extant Eukaryotes

Over the past two decades, >500 complete mitochondrial genome sequences have been determined. Here, we will only summarize the distinctive features of mtDNAs from the major eukaryotic groups. Figure 2 depicts the maps of some selected mitochondrial genomes, demonstrating the diversity of mtDNA size, gene organization, and gene content.

Animal mtDNAs

To date, complete mtDNA sequences of more than 400 animals have been deposited in public databases. Animal mtDNAs are typically small (14–17 kbp in size) and carry intronless genes that are compactly arranged on both DNA strands. Mitochondrial genes code for the small and large subunit ribosomal RNAs, 13 proteins,

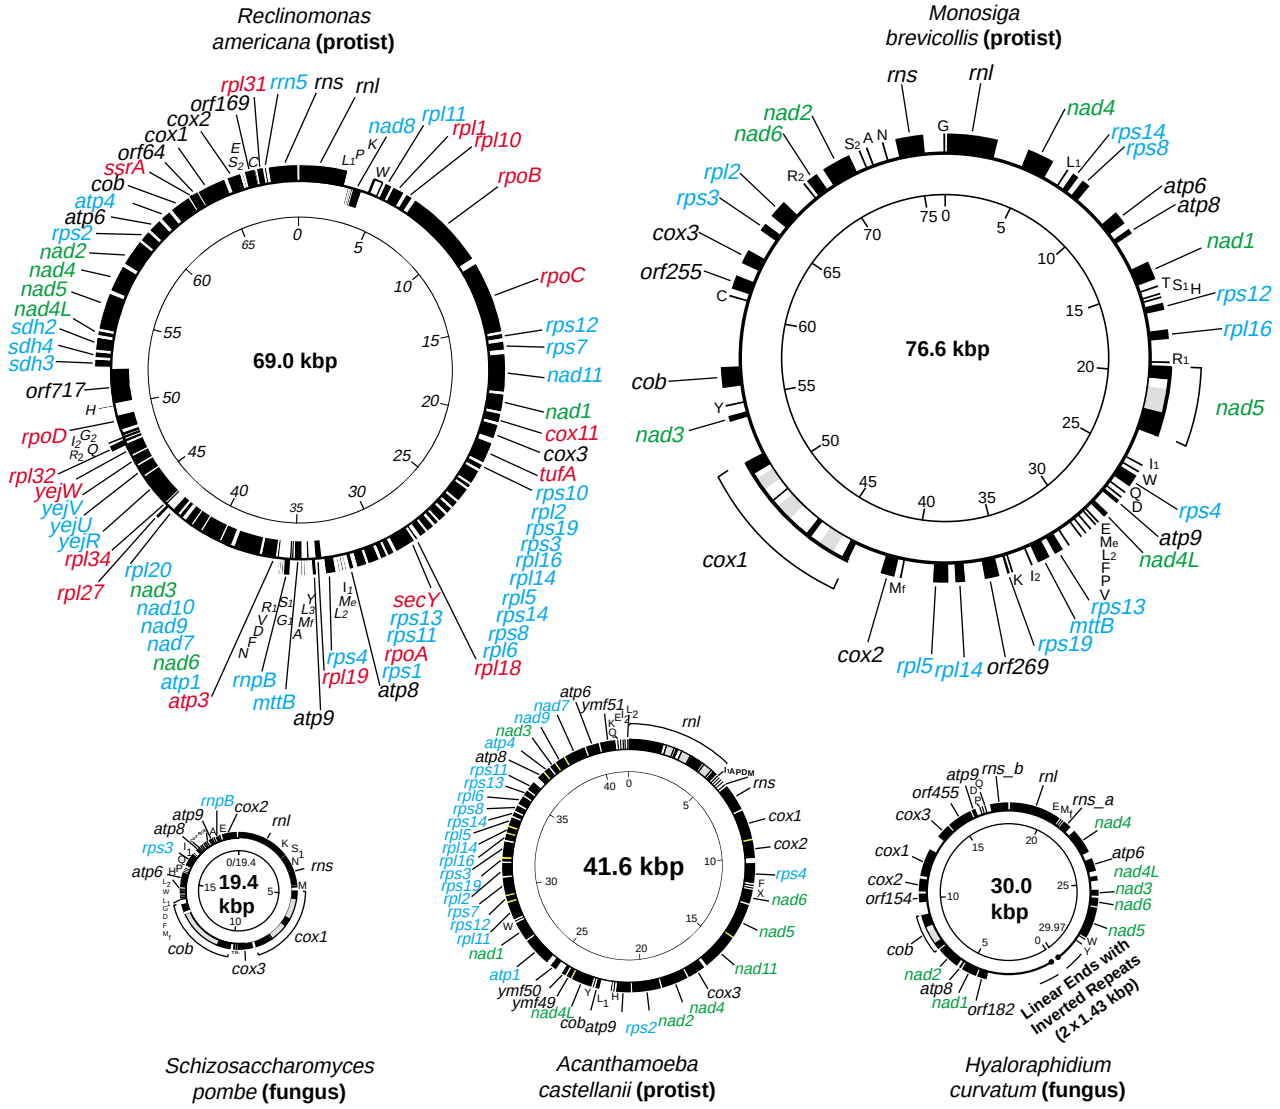

FIGURE 2 Diversity of mitochondrial genomes from various eukaryotic groups. Genetic maps of mtDNAs from protists and fungi, demonstrating the wide range of coding capacity, size, and organization (the mtDNA of *Hyaloraphidium* is linear, but is depicted as a circle to facilitate comparisons). Outer ring, transcription is clockwise; black rectangles, genes; white rectangles with gray-shaded sections, introns and intronic open reading frames. Gene names in black are genes of the basic gene complement common to all fungal and animal mtDNAs, and unidentified open reading frames (ORFs); green, extended gene set common to fungi and animals (and most other eukaryotes); blue, extra genes common to most protists; red, extra genes only found in jakobid flagellates.

and up to 22 tRNAs (Table I). Genes are arrayed in an order that is well conserved within and, to a lesser degree, among animal phyla. Exceptions are found among corals and sea anemones (phylum Cnidaria), which are the only animals whose mitochondrial genes contain introns, and which have lost all but two tRNA genes. In addition, all animals studied to date use modified mitochondrial translation codes, and tRNA and rRNA structures are highly reduced and derived compared to bacterial systems.

Animal phylogenies, even when using complete sets of mitochondrial proteins, often fail to generate wellsupported tree topologies. This lack of support results from the unusually high evolutionary rate of most animal mtDNAs. In contrast, rearrangements in animal mitochondrial genomes are exceptionally rare events, which allows the use of mitochondrial gene order data for inferring evolutionary relationships in animals.

Fungal mtDNAs

Currently, completely sequenced mtDNAs are available from 22 fungal taxa, including representatives of all four major divisions of this kingdom: Ascomycota, Basidiomycota, Zygomycota, and Chytridiomycota. Fungal mtDNAs are highly variable in terms of size, structure, and content of genes and introns. For instance, in two groups of Ascomycota, all seven genes for subunits of the NADH dehydrogenase typically encoded by the mtDNA are absent. The chytridiomycete *Rhizophydium136* contains as many as 37 introns whereas other members of this group (e.g., *Harpochytrium* species) contain none. Several fungi encode highly reduced sets of only 7–9 mitochondrial tRNAs. Additional differences in coding content include unidentified reading frames and plasmid-encoded polymerases, which are quite common in filamentous fungi.

Despite this variability, the basic set of fungal mitochondrial genes resembles that of animals (Table I), apparently a result of independent events of gene loss in the two lineages.

Plant mtDNAs

Mitochondria of land plants have the largest known mtDNAs, with sizes from 180 to 2400 kbp. Despite ~100-fold increase in genome size, the number of mitochondrial genes of plants is not even twice as high as in animals, and lower than in most protists (Table I). The few sequenced plant mitochondrial genomes suggest that the increase in size is due to a progressive accumulation of noncoding DNA. Although mtDNAs of angiosperms have generally high rates of genome rearrangements and frequently contain insertions of chloroplast and nuclear DNA, the evolutionary rate of mitochondrial genes is exceptionally low relative to nuclear genes.

Protist mtDNAs

Protists are a heterogeneous group of eukaryotes that are negatively defined as not belonging to the animal, fungal, or plant kingdoms. Based on ultrastructural characteristics, several dozen protist phyla are distinguished, but the evolutionary relationships among these phyla are mostly contentious. Many protist mitochondrial genomes are more bacteria-like, and encode a substantially larger set of genes than those of animals and fungi (Table I). However, mtDNA of several parasitic protists exhibit novel and puzzling features. For instance, the linear mtDNA (6 kbp) of the malaria parasite *Plasmodium falciparum* carries only five genes. Its rRNAs are encoded by many small gene pieces. Another oddity is found in trypanosomatid parasites, whose mtDNA consists of a network of thousands of concatenated minicircles and a few dozen maxicircles. The RNAs transcribed from maxicircle genes undergo massive RNA editing through nucleotide insertions and deletions to generate translatable mRNAs.

Conclusion

Protists comprise more biological diversity than animals, plants, and fungi together. Without a doubt, investigations of mtDNAs from poorly studied protist groups will lead to further discoveries of novel genome structures and molecular mechanisms, and provide insights into the evolutionary forces that have brought about the eukaryotic cell as we know it today.

Biography

B. Franz Lang and G. Burger are both Professors in the biochemistry department at the Université de Montréal, Canada. Their principal research interests are in the fields of comparative genomics, molecular evolution, and bioinformatics. They are best known for their work on organellar genome evolution and a publicly accessible organelle database. Dr. Lang holds a Ph.D. from the University of Munich, Germany. He has been Fellow of the Canadian Institute for Advanced Research (CIAR) for over 10 years. Dr. Burger also holds a Ph.D. from the University of Munich. She is a CIAR associate, and leader of the bioinformatics programs at the Université de Montréal.

Dennis Lavrov obtained his Ph.D. from the University of Michigan and is currently a postdoctoral fellow at the Canadian Institute of Health Research, with BFL.

Mitochondrial Genome, Overview

Douglas C. Wallace
University of California, Irvine, California, USA

The mitochondrial genome is the sum of the genes that are required to assemble a mitochondrion. These genes are distributed between a DNA molecule located in the mitochondrion, the mitochondrial DNA (mtDNA), and the nuclear DNA (nDNA). Whereas the genes encoded by the mtDNA vary between different species, essentially all mtDNAs code for three or more essential proteins of the mitochondrial energy-generating process of oxidative phosphorylation (OXPHOS), plus the small and large ribosomal RNAs (rRNAs) for the mitochondria-specific ribosomes. The rest of the genes necessary to assemble a mitochondrion reside in the nDNA.

Structure, Biology, and Origins

Mitochondria are present in virtually all eukaryotic cells (cells with a nucleus), and each eukaryotic cell contains multiple mitochondria that generate most of the cellular energy by oxidative phosphorylation (OXPHOS). The mitochondria became a component of the eukaryotic cell about 2 billion years ago through a symbiotic association between a motile nucleated cell and the α-proteobacterium, a *Rickettsia*-like oxidative bacterium. Because the mitochondrion was a bacterial cell, it had (and still retains) a complete information storage and retrieval system, based on the mtDNA. The mtDNA is replicated within the mitochondrion and transcribed into structural RNAs (rRNAs and tRNAs) and messenger RNAs (mRNA), and the mRNAs are translated into proteins on chloramphenicol (CAP)-sensitive mitochondrial ribosomes.

While the actual physiological interactions that stabilized the original symbiosis are unknown, one scenario is that the protomitochondrion, which carried the mitochondrial antioxidant enzyme manganese superoxide dismutase (MnSOD), provided protection to the host cell against the increasing toxicity of the global atmospheric oxygen that was being generated by the cyanobacteria during photosynthesis. Later, the host cell invented the adenine nucleotide (ADP/ATP) translocator (ANT), which permitted it to extract ATP from the mitochondrion in exchange for spent cytosolic ADP. This established the energetic interrelationship between the host and symbiont that still exists today.

As the symbiotic relationship evolved, most of the original genes of the bacterial genome were either lost or transferred to the nDNA, where they were scattered across the various chromosomes. Chromosomal mitochondrial genes are now transcribed using nuclear RNA polymerase; the mRNAs are then translated on 80S cytosolic ribosomes. The resulting proteins destined for the mitochondrion contain specific amino-terminal or internal mitochondrial-targeting sequences, permitting them to bind to the mitochondrion and to traverse the outer and inner mitochondrial membranes through the transport across the outer (TOM) and transport across the inner (TIM) complexes. These mitochondrial proteins first interact with the 70 kDa heart shock protein (HSP) and the mitochondrial import-stimulating factor (MSF); then they bind to one of two receptors (Tom20 + Tom22 or Tom37 + Tom70). These receptors interact with the general insertion pore of the TOM complex composed of Tom40, 22, 5, 6, and 7 polypeptides. Those polypeptides that are targeted to the matrix then interact with the TIM complex composed of Tim33, 23, 17, and 11 polypeptides. As the polypeptide traverses the inner membrane, it interacts with Tim44 and mitochondrial HSP70; the amino-terminal peptide is cleaved off by the mitochondrial-processing peptidase and, in some cases, the mitochondrial intermediate peptidase. By contrast, hydrophobic mitochondrial carrier proteins destined for insertion in the mitochondrial inner membrane are complexed in the intermembrane space by either the Tim9,10 or the Tim8,9,13 polypeptide complexes. These proteins are then delivered into the inner membrane by the 300 kDa TIM complex composed of the Tim54, 22, 12, 10, and 9 proteins.

Different protist genera harbor a wide variety of mtDNA structures and gene complements. Common mtDNA-encoded genes include the small and large rRNA, one subunit (cytochrome b [cytb]) of respiratory complex III (bc_1 complex), two or three subunits (COI, COII, COIII) of cytochrome c oxidase (COX or complex IV) and one or more subunits (ATP6, ATP8, ATP9) of complex V (ATP synthase [ATPsyn]). The most complex mtDNA genome analyzed to date is that of *Reclinomonas americana*. This mtDNA encodes eubacteria-like 23S, 16S, and 5S rRNA genes; a nearly

complete set of tRNA genes employing the standard genetic code; and 62 protein coding genes, including subunits for a bacteria-like RNA polymerase, multiple ribosomal proteins, additional subunits of complexes I, II, and V, etc. Modern human and vertebrate mtDNAs encode a 12S and 16S rRNA; 22 tRNAs; and 13 proteins: ND1, 2, 3, 4L, 4, 5, and 6 of the roughly 46 polypeptides of complex I, cytb of the 11 subunits of complex III, COI, II, and III of the 13 subunits of complex IV, and ATP6 and 8 of the ~17 polypeptides of complex V (Figure 1).

Some mtDNAs can have altered genetic codes. For example the mtDNA lineage leading from fungi to mammals encompasses a progression of codon changes. The earliest change, found in all fungal and animal mtDNAs, was an alteration in the tryptophan anticodon that suppressed the opal stop codon. The tryptophan codon 5′-UGG-3′ is read by the anticodon 3′-ACC-3′. Since C cannot pair with the terminal A in the adjacent opal codon (5′-UGA-3′), this is a stop codon. However, in fungal and animal mtDNAs, the tryptophan anticodon is converted to 3′-ACU-5′, and the U can pair with A, converting the opal stop codon to a tryptophan codon. Other changes include expansion of the number of methionine codons and alteration of the isoleucine codons. Finally, in the transition from *Xenopus* to mammals, the tRNA that interprets the arginine codons 5′-AGA-3′ and 5′-AGG-3′ was deleted, rendering these stop codons. Possibly these genetic code changes became established to reduce the inadvertent translation of mRNAs in the wrong compartment. The use of 5′-UGA-3′ as tryptophan in the mitochondrion would mean that mtDNA mRNAs would prematurely terminate in the cytosol. Similarly, the loss of the tRNA for the arginine AGA and AGG codons would mean that the cytosolic mRNAs could not be translated in the mitochondrion. By blocking erroneous crosstalk between the mitochondrial matrix and the cytosol, this system would increase the efficiency of protein synthesis in both compartments. However, it also means that functional

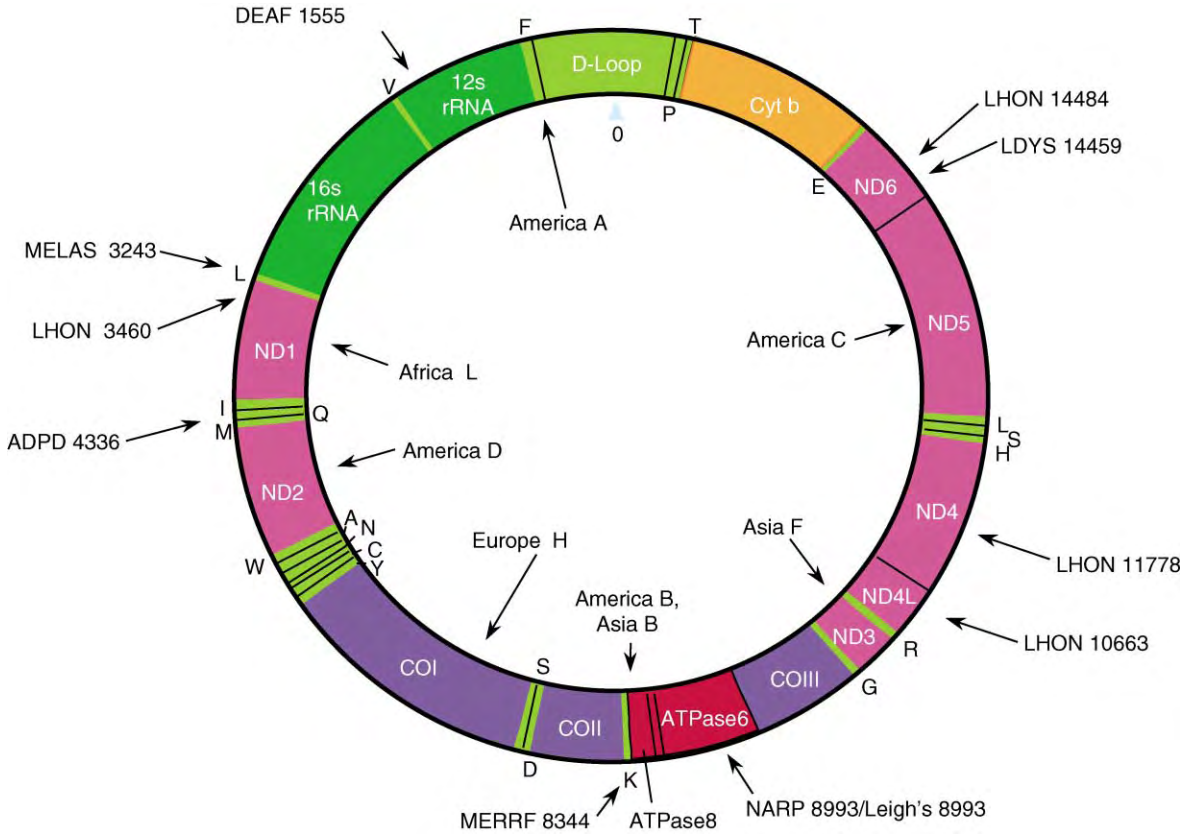

FIGURE 1 Human mitochondrial DNA map. D-loop = control region. Letters around the outer perimeter indicate cognate amino acids of the tRNA genes. Other gene symbols are defined in the text. Arrows leading from continent names and associated letters on the inside of the circle indicate the position of defining polymorphisms of selected region-specific mtDNA lineages. Arrows leading from abbreviations followed by numbers around the outside of the circle indicate representative pathogenic mutations; the number indicates the nucleotide position of the mutation. Abbreviations: DEAF, deafness; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; LHON, Leber's hereditary optic neuropathy; ADPD, Alzheimer's and Parkinson's disease; MERRF, myoclonic epilepsy and ragged red fiber disease; NARP, neurogenic muscle weakness, ataxia, retinitis pigmentosum; LDYS, LHON + dystonia. From http://www.mitomap.org.

mtDNA genes can no longer be incorporated into the nDNA. Hence, the mtDNA gene complement has been substantially conserved from fungi to humans.

All mitochondria generate energy via OXPHOS (Figure 2). OXPHOS burns hydrogen derived from carbohydrates and fats with oxygen to generate water (H_2O). In endotherms such as humans, the energy that is released is used to maintain body temperature and to generate ATP. The reducing equivalents (electrons) from dietary calories are collected by the tricarboxylic acid (TCA) cycle and transferred to either NAD^+ to generate NADH or FAD to give $FADH_2$. The electrons are then oxidized by the electron transport chain (ETC). The ETC collects electrons from NADH through complex I (NADH dehydrogenase) or from succinate in the TCA cycle through complex II (succinate dehydrogenase) and transfers them to ubiquinone (coenzyme Q_{10}, or CoQ) to generate ubisemiquinone (CoQH·) and then ubiquinol ($CoQH_2$). From $CoQH_2$, the electrons are transferred to complex III, then cytochrome c, then complex IV, and finally to ½ O_2 to give water. The energy that is released during electron transport is used to pump protons from the matrix out across the mitochondrial inner membrane to create an electrochemical gradient ($\Delta P = \Delta\Psi + \Delta\mu^{H+}$). This biological capacitor serves as a source of potential energy to drive complex V to condense ADP + Pi to give ATP. The mitochondrial ATP is then exchanged for cytosolic ADP by the ANT. The efficiency by which ΔP is converted to ATP is known as the coupling efficiency. Tightly coupled OXPHOS generates the maximum ATP and minimum heat, whereas loosely coupled OXPHOS generates less ATP but more heat.

As a toxic by-product of OXPHOS, the mitochondria generate most of the reactive oxygen species (ROS), or oxygen radicals, generated within eukaryotic cells. This results from the misdirection of electrons from the early stages of the ETC surrounding CoQH· directly to O_2 to generate superoxide anion ($O_2^{\cdot-}$). Superoxide anion is highly reactive but can be detoxified by MnSOD

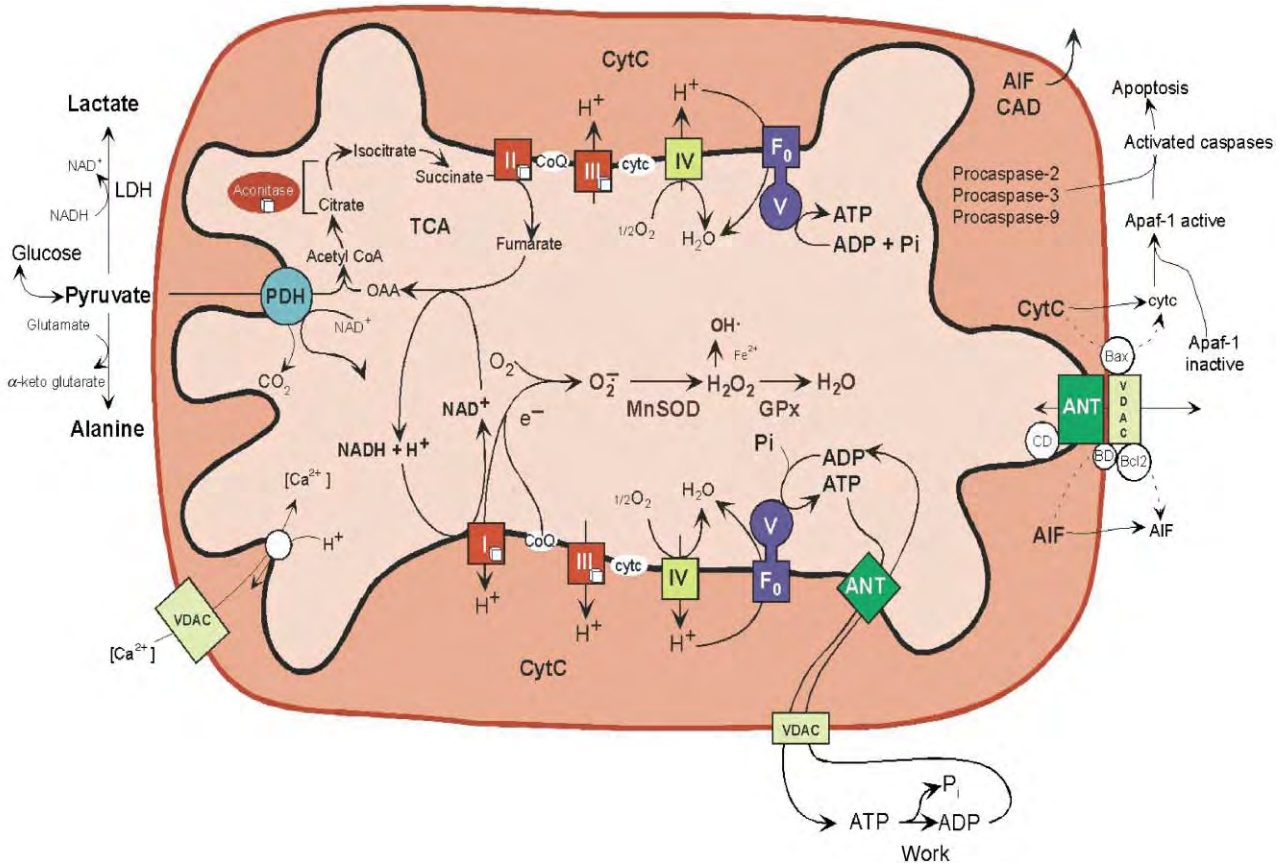

FIGURE 2 Three features of mitochondrial metabolism relevant to the pathophysiology of disease: (1) energy production by oxidative phosphorylation (OXPHOS), (2) reactive oxygen species (ROS) generation as a toxic by-product of OXPHOS, and (3) regulation of apoptosis through activation of the mitochondrial permeability transition pore (mtPTP). Abbreviations: I, II, III, IV, and V, OXPHOS complexes I–V; ADP, adenosine diphosphate; ATP, adenosine triphosphate; ANT, adenine nucleotide translocator; cytc, cytochrome c; GPx, glutathione peroxidase-1; LDH, lactate dehydrogenase; MnSOD, manganese superoxide dismutase or SOD2; NADH, nicotinamide adenine dinucleotide; TCA, tricarboxylic acid cycle; VDAC, voltage-dependent anion channel.

to generate hydrogen peroxide (H_2O_2). Hydrogen peroxide is relatively stable. In the presence of transition metals, however, it can be reduced to hydroxyl radical ($^{\cdot}OH$), which is the most toxic ROS. Consequently, H_2O_2 is reduced to water by glutathione peroxidase (GPx1) or catalase (Figure 2). ROS damage mitochondrial proteins, lipids, and nucleic acids, which inhibit OXPHOS and further exacerbate ROS production. Ultimately, the mitochondria become so energetically impaired that they malfunction and must be removed from the tissue.

Cells with faulty mitochondria are removed by programmed cell death (apoptosis) through the activation of the mitochondrial permeability transition pore (mtPTP). The mtPTP is thought to be composed of the outer membrane voltage-dependent anion channel (VDAC) proteins, the inner membrane ANT, the pro- and antiapoptotic Bcl2-Bax gene family proteins, and cyclophilin D. This complex senses changes in mitochondrial ΔP, adenine nucleotides, ROS, and Ca^{2+}, and when these factors get sufficiently out of balance, the mtPTP becomes activated and opens a channel between the cytosol and the mitochondrial matrix, depolarizing ΔP and causing the mitochondrion to swell. Proteins from the mitochondrial intermembrane space are then released into the cytosol. Among these is cytochrome c, which activates cytosolic Apaf-1 to convert procaspases 2, 3, and 9 to active caspases that degrade cellular and mitochondrial proteins. Apoptosis-initiating factor (AIF) and caspase-activated DNase (CAD) are transported to the nucleus, where they degrade the nDNA. As a consequence, the cell with faulty mitochondria is removed from the tissue so that its energetic failure dose not compromise the normal cells of the tissue and organ (Figure 2).

MtPTP-induced apoptosis means that only cells with optimally functioning mitochondria are retained in the tissue. However, postmitotic tissues have a finite number of cells, generally enough for the organ to function optimally until postreproductive age. Cell loss due to mitochondrial decline results in organ failure and the symptoms we call aging. Thus, the pathophysiology of degenerative diseases and aging results from the interplay between three central mitochondrial processes: energy production via OXPHOS, ROS generation and oxidative stress, and mtPTP activation initiating apoptosis.

Because of its extrachromosomal location, the mtDNA has unique genetics. In vertebrates, the mtDNA is inherited exclusively through the mother. However, each cell can harbor thousands of copies of the mtDNA, which can be pure normal (homoplasmic wild-type), a mixture of mutant and normal (heteroplasmic), or homoplasmic mutant. The percentage of mutant mtDNAs determines the relative energy deficiency of the cell and thus the probability of apoptosis. The tissues most sensitive to the adverse effects of mitochondrial decline are the central nervous system, heart, muscle, and renal and endocrine systems, the tissues most affected by aging.

Because of its chronic exposure to ROS, mammalian mtDNAs have a very high mutation rate. Hence, even though the human mtDNA is small, mtDNA diseases are common. Germline mtDNA mutations result in maternally inherited diseases. However, mtDNA mutations also accumulate in postmitotic somatic tissues, resulting in tissue decline.

Mitochondrial Variation and Human Origins

Because of its exclusive maternal inheritance and high mutation rate, human mtDNA variation has been used to reconstruct the ancient origins and migrations of women (Figure 3). These studies revealed that humans arose in Africa approximately 150,000 to 200,000 years before present (YBP), with sub-Saharan African mtDNAs radiating into four African-specific lineages: L0, L1, L2, and L3. The most ancient mtDNA lineages are found among the Khoisan Bushmen. About 65,000 YBP, L3 gave rise to two new lineages in northeastern Africa, designated M and N. Only M and N left Africa to colonize the rest of the world. One group migrated along the southeastern Asian coast to colonize Australia, while others bearing M and N radiated into Eurasia. In Europe, lineage N gave rise to the European-specific lineages H, I, J, K, T, U, V, W, and X. In Asia, both M and N radiated to generate a plethora of Asian-specific mtDNA lineages, including A, B, and F from N and C, D, and G from M. Among all of the Asian mtDNA lineages, only A, C, and D successfully occupied arctic Chukotka in northeastern Siberia. When the Bering land bridge appeared, individuals bearing these mtDNAs moved into the Americas about 20,000 YBP. Subsequently, a coastal migration brought lineage B to mix with A, C, and D about 12,000–15,000 YBP, thus generating the final Paleo-Indian mtDNA complement. Another migration across the arctic brought the European haplogroup X to the Great Lakes region of North America approximately 15,000 YBP. A migration from around the Sea of Okhotsk about 7,000–9,000 YBP brought a modified A to found the Na-Dene. Finally, a migration bringing A and D mtDNAs gave rise to the Eskimos and Aleuts.

MtDNA Variation and Human Adaptation to Cold

One geographical constraint that could have acted on mtDNA variation is climate. The mitochondria utilize

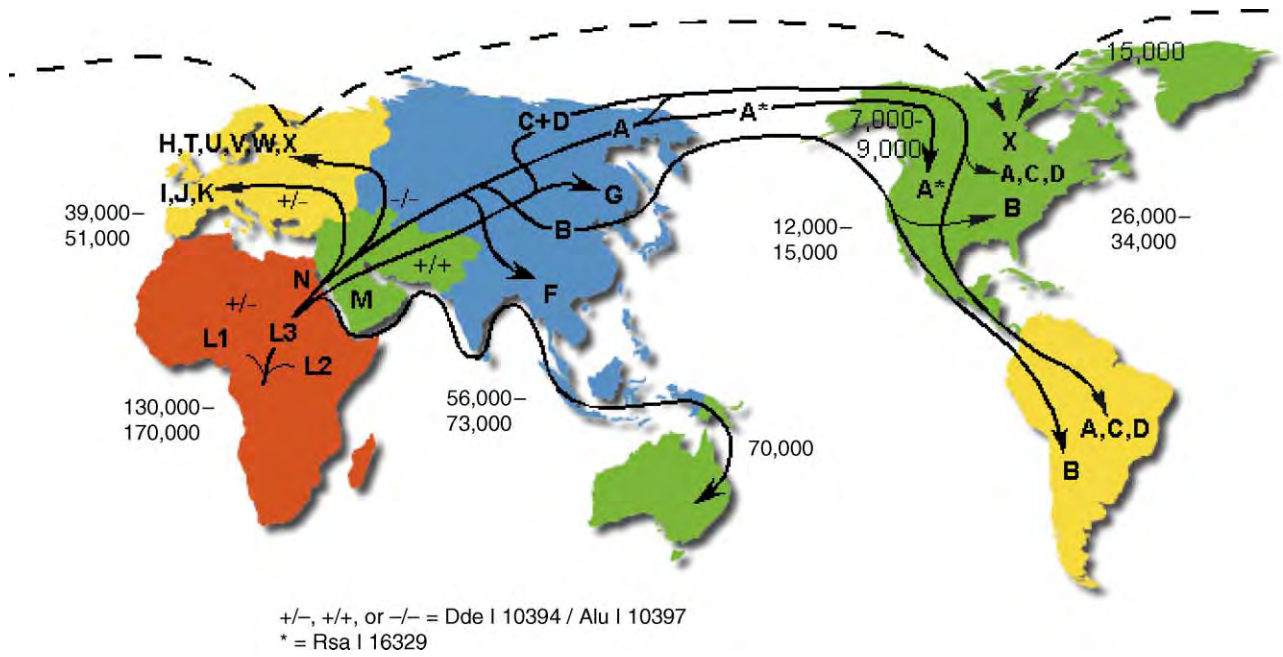

FIGURE 3 Global radiation of mtDNA types showing the regional association of mtDNA types. Capital letters represent major region groups of related haplotypes (haplogroups). In sub-Saharan Africa, haplogroup L0, which arose between 150,000 and 200,000 years before present (YBP), radiated into haplogroups L1, L2, and L3. At about 65,000 YBP, haplogroup L3 gave rise to haplogroups M and N in northeastern Africa. M and N then left Africa in two directions. A southeastern migration moved through Southeast Asia, ultimately giving rise to Australian mtDNAs. A northeastern migration colonized Eurasia, with haplogroup N giving rise to the European mtDNA haplogroups H, I, J, K, T, U, V, W, and X and to the Asian haplogroups A, B, F, etc. Haplogroup M radiated into Asia to give rise to Asian haplogroups C, D, G, etc. Haplogroups A, C, and D became enriched in northeastern Siberia and crossed the Bering land bridge between 20,000 and 30,000 YBP to found the Paleo-Indians. Haplogroup B migrated along the Asian and Bering coasts to mix with Native American haplogroups A, C, and D about 12,000–15,000 YBP. European-like haplogroup X arrived in Central North America about 15,000 YBP; derivatives of haplogroup A crossed the Bering Strait about 7,000–9,000 YBP to generate the Na-Dene; and derivatives of haplogroups A and D crossed the Bering Strait approximately 3,000–5,000 YBP to give rise to the Eskimos and Aleuts. The +/+, +/−, −/− represent important diagnostic restriction sites. The ages were calculated using the empirically determined mtDNA sequence evolution rate of 2.2–2.9%/million years (MYR). From http://www.mitomap.org.

dietary calories not only to synthesize ATP but also to generate heat to maintain body temperature. Individuals in the tropics would need tightly coupled mitochondria to maximize ATP production and minimize heat production, while individuals from the arctic would need uncoupled mitochondria to increase heat production at the expense of ATP generation.

This concept is supported by the nonrandom distribution of mtDNA gene amino acid substitutions. The mtDNA ATP6 protein sequence is hypervariable in the arctic Siberians and North Americans but conserved in the tropical Africans and temperate zone Europeans. The cytb protein sequence is hypervariable in temperate Europeans but conserved in the Africans and Siberians. COI is most variable in Africans, and so on. A detailed study of the sequences of more than 1000 mtDNAs from around the world permitted the assembly of a global human mtDNA phylogenetic tree, in which every mutation was positioned according to the relative time that it occurred. This revealed that ancient conserved amino acid substitution mutations occurred at the base of many of the temperate and arctic zone mtDNA lineages. These mutations appear to reduce OXPHOS coupling efficiency by reducing the efficiency of either proton pumping by the ETC or ATP generation by the ATP synthase. Hence, as people moved north, mtDNA lineages from the warmer climates were excluded, while mtDNA lineages with new mutations that reduced coupling efficiency and increased heat production survived and expanded into the colder latitudes.

These same nodal mutations have been found to correlate with longevity and protection against neurodegenerative diseases. European lineages J and K, which harbor cytb mutations in the inner and outer CoQ-binding sites, are protective for Alzheimer's or Parkinson's disease and also are associated with increased longevity. Mutations in the CoQ-binding sites would inhibit the Q cycle of complex III and thus reduce the efficiency of proton pumping. Because uncoupled mitochondria would oxidize more electrons, fewer would be available to generate ROS. Hence, cold-adapted mtDNAs would be associated with less

oxidative stress, thus increasing the longevity of postmitotic cells. Thus, ancient adaptive mtDNA variants are affecting individual predisposition to degenerative diseases and aging today.

Diseases of the mtDNA

The high mtDNA mutation rate that generated the ancient adaptive polymorphisms also results in a high frequency of pathogenic mutations today. Pathogenic base substitution and rearrangement mutations are both common in the human mtDNA. Base substitution mutations can alter proteins. For instance, the ND4 missense mutation (R340H) at nucleotide pair (np) 11778 causes Leber's hereditary optic neuropathy (LHON), a form of sudden-onset, midlife blindness. mtDNA mutations can also change protein synthesis genes, tRNAs, or rRNAs. For example, a $tRNA^{Lys}$ mutation at np 8344 causes myoclonic epilepsy and ragged red fiber disease (MERRF). Rearrangement mutations can occur throughout the mtDNA and result in multisystem disorders such as chronic progressive external ophthalmoplegia (CPEO), the Kearns-Sayre syndrome, or the Pearson's marrow pancreas syndrome. A plethora of pathogenic mutations in the mtDNA have now been described and are catalogued at www.mitomap.org. These diseases involve the following: the central nervous system, affecting vision, hearing, movement, balance, and memory; muscle, causing progressive weakness; heart, leading to hypertrophic and dilated cardiomyopathy; the endocrine system, including diabetes mellitus; and the renal system. Hence, it is now clear that mitochondrial defects represent one of the most common forms of human inborn errors of metabolism.

The pathogenicity of mildly deleterious mutations can also be augmented by the mtDNA lineage on which the mutation occurred. LHON can be caused by a number of mtDNA point mutations in the ND genes. The more biochemically severe mutations can cause LHON independent of the background mtDNA. However, the milder ND mutations cause LHON only when they co-occur on the European mtDNA lineage J. Hence, the diminished ATP production of partially uncoupled haplogroup J mtDNAs must augment the energetic defect of the mild ND mutations.

Somatic mtDNA Mutations in Aging

One of the most distinctive features of mitochondrial diseases is that they have a delayed onset and a progressive course. Because known mtDNA mutations can cause all of the same symptoms as seen in the elderly, it has been suggested that the accumulation of mtDNA mutations provides the aging clock. The age-related decline of mitochondrial function and an associated accumulation of somatic mtDNA mutations have been documented in a variety of animal species, with the level of mtDNA damage being proportional to lifespan, not absolute time. The accumulation of mtDNA deletions is observed in most tissues, but the

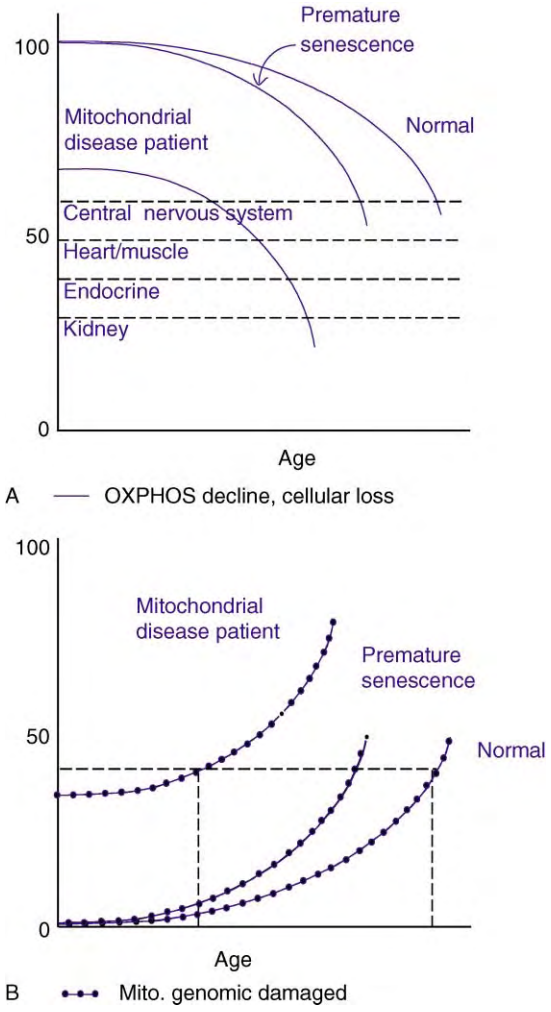

FIGURE 4 Hypothesis for the role of mitochondrial energetic decline and mitochondrial nDNA and mtDNA gene mutations in aging and degenerative disease. (A) Relationship between mitochondrial energy-generating capacity and age. (B) Relationship between defective mitochondrial genes and age. The initial energetic capacity (A) is determined by the inherited mitochondrial genotype (B), with some individuals having a lower proportion of deleterious mitochondrial variants and thus a higher initial energetic output than others. However, as individuals age they accumulate somatic mtDNA mutations in their postmitotic tissues (B) that causes the erosion of their mitochondrial energetic capacity (A). Ultimately, the sum of the inherited genetic defects plus the acquired somatic mtDNA defects cause the mitochondrial energetic capacity to fall below the minimum levels necessary for normal tissue function. If this occurs early in life, it is called disease, whereas if it occurs late in life, it is called senescence.

age-related accumulation of somatic mtDNA point mutations has been observed in the control region and appears to be tissue specific.

Aging is also the most significant risk factor for developing cancer, which implicates somatic mtDNA mutations in cancer as well. Consistent with this concept, somatic mtDNA mutations have been identified in a variety of cancers, including an ND1 intragenic deletion in a renal adenocarcinoma, base substitutions and small deletions in colon carcinomas, various point mutations in bladder, head, and neck, and lung primary tumors.

Therefore, mitochondrial diseases, aging, and cancer can be envisioned as related processes, differing only in their time course (Figure 3). Each individual starts life with a particular energetic capacity determined by his inherited mtDNA and nDNA mitochondrial variants. If the individual inherits a robust mitochondrial genotype, he starts high on the energetic scale. If he harbors one or more partially deleterious variants in the mitochondrial genome, however, he starts lower on the energetic scale (Figure 4). As the individual ages, he accumulates somatic mtDNA mutations that further erode his cellular mitochondrial function and thus tissue integrity and function. Eventually, cellular loss results in organ failure and symptoms. If thresholds are crossed early, it is called mitochondrial disease; if they are crossed late, it is known as aging.

Glossary

apoptosis A process of programmed cell death resulting in the activation of caspase enzymes and degradation of cellular proteins that can be initiated via the mitochondrion through the activation of the mitochondrial permeability transition pore (mtPTP) in response to energy deficiency, increased oxidative stress, excessive Ca^{2+}, and/or other factors.

mitochondrial DNA (mtDNA) The portion of the mitochondrial genome that resides in the matrix of the mitochondrion, often as a circular DNA molecule containing the mitochondrial rRNA genes, some tRNA genes, and at least three cytochrome *b* and cytochrome *c* oxidase subunits I and III (COI and COIII) mitochondrial protein genes.

mitochondrion Cellular organelle of endosymbiotic origin residing in the cytosol of most nucleated (eukaryotic) cells that produces energy by oxidizing organic acids and fats with oxygen by the process of oxidative phosphorylation (OXPHOS).

oxidative phosphorylation (OXPHOS) The process by which the mitochondrion generates energy through oxidation of organic acids and fats with oxygen to create a capacitor [electron chemical gradient ($\Delta P = \Delta\Psi + \Delta^{pH}$)] across the mitochondrial inner membrane and uses this stored potential energy to generate adenosine triphosphate (ATP), transport substrates or ions, or produce heat.

reactive oxygen species (ROS) Toxic by-products [primarily superoxide anion ($O_2^{\cdot-}$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($^{\cdot}OH$)], commonly referred to as oxygen radicals, that are generated by oxidative phosphorylation, which damages the mitochondrial and cellular DNA, proteins, lipids, and other molecules causing oxidative stress.

Biography

Douglas C. Wallace received his B.S. degree from Cornell University in 1968 and Ph.D. from Yale University in 1975 in microbiology and human genetics. He was Assistant Professor of Genetics at Stanford University from 1976 to 1983 and Professor of Biochemistry and Genetics at Emory University from 1983 to 2002. In 2002 he joined the University of California, Irvine as Donald Bren Professor of Molecular Medicine and Director, Center for Molecular and Mitochondrial Medicine and Genetics.

Mitochondrial Inheritance

Eric A. Shoubridge
McGill University, Montréal, Québec, Canada

Mitochondria are small cellular organelles whose primary function is the provision of cellular energy by the process of oxidative phosphorylation. They are surrounded by a double membrane and are about the size of the bacteria from which they were derived by endosymbiosis more than a billion years ago. Mitochondria contain their own DNA that codes for a relatively small number of proteins and RNAs. The size of the mitochondrial genome varies enormously in the biological world, and it generally exists as multiple copies per organelle, with tens to thousands of copies per cell. Mitochondrial genomes do not obey Mendelian laws of segregation and independent assortment. Allelic variants of mitochondrial DNA segregate during mitosis and meiosis, and even in postmitotic cells as mitochondria turn over. This results from the lack of stringent control on mitochondrial DNA replication, and on the random partitioning of mitochondrial genomes to daughter mitochondria. Mitochondrial DNA is uniparentally transmitted in nearly all organisms, in most cases through the female germ line.

Mitochondrial Structure and Function

Mitochondria are cytoplasmic organelles of $\sim 0.5-1.0\ \mu M$ in diameter. They are bounded by a double membrane: an outer membrane that is permeable to small molecules, and an impermeable inner membrane, across which an electrochemical proton gradient formed by electron transport is used to drive ATP synthesis. The inner membrane is a specialized structure, rich in cardiolipin, containing the respiratory chain complexes and carriers that move metabolites in and out of the matrix compartment. This membrane is highly convoluted into folds called cristae, which act to increase the surface area of this membrane. The matrix space bounded by the inner membrane contains soluble enzyme components required for the myriad other functions of mitochondria including the tricarboxylic acid cycle, heme biosynthesis, urea cycle, iron-sulfur cluster biosynthesis, fatty acid oxidation, and amino acid metabolism. It also contains the mitochondrial genome and the machinery necessary for its replication, transcription and translation. It is thought that mitochondria cannot be made *de novo*, but only from other mitochondria. Although mitochondria are often depicted in textbooks as small spherical bodies, they can in fact take on a variety of shapes from simple spheres to large interconnected reticular networks. Mitochondria actively move within the cell and are in a dynamic equilibrium that involves fusion and fission of individual organelles.

Structure of Mitochondrial Genomes

The mitochondrial genomes of all eukaryotes are generally much smaller than bacterial genomes, most of the genes in the original endosymbiont having been transferred to the nucleus during the course of evolution. All animal mitochondrial genomes that have been studied are less than 20 kbp in size, and the majority of these are circular. Mammalian mitochondrial genomes contain only 13 protein-coding genes and the 22 tRNAs and 2 rRNAs necessary to translate these proteins in the mitochondrial matrix. There are no introns, and few noncoding bases outside of the control regions that contain sequences essential for replication and transcription of the genome. Some animal mitochondrial genomes do not contain a full complement of tRNAs and these must therefore be imported. The mitochondrial genomes of the fungi are generally 20–100 kbp in size. They often contain fewer genes than animal mitochondrial genomes, the larger size being attributable to the presence of introns and other large pieces of noncoding DNA. Flowering plants have the largest mitochondrial genomes; most are a few to several hundred kbp in size. These circular genomes contain large direct-repeat sequences that actively recombine to produce large full-length genomes and families of smaller subgenomic circles. Plant mitochondrial genomes often contain sequences derived from the chloroplast genome, the other organellar genome in plants. Many plant mitochondrial genomes contain coding

sequences for chimeric proteins that are responsible for cytoplasmic male sterility.

Mitochondrial DNA is complexed with proteins in the mitochondrion in a structure called the nucleoid, which may be physically associated with the inner mitochondrial membrane.

Genetic Code

The mitochondrial genetic code in animals and fungi is different from the universal genetic code. For instance, the universal stop codon UGA specifies tryptophan in the mitochondrial code, preventing the translation of full-length mitochondrial polypeptides on cytosolic ribosomes. The mitochondrial (and chloroplast) genetic code in flowering plants is the same as the universal code. Transfer of functional genes from the mitochondrial genome to the nucleus thus can and does still occur in plants.

Heteroplasmy and the Segregation of Mitochondrial DNA

New mutations in mitochondrial DNA, which can arise in somatic or germ cells, lead to a situation in which more than one mitochondrial DNA sequence variant (allele) is present in the cell. This generally transient state is referred to as mitochondrial DNA heteroplasmy. Segregation of the different alleles eventually returns the system to the homoplasmic state in which there is no allelic variation. Mitochondrial DNA does not obey the Mendelian laws that apply to the segregation and independent assortment of chromosomal DNA in the nucleus. Although the copy number of mitochondrial DNA is regulated according to the cellular requirements for mitochondrial function, the stringent control that the cell exerts over the replication of nuclear DNA, in which only one copy of each chromosome can be made at each cell cycle, does not exist for mitochondrial DNA. Like some bacterial plasmids, replication of mitochondrial DNA is relaxed and not linked to the cell cycle; the only control is over the copy number. Thus, individual templates may replicate more than once or not at all during mitochondrial proliferation and division. In a dividing cell, mitochondrial DNAs will partition randomly to the daughter cells. In the absence of selection for one allele or another, the relative proportion of the different alleles will be subject to random genetic drift. The rate of genetic drift depends on the copy number and half-life of mitochondrial DNA in the cell. Genetic drift will be fastest in cells containing few copies of mitochondrial DNA with a short half-life. The unit of inheritance of mitochondrial DNA, which determines the effective mitochondrial DNA copy number, is likely to be larger than the genome itself, as multiple genomes can exist per nucleoid and multiple nucleoids populate a mitochondrion.

Transmission of Mitochondrial DNA between Generations

In most organisms, mitochondrial genomes are inherited from one parent, usually, but not universally, the female. The mitochondrial DNA copy number is usually larger in oocytes than in somatic cells. There are 100,000–200,000 copies of mitochondrial DNA in a mammalian oocyte, distributed as ~one per organelle. Despite this large copy number, new allelic variants have been observed to segregate rapidly between generations, with complete fixation often occurring in a few generations. This apparent paradox is the result of a mitochondrial bottleneck that occurs in oogenesis. The number of mitochondria changes dramatically during early embryogenesis and oogenesis. After fertilization, mitochondrial DNA replication does not resume until implantation of the early mammalian embryo. This effectively reduces the copy number of mitochondrial DNA per cell by a factor of ~1000, returning it to that typical of a somatic cell. In the early embryo, a small population of cells is set aside called primordial germ cells. These cells will give rise to all of the gametes that will eventually colonize the gonads. Ultrastructural analyses show that these cells contain only about ten mitochondria, and this is where the bottleneck for transmission occurs. The number of mitochondria increases to ~200 in the oogonia, the migratory cells that populate the genital ridge, and then to a few thousand in the primary oocyte of primordial follicles. A nearly 100-fold amplification of mitochondrial DNA is associated with maturation of the pre-ovulatory oocyte. Thus, although the oocyte contributes at least 100,000 mtDNAs to the zygote in mammals, the effective number of mitochondrial DNA molecules that are transmitted between generations is determined by the relatively small number of mitochondrial DNAs, perhaps as few as ten, which pass through the primordial germ cells. This accounts for the rapid segregation of allelic variants of mitochondrial DNA between generations. Transmission of different alleles through the female germline is, however, a stochastic process. The proportion of a particular allelic variant varies considerably among offspring because of the bottleneck, but the mean proportion in all offspring is similar to that in the mother. In other words, the level of heteroplasmy for an allelic variant in an individual is just as likely to have increased or decreased compared to that of the mother.

Uniparental Inheritance

Uniparental inheritance may be achieved passively by simple dilution of mitochondrial genomes in organisms where the sizes of the two gametes are unequal, or by active processes that exclude or eliminate the contribution from one parent. Examples of active processes include exclusion of organelles from gametes or zygotes, degradation of organelles in the gamete or zygote, and exclusion of organelles from embryonic tissue. The largest variety of active mechanisms is found in plants, where uniparental inheritance of the chloroplast genome (sometimes from a different parent) is also the rule. In mammals, sperm mitochondria, which contain ~100 copies of mitochondrial DNA, enter the zygote, but they are actively eliminated with the sperm remnants during early embryogenesis. Male leakage of mtDNA has been observed in interspecific crosses in mice, suggesting that the factors controlling the elimination of paternal mitochondria are species-specific. Male transmission of mtDNA appears to be extremely rare in humans, a single case having been reported. The fact that uniparental inheritance of organellar genomes is so pervasive suggests that there has been strong selection for this trait throughout evolution. Such a system may have evolved to prevent the spread of mitochondrial genomes with a replicative advantage, but without significant coding-gene content (selfish genomes) in a population. Such genomes have been identified in yeast. Uniparental inheritance would confine selfish genomes to the particular lineage in which they arose.

Mitochondrial Diseases

Diseases resulting from pathogenic mutations in human mitochondrial DNA occur with a frequency of about 1 in 8500 live births and are thus relatively frequent causes of genetic disease. They produce a wide variety of clinical phenotypes with prominent involvement of muscles and nerves. Most mitochondrial DNA mutations exist in a heteroplasmic state because homoplasmy for the severe mutations would be lethal. There are marked tissue-specific differences in the segregation patterns of pathogenic mutations, suggesting that pathogenic mutations are under differing selective pressures in different tissues. The segregation pattern is also influenced by the particular mutation. Generally, a high proportion (85–90%) of mitochondrial DNAs carrying the pathogenic mutation must accumulate in the cell for expression of a pathological biochemical and clinical phenotype. This phenomenon is referred to as threshold expression. It results from intraorganellar genetic complementation in which the products of wild-type mitochondrial DNAs are able to functionally rescue the products of the mutant genomes. Mitochondrial DNAs carrying pathogenic mutations are transmitted to the next generation in a largely stochastic fashion, implying that there is weak selection for mitochondrial respiratory chain function during oogenesis, embryogenesis or fetal life.

The best-studied mitochondrial disease of flowering plants is cytoplasmic male sterility because of its agricultural importance in hybrid seed production. It results from the presence of a chimeric gene in mitochondrial DNA that usually consists of an unidentified open reading frame, fused in frame with a fragment of a mitochondrial protein-coding gene. The product of this gene specifically disrupts the production of fertile pollen. Nuclear restorer genes have been identified that suppress this phenotype.

Glossary

genetic bottleneck (mitochondrial) A restriction in the number of mitochondria and mitochondrial DNAs that occurs in mammalian oogenesis, decreasing the effective number of mitochondrial DNAs that contribute to the next generation.

heteroplasmy A state in which more than one allelic variant of mitochondrial DNA exists in a cell.

homoplasmy A state in which all copies of mitochondrial DNA in the cell have the same sequence.

mitochondrial DNA The mitochondrial genome.

nucleoid A structure containing mitochondrial DNA complexed with protein that associates with the inner mitochondrial membrane.

relaxed replication Mitochondrial DNA can be replicated at any stage during the cell cycle and individual templates can be copied more than once or not at all.

segregation (mitochondrial) The process by which different alleles of mitochondrial DNA are separated when mitochondria proliferate. This happens during mitosis, meiosis, and in postmitotic cells.

threshold expression Refers to notion that a certain proportion of mutant mitochondrial DNA must be present in the cell for an abnormal phenotype to be expressed.

Biography

Eric A. Shoubridge is a Professor in the Department of Neurology and Neurosurgery and the Department of Human Genetics at the Montreal Neurological Institute of McGill University. His principal research interests are in mammalian mitochondrial genetics and mitochondrial diseases. He holds a Ph.D. from the University of British Columbia and received his postdoctoral training at Oxford University. He is an International Scholar of the Howard Hughes Medical Institute and a Senior Investigator of the Canadian Institutes for Health Research.

Mitochondrial Membranes, Structural Organization

Carmen A. Mannella
Wadsworth Center, New York State Department of Health, Albany, New York, USA

The mitochondrion is the organelle in eukaryotic cells that is the primary generator of ATP, the molecule that fuels most of the cell's machinery. The chemiosmotic mechanism of ATP production involves establishment of an electrochemical gradient across the mitochondrial inner membrane by the respiratory chain complexes. The free energy in this gradient is coupled to phosphorylation of ADP by the F_1F_0 ATP synthase on the inner membrane. Since chemiosmosis entails very rapid fluxes of ions and metabolites between the mitochondrial interior and the cytosol, the shape as well as the permeability properties of the energy-transducing inner membrane can be expected to affect mitochondrial function.

Electron Microscopy and the Structure of Mitochondria

Pioneering work of Palade, Sjostrand and others in the 1950s led to the first high-quality electron microscopic images of mitochondria. Controversies ensued, partly due to the inherent difficulty of interpreting images of plastic sections that were too thin (80 nm) to convey three-dimensional (3-D) structure. Conversely, this section thickness imposed a lower limit on resolution in the axial direction (parallel to the electron beam) in these images. Thus, despite the general acceptance of a model by the early 1960s (Figure 1), work on determining the structure of mitochondria has been a work in progress. An important advance was the development of electron tomography in the 1990s, in which numerous micrographs of a serially tilted specimen are combined to yield a 3-D image. Using high-voltage electron microscopes, this technique has provided actual 3-D images of mitochondria in thick sections (200–1000 nm) with axial resolution on the order of 5 nm (Figure 2). Moreover, with computer-controlled cryo-electron microscopes, it is possible to image intact, frozen-hydrated mitochondria, rapidly frozen in aqueous buffer, without the chemical fixatives or metal stains employed with plastic sections (Figure 3).

Mitochondrial Membranes and Compartments

The mitochondrion is formed by two nested membranes, which define three classes of compartments.

Outer Membrane

The mitochondrial outer membrane is the interface between the organelle and the cytosol. It excludes proteins and other macromolecules, but is thought to be permeable to most solutes below a molecular weight of ~2000 since it carries many copies of a pore-forming protein called VDAC (voltage-dependent, anion selective channel) or mitochondrial porin.

Inner Membrane

The inner membrane is the site of the respiratory chain, the ATP synthase, and numerous carrier proteins such as ANT, the adenine nucleotide transporter that exchanges ADP and ATP.

Intermembrane Space

The space between the outer and inner membranes is called the intermembrane (or peripheral) space. Its protein content, which is much lower than that of the matrix, includes kinases (for interconversion of phosphorylated metabolites) and cytochrome *c* (involved in both electron transfer and apoptosis).

Matrix Space

The space enclosed by the inner membrane is occupied by a very dense, largely protein matrix. This compartment contains a variety of enzymes, particularly those of the Krebs cycle, along with several copies of the circular mitochondrial genome and numerous mitochondrial ribosomes. (Mitochondria synthesize a small number of respiratory chain proteins; 90% of the mitochondrial protein mass is imported from the cytosol.)

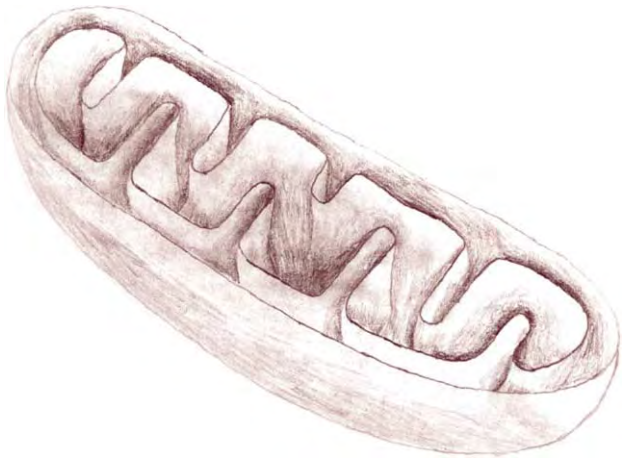

FIGURE 1 The conventional model for mitochondrial structure From Philomena Sculco, Wadsworth Center.

Cristae

The inner membrane has a much larger surface area than the outer membrane, typically by a factor of 2.5–10. There is a correlation between the energy demand in a particular tissue and the inner membrane surface, e.g., heart mitochondria have more inner membrane (and so more ATP generating capacity) than liver mitochondria. The inner membrane is contained by the smaller outer membrane because it is invaginated or involuted. The internal compartments defined by the infoldings of the inner membrane are called cristae and the space they enclose is the intracristal space. The intracristal space connects to the intermembrane space through the openings of the cristae in the peripheral region of the inner membrane.

Mitochondrial Inner Membrane Topology

The early model of mitochondrial structure portrayed the cristae as baffle-like folds in the inner membrane (Figure 1). Three-dimensional images provided by electron tomography of a wide variety of mitochondria, isolated and *in situ*, indicate a different internal architecture. The inner membrane comprises numerous pleiomorphic compartments, which are connected to each other and to the periphery of the inner membrane by narrow (20–30 nm diameter) tubular segments (Figure 2). These tubular connecting regions (called cristae junctions) can vary in length from a few tens to several hundred nanometers.

Functional Implications of the Cristae Junctions

The fact that cristae open into the intermembrane space through narrow, sometimes very long tubular segments suggests that diffusion of solutes between the internal compartments of mitochondria might be restricted. This was not a concern with the early structural model, which depicted the baffle-like cristae with wide, slot-shaped

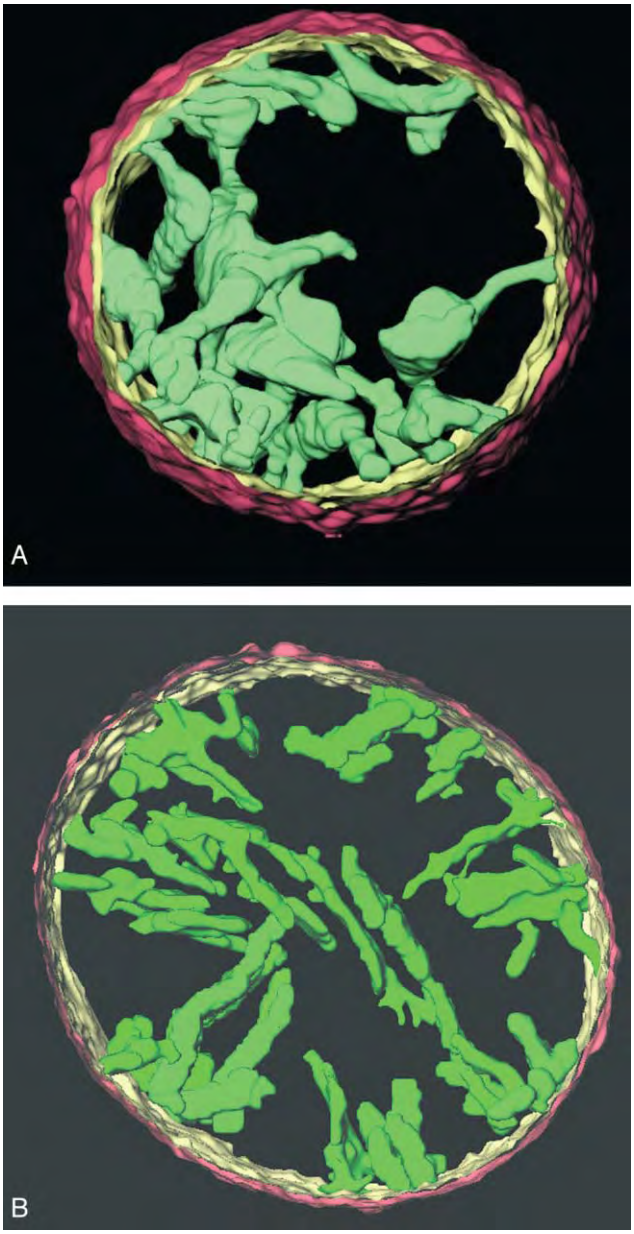

FIGURE 2 Tomographic reconstruction of membranes in isolated rat liver mitochondria in (A) condensed and (B) orthodox conformations. Mitochondria were chemically fixed, plastic-embedded and stained by conventional procedures. Approximate dimensions: (A) 1500 nm diameter, 500 nm thick, and (B) 500 nm diameter, 200 nm thick. (A) Adapted with permission from Mannella *et al.* (2001), Figure 1a.

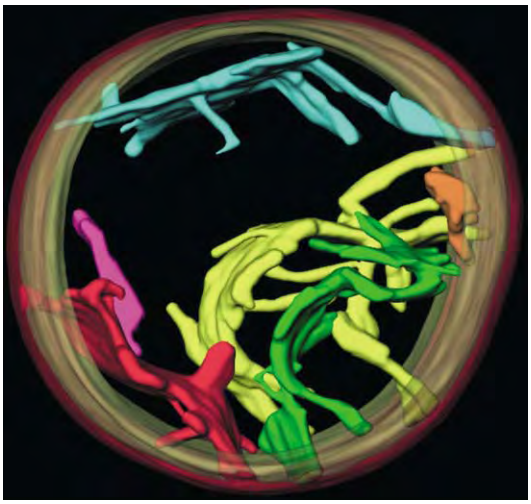

FIGURE 3 Tomographic reconstruction of membranes in an intact, frozen-hydrated rat liver mitochondrion, prepared with no chemical fixatives or stains. Approximate dimensions: 700 nm diameter, 450 nm thick. Adapted with permission from Mannella *et al.* (2001), Figure 4b.

openings into the intermembrane compartment. Computer simulations indicate that diffusion of ADP between the intermembrane and intracristal compartments via long, narrow tubes (the cristae junctions) can cause depletion of ADP in the intracristal space and locally diminished ADP phosphorylation. Thus, the topology of the mitochondrial inner membrane may directly influence the efficiency of ATP generation by the organelle.

Cristae Junctions Form Spontaneously

Tubular cristae junctions appear to be a highly conserved feature of the mitochondrial inner membrane. If they are functionally important (as implied above), it is expected that their formation would be spontaneous or energetically favored. This has been demonstrated with yeast mitochondria. Tubular connections between cristae and the peripheral region of the inner membrane form spontaneously in membranes, which initially lack cristae due to extreme osmotic swelling of the mitochondria. (Osmotic effects on mitochondrial structure are discussed in detail below.)

Changes in Mitochondrial Inner Membrane Topology

Although the mitochondrial inner membrane has a high protein-to-lipid ratio and encases a dense protein matrix, it is very flexible. The morphology of this membrane in isolated mitochondria changes readily in response to osmotic and metabolic conditions.

Osmotic Adjustments in Inner Membrane Topology

Tedeschi and Harris showed in the 1950s that mitochondria behave as "perfect osmometers" over a range of osmotic conditions. The matrix volume adjusts to changes in osmotic conditions (external solute concentration) by expanding (water influx) or shrinking (water efflux). Isolated mitochondria with a shrunken matrix (caused by water efflux in response to hyper-osmotic external conditions) are said to be in the condensed conformational state (Figure 2A). Mitochondria with a more expanded matrix (exposed to iso-osmotic or slightly hypo-osmotic conditions) are said to be in the orthodox (cell-like) state (Figure 2B). Exposure of mitochondria to very hypo-osmotic media causes extreme matrix swelling, and can lead to rupture of the outer membrane. (The latter is considered osmotically inactive due to its permeability to small solutes.)

Changes in Inner Membrane Topology Associated with Metabolic State

In the 1960s, Hackenbrock demonstrated that isolated mitochondria could reversibly switch between orthodox and condensed conformations during respiration. When ADP is added, respiring mitochondria change from orthodox to condensed conformation, then back to orthodox as ADP runs out. Condensed mitochondria tend to have larger internal compartments with longer cristae junctions, which can limit ADP diffusion into the cristae (above). Thus, the switch to orthodox conformation (smaller internal compartments, shorter tubular junctions) as ADP levels drop may prevent intracristal depletion of ADP and so maintain more efficient ATP production. Note that cellular ADP levels are normally low and mitochondria are usually in the orthodox conformation.

Inner Membrane Fusion and Fission

Comparison of 3-D images of condensed and orthodox mitochondria suggest an important role for membrane fusion and fission in regulation of inner membrane topology. Condensed mitochondria have large cristae with multiple tubular connections (cristae junctions) to the periphery of the inner membrane (Figure 2A). Conversely, orthodox mitochondria have predominantly narrower cristae with single peripheral connections (Figure 2B). Interconversion of these two membrane topologies cannot be achieved by simple unfolding and refolding of the inner membrane.

The topologies can be reconciled by postulating that large cristae with multiple tubular segments form by fusion of individual narrower cristae which make contact during matrix contraction. Likewise, matrix expansion and associated stress on the inner membrane may trigger fissioning of larger cristae into individual tubular membranes. Support for this mechanism is provided by tomographic images of frozen-hydrated mitochondria, in which large cristae clearly appear to be composed of fused tubular membranes (Figure 3). Dynamin-like proteins such as Mgm-1 and Drp-1 are involved in fusion and fission of mitochondria during organelle biogenesis and transport. These or other related proteins may regulate inner membrane fusion and fission during conformational changes as well.

Unusual Inner Membrane Topologies

While cristae in mitochondria from many animal, plant, and fungal cells have a more or less common appearance, there are numerous exceptions. For example, mitochondria in steroidogenic tissues like adrenal glands have cristae that are arranged in parallel tubular arrays. Densely packed cristae in some muscle mitochondria are arranged concentrically. Other specialized tissues (in gastropods and insects, for example) have cristae with triangular or square cross-sections. Several examples of unusual inner membrane topologies appear to be associated (at least in part) with abnormal inner membrane fusion or fission.

Cubic Paracrystalline Inner Membrane

Mitochondria in protists tend to have randomly arranged tubular cristae. In the amoeba, chaos carolinensis, fasting induces a dramatic change in inner membrane topology to an interconnected labyrinth of internal compartments with threefold (cubic) paracrystalline order. Deng and co-workers have shown that this structural transition is associated with several metabolic changes in the organism, including increased free radical production (oxidative stress). Conversion of the normally tubular inner membranes to a continuous membrane network implies induction of large-scale fusion. The highly symmetric shape of the membranes further implies that a change in membrane composition has occurred that imposes constant curvature everywhere.

Vesicular Cristae

Cristae that do not connect with the peripheral region of the inner membrane have been observed in several types of mitochondria, including muscle mitochondria from patients with a rare disorder called Senger's syndrome. This appears to be a case in which either the cristae junctions are unstable or inner membrane fission has become dominant over fusion. The specific genetic defect is unknown in Senger's syndrome, but research carried out by Huizing and co-workers suggests a tentative association with decreased ANT content.

Cytochrome *c* Release During Apoptosis

The process of apoptosis, or programmed cell death, in many cell types requires release of mitochondrial factors, including cytochrome *c*, to activate caspases involved in cellular degradative reactions. This process of mitochondrial protein release involves members of the Bcl-2 family of proteins. A key event is migration of Bax from cytosol to the mitochondrial surface, where it oligomerizes and causes protein release across the outer membrane. The trigger for this event is the truncated form of the protein Bid (tBid). Scorrano, Korsmeyer and co-workers have recently shown that tBid alone induces a dramatic change in topology of the mitochondrial inner membrane that correlates with increased accessibility of cytochrome *c* to the intermembrane space. After tBid exposure, the cristae have reversed curvature and appear to be fused into a continuum, not unlike the paracrystalline inner membrane of the fasting amoeba. Importantly, the openings of the cristae into the peripheral region of the inner membrane are considerably wider (55 nm versus 20 nm), which may account for improved diffusion of soluble proteins between compartments.

Biography

Carmen A. Mannella is a research scientist and Director of the Division of Molecular Medicine at the Wadsworth Center, New York State Department of Health in Albany, NY. His main research interests are in mitochondrial membrane structure and permeability. He holds a Ph.D. from the University of Pennsylvania and received his postdoctoral training at Roswell Park Cancer Institute and St. Louis University. As co-director of the Wadsworth Center's Resource for the Visualization of Biological Complexity (a NIH NCRR biomedical technology resource center), he participates in the development of electron tomography and its application to a wide range of biological problems.

Mitochondrial Metabolite Transporter Family

Ferdinando Palmieri
University of Bari, Bari, Italy

Martin Klingenberg
University of Munich, Munich, Germany

The mitochondrial transporters are a family of nuclear-coded, membrane-embedded proteins that, with one exception, are found in the inner membranes of mitochondria and catalyze the translocation of solutes across the membrane. Since mitochondria and cytosol cooperate in a large number of metabolic cellular processes, a continuous and highly diversified flux of metabolites, nucleotides, and cofactors into and out of the mitochondria is needed. Functional studies in intact mitochondria have indicated the presence of more than 20 carrier systems for the transport of metabolites involved in the citric acid cycle, oxidative phosphorylation, fatty acid oxidation, gluconeogenesis, lipogenesis, transfer of reducing equivalents, urea synthesis, amino acid degradation, and other functions shared between cytosol and mitochondria. The central role of some mitochondrial carriers in cell metabolism is illustrated in this entry.

Purification

Eleven carrier proteins have been purified to homogeneity from mitochondria using a procedure that, with very few exceptions, involved chromatographic steps on hydroxyapatite and celite. Purification and subsequent reconstitution of pure protein into phospholipid vesicles (liposomes) was useful for identification, functional characterization, and some structural studies.

Structure

Early studies elucidated the primary structure of six purified and biochemically well-characterized mitochondrial-carrier proteins. These are the ADP/ATP carrier (AAC, in fact the first metabolite transporter to be sequenced), the uncoupling protein (UCP), and the carriers for phosphate (PiC), oxoglutarate (OGC), citrate (CIC), and carnitine/acylcarnitines (CAC) (Figure 1). Their primary structures were derived by sequencing the full-length peptide chain, or by molecular biological techniques initiated with partial amino acid sequence information. A unique feature of these six mitochondrial carriers is their tripartite sequence structure, i.e., they consist of three tandemly repeated homologous domains ~100 amino acids in length. Each domain contains two hydrophobic stretches, which are thought to span the membrane as α-helices. All carriers contain, in at least one of the repeats, the characteristic sequence motif P-h-D/E-X-h-K/R-X-R/K-(20–30 residues)-D/E-G-(4 residues)-a-K/R-G, where "h" represents a hydrophobic and "a" represents an aromatic residue. Therefore, they all belong to the same protein family.

A generally accepted two-dimensional model of mitochondrial carriers is illustrated in Figure 2 based on the sequence features described above and on the accessibility of carriers to impermeable reagents, proteolytic enzymes, and peptide-specific antibodies. According to this model, the typical mitochondrial carrier monomer has six helices traversing the membrane connected by hydrophilic loops with both the N and C termini on the cytosolic side of the inner mitochondrial membrane. The matrix loops of the AAC, CAC, and UCP have been proposed to protrude into the membrane between the transmembrane segments of the protein, based on observations that residues located in the hydrophilic matrix region of these carriers react with membrane-impermeable reagents applied from the cytosolic side. It should also be noted that the transmembrane segments IV of CIC and OGC have been shown to be in α-helical structure using spin labels on engineered single-Cys residues.

Most of the isolated carrier proteins are shown to be homodimers and this may apply to all members of the mitochondrial carrier family (MCF). The evidence is based on direct MW determination of isolated proteins, on chemical, and recombinant cross-linking. The role of the homodimers in the transport mechanism, involving,

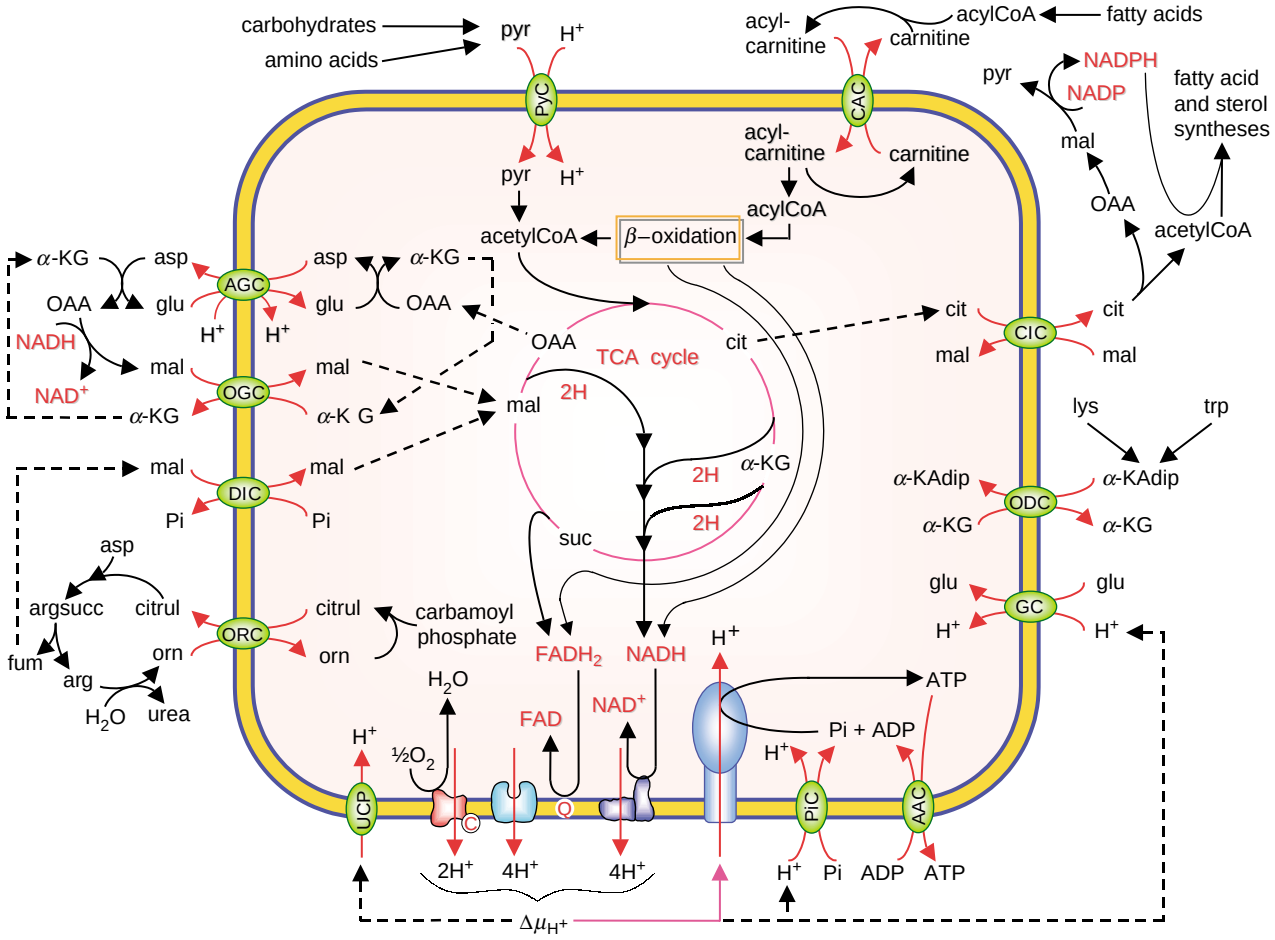

FIGURE 1 Metabolic roles of mitochondrial carriers. The scheme shows 12 carriers catalyzing metabolite transport through the inner mitochondrial membrane. These carriers are involved in oxidative phosphorylation (AAC, PiC, UCP), in oxidation/reduction pathways (AGC, OGC, DIC, CIC, CAC, PyC), and, with partial overlap, in amino acid metabolism (AGC, ORC, GC, ODC). The scheme does not include all of the carriers listed in Table I and does not show all the metabolic pathways in which individual carriers are involved (see Table I).

for example, a central channel or cooperative interactions between the monomers is still being elucidated.

Extension of the Mitochondrial Carrier Family

With the availability of DNA banks, the characteristic sequence features of the MCF were used to search for carriers of unknown function within the same family. Thus, a subfamily of UCPs (UCP 1–5) has been discovered with a wide variety of functions such as thermogenesis, oxygen radical suppression, regulation of fatty acid oxidation, immune response, and insulin secretion. The *Saccharomyces cerevisiae* genome contains 35 MCF members, and the human one presumably more. In this context, a breakthrough was achieved when the bovine OGC was overexpressed in *Escherichia coli*. The recombinant OGC, accumulated as inclusion bodies in the bacteria, was solubilized with sarkosyl and functionally reconstituted into liposomes. This was the first eukaryotic membrane protein to be produced in *E. coli* and recovered in active form. Using this strategy, i.e., gene expression and transport assays in the reconstituted system, the nucleotide and amino acid sequences of eight new mitochondrial carriers in *S. cerevisiae*, four in plants, and nine in man (including isoforms) have so far been identified (see Table I). The transporters identified first in yeast are the carriers for dicarboxylates (DIC), succinate/fumarate (SFC), ornithine (ORC), oxaloacetate/sulfate (OAC), oxodicarboxylates (OAC), thiamine pyrophosphate (TPC), and adenine nucleotides (ANT). The main function of DIC in yeast is to import succinate (produced by the glyoxylate cycle in the cytosol) or other dicarboxylates into mitochondria, whereas SFC directs the carbon skeleton of succinate to gluconeogenesis. The yeast OAC

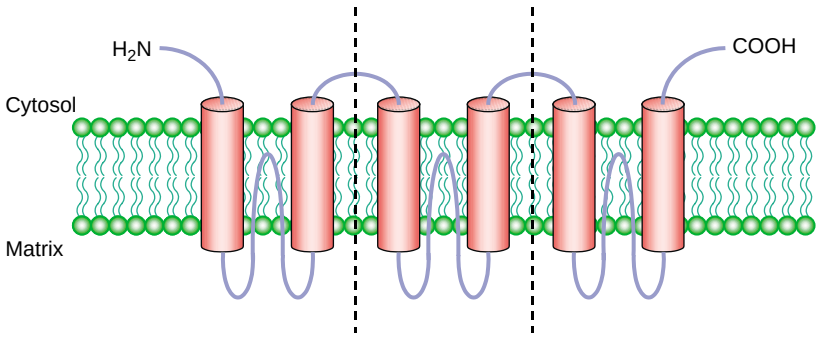

FIGURE 2 Suggested folding pattern of the mitochondrial solute carriers. Six helices traverse the inner mitochondrial membrane with the C and N termini facing the cytosol. The whole sequence is divided into three similar domains each with two transmembrane helices. Within each domain the two helices are connected by a long hydrophilic matrix loop (A, B, C respectively) which is assumed to protrude into the membrane space.

has also an anaplerotic role, as the *S. cerevisiae* pyruvate carboxylase is cytoplasmic. The main function of ORC in yeast is to export ornithine in exchange for H^+ to the cytosol, where it is converted into arginine and polyamines. The yeast ODC transports oxoadipate in exchange for oxoglutarate or malate from the mitochondria to the cytosol where it is converted into Lys. The essential cofactor thiamine pyrophosphate, produced in the cytosol, is transported into mitochondria by TPC. The peroxisomal ANT transports ATP, ADP, and AMP and its function is to transport cytosolic ATP into the peroxisomal lumen in exchange for AMP generated in the activation of fatty acids (in yeast fatty acid β-oxidation occurs in the peroxisomes). It differs from the mitochondrial AAC because it transports AMP and is unaffected by the AAC inhibitors CATR and BK. ANT is the first member of the MCF found to be located in a nonmitochondrial membrane, and it is the first peroxisomal protein proven to perform a transport function.

Other carriers were identified first in man. Among them, the human DNC transports dNDPs and dNTPs (in exchange for ADP or, more likely, ATP and pyrophosphate) into mitochondria for mDNA synthesis. Interestingly, DNC can transport dideoxynucleotides efficiently, which explains the toxic side effects of nucleoside analogues in the treatment of viral illnesses including AIDS. Other examples are the aspartate/glutamate carrier (AGC), which had previously been purified but not sequenced, and the glutamate/H^+ carrier (Table I).

Driving Forces for Transport

The majority of mitochondrial carriers catalyze strict solute exchange reactions. Those mediating H^+-compensated unidirectional substrate flux may also fall into the above category, because at least PiC has been shown to function in a phosphate/OH^- antiport mode. CAC has an unusual dual function mediating both unidirectional transport of carnitine and carnitine/acylcarnitine exchange, whereas UCP catalyzes uniport as exclusive transport mode.

Mitochondrial carriers can be divided into electrogenic (or electrophoretic) and electroneutral transporters. So far, three well-characterized carriers have been shown to be electrophoretic. AAC and AGC catalyze exchanges that result in a charge imbalance because they transport ADP^{3-} for ATP^{4-} and $aspartate^-$ for $glutamate^- + H^+$, respectively, across the mitochondrial membrane. The third, UCP, catalyzes the unidirectional transport of H^+. Electroneutral balance can be achieved by cotransport (symport) of solutes, countertransport of solutes, and uniport of electroneutral metabolites. The carriers for Pi, glutamate, pyruvate, and in yeast for oxaloacetate/sulfate facilitate the transport of anions together with an equivalent amount of H^+ (anion/H^+ symport) or in exchange for OH^- (anion/OH^- antiport). Other carriers catalyze an exchange of anions or cations. OGC, for example, transports $oxoglutarate^{2-}$ for $malate^{2-}$ and ORC ornithine for lysine, arginine, or H^+. In some cases electroneutrality is imposed by simultaneous carrier-mediated H^+ movement. CIC, for example, transports H-$citrate^{2-}$ against $malate^{2-}$ and the human ORC can transport $ornithine^+$ against citrulline and H^+.

The mitochondrial carriers utilize, as their driving force, the concentration gradient of the solutes and/or the H^+ electrochemical potential generated across the inner mitochondrial membrane by the functioning of the respiratory chain. Since the electrical component of $\Delta\mu H^+$ is rather high, the electrical nature of AAC and AGC provides a powerful means of ejecting ATP and aspartate against the concentration gradient from the mitochondrial matrix to the cytosol. In cases of H^+ symport or H^+ exchange, the transmembrane pH gradient regulates the distribution of anionic and

cationic solutes across the membrane. For example, with a higher pH inside, the carrier-mediated H^+-compensated uptake of Pi or glutamate is stimulated, as well as the efflux of cationic solutes such as the export of ornithine.

Functional Models for Mitochondrial Exchange Carriers

Two models of transport have been proposed for mitochondrial exchange carriers. According to the "single site gated pore" mechanism, suggested for the AAC, the transporter has only one binding site which is exposed alternately to the two different sides of the membrane (Figure 3A). On binding the substrate to one side, the carrier–substrate complex undergoes a conformational change and the binding site becomes exposed to the opposite side. The transported substrate now has to leave the transport site before another substrate to be transported in the opposite direction is bound. In the alternative hypothesis, the "double site gated pore" mechanism, two binding sites are exposed on the opposite sides of the membrane at the same time and both have to be occupied by the exchanging substrates before the conformational change and the substrate translocation occurs (Figure 3B). For AAC, the reorientation of the binding is well documented at carrier protein level since high-affinity inhibitor ligands exist which bind to the carrier either on the cytosolic side (atractyloside, ATR) or on the matrix side (bongkrekate, BK). These ligands remove ADP or ATP and their binding is mutually exclusive, indicating a single reorienting binding site.

The second possibility is supported by kinetic analysis of several carriers. Two-reactant initial-velocity studies varying both the internal and external substrate concentrations have conclusively shown that the reconstituted AGC, OGC, CIC, DIC, PiC, ORC, and possibly AAC function according to a simultaneous (sequential) mechanism, implying that one internal and one external substrate molecule form a ternary complex with the

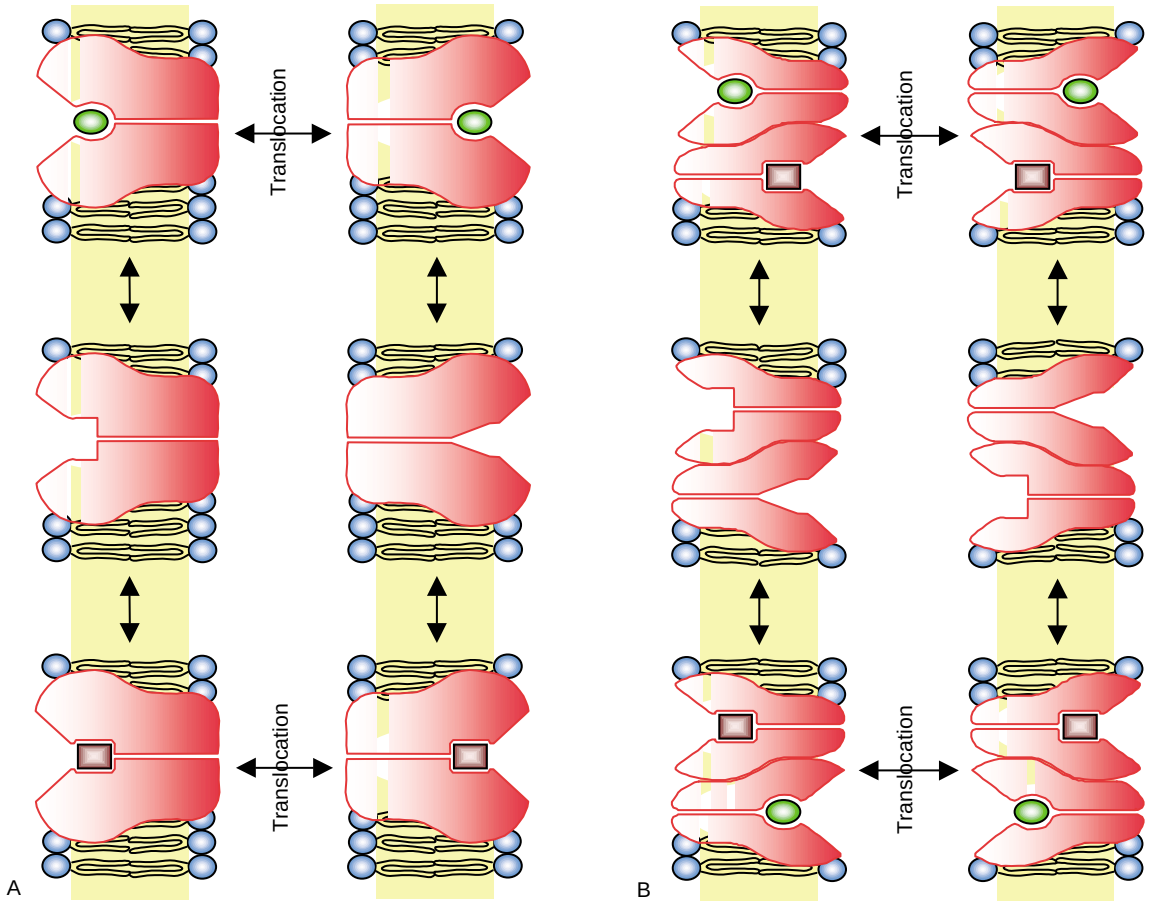

FIGURE 3 Functional models for mitochondrial exchange carriers. (A) The single site gated pore model of translocation corresponding to a ping-pong kinetic mechanism of exchange. The transport pathway is assumed to be formed between the two monomers. (B) The double site gated pore model of translocation corresponding to a simultaneous kinetic mechanism of exchange. Two separate and coordinated substrate translocation pathways are assumed, one in each monomer.

carrier before transport occurs, in agreement with the "double site gated pore" mechanism. The CAC differs from the other mitochondrial carriers analyzed so far, since it follows a ping-pong mechanism indicating only binary carrier–substrate complexes according to the existence of a single binding site. As CAC mediates uniport besides exchange of substrates, it is likely that the activation energy barrier for the reorientation of the unloaded carrier form is much lower for the CAC than for exchange carriers. As the uniport function is essential in a transport system like the carnitine carrier, the common sequential mechanism has apparently been changed into a ping-pong type of mechanism.

Channel-Like Properties

Unidirectional, partially unspecific transport can be induced in exchange-type carriers by various influences. A general effect is the induction of uniport by mercurials in various exchange carriers. In this state the transport can approach open channel-like characteristics. For AAC a slow specific uniport can be induced by phosphate and Mg^{2+} which prestages a wide unspecific channel induced by Ca^{2+}. This "megachannel" plays a central role in mitochondrial pore transition (MPT). The specific AAC ligands ADP and BK inhibit, while ATR sustains, MPT. The pore can also be induced by pro-oxidants at low Ca^{2+} and seems to be a major target of oxygen radical damage. Very important is the formation of this pore and thus of AAC as an early trigger of apoptosis by inducing the release of cytochrome *c*.

The appearance of channel-like functions reveals an intrinsic property of the MCF, i.e., the presence of an unspecific channel within the carrier protein which is normally hidden by appropriate gates. This model, which can in principle be reconciled with a gated pore mechanism, has of course to be substantiated by further studies leading to a molecular description of the putative channel pathway.

Structure and Function Studies: The Use of Mutant Proteins

Recombinant expression of the mitochondrial carriers in yeast and in *E. coli* enabled site-directed mutagenesis for structure–function studies. The mutation of Cys to Ser, one at a time or all together, evidenced the absence of essential cysteines in several carriers, although transport could be inhibited by SH reagents. Thus, the cysteine reagents may cause sterical hindrance or conformational changes. Inversely, by systematically substituting single amino acids with Cys, essential residues could be identified, e.g., G183, R190, and Q198 in transmembrane segment IV (TMSIV) of OGC, and R181 and R189 in TMSIV of CIC.

In AAC, three types of charged residues have been probed by mutagenic charge neutralization: positively charged residues located within TMSs (K38A, R96A, R204L, and R294A) and within the matrix loops (K48A, R152A, K179I, K182I, R252I, R253I, and R254I); and negatively charged residues at the end of TMSI, TMSIII, and TMSV (E45G, D149S, D249S). By comparing the *in vivo* (yeast aerobic growth) and *in vitro* effects (reconstituted transport), these residues could be assigned to transport or structure maintenance to varying degrees. Using a regain-of-function approach in yeast, in second site mutations negatively charged residues were affected, which evidenced ion-pair interactions R294-E45, K38-E45, R152-E45, R152-D149, and D149-R252 and indicated an arrangement where TMSI and TMSVI are in vicinal and skewed position.

Using the *E. coli* expression system, R90 and R98 in TMSII, R190 in TMSIV, and R288 in TMSVI of OGC, mutated into Leu, and R181 and R189 in TMSIV of CIC, mutated into Cys, were found to be essential for activity. A positive charge either from Arg or from Lys sufficed for transport activity at all positions, except at positions 98 and 190 of OGC where the guanidinium moiety of Arg was indispensable. Furthermore, by a combination of Cys-scanning mutagenesis, spin-labeling, and chemical modification studies, a water-accessible face of helix IV in both CIC and OGC has been identified and suggested to line part of the substrate translocation pathways through these proteins.

In PiC H32 in TMSI, E126 and E137 in TMSIII, and D39 and D236 at the matrix ends of the first and fifth TMS were found to be indispensable for normal growth in yeast and transport function. The six charged residues (H32, E126, and E137 of both subunits) are proposed to form the proton cotransport channel within the homodimer. An inhibitory disulfide formation under oxidizing conditions between the two Cys-28 residues (also located in the TMSI) of two PiC molecules is in agreement with this model.

A direct involvement of charged residues in proton transport pathway through UCP1 has been demonstrated. D27 within TMSI and the H145/H147 unit within loop B are thought to function as proton donor/acceptors, respectively, in the channel and the matrix-side entrance of the H^+ transport pathway. Further mutagenesis studies carried out on charged residues positioned in TMSII (R83 and E129), TMSIV (R182), TMSVI (R276), and in the TMSV at the cytosolic interface (H214) suggested that the three arginines are part of the purine-nucleotide-binding site and H214 and E190 act as pH sensors for the control of access of the phosphate moiety of the nucleotide to its binding cleft. Deletion of F267-K268-G269 in the

matrix loop C, as well as analogous deletions in loops A and B, caused loss of nucleotide regulation, suggesting a gating function of the three hydrophilic matrix loops in the regulation of UCP by purine nucleotides.

Diseases

At least four autosomal-recessive diseases are caused by defects in a specific mitochondrial carrier gene. Mutations in the human gene SLC25A20 coding the carnitine carrier are responsible for the Stanley syndrome (MIM 212138). The fatty acid β-oxidation and carnitine carrier activity are very low or absent in patients' fibroblasts. The disease generally presents with acute, potentially life-threatening episodes of hypoglycemic coma induced by fasting. Defects in the gene SLC25A13 coding isoform 2 of the aspartate/glutamate carrier (the only isoform present in liver) cause type II citrullinemia (MIM 215700). The lack of AGC2-mediated aspartate supply to the cytosol of liver cells causes: (1) deficiency of arginosuccinate synthetase, an enzyme of the urea cycle and (2) deficiency of the malate/aspartate shuttle leading to an increased NADH/NAD ratio in the cytosol that inhibits glycolysis and gluconeogenesis from reduced substrates.

The hyperornithine-hyperammone-homocitrullinemia (HHH) syndrome (MIM 23970) is caused by alterations of the ornithine carrier (isoform 1, gene SLC25A15) that catalyzes the exchange between cytosolic ornithine and mitochondrial citrulline, an important step in the urea cycle. The main features are homocitrullinuria, hyperammonemia, and consequent symptoms. Amish microcephaly (MIM 607196) is associated with mutant deoxynucleotide carrier (gene SLC25A19) and is characterized by severe congenital microcephaly and premature death. Although the molecular defect(s) responsible for 2-oxoadipate acidemia have not yet been characterized, this disease has been suggested to be due to defective oxodicarboxylate carrier or oxoadipate dehydrogenase (the two enzymes that transport into mitochondria and oxidize 2-oxoadipate, respectively). Finally, one of the three distinct loci involved in autosomal-dominant progressive external ophthalmoplegia (adPEO) (MIM 103220) includes the heart and skeletal muscle specific isoform of the ADP/ATP carrier (gene SLC25A4).

Martin Klingenberg is Professor Emeritus at the University of Munich. His principal interest in recent years has been in the field of characterizing the mechanism of mitochondrial carriers.

Mitochondrial Outer Membrane and the VDAC Channel

Marco Colombini
University of Maryland, College Park, Maryland, USA

Mitochondria are organelles found in virtually all eukaryotic cells. They are composed of two membranes. The inner membrane is highly convoluted and of quite variable morphology. The outer membrane forms the boundary between the mitochondrial spaces and the cytosol. It contains membrane channels, called VDAC, that allow metabolites to cross this membrane while restricting the passage of proteins.

Origin and Structure of the Outer Membrane

Mitochondria have most likely evolved from endosymbiotic bacteria. The outer membrane may have originated as an endosomal membrane that engulfed the original endosymbiotic bacterium or may be related to the bacterial outer membrane. Whatever its origin, structurally it is a relatively simple limiting membrane forming a continuous boundary (Figure 1). It seems to limit the boundary of the mitochondrial space and, unlike the inner membrane, maintains a fairly constant total mitochondrial volume.

Further aspects of mitochondrial structure and function vary depending on the source and thus most of what will be presented applies to mammalian sources.

The outer membrane interacts intimately with neighboring membranes. Rivet-like connections between the outer and inner membranes often exist and are referred to as contact sites. These are mechanically sturdy as they interfere with the experimental separation of the outer and inner membranes. These contacts are proposed to serve a number of functions including the formation of macromolecular complexes between transporters and enzymes to expedite metabolic flow. The outer membrane also interacts closely with the endoplasmic reticulum and this close apposition may be the reason for preferential transfer of Ca^{2+} from the endoplasmic reticulum to the mitochondrial matrix compartment. This has been especially well studied in the heart where changes in Ca^{2+} level on a beat-by-beat basis alter dehydrogenase activity matching cellular energy consumption. If specialized docking structures are involved in this interaction with the endoplasmic reticulum, they must be more labile than the contact sites because isolation of mitochondria from endoplasmic reticulum is quite easy.

Functions of the Outer Membrane

The outer membrane of isolated mitochondria is highly permeable to metabolites due to the presence in this membrane of large aqueous channels formed by the protein called voltage-dependent anion-selective channel (VDAC). Their similarity to channel-forming proteins in bacterial outer membranes collectively referred to as porins has led some to refer to VDAC as mitochondrial porin. Although the permeability characteristics conferred to the outer membrane by VDAC are rather complex, physical size is a major factor. Thus, under normal conditions the outer membrane is essentially impermeable to molecules larger than 5 kDa. This allows proteins to be sequestered in the intermembrane space, the compartment between the outer and inner membranes. This sequestration serves at least two functions. First, it localizes proteins that could diffuse away to the site where they are needed. For example, the soluble protein, cytochrome *c*, is a member of the electron transport chain and must transmit electrons between complex III and IV so that respiration may proceed. Second, the sequestration prevents pro-apoptotic proteins from being released into the cytosol as this would initiate programmed cell death (apoptosis). Cytochrome *c* is also an example of a sequestered proapoptotic protein. The permeability barrier to pro-apoptotic proteins and others of similar size is lifted under some conditions that lead to cellular apoptosis.

The permeability of the outer membrane to small molecules can be regulated resulting in the outer membrane limiting metabolite flux and consequently the level of metabolic activity. This regulation is probably critical to changes in cell function.

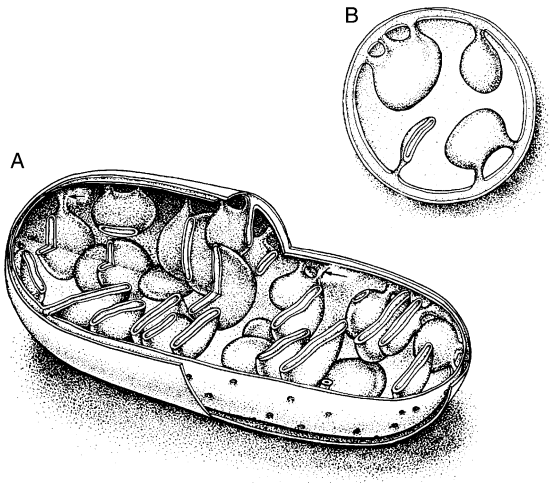

FIGURE 1 A drawing of the membranes and compartments of a typical small mitochondrion. (A) shows the mitochondrion with portions of the membranes cut out so as to reveal inner structure and compartmentation. (B) Illustrates a cross-section. Reproduced from Lea, P. J., and Hollenberg, M. J. (1989). Mitochondrial structure revealed by high-resolution scanning electron microscopy. *The American Journal of Anatomy* **184**, 245–257. Drawings made by Karen Visser. With permission of Wiley-Liss, Inc., a Subsidary of John Wiley & Sons, Inc.

Most mitochondrial proteins and RNA molecules are synthesized in the cytosol and imported into mitochondria. The Tom complex is responsible for much of the protein import through the outer membrane. Leader sequences on the proteins are recognized by Tom and the protein is treaded through a pore in the complex and delivered to the intermembrane space where it is picked up by the Tim complex in the inner membrane for translocation through that membrane. The processing of outer membrane proteins by this complex is less clear.

Mitochondria are usually found in the portion of cells where they are needed. For example, to minimize diffusion limitations they are located close to sites of high-energy dissipation. Sometimes they need to be delivered to distal sites in a cell (e.g., from cell body to nerve terminal of a neuron or to the reproductive bud of a yeast cell). Motors located either on microtubules or actin filaments move mitochondria from one location in the cell to another. The outer membrane must provide sites of attachment for the motors that perform the translocation.

Composition

The composition of the outer membrane varies somewhat depending not only on the species but also the tissue from which it was isolated. With that caveat, it can be said that there are a number of similarities between the constituents of the outer membrane and the endoplasmic reticulum. For example, the presence of cytochromes b and b_5, antimycin-insensitive NADH-cytochrome c reductase, and ceramide synthase. Yet there are also many differences and the enzymes present in the two locations are usually different isoforms. Thus, the similarity may reflect similar origins but certainly these two membranous compartments are distinct.

The outer membrane also contains enzymes involved in fatty acid and phospholipid metabolism and an amine oxidase. The liver mitochondria contain a peripheral benzodiazepine receptor whose role is unclear. The membrane can also bind some kinases that are typical soluble enzymes and the binding is thought to accelerate energy transduction.

The outer membrane has a higher lipid content than the inner membrane, one more typical of other cell membranes. The lipid composition is also drastically different from that of the inner membrane, the outer membrane being rich in sterol, while the inner has higher levels of cardiolipin.

VDAC Channels in the Outer Membrane

VDAC Structure

Mitochondria from all eukaryotic kingdoms contain VDAC channels in their outer membrane. These are formed by a single polypeptide of approximately 30 kDa and form a single large aqueous pore. In some plant and fungal mitochondria, VDAC channels form two-dimensional crystals (Figure 2), which upon further analysis reveal fundamentally cylindrical proteins forming water-filled transmembrane pathways. The wall of the channel is almost certainly a single layer of protein mainly consisting of a beta structure. Experimental evidence leads to the conclusion that the transmembrane portion consists of 1 α-helix and 13 β-strands. The surface domains (yellow regions in Figure 2) likely act as binding sites for a variety of proteins that bind or interact with the channel.

VDAC Function and Dynamics

The primary role of mitochondria is metabolism that is closely integrated with the metabolism occurring in the cytosol. This requires the continuous and rapid exchange of metabolites between these two major compartments. VDAC channels in the outer membrane can exist in conformational states that either favor or hinder metabolite flux. The state that favors metabolite flux, the open state, does so by having an electrostatic environment that favors anions. In addition, the charge distribution in the lining of the channel is

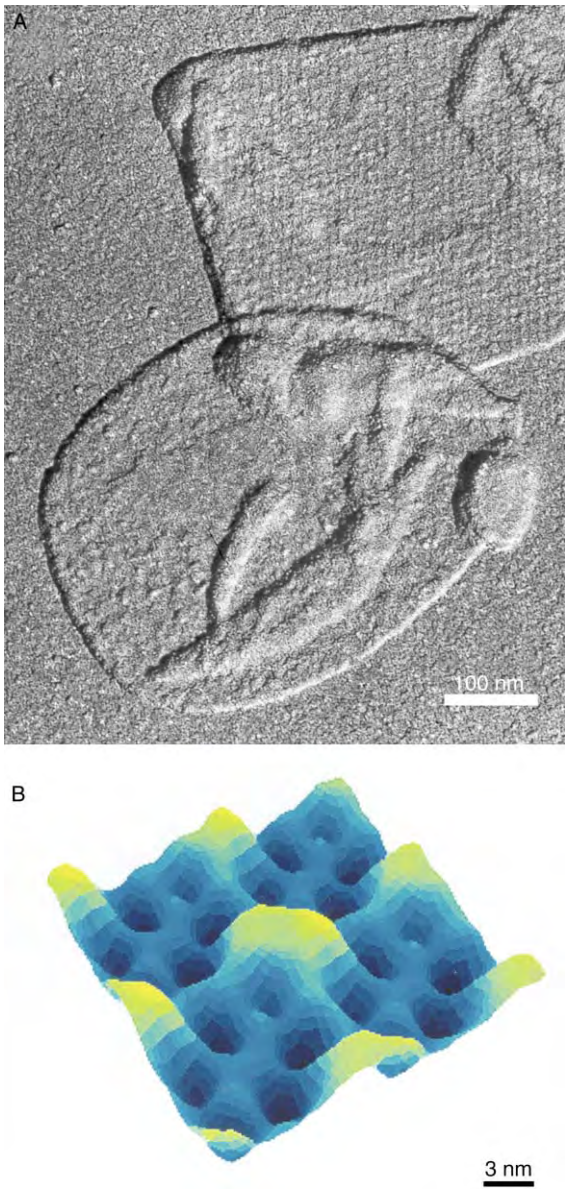

FIGURE 2 Views of mitochondrial outer membranes and the ubiquitous VDAC channels in these membranes. Panel (A) shows electron micrographs of freeze-dried mitochondrial outer membranes with two-dimensional crystals of VDAC channels (membrane with squared edges and ordered array of particles) and without such crystals (smooth membrane with rounded edges). Outer membrane vesicles isolated from mitochondria are dried down on a surface and they form collapsed sacs. Panel (B) shows a surface view of the VDAC channels obtained after computer filtration and averaging of multiple micrographs containing images of two-dimensional crystals. The yellow shows regions of elevation and the dark blue areas are the openings of the pores (holes) that are formed through the membrane. These allow the metabolites to cross the outer membrane. This figure was assembled from the work of Dr. Lorie Thomas. Adapted from Thomas, L., Kocsis, E., Colombini, M., Erbe, E., Trus, B.L., and Steven, A.C. (1991). Surface topography and molecular stoichiometry of the mitochondrial channel, VDAC, in crystalline arrays. *Journal of Structural Biology* **106**, 161–171.

such that it favors the translocation of ATP over that of anions of similar size and charge. In the closed states, the water-filled channel is somewhat narrower (the pore size decreases from 2.5 nm in the open state to 1.8 nm in the larger of the population of closed states) but, most importantly, the electrostatic nature is such that it hinders the flow of anions. A positively charged region lining the channel in the open state is translocated out of the channel resulting in a pathway with a net negative charge. This excludes ATP and drastically reduces the permeability of other anionic metabolites. At the same time this change favors the flux of cations.

This gating of VDAC is voltage dependent and thus the channels can respond to changes in the voltage across the outer membrane. An electrical potential across this membrane may arise from the presence of different charged macromolecules in the aqueous compartments (Donnan potential) and/or differential metabolite flux responding to metabolic rates. In addition, numerous factors influence this gating process including cytosolic NADH levels and specific proteins in the cytosol and intermembrane space. The importance of this regulation is indicated by its remarkable conservation of VDAC from all species tested (including all eukaryotic kingdoms). The diversity of influences on the gating of VDAC indicates that VDAC may integrate the influence of a variety of cellular factors and thus tune mitochondrial activity appropriately.

VDAC's ability to bind with cytosolic hexokinase and intermembrane space creatine kinase has been proposed to result in organized structures that increase the efficiency of energy transduction.

The Outer Membrane and Apoptosis

Apoptosis, programmed cell death, is a process by which a cell repackages itself to be ingested by other cells, generally macrophages. The outer membrane separates proteins that once combined initiate an amplification cascade leading to "full blown" apoptosis. The leakage of proteins from the intermembrane space into the cytosol is sufficient to cause apoptosis. Even injecting just one of these proteins, cytochrome c, into the cytosol is sufficient.

How the outer membrane becomes permeable to proteins is an area of intense investigation. The proteins that cross this membrane can be as large as 50–100 kDa. Proteins of the Bcl-2 family partition between the cytosol and the outer membrane. They can exist both as soluble proteins and intrinsic membrane proteins capable of generating ion channels.

Some of these are pro-apoptotic and others are anti-apoptotic. Some anti-apoptotic proteins are often associated with the outer membrane under normal conditions, i.e., cells functioning normally, and may favor normal mitochondrial function. Others translocate to the outer membrane at the early stages of apoptosis, perhaps forming the protein efflux pathways. The sphingolipid, ceramide, can also be produced in mitochondria early in the apoptotic process and has been shown to be able to form channels large enough for protein flux.

Under some conditions of apoptosis induction, exchange of nucleotides between mitochondria and the cytosol is greatly inhibited. The outer membrane becomes poorly permeable to ATP and ADP and other anionic metabolites. This phase precedes the release of intermembrane space proteins and in this phase cells can be rescued. This gives the outer membrane the role of deciding between life and death.

Emerging Importance of the Outer Membrane

Once considered relatively unimportant, the mitochondrial outer membrane is emerging as a site for control of overall mitochondrial function and a location where the fate of the entire cell is decided. Despite its deceptively simple appearance, this membrane performs a variety of vital functions. By hindsight, its location at the frontier between the cytosol and the mitochondrial spaces makes it an ideal site for control of the flux of matter and transduction of information.

Biography

Dr. Marco Colombini is a Professor in the Department of Biology at the University of Maryland in College Park. His research is in the area of membrane biophysics with specific focus on channels in the mitochondrial outer membrane. He was part of the group that originally discovered and named the outer membrane channel called VDAC. Research from his laboratory continues to yield new insights into the structure and molecular mechanisms of mitochondrial channels and their role in regulation of mitochondrial function.

Dr. Colombini holds a Ph.D. from McGill University and is an active member of the Biophysical Society.

Mitogen-Activated Protein Kinase Family

Hidemi Teramoto and J. Silvio Gutkind
National Institute of Dental and Craniofacial Research, Bethesda, Maryland, USA

Mitogen-activated protein kinases (MAPKs) are a group of protein kinases that play an essential role in signal transduction by modulating gene transcription in the nucleus in response to changes in the cellular environment. MAPKs also play a key role in intracellular communication, and their activating pathways have been conserved throughout evolution, from plants, fungi, nematodes, insects, to mammals. In humans, there are at least 11 members of the MAPK superfamily, which can be divided into 6 groups: the extracellular signal-regulated protein kinases (ERK1 and ERK2); c-Jun N-terminal kinases (JNK1, JNK2, JNK3); p38s (p38α, p38β, p38γ, p38δ); ERK5 (ERK5); ERK3s (ERK3, p97 MAPK, ERK4); and ERK7s (ERK7, ERK8). Each group of MAPKs can be stimulated by a separate signal transduction pathway in response to different extracellular stimuli. In turn, MAPKs exhibit distinct substrate specificities. Thus, individual extracellular stimuli can lead to the differential activation of each MAPK and the consequent phosphorylation of a distinct set of MAPK substrates. Whereas components of some of these biochemical routes are now well established, others are still poorly understood. The specificity of the molecular mechanisms by which each MAPK can be activated ensures that cells mount an appropriate response to extracellular stimulation, as the resulting pattern of gene expression will depend on the integration of the combinatorial signals provided by the temporal activation of each of these groups of MAPKs.

ERK Family

ERK1 and ERK2

The extracellular signal-regulated protein kinase (ERK) group of MAPK includes ERK1 and ERK2. In certain cells their activation contributes to normal and aberrant growth, including malignant transformation, while in other cells this pathway can promote cell survival or initiate differentiation processes in others. The enzymatic activity of ERK1 and ERK2 is enhanced by dual phosphorylation on Thr and Tyr residues within a short sequence that forms the "activation loop", located close to the kinase active site, by a group of dual-specificity protein kinases (MAPK kinases; MAPKKs), represented by MEK1 and MEK2. Each MAPK family exhibits a distinct phosphor–acceptor motif in their activation loop (Figure 1), which provides specificity for the MAPKK–MAPK interactions. This phosphorylation leads to conformational changes in ERKs, thereby promoting their activation and nuclear localization. Subsequently, ERK activity is terminated by dephosphorylation on either Thr or Tyr by a Ser/Thr or Tyr phosphatase. This dephosphorylation can be mediated also by a dual specificity MAPK phosphatase. Similarly, the mammalian MAPKK, such as MEK1 and MEK2, are activated by phosphorylation mediated by MAPK kinase kinases (MAPKKK), which includes the Ras effector, Raf. Thus, the Raf group of MAPKKK that includes A-Raf, B-Raf, and c-Raf-1, plays an important role in the coupling of ERK MAPK activation to the Ras signaling pathway (see Figure 2).

The discovery of the Ras-Raf-MEK-ERK signaling route represented a breakthrough in cancer biology, and emerged as the product of the conversion of a large number of research efforts in a variety of otherwise poorly connected fields. Indeed, a large body of information was derived from genetic analyses of model organisms including *Drosophila*, *Saccharomyces cerevisiae*, and *Caenorhabditis elegans*, in addition to biochemical and biological studies in mammalian cells. They, collectively, led to the identification of Ras as a key downstream component of the pathway initiated by polypeptide growth factor receptors, and to the realization that this small GTPase acts subsequently as a master switch initiating the activity of a cascade of cytoplasmic kinases that culminate with the activation of the ERK1 and ERK2. ERKs, in turn direct the activities of many nuclear transcription factors, thus regulating gene expression. These findings provided a better understanding of the molecular basis for the transduction of proliferative signals, as well as the first clue as to how the aberrant function of Ras proteins may contribute to the malignant conversion of cancer cells.

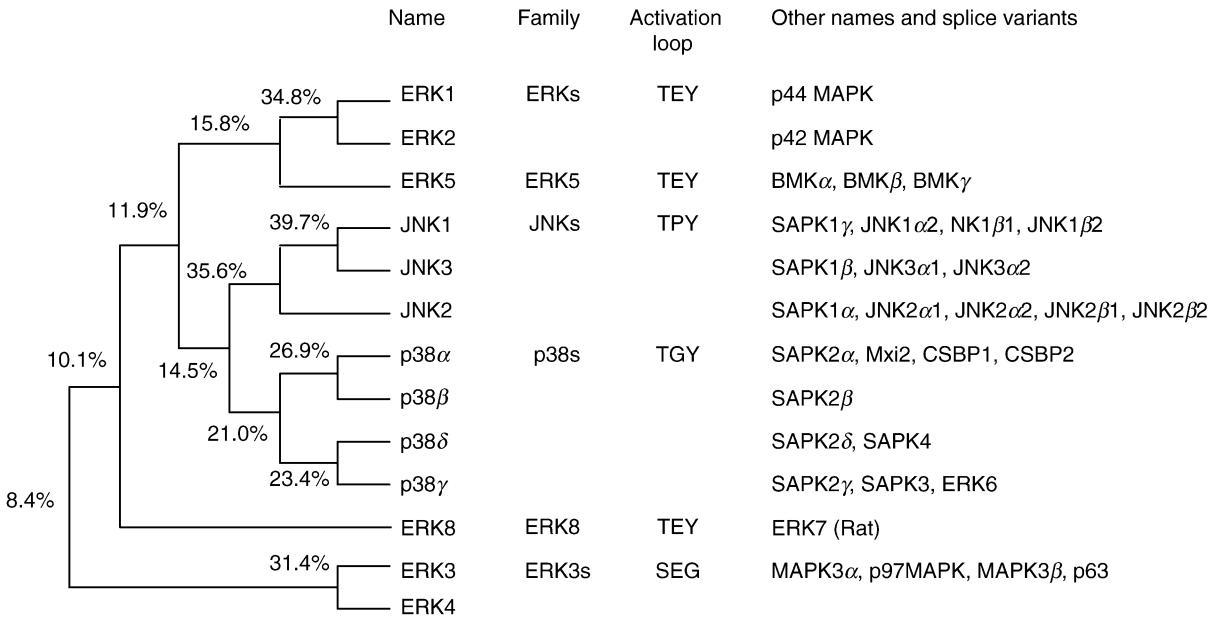

FIGURE 1 Phylogenetic tree of human MAPKs. A computer-generated phylogenetic tree of the MAPKs. The GenBank accession numbers are human ERK1 (X60188), human ERK2 (M84489), human ERK3 (S23429), human p97 (X80692), human ERK4 (P31152), human ERK5(U25278), human BMK (U29725), Rat ERK7 (AF078798), human ERK8 (AY065978), human JNK1 (U34822), human JNK2 (U34821), human JNK3 (U34820), human Mxi2 (U19775), CSBP1 (S52419), CSBP2 (S52420), human p38β (U53442), and human p38γ (U66243).

c-Jun N-Terminal Kinases (JNK1, JNK2, JNK3)

JNK was initially discovered by its ability to phosphorylate the N-terminal transactivating domain of the transcription factor c-Jun. As its activity was stimulated primarily by cellular stress rather than by mitogens, contrary to ERKs, it was also termed stress-activated protein kinase (SAPK). It is now known that there are three members of the JNK family, JNK1–3, and that they play numerous biological roles in response to a large variety of cell surface receptors as well as physical and chemical stresses. Whereas the JNK1 and JNK2 genes and their alternatively spliced variants are expressed ubiquitously, generating a total of eight JNK isoforms, the JNK3 gene has a more restricted expression pattern, being its two alternative spliced transcripts expressed the highest in brain and testis. Studies of mammalian cells demonstrated that JNK is required for neuroexcitatory stress-induced neuronal apoptosis, as well as for certain inflammatory responses and for the survival and malignant transformation of specific cell types (e.g., B cells).

Following the distinct pattern of activation of ERK and JNK by cellular receptors, an unexpected discovery was that whereas Ras regulates ERKs, two members of the Rho family of GTPases, Rac1 and Cdc42, initiate an independent kinase cascade regulating JNK activity. These findings provided direct evidence of a role for Rho GTPases in transcriptional regulation, thus expanding previous efforts addressing the function of these Rho related proteins, which were primarily focused on the molecular dissection of the mechanism(s) involved in their ability to control the dynamic assembly and remodeling of actin-containing cytostructures. Components of this pathway include several MAPKKKs: MEKK1, MEKK2, MEKK3, and MEKK4, apoptosis-stimulated kinase 1 (ASK1), mixed-lineage kinase 3 (MLK3), tumor progression locus 2, also known as Cot (TPL2), TGF-β-activated kinase (TAK), MAPK upstream kinase (MUK), germinal center kinase (GCK), and PAK, which can all contribute to activation of JNKs, apparently through two MAPKKs, MKK4 (also called Sek or JNKK1), and MKK7. Substrates for JNK include transcription factors of the c-Jun family, as well as other transcription factors, including Elk-1 and Elk-2, serum response factor accessory protein-1 (Sap-1), nuclear factor of activated T cells 4 (NFAT4), and activating transcription factor 2 (ATF2).

p38s (p38α, p38β, p38γ, p38δ)

The family of p38 kinases has expanded over the past few years, including now four members known as p38α (or CSBP-1), p38β, p38γ (also known as SAPK3 or ERK6) and p38δ (or SAPK4), and in some cases their corresponding splice variants. These MAPKs share a Thr-Gly-Tyr phosphorylation motif in their activation loop, and are

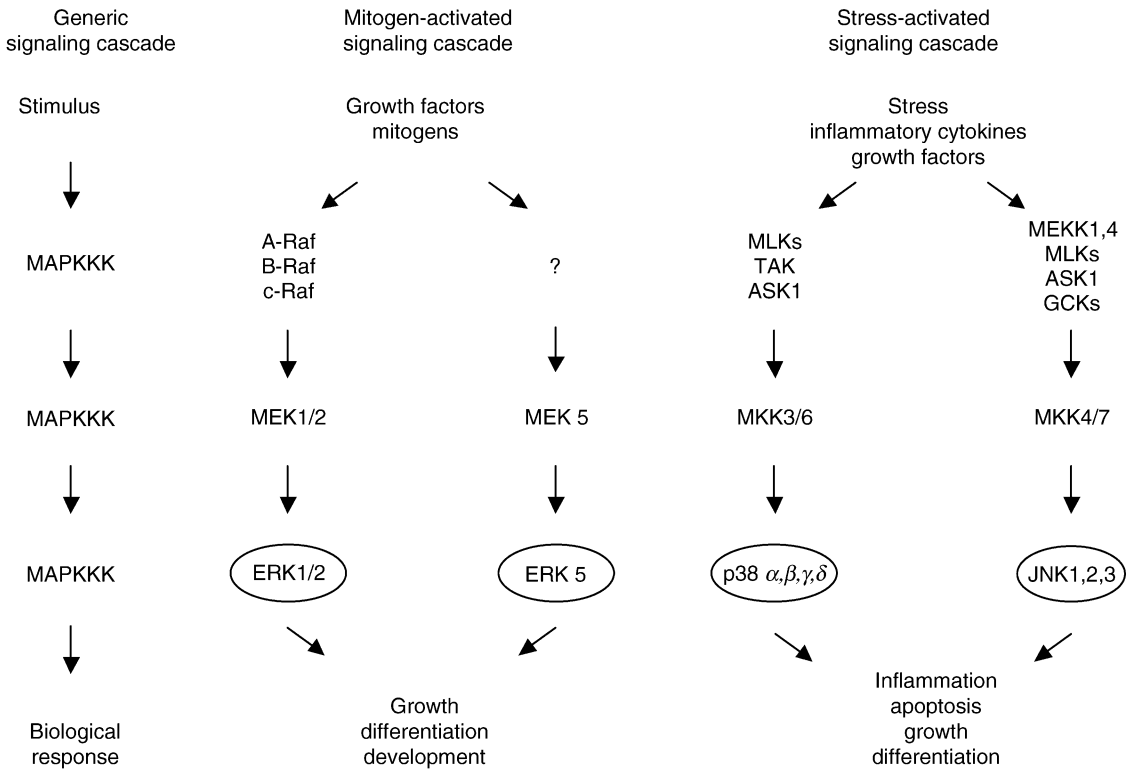

FIGURE 2 MAPK signaling cascades. Schematic representation of generic (left), mitogen activated (center), and stress activated (right) signaling cascades. Separate signal transduction pathways initiated by different extracellular stimuli activate each group of MAPKs that, in turn, exhibit distinct substrate specificities.

stimulated by receptors and environmental stresses similar to those provoking the activation of JNKs. These enzymes are particularly sensitive to their stimulation by exposure of cells to endotoxins, including bacterial lipopolysaccharides. Evidence of their role in transducing stress signals can be found as far philogenetically as in yeast, where genetic analysis indicates that the Hog1p MAPK, the yeast homologue of p38, is required for the response to osmotic stress that involves the enhanced expressions of genes participating in the biosynthetic pathway of the osmotic stabilizer glycerol.

As for the ERKs, p38s are activated by dual phosphorylation on Thr and Tyr residues by MKK3 and MKK6, the latter being a general stimulator for p38s, and the former exhibiting certain preference for p38α. The immediate upstream activators for these kinases are not yet well defined, and include the potential p38 MAPKKKs known as ASK1 and TAK1. The specific transcription factors that can be regulated by p38s include cAMP-responsive element-binding protein (CREB), activating transcription factor 1 (ATF1), ATF2, Max, C/EBP homologous protein (CHOP), and MEF2C. In addition, these MAPKs can also trigger the activation of other serine-threonine kinases such as Mnk1 (MAPK-interacting kinase 1) and Mnk2 and MAPKAPKs (MAPK-activated protein kinases).

ERK5

ERK5, also known as big mitogen-activated protein kinase (BMK1), is distantly related to ERK1 and ERK2. Although it contains a Thr-Glu-Tyr motif in its activation loop, similar to that of ERK1 and ERK2, ERK5 is larger than any other known MAPK ($\sim$80 kDa) and is selectively activated by MEK5 but not by MEK1 or MEK2. This kinase can be stimulated by oxidative stress, and can play a role in early gene expression triggered by EGF and serum by the direct phosphorylation of the transcription factors MEF2C or c-Myc, thereby participating in cell proliferation and progression through the cell cycle. Although information on this MAPK is still limited, evidence supporting its role in cell growth is also provided by its ability to cooperate with the activated Raf or MEK, which act on ERK1 and ERK2, to promote neoplastic transformation. The physiological function of ERK5 is nevertheless still unclear, and further studies are required to establish the biological role of this MAPK signaling pathway.

Others (ERK3, ERK4, ERK7, and ERK8)

Novel member of the MAPK family, ERK 7 (61 kDa) and ERK8 also contain a Thr-Glu-Tyr activation motif. ERK8 was cloned using the rat ERK7 cDNA to screen a human multiple tissue cDNA library and share an overall amino acid sequence identity of 69%. In contrast to rat ERK7, ERK8 does not display significant constitutive kinase activity, does not phosphorylate c-Fos, and is activated in response to stimulation by Src or serum. ERK3 contains a Ser-Glu-Gly activation motif, with gly in place of the tyr. The ERK3 subfamily of MAPKs is composed of two functional genes, MAPK6 (p97 MAPK) and MAPK4 (ERK4), and several pseudogenes. Upstream activators of ERK3 are still poorly defined, and this kinase is not present in yeast or *C. elegans*. None of the currently known MEK family members is able to phosphorylate and activate ERK3 and no physiological substrates of ERK3 have been found. ERK3 is localized constitutively to the nucleus without a conventional nuclear localization sequences.

Specificity and Fidelity in Nuclear Signal Transmission by MAPK Signaling Pathways

Protein kinases typically interact with their substrates by recognizing primary sequence determinants that surround the phosphorylation site(s). In the case of MAPK, the minimum general primary sequence required to be a substrate for protein phosphorylation is the presence of a Ser or Thr residue followed by Pro. Additionally, most MAPKs also appear to interact with their substrates by binding to a second site. This "docking" interaction is required for substrate phosphorylation by MAPK *in vitro* and is likely to be a relevant mechanism for the selection of high affinity substrates by these kinases *in vivo*. The current view is that for substrate recognition, MAPKs first dock to the substrate through a binding interaction at one site leading to phosphorylation of the substrate at a second site at one or more Ser/Thr-Pro motifs. Recent studies demonstrate that the selective interaction of MAPK with substrates may influence the physiological regulation of MAPK targets *in vivo*. Examples of such docking interactions include the interaction of ERK or JNK with the transcription factor Elk-1. Furthermore, there is substantial evidence that the normal function of MAPK signaling modules requires the proper organization of their components within the cell.

Of interest, in the past decade, scaffolding proteins have emerged as general regulatory mechanisms ensuring the fidelity of intracellular pathways. These proteins bind components of signaling routes, physically organizing them to enable rapid physiological responses. The prototypical signaling scaffold is the yeast protein Ste5p which binds the components of the yeast MAPK cascade leading to the mating response after activation of the pheromone receptor, thus maintaining the signaling fidelity of this cascade. Several scaffold-binding components of MAPK cascades have now been described in multicellular organisms, including Kinase Suppressor of RAS (KSR) and c-Jun Terminal Kinase Interacting Protein family (JIPs). Their role is to maintain the integrity of biochemical routes connecting cell surface receptors to the nucleus. For example, the JIP family of scaffolding proteins consists of three mammalian homologues JIP/IB-1, -1b, and -2. These molecules bind members of the mixed-lineage group of MAPKKK's (MLK) that have been reported to activate both JNK and p38. In addition, both IB1/JIP1 and IB2/JIP-2 have been found to bind the JNK MAPKK, MKK7, while IB2/JIP-2 has also been reported to bind MLK3 and p38γ. An emerging concept derived from recent studies is that these scaffold proteins are organizers and keepers of signal specificity and fidelity. Indeed, it may be as important to keep signals separate between closely related MAPK cascades, as it is to integrate them in a coordinated response, particularly in gene expression control.

The activation of MAPK-mediated signaling pathways is often initiated by stimuli acting at the cell surface. However, many of the transcription factors that act as MAPK substrates are located in the nucleus, thus suggesting the existence of mechanisms by which the signals can be transmitted from the cytoplasm to the nucleus. This has been extensively investigated for the ERK1/2 pathway. For example, the activated forms of Raf (MAPKKK) are present at the plasma membrane, while activated MEK1 and MEK2 (MAPKK) are located in the cytoplasm, due to the presence of a nuclear export signal (NES) in the protein. Thus, the final step in signal transmission from the cytoplasm to the nucleus appears to be directly mediated by ERK1/2. Indeed, these ERKs are located in the cytoplasm of quiescent cells but in the nucleus of activated cells. The mechanism by which activation promotes the translocation of ERKs to the nucleus is still unclear. It has been suggested that ERKs may be actively sequestered in the cytoplasm by inactive MEK1/2, and upon their activation by Raf, MEK1 and MEK2 may dissociate from ERK1 and ERK2, which may then be able to migrate to the nucleus as homodimers. Whereas available evidence supports this model, it is still unclear whether the release of ERKs from their MAPKK, MEK1 and MEK2, is sufficient to promote the nuclear

accumulation of ERKs or whether additional processes are involved. Furthermore, whether other MAPKs use similar or distinct mechanisms to ultimately phosphorylate nuclear proteins is also poorly understood, and under current intense investigation.

Regulation of Gene Expression through MAPK Signaling Pathways

Although MAPKs can phosphorylate cytoplasmic substrates, most MAPK signaling pathways ultimately converge in the nucleus to regulate gene expression, either by acting at the pretranscriptional, transcriptional, and posttranscriptional level. The most widely used mechanism by which MAPKs regulate gene expression is the phosphorylation of transcription factors, thereby enhancing their activity. For example, phosphorylation of the transcriptional activation domains of ATF2, CHOP, Elk-1, and c-Jun causes increased transcription. As studied in detail for the transcription factor CREB, transcription factor phosphorylation can cause changes in the interaction with coactivator molecules, including CBP and p300, which function, in part, through the regulation of the chromatin structure by acetylating histones.

Less frequent cases are found where MAPKs negatively regulate transcription factors by promoting their retention in the cytoplasm upon phosphorylation, and active dephosphorylation of these factors is then needed for their migration to the nucleus to stimulate gene transcription. As examples, phosphorylation of the transcription factors SMAD1 and NFAT4 by ERK1/2 and JNK, respectively, causes their cytoplasmic retention and therefore the inhibition of their transcriptional activity. Whether instead the phosphorylation by MAPKs of cytoplasmic transcription factors may cause their nuclear translocation is still unclear. Regulation of the DNA-binding activity is also a mechanism employed by MAPKs to control transcription factor activity. An example is the transcription factor Elk-1, which is phosphorylated by ERK, JNK, and p38 MAPKs leading to increased DNA binding.

Regulation of translation represents a fourth mechanism of regulation of gene expression by MAPKs. The best example is the translational regulation of cytokine expression observed in macrophages exposed to endotoxin. In this case, p38 MAPK acts on a *cis*-acting element in the TNFα mRNA to regulate its translation. Modulation of mRNA processing and nuclear export has not been described, although these biosynthetic steps also represent potential sites for intervention by MAPK.

The final mechanism employed by MAPK to regulate gene expression is the regulation of protein degradation. This is exemplified by the short-lived transcription factor c-Jun, which is rapidly degraded by the ubiquitin–proteasome pathway. Phosphorylation of c-Jun by JNK inhibits the ubiquitination of c-Jun and, therefore, its rapid degradation. Consequently, JNK activation prolongs the half-life of c-Jun, leading to the accumulation of the c-Jun protein. The regulation of protein stability by MAPK therefore contributes to the regulation of gene expression mediated by these signaling pathways.

Glossary

extracellular signal-regulated protein kinase (ERK) One class of MAPKs.

GTPases Molecular switches that control cellular responses by exchanging GDP (inactive form) for GTP (active form) in response to a variety of stimuli. In the GTP-bound form they interact with effector molecules. Subsequently, they hydrolyze GTP to GDP, thereby returning to their inactive state.

mitogen-activated protein kinases (MAPKs) A group of serine/threonine protein kinases that play an essential role in signal transduction in response to changes in the cellular environment.

protein kinases Phosphotransferases that catalyze the transfer of a phosphate group from ATP, or in some cases from GTP, to a protein substrate. Most protein kinases phosphorylated serine or threonine residues (serine-threonine protein kinases) or tyrosine residues (protein tyrosine kinases).

Ras A small GTPase that controls the activation of the ERK kinase cascade, as well as other downstream targets.

Biography

Hidemi Teramoto is a visiting scientist at Cell Growth Regulation Section, Pharyngeal Cancer Branch, National Institute of Dental and Craniofacial Research, National Institutes of Health. He holds M.D. and Ph.D. degrees from University of Tottori in Japan.

J. Silvio Gutkind is the Chief of the Oral and Pharyngeal Cancer Branch, National Institute of Dental and Craniofacial Research, National Institutes of Health. He holds a Ph.D. degree from University of Buenos Aires in Argentina.

Their principal research interest is in the molecular basis of cancer, which they have addressed by studying normal and aberrant functions of molecules involved in the transduction of proliferative signals. The laboratory has made seminal contributions to the field, and helped elucidate some of the basic molecular mechanisms whereby cell surface receptors regulate the nuclear expression of growth promoting genes.

Mitosis

Patricia Wadsworth and Nasser M. Rusan
University of Massachusetts, Amherst, Massachusetts, USA

Mitosis is the phase of the cell division cycle when the duplicated chromosomes are equally partitioned into two daughter cells. Chromosome motion occurs on the mitotic spindle, a dynamic structure that is assembled at the beginning of mitosis and subsequently disassembled. Mitosis is followed by cytokinesis, the division of the cytoplasm. Together, mitosis and cytokinesis constitute cell division and result in the generation of a pair of daughter cells.

The Cell Cycle

Dividing mammalian cells experience an ~24 h long cell cycle, during which the cells grow, replicate their DNA, and divide into two daughter cells. The cell cycle is composed of interphase, which lasts ~22 h, and mitosis, which is completed in ~2 h. Interphase can be subdivided into three parts. During S phase or synthetic phase of interphase, DNA is synthesized, or replicated. The interval between the end of mitosis and the beginning of S phase is called first gap (G1) phase. During G1, cells grow in preparation for division. However, if nutrients or growth signals are lacking, cell cycle progression can be slowed, or stopped. The phase after DNA replication and before the initiation of cell division is called gap 2 (G2). During G2, cells evaluate DNA replication; if damaged, or unreplicated, DNA is detected, the cell cycle is delayed. If no DNA damage is detected, cells progress through G2, and enter mitosis.

Spindle Structure

The mitotic spindle at metaphase is a bilaterally symmetric, microtubule-based structure with chromosomes aligned in the middle. The spindle is bipolar: the two spindle poles define the spindle axis and are the sites to which the chromatids are moved during anaphase (Figure 1). In many animal cells, a centrosome, composed of a pair of centrioles and associated pericentriolar microtubule-nucleating material, is present at the spindle poles (Figure 1). The major structural elements of the spindle are microtubules, dynamic cytoskeletal filaments that radiate from the two spindle poles. Microtubules attach chromosomes to the spindle and are essential for chromosome motion. Spindle microtubules are classified by their location in the spindle (Figure 1). Interpolar microtubules extend from each spindle pole and overlap in the middle of the spindle. Kinetochore microtubules have one end embedded in a specialized attachment site on the chromosome, the kinetochore. The third class of spindle microtubules, astral microtubules, extend away from the centrosomes toward the cell cortex. Astral microtubules contribute to spindle positioning and in defining the position of the contractile ring at cytokinesis.

Considerable variation in spindle structure exists among diverse cells. In cells of higher plants, the spindle pole lacks centrioles and is broad, not focused. Plant spindles are also anastral, lacking astral microtubules. In yeasts, which undergo closed mitosis inside of an intact nuclear envelope, a spindle pole body is present at the two ends of the spindle. The spindle pole body, a trilaminar plaque-like structure embedded in the nuclear envelope, nucleates microtubules that radiate into the nucleus and cytoplasm. The number of spindle microtubules also varies among cell types. Yeasts have a simple spindle, and a single microtubule links each kinetochore to the spindle pole body. In contrast, ~20 microtubules are associated with each kinetochore in a typical animal cell and hundreds of microtubules are present in each half-spindle. Despite these differences in spindle structure, in all cases, mitosis accomplishes the accurate segregation of the replicated genetic material into the two daughter cells.

Phases of Mitosis

Prophase

Chromosome Condensation

Prior to mitosis, during the S phase of interphase, each chromosome is replicated, resulting in two identical sister chromatids that are bound together by protein complexes called cohesions. The sister chromatids are very long strands of DNA and must be compacted for division. This process, called chromosome condensation, occurs as specialized proteins called condensins

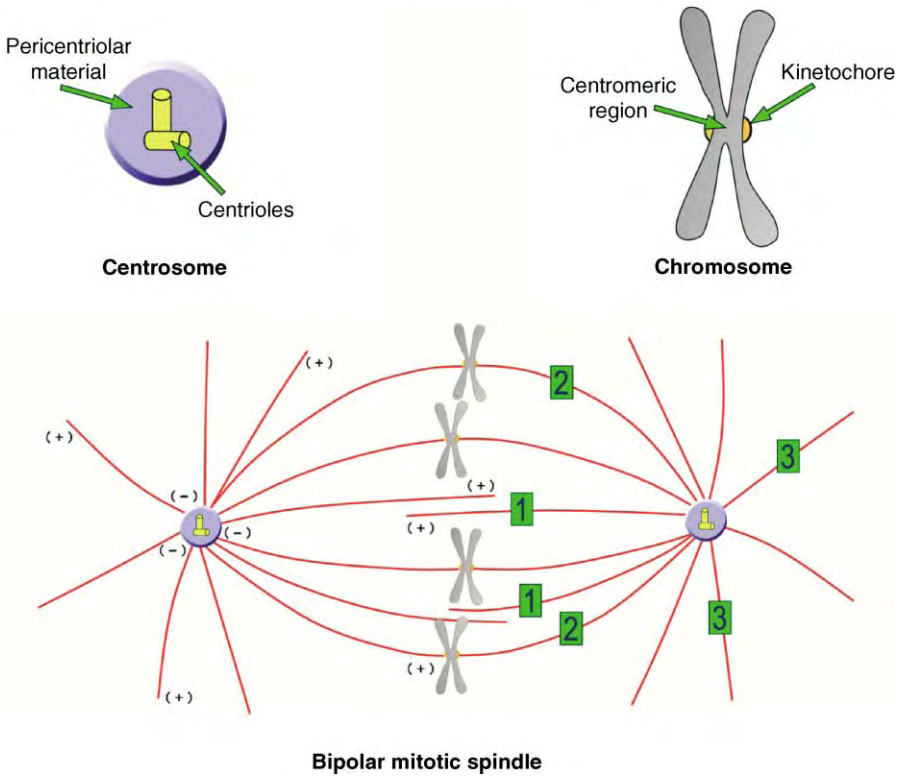

FIGURE 1 Highly schematic diagram of a mammalian mitotic spindle at metaphase of mitosis. Microtubules are depicted as red lines; interpolar, kinetochore, and astral microtubules are labeled 1, 2, and 3, respectively. The plus and minus ends of the microtubules are marked. Inset, upper left, shows a schematic diagram of a centrosome consisting of pericentriolar material, purple, and centrioles, yellow. Inset, upper right, shows a diagram of a chromosome; the centromeric region and the kinetochore are shown.

coil the DNA into loops. As prophase progresses, the chromosomes become increasingly visible in the nucleus, first as threads or strands and later as highly condensed rod-like structures called chromosomes, each of which is composed of two chromatids (Figure 2). The term mitosis comes from the Greek word *mito* meaning thread, referring to the appearance of thread-like structures in the prophase nucleus.

Kinetochore Assembly

In order for the chromatids to be accurately segregated into the two daughter nuclei, they must be attached to, and later moved by, the spindle machinery. Mitotic chromosomes are characterized by an indentation, or primary constriction, called the centromere (Figure 1). The centromere is a region of highly repeated DNA sequences that serves as the assembly site for a plate-like structure called the kinetochore. The kinetochore functions to link each chromatid to the spindle via kinetochore microtubules and also functions as a signaling device that regulates progression through the cell cycle. Kinetochores of sister chromatids are arranged back-to-back so that the binding sites for spindle microtubules face in opposite directions to facilitate the association of each chromatid with microtubules from opposite spindle poles.

Centrosome Separation

In animal cells, the centrosome is also duplicated during S phase of interphase, and the two daughter centrosomes remain adjacent to one another. Centrosome duplication ensures that two centrosomes are present at the beginning of mitosis to form the spindle poles and guarantees that each daughter cell inherits one centrosome. In prophase, the duplicated centrosomes separate and begin moving to opposite sides of the nucleus to establish a bipolar spindle. The microtubule nucleating capacity of each centrosome also increases dramatically at prophase.

PROMETAPHASE

Nuclear Envelope Breakdown

In cells with an open mitosis, the breakdown of the nuclear envelope marks the beginning of prometaphase.

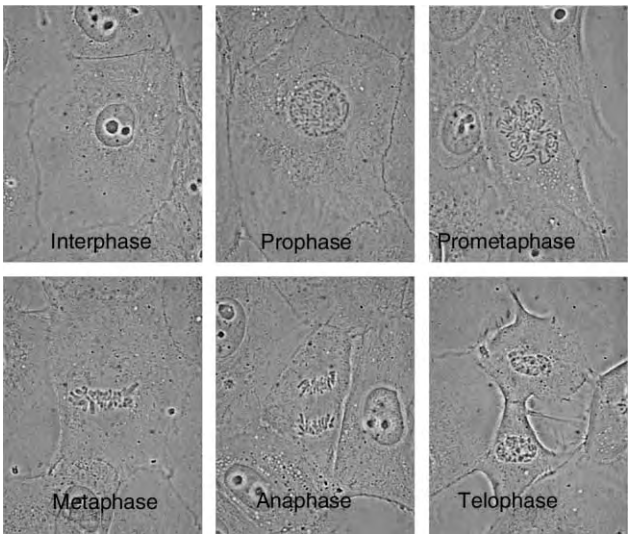

FIGURE 2 Phase contrast light micrographs of living LLCPK1 mammalian cells in mitosis. Each panel shows a different cell at the indicated stage of mitosis.

Microtubules assist nuclear envelope breakdown resulting in the fragmentation of the nuclear membrane into small vesicles and consequently releasing the chromosomes into the cytoplasm.

Spindle Assembly

Spindle assembly requires dynamic microtubules. Because microtubules are polar polymers, their two ends have different dynamic properties. The less dynamic end, called the minus end, is associated with the spindle pole material; the more dynamic end, called the plus end, extends outward toward the cell periphery (Figure 1). Microtubule plus ends display a behavior called dynamic instability, in which they switch stochastically between phases of assembly and disassembly. The result of dynamic instability behavior is that microtubule plus ends continually probe the cytoplasm as they grow and shorten. Microtubules in mitotic cells are more dynamic than microtubules in interphase cells because they switch from growing to shortening more frequently and shorten further before resuming growth. The result is a population of relatively short, highly dynamic microtubules that radiate from each spindle pole. At nuclear envelope breakdown, chromosomes are released into the cytoplasm and dynamic microtubules can interact with each kinetochore. Once a connection between a microtubule and kinetochore is established, the microtubule becomes less dynamic in order to maintain the connection. Cells monitor the attachment of chromosomes to the mitotic spindle and mitosis is delayed if even a single chromosome is unattached. This regulatory system is called the spindle assembly checkpoint, or metaphase checkpoint.

Microtubule motor proteins, which utilize the energy of ATP hydrolysis to perform work in cells, are also important for spindle assembly. The type and properties of the motor protein govern the direction of motion, either toward the minus end or the plus end of the microtubule. Multifunctional motors or motor protein complexes can exert force on microtubules by cross-linking neighboring microtubules and sliding them relative to one another or by binding to one microtubule while walking along an adjacent one. Alternatively, the nonmotor region of the motor protein can bind to a tethered structure, the cell cortex for example, while the motor region of the protein applies a pulling force on the microtubule. Motor proteins are present at the kinetochores, between interpolar microtubules, along kinetochore microtubules and at the cell cortex.

Motor proteins contribute to various motions during mitosis. During centrosome separation in prophase, motors located between the antiparallel, interpolar microtubules contribute to the separation of the two spindle poles. At the kinetochores, motors contribute to the initial bipolar attachment of chromosomes to spindle microtubules. Motors also contribute to congression, the movement of the chromosomes to the spindle equator, or metaphase plate, following initial attachment. In the assembled spindle, a balance of the activities of oppositely directed motor proteins maintains spindle length; some motors tend to pull the poles together, and this is resisted by motors that act to push the poles apart. Motor proteins also contribute to spindle positioning in mitotic cells, and to the dynamic turnover of mitotic microtubules.

Spindle assembly can also occur in the absence of centrosomes. In this situation, microtubules assemble in the vicinity of chromosomes and are subsequently sorted into a bipolar array by the activity of motor proteins. In both the presence and absence of centrosomes, dynamic microtubules and motor proteins contribute to spindle formation.

Metaphase

The cell is in metaphase when all of the duplicated chromosomes are aligned midway between the two spindle poles (Figures 2 and 3), a location referred to as the metaphase plate or spindle equator. Spindle length remains relatively constant at metaphase, but the spindle microtubules are not static. Rather, they undergo a behavior called spindle flux, in which spindle microtubules continually assemble at their plus ends and disassemble at the minus ends, coupled to poleward translocation of the polymer. As a result of flux, marks placed on spindle microtubules are observed to move slowly toward the poles during metaphase and anaphase of mitosis.

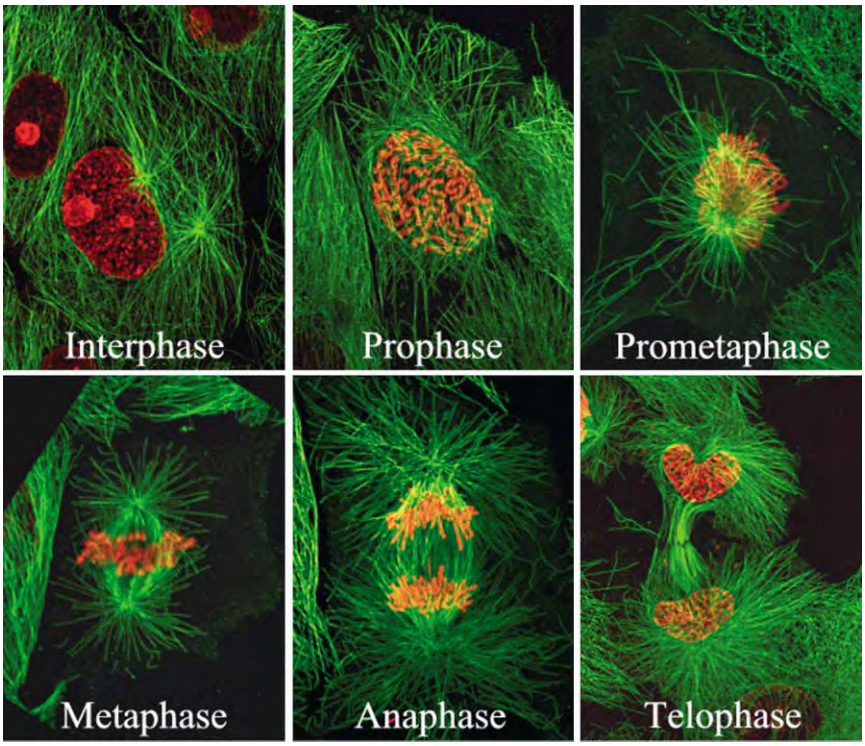

FIGURE 3 Distribution of microtubules and DNA throughout mitosis. Fluorescence light micrographs of cells that have been fixed and stained with antibodies to tubulin, to label microtubules, and propidium iodide, to stain DNA. Microtubules are shown in green and DNA in red. Images are maximum projections of deconvolved image stacks taken with a spinning disc confocal microscope.

Not only are microtubules dynamic at metaphase, the chromosomes are also active, oscillating towards and away from each spindle pole. Chromosomes are also under tension, ready for subsequent movement in anaphase. If the connection between one sister chromatid and the pole is severed at metaphase, the chromosome moves to the pole to which it remains attached, demonstrating that the metaphase position results from a balance of pole directed forces acting on the chromosomes.

Anaphase

During anaphase, sister chromatids separate and move to the spindle poles (Figures 2 and 3). Anaphase consists of two phases, anaphase A and B. During anaphase A, the chromosomes move to the poles and kinetochore fiber microtubules shorten; during anaphase B, the spindle poles move apart as interpolar microtubules elongate and slide past one another. Many cells undergo both anaphase A and B motions, but in some cases one or the other motion dominates.

Separation of the paired sister chromatids is required for poleward motion in anaphase. Chromatid separation results from the proteolytic degradation of components that link the chromatids at the centromere. Degradation is triggered by the activity of the anaphase-promoting complex, which regulates cell cycle progression. Chromatid separation is not the result of tugging by microtubules and motor proteins, and can be observed even in the absence of microtubules.

Although the motion of the chromosomes to the spindle poles in anaphase has fascinated biologists for many years, the molecular basis for this motion remains controversial and incompletely understood. During anaphase A, kinetochore microtubules must shorten as the chromosomes move poleward. Measurements of spindle flux show that subunit loss from microtubules occurs at the spindle poles during anaphase. In many cells, however, the rate that chromosomes move exceeds the rate of subunit loss at the pole, and thus subunit loss must also occur at the kinetochore.

Pioneering studies of mitosis in living embryonic cells demonstrated that assembly and disassembly of microtubule polymers result in chromosome motion. This work led to the hypothesis that microtubule disassembly drives chromosome motion. Later work identified molecular motors at the kinetochore, leading to the alternative hypothesis that forces generated by molecular motors drive chromosome motion. One possibility is that molecular motors power chromosome motion, but the rate of chromosome motion is limited by kinetochore microtubule disassembly. Alternatively,

disassembly may be responsible for chromosome motion, and motors may tether the chromosomes to the shortening fiber. The presence of potentially redundant mechanisms for chromosome motion may reflect the fact that mitotic fidelity is of utmost importance.

Telophase

In telophase, the chromosomes decondense, and the nuclear envelope begins to reform around them (Figures 2 and 3), returning the cell to the interphase condition. The short dynamic microtubules of the spindle are replaced with the less dynamic microtubules of the interphase array that extend to the cell periphery (Figure 3). During telophase the contractile ring assembles midway between the spindle poles in preparation for cytokinesis.

Cytokinesis

Cytokinesis is the process of constricting the cytoplasm between the two forming daughter nuclei resulting in the formation of two cells. Cytokinesis is achieved by a contractile ring, or belt, composed of filaments of the cytoskeletal polymer, actin, and the molecular motor protein, myosin II, which provides the force for cytokinesis. The contractile ring is tethered to the cell membrane, and its contraction creates a cleavage furrow, or indentation of the plasma membrane, during cytokinesis. The contractile ring assembles midway between the two spindle poles in telophase, and disassembles when cytokinesis is completed. The signals that determine the location of contractile ring formation in the cell cortex have yet to be identified, but microtubules are involved in their delivery to the cortex. In some cells, radiating astral microtubules that overlap midway between the spindle poles dictate the site of contractile ring formation. In other cases, interzonal microtubules located between the separating chromosomes play an important role in specifying the location of furrow formation. The completion of cytokinesis marks the end of mitosis and the birth of two completely independent daughter cells in interphase of their cell cycle.

Dr. Patricia Wadsworth is a Professor in the Department of Biology at the University of Massachusetts, Amherst. Her principal research interests are in the area of mitosis and the cytoskeleton, with particular focus on the dynamic behavior of microtubules. She received a Ph.D. from Dartmouth College and was a post-doctoral fellow at the University of North Carolina, Chapel Hill.

Nasser M. Rusan is a Ph.D. candidate in molecular and cellular biology at the University of Massachusetts, Amherst. His research interest is in the cytoskeleton, with particular emphasis on microscopy and digital imaging technology.

mRNA Polyadenylation in Eukaryotes

Mary Edmonds
University of Pittsburgh, Pittsburgh, Pennsylvania, USA

Polyadenylation is a process used by all cells to generate the polyA sequence on the 3′ end of messenger RNA (mRNA). The restriction of this modification to mRNAs is achieved through two conserved sequences in the 3′ non-coding region of the RNA polymerase transcript. These sequences direct four multisubunit cleavage complexes to these sites for a specific endonucleolytic cleavage that produces the hydroxyl group on which the polyA tail is generated by a polyA polymerase along with a polyA binding processivity factor.

An unexpectedly large number of proteins are needed for this simple two step enzymatic reation. Additional roles for these specific proteins within the cleavage complexes account in part for this complexity. Some regulate levels of mRNA and even choice of specific mRNA from transcripts with multiple polyA sites. Others interact with processing complexes for 5′ end capping and intron removal. Still others couple RNA processing to transcription through binding of cleavage complexes to the C-terminal domain of RNAP11. Along with capping and splicing complexes a dynamic complex linking RNA processing to transcription results which persists through all phases of transcription up to termination where cleavage factors play a decisive role.

Polyadenylation is a cellular process that generates the poly A sequence on the 3′ end of mRNA. A nuclear poly A polymerase (PAP) adds AMP units from ATP to the 3′ hydroxyl group at the 3′ end of mRNA and processively elongates the sequence to ~200 nucleotides (nts) in mammals and 60 in *Saccharomyces cerevisiae*. A critical feature that bestows specificity on the process is the selection of the site in the mRNA to be polyadenylated. Rather than addition to the 3′ end of the transcript produced by RNA polymerase II (RNAP II), a specific site within this precursor mRNA transcript is created by endonucleolytic cleavage. The site is defined in mammals by a conserved hexanucleotide upstream of the cleavage site and by a less conserved site 10–50 nts downstream of the cleavage site.

A large number of proteins is needed to achieve this cleavage specificity. Most exist within two large cleavage complexes, one of which binds to an upstream site and the other to a downstream site. Two other less well-understood complexes are essential only for cleavage, while PAP and a poly A-binding protein, add AMPs processively to the 3′ hydroxyl group at the 3′ end of the upstream cleavage product.

Although the major RNA processing reactions of 5′ capping, splicing, and polyadenylation occur independently *in vitro*, mutual stimulation of one processing reaction on another is common, i.e., polyadenylation and terminal exon splicing and 5′ capping and polyadenylation. These mutual effects are now understood to result from the coordination of RNA processing with transcription through a dynamic assembly of processing factors with the C-terminal domain (CTD) of the large subunit of RNAP II.

The role of the poly A sequence long remained a mystery in spite of its potential effects either on mRNA stability, nuclear export, or translation. Poly A is now known to participate in each of these processes, often serving as an anchor for a poly A-binding protein that interacts with components of each of these reactions in a manner that modulated gene expression.

Sequences Required for Polyadenylation

Sequences Upstream of the Poly A Site

Point mutations of the AAUAAA signal result in greatly extended nascent RNAP II transcripts. This finding led to the prediction that the poly A addition site was created by cleavage rather than by transcription termination. A high degree of conservation of AAUAAA was evident when about 90% of 250 sequenced mRNAs had an AAUAAA sequence (with 10% as AUUAAA) near their 3′ ends.

More recent analyses of several thousand human expressed sequence tags (ESTs) showed a higher incidence of alternative hexanucleotide signals as only 60% were AAUAAA with 12% AUUAAA. Biological evidence for more extensive use of alternative signals is

most clearly seen in male germ cells where frequencies of AAUAAA resemble those from the EST data, raising the possibility of tissue-specific polyadenylation. A variant cleavage stimulation factor CstF subunit (CstF-64) of the male germ cells but not present in HeLa cells CstF may recognize an alternative poly A signal. Experimental data indicate that AAUAAA functions in a single-stranded form, a finding compatible with the limited number of folded structures examined thus far.

Sequences Downstream of the Poly A Site

Correct 3′ end processing requires a sequence 10–50 nts downstream of the cleavage site that is far less conserved than AAUAAA. This sequence is often a 5nt UMP-rich element (U_4N) and less commonly a 5nt 2(GU)N sequence. However, ~20% of human pre-mRNAs have a downstream sequence that differs somewhat from both of these elements, emphasizing the lack of conservation of downstream elements. Spacing between upstream and downstream elements is crucial for the interaction between cleavage polyadenylation specificity factor (CPSF), bound to AAUAAA and CstF bound to $U_4(N)$ downstream that initiates cleavage.

Proteins of Cleavage/ Polyadenylation

mRNA 3′ end formation and polyadenylation (Figure 1) is deceptively simple. However, as shown in Table I, four multisubunit complexes are required for cleavage along with the polymerase and a poly A-binding protein. Together, at least 14 polypeptides are involved in the reaction. Most have been cloned and sequenced and several expressed as recombinant forms. Table I summarizes features and general functions of the core components responsible for 3′ end formation.

CPSF

CPSF is a complex of 160, 100, 73, and 30 kDa subunits that binds to the AAUAAA poly A signal through the 160 kDa subunit. Binding is stabilized by the other subunits including the 30 kDa protein that binds to pre-mRNA. Little is known of the roles of the 100 and 73 kDa proteins, although these two proteins share 23% sequence identity. The 30 kDa protein has been proposed to be the nuclease for cleavage based on a marked sequence similarity to a 30 kDa *Drosophila* endonuclease, although CPSF-30 lacks such activity, as do all the core proteins.

In vivo CPSF is recruited to the transcript promoter by the TFIID transcription factor where it binds to the CTD of RNAP II. Upon initiation of transcription it interacts cooperatively with the CstF complex, which also binds to the CTD. CPSF remains bound as RNAP II transcribes the gene up to and beyond the poly A site to the termination site.

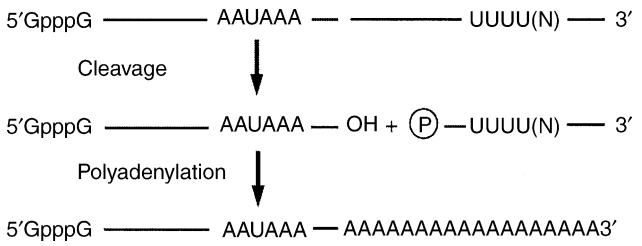

FIGURE 1 The two steps in mRNA 3′ end processing. Endonucleolytic cleavage between the AAUAAA sequence and the downstream element shown as an oligo U-rich sequence generates an upstream fragment with a 3′ OH group and a downstream fragment with a 5′ phosphate group. The upstream fragment is polyadenylated and the downstream fragment is degraded. (Reproduced from Wahle, E., and Keller, W. (1996). The Biochemistry of Polyadenylation. *Trends Biochem. Sci.* **21**, 247.

Cleavage Stimulation Factor

CstF is a trimeric complex needed only for cleavage. The 77 kDa subunit bridges the 64 and 50 kDa subunits of CstF and the trimer interacts cooperatively with CPSF most likely through a strong interaction between CstF-77 and CPSF-160.

CstF-77 is homologous to a suppressor protein of *Drosophila* implicated in the regulation of poly A site

TABLE I

Mammalian Cleavage and Polyadenylation Factors

Factor	Subunits (kDa)	Function
CPSF	160 100 73 30	Cleavage and polyadenylation binds AAUAAA
CstF	77 64 50	Cleavage; binds downstream element
$CF1_m^a$	25 (72, 68, 55)[b]	Cleavage; binds RNA
$CF11_m^a$	47	Cleavage
PAP	82	Cleavage and polyadenylation; catalyzes AMP polymerization
PABP2	33	Poly A extension; stimulates PAP; controls poly A length
RNA pol II (large subunit)	200	Cleavage; binds CPSF and CstF

[a] One of these three interacts with the 25 kDa subunit to give a functional heterodimer.

[b] Mammalian.

choice. However, it is CstF-64 that has been assigned this role in human and chicken cells. Increased levels of CstF-64 favor the use of weak poly A sites normally underused relative to stronger sites. If such sites are in different coding exons, proteins with different sequences will be produced that may have different functions. This occurs during differentiation of β cells into antibody-secreting plasma cells. In undifferentiated β cells the use of a stronger downstream poly A site generates an mRNA for the immunoglobulin heavy chain that codes for a membrane-bound protein, while a weaker upstream polyA site is more active in plasma cells, and leads to a shorter mRNA coding for a secreted immunoglobulin heavy chain. The switch from membrane mRNA to the secreted form is correlated with large increases of CstF-64 while levels of other subunits of CstF remain unchanged. Other activators and inhibitors of the switch are known that may increase upon cytokine stimulation of differentiation.

The CstF-50 subunit is characterized by a seven WD-40 repeat of 40 amino acids that are also in the transducin repeats of the β-subunit of tripartite G proteins. CstF-50 forms a complex with the nuclear protein, BARD1, which is known to associate *in vivo* with the breast cancer tumor suppressor BRCA1. This complex inhibits polyadenylation *in vitro*. Both CstF-50 and BARD1 interact with the CTD of RNAP II leading to speculations that BARD1 may prevent inappropriate 3′ end formation.

$CF1_M$ and $CF11_M$ Cleavage Factors

Both are required for cleavage. CF1 has subunits of 68, 59, and 25 kDa; however, a dimer of the 68 and 25 kDa proteins can replace CF1 *in vitro*. CF1 binds to CPSF at an early stage of assembly of the cleavage complex. CF11 has only been partially purified, but has a subunit of 47 kDa that is homologous to the yeast 3′ end-processing factor, Clp1. CF11-47 interacts with CPSF and $CF1_m$.

Poly A Polymerase

PAP was characterized initially by its specificity for ATP but it lacked specificity for an RNA primer. Specificity for mRNA is now known to be conferred by CPSF. Two functional isoforms, PAP I (77 kDa) and PAP II (82 kDa) are generated by alternative splicing of a mouse gene with 22 introns. Although PAP II is more common, both have identical activities and specificities. The highly conserved amino two-thirds of the molecule has the catalytic site while the C-terminal regions contain an RNA-binding domain and two nuclear localization signals as well as serine/threonine-rich phosphorylation sites.

Crystals of calf and yeast PAPs both show a cylindrical U-shaped molecule with the N-terminal catalytic site spread along one wall of the cavity. The locus of the RNA-binding site awaits analysis of RNA:protein cocrystals.

PABP2

The nuclear 33 kDa poly A-binding protein (PAB2) is responsible for processive elongation by the polymerase and for control of poly A tail length.

RNAP II

RNAP II has recently been recognized as the engine of an RNA machine that carries RNA processing complexes including CPSF and CstF on the CTD of its large subunit. CTD is a separate domain of heptad repeats of seven amino acids repeated 52 times in mammals and 26 times in yeast where two of its serines undergo phosphorylation after transcription is initiated.

Transcription Termination and Polyadenylation are Linked

Evidence for a link between mRNA 3′ end formation and transcription was first seen with point mutations of the AAUAAA poly A signal that resulted in greatly elongated nascent transcripts. This was also seen *in vivo* in a transcript from a thalessemia patient with a point mutation in the AAUAAA signal of the α-globin gene. Defining a mechanism for this linkage of transcription termination to 3′ end processing was difficult until the dependence of mRNA 3′ end processing on an intact CTD of RNAP II was established. The binding of cleavage/polyadenylation complexes CPSF and CstF to the CTD occurs prior to initiation of transcription, and they can remain affiliated with the polymerase up to sites of termination. This finding has stimulated new analytical approaches emphasizing accumulation of nascent transcripts, especially the highly unstable downstream cleavage products.

It is now clear that transcription termination occurs before cleavage as RNAP II moves far beyond the cleavage site producing uncleaved nascent transcripts. The fact that this requires a functional poly A site, usually hundreds of nucleotides upstream of the termination site, suggests a model in which the nascent RNA is looped out between the CTD bound cleavage/polyadenylation factors and the RNA exit channel of RNAP II. The identification of specific sequences including pause sites in this 3′ flanking region and termination factors that may interact with

cleavage/polyadenylation factors to drive mRNA 3′ end formation has introduced a new level of complexity into the nature of this coupling.

Polyadenylation in Yeast

The mechanism of mRNA 3′ end formation in yeast generally resembles that of mammals, although the length of the poly A tail is only ~50–70 nts. The yeast poly A polymerase N-terminal half is essentially identical to that of the N terminus of the mammalian enzyme. Yeast mRNAs have two poorly conserved poly A signals including an upstream U-rich site and an A-rich site downstream but both are upstream of the poly A addition site. Two large multisubunit complexes required for cleavage have subunits homologous to those of CPSF and CstF emphasizing their shared evolutionary history.

A role for poly A in translation has been established with a yeast extract. The poly A tail of mRNA serves as an anchor for a poly A-binding protein that binds to a translation initiation factor, eIF4G to which a 5′ cap-binding protein is also bound at a distinct site. This complex brings 5′ and 3′ ends of mRNA together to initiate translation.

Role of Polyadenylation in Regulating Gene Expression

The type and level of mRNA expressed from nascent transcripts can affect cell growth, differentiation, or function. Like other RNA modifications, polyadenylation can be critical for regulating functional mRNA levels beginning with nuclear export. This occurs in influenza virus-infected cells that produce a viral protein that inhibits cellular mRNA 3′ end formation by binding both cleavage and polyadenylation factors leading to accumulation of non- or underpolyadenylated cellular mRNAs in the nucleus while polyadenylated viral mRNAs processed by a different mechanism exit to the cytoplasm.

Early evidence for a poly A function in the regulation of mRNA activity was seen in maturing oocytes and zygotes where activation of cytoplasmic dormant mRNAs became translationally active upon 3′ end polyadenylation. This activation depended on an intact AAUAAA poly A signal and a specific U-rich sequence in the 3′ untranslated region of a restricted set of mRNAs to which specific proteins bind. A specific cytoplasmic polymerase with unique properties has recently been reported in *Caenorhabditis elegans* suggesting that cytoplasmic polyadenylation may also occur in mammals, a likely possibility that needs to be re-examined.

The regulated choice between two functional poly A sites in different coding exons of a pre-mRNA can produce two mRNAs coding for proteins with different biological functions. One well-studied example is the immunoglobulin heavy chain in β cells where a switch in poly A site usage occurs during β cell differentiation into plasma cells. The role of the 64 kDa subunit of CstF cleavage complex in this switch has already been described. Another involves the calcitonin gene transcript that codes for the Ca^{2+}-activated protein that is produced in most tissues, but not in neuronal cells where an mRNA with two additional exons is processed at a poly A site farther downstream leading to the production of a larger protein, the calcitonin gene-related protein with several neurotrophic activities. The restriction of this choice to neuronal tissues was originally attributed to activator or inhibitor proteins not present in other tissues, while use of the upstream poly A site to produce calcitonin was considered the default mechanism. Surprisingly a novel mechanism for stimulating cleavage and polyadenylation at this upstream poly A site involved an enhancer sequence in the downstream adjacent intron. This enhancer sequence includes partial 5′ and 3′ splice sites that bind a splicing factor that interacts with the cleavage complex at the poly A site of the upstream exon to stimulate polyadenylation. Factors in neuronal tissue that may over-ride this intron enhancer mechanism have not yet been identified.

Finally phosphorylation:dephosphorylation of the serine/threonine-rich C-terminal domain of poly A polymerase can regulate its enzymatic activity *in vivo* and *in vitro*. This is under the control of the cell cycle as a hyperphosphorylated PAP accumulates during mitosis reducing its enzymatic activity that coincides with a general shutdown of RNA and protein synthesis while hypophosphorylation of PAP is characteristic of other phases of the cell cycle.

Biography

Mary Edmonds is a Professor Emerita in the Department of Biological Sciences at the University of Pittsburgh. Her research has been in the area of RNA processing beginning with the discovery of poly A polymerases and polyadenylated pre-mRNAs and messenger RNA in human cells. Later with John Wallace, a graduate student they discovered branched polyadenylated nuclear RNAs that are key intermediates in the splicing reaction that removes introns from nascent RNA transcripts.

mRNA Processing and Degradation in Bacteria

Deborah A. Steege
Duke University, Durham, North Carolina, USA

Messenger RNA molecules in bacteria are subject to cleavage by ribonucleases (RNases) and to extension by addition of A residues to their 3′-terminal ends. In a few instances, the function of RNase digestion is the processing of precursor mRNAs during biosynthesis to generate the mature ends found on the mRNAs translated by ribosomes. However, the primary function of RNase action on mRNA is to effect its degradation and make the nucleotide units available for use in synthesis of new mRNAs. This enables bacterial cells to modulate the levels of particular mRNAs in response to changes in the environment. The defining feature of mRNA at the time of its discovery during the 1960s was instability. At any one time in a bacterial cell mRNA represents a substantial fraction of the RNA being made by RNA polymerase, but it is degraded quickly. Only a few enzymes are required to degrade mRNA, several of which are coordinated in a large complex termed the degradosome. During the steps of degradation, stable RNA structures in mRNAs pose strong barriers to decay. In these instances, addition of a stretch of single-stranded A residues (a poly(A) tail) to the 3′ end of the mRNA facilitates continued degradation of the mRNA molecule.

Ribonucleases that Mediate mRNA Degradation in the Bacterium *Escherichia coli*

In bacteria, mRNA is degraded by the sequential action of endonucleases and exonucleases (Figure 1). The only bacterial species for which sufficient information about mRNA decay pathways is available for discussion is *Escherichia coli* (*E. coli*). RNases are defined by two properties: (1) whether they act on internal phosphodiester bonds within an RNA chain (endonuclease) or on an end of an RNA chain (exonuclease); and (2) whether the exonuclease degrades from the 3′ or the 5′ end of an RNA chain. In bacteria only 3′ to 5′ exonucleases have been found. The combined action of endonuclease cleavage and 3′ to 5′ exonuclease digestion on an mRNA generally produces an apparent 5′ to 3′ wave of degradation intermediates. Only six of some 20 RNases identified in *E. coli* are currently known or implicated to function in mRNA decay (Table I). Three are endonucleases and three are 3′ to 5′ exonucleases. The principal endonuclease that initiates decay is the large enzyme RNase E, which is specific for single-stranded regions in mRNA. This enzyme has the unique property of preferring as substrates the monophosphorylated 5′ ends on the downstream products of mRNA cleavage. This feature, in combination with the direction of ribosome movement on an mRNA, probably accounts for the apparent 5′ to 3′ directionality of decay observed for many mRNAs. The other two endonucleases have many fewer substrates on mRNAs than RNase E. RNase G is homologous to the N-terminal catalytic domain of RNase E and shares the other properties of RNase E. RNase III is specific for double-stranded regions of mRNAs and often makes staggered cleavages on opposite strands of the stem in an RNA stem-loop. The exonuclease RNase II, which accounts for the bulk of exonucleolytic activity on mRNA in *E. coli*, is a hydrolytic enzyme that removes nucleoside 5′ monophosphates from RNA 3′ ends. The exonuclease polynucleotide phosphorylase (PNPase), by contrast, acts in a phosphorolytic manner using inorganic phosphate to produce nucleoside 5′ diphosphates. A puzzling feature of these two enzymes is that they both have difficulty digesting through stable stem-loop structures on RNA 3′ ends. Such structures are a characteristic feature of the 3′ ends of many bacterial mRNAs. Another property of these two exonucleases is that they digest the limit products of mRNA decay very inefficiently. The small fragments remaining from mRNA, 2–5 nt long, are in fact degraded by oligoribonuclease, an exonuclease conserved across a wide range of organisms. Overall, the RNases for mRNA decay define a small group of genes, most of which are required either alone or in combination for viability of the bacterial cell.

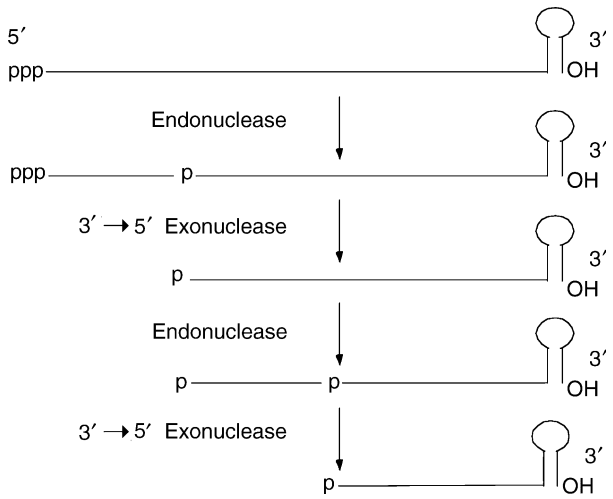

FIGURE 1 mRNA is degraded by the sequential action of endonucleases and 3′ to 5′ exonucleases. A triphosphorylated mRNA synthesized by RNA polymerase and terminated beyond a stem-loop is shown. The products of endonucleolytic cleavage bear monophosphates on their 5′ ends and hydroxyl groups on their 3′ ends.

Control of Gene Expression by RNase III Processing

Although the major function of RNase III in the bacterial cell is synthesis of mature ribosomal RNAs from their large precursors, RNase III is also known to process a number of mRNA species. Processing of mRNA generally functions to alter the stability of one or more coding regions on mRNAs encoding multiple genes, or to regulate the efficiency with which a gene is translated. An example of translational regulation is provided by the well-studied *E. coli* virus lambda. This virus selects one of two modes of growth when it first enters the bacterial cell. If the cells are growing in a rich medium that permits a high rate of growth, the virus multiplies and releases progeny into the medium. In poor media, cell growth rates are much lower. Under these conditions the incoming viral DNA molecule simply integrates into the bacterial chromosome and is then replicated by the host machinery until intracellular conditions become more suitable for production of new viruses. The cellular sensor of physiological conditions is the endonuclease RNase III. Expression of the gene encoding RNase III is regulated by growth rate, with the result that the intracellular concentration of RNase III is a direct function of growth rate. When lambda enters the bacterial cell, one of the first viral genes expressed is N, which is located at the 5′ end of an mRNA transcript encoding many genes (Figure 2). Just upstream of the initiator AUG codon for N gene translation (position 223) lies a hairpin stem that is a substrate for a pair of RNase III cleavages on opposite sides of the stem. When RNase III is abundant, this hairpin is cleaved, and the remaining lower half of the stem unfolds to make the mRNA more accessible for ribosome binding. The result of RNase III cleavage is thus to increase the efficiency of N gene translation. The protein product of the N gene is part of a complex that permits RNA polymerase to read through transcription termination sites at several positions downstream from the N gene on lambda DNA. When N protein is abundant, the genes downstream of the N gene are transcribed and translated, and virus production can proceed. When RNase III is scarce, the RNase III-sensitive hairpin is left uncleaved, less N protein is translated, and little transcription of downstream genes takes place. This is the signal indicating that growth conditions do not favor virus production. Lambda DNA accordingly enters the quiescent state as part of the bacterial chromosome. Thus, mRNA processing in this case plays a critical role in regulating the appropriate choice between the two possible modes of viral development.

TABLE I

***E. coli* RNases in mRNA Decay**

Enzyme	Gene	Monomer size (kDa)
Endoribonucleases		
RNase E	*rne*	118
RNase G	*rng*	55
RNase III	*rnc*	25
3′ → 5′ Exoribonucleases		
RNase II	*rnb*	72.5
Polynucleotide phosphorylase	*pnp*	77
Oligoribonuclease	*orn*	20.7

The Degradosome, a Multiprotein Complex for RNA Degradation

Once many of the decay RNases were purified and characterized, evidence began to appear that at least two of the RNases were associated with other enzymes in a high molecular weight complex that has come to be called the degradosome. At minimum, the purified degradosome contains two RNases: the endonuclease RNase E and the exonuclease PNPase. Present as well are two additional proteins, the ATP-dependent RNA helicase RhlB and the glycolytic enzyme enolase. Polyphosphate kinase is seen in substoichiometric amounts in some degradosome preparations. A functional degradosome containing only RNase E, PNPase, and RhlB assembles spontaneously *in vitro* and shows ATP-activated degradation of an mRNA substrate that is indistinguishable from the activity observed with

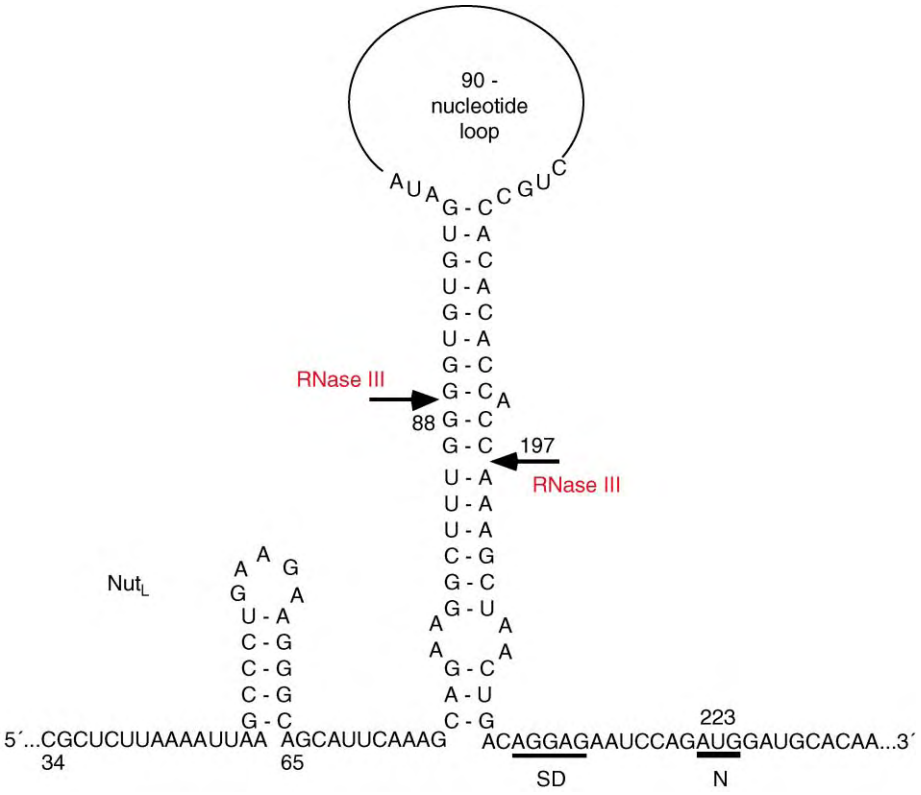

FIGURE 2 Structure of the leader region preceding the translational start of the lambda N gene. Nucleotides are numbered from the 5′ end of the transcript. Nut_L, the site at which RNA polymerase can be modified so as to read through transcription terminators; SD, Shine–Dalgarno sequence in the N gene ribosome binding site; RNase III, sites of cleavage by RNase III.

purified degradosomes. It is evident that the C-terminal half of the RNase E protein functions as the scaffold for association of the other degradosome components because the degradosome complex does not form in a mutant RNase E strain missing the C-terminal half of the protein. The discovery of RNase E, PNPase, and RhlB in a complex immediately raised the possibility that the degradosome might coordinate endo- and exonucleolytic digestion and the unwinding of RNA secondary structure. Evidence from studying the degradation of structured mRNA substrates supports this idea. The stoichiometry of degradosome components remains uncertain, but size estimates for degradosome preparations are indicative of a complex of $(1.5–2.4) \times 10^6$ Da. This is a large enough size that degradosomes can be seen by electron microsopy at the outer edge of the bacterial cell near the inner membrane.

The question of whether the bacterial degradosome is related to any of the high molecular weight complexes observed in the eukaryotic cell has recently taken a very interesting turn with the publication of an X-ray crystal structure for a bacterial PNPase. Whereas comparisons of the mRNA decay pathways in bacteria and eukaryotes have until now indicated few similarities, the bacterial PNPase structure revealed the presence of two repeats per monomer unit of a motif found in the phosphorolytic *E. coli* exonuclease RNase PH. This indicates that the degradosome contains multiple copies of homologues to RNase PH. Similar homologues of RNase PH are found in the exosome, a macromolecular complex present in the eukaryotic cell. A plausible prediction is that the central structure of the two complexes may prove to be quite similar. A second similarity emerging between bacteria and eukaryotes is that these high molecular weight machines are involved in processing and degradation of all three types of RNA: mRNA, rRNA, and small stable RNAs.

Polyadenylation Maintains the Momentum of mRNA Decay

Polyadenylation in bacteria, rediscovered during the 1990s, plays a significant role in the degradation of mRNA. Polyadenylation also appears to function in cellular quality control by removing defective rRNA and tRNA precursors from the cell. Poly(A) tails on bacterial mRNAs are short (10–40 nt), and the extent to which any given mRNA species is polyadenylated is low. Most poly(A) tails are synthesized by poly(A) polymerase I

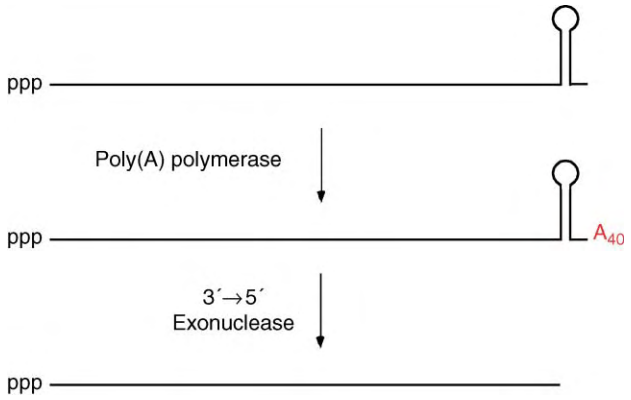

FIGURE 3 Polyadenylation of an mRNA facilitates exonuclease digestion through structural barriers.

(PAP I), an enzyme that is not required for viability of the cell. However, a residual level of polyadenylation is observed in the absence of PAP I and is due to PNPase working in the biosynthetic direction. In contrast to eukaryotic poly(A) tails, which function as stability determinants, addition of a poly(A) tail to a bacterial mRNA stimulates its degradation by exonuclease digestion (Figure 3). This can be understood in light of the difficulty PNPase and RNase II have in digesting through structured regions within and at the ends of mRNA. By providing a single-stranded region of A residues at the 3′ end of an mRNA, the poly(A) tail serves as a toehold for tight binding of the exonucleases as they establish a processive mode of digestion. Thermodynamically stable structures appear to require repeated steps of adding single-stranded poly(A) extensions followed by exonuclease digestion to complete exonucleolytic degradation through highly structured decay intermediates. Thus, polyadenylation appears to be a dynamic process which maintains the momentum of 3′ to 5′ exonucleolytic decay through structural barriers. The question of when, during the lifetime of an mRNA, polyadenylation takes place has recently been resolved. Although polyadenylation was believed to function as the initiating step of decay, it is now clear from following the decay of specific mRNAs over time that PAP I only slowly accesses the 3′ ends of mRNAs. In general, polyadenylation is a later rather than the initiating step of decay, although there certainly are some mRNAs or decay intermediates that require polyadenylation for degradation even to begin.

Decay Pathways Vary with the Position of the Initiating Cleavage

The extent to which molecular models for mRNA decay can be formulated using currently known enzymes is limited (Figure 4). It is relatively straightforward using

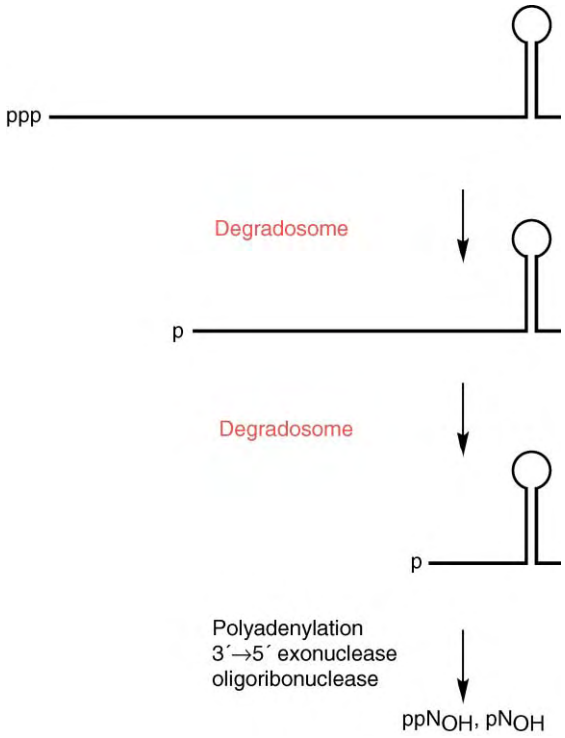

FIGURE 4 General model for mRNA decay based on current knowledge.

mutants deficient in RNase E or RNase III to assign which endonuclease initiates decay. In most cases, decay is initiated by RNase E in the degradosome. Since oligoribonuclease shows specificity for the limit products of mRNA decay, this enzyme can be placed at the end of the decay pathway. By contrast, assigning PNPase or RNase II to the exonucleolytic steps of a decay pathway is often difficult, although it is likely that PNPase in the degradosome digests the upstream fragments produced by endonuclease cleavage. The fact that excess PNPase is present in free form in the cell as well will complicate determining whether degradosome-bound PNPase is in fact responsible for degradation of such products. A similar problem is posed by the existence of at least two mechanisms (polyadenylation and unwinding by the RhlB helicase) for clearing the barriers presented by RNA secondary structure. At present the lack of mutant strains without RhlB activity precludes monitoring decay in the absence of RhlB, so it is not known under what conditions which mechanism is operating to unwind RNA structure. These problems aside, it is abundantly clear that multiple pathways for decay exist. In large part the mode of decay and overall appearance of a pathway is governed by the position of the initiating cleavage. This position must be determined empirically for each mRNA through a combination of *in vivo* experiments and *in vitro* biochemical studies. From in-depth study of

several mRNAs, it appears that if the initiating cleavage is near the 5′ end of an mRNA, the wave of endonucleolytic decay may move in the 5′ to 3′ direction, followed by rapid exonucleolytic degradation of the upstream products. If instead the initiating endonucleolytic cleavage serves to remove the terminator structure at the 3′ end of an mRNA, decay may show a predominantly 3′ to 5′ exonucleolytic mode which may be accelerated by additional RNase E cleavages within the body of the mRNA. A third alternative is that the initiating cleavage occurs at an internal position within an mRNA. Cleavage at this position gives two products that undergo further degradation at a rate determined by the extent to which structural barriers impede exonuclease digestion on each intermediate. Whatever the mode of decay, it is likely that RhlB helicase activity and polyadenylation cooperate to minimize the number of rounds of polyadenylation required for complete degradation of highly structured mRNA decay intermediates.

Biography

Dr. Deborah Steege is a Professor in the Department of Biochemistry at Duke University. Her principal research interests are molecular mechanisms in gene expression, in particular those steps that take place after RNA polymerase has synthesized an mRNA. She holds a Ph.D. from Yale University and served as a postdoctoral fellow at the same institution. She has authored research papers for 30 years in several areas of the broad field of RNA biology.

Mucin Family of Glycoproteins

Juan Perez-Vilar
University of North Carolina at Chapel Hill, North Carolina, USA

Robert L. Hill
Duke University, Durham, North Carolina, USA

Mucins are glycoproteins found in epithelial membranes and as components of the mucus secretions that cover the epithelial cells in the gastrointestinal, urogenital, tracheobronchial, ocular, and auditory systems of all vertebrates and the epidermis of amphibians. Mucins are not exclusive of vertebrates, and they can be found in almost all eukaryotes. Mucus production is considered to be a critical feature for multi-cellular organisms to survive the presence of noxious agents that are part of their environment. All members of the mucin family are rich in carbohydrates and many of them are among the largest proteins known, with complex structures and different protein domains.

General Features

Definitions

Mucins are structurally diverse but share similar structural features. One region of the polypeptide backbone of mucins has an amino acid sequence rich in threonine and/or serine residues that is repeated several times. O-linked oligosaccharide chains are covalently bound to these residues, resulting in the formation of highly glycosylated domains, known as the tandem repeat domains, O-glycosylated domains, or just mucin domains. Because proline residues are commonly found in the mucin domains, they are also known as PTS domains. The term mucin domain is preferred because it is not in conflict with the existence of nonglycosylated repeated domains in many mucins, O-glycosylated regions in the polypeptide chains of many glycoproteins, and mucins (e.g., MUC2) with either serine or threonine residues, but not both, in their mucin domains.

Mucin Members

The exact number of mucins in humans or other vertebrates is unknown. Proteins with well-characterized biological activities that contain mucin domains in their structures are not considered members of the mucin family. In these cases, the functional, rather than structural, properties prevail. This is the case of many membrane receptors that have mucin domains that help to expose their ligand-binding domains. However, 17 potential human mucin genes have been reported, 12 of which (*MUC1*, *MUC2*, *MUC3A*, *MUC3B*, *MUC4*, *MUC5AC*, *MUC5B*, *MUC6*, *MUC7*, *MUC9*, *MUC13*, and *MUC15*) are fully sequenced. The others (*MUC8*, *MUC11*, *MUC12*, *MUC16*, and *MUC17*) are only partially sequenced. Human mucin proteins and genes are designated by the notation MUC and *MUC*, respectively, followed by a number that indicates the specific mucin. The notation for animal mucins is similar but includes upper/lower case letters (Muc and *Muc* for protein and genes, respectively) and an additional lower case letter for designating the particular species (e.g., mMuc1 and *mMuc1* indicate the mouse mucin homologous to MUC1 and *MUC1*, respectively). However, it is common to find in the literature that many animal mucins are designated following the name of the tissue in which they are predominant (e.g., porcine gastric mucin). In many of these cases, biochemical studies started prior to the cloning of their corresponding genes. For instance, porcine submaxillary mucin (pMuc5b) was the focus of many biochemical studies years before its gene was sequenced.

Mucin Subtypes

Mucins can be divided into membrane and secreted mucins based on the presence or absence of a transmembrane domain-encoding sequence in their genes. Membrane mucins are anchored to the apical side of epithelial cells by a transmembrane domain, whereas secreted mucins, which do not have such a domain, are secreted into the extracellular space. However, some membrane mucins (e.g., MUC1 and MUC4) are partially proteolytically cleaved during their biosynthesis, resulting in formation of membrane-attached and soluble subunits. Because these two subunits can be anchored in the membrane as a noncovalent complex, the term

membrane-tethered or tethered mucins can be found in the literature. In addition, splicing of some membrane mucin genes (e.g., *MUC1*) may lead to synthesis of variants lacking transmembrane domains.

Structural subtypes within membrane and secreted mucins can be recognized by comparing the primary sequences of the nonmucin domains. Though the mucin domains in all mucins have similar amino acid composition (e.g., threonine and/or serine rich), they do not share significant protein sequence similarities when compared.

Membrane Mucins

In general, membrane mucins have short cytoplasmic regions at their C-terminal end while their extracellular regions are much larger and contain the mucin domains. Their sizes vary from 334 amino acid residues (MUC15) to more than 6000 amino acid residues (MUC4). *E*pidermal *g*rowth *f*actor (EGF)-, *s*ea-urchin/*e*nterokinase/*a*grin (SEA)-, von Willebrand factor D (D)-, and/or nidogen (NIDO)-like domains can be found in membrane mucin polypeptides. Because MUC3A, MUC3B, MUC12, MUC13, and MUC17 all have EGF- and SEA-like domains, whereas MUC4 lacks SEA-like domains, the former set of mucins likely represent a functional subgroup within membrane mucins. MUC1 and MUC15 are relatively short membrane mucins lacking EGF-, SEA-, D-, and NIDO-like domains.

Secreted Mucins

All secreted mucins, except MUC7 and MUC9, have polypeptide chains with thousands of amino acid residues. These large mucins – including MUC2, MUC5AC, MUC5B, and MUC6 – are known as secreted, gel-forming mucins, because they are found in mucus secretions and endow mucus with their viscoelastic and adhesive properties. Moreover, they all share a similar structural organization that includes nonmucin domains homologous to protein domains found in human von Willebrand factor (e.g., B-, C-, CK-, and D-domains), a protein essential for blood clotting. MUC6, however, lacks B-, C-, and one of the four D-like domains found in the others. In addition, MUC2, MUC5AC, and MUC5B have several copies of a domain, known as the Cys subdomain or CS-domain, which is scattered along their corresponding mucin domains. Similar domains are also found repeated in oikosin-1 (a mucous protein found in certain tunicates) and human cartilage intermediate protein (a cartilage protein of unknown function), but not in von Willebrand factor. MUC7 and MUC9, also known as oviductin or oviductal glycoprotein 1, are secreted mucins not related to gel-forming mucins. MUC7 is a small mucin present in the oral cavity and likely involved in the clearance of bacteria that bind to it. MUC9 is a 678 amino acid residues mucin found exclusively in the oviduct, where it may have a function in fertilization and early embryo development.

Mucin Genes

In general, mucin genes consist of large central exons encoding the entire mucin domains. Alleles of some mucin genes (e.g., *MUC1, MUC2, MUC4*, and *MUC6*) differ in the number of tandem repeats encoded by the central exons, a feature known by the acronym VNTR (*v*ariable *n*umber of *t*andem *r*epeats), although polymorphism due to nucleotide changes has been reported as well. Sequences encoding other domains and regions in the mucin polypeptides are usually constituted by short exons interrupted by large introns. The genes for structurally related mucins are located in specific chromosomal regions. Thus, *MUC3A, MUC3B, MUC11*, *MUC12*, and *MUC17* are located in 7q22, whereas *MUC2, MUC5AC, MUC5B*, and *MUC6* are positioned at 11p15. However, their promoter sequences have little overall homologies and, in general, contain elements for tissue-specific expression and regulation.

Mucin Cell and Tissue Distribution

In general, membrane mucins are secreted by several types of epithelial cells, whereas gel-forming mucins are predominantly synthesized in and secreted from epithelial and submucosal goblet/mucous cells. Each organ/tissue is characterized by the synthesis of a set of mucins with one or two major ones, although a given mucin is usually found in more than one tissue/organ (Table I).

Roles in Health and Diseases

Because of their large size, extent of glycosylation, and locations, mucins protect epithelial cells from dehydration, noxious agents and physical injury, as well as aid the passage of materials through a tract. However, the roles of mucins in mucosal homeostasis likely are more important and complex than previously anticipated. For instance, MUC1 and MUC4 may be involved in cell signaling. The fact that mucin production is regulated in mammals by mechanisms operating at different levels attests to the central role of these glycoproteins. Thus, the number and differentiation state of the cells producing mucin/mucus, the rate of mucin secretion, and the activities of mucin genes are all responsive to bacterial and viral compounds, chemicals and inflammatory mediators.

Many mucin genes have been described but gene deletion studies to assess mucin function are not yet

TABLE I

Tissue Distribution of Human Mucins

MUC1	Widely distributed among epithelial cells. Present in some nonepithelial cells (e.g., fibroblasts) and body fluids (e.g., urine)
MUC2	Colon and small intestine (goblet cells), salivary gland ducts, inferior turbinates, conjunctival epithelium
MUC3A	Colon and small intestine (goblet and absorptive cells)
MUC3B	Colon and small intestine (goblet and absorptive cells)
MUC4	Bronchus, colon, conjuctival epithelium, middle ear
MUC5AC	Bronchus (superficial goblet cells and submucosal mucus cells), colon (goblet cells), superficial stomach epithelium, endocervical epithelium, inferior turbinates, conjunctival epithelium, middle ear
MUC5B	Bronchus (submucosal mucus cells, salivary glands, submandibular glands, gall bladder epithelium, endocervical epithelium, inferior turbinates (submucosal glands), colon (goblet cells), middle ear
MUC6	Gastric epithelium (mucus neck cells; antral mucus cells) small intestine (goblet cells), colon, gall bladder epithelium, seminal vesicle, pancreas (centroacinar cells and ducts), endocervical epithelium, endometrial epithelium, biliary epithelial cells, middle ear
MUC7	Salivary glands (mucus cells), bronchus (submucosal glands), conjunctival epithelium, middle ear
MUC8	Bronchus (submucosal glands), middle ear, urogenital system
MUC9	Oviduct, middle ear
MUC11	Colon, bronchus, middle ear
MUC12	Colon, middle ear
MUC13	Colon and small intestine (columnar and goblet cells), bronchus, kidney, small intestine, conjunctival epithelium, lymphoid cells
MUC15	Widely distributed among epithelial cells. Expressed in some nonepithelial cells
MUC17	Intestine (absorptive cells), colon, gastric epithelium, conjunctival epithelium

completed. However, lack of functional mucins is expected to have profound effects of mucosal homeostasis. Thus, mMuc2-deficient mice develop colorectal cancer in contrast to normal littermates. Conversely, overproduction of mucins/mucus is a serious and sometime devastating feature in several chronic lung diseases, including chronic obstructive pulmonary disease, chronic bronchitis, asthma, bronchiectasis, and, especially, cystic fibrosis. An excess of mucus accumulation can lead to excessive sputum production, respiratory infections, and airways obstruction, and ultimately contribute to the morbidity and mortality associated with these diseases.

Structural Features

Signal Peptides

Both membrane and secreted mucins have short signal peptides at their N-terminal ends that allow them to be synthesized and processed along the organelles involved in the secretory pathway. In general, these sequences are rich in hydrophobic residues but do not have significant homologies among different mucins.

Mucin Domains

Characteristically, the mucin domains are centrally located in the mucin polypeptide backbone (Figure 1). These domains are constituted by a repeated Ser/Thr-rich sequence together with degenerate repeats and unique Thr/Ser-rich sequences at both ends of the repeated regions. The sequence, length, and number of the Thr/Ser-rich repeats vary among mucins. In general, there are as many repeated sequences as mucins described. Some mucins (e.g., MUC3A, MUC3B, and MUC4) have two different mucin domains, each one with different repeated sequences. Only a few kinds of amino acids, in addition to threonine and serine, are found in the mucin domains, with proline and glycine among the most common.

Major Nonmucin Domains in Secreted Mucins

D-Like Domains

Gel-forming mucins contain three homologous N-terminal D-domains (designated D1, D2, and D3) and, all but MUC6, a fourth domain, D4, at the C-terminus. A partial D-domain, D′, is between D2 and D3 in all secreted mucins. Each D-like domain has 325–400 amino acid residues and contains up to 30 cysteines. The D-like domains have several conserved N-glycosylation acceptor motifs and are N-glycosylated when expressed in cultured cells. The available data indicate that the D1-, D2-, and D3-like domains are involved in the assembly of disulfide-linked mucinmultimers.

CK (Cystine Knot)-Like Domains

The CK-like domain is 90–100 amino acid residues long, cysteine-rich domain, located at the C terminus of gel-forming mucins. This domain is homologous to the cystine knot domain in several growth factors and norrin. The CK-like domain is N-glycosylated when expressed in cultured cells. The CK-domain is involved in the assembly of disulfide-linked mucin multimers.

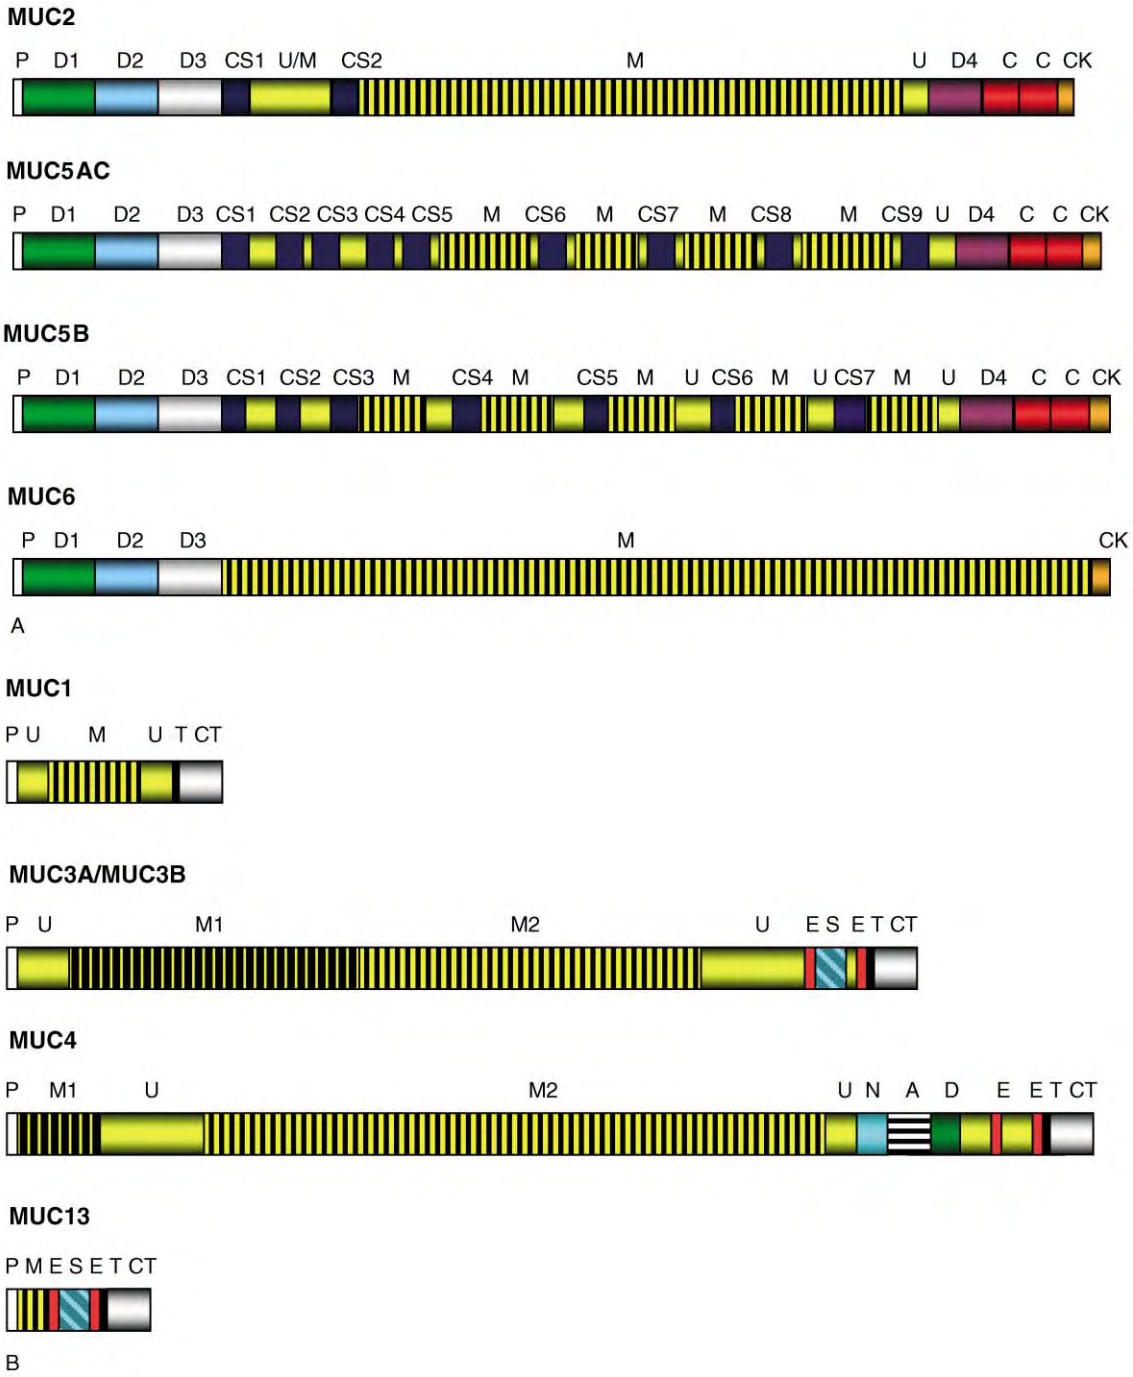

FIGURE 1 Domains in the polypeptide chains of some mucins. Comparisons of the protein domains in secreted (gel-forming) mucins (*A*) and four membrane mucins (*B*), respectively. The length of the corresponding domains is approximately proportional to the number of amino acid residues. *A* and *B* are not drawn to the same scale. P, signal peptide; U, unique sequences (usually Ser/Thr-rich); M, mucin domains; D, D-domains; CS, Cys subdomains; C, C-domains; CK, CK (cystine-knot)-like domain; T, transmembrane domains; CT, cytoplasmic domain; E, EGF-like domains; S, SEA-like domains; N, NIDO (nidogen)-like domain; A, AMOP (adhesion-associated domain in MUC4 and other proteins)-like domain.

CS (Cys Subdomain)-Domains

The CS-domains, also known as the Cys subdomains, are short (100 amino acid residues long) cysteine-rich domains that are scattered along the mucin domains of MUC2, MUC5AC, and MUC5B. Nine, seven, and two CS-domains are found in MUC5AC, MUC5B, and MUC2, respectively. All CS-domains have one C-mannosylation acceptor motif (WXXW) at their

N-terminal side. C-Mannosylation has been reported in recombinant CS-domains expressed in cultured cells. The role of the CS domains is unclear at present.

Major Nonmucin Domains in Membrane Mucins

Transmembrane and Cytoplasmic Domains

The transmembrane domain in mucins comprises a short stretch of hydrophobic amino acid residues. The mucin cytoplasmic domains are short (20–79 amino acid residues long) and contain tyrosine and serine residues that can be phosphorylated.

EGF-Like Domains

EGF-like domains are 45–60 amino acids long domains located between the transmembrane domains and the mucin domains in MUC3A, MUC3B, MUC4, MUC12, MUC13, and MUC17 (Figure 1). They have six cysteine and two glycine residues conserved. The roles of these domains have not been clearly established, but recent studies suggest that they might be involved in cell signaling.

SEA-Like Domains

The SEA-like domain is an 85–110 amino acids long domain found conserved in many extracellular proteins. It is located between the transmembrane and mucin domains in MUC3A, MUC3B, MUC12, MUC13, and MUC17 (Figure 1). The role of the SEA-like domains is not yet defined, but they contain the GSVVV peptide motif that may be cleaved during the biosynthesis of these mucins.

Other Domains

Other protein domains in mucins are the *A*dhesion-associated domain in *M*UC4 and *O*ther *P*roteins (AMOP) and the *nido*gen (NIDO)-like domains that are found in MUC4. Their functions are not yet established, but similar domains are also present in extracellular or surface proteins involved in cellular adhesion.

O- and N-Linked Oligosaccharide Chains

O-linked oligosaccharides in the mucin domains comprise up to 90%, but not less than 50%, of the weight of the native mucins. They decisively contribute to formation of an extended mucin structure by limiting the rotation around peptide bonds, and by the repulsion generated among the neighboring, negatively charged oligosaccharide and sulfate groups. Such long, extended molecules have a much greater solution volume than native or denatured proteins with little or no carbohydrate, and endow aqueous solutions of mucins a high viscosity.

N-linked oligosaccharides are not present in the mucin domains but in many of the nonmucin, cysteine-rich, domains. They may have a role during folding of the nascent mucin polypeptide in the endoplasmic reticulum.

Sulfation

Several monosaccharides in mucin N- and O-linked oligosaccharide chains, especially galactose, N-acetyl-galactosamine, and N-acetyl-glucosamine, are sulfated. Sulfation contributes to the stiffness of the mucin domains by increasing the negative charges of their O-linked oligosaccharide chains, which, as mentioned above, is critical for their viscoelastic properties. In addition, sulfation protects oligosaccharide chains from bacterial glycosidases.

Biosynthesis

Mucin biosynthesis occurs along the endoplasmic reticulum and the Golgi complex and involves folding, N- and O-glycosylation, sulfation, proteolytic processing, and, in the case of secreted gel-forming mucins, covalent assembly.

Membrane Mucins

Like other membrane proteins, membrane mucins are synthesized and N-glycosylated in the endoplasmic reticulum. Some membrane mucins (e.g., MUC1 and MUC4) may be cleaved while inside this organelle. This produces two subunits that can form a noncovalent complex and, ultimately, secretion of soluble forms of these mucins. The cleavage motif in MUC1 (GSVVV) is also found in the SEA-like domains of MUC3A, MUC3B, MUC12, and MUC17. Membrane mucins are O-glycosylated and sulfated in the Golgi complex, but, contrary to gel-forming mucins (see below), they do not form interchain disulfide bond oligomers/multimers.

Secreted (Gel-Forming) Mucins

Except for MUC7 and likely MUC9, the rest (MUC2, MUC5AC, MUC5B, and MUC6) are assembled to disulfide-linked oligomers/multimers prior secretion.

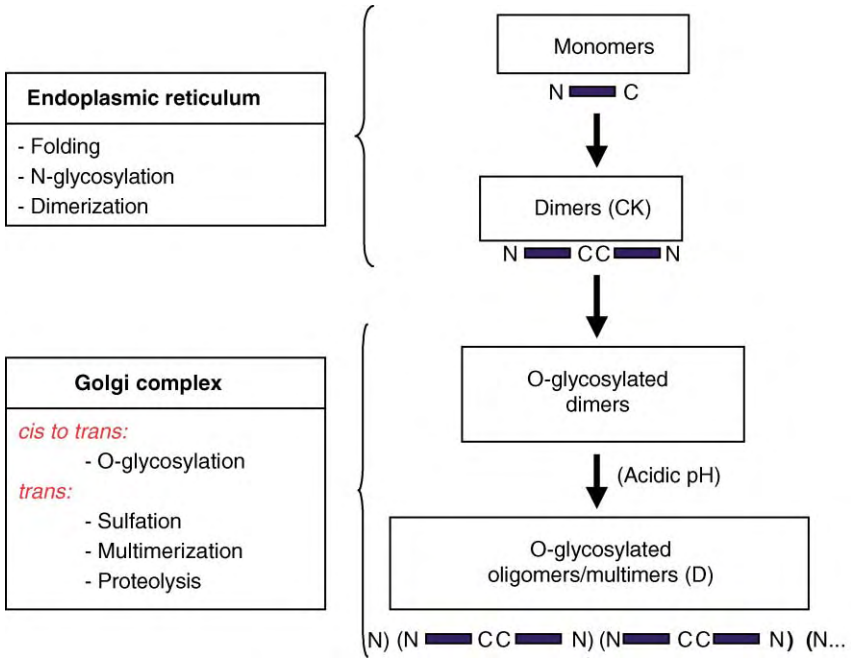

FIGURE 2 Biosynthesis and assembly of secreted, gel-forming mucins. Mucin polypeptide chains are synthesized and translocated into the endoplasmic reticulum. Folding and N-glycosylation of the nascent polypeptide chain is followed by rapid formation of disulfide bonds between the C-terminal CK-like domains in two mucin monomers. Thereafter, dimeric mucins are transported to the Golgi complex where O-glycosylation of the mucin domains and unique Thr/Ser-rich sequences takes place, starting in the *cis*-Golgi compartment and finishing in the late, *trans*-Golgi compartments. In the later compartments, mucins are sulfated and the dimeric forms are assembled into disulfide-bonded oligomers/multimers through their N-terminal D-domains.

Endoplasmic Reticulum

Nascent mucin polypeptides are N-glycosylated and, perhaps, C-mannosylated in their respective NXS/T and WXXW peptide motifs. Mucin assembly starts by formation of dimers via interchain disulfide bonds connecting the CK-domains in two mucin monomers (Figure 2). The CXCC peptide motifs in these domains are critical for dimerization.

Golgi Complex

Mucin dimers are O-glycosylated and sulfated along different compartments of the Golgi complex by resident glycosyltransferases and sulfotransferases. Glycosylated dimers are then assembled into oligomers/multimers via disulfide linkages connecting their NH_2-terminal D-domains (Figure 2). This step likely occurs just before secretion, in the late, acidic, compartments of the Golgi complex and/or beyond. The thiol/disulfide oxido/reductase motifs (CGLC) in the D1 and D3 domains and the CXWXYXPCG sequence in the D3 domains seem to be critical for proper mucin assembly. While light scattering and electron microscopic studies indicate that mucin multimers form linear structures, recent studies suggest the existence of branched polymers as well.

In the *trans*-Golgi compartment, some mucins, including MUC2 and likely MUC5B, may be processed by proteases recognizing the GSDS peptide motif at their corresponding C-terminal regions.

Storage and Secretion

Fully processed gel-forming mucins are stored in high amounts in large secretory vesicles, known as mucous or mucin granules, which occupy the majority of the cytoplasm in goblet/mucous cells. High calcium content and acidic pH are thought to be critical for mucin packing. Mucins are secreted constitutively, which may involve steady exocytosis of mucous granules, small vesicles, or both, or, alternatively, via a regulated pathway involving exocytosis of mucous granules. Regulated secretion is activated by a variety of physiological agents, including cytokines/chemokines, bacterial exoproducts, nucleotides, neurotransmitters, and proteases.

Biography

Juan Perez-Vilar is an Assistant Professor of Medicine at the Cystic Fibrosis/Pulmonary Research and Treatment Center, University of North Carolina at Chapel Hill, North Carolina. His research interests are in the biochemistry and cellular biology of airway mucins and their roles in obstructive lung diseases. He graduated from the University of Seville in Spain and did postdoctoral studies with Professor Robert L. Hill at Duke University.

Robert L. Hill is a James B. Duke Professor of Biochemistry at the Duke University Medical Center, Duke University, Durham, North Carolina. His research interests since the 1950s have centered around the structure/function relationship of proteins, including enzymes and more recently, complex glycoproteins.

Mucins in Embryo Implantation

Daniel D. Carson
University of Delaware, Newark, Delaware, USA

Mucin glycoproteins are defined as proteins heavily substituted with oligosaccharides in O-glycosidic linkage between N-acetylgalactosamine and S/T residues. Carbohydrates can account for 50–90% of the mucin molecular weight and greatly influence the physical properties of these molecules. Mucins also are predominant constituents of the apical surfaces of reproductive tract epithelia. In many species, uterine mucin expression changes dynamically during the reproductive cycle and in preparation for embryo attachment. This article will summarize current knowledge of factors controlling the expression and function of uterine mucins with particular emphasis on MUC1 and the process of embryo implantation.

The Implantation Process

The process of embryo implantation (Figure 1) into the uterine wall involves complex interactions between embryonic- and uterine-derived factors. These factors include secreted signals as well as cell-surface recognition events. In regard to the latter, a number of cell-surface components have the ability to support embryo attachment and are located at sites of embryo uterine attachment. These include integrins, proteoglycans, and cadherins. The failure of gene knockouts of any of these receptors to prevent the initial events in implantation indicates that there is considerable redundancy in function. This is consistent with *in vitro* studies demonstrating the ability of embryos to attach to a wide variety of cell types and substrates via different cell-surface receptor systems as well as the ability of trophoblast to modulate their cell-surface expression of such receptors in response to the extracellular matrix they encounter.

In spite of the highly invasive nature of blastocysts and trophoblast, the uterus displays the remarkable ability to limit both embryo and tumor cell attachment and invasion. Only during a well-defined "window" in time does the uterus permit attachment to and penetration of the endometrium. This control appears to be primarily exerted at the first point of encounter, namely the apical surface of the lumenal epithelium. In response to ovarian steroid influences, the uterus develops through a series of stages that may be defined as prereceptive, receptive, and postreceptive with regard to the ability to support embryo attachment. The end of the ovarian cycle is marked by a fall in steroid hormone levels and resetting of the uterine clock to begin another cycle of receptivity. In menstruating species, the endometrium is largely sloughed and new tissue formed; however, in most species menstruation does not occur and the endometrium is restructured via processes involving controlled apoptosis and cell proliferation as well as extracellular matrix remodeling. If implantation occurs, steroid hormone levels are maintained and the endometrium not only remains, but also differentiates further in many species in a process called the decidual response.

During the receptive phase, the uterine epithelium also displays remodeling evident by electron microscopy as well as light microscopy if staining for specific markers is used. While there are many species-specific variations on the theme, there are features of this process that are well-conserved across species. These include retraction of apical microvilli and reorganization of the cortical actin filaments, the transient appearance of large membrane protrusions (pinopods or uterodomes), and alterations in the apical glycocalyx. Much of the apical glycocalyx is composed of large, heavily glycosylated glycoproteins identified as mucins. The article will briefly summarize our current knowledge of the function and expression of mucins in the context of the embryo implantation process.

Mucins

Functions

As a general principle, mucins heavily coat the lumenal surfaces of epithelia where they provide the first line of defense against infectious agents as well as degradative enzymes. Consistent with this role, mucin glycoproteins are highly resistant to proteolytic attack and require the actions of multiple glycosidases to remove their constituent carbohydrates. While mucins provide a barrier to infection, it is clear that many bacteria and viruses bind well to mucins. Thus, the concept emerges that these molecules serve as "traps" for the infectious agents

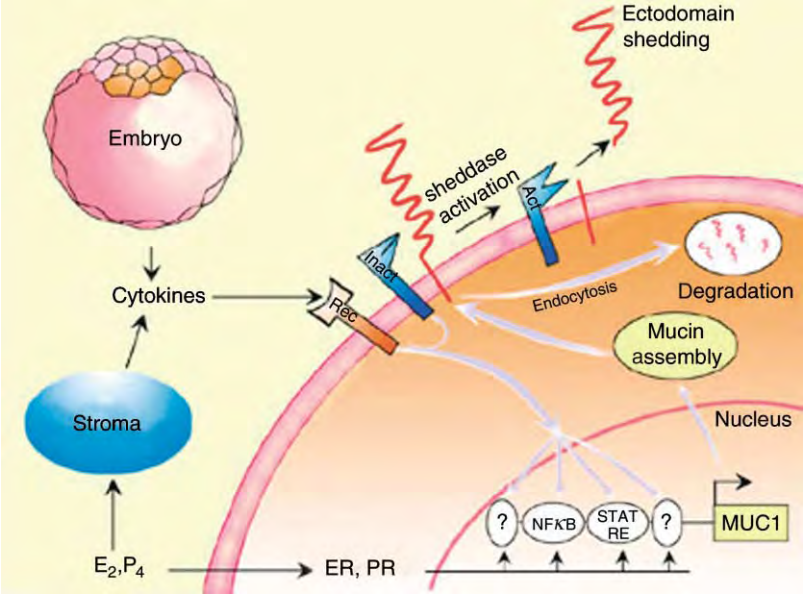

FIGURE 1 Mucin dynamics during embryo implantation. Uterine epithelial cells produce mucins, including transmembrane mucins like MUC1 (represented by the squiggly lines in the figure). In general, these mucins are believed to be a barrier to embryo attachment that must be removed to create access to the apical surface of the uterine epithelium. In some cases, mucin gene expression can be regulated by ovarian steroids, estrogen (E_2) and progesterone (P_4) that may act through their nuclear receptors (ER and PR) directly or indirectly on the MUC1 promoter. Cytokines, produced by neighboring stromal cells or the embryo, bind to cell surface receptors (Rec) on uterine epithelia also can regulate MUC1 gene expression via NFκB and STAT binding. These same elements also may be downstream of steroid hormone actions. Cytokines also can trigger loss of mucin protein by causing increased expression or conversion of latent (Inact) cell-surface proteases or sheddases to active forms (Act) that catalyze mucin ectodomain release. Mucins also may be removed by endocytosis and intracellular degradation pathways.

that interact with them before they can establish contact with the plasma membrane of the host epithelium. A number of mucins occur as transmembrane proteins (see Table I). MUC1 is an example of a transmembrane mucin glycoprotein and experiments with MUC1 null mice demonstrate that these animals are much more prone to bacterial infection and inflammation than their wild-type counterparts. Thus, a paradox arises over how a glycoprotein that can promote attachment of an infectious agent simultaneously serves to protect against the microbe. As discussed below, the host may be able to recognize attachment and shed the ectodomains of transmembrane mucins in response. This process then would convert the shed mucins into a soluble mucin trap removing the potential pathogen from the cell surface.

In the context of embryo implantation, mucins also appear to be antiadhesive. Polarized uterine epithelia of rodents are constitutively nonreceptive *in vitro* and abundantly express mucins. Selective, enzymatic removal of mucins or genetic ablation of Muc1 converts these cells to a functionally receptive state. Moreover, transfection and overexpression of MUC1 into cells that normally adhere well to blastocysts markedly reduces their adhesive activity. In contrast, under some conditions, mucins can carry selectin ligands and, thereby, potentially support cell attachment. Recent studies indicate that this occurs at the fetal–maternal interface and may contribute to aspects of trophoblast binding.

In addition to being abundantly expressed at the apical surface of uterine epithelia, mucins are physically very large with individual molecules being hundreds of nanometers in length. In contrast, typical cell-surface receptors extend 10–30 nm from the cell surface. Due to their heavily glycosylated nature, individual mucins have large hydration spheres. In addition, mucins often form complex aggregates or gels. Consequently, the mucin coat presents a large, formidable matrix that must be somehow traversed or removed in order for molecules or cells to establish contact with the plasma membrane. The size of the ectodomains is an important determinant of transmembrane mucin function as an anti-adhesive molecule. Truncation mutations of the ectodomains of both MUC1 and MUC4 demonstrate that these mucins must extend more than 50 nm from the cell surface to be effective. This would extend well beyond the distance spanned by most cell-surface receptors.

Other interesting functions associated with mucins include immunosupression and association with intracellular signal-transducing molecules. In the former case, the mechanism of action is not clear although effects on several cell types involved in cell-mediated immunity have been reported. In the case of signal transduction, MUC1 has been shown to be associated

with β-catenin, Grb2, and EGF receptor. Furthermore, tyrosine phosphorylation of the cytoplasmic tail is stimulated when ligand is added to cells expressing a fusion protein consisting of a ligand binding extracellular domain and the MUC1 cytoplasmic tail. The physiological significance of these interactions has not been demonstrated although EGF treatment appears to both increase MUC1 association with EGF receptor and activated EGF receptor can tyrosine-phosphorylate the cytoplasmic tail of MUC1, an event suggested to increase MUC1:β-catenin association.

Expression

To date 18 mammalian mucin genes have been identified. The predicted protein structures indicate that the protein cores fall into two classes, soluble and transmembrane. As discussed below, even transmembrane mucins may be shed from the cell surface and so may contribute to the pool of soluble mucins. As a general principle, much of the core protein structure is composed of tandemly repeated sequences rich in serine, threonine, and proline, thereby capable of carrying many O-linked oligosaccharide chains. Secreted mucins also usually contain multiple cysteine-rich regions that participate in disulfide bond formation and the assembly of mucin gels. A hallmark feature is the presence of a large number of O-linked oligosaccharides that can constitute 50–90% of the molecular weight of the glycoprotein. A number of mucin oligosaccharide structures have been determined and considerable information on the glycosyltransferases that assemble these structures is available. The oligosaccharides are branched, can be reasonably complex, and carry a net negative charge due to the presence of sialic acid and/or sulfate residues.

The structures of reproductive tract mucin oligosaccharides change during the cycle under the influence of ovarian steroids. Consistent with this are studies showing that glycosyltransferase activities in endometrium also change in parallel. Expression of mRNA encoding certain mucin core proteins also changes during the cycle; however, only changes in the expression of MUC1 and MUC4 have been studied in any detail, in this regard (see Table I). In rodents, estrogen strongly stimulates MUC1 expression. Progesterone alone has no effect on MUC1 expression, but antagonizes this estrogen action. Both the actions of estrogen and progesterone on MUC1 expression are mediated by their corresponding nuclear receptors. The murine MUC1 promoter contains a number of sequences that are good candidates for estrogen receptor

as well as progesterone receptor-binding sites; however, none of these sites appear to be functional with regard to estrogen receptor-α or -β. Thus, estrogen actions are likely to be indirect and may be mediated in a paracrine fashion by estrogen-regulated growth factors or cytokines. Consistent with this is the conservation of a functional STAT-binding site in the mouse and human MUC1 promoter. Proinflammatory cytokines strongly stimulate MUC1 expression in mammary epithelium by recruiting STAT1α to this site. Synergy with other cytokines has been observed, notably TNFα. In this case, co-operativity with p65 and a corresponding NFκB-binding site appears to further enhance MUC1 transcription. It is noteworthy that these cytokines are highly expressed in the mouse uterus at times when MUC1 levels are high as well, e.g., estrus and day 1–2 *post coitum*, most likely in response to the microbial challenge associated with coitus. Thus, this response may help protect the reproductive tract from infections that would trigger implantation failure or abortion.

Hormonal regulation of reproductive tract mucin expression is observed in other species as well, although in many cases progesterone stimulates mucin expression. Potential progesterone receptor-binding sites are found in the mouse and human MUC1 promoters; however, it is not clear if these are functional. In rats, MUC4 expression also is strongly regulated by progesterone and estrogen. In addition, TGF-β down-regulates MUC4 expression in both mammary and uterine epithelium. Nonetheless, mucin expression changes differently in different parts of the female reproductive tract in response to steroid hormone influences. Thus, regulation of these genes is tissue-specific and complex. MUC1 appears to be differentially spliced as well since forms lacking the extracellular tandem repeats or the cytoplasmic tail also can be detected in certain cell types. It is not clear what fraction of the total MUC1 pool are contributed by these splice variants or exactly what functions these forms play in the implantation process. Other mucins including MUC3 and MUC4 also undergo alternative splicing to generate transmembrane or soluble variants.

Transport and Metabolism

Mucin assembly involves synthesis and transit of the core protein from the rough endoplasmic reticulum through the Golgi apparatus where most of the glycosylation occurs. Subsequently, the fully assembled mucin is transported to the cell surface. The entire process described above takes 60–90 min for the average mucin molecule in several cell types. Both MUC1 and MUC4 are synthesized from a single mRNA, but are proteolytically cleaved during their biosynthesis resulting in the formation of stable heterodimers of their respective ectodomains and transmembrane/cytoplasmic tail domains. While the exact nature of the association is not clear, in the case of MUC1 the complex is not dissociable by a number of agents including urea, heating, high salt, or reducing agents; however, it is readily dissociable by sodium dodecyl sulfate in a variety of normal cells and tumor-derived cell lines.

After arriving at the cell surface, MUC1 undergoes one of the three fates – (1) it can be recycled and further sialylated intracellularly and returned to the cell surface, or (2) it may be endocytosed and degraded in acidic compartments, presumably lysosomes, or (3) the ectodomains may be released or shed from the cell surface. Although the process of mucin shedding has been recognized for many years, the identity of the "sheddases" mediating this release has remained elusive. Recent evidence indicates that TACE/ADAM17 is one such sheddase. Other studies indicate that additional activities are involved as well. Mucin shedding is a property of both normal and tumor cells and, indeed, serum levels of shed ectodomains are used as markers of tumor burden in certain cancers. Shedding also may be stimulated by physiologically relevant agents, e.g., cytokines, as well as other compounds, e.g., phorbol esters. In the context of embryo implantation, stimulation of mucin shedding may be the key method to create cell-surface access to embryo receptors in certain species, e.g., rabbits and humans. In other species, shedding may be coupled with decreased mucin expression to clear the apical cell surface in preparation for embryo attachment.

Summary and Future Directions

The process of embryo implantation is under the control of the actions of ovarian steroids that coordinate the development of the embryo with the maturation of the endometrium. A panorama of receptors and binding factors may participate in a redundant fashion to promote embryo–uterine interactions during implantation. Nonetheless, the thick mucin-coat that covers the apical surface of the uterine epithelium under most conditions not only serves as a protective barrier to infection and enzymatic digestion, but also as a barrier to embryo attachment. This barrier must be removed in order for embryo attachment to occur. In many species, the same ovarian steroids that coordinate the implantation process also control mucin expression leading to the loss of the mucin coat at the time of implantation. In other species, including humans, ovarian steroids do not down-regulate mucin expression. Rather, localized activation of mucin-shedding at the cell surface has been proposed as a mechanism to create access to the apical cell surface of the uterine epithelium. Identification of factors responsible for regulation of mucin gene

expression as well as shedding may provide novel avenues to promote fertility as well as improve protection of the reproductive tract from infectious agents. In addition, recent, surprising findings that certain transmembrane mucins interact with intracellular signal transducing molecules suggest novel roles for these complex glycoproteins in sensing and triggering responses to the extracellular environment.

Glossary

embryo implantation The process by which the mammalian embryo binds to and implants into the uterine wall.

mucin Any member of a class of glycoproteins that contain a large number of oligosaccharides linked through the hydroxyl groups of serine or threonine via N-acetylgalactosamine.

MUC1 The first transmembrane mucin glycoprotein to be completely molecularly cloned.

uterus The upper portion of the female reproductive tract into which the mammalian embryo normally implants and in which the fetus develops.

Biography

Daniel Carson is the Trustees Distinguished Professor and Chairman of the Department of Biological Sciences at the University of Delaware. His principal research interests are in the area of cell surface and extracellular matrix biology with particular emphasis on reproduction and development. He holds a Ph.D. from Temple University Medical School and served as a postdoctoral fellow at Johns Hopkins University and a faculty member at the M.D. Anderson Cancer Center in Houston, Texas. He has authored many primary research and review articles and is a member of several professional societies including the American Society for Molecular Biology and Biochemistry, the Society for the Study of Reproduction, the American Society for Cell Biology, the Society for Developmental Biology, and the American Society for Matrix Biology.

Multiple Sequence Alignment and Phylogenetic Trees

Russell F. Doolittle
University of California, San Diego, California, USA

The alignment of macromolecular sequences is a computer-assisted procedure for gathering information about the evolutionary relatedness of nucleotide or amino acid sequences. Algorithms of various kinds can then be used to analyze the alignments in a way that reflects similarities or differences among the individual sequences. Phylogenetic trees depict these relationships graphically. Phylogenetic trees constructed from nucleotide or amino acid sequences have provided remarkable insights, both with regard to the evolution and relationships of life forms, and to the evolution and functions of the macromolecules themselves.

The two kinds of macromolecule, nucleic acids and proteins, present somewhat different challenges for alignment. Nucleic acids usually involve only four character states (A, G, C, and T/U), whereas protein sequences involve, with rare exception, 20 character states (the 20 amino acids). (Formally, "characters" are the positions in a sequence and the "character states" are the bases or amino acids that occupy them.) In either case the problem involves distinguishing chance matches from those due to common ancestry.

Alignment implies adjusting one or the other character strings by the insertion of gaps. The gaps are justified because, it is known that the insertion or deletion of nucleotides can occur in genetic material. Still, some limit needs to be imposed on the number of gaps, or any two strings of characters could be made virtually identical simply by skipping along until a match is found. Accordingly, a system is usually employed that has appropriate rewards for matches and penalties for gaps. The penalty for a gap can also be set to be dependent on the length of the gap, although gap length is seldom a major concern.

The quality (reliability) of an alignment will depend on how dissimilar the two sequences are. As two proteins or nucleic acids continue to diverge, a point will eventually be reached where it will not be possible to distinguish common ancestry from chance matching on the basis of sequence comparison alone. No matter what kind of scoring scheme is employed, there is no sharp cut-off. Because of the intrinsic variance of the process, there will always be a nebulous region referred to as the "twilight zone." For a pair of sufficiently long amino acid sequences, say a hundred residues or more, the region of uncertainty is usually thought to be between 15 and 25% identity (Figure 1). When shorter sequences are compared, chance matches will be an even bigger concern. A measure of confidence about common ancestry can be obtained by comparing the alignment scores of randomized sequence pairs of the same lengths and compositions, as the two sequences under study.

Binary Alignment

Nucleotide Sequences

The alignment of two strings of characters with a computer depends on pre-determined criteria. In the simplest case, only identities are tallied, i.e., a match involves having exactly the same character state. The use of matched non-identities can provide much information, however, especially when highly divergent sequences are involved. For example, in nucleic acids, transitions (A/G and C/T or C/U) occur much more frequently than do transversions (A/T and G/T or A/U and G/U), and are much more common when corrected for what would be expected from random occurrence. As a result, matches that are the apparent result of transversions may weigh more heavily in order to compensate for the likelihood of multiple transitions at a single site.

As might be expected, interchanges between similar amino acids are much more common than between those with very different structures and properties. Alignment schemes that use substitution tables (matrices) can be constructed that take account of the favored likelihood of such matches and weigh their occurrences accordingly.

Ribosomal RNA

The alignment of ribosomal RNA sequences, and the phylogenetic inferences made from them was the original basis for dividing all of life into three realms,

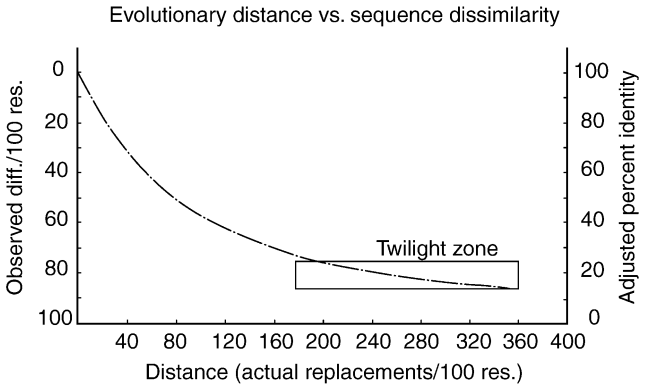

FIGURE 1 Partly as a result of back mutations and multiple mutations at the same site, the divergence of two sequences from a common ancestral sequence follows the course of a negative exponential. Other factors, including the favored likelihood of certain interchanges over others, also contribute. See glossary and text for explanation of twilight zone.

an observation since borne out by many other considerations. Since then, various kinds of ribosomal RNA sequences (5S, small subunit and large subunit) from thousands of different organisms have been determined and used to a great advantage in charting phylogenetic relationships. For these purposes, computer alignments are often limited to certain sets of preferred sites that are well calibrated with regard to their propensity for change.

Mitochondrial DNA

Phylogenetic studies of eukaryotes have been greatly aided by the now routine determination of complete mitochondrial DNA sequences. Generally speaking, these sequences change at a faster rate than nuclear DNA, making mitochondrial DNA sequences especially useful for determining relationships between closely related organisms.

Amino Acid Sequences

The simplest and arguably most informative expression of resemblance for two amino acid sequences is their percent identity. Even so, sequence alignments can be greatly improved by the use of substitution tables that provide scores for every possible amino acid interchange. A substitution table provides a weight for each interchange relative to what would be expected if those interchanges only occurred by chance and were not favored by genetic or structural considerations. Typically, these matrices give weights to each of the 20 sets of (matched) identical residues, as well as to the 190 possible interchanges. Many such tables have been devised, each based on some logical premise. Among the most commonly used are the accepted point mutation 250 (PAM250) matrix and blocks substitution matrix 62 (BLOSUM62) (Figure 2). In these two tables, interchanges with positive scores are more likely to occur than expected by chance, and those with negative scores less likely.

PAM matrices are generated in a sophisticated manner and take into account not only the frequencies of the individual amino acids but also their propensities for change. The suffix attached to the acronym, as in PAM120 or PAM250, denotes how many cycles of calculated mutation were conducted to generate a particular matrix. For example, PAM250 implies 250 rounds of change, and is most useful for rather dissimilar sequences.

An alternative set of tables can be constructed simply on the basis of amino acid frequencies in the individual columns of block alignments. Block alignments are prepared from ungapped segments of large numbers of homologous sequences. Scores for all possible interchanges can be calculated simply by comparing the observed frequency of an interchange with the frequency expected on the basis of the overall occurrences of the two amino acids. These BLOSUM tables have proved surprisingly effective. Suffices are used here to indicate how dissimilar the sequences were in the blocks from which values were calculated. In BLOSUM62, for example, all of the sequences in the block alignment were less than 62% identical.

Global versus Local Alignments

A global alignment ordinarily involves an entire protein sequence, whereas a local alignment involves only a portion of a sequence. The popular searching program basic local alignment search tool (BLAST) finds the highest scoring matching segments within two sequences. The Smith–Waterman algorithm also searches for best matching subsets for two sequences.

In contrast, the Needleman–Wunsch algorithm is designed to find the best global alignment between two amino acid sequences. It is also, well suited for accommodating any kind of substitution matrix and allows for suitable penalties for gaps.

Multiple Alignments

Considerably more information accrues when several homologous sequences are available for alignment. Such alignments can aid the protein scientist in determining the most essential residues in a protein, to the point that given enough divergent sequences, the active site of an enzyme may be inferred even without experimental data. More commonly, the evolutionary history of organisms or proteins is the target. Multiple alignments

can also be used to construct "profiles" or "patterns" that are then used to search databases for more distantly related sequences.

Various methods of multiple sequence alignments may vary subtly. The mathematically optimal alignment of multiple sequences may differ significantly from the real history of events leading to the sequences, and these alignments may differ from those based on three-dimensional structure information. Because it is usually history that is being sought, and because the biological processes of interest operate in a binary fashion (species divergences and gene duplications), the preferred clustering process begins with the most similar pair of sequences, progressively incorporating more distant relatives. More weight is accorded to the more similar pairs, the logic being that those are the more reliable data.

Constructing Phylogenetic Trees

Many different ways of constructing phylogenetic trees from aligned sequences have been developed, and numerous programs are available that perform the operations automatically. Although some procedures actually construct the alignment and the tree simultaneously, in most cases the alignment is made first, after which the tree is calculated from it. One of the most important caveats for all molecular phylogenists is embodied in the slogan "Bad alignment, bad tree." Thus, many workers submit a set of sequences to some computerized regimen and accept the emergent tree, together with some formulized set of statistics allegedly providing some measure of confidence in it. It is always prudent to examine the alignment first. One common shortcoming becomes evident when one or more of the sequences being aligned are significantly shorter than the others. Long unmatched stretches will distort the relative global resemblances. Similar problems will occur with mosaic proteins in which only parts of the sequences are homologous or in which segments have been interchanged. The worst outcomes are the results of including sequences that are not homologous.

Phylogenetic trees can be dissected into two components, the branching order and the branch lengths.

Sometimes cladograms are made that make no attempt to quantify branch lengths, concentrating only on the grouping (branching order) of the entries. On another note, there is always the problem of determining the root of a phylogenetic tree. Ordinarily, accessory information over and beyond that contained in the sequences is needed to establish the root with any confidence.

Distance Methods

Distance methods depend on a table of pairwise distances being derived from the scores accumulated during the alignment process. In the simplest case, the number of differences between each pair of sequences can be used. More commonly, scores determined with a substitution matrix are transformed into units of evolutionary distance. Once the distance matrix has been constructed, the tree can be calculated by a clustering algorithm. These often involve the method of least squares, an effort being made to reconcile the individual pairwise distances with the smaller number of constituent branch lengths in a global tree.

Maximum Parsimony

Maximum parsimony strives to find the tree that can be constructed from the smallest number of mutations. There are numerous versions of the procedure, the most common of which attempt to minimize the overall tree length. In these procedures the individual positions in the sequences are considered column by column, in contrast to the overall pairwise distances used in distance matrix methods.

Maximum Likelihood

Maximum likelihood involves an evaluation procedure based on the probabilities of interchange at different nodes in the tree. In this case one starts with a model tree, and tests it for the probabilities of observed character matches and interchanges based on the character states that exist at neighboring nodes. The probabilities for all nodes are summed, and the most probable tree is the one with the highest total likelihood score.

Summary

The tremendous power of multiple sequence alignment procedures stems directly from the fact that all life forms descend from a common ancestor (or a small number of forms that could freely exchange genes). That most of biology and biochemistry is the result of the duplication and modification of a set of primitive genes seems beyond dispute. During evolution, an enormous binomial expansion of homologous sequences has occurred, the radiation of species on the one hand leading to orthologous genes with the same function in different organisms, and gene duplications on the other allowing for diversification of function within species by parologous genes. When sufficient data are available, properly constructed phylogenetic trees can distinguish between these two. Occasionally, sequence entries may occur on phylogenetic trees in unexpected positions, the result of genes having been transferred laterally between species. In any case, the relatively slow rate of change in many genes is what has made possible the enlightened reconstruction of ancient events.

Glossary

BLOSUM (BLOcks SUbstitution Matrix) A table of values reflecting the frequencies of amino acids at the same positions in a series of block alignments.

bootstrap A method for determining the confidence level for a branching order in a phylogenetic tree.

homologue A sequence related to another by common ancestry.

indel An insertion or deletion of characters in a macromolecular sequence leading to a gap in the alignment.

orthologue A homologous sequence reflecting a pair of gene products related by direct (orthologous) descent.

PAM A pronounceable acronym for an Accepted Point Mutation that has led to an amino acid replacement.

paralogue A homologous sequence reflecting a pair of genes related as a result of a gene duplication.

twilight zone The region of low similarity for pairs of sequences for which the distinction between common ancestry and chance matching is difficult.

BIOGRAPHY

Russell F. Doolittle is a Research Professor at the Center for Molecular Genetics, University of California, San Diego. His principal research interests center around the evolution of protein structure and function. He has a Ph.D. in biochemistry from Harvard (1962) and did post-doctoral work in Sweden. He was an early advocate of using computers to study amino acid sequences as an aid to characterizing proteins.

Muscarinic Acetylcholine Receptors

Neil M. Nathanson
University of Washington, Seattle, Washington, USA

Acetylcholine (ACh) is an important neurotransmitter in both the central and peripheral nervous systems. ACh is synthesized in the cytoplasm of nerve terminals by the enzyme choline acetyltransferase, and is then transported into synaptic vesicles. Depolarization of the nerve terminal causes an influx of calcium into the nerve terminal and evokes the release of ACh into the synaptic cleft; the release of ACh can be blocked by botulinum toxin. The actions of ACh are terminated by the enzyme ACh-sterase, which hydrolyzes ACh. The activity of ACh-sterase can be inhibited by drugs such as neostigmine and the nerve gas agent sarin.

ACh is released from a nerve terminal and binds to a receptor on the cell surface of a target cell to allow transfer of information across a chemical synapse. Sir Henry Dale in 1914 divided receptors for ACh into two classes based on their distinct pharmacological properties, nicotinic and muscarinic. Muscarinic ACh receptors (mAChR) are present on central and peripheral neurons, and in such target organs of the parasympathetic nervous systems as cardiac and smooth muscle, and many exocrine glands. The binding of ACh to mAChR can be blocked by antagonists such as atropine.

The Muscarinic Acetylcholine Receptor Gene Family

While pharmacological and biochemical analyses suggested for many decades after Dale's classification that there was only a single type of muscarinic receptor, drugs were eventually developed that distinguished between muscarinic receptors in different tissues. For example, gallamine was an antagonist at nicotinic receptors that selectively blocked muscarinic receptors in the heart compared to other tissues, while pirenzepine blocked muscarinic acetylcholine receptor (mAChR) in certain neurons with higher affinity than in the heart. These studies indicated that there were multiple pharmacologically distinct muscarinic receptors. In the 1980s, mAChR were purified from both heart and brain, which allowed the isolation of cDNA and genomic clones encoding the mAChR. There are five subtypes of mAChR, termed M_1, M_2, M_3, M_4, and M_5, which are encoded by distinct genes and differentially expressed in various organs and parts of the nervous system (Table I).

Muscarinic Receptor-Mediated Signal Transduction

Muscarinic Receptors Signaling Utilizes G Proteins

While nicotinic acetylcholine (ACh) receptors are ligand-gated ion channels (i.e., the same protein both binds ACh and acts as an ion channel), mAChR are members of the G protein-coupled-receptor (GPCR) superfamily. G proteins are a family of GTP-binding heterotrimeric proteins (they consist of three non-identical subunits) and they couple receptors to various effector proteins, such as adenylyl cyclase, phospholipase C, and ion channels. In the inactive state, GDP is bound to the α-subunit. The binding of ACh to mAChR promotes the dissociation of GDP and the binding of GTP to the α-subunit. This in turn causes the dissociation of the α-subunit from the $\beta\gamma$-subunits; both the α- and $\beta\gamma$-subunits can interact with effector proteins to regulate their activity. The α-subunits have GTPase activity which can be increased by the action of regulator of G protein signaling (RGS) proteins. This hydrolysis of GTP to GDP promotes the reassociation of the α- and $\beta\gamma$-subunits and terminates signaling unless ACh is still present to reinitiate the signaling cycle.

Muscarinic Receptor-Mediated Regulation of Second Messenger Pathways

The mAChR can be divided into two groups on the basis of both sequence similarities and functional responses. The M_1, M_3, and M_5 receptors preferentially couple to the Gq family of G proteins, whose α-subunits can activate phospholipase C (PLC). PLC activity produces two intracellular second messenger, inositol trisphosphate, which causes release of calcium from intracellular stores, and diacylglycerol, which activates protein

TABLE I

Subtypes of Muscarinic Receptors

Subtype	Number of amino acids	G-protein family	Some tissues with high expression
M_1	460	G_q	Cortex, hippocampus, striatum
M_2	466	G_i/G_o	Heart, cerebellum
M_3	590	G_q	Exocrine glands, smooth muscles cortex, thalamus
M_4	479	G_i/G_o	Striatum
M_5	532	G_q	Hippocampus, ventral tegmentum

The table shows the number of amino acids in the five human mAChR subtypes, the G-protein family to which each receptor preferentially couples, and representative tissues which express the various subtypes.

kinase C. The increased intracellular calcium in turn can produce many potential effects, such as activation of protein kinases, activation or inhibition of adenylyl cyclase, activation of phoshodiesterases, and activation of nitric acid synthetase, which can result in increased intracellular cGMP levels. The M_2 and M_4 receptors preferentially couple to the Gi family of G proteins to inhibit adenylyl cyclase activity, thus lowering intracellular cAMP levels. The types of signals produced by any mAChR can depend on both the level of receptor expression and the particular complement of signaling proteins expressed in a given cell.

Ion Channels

Many of the physiological responses mediated by the activation of mAChR on excitable cells are due to the regulation of the activity of ion channels. Regulation of ion channel activity can occur by many different mechanisms. Modulation of ion channel activity can occur due to protein phosphorylation. For example, activation of protein kinase C or decreased activity of cAMP-dependent protein kinase (due to inhibition of adenylyl cyclase activity) can lead to decreased activity of sodium and calcium channels, respectively. Activation of tyrosine kinases can regulate potassium channel activity.

Another mechanism is the regulation of ion channel activity directly by intracellular second messengers. Increased intracellular calcium can increase the activity of calcium-activated potassium channels, and increased cyclic GMP can activate cyclic nucleotide-gated ion channels. In addition, $\beta\gamma$-subunits released following activation of Gi-family G protein can interact with and regulate ion channel activity. For example, inwardly rectifying potassium channels in the heart are activated in this manner following M_2 mAChR activation.

Mitogen-Activated Protein Kinase (MAPK) and Related Pathways

Muscarinic receptors can mediate regulation of a series of protein kinase cascades implicated in a wide variety of processes, including cell growth, differentiation, and apoptosis. These protein kinase cascades lead to activation of the MAPKs Erk1 and Erk2, p38 kinase, and c-Jun terminal kinase. The particular cascades which are regulated, the mechanisms responsible for this regulation, and whether there is activation or inhibition of a particular kinase pathway depend both on the specific subtype of mAChR and the cell type the receptor is expressed in.

Structural Studies

Transmembrane Topology

Like other members of the GPCR superfamily, the muscarinic receptors are heptahelical, that is, they have seven helical transmembrane domains, with the amino-terminal extracellular and the carboxyl-terminal intracellular. The amino-terminal domains of the various mAChR subtypes contain asparagine residues which are sites for N-linked glycosylation. Based on the crystal structure determined for the prototypical GPCR rhodopsin and on mutagenesis and structural analyses of both the mAChr and other GPCR, it is likely that the transmembrane helices are arranged in a bundle.

Ligand Binding to the mAChR

ACh binds to the mAChR by interacting in a crevice with multiple transmembrane domains in the plane of the membrane. A negatively charged aspartic acid residue in the third transmembrane domain interacts with the positively charged ammonium group of ACh. Mutagenesis experiments have also implicated specific residues in the second, fifth, sixth, and seventh transmembrane domains in the binding of cholinergic ligands.

Regions of the mAChR Involved in Coupling to G Proteins

The binding of ACh to the mAChR induces a conformational change in the receptor which allows it to activate the appropriate G protein(s). The regions responsible for determining the specificity of coupling of the mAChR to G proteins has been determined primarily by construction of chimeric receptors between two mAChR, such as M_2 and M_3, which couple to different G proteins. The membrane proximal portions of the third cytoplasmic loop are the main determinants of the specificity of G protein coupling, although other regions such as the second intracellular domain may also play a role in mAChR-G protein interactions.

Muscarinic Receptor Actions *in vivo*

Muscarinic Receptor Actions in the Periphery

Muscarinic receptors are present in many target organs of the autonomic nervous system. A generalization based on pharmacological and molecular genetic approaches is that the M_2 receptors are present in heart, while the M_3 receptor is present in smooth muscles and exocrine glands, however, this generalization must be tempered by the presence of additional subtypes of mAChR present in low abundance in both cardiac and smooth muscles and by the possibility of differences in subtype expression between different animal species. Muscarinic receptors decrease the rate and force of contraction of the heart, and increase the tone and motility of the gastro-intestinal and urinary tracts. Muscarinic receptors increase secretions from salivary and sweat glands, and cause bronchoconstriction and increased bronchial secretions. Intravenous administration of ACh causes vasodilation. This is due not to activation of mAChR on the smooth muscle cells but to activation of the mAChR on the endothelial cells in the blood vessel. mAChR activation results in the production of NO, which then diffuses out of the endothelial cells and into the smooth muscle cells, resulting in relaxation of the blood vessel.

Muscarinic Receptor Actions in the Central Nervous System

Muscarinic receptors play an important role in the central nervous system. Many studies have implicated mAChR in learning and memory. Administration of muscarinic antagonists interfere with performance in many learning and memory tests, and the decreased cognition in patients with Alzheimer's disease is thought to be due in part to impaired muscarinic transmission. Both pharmacological and genetic experiments have implicated the M_1 mAChR in memory and learning, although it is likely that multiple muscarinic receptor subtypes play a role in these processes.

Muscarinic receptors in the spinal cord and at supraspinal sites (i.e., the brain) can mediate an analgesic response. Genetic studies in mice show that both the M_2 and M_4 receptors are involved in this anti-nociceptive effect.

Muscarinic receptors have been implicated in many other processes as well. For example, muscarinic receptors regulate the function of the basal ganglia, where multiple subtypes of muscarinic receptors modulate dopaminergic signaling. M_5 receptors are present in the ventral tegmentum and are involved in drug reward mechanisms.

Pharmacological analyses carried out over many years have led to the development of a number of drugs which produce their therapeutic actions by either activating or blocking muscarinic receptors. The increased understanding of the actions of individual mAChR subtypes should be a great aid in the development of drugs with increased therapeutic actions while decreasing effects at undesired mAChR subtypes.

Biography

Neil M. Nathanson is a Professor in the Department of Pharmacology, University of Washington School of Medicine. He received the Ph.D. in Biochemistry from Brandies University, and carried out postdoctoral training at the National Institutes of Health and the University of California, San Francisco. His research interests are focused on the regulation of signaling and expression of muscarinic receptors and receptors for neurotrophic factors.

Myosin Motors

Roy E. Larson
University of Sao Paulo, Sao Paulo, Brazil

Movement is a fundamental property of living matter. Specialized molecules with mechano-chemical properties are responsible for cellular motility and its macroscopic manifestations, such as muscle contraction. The myosins make up a large family of molecular motors that feature a conserved mechano-chemical domain, capable of transforming the chemical energy of ATP hydrolysis into the generation of force and movement along filamentous actin tracks. Although first characterized as the molecular power generator of muscle contraction, myosins are now known to be ubiquitous in virtually all mammalian cell types as well as widely distributed amongst eukaryotic organisms, both in plants and animals. They have multifunctional roles in many cellular processes, ranging from cytokinesis and pseudopodia extension to pigment granule transport and cytoplasmic streaming. Over the past 15 years, researchers have identified ~150 myosin genes, making up ~18 distinct structural classes, referred to as myosins I–XVIII, within what is now called the myosin superfamily of molecular motors. Although structural variations amongst the myosins reflect their specific cellular type and function, and also their phylogeny, there is a basic architectural plan followed by these motors.

Overall Molecular Architecture

The protein structure of myosins can be divided into three principal structural and functional domains. The highly conserved, mechano-chemical generator, usually referred to as the "head domain," is almost universally positioned at the amino terminal portion of the protein and contains the actin-binding and adenosine triphosphate (ATP) hydrolysis sites (Figure 1). The crystal structures have been determined from at least five myosins, widely distant on the evolutionary scale (vertebrate skeletal and smooth muscle myosin, slime mold myosin, scallop muscle myosin, and vertebrate class V myosin), which revealed very similar atomic structures amongst them, indicating that the basic machinery for movement has been highly conserved. Immediately following the head domain is an elongated, α-helical region to which calmodulin and/or calmodulin-like light chains bind, forming the regulatory or "neck domain" (Figure 1). This domain acts as a lever arm to amplify small movements in the head domain. In several myosins the neck domain inhibits the mechano-chemical cycle and thus acts as the regulatory element that triggers the mechano-chemical events when this inhibition is released by factors, such as calcium binding to or phosphorylation of the light chains. The rest of the molecule is referred to as the "tail domain" and is the most structurally diverse part, varying extensively between classes, yet maintaining significant homology within a class. The tail domains are regions of interaction with lipid membranes, proteins, and signaling molecules, important for site recognition, receptor binding, and specific functions. Many myosins are dimerized via the formation of intertwined α-helices, referred to as coiled coils (Figure 2). The prime example is skeletal muscle myosin II whose tail domain is completely composed of a coiled-coil motif, which aligns and joins together with other tail domains to form the bipolar thick filaments of the sarcomere. The myosin II class is often referred to as "conventional" myosin due to its historical identification and characterization. However, it is now viewed as being quite unique in that no other class within the myosin superfamily is known to organize into filaments. Clearly the myosins II have been refined by evolution, culminating in their role in the generation of macroscopic force and velocity of skeletal muscle contraction. The tail domains of all other myosins have globular regions, and are without the propensity for filament formation, although they may or may not form coiled coils and, thus, can exist as monomeric or dimeric structures (Figure 2).

Evolutionary Diversity and Phylogenic Classification

With the advent of DNA sequencing, ~18 classes of myosin genes have been identified based on comparisons of the amino acid sequences of the head domains, even though this domain is highly conserved across the board for the myosin superfamily. On the other hand, the tail domains are quite unique for each myosin class,

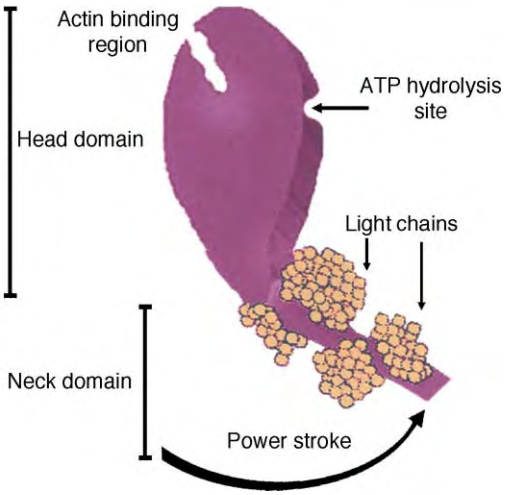

FIGURE 1 Schematic diagram of the head and neck domains of myosin showing the relative positions of the actin-binding region to the ATP site and to the light chains in the neck domain. The rotation of the neck domain which represents the power stroke is indicated as a curved arrow. (Drawn by Silvia Andrade.)

indicating that evolution selected a tail-domain design for the specific cellular function(s) of that particular myosin class. Phylogenetic analysis of the head sequences also indicated that myosins diversified quite early in eukaryotic evolution. Curiously, myosin precursors have not been identified in prokaryotes. It is tempting to speculate that the appearance of myosin motors with their diversity of tails was an evolutionary innovation that furnished impetus for eukaryotic cells to experiment and gain new niches.

Mechano-Chemical Features and Regulation

A description of the molecular mechanism of energy transduction by mechanoenzymes has been a challenge for workers in the field for half a century. The determination, during the last decade, of the atomic structures of myosin in several conformational states with nucleotide derivatives bound has brought this goal close to realization. An overall description of the molecular events taking place during the mechano-chemical cycle, which lead to movement and force generation, is given here. There are three elements to keep in mind: first, ATP binds to the myosin head domain at an active site capable of hydrolyzing it to adenosine diphosphate (ADP) and inorganic phosphate (Pi); second, myosin binds to filamentous actin (F-actin) either strongly or weakly depending on the molecular conformation of the myosin; third, conformational changes in myosin structure occur depending on the nucleotide occupying the active site. Beginning with the binding of ATP to the nucleotide-binding site in the head domain of myosin, this event puts the myosin in a weak F-actin-binding conformation, i.e., most of the myosin is not bound to F-actin. Myosin quickly hydrolyzes the ATP; however, the hydrolysis products, ADP and Pi, are only slowly released from the active site. The energy of ATP binding and hydrolysis is conserved in the high-energy conformation of the myosin at this point, which is considered to be the fully cocked state. The slow release of products from the active site dissipates this conformational energy and puts myosin into its lowest energy state, ready for the binding of another ATP molecule. In the absence of F-actin the energy of this conformational change from the high to low energy state is dissipated as heat. However, when F-actin is bound to myosin, the rate of release of ADP and/or Pi dramatically increases, while the myosin is converted to its strong F-actin-binding conformation. Thus, when F-actin is present, the conformational change in the myosin molecule associated with product release occurs simultaneously with tight coupling to F-actin and, rather than being immediately dissipated as heat, is now converted to tension development and work. The exact conformational change that occurs, referred to as the "power stroke," is a rotation of ~90° of the myosin neck domain relative to the F-actin orientation (see Figure 1). Thus, for native muscle myosin with the neck domain connected to its tail domain that, in turn, is embedded in a thick filament, the power stroke will move the thick filament relative to the actin filament. A return to the weak binding state and disassociation of myosin from F-actin occurs with the rebinding of ATP to the nucleotide site, thus initiating a new cycle. In summary, the mechano-chemical cycle results from the tight coupling of protein conformational energy in the myosin head and neck domains with chemical energy (ATP binding and hydrolysis) and cyclic transitions between strong and weak binding between myosin and F-actin. As presented, this cycle will continue as long as myosin can contact actin and a steady

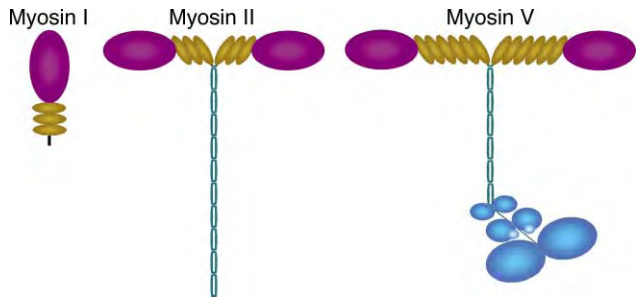

FIGURE 2 Schematic diagram of three typical myosins representing classes I, II, and V. supply of ATP is maintained. (n.b. *Rigor mortis* results from the interruption of the metabolic supply of ATP that comes with death and represents the strong binding, low-conformational energy state of the actomyosin in muscle at the end of the power stroke).

As with any motor, it is desirable to be able to turn the myosin mechano-chemical cycle on and off, depending on need. There are several mechanisms to do this, most of which use calcium ion as the triggering element. For example, in striated muscles a calcium-sensitive system of regulator proteins decorates F-actin and sterically blocks access of the myosin head to the actin sites. Calcium relieves this blockage, such that an increase in its intracellular concentration determines actomyosin activation. For molluscan myosin and vertebrate smooth muscle myosin, regulation is myosin-based, in that an inhibitory effect of the neck domain can be relieved by calcium binding to a light chain or by calcium-activated phosphorylation. For other myosins the mechanisms of regulation are less well understood, although calcium and/or phosphorylation most likely play a role.

A Multitude of Cellular Functions

Simplistically, myosins have two functional ends: the motor end, which generates force and movement on actin filaments, and the tail end, which links it to its cargo or, as in the special case of muscle, to itself forming bipolar filaments. Surprisingly, in spite of their highly conserved structure, the myosin heads differ in a fundamental property related to their mechano-chemical cycle, which affects their cellular function. Individual myosin II molecules bind to actin for only a small fraction of the cycle duration. This property is essential for the smooth sliding of myosin filaments in muscle with their arrays of many heads interacting with the organized actin filaments of the sarcomere. On the other hand, at least two myosins (a class V and a class VI myosin) have the property of "processivity," i.e., they are able to move as individual molecules along actin filaments for some distance without losing contact. Present evidence indicates that these two-headed myosins walk in a "hand-over-hand" manner along the actin filament, each head binding to actin for more than 50% of the cycle duration. This property, therefore, allows these myosins, acting alone, to carry cargo without losing a grip on the actin track.

The tail domain determines the enormous diversity of function within the myosin superfamily and dictates the specific function of each myosin. To exemplify this diversity, it is noted that in a single vertebrate cell type – the human intestinal epithelial cell – there have been identified at least 12 myosins, representing 6 classes. Sorting out the specific functions of individual myosins and myosin classes has been a formidable challenge to researchers in the field. The involvement of myosins in three general areas has been described: membrane-associated movements, intracellular vesicle and particle transport, and intracellular signaling. Besides their role in contraction of muscle cells, myosins are involved in amoeboid movements, pseudopodia extensions, phagocytosis, exocytosis, cytokinesis, cell gliding over a surface, and other manifestations of plasma membrane dynamics. The myosins of class II, which include the muscle myosins, are one of the principal actors in these processes, due in part to their tail's ability to form bipolar filaments and thus generate constrictive forces. Also, however, the single-headed, class I myosins are involved in membrane interactions due to the phospholipid-binding regions in their tail domains, thus giving them the ability to orient force generation directly toward membranes.

Many examples of intracellular vesicle and organelle transport that depend on myosin motors have been found. The dramatic cytoplasmic streaming in plants is a good example. This process involves class XI myosins, one of only two classes found in plants (the other is class VIII). Mutations in class V myosins result in defective distribution of pigment granules in melanocytes of vertebrates and of membrane vesicles in dividing yeast. Several linker proteins have been described that connect myosin motors to their cargo, such as melanophilin and Rab27a, which link pigment granules to myosin V, and Vac17p, a key component of the myosin receptor on yeast vacuoles. The demonstration in squid axoplasm of translocation of moving vesicles from microtubule tracks to actin filaments suggested that organelle transport involves cooperative interactions between microtubule- and actin-based systems. These examples serve to illustrate that myosin motors have important roles in the transport of membrane delimited organelles, but attention has been given to recent evidence that myosins also transport macromolecular complexes. Myo4p, a class V myosin in yeast, is directly involved, together with at least two other proteins, in the transport of a specific mRNA, encoding a transcription factor, to the daughter cell of budding yeast, thus playing an essential role in regulation of differential gene expression in these organisms.

Being molecular effectors, one may expect that myosins are end-targets for cell signaling. As previously discussed, myosins bind to calmodulin and are indeed activated or modulated by ionic calcium and protein kinases, all of which are important intracellular messengers for signal transduction pathways. However, it is noteworthy that myosins also seem to participate in the signaling pathways themselves, as a kind of motorized signaling devise. Evidence for this first appeared upon analysis of the tail sequences, where sequence motifs related to cell signaling pathways, such as the SH3, PDZ, and PH motifs, were recognized in several distinct

myosin classes. These motifs are signals for protein–protein and protein–phosphoinositide binding that participate in the assembly of signaling complexes, although the functional role of myosins containing these signal motifs is still not clear. The tail domain of myosins IX has a region with homology to GTPase-activating proteins (GAPs), which act as molecular switches in the organization of the actin cytoskeleton, particularly in the formation of cell–matrix focal adhesions. Overexpression of a myosin IX in HeLa cells caused the cells to lose actin filament organization and substrate contact, resulting in their rounding up and release from the substrate. These examples illustrate that myosins are not only final targets for cellular signaling, but potential intermediate players in the signaling cascades. Myosins are involved in other cell processes in ways not well understood, such as mitotic spindle orientation in yeast, phototransduction in *Drosophila* retina and auditory function of the vertebrate inner ear. There is much to be learned about the functional roles of myosin motors throughout the biosphere.

Myosins in Disease

The human genome has ~40 myosin genes, composing 12 classes. As described above, myosins are fundamentally important in many cellular processes and thus would be expected to underlie cellular dysfunction in human disease. In fact, several myosins have been identified as the causes of hereditary diseases. A major cause of familial hypertrophic cardiomyopathy lies in mutations of the head domain of cardiac muscle myosin II. Usher syndrome, the most common cause of inherited deaf–blindness in children, has been linked to mutations in myosin VII. Also, mutations in myosin XV have been identified in human nonsyndromic deafness; and in myosin VI in the Snell's Waltzer mouse, which suffers from deafness due to degeneration of the sensory neuroepithelia in the inner ear. Thus, different myosin classes have important roles that converge in the auditory system. In Griscelli syndrome, where children exhibit hair hypopigmentation, linked to severe immunological and neurological deficits that frequently lead to early death, mutations have been identified in myosin V or Rab27a, a protein that links myosin V to organelles. It is likely that more connections will be made between human disease and myosin function as genetic probes and analyses increase.

Biography

Roy E. Larson is a Professor and Chairman of the Department of Cellular and Molecular Biology and Pathogenic Bioagentes at the Faculdade de Medicina de Ribeirao Preto, Universidade de Sao Paulo, Brazil. He holds a Ph.D. in molecular biology from the University of Pennsylvania and received his postdoctoral training at Yale University. His principal research interests are in cytoskeletal dynamics. He initially purified and identified myosin V from vertebrate brain and was instrumental in its biochemical and structural characterization.

Editors-in-Chief

William J. Lennarz

State University of New York at Stony Brook, Stony Brook, New York, USA

Section: Lipids, Carbohydrates, Membranes and Membrane Proteins

WILLIAM J. LENNARZ received his B.S. in Chemistry from Pennsylvania State University and a Ph.D. in Organic Chemistry from the University of Illinois. Subsequently he carried out postdoctoral work at Harvard with Konrad Bloch on fatty acid biosynthesis. In 1962 he was appointed Assistant Professor at Johns Hopkins in the Department of Physiological Chemistry. After promotion to Associate Professor in 1967, and full Professor in 1971, he remained at Hopkins until 1983. At that time, he was appointed Robert A. Welch Professor and Chair of the Department of Biochemistry and Molecular Biology at the University of Texas Cancer Center, M.D. Anderson Hospital. In 1989 he became a Leading Professor and Chair of the Department of Biochemistry and Cell Biology at SUNY at Stony Brook. In 1990 he founded and became Director of the Institute for Cell and Developmental Biology at Stony Brook.

Dr. Lennarz has served on many national and international committees. He has served as President of the Biochemistry Chairman's Organization, President of the American Society for Biochemistry and Molecular Biology and President of the Society for Glycobiology. He was a member of the Executive Committee of the International Union of Biochemistry and Molecular Biology for almost a decade.

He has presented special lectures at the University of Notre Dame, the NIH, the University of West Virginia, Johns Hopkins University, Florida State University, the University of California at San Diego, the University of Arkansas, Indiana University and the Medical College of Virginia.

He is a member of the National Academy of Sciences. The focus of his early work was on lipids and bacterial cell surfaces. More recent efforts have been in the structure, biosynthesis and function of cell surface glycoproteins. The biosynthesis studies initially were carried out in liver and oviduct, but these efforts now are focused in yeast. The functional studies have concentrated on the role of cell surface glycoproteins in fertilization and early development in the sea urchin and, more recently, the frog. For over 30 years Dr. Lennarz' research has been supported by federal sources, primarily the National Institutes of Health. Recently he was appointed Distinguished Professor and Chair of his department.

M. Daniel Lane

The Johns Hopkins University, School of Medicine, Baltimore, Maryland, USA

Section: Metabolism, Vitamins and Hormones

M. DANIEL LANE received B.S. and M.S. degrees in 1951 and 1953 from Iowa State University and a Ph.D. in 1956 from the University of Illinois. He was a Senior Postdoctoral Fellow with Professor Feodor Lynen at the Max-Planck Institute Fur Zellchemie in Munich. Following faculty positions at Virginia Polytechnic Institute and New York University School of Medicine, he joined the faculty at the Johns Hopkins University School of Medicine in 1969 and served as DeLamar Professor and Director of the Department of Biological Chemistry from 1978 to 1997. He is presently Distinguished Service Professor at Johns Hopkins. In 2002 he received an honorary degree, Doctor of Humane Letters, from Iowa State University.

Dr. Lane was elected to membership in the National Academy of Sciences (in 1987) and was elected as a Fellow of the American Academy of Arts and Sciences (in 1982) and of the American Society of Nutritional Sciences (in 1996). He received the Mead Johnson Award from the American Society for Nutritional Sciences in 1966 for his research on biotin-dependent enzymes and in 1981, the William C. Rose Award from the American Society for Biochemistry and Molecular Biology for his work on the insulin receptor. In 1990–1991 Lane served as President of the American Society of Biochemistry and Molecular Biology. He has presented many named lectureships (including the

Feodor Lynen Lecture in Germany in 1999) and served on numerous editorial boards including the Journal of Biological Chemistry and the Annual Reviews of Biochemistry. Currently he is Associate Editor for Biochemical and Biophysical Research Communications.

Dr. Lane has published 280 research papers in major scientific journals. His early work focused on various enzymatic CO_2 fixation reactions, notably the mechanisms by which the B-vitamin, biotin, functions in enzymes to catalyze carboxylation. Dr. Lane's work on the regulation of acetyl-CoA carboxylase, the key regulatory enzyme of fatty acid synthesis, led him to his present interests which are to understand the basic mechanisms of lipogenesis, adipogenesis and the consequence of aberrations in these processes, most notably obesity. Research currently underway in his laboratory focuses on: (1) the genes that signal stem cell "commitment" to the adipocyte lineage and subsequent differentiation into adipocytes, and (2) the mechanisms by which the region of the brain, known as the hypothalamus, monitors and controls the drive to eat.

Associate Editors

Ernesto Carafoli

Università degli Studi di Padova, Padova, Italy
Section: Bioenergetics

ERNESTO CARAFOLI earned his M.D. degree at the University of Modena in Italy in 1957. After postdoctoral studies in the Laboratory of Albert L. Lehninger at Johns Hopkins University in the mid 1960s he returned to his home institution in Italy where he worked until 1973, when he was appointed Professor of Biochemistry at the Swiss Federal Institute of Technology (ETH) in Zurich. He returned to Italy in 1998 as a Professor of Biochemistry at the University of Padova, where he now also directs the newly founded Venetian Institute of Molecular Medicine (VIMM).

Dr. Carafoli became interested in calcium as a signaling agent during his post-doctoral days at Johns Hopkins. When he arrived there his main interests were in mitochondrial bioenergetics and it was thus natural for him to expand them to the newly discovered area of mitochondrial calcium transport. He was involved in most of the early discoveries in the field, and he continued to work on mitochondria and calcium after his return to Italy and until he moved to the ETH. There his interests still remained focused on calcium, but the emphasis shifted to the proteins that transport it across membranes and to those that process its signal. His favorite object of study became the calcium pumps, especially that of the plasma membrane, an enzyme which is essential to the regulation of calcium homeostasis and thus to the well being of cells. His contributions on the enzyme, especially after he purified it in 1979, have helped establishing most of its properties and have clarified important problems of mechanism, regulation and structure.

Dr. Carafoli has authored or co-authored about 450 peer-reviewed articles and reviews, and has edited or co-edited about 20 books. He has served on the Editorial or Advisory Boards of several periodicals and has organized about 30 International Workshops and Symposia. He has been featured as a plenary or honorary lecturer at numerous events ranging from specialized Workshops to International Symposia and Congresses. Dr. Carafoli's honors and awards include several international prizes and medals, memberships in several Academies, and three honorary degrees.

Don W. Cleveland

University of California, San Diego, La Jolla, CA, USA
Section: Cell Architecture and Function

DON W. CLEVELAND has been a longstanding contributor to the elucidation of regulation of assembly of mitotic spindles and chromosome movement and how errors in these contribute to the chromosome loss characteristic of human tumors. He discovered the tubulin gene families encoding the major subunits of microtubules and the first mammalian example of control of gene expression through regulated RNA instability. He identified components required for microtubule nucleation and anchoring during spindle assembly. He identified the first human centromeric protein (CENP-B). He then discovered CENP-E, the centromere-associated, microtubule-motor that he showed to be essential for chromosome attachment and for activation and silencing of the mitotic checkpoint, the cell cycle control mechanism that prevents errors of chromosome segregation in mitosis.

Dr. Cleveland has also been a leading force in dissecting the disease mechanism for major human neurodegenerative disorders. He initially purified and characterized tau, the microtubule-associated protein that assembles aberrantly in human dementias including Alzheimer's disease and Pick's disease. He established that the extreme asymmetry of neurons acquired during development is achieved with a deformable array of interlinked neurofilaments, microtubules and actin. He showed that disorganization of neurofilament arrays caused selective death of motor neurons in mice and humans. He also demonstrated that neuronal death could also arise by a toxicity of mutant superoxide dismutase unrelated to its normal activity, thereby uncovering the mechanism underlying the major genetic form of amyotrophic lateral sclerosis. He showed that this toxicity could be

sharply ameliorated by lowering the content of neurofilaments.

Dr. Cleveland is currently Head, Laboratory for Cell Biology in the Ludwig Institute for Cancer Research and Professor of Medicine, Neurosciences and Cellular and Molecular Medicine at the University of California at San Diego. He is also the Editor of the Journal of Cell Biology and Current Opinion in Cell Biology.

Jack E. Dixon

University of California, San Diego School of Medicine,
La Jolla, CA, USA
Section: Protein/Enzyme Structure, Function, and Degradation

JACK E. DIXON earned his Ph.D. in Chemistry at the University of California, Santa Barbara in 1971 and did his postdoctoral training in Biochemistry at the University of California, San Diego.

Dr. Dixon is a pioneer and leader in the structure and function of the protein tyrosine phosphatases (PTPases). He demonstrated that the unique catalytic mechanism of the PTPases proceeds via a novel cysteine-phosphate intermediate. He discovered the first dual-specificity phosphatase, which led to the identification of the cell cycle protein, $p80^{cdc25}$, as a phosphatase. He also showed that the bacteria responsible for the plague or "black death" harbor the most active PTPase ever described. He and his colleagues went on to demonstrate that this PTPase gene product is essential for the pathogenesis of the bacteria. Dr. Dixon and his colleagues determined X-ray structures for both tyrosine and dual specificity phosphatases. Dr. Dixon also found that sequences outside of the PTPase catalytic domain could function to direct the subcellular localization of the PTPases and to restrict their substrate specificity. This is now a widely acknowledged regulatory paradigm for the PTPases. Recently, his laboratory demonstrated that the tumor suppressor gene, PTEN, which shares sequence identity with the PTPases, catalyzes the dephosphorylation of a lipid second messenger, phosphatidylinositol 3,4,5-trisphosphate (PIP3). This represents the first example of a PTPase dephosphorylating a lipid second messenger. PIP3 activates the protein kinase, AKT, which plays a critical role in controlling the balance between apoptosis and cell survival. The loss of the PTEN gene elevates PIP3 levels leading to constitutive activation by AKT and oncogenesis. Recently, Dr. Dixon in collaboration with Nikola Pavletich determined the X-ray structure of PTEN. Their structure–function studies explain the PIP3 substrate specificity of PTEN and also provide a rationale for many of the mutations seen in human cancers. Earlier in his career, Dr. Dixon adopted the tools of molecular biology as they became available in the 1970s, and his laboratory was among the first to use synthetic oligonucleotides to isolate and extensively characterize cDNAs encoding peptide hormones.

Dr. Dixon is Professor of Pharmacology, Cellular and Molecular Medicine and Chemistry and Biochemistry and Dean of Scientific Affairs at the University of California, San Diego. He is a member of the National Academy of Sciences, the Institute of Medicine and the American Academy of Arts and Sciences. Dr. Dixon was the recipient of the 2003 William C. Rose Award from the American Society for Biochemistry and Molecular Biology.

John H. Exton

Howard Hughes Medical Institute, Vanderbilt University School of Medicine, Nashvillie, TN, USA
Section: Signaling

JOHN H. EXTON was born and educated in New Zealand where he received his medical training and a Ph.D. in Biochemistry from the University of Otago in 1963. He did postdoctoral work at Vanderbilt University under Charles R. Park and Earl W. Sutherland, and became an Investigator of the Howard Hughes Medical Institute in 1968 and Professor of Physiology in 1970. He is presently Professor of Molecular Physiology and Biophysics, Professor of Pharmacology and a Hughes Investigator at Vanderbilt.

Dr. Exton's research initially focused on the changes in carbohydrate metabolism in liver during diabetes and treatment with various hormones using the perfused rat liver as the experimental system. His work concentrated on gluconeogenesis and identified the enzymatic reactions that were under control by insulin, epinephrine (adrenaline), glucagon and glucocorticoids, and demonstrated the importance of cyclic AMP in the regulation of these reactions. The role played by the supply of substrates, especially of alanine, was also shown.

Dr. Exton then turned his attention to the action of epinephrine (adrenaline) and demonstrated that many of its actions were not mediated by cyclic AMP but by calcium ions. This led to study of the breakdown of inositol phospholipids by phospholipase C that underlay the increase in calcium. Later this resulted in the discovery of G_q, a novel G protein that activated phospholipase C. Further studies demonstrated that agonists caused the breakdown of another phospholipid (phosphatidylcholine) by another phospholipase (phospholipase D). Current work is focused on the physiological role of phospholipase D.

Dr. Exton has authored over 350 scientific articles and is presently an Associate Editor of the Journal of Biological Chemistry. He has served on many scientific review groups and as a reviewer for many journals. He has won numerous awards, most notably the Lilly

Award of the American Diabetes Association, Fellow of the American Association for the Advancement of Science and election to membership in the National Academy of Sciences.

Paul Modrich

Duke University Medical Center, Durham, NC, USA
Section: Molecular Biology

PAUL MODRICH is an Investigator of the Howard Hughes Medical Institute and James B. Duke Professor of Biochemistry at Duke University Medical Center. He received his undergraduate degree from M.I.T. and his Ph.D. in Biochemistry from Stanford University. His current research addresses the mechanisms of DNA repair. He has served on the editorial boards of the Journal of Biological Chemistry, Biochemistry, Proceedings of the National Academy of Sciences, and DNA Repair. His honors include election to National Academy of Sciences and the Institute of Medicine, the Pfizer Award in Enzyme Chemistry, the General Motors Mott Prize in Cancer Research, and the Pasarow Foundation Award in Cancer Research.

Preface

Biological Chemistry is defined as the chemistry of the compounds and processes that constitute living organisms. The ultimate goal, of course, is to understand and define biology at a mechanistic level. This was aptly stated in an historical treatise on the founding of the *Journal of Biological Chemistry*, where John Edsall quoted a statement in a letter from J. L. Loeb (in Berkeley), "The future of biology lies with those who attack its problems from a chemical point of view." What was an emerging field in 1900 with its origins in physiology, nutrition and chemistry has broadened and expanded to include numerous other fields including mechanistic enzymology, molecular biology, structural biology, cell biology, genomics, proteomics, bioinformatics, metabolomics and others, that were not defined as discrete fields at that time.

Modern biochemistry (biological chemistry) began with the accidental discovery by Eduard Buchner in 1897 that a cell-free yeast extract could carry out fermentation of glucose to alcohol and CO_2 *in the absence of intact cells*. He named the dissolved substance responsible for this process zymase, the substance(s) we now refer to as enzymes. Importantly, Buchner recognized the significance of his discovery. This ended the dogma of the time, perpetuated by Pasteur, the concept of *vitalism*; i.e., that fermentation (and presumably other complex biological phenomena) required the action of intact cells. Thus, serendipity and a prepared mind ushered in a new era of discovery. Now it became possible to dissect complex physiological processes and to study them with preparations free of the constraints of intact cells. Once a metabolic pathway/process was established, it became possible to purify the enzymes, cofactors and substrates involved, to reconstitute the process with purified components and to characterize the components chemically. What followed was an information explosion in the field of biochemistry and progression through a series of trends, each "in vogue" in its time. The identification of the dietary essentials, the hunt for the vitamins/cofactors, the hormones, identification of metabolic pathways and the enzymes involved, oxidative phosphorylation, protein synthesis, molecular biology—each developed as a primary focus.

The need to associate chemistry with function came early and was evident in the naming of departments and journals. Over time names changed from Agricultural Chemistry to Physiological Chemistry to Biochemistry to Biological Chemistry. An example is the Department of Biochemistry at the University of Wisconsin, which began in 1883 as the Department of Agricultural Chemistry.

Where are we headed? We have reached the point where the borders of these areas have become blurred. What constitutes cell biology, molecular biology/genetics, developmental biology, physiology, immunology—ultimately reduces to chemistry. To understand these processes we must know what the molecules are and understand how they interact, i.e. the basic chemistry. That is what this encyclopedia is about.

The breadth of content of this encyclopedia aims to cover major topics of modern biochemistry, each authored by an expert in the area. We feel that the coverage is broad and we have been inclusive in choice of topics. The encyclopedia is a reference work encompassing four volumes containing over 500 articles with more than 750 authors or coauthors. Each article/topic covers an important area of the field which reflects the point of view of the authors. Together the articles cover virtually every aspect of biology for which we have "mechanistic" information. For those who wish to probe more deeply into a topic, references to further readings are included at the end of each article. The editorial board that made decisions on coverage consists of seven members, each an expert representing a major area in the field of biochemistry. A dedicated effort was made to provide coverage that is as complete as possible. The content is presented at a level that we hope will be interpretable to interested individuals with some background in chemistry and biology. It is intended for such individuals rather than specialists with extensive scientific backgrounds in specific areas. It is aimed at the generalist as opposed to the specialist.

Finally, we would like to single out Gail Rice and Dr. Noelle Gracy for their enormous contribution in putting this encyclopedia together. They, in fact, were a driving force that brought this major work to completion.

Notes on the Subject Index

Abbreviations used in subentries without explanation:

CoA	coenzyme A
DAG	diacylglycerol
ELISA	enzyme-linked immunosorbent assay
ERK	extracellular-signal regulated kinase
GlcNAC	N-Acetylglucosamine
HPLC	high-pressure liquid chromatography
IP_3	inositol 1,4,5-triphosphate
MAP	mitogen-activated protein
MMP	matrix metalloproteinase
mtDNA	mitochondrial DNA
NADPH	nicotinamide-adenine dinucleotide phosphate
PFK-2/ FBPase-2	6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase
PI3K	phosphatidylinositol 3-kinase
PIP_2	phosphatidylinositol 4,5-bisphosphate
PIP_3	phosphatidylinositol-3,4,5-triphosphate
PPAR	peroxisome proliferator-activated receptor
RPLC	reversed-phase high-performance liquid chromatography

Volume 1

ABC Transporters, Pages 1-5, Andre Goffeau, Benoit De Hertogh and Philippe V. Baret

Abscisic Acid (ABA), Pages 6-11, Ramanjulu Sunkar and Jian-Kang Zhu

Actin Assembly/Disassembly, Pages 12-18, Henry N. Higgs

Actin-Capping and -Severing Proteins, Pages 19-26, Sankar Maiti and James R. Bamburg

Actin-Related Proteins, Pages 27-33, R. Dyche Mullins

Adenosine Receptors, Pages 34-39, Lauren J. Murphree and Joel Linden

Adenylyl Cyclases, Pages 40-45, Ronald Taussig

Adrenergic Receptors, Pages 46-50, David B. Bylund

Affinity Chromatography, Pages 51-56, Pedro Cuatrecasas and Meir Wilchek

Affinity Tags for Protein Purification, Pages 57-63, Joseph J. Falke and John A. Corbin

A-Kinase Anchoring Proteins, Pages 64-67, Lorene K. Langeberg and John D. Scott

Allosteric Regulation, Pages 68-73, Barry S. Cooperman

Alternative Splicing: Regulation of Fibroblast Growth Factor Receptor (FGFR), Pages 74-77, Mariano A. Garcia-Blanco

Alternative Splicing: Regulation of Sex Determination in Drosophila melanogaster, Pages 78-84, Jill K. M. Penn, Patricia Graham and Paul Schedl

Amine Oxidases, Pages 85-89, Giovanni Floris and Alessandro Finazzi Agro

Amino Acid Metabolism, Pages 90-95, Luc Cynober

Aminopeptidases, Pages 96-98, Ralph A. Bradshaw

Amyloid, Pages 99-104, Ronald Wetzel

Anaplerosis, Pages 105-110, Raymond R. Russell, III and Heinrich Taegtmeyer

Angiotensin Receptors, Pages 111-115, Tadashi Inagami

ara Operon, Pages 116-119, Robert F. Schleif

ARF Family, Pages 120-122, Gustavo Pacheco-Rodriguez, Joel Moss and Martha Vaughan

Aspartic Proteases, Pages 123-127, Ben M. Dunn

ATP Synthesis in Plant Mitochondria: Substrates, Inhibitors, Uncouplers, Pages 128-132, Kathleen L. Soole and R. Ian Menz

ATP Synthesis: Mitochondrial Cyanide-Resistant Terminal Oxidases, Pages 133-137, James N. Siedow

Autophagy in Fungi and Mammals, Pages 138-143, Daniel J. Klionsky and Ju Guan

B12-Containing Enzymes, Pages 145-151, Vahe Bandarian and Rowena G. Matthews

Bax and Bcl2 Cell Death Enhancers and Inhibitors, Pages 152-154, David L. Vaux

B-Cell Antigen Receptor, Pages 155-158, Thomas M. Yankee and Edward A. Clark

Bile Salts and their Metabolism, Pages 159-163, Ulrich Beuers and Thomas Pusl

Biliary Cirrhosis, Primary, Pages 164-169, Marshall M. Kaplan

Bioenergetics: General Definition of Principles, Pages 170-173, David G. Nicholls

Biotin, Pages 174-178, Steven W. Polyak and Anne Chapman-Smith

Biotinylation of Proteins, Pages 179-181, Ronald A. Kohanski

Bradykinin Receptors, Pages 182-185, Ronald M. Burch

Branched-Chain -Ketoacids, Pages 186-191, David T. Chuang

Brassinosteroids, Pages 192-197, Steven D. Clouse

Cadherin Signaling, Pages 199-204, David B. Sacks and Jonathan M. G. Higgins

Cadherin-Mediated Cell-Cell Adhesion, Pages 205-211, Frauke Drees and W. James Nelson

Calcitonin Gene-Related Peptide and Adrenomedullin Receptors, Pages 212-216, Debbie L. Hay, Alex C. Conner and David R. Poyner

Calcitonin Receptor, Pages 217-220, Samia I. Girgis, Niloufar Moradi-Bidhendi, Lucia Mancini and Iain MacIntyre

Calcium Buffering Proteins: Calbindin, Pages 221-225, Willi Hunziker and Igor Bendik

Calcium Buffering Proteins: ER Luminal Proteins, Pages 226-230, Jody Groenendyk and Marek Michalak

Calcium Oscillations, Pages 231-234, Marisa Brini

Calcium Sensing Receptor, Pages 235-240, Jacob Tfelt-Hansen and Edward M. Brown

Calcium Signaling: Calmodulin-Dependent Phosphatase, Pages 241-245, Claude Klee, Hao Ren and Shipeng Li

Calcium Signaling: Cell Cycle, Pages 246-249, Luigia Santella

Calcium Signaling: Motility (Actomyosin-Troponin System), Pages 250-255, Takeyuki Wakabayashi and Setsuro Ebashi

Calcium Signaling: NO Synthase, Pages 256-260, Zhi-Qiang Wang and Dennis J. Stuehr

Calcium Transport in Mitochondria, Pages 261-266, Rosario Rizzuto and Marisa Brini

Calcium Waves, Pages 267-269, Lionel F. Jaffe

Calcium, Biological Fitness of, Pages 270-273, Robert J. P. Williams

Calcium/Calmodulin-Dependent Protein Kinase II, Pages 274-280, Andy Hudmon and Howard Schulman

Calcium/Calmodulin-Dependent Protein Kinases, Pages 281-286, J. Robison and Roger J. Colbran

Calcium-Binding Proteins: Cytosolic (Annexins, Gelsolins, C2-Domain Proteins) , Pages 287-293, Joachim Krebs

Calcium-Modulated Proteins (EF-Hand), Pages 294-299, Robert H. Kretsinger

Calpain, Pages 300-306, Hiroyuki Sorimachi and Yasuko Ono

Carbohydrate Chains: Enzymatic and Chemical Synthesis, Pages 307-313, Thomas J. Tolbert and Chi-Huey Wong

Carnitine and -Oxidation, Pages 314-318, Janos Kerner and Charles L. Hoppel

Caspases and Cell Death, Pages 319-327, Don W. Nicholson, Pierluigi Nicotera and Gerry Melino

Cell Cycle Controls in G1 and G0, Pages 328-331, WengeShi and Steven F. Dowdy

Cell Cycle: Control of Entry and Progression Through S Phase, Pages 332-337, Susan L. Forsburg

Cell Cycle: DNA Damage Checkpoints, Pages 338-344, Jean Y. J. Wang

Cell Cycle: Mitotic Checkpoint, Pages 345-351, Tim J. Yen

Cell Death by Apoptosis and Necrosis, Pages 352-355, Pierluigi Nicotera

Cell Migration, Pages 356-361, J. Victor Small and Emmanuel Vignal

Cell-Matrix Interactions, Pages 362-366, Janet A. Askari and Martin J. Humphries

Centromeres, Pages 367-371, Beth A. Sullivan

Centrosomes and Microtubule Nucleation, Pages 372-376, Reiko Nakajima, Ming-Ying Tsai and Yixian Zheng

c-fes Proto-Oncogene, Pages 377-382, Thomas E. Smithgall and Robert I. Glazer

Chaperones for Metalloproteins, Pages 383-386, Valeria C. Culotta and Edward Luk

Chaperones, Molecular, Pages 387-392, Sue Wickner and Joel R. Hoskins

Chaperonins, Pages 393-398, Arthur L. Horwich, Wayne A. Fenton and George W. Farr

Chemiluminescence and Bioluminescence, Pages 399-404, Thomas O. Baldwin

Chemiosmotic Theory, Pages 405-412, Keith D. Garlid

Chemokine Receptors, Pages 413-418, Ann Richmond and Guo-Huang Fan

Chemolithotrophy, Pages 419-424, Alan B. Hooper

Chemotactic Peptide/Complement Receptors, Pages 425-429, Eric R. Prossnitz and Larry A. Sklar

Chlorophylls and Carotenoids, Pages 430-437, Hugo Scheer

Chloroplast Redox Poise and Signaling, Pages 438-445, John F. Allen

Chloroplasts, Pages 446-450, Nicoletta Rascio

Cholesterol Synthesis, Pages 451-455, Peter A. Edwards

Chromatin Remodeling, Pages 456-463, Eric Kallin and Yi Zhang

Chromatin: Physical Organization, Pages 464-468, Christopher L. Woodcock

Chromosome Organization and Structure, Overview, Pages 469-474, Elena Gracheva and Sarah C. R. Elgin

Coenzyme A, Pages 475-477, M. Daniel Lane

Collagenases, Pages 478-481, Kenn Holmbeck and Henning Birkedal-Hansen

Collagens, Pages 482-487, Darwin J. Prockop

Cyclic AMP Receptors of Dictyostelium, Pages 488-493, Dale Hereld and Peter N. Devreotes

Cyclic GMP Phosphodiesterases, Pages 494-500, Sharron H. Francis and Jackie D. Corbin

Cyclic Nucleotide Phosphodiesterases, Pages 501-505, Vincent C. Manganiello and Eva Degerman

Cyclic Nucleotide-Dependent Protein Kinases, Pages 506-511, Sharron H. Francis and Jackie D. Corbin

Cyclic Nucleotide-Regulated Cation Channels, Pages 512-515, Martin Biel and Franz Hofmann

Cysteine Proteases, Pages 516-520, David J. Buttle and John S. Mort

Cytochrome b6f Complex, Pages 521-527, Gunter A. Hauska and Thomas Schodl

Cytochrome bc1 Complex (Respiratory Chain Complex III), Pages 528-534, Bernard L. Trumpower

Cytochrome c, Pages 535-538, Hans Tuppy and Gunther Kreil

Cytochrome Oxidases, Bacterial, Pages 539-543, Peter Brzezinski and Pia Adelroth

Cytochrome P-450, Pages 544-549, Rita Bernhardt

Cytokines, Pages 550-555, Andrea L. Wurster and Michael J. Grusby

Cytokinesis, Pages 556-561, Masanori Mishima and Michael Glotzer

Cytokinin, Pages 562-567, Thomas Schmulling

Desmosomes and Hemidesmosomes, Pages 569-576, Rachel L. Dusek, Jonathan C. R. Jones and Kathleen J. Green

Detergent Properties, Pages 577-581, Darrell R. McCaslin

Diabetes, Pages 582-592, David W. Cooke

Diacylglycerol Kinases and Phosphatidic Acid Phosphatases, Pages 593-597, Stephen M. Prescott and Matthew K. Topham

Disulfide Bond Formation, Pages 598-602, Hiram F. Gilbert

DNA Base Excision Repair, Pages 603-608, Hilde Nilsen and Tomas Lindahl

DNA Damage: Alkylation, Pages 609-613, Anton B. Guliaev and B. Singer

DNA Glycosylases: Mechanisms, Pages 614-617, Daniel J. Krosky and James T. Stivers

DNA Helicases: Dimeric Enzyme Action, Pages 618-623, Timothy M. Lohman

DNA Helicases: HexamericEnzyme Action, Pages 624-631, Smita S. Patel

DNA Ligases: Mechanism and Functions, Pages 632-636, Alan E. Tomkinson and John B. Leppard

DNA Ligases: Structures, Pages 637-643, C. Kiong Ho, Mark Odell and Dimitar B. Nikolov

DNA Methyltransferases, Bacterial, Pages 644-651, Albert Jeltsch and Richard I. Gumport

DNA Methyltransferases, Structural Themes, Pages 652-659, Sanjay Kumar

DNA Methyltransferases: Eubacterial GATC, Pages 660-664, Martin G. Marinus

DNA Mismatch Repair and Homologous Recombination, Pages 665-670, Ivan Matic and Miroslav Radman

DNA Mismatch Repair and the DNA Damage Response, Pages 671-674, Guo-Min Li and Steven R. Presnell

DNA Mismatch Repair Defects and Cancer, Pages 675-681, Richard D. Kolodner

DNA Mismatch Repair in Bacteria, Pages 682-686, A-Lien Lu

DNA Mismatch Repair in Mammals, Pages 687-690, James T. Drummond

DNA Mismatch Repair: E. coli Vsr and Eukaryotic G-T Systems, Pages 691-693, Margaret Lieb

DNA Oxidation, Pages 694-697, Arthur P. Grollman and Dmitry O. Zharkov

DNA Photolyase, Pages 698-702, Carrie L. Partch and Aziz Sancar

DNA Polymerase, Eukaryotic α, Pages 703-707, Teresa S. -F. Wang

DNA Polymerase, Eukaryotic β, Pages 708-712, William A. Beard and Samuel H. Wilson

DNA Polymerase, Eukaryotic δ, Pages 713-715, Antero G. So and Kathleen M. Downey

DNA Polymerase, Eukaryotic ε, Pages 716-719, Yasuo Kawasaki and Akio Sugino

DNA Polymerase I, Bacterial, Pages 720-725, Catherine M. Joyce

DNA Polymerase II, Bacterial, Pages 726-728, Judith L. Campbell

DNA Polymerase III, Bacterial, Pages 729-733, Hisaji Maki

DNA Polymerases: Kinetics and Mechanism, Pages 734-739, Kenneth A. Johnson

DNA Replication Fork, Bacterial, Pages 740-744, Nancy G. Nossal

DNA Replication Fork, Eukaryotic, Pages 745-748, Lori M. Kelman, Jerard Hurwitz and Zvi Kelman

DNA Replication, Mitochondrial, Pages 749-752, David A. Clayton

DNA Replication: Eukaryotic Origins and the Origin Recognition Complex, Pages 753-760, Melvin L. DePamphilis and Cong-jun Li

DNA Replication: Initiation in Bacteria, Pages 761-766, Jon M. Kaguni

DNA Restriction and Modification: Type I Enzymes, Pages 767-771, David T. F. Dryden

DNA Restriction and Modification: Type II Enzymes, Pages 772-777, Darren M. Gowers and Stephen E. Halford

DNA Restriction and Modification: Type III Enzymes, Pages 778-781, Desirazu N. Rao and S. Srivani

DNA Secondary Structure, Pages 782-787, Albino Bacolla and Robert D. Wells

DNA Sequence Recognition by Proteins, Pages 788-793, Arabela A. Grigorescu and John M. Rosenberg

DNA Supercoiling, Pages 794-797, Tao-shih Hsieh

DNA Topoisomerases: Type I, Pages 798-805, James J. Champoux

DNA Topoisomerases: Type II, Pages 806-811, Renier Velez-Cruz and Neil Osheroff

DNA Topoisomerases: Type III-RecQ Helicase Systems, Pages 812-816, Rodney Rothstein and Erika Shor

Dopamine Receptors, Pages 817-822, Kim A. Neve

Dynactin, Pages 823-826, Trina A. Schroer

Dynein, Pages 827-831, K. Kevin Pfister

Volume 2

EF-G and EF-Tu Structures and Translation Elongation in Bacteria, Pages 1-5, Poul Nissen and Jens Nyborg

Eicosanoid Receptors, Pages 6-9, Richard M. Breyer and Matthew D. Breyer

Elastin, Pages 10-12, Judith Ann Foster

Endocannabinoids, Pages 13-15, Daniele Piomelli

Endocytosis, Pages 16-19, Julie G. Donaldson

Endoplasmic Reticulum-Associated Protein Degradation, Pages 20-23, Maurizio Molinari

Energy Transduction in Anaerobic Prokaryotes, Pages 24-30, Gottfried Unden

Enzyme Inhibitors, Pages 31-37, Vern L. Schramm

Enzyme Kinetics, Pages 38-44, Irwin H. Segel

Enzyme Reaction Mechanisms: Stereochemistry, Pages 45-50, Ming-Daw Tsai, Li Zhao and Brandon J. Lamarche

Epidermal Growth Factor Receptor Family, Pages 51-55, Denis Tvorogov and Graham Carpenter

ER/SR Calcium Pump: Function, Pages 56-60, Giuseppe Inesi

ER/SR Calcium Pump: Structure, Pages 61-65, Chikashi Toyoshima and Yuji Sugita

Exonucleases, Bacterial, Pages 66-72, Susan T. Lovett

F1-F0 ATP Synthase, Pages 73-79, Donata Branca

FAK Family, Pages 80-84, Steven K. Hanks

Fat Mobilization: Perilipin and Hormone-Sensitive Lipase, Pages 85-89, Constantine Londos and Alan R. Kimmel

Fatty Acid Oxidation, Pages 90-94, Horst Schulz

Fatty Acid Receptors, Pages 95-98, Christer Owman and Bjorn Olde

Fatty Acid Synthesis and its Regulation, Pages 99-103, Steven D. Clarke and Manabu T. Nakamura

Ferredoxin, Pages 104-106, Giuliana Zanetti and Vittorio Pandini

Ferredoxin-NADP+ Reductase, Pages 107-111, Giuliana Zanetti and Alessandro Aliverti

Fibroblast Growth Factor Receptors and Cancer-Associated Perturbations, Pages 112-117, Marko Kornmann and Murray Korc

Flavins, Pages 118-122, Barrie Entsch and David P. Ballou

Flippases, Pages 123-127, Charles J. Waechter

Focal Adhesions, Pages 128-133, Eli Zamir and Benjamin Geiger

Free Radicals, Sources and Targets of: Mitochondria, Pages 134-142, Alberto Boveris and Enrique Cadenas

Friedreich's Ataxia, Pages 143-145, Paul E. Hart and Anthony H. V. Schapira

G Protein Signaling Regulators, Pages 147-151, John H. Exton

G Protein-Coupled Receptor Kinases and Arrestins, Pages 152-157, Jeffrey L. Benovic

G12/G13 Family, Pages 158-161, Stefan Offermanns

GABAA Receptor, Pages 162-166, Richard W. Olsen and Gregory W. Sawyer

GABAB Receptor, Pages 167-170, S. J. Enna

Galectins, Pages 171-174, R. Colin Hughes

Genome-Wide Analysis of Gene Expression, Pages 175-180, Karine G. Le Roch and Elizabeth A. Winzeler

Gi Family of Heterotrimeric G Proteins, Pages 181-185, Maurine E. Linder

Giant Mitochondria (Megamitochondria), Pages 186-188, Bernard Tandler and Charles L. Hoppel

GlcNAc Biosynthesis and Function, O-Linked, Pages 189-192, Kaoru Sakabe and Gerald W. Hart

Glucagon Family of Peptides and their Receptors, Pages 193-196, Laurie L. Baggio and Daniel J. Drucker

Gluconeogenesis, Pages 197-203, Richard W. Hanson and Oliver E. Owen

Glucose/Sugar Transport in Bacteria, Pages 204-207, Lan Guan and H. Ronald Kaback

Glucose/Sugar Transport in Mammals, Pages 208-212, Silvia Mora and Jeffrey Pessin

Glutamate Receptors, Ionotropic, Pages 213-219, Derek B. Scott and Michael D. Ehlers

Glutamate Receptors, Metabotropic, Pages 220-223, P. Jeffrey Conn

Glutathione Peroxidases, Pages 224-228, Fulvio Ursini and Matilde Maiorino

Glycation, Pages 229-236, Suzanne R. Thorpe and John W. Baynes

Glycine Receptors, Pages 237-243, Bodo Laube and Heinrich Betz

Glycogen Metabolism, Pages 244-248, Peter J. Roach

Glycogen Storage Diseases, Pages 249-254, George H. Sack, Jr.

Glycogen Synthase Kinase-3, Pages 255-260, James R. Woodgett

Glycolipid-Dependent Adhesion Processes, Pages 261-265, Senitiroh Hakomori

Glycolysis, Overview, Pages 266-271, Robert A. Harris

Glycoprotein Folding and Processing Reactions, Pages 272-276, Armando J. Parodi

Glycoprotein-Mediated Cell Interactions, O-Linked, Pages 277-282, Robert S. Haltiwanger

Glycoproteins, N-Linked, Pages 283-292, Mark A. Lehrman

Glycoproteins, Plant, Pages 293-296, Carolyn J. Schultz

Glycosylation in Cystic Fibrosis, Pages 297-301, Andrew D. Rhim, Thomas F. Scanlin and Mary Catherine Glick

Glycosylation, Congenital Disorders of, Pages 302-307, Hudson H. Freeze

Glycosylphosphatidylinositol (GPI) Anchors, Pages 308-311, Anant K. Menon

Golgi Complex, Pages 312-315, Mark Stamnes

Gq Family, Pages 316-320, Wanling Yang and John D. Hildebrandt

Green Bacteria: Secondary Electron Donor (Cytochromes), Pages 321-324, Hirozo Oh-oka and Robert E. Blankenship

Green Bacteria: The Light-Harvesting Chlorosome, Pages 325-330, John M. Olson

Green Sulfur Bacteria: Reaction Center and Electron Transport, Pages 331-336, Gunter A. Hauska and Thomas Schodl

Gs Family of Heterotrimeric G Proteins, Pages 337-341, Susanne M. Mumby

Heat/Stress Responses, Pages 343-347, Davis T. W. Ng

Hematopoietin Receptors, Pages 348-353, Barbara A. Miller and Joseph Y. Cheung

Heme Proteins, Pages 354-361, Johannes Everse

Heme Synthesis, Pages 362-366, Gloria C. Ferreira

Hepatocyte Growth Factor/Scatter Factor Receptor, Pages 367-371, Selma Pennacchietti and Paolo M. Comoglio

Hexokinases/Glucokinases, Pages 372-377, Emile Van Schaftingen

Histamine Receptors, Pages 378-383, Stephen J. Hill and Jillian G. Baker

HIV Protease, Pages 384-387, Ben M. Dunn

HIV-1 Reverse Transcriptase Structure, Pages 388-392, Kalyan Das, Stefan G. Sarafianos, Eddy Arnold and Stephen H. Hughes

Homologous Recombination in Meiosis, Pages 393-397, Nancy M. Hollingsworth

HPLC Separation of Peptides, Pages 398-403, James D. Pearson

Imaging Methods, Pages 405-410, Gyorgy Szabadkai and Rosario Rizzuto

Immunoglobulin (Fc) Receptors, Pages 411-416, Mark Hogarth

Inorganic Biochemistry, Pages 417-420, Robert J. P. Williams

Inositol Lipid 3-Phosphatases, Pages 421-426, Gregory S. Taylor and Jack E. Dixon

Inositol Phosphate Kinases and Phosphatases, Pages 427-429, Stephen B. Shears

Insulin- and Glucagon-Secreting Cells of the Pancreas, Pages 430-435, Franz M. Matschinsky

Insulin Receptor Family, Pages 436-440, Paul F. Pilch and Jongsoon Lee

Integrin Signaling, Pages 441-445, Lawrence E. Goldfinger and Mark H. Ginsberg

Interferon Receptors, Pages 446-451, Christopher P. Elco and Ganes C. Sen

Intermediate Filament Linker Proteins: Plectin and BPAG1, Pages 452-457, Peter Fuchs and Gerhard Wiche

Intermediate Filaments, Pages 458-464, Kelsie M. Bernot and Pierre A. Coulombe

Intracellular Calcium Channels: cADPR-Modulated (Ryanodine Receptors), Pages 465-468, Antony Galione

Intracellular Calcium Channels: NAADP+-Modulated, Pages 469-472, Armando A. Genazzani and Marcella Debidda

Ion Channel Protein Superfamily, Pages 473-477, William A. Catterall

IP3 Receptors, Pages 478-481, Colin W. TaylorEdward Morris and Paula da Fonseca

Iron-Sulfur Proteins, Pages 482-489, Helmut Beinert

JAK-STAT Signaling Paradigm, Pages 491-496, Edward Cha and Christian Schindler

Keratins and the Skin, Pages 497-504, Pierre A. Coulombe and Kelsie M. Bernot

Ketogenesis, Pages 505-507, Janos Kerner and Charles L. Hoppel

Kinesin Superfamily Proteins, Pages 508-516, Nobutaka Hirokawa and Reiko Takemura

Kinesins as Microtubule Disassembly Enzymes, Pages 517-521, Susan L. Kline-Smith and Arshad Desai

Kinetic Isotope Effects, Pages 522-527, Justine P. Roth and Judith P. Klinman

lac Operon, Pages 529-534, Liskin Swint-Kruse and Kathleen S. Matthews

Lectins, Pages 535-540, Nathan Sharon and Halina Lis

Leptin, Pages 541-545, Thomas W. Gettys

LexA Regulatory System, Pages 546-550, Veronica G. Godoy, Penny J. Beuning and Graham C. Walker

Ligand-Operated Membrane Channels: Calcium (Glutamate), Pages 551-561, Elias K. Michaelis

Ligand-Operated Membrane Channels: GABA, Pages 562-566, F. Minier and Erwin Sigel

Light-Harvesting Complex (LHC) I and II: Pigments and Proteins, Pages 567-570, Stefan Jansson

Lipases, Pages 571-575, Howard L. Brockman

Lipid Bilayer Structure, Pages 576-579, Erwin London

Lipid Modification of Proteins: Targeting to Membranes, Pages 580-583, Marilyn D. Resh

Lipid Rafts, Pages 584-587, Deborah A. Brown

Lipoproteins, HDL/LDL, Pages 588-593, Fayanne E. Thorngate and David L. Williams

Low Barrier Hydrogen Bonds, Pages 594-598, Perry A. Frey

Luft's Disease, Pages 599-601, Salvatore DiMauro

Lysophospholipid Receptors, Pages 602-604, Gabor J. Tigyi

MDR Membrane Proteins, Pages 605-609, Nathan C. Rockwell

Meiosis, Pages 610-616, Neil Hunter

Melanocortin System, Pages 617-620, Roger D. Cone

Membrane Fusion, Pages 621-626, Joshua Zimmerberg and Leonid V. Chernomordik

Membrane Transport, General Concepts, Pages 627-630, Stanley G. Schultz

Membrane Transporters:Na+/Ca2+ Exchangers, Pages 631-636, Jonathan Lytton

Membrane-Associated Energy Transduction in Bacteria and Archaea, Pages 637-645, Gunter Schafer

Metabolite Channeling: Creatine Kinase Microcompartments, Pages 646-651, Uwe Schlattner and Theo Wallimann

Metalloproteases, Pages 652-656, David S. Auld

Metalloproteinases, Matrix, Pages 657-665, Hideaki Nagase and Gillian Murphy

Metaphase Chromosome, Pages 666-671, Sharron Vass and Margarete M. S. Heck

Methyl-CpG-Binding Proteins, Pages 672-675, David G. Skalnik

Microtubule-Associated Proteins, Pages 676-682, Nobutaka Hirokawa and Reiko Takemura

Mitochondrial Auto-Antibodies, Pages 683-688, Harold Baum

Mitochondrial Channels, Pages 689-692, M. Catia Sorgato and Alessandro Bertoli

Mitochondrial DNA, Pages 693-696, Gottfried Schatz

Mitochondrial Genes and their Expression: Yeast, Pages 697-702, Piotr P. Slonimski and Giovanna Carignani

Mitochondrial Genome, Evolution, Pages 703-708, B. Franz Lang, Dennis V. Lavrov and Gertraud Burger

Mitochondrial Genome, Overview, Pages 709-715, Douglas C. Wallace

Mitochondrial Inheritance, Pages 716-719, Eric A. Shoubridge

Mitochondrial Membranes, Structural Organization, Pages 720-724, Carmen A. Mannella

Mitochondrial Metabolite Transporter Family, Pages 725-732, Ferdinando Palmieri and Martin Klingenberg

Mitochondrial Outer Membrane and the VDAC Channel, Pages 733-736, Marco Colombini

Mitogen-Activated Protein Kinase Family, Pages 737-742, Hidemi Teramoto and J. Silvio Gutkind

Mitosis, Pages 743-747, Patricia Wadsworth and Nasser M. Rusan

mRNA Polyadenylation in Eukaryotes, Pages 748-752, Mary Edmonds

mRNA Processing and Degradation in Bacteria, Pages 753-757, Deborah A. Steege

Mucin Family of Glycoproteins, Pages 758-764, Juan Perez-Vilar and Robert L. Hill

Mucins in Embryo Implantation, Pages 765-769, Daniel D. Carson

Multiple Sequence Alignment and Phylogenetic Trees, Pages 770-774, Russell F. Doolittle

Muscarinic Acetylcholine Receptors, Pages 775-777, Neil M. Nathanson

Myosin Motors, Pages 778-781, Roy E. Larson

Volume 3

Natriuretic Peptides and their Receptors, Pages 1-5, Lincoln R. Potter

N-End Rule, Pages 6-10, Alexander Varshavsky

Neoglycoproteins, Pages 11-15, Y. C. Lee and Reiko T. Lee

Neuronal Calcium Signal, Pages 16-20, Hilmar Bading

Neuronal Intermediate Filaments, Pages 21-25, Ronald K. H. Liem

Neuropeptide Y Receptors, Pages 26-31, Eric M. Parker

Neurotensin Receptors, Pages 32-36, William Rostene, Patrick Kitabgi and Didier Pelaprat

Neurotransmitter Transporters, Pages 37-40, Aurelio Galli, Randy D. Blakely and Louis J. DeFelice

Neurotrophin Receptor Signaling, Pages 41-45, Jennifer J. Gentry and Bruce D. Carter

Nicotinamide Nucleotide Transhydrogenase, Pages 50-56, Jan Rydstrom

Nicotinic Acetylcholine Receptors, Pages 57-61, Nivalda O. Rodrigues-Pinguet and Henry A. Lester

Nitric Oxide Signaling, Pages 62-65, Michael A. Marletta

N-Linked Glycan Processing Glucosidases and Mannosidases, Pages 46-49, Linda O. Tremblay and Annette Herscovics

Non-Homologous End Joining, Pages 66-70, Penny A. Jeggo

Nonhomologous Recombination: Bacterial Transposons, Pages 71-79, Bao Ton Hoang and Michael G. Chandler

Nonhomologous Recombination: Retrotransposons, Pages 80-86, Siew Loon Ooi and Jef D. Boeke

Nuclear Compartmentalization, Pages 87-91, Kelly P. Smith and Jeanne B. Lawrence

Nuclear Envelope and Lamins, Pages 92-95, Bryce M. Paschal

Nuclear Factor kappaB, Pages 96-99, Thomas D. Gilmore

Nuclear Genes in Mitochondrial Function and Biogenesis, Pages 100-104, Alexander Tzagoloff and Carol L. Dieckmann

Nuclear Organization, Chromatin Structure, and Gene Silencing , Pages 105-108, Lori L. Wallrath, John R. Danzer, Oya Yazgan and Pamela K. Geyer

Nuclear Pores and Nuclear Import/Export, Pages 109-114, Anita H. Corbett

Nucleoid Organization of Bacterial Chromosomes, Pages 115-118, Charles J. Dorman

Nucleolus, Overview, Pages 119-122, Thoru Pederson

Nucleotide Excision Repair and Human Disease, Pages 123-129, James E. Cleaver

Nucleotide Excision Repair in Eukaryotes, Pages 130-133, Laura A. Lindsey-Boltz and Aziz Sancar

Nucleotide Excision Repair, Bacterial: The UvrABCD System, Pages 134-142, Bennett Van Houten and Lawrence Grossman

Nucleotide Excision Repair: Biology, Pages 143-147, Errol C. Friedberg

Olfactory Receptors, Pages 149-154, Sigrun I. Korsching

Oligosaccharide Analysis by Mass Spectrometry, Pages 155-160, Andrew J. Hanneman and Vernon N. Reinhold

Oligosaccharide Chains: Free, N-Linked, O-Linked, Pages 161-164, Tadashi Suzuki

Oncocytes, Pages 165-166, Bernard Tandler and Charles L. Hoppel

Opioid Receptors, Pages 167-171, P. Y. Law and Horace H. Loh

Ornithine Cycle, Pages 172-177, Malcolm Watford

Oxygenases, Pages 178-182, Osamu Hayaishi

P2X Purinergic Receptors, Pages 183-187, Annmarie Surprenant

P2Y Purinergic Receptors, Pages 188-191, George R. Dubyak

p53 Protein, Pages 192-195, Jamie Hearnes and Jennifer Pietenpol

p70 S6 Kinase/mTOR, Pages 196-200, Christopher G. Proud

Parathyroid Hormone/Parathyroid Hormone-Related Protein Receptor, Pages 201-207, Thomas J. Gardella

PCR (Polymerase Chain Reaction), Pages 208-210, Michael J. Brownstein

Pentose Phosphate (Hexose Mono Phosphate) Pathway, Pages 211-215, Bernard R. Landau

Pentose Phosphate Pathway, History of, Pages 216-225, John F. Williams

Peptide Amidation, Pages 226-230, Mark J. Niciu, Richard E. Mains and Betty A. Eipper

Periplasmic Electron Transport Systems in Bacteria, Pages 231-238, David J. Richardson, Gary Sawers and Rob J. M. Van Spanning

Peroxisome Proliferator-Activated Receptors, Pages 239-245, Mary C. Sugden, Edward A. Sugden and Mark J. Holness

Peroxisomes, Pages 246-250, Suresh Subramani

Phage Display for Protein Binding, Pages 251-255, Henry B. Lowman

Pheromone Receptors (Yeast), Pages 256-261, James B. Konopka and Jeremy W. Thorner

PHO Regulon, Pages 262-265, Bengt L. Persson

Phosphatidylinositol Bisphosphate and Trisphosphate, Pages 266-271, Alex Toker

Phosphatidylinositol-3-Phosphate, Pages 272-276, Joseph V. Virbasius and Michael P. Czech

Phosphofructokinase-2/Fructose Bisphosphatase-2, Pages 277-280, Daniel M. Raben

Phosphoinositide 3-Kinase, Pages 281-286, Khatereh Ahmadi and Michael Waterfield

Phosphoinositide 4- and 5-Kinases and Phosphatases, Pages 287-291, Shawn F. Bairstow, Matthew W. Bunce and Richard A. Anderson

Phosphoinositide-Dependent Protein Kinases, Pages 292-296, Nick R. Leslie and C. Peter Downes

Phospholipase A2, Pages 297-300, Timothy R. Smith and Edward A. Dennis

Phospholipase C, Pages 301-305, Fujio Sekiya, Yeun Ju Kim and Sue Goo Rhee

Phospholipase D, Pages 306-313, Mary M. LaLonde and Michael A. Frohman

Phospholipid Metabolism in Mammals, Pages 314-320, Claudia Kent

Phospholipid Synthesis in Yeast, Pages 321-325, Gil-Soo Han and George M. Carman

Photoreceptors, Pages 326-329, King-Wai Yau

Photosynthesis, Pages 330-335, Richard C. Leegood

Photosynthetic Carbon Dioxide Fixation, Pages 336-341, Matthew J. Paul

Photosystem I, Structure and Function, Pages 342-347, Petra Fromme

Photosystem I: FX, FA, and FB Iron-Sulfur Clusters, Pages 348-356, Mikhail L. Antonkine and John H. Golbeck

Photosystem II Light Harvesting System: Dynamic Behavior, Pages 357-362, Peter Horton and Alexander Ruban

Photosystem II: Assembly and Turnover of the D1 Protein, Pages 363-366, Eira Kanervo and Eva-Mari Aro

Photosystem II: Protein Components, Pages 367-374, James Barber

Photosystem II: Water Oxidation, Overview, Pages 375-380, Fabrice Rappaport and Pierre Joliot

Plant Signaling: Peptides, Pages 381-384, Clarence A. Ryan and Gregory Pearce

Plasma-Membrane Calcium Pump: Structure and Function, Pages 385-389, Emanuel E. Strehler

Plastocyanin, Pages 390-393, Elizabeth L. Gross

Platelet-Activating Factor Receptor, Pages 394-398, Katherine M. Howard and Merle S. Olson

Platelet-Derived Growth Factor Receptor Family, Pages 399-406, Marina Kovalenko and Andrius Kazlauskas

Polysialic Acid inMolecular Medicine, Pages 407-414, Frederic A. Troy, II

Porphyrin Metabolism, Pages 415-419, Mark Shepherd and Harry A. Dailey

Pre-tRNA and Pre-rRNA Processing in Bacteria, Pages 420-424, Sidney R. Kushner

Pre-tRNA and Pre-rRNA Processing in Eukaryotes, Pages 425-431, Hendrik A. Raue

Prions and Epigenetic Inheritance, Pages 432-436, Reed B. Wickner

Prions, Overview, Pages 437-440, Cedric Govaerts and Fred E. Cohen

Processivity Clamps in DNA Replication: Clamp Loading, Pages 441-446, Megan J. Davey and Mike O'Donnell

Propionyl CoA-Succinyl CoA Pathway, Pages 447-451, Wayne A. Fenton

Prostaglandins and Leukotrienes, Pages 452-456, William L. Smith and Robert C. Murphy

Proteases in Blood Clotting, Pages 457-463, John D. Kulman and Earl W. Davie

Proteasomes, Overview, Pages 464-468, Martin Rechsteiner

26S Proteasome, Structure and Function, Pages 469-473, Peter Zwickl and Wolfgang Baumeister

Protein Carboxyl Esterification, Pages 474-477, Shilpa G. Lalchandani and Jeffry B. Stock

Protein Data Resources, Pages 478-483, Philip E. Bourne

Protein Degradation, Pages 484-492, Tomo ari and Alfred L. Goldberg

Protein Folding and Assembly, Pages 493-499, David P. Goldenberg

Protein Glycosylation Inhibitors, Pages 500-503, Alan D. Elbein

Protein Glycosylation, Overview, Pages 504-509, Natasha E. Zachara and Gerald W. Hart

Protein Import into Mitochondria, Pages 510-515, Johannes M. Herrmann and Walter Neupert

Protein Kinase B, Pages 516-522, Bettina A. Dummler and Brian A. Hemmings

Protein Kinase C Family, Pages 523-526, Alexandra C. Newton

Protein N-Myristoylation, Pages 527-531, Erica Dutil Sonnenburg and Jeffrey I. Gordon

Protein Palmitoylation, Pages 532-535, Robert J. Deschenes

Protein Tyrosine Phosphatases, Pages 536-542, David J. Pagliarini, Fred L. Robinson and Jack E. Dixon

Proteinase-Activated Receptors, Pages 543-548, Kristina K. Hansen and Morley D. Hollenberg

Proteoglycans, Pages 549-555, Sara K. Olson and Jeffrey D. Esko

Pteridines, Pages 556-560, S. Colette Daubner and Paul F. Fitzpatrick

P-Type Pumps: Copper Pump, Pages 561-564, Ilia Voskoboinik and James Camakaris

P-Type Pumps: H+/K+ Pump, Pages 565-570, Jai Moo Shin and George Sachs

P-Type Pumps: Na+/K+ Pump, Pages 571-576, Peter L. Jorgensen

P-Type Pumps: Plasma-Membrane H+ Pump, Pages 577-581, A. Brett Mason and Carolyn W. Slayman

Purple Bacteria: Electron Acceptors and Donors, Pages 582-585, Evaldas Katilius and Neal W. Woodbury

Purple Bacteria: Photosynthetic Reaction Centers, Pages 586-594, C. Roy D. Lancaster

Pyridoxal Phosphate, Pages 595-599, David E. Metzler

Pyrimidine Biosynthesis, Pages 600-605, Monika Loffler and Elke Zameitat

Pyruvate Carboxylation, Transamination, and Gluconeogenesis, Pages 606-610, Sarawut Jitrapakdee and John C. Wallace

Pyruvate Dehydrogenase, Pages 611-615, Sam A. Johnson and James G. McCormack

Pyruvate Kinase, Pages 616-619, Kosaku Uyeda

Quinones, Pages 621-627, Giorgio Lenaz and Maria Luisa Genova

Rab Family, Pages 629-634, Mary W. McCaffrey and Andrew J. Lindsay

Ran GTPase, Pages 635-639, Mary Shannon Moore

Ras Family, Pages 640-644, Lawrence A. Quilliam

Recombination: Heteroduplexand Mismatch Repair in vitro, Pages 645-648, Leroy Worth

Recombination: Strand Transferases, Pages 649-653, Floyd R. Bryant

Recombination-Dependent DNA Replication, Pages 654-659, Kenneth N. Kreuzer

recQ DNA Helicase Family in Genetic Stability, Pages 660-664, Mary A. Risinger and Joanna Groden

Regulated Intramembrane Proteolysis (Rip), Pages 665-670, Jin Ye, Michael S. Brown and Joseph L. Goldstein

Respiratory Chain and ATP Synthase, Pages 671-675, David G. Whitehouse and Anthony L. Moore

Respiratory Chain Complex I, Pages 676-680, Ulrich Brandt

Respiratory Chain Complex II and Succinate: Quinone Oxidoreductases, Pages 681-687, C. Roy D. Lancaster

Respiratory Chain Complex IV, Pages 688-694, Hartmut Michel

Respiratory Processes in Anoxygenic and Oxygenic Phototrophs, Pages 695-699, Roberto Borghese and Davide Zannoni

Retinoblastoma Protein (pRB), Pages 700-703, Nicholas Dyson and Maxim Frolov

Retinoic Acid Receptors, Pages 704-707, Martin Petkovich

Reverse Transcriptase and Retroviral Replication, Pages 708-713, Laura Tarrago-Litvak, Marie-Line Andreola and Simon Litvak

Rho GTPases and Actin Cytoskeleton Dynamics, Pages 714-718, Priam Villalonga and Anne J. Ridley

Ribosome Assembly, Pages 719-724, John L. Woolford

Ribosome Structure, Pages 725-732, Brian T. Wimberly

Ribozyme Mechanisms, Pages 733-737, John Hsieh and Carol A. Fierke

Ribozyme Structural Elements: Group I Introns, Pages 738-742, Barbara L. Golden

Ribozyme Structural Elements: Hairpin Ribozyme, Pages 743-746, Adrian R. Ferre-D'Amare

Ribozymes and Evolution, Pages 747-752, Niles Lehman

RNA Editing, Pages 753-758, Charles E. Samuel

RNA Polymerase I and RNA Polymerase III in Eukaryotes, Pages 759-762, Robert J. White

RNA Polymerase II and Basal Transcription Factors in Eukaryotes, Pages 763-765, Joan Weliky Conaway and Ronald C. Conaway

RNA Polymerase II Elongation Control in Eukaryotes, Pages 766-769, David H. Price

RNA Polymerase II Structure in Eukaryotes, Pages 770-774, Patrick Cramer

RNA Polymerase Reaction in Bacteria, Pages 775-780, Arkady A. Mustaev and Alexander D. Goldfarb

RNA Polymerase Structure, Bacterial, Pages 781-784, Michael Anikin, Dmitri Temiakov and William T. McAllister

Volume 4

Secondary Structure in Protein Analysis, Pages 1-6, George D. Rose

Secretases, Pages 7-10, Robert L. Heinrikson

Secretory Pathway, Pages 11-16, Karen J. Colley

Selenoprotein Synthesis, Pages 17-21, August Bock

Septins and Cytokinesis, Pages 22-26, Makoto Kinoshita and Christine M. Field

Serine/Threonine Phosphatases, Pages 27-32, Thomas S. Ingebritsen

Serotonin Receptor Signaling, Pages 33-37, Paul J. Gresch and Elaine Sanders-Bush

Siglecs, Pages 38-40, Ajit Varki

Sigma Factors, Pages 41-44, John D. Helmann

Sliding Clamps in DNA Replication: E. coli -Clamp and PCNA Structure, Pages 45-47, Eric R. Goedken and John Kuriyan

Small GTPases, Pages 48-54, Adam Shutes and Channing J. Der

Somatostatin Receptors, Pages 55-60, Agnes Schonbrunn

Spastic Paraplegia, Pages 61-66, Elena Irene Rugarli and Andrea Ballabio

Spectrophotometric Assays, Pages 67-75, Britton Chance

Sphingolipid Biosynthesis, Pages 76-81, Martina Leipelt and Alfred H. Merrill

Sphingolipid Catabolism, Pages 82-87, Akira Abe and James A. Shayman

Spliceosome, Pages 88-92, Timothy W. Nilsen

Src Family of Protein Tyrosine Kinases, Pages 93-98, Jonathan A. Cooper

Starvation, Pages 99-110, Oliver E. Owen and Richard W. Hanson

Steroid/Thyroid Hormone Receptors, Pages 111-116, Ramesh Narayanan and Nancy L. Weigel

Store-Operated Membrane Channels: Calcium, Pages 117-122, Indu S. Ambudkar

Substrate Binding, Catalysis, and Product Release , Pages 123-126, W. Wallace Cleland

Sugar Nucleotide Transporters, Pages 127-129, Carlos B. Hirschberg

SUMO Modification, Pages 130-134, Frauke Melchior and Andrea Pichler

Superoxide Dismutase, Pages 135-138, Irwin Fridovich

Syk Family of Protein Tyrosine Kinases, Pages 139-145, Andrew C. Chan

T7 RNA Polymerase, Pages 147-151, Rui Sousa

Tachykinin/Substance P Receptors, Pages 152-157, Mark D. Richardson and Madan M. Kwatra

Taste Receptors, Pages 158-161, John D. Boughter, Jr. and Steven D. Munger

T-Cell Antigen Receptor, Pages 162-168, Andrea L. Szymczak and Dario A. A. Vignali

Tec/Btk Family Tyrosine Kinases, Pages 169-173, Shuling Guo and Owen N. Witte

Telomeres: Maintenance and Replication, Pages 174-179, Alessandro Bianchi and David Shore

Thyroid-Stimulating Hormone/Luteinizing Hormone/Follicle-Stimulating Hormone Receptors, Pages 180-186, Deborah L. Segaloff, Dario Mizrachi and Mario Ascoli

Tight Junctions, Pages 187-189, Shoichiro Tsukita

Title, Pages, Authors

Toll-Like Receptors, Pages 190-194, Himanshu Kumar, Kiyoshi Takeda and Shizuo Akira

Transcription Termination, Pages 195-199, Thomas J. Santangelo and Jeffrey W. Roberts

Transcriptional Silencing, Pages 200-203, Ann Sutton and Rolf Sternglanz

Transcription-Coupled DNA Repair, Overview, Pages 204-208, Isabel Mellon

Transforming Growth Factor-β Receptor Superfamily, Pages 209-213, Mark de Caestecker

Translation Elongation in Bacteria, Pages 214-223, Oliver Vesper and Knud H. Nierhaus

Translation Elongation in Eukaryotes, Pages 224-229, William C. Merrick and Anton A. Komar

Translation Initiation in Bacteria: Factors and Mechanisms, Pages 230-236, Cynthia L. Pon and Claudio O. Gualerzi

Translation Initiation in Eukaryotes: Factors and Mechanisms, Pages 237-241, Tatyana V. Pestova and Christopher U. T. Hellen

Translation Termination and Ribosome Recycling, Pages 242-246, Nadja Koloteva-Levin and Mick F. Tuite

Translesion DNA Polymerases, Eukaryotic, Pages 247-250, Alexandra Vaisman and Roger Woodgate

Trehalose Metabolism, Pages 251-255, Alan D. Elbein

Tricarboxylic Acid Cycle, Pages 256-262, Richard L. Veech

tRNA Synthetases, Pages 263-266, Karla L. Ewalt and Paul Schimmel

trp Operon and Attenuation, Pages 267-271, Paul Gollnick

Tubulin and its Isoforms, Pages 272-276, Eva Nogales

Tumor Necrosis Factor Receptors, Pages 277-283, Karen G. Potter and Carl F. Ware

Two-Dimensional Gel Electrophoresis, Pages 284-289, Gerhard Schmid, Denis Hochstrasser and Jean-Charles Sanchez

Two-Hybrid Protein-Protein Interactions, Pages 290-293, Ilya Serebriiskii and Erica A. Golemis

Tyrosine Sulfation, Pages 294-297, Denis Corbeil and Wieland B. Huttner

Ubiquitin System, Pages 299-303, Aaron Ciechanover and Michael H. Glickman

Ubiquitin-Like Proteins, Pages 304-307, Edward T. H. Yeh

UmuC, D Lesion Bypass DNA Polymerase V, Pages 308-312, Zvi Livneh

Uncoupling Proteins, Pages 313-318, Daniel Ricquier and Frederic Bouillaud

Unfolded Protein Responses, Pages 319-325, David Ron

Urea Cycle, Inborn Defects of, Pages 326-330, Marsha K. Fearing and Vivian E. Shih

Vacuoles, Pages 331-336, Christopher J. Stefan and Scott D. Emr

Vascular Endothelial Growth Factor Receptors, Pages 337-342, Kenneth A. Thomas

Vasopressin/Oxytocin Receptor Family, Pages 343-348, Michael J. Brownstein

V-ATPases, Pages 349-353, Michael Forgac

Vitamin A (Retinoids), Pages 354-359, Joseph L. Napoli

Vitamin B12 and B12-Proteins, Pages 360-366, Bernhard Krautler

Vitamin C, Pages 367-371, Robert B. Rucker and Francene Steinberg

Vitamin D, Pages 372-377, Hector F. DeLuca and Margaret Clagett-Dame

Vitamin D Receptor, Pages 378-383, Diane R. Dowd and Paul N. MacDonald

Vitamin E, Pages 384-388, Ute C. Obermuller-Jevic and Lester Packer

Vitamin K: Biochemistry, Metabolism, and Nutritional Aspects, Pages 389-393, J. W. Suttie

Vitamin K: Blood Coagulation and Use in Therapy, Pages 394-398, Matthew D. Stone and Gary L. Nelsestuen

Voltage-Dependent K+ Channels, Pages 399-404, Ramon Latorre and Francisco J. Morera

Voltage-Sensitive Ca2+ Channels, Pages 405-408, Harald Reuter

Voltage-Sensitive Na+ Channels, Pages 409-415, William J. Brammar

Von Hippel-Lindau (VHL) Protein, Pages 416-418, Ronald C. Conaway and Joan Weliky Conaway

XPV DNA Polymerase and Ultraviolet Damage Bypass, Pages 419-421, Alan R. Lehmann

X-Ray Determination of 3-D Structure in Proteins, Pages 422-428, Martha L. Ludwig

Yeast GAL1-GAL10 System, Pages 429-433, Dennis Lohr and Ralph Bash

Zinc Fingers, Pages 435-439, Mark Isalan

Lipids, Carbohydrates, Membranes and Membrane Proteins

Carbohydrate Chains: Enzymatic and Chemical Synthesis; Vol.1 - Pages 307-313, Thomas J. Tolbert and Chi-Huey Wong

Cell–Matrix Interactions; Vol.1 - Pages 362-366, Janet A. Askari and Martin J. Humphries

Detergent Properties; Vol.1 - Pages 577-581, Darrell R. McCaslin

Endocytosis; Vol.2 - Pages 16-19, Julie G. Donaldson

Flippases; Vol.2 - Pages 123-127, Charles J. Waechter

Galectins; Vol.2 - Pages 171-174, R. Colin Hughes

GlcNAc Biosynthesis and Function, O-Linked; Vol.2 - Pages 189-192, Kaoru Sakabe and Gerald W. Hart

Glycation; Vol.2 - Pages 229-236, Suzanne R. Thorpe and John W. Baynes

Glycolipid-Dependent Adhesion Processes; Vol.2 - Pages 261-265, Senitiroh Hakomori

Glycoprotein Folding and Processing Reactions; Vol.2 - Pages 272-276, Armando J. Parodi

Glycoprotein-Mediated Cell Interactions, O-Linked; Vol.2 - Pages 277-282, Robert S. Haltiwanger

Glycoproteins, N-Linked; Vol.2 - Pages 283-292, Mark A. Lehrman

Glycoproteins, Plant; Vol.2 - Pages 293-296, Carolyn J. Schultz

Glycosylation in Cystic Fibrosis; Vol.2 - Pages 297-301, Andrew D. Rhim, Thomas F. Scanlin and Mary Catherine Glick

Glycosylation, Congenital Disorders of; Vol.2 - Pages 302-307, Hudson H. Freeze

Glycosylphosphatidylinositol (GPI) Anchors; Vol.2 - Pages 308-311, Anant K. Menon

Ion Channel Protein Superfamily; Vol.2 - Pages 473-477, William A. Catterall

Lectins; Vol.2 - Pages 535-540, Nathan Sharon and Halina Lis

Lipases; Vol.2 - Pages 571-575, Howard L. Brockman

Lipid Bilayer Structure; Vol.2 - Pages 576-579, Erwin London

Lipid Rafts; Vol.2 - Pages 584-587, Deborah A. Brown

Lipoproteins, HDL/LDL; Vol.2 - Pages 588-593, Fayanne E. Thorngate and David L. Williams

MDR Membrane Proteins; Vol.2 - Pages 605-609, Nathan C. Rockwell

Membrane Fusion; Vol.2 - Pages 621-626, Joshua Zimmerberg and Leonid V. Chernomordik

Mucin Family of Glycoproteins; Vol.2 - Pages 758-764, Juan Perez-Vilar and Robert L. Hill

Mucins in Embryo Implantation; Vol.2 - Pages 765-769, Daniel D. Carson

Neoglycoproteins; Vol.3 - Pages 11-15, Y. C. Lee and Reiko T. Lee

N-Linked Glycan Processing Glucosidases and Mannosidases; Vol.3 - Pages 46-49, Linda O. Tremblay and Annette Herscovics

Oligosaccharide Chains: Free, N-Linked, O-Linked; Vol.3 - Pages 161-164, Tadashi Suzuki

Phospholipid Metabolism in Mammals; Vol.3 - Pages 314-320, Claudia Kent

Phospholipid Synthesis in Yeast; Vol.3 - Pages 321-325, Gil-Soo Han and George M. Carman

Prostaglandins and Leukotrienes; Vol.3 - Pages 452-456, William L. Smith and Robert C. Murphy

Protein Glycosylation Inhibitors; Vol.3 - Pages 500-503, Alan D. Elbein

Proteoglycans; Vol.3 - Pages 549-555, Sara K. Olson and Jeffrey D. Esko

Secretory Pathway; Vol.4 - Pages 11-16, Karen J. Colley

Siglecs; Vol.4 - Pages 38-40, Ajit Varki

Sphingolipid Biosynthesis; Vol.4 - Pages 76-81, Martina Leipelt and Alfred H. Merrill, Jr.

Sphingolipid Catabolism; Vol.4 - Pages 82-87, Akira Abe and James A. Shayman

Sugar Nucleotide Transporters; Vol.4 - Pages 127-129, Carlos B. Hirschberg

Trehalose Metabolism; Vol.4 - Pages 251-255, Alan D. Elbein

Metabolism, Vitamins and Hormones

Amino Acid Metabolism; Vol.1 - Pages 90-95, Luc Cynober

Anaplerosis; Vol.1 - Pages 105-110, Raymond R. Russell, III and Heinrich Taegtmeyer

Bile Salts and their Metabolism; Vol.1 - Pages 159-163, Ulrich Beuers and Thomas Pusl

Biliary Cirrhosis, Primary; Vol.1 - Pages 164-169, Marshall M. Kaplan

Branched-Chain -Ketoacids; Vol.1 - Pages 186-191, David T. Chuang

Carnitine and -Oxidation; Vol.1 - Pages 314-318, Janos Kerner and Charles L. Hoppel

Cholesterol Synthesis; Vol.1 - Pages 451-455, Peter A. Edwards

Diabetes; Vol.1 - Pages 582-592, David W. Cooke

Fat Mobilization: Perilipin and Hormone-Sensitive Lipase; Vol.2 - Pages 85-89, Constantine Londos and Alan R. Kimmel

Fatty Acid Oxidation; Vol.2 - Pages 90-94, Horst Schulz

Fatty Acid Synthesis and its Regulation; Vol.2 - Pages 99-103, Steven D. Clarke and Manabu T. Nakamura

Gluconeogenesis; Vol.2 - Pages 197-203, Richard W. Hanson and Oliver E. Owen

Glucose/Sugar Transport in Bacteria; Vol.2 - Pages 204-207, Lan Guan and H. Ronald Kaback

Glucose/Sugar Transport in Mammals; Vol.2 - Pages 208-212, Silvia Mora and Jeffrey Pessin

Glycogen Metabolism; Vol.2 - Pages 244-248, Peter J. Roach

Glycogen Storage Diseases; Vol.2 - Pages 249-254, George H. Sack, Jr.

Glycolysis, Overview; Vol.2 - Pages 266-271, Robert A. Harris

Hexokinases/Glucokinases; Vol.2 - Pages 372-377, Emile Van Schaftingen

Insulin- and Glucagon-Secreting Cells of the Pancreas; Vol.2 - Pages 430-435, Franz M. Matschinsky

Ketogenesis; Vol.2 - Pages 505-507, Janos Kerner and Charles L. Hoppel

Ornithine Cycle; Vol.3 - Pages 172-177, Malcolm Watford

Pentose Phosphate (Hexose Mono Phosphate) Pathway; Vol.3 - Pages 211-215, Bernard R. Landau

Pentose Phosphate Pathway, History of; Vol.3 - Pages 216-225, John F. Williams

Phosphofructokinase-2/Fructose Bisphosphatase-2; Vol.3 - Pages 277-280, Daniel M. Raben

Photosynthesis; Vol.3 - Pages 330-335, Richard C. Leegood

Photosynthetic Carbon Dioxide Fixation; Vol.3 - Pages 336-341, Matthew J. Paul

Porphyrin Metabolism; Vol.3 - Pages 415-419, Mark Shepherd and Harry A. Dailey

Propionyl CoA–Succinyl CoA Pathway; Vol.3 - Pages 447-451, Wayne A. Fenton

Pyruvate Carboxylation, Transamination, and Gluconeogenesis; Vol.3 - Pages 606-610, Sarawut Jitrapakdee and John C. Wallace

Pyruvate Dehydrogenase; Vol.3 - Pages 611-615, Sam A. Johnson and James G. McCormack

Pyruvate Kinase; Vol.3 - Pages 616-619, Kosaku Uyeda

Starvation; Vol.4 - Pages 99-110, Oliver E. Owen and Richard W. Hanson

Tricarboxylic Acid Cycle; Vol.4 - Pages 256-262, Richard L. Veech

Urea Cycle, Inborn Defects of; Vol.4 - Pages 326-330, Marsha K. Fearing and Vivian E. Shih

Vitamin A (Retinoids); Vol.4 - Pages 354-359, Joseph L. Napoli

Vitamin B12 and B12-Proteins; Vol.4 - Pages 360-366, Bernhard Krautler

Vitamin C; Vol.4 - Pages 367-371, Robert B. Rucker and Francene Steinberg

Vitamin D; Vol.4 - Pages 372-377, Hector F. DeLuca and Margaret Clagett-Dame

Vitamin E; Vol.4 - Pages 384-388, Ute C. Obermuller-Jevic and Lester Packer

Vitamin K: Biochemistry, Metabolism, and Nutritional Aspects; Vol.4 - Pages 389-393, J. W. Suttie

Vitamin K: Blood Coagulation and Use in Therapy; Vol.4 - Pages 394-398, Matthew D. Stone and Gary L. Nelsestuen

Cell Architecture and Function

Actin Assembly/Disassembly; Vol.1 - Pages 12-18, Henry N. Higgs

Actin-Capping and -Severing Proteins; Vol.1 - Pages 19-26, Sankar Maiti and James R. Bamburg

Actin-Related Proteins; Vol.1 - Pages 27-33, R. Dyche Mullins

Autophagy in Fungi and Mammals; Vol.1 - Pages 138-143, Daniel J. Klionsky and Ju Guan

Bax and Bcl2 Cell Death Enhancers and Inhibitors; Vol.1 - Pages 152-154, David L. Vaux

Cadherin-Mediated Cell–Cell Adhesion; Vol.1 - Pages 205-211, Frauke Drees and W. James Nelson

Caspases and Cell Death; Vol.1 - Pages 319-327, Don W. Nicholson, Pierluigi Nicotera and Gerry Melino

Cell Cycle Controls in G1 and G0; Vol.1 - Pages 328-331, WengeShi and Steven F. Dowdy

Cell Cycle: Control of Entry and Progression Through S Phase; Vol.1 - Pages 332-337, Susan L. Forsburg

Cell Cycle: DNA Damage Checkpoints; Vol.1 - Pages 338-344, Jean Y. J. Wang

Cell Cycle: Mitotic Checkpoint; Vol.1 - Pages 345-351, Tim J. Yen

Cell Migration; Vol.1 - Pages 356-361, J. Victor Small and Emmanuel Vignal

Centromeres; Vol.1 - Pages 367-371, Beth A. Sullivan

Centrosomes and Microtubule Nucleation; Vol.1 - Pages 372-376, Reiko Nakajima, Ming-Ying Tsai and Yixian Zheng

Chaperones for Metalloproteins; Vol.1 - Pages 383-386, Valeria C. Culotta and Edward Luk

Chaperones, Molecular; Vol.1 - Pages 387-392, Sue Wickner and Joel R. Hoskins

Chaperonins; Vol.1 - Pages 393-398, Arthur L. Horwich, Wayne A. Fenton and George W. Farr

Chromosome Organization and Structure, Overview; Vol.1 - Pages 469-474, Elena Gracheva and Sarah C. R. Elgin

Cytokinesis; Vol.1 - Pages 556-561, Masanori Mishima and Michael Glotzer

Desmosomes and Hemidesmosomes; Vol.1 - Pages 569-576, Rachel L. Dusek, Jonathan C. R. Jones and Kathleen J. Green

Dynactin; Vol.1 - Pages 823-826, Trina A. Schroer

Dynein; Vol.1 - Pages 827-831, K. Kevin Pfister

Endoplasmic Reticulum-Associated Protein Degradation; Vol.2 - Pages 20-23, Maurizio Molinari

Focal Adhesions; Vol.2 - Pages 128-133, Eli Zamir and Benjamin Geiger

Golgi Complex; Vol.2 - Pages 312-315, Mark Stamnes

Heat/Stress Responses; Vol.2 - Pages 343-347, Davis T. W. Ng

Inositol Lipid 3-Phosphatases; Vol.2 - Pages 421-426, Gregory S. Taylor and Jack E. Dixon

Intermediate Filament Linker Proteins: Plectin and BPAG1; Vol.2 - Pages 452-457, Peter Fuchs and Gerhard Wiche

Intermediate Filaments; Vol.2 - Pages 458-464, Kelsie M. Bernot and Pierre A. Coulombe

Keratins and the Skin; Vol.2 - Pages 497-504, Pierre A. Coulombe and Kelsie M. Bernot

Kinesin Superfamily Proteins; Vol.2 - Pages 508-516, Nobutaka Hirokawa and Reiko Takemura

Kinesins as Microtubule Disassembly Enzymes; Vol.2 - Pages 517-521, Susan L. Kline-Smith and Arshad Desai

Meiosis; Vol.2 - Pages 610-616, Neil Hunter

Metalloproteinases, Matrix; Vol.2 - Pages 657-665, Hideaki Nagase and Gillian Murphy

Microtubule-Associated Proteins; Vol.2 - Pages 676-682, Nobutaka Hirokawa and Reiko Takemura

Mitosis; Vol.2 - Pages 743-747, Patricia Wadsworth and Nasser M. Rusan

Myosin Motors; Vol.2 - Pages 778-781, Roy E. Larson

N-End Rule; Vol.3 - Pages 6-10, Alexander Varshavsky

Neuronal Intermediate Filaments; Vol.3 - Pages 21-25, Ronald K. H. Liem

Nuclear Compartmentalization; Vol.3 - Pages 87-91, Kelly P. Smith and Jeanne B. Lawrence

Nuclear Envelope and Lamins; Vol.3 - Pages 92-95, Bryce M. Paschal

Nuclear Pores and Nuclear Import/Export; Vol.3 - Pages 109-114, Anita H. Corbett

Peroxisomes; Vol.3 - Pages 246-250, Suresh Subramani

26S Proteasome, Structure and Function; Vol.3 - Pages 469-473, Peter Zwickl and Wolfgang Baumeister

Protein Glycosylation, Overview; Vol.3 - Pages 504-509, Natasha E. Zachara and Gerald W. Hart

Rho GTPases and Actin Cytoskeleton Dynamics; Vol.3 - Pages 714-718, Priam Villalonga and Anne J. Ridley

Septins and Cytokinesis; Vol.4 - Pages 22-26, Makoto Kinoshita and Christine M. Field

SUMO Modification; Vol.4 - Pages 130-134, Frauke Melchior and Andrea Pichler

Tight Junctions; Vol.4 - Pages 187-189, Shoichiro Tsukita

Transcriptional Silencing; Vol.4 - Pages 200-203, Ann Sutton and Rolf Sternglanz

Tubulin and its Isoforms; Vol.4 - Pages 272-276, Eva Nogales

Unfolded Protein Responses; Vol.4 - Pages 319-325, David Ron

Vacuoles; Vol.4 - Pages 331-336, Christopher J. Stefan and Scott D. Emr

Protein/Enzyme Structure Function and Degradation

Allosteric Regulation; Vol.1 - Pages 68-73, Barry S. Cooperman

Aminopeptidases; Vol.1 - Pages 96-98, Ralph A. Bradshaw

Amyloid; Vol.1 - Pages 99-104, Ronald Wetzel

Aspartic Proteases; Vol.1 - Pages 123-127, Ben M. Dunn

B12-Containing Enzymes; Vol.1 - Pages 145-151, Vahe Bandarian and Rowena G. Matthews

Biotin; Vol.1 - Pages 174-178, Steven W. Polyak and Anne Chapman-Smith

Biotinylation of Proteins; Vol.1 - Pages 179-181, Ronald A. Kohanski

Calpain; Vol.1 - Pages 300-306, Hiroyuki Sorimachi and Yasuko Ono

Chemiluminescence and Bioluminescence; Vol.1 - Pages 399-404, Thomas O. Baldwin

Coenzyme A; Vol.1 - Pages 475-477, M. Daniel Lane

Collagenases; Vol.1 - Pages 478-481, Kenn Holmbeck and Henning Birkedal-Hansen

Collagens; Vol.1 - Pages 482-487, Darwin J. Prockop

Cysteine Proteases; Vol.1 - Pages 516-520, David J. Buttle and John S. Mort

Disulfide Bond Formation; Vol.1 - Pages 598-602, Hiram F. Gilbert

Elastin; Vol.2 - Pages 10-12, Judith Ann Foster

Enzyme Inhibitors; Vol.2 - Pages 31-37, Vern L. Schramm

Enzyme Kinetics; Vol.2 - Pages 38-44, Irwin H. Segel

Enzyme Reaction Mechanisms: Stereochemistry; Vol.2 - Pages 45-50, Ming-Daw Tsai, Li Zhao and Brandon J. Lamarche

Flavins; Vol.2 - Pages 118-122, Barrie Entsch and David P. Ballou

Heme Proteins; Vol.2 - Pages 354-361, Johannes Everse

HIV Protease; Vol.2 - Pages 384-387, Ben M. Dunn

Kinetic Isotope Effects; Vol.2 - Pages 522-527, Justine P. Roth and Judith P. Klinman

Lipid Modification of Proteins: Targeting to Membranes; Vol.2 - Pages 580-583, Marilyn D. Resh

Low Barrier Hydrogen Bonds; Vol.2 - Pages 594-598, Perry A. Frey

Metalloproteases; Vol.2 - Pages 652-656, David S. Auld

Peptide Amidation; Vol.3 - Pages 226-230, Mark J. Niciu, Richard E. Mains and Betty A. Eipper

Phage Display for Protein Binding; Vol.3 - Pages 251-255, Henry B. Lowman

Prions, Overview; Vol.3 - Pages 437-440, Cedric Govaerts and Fred E. Cohen

Proteases in Blood Clotting; Vol.3 - Pages 457-463, John D. Kulman and Earl W. Davie

Proteasomes, Overview; Vol.3 - Pages 464-468, Martin Rechsteiner

Protein Carboxyl Esterification; Vol.3 - Pages 474-477, Shilpa G. Lalchandani and Jeffry B. Stock

Protein Degradation; Vol.3 - Pages 484-492, Tomo ari and Alfred L. Goldberg

Protein Folding and Assembly; Vol.3 - Pages 493-499, David P. Goldenberg

Protein N-Myristoylation; Vol.3 - Pages 527-531, Erica Dutil Sonnenburg and Jeffrey I. Gordon

Protein Palmitoylation; Vol.3 - Pages 532-535, Robert J. Deschenes

Pteridines; Vol.3 - Pages 556-560, S. Colette Daubner and Paul F. Fitzpatrick

Pyridoxal Phosphate; Vol.3 - Pages 595-599, David E. Metzler

Regulated Intramembrane Proteolysis (Rip); Vol.3 - Pages 665-670, Jin Ye, Michael S. Brown and Joseph L. Goldstein

Secretases; Vol.4 - Pages 7-10, Robert L. Heinrikson

Selenoprotein Synthesis; Vol.4 - Pages 17-21, August Bock

Substrate Binding, Catalysis, and Product Release; Vol.4 - Pages 123-126, W. Wallace Cleland

Two-Hybrid Protein–Protein Interactions; Vol.4 - Pages 290-293, Ilya Serebriiskii and Erica A. Golemis

Tyrosine Sulfation; Vol.4 - Pages 294-297, Denis Corbeil and Wieland B. Huttner

Ubiquitin System; Vol.4 - Pages 299-303, Aaron Ciechanover and Michael H. Glickman

Ubiquitin-Like Proteins; Vol.4 - Pages 304-307, Edward T. H. Yeh

Zinc Fingers; Vol.4 - Pages 435-439, Mark Isalan

Bioenergetics

ABC Transporters; Vol.1 - Pages 1-5, Andre Goffeau, Benoit De Hertogh and Philippe V. Baret

Amine Oxidases; Vol.1 - Pages 85-89, Giovanni Floris and Alessandro Finazzi Agro

ATP Synthesis in Plant Mitochondria: Substrates, Inhibitors, Uncouplers; Vol.1 - Pages 128-132, Kathleen L. Soole and R. Ian Menz

ATP Synthesis: Mitochondrial Cyanide-Resistant Terminal Oxidases; Vol.1 - Pages 133-137, James N. Siedow

Bioenergetics: General Definition of Principles; Vol.1 - Pages 170-173, David G. Nicholls

Calcium Buffering Proteins: Calbindin; Vol.1 - Pages 221-225, Willi Hunziker and Igor Bendik

Calcium Buffering Proteins: ER Luminal Proteins; Vol.1 - Pages 226-230, Jody Groenendyk and Marek Michalak

Calcium Oscillations; Vol.1 - Pages 231-234, Marisa Brini

Calcium Sensing Receptor; Vol.1 - Pages 235-240, Jacob Tfelt-Hansen and Edward M. Brown

Calcium Signaling: Calmodulin-Dependent Phosphatase; Vol.1 - Pages 241-245, Claude Klee, Hao Ren and Shipeng Li

Calcium Signaling: Cell Cycle; Vol.1 - Pages 246-249, Luigia Santella

Calcium Signaling: Motility (Actomyosin–Troponin System); Vol.1 - Pages 250-255, Takeyuki Wakabayashi and Setsuro Ebashi

Calcium Signaling: NO Synthase; Vol.1 - Pages 256-260, Zhi-Qiang Wang and Dennis J. Stuehr

Calcium Transport in Mitochondria; Vol.1 - Pages 261-266, Rosario Rizzuto and Marisa Brini

Calcium Waves; Vol.1 - Pages 267-269, Lionel F. Jaffe

Calcium, Biological Fitness of; Vol.1 - Pages 270-273, Robert J. P. Williams

Calcium/Calmodulin-Dependent Protein Kinase II; Vol.1 - Pages 274-280, Andy Hudmon and Howard Schulman

Calcium-Binding Proteins: Cytosolic (Annexins, Gelsolins, C2-Domain Proteins); Vol.1 - Pages 287-293, Joachim Krebs

Calcium-Modulated Proteins (EF-Hand); Vol.1 - Pages 294-299, Robert H. Kretsinger

Cell Death by Apoptosis and Necrosis; Vol.1 - Pages 352-355, Pierluigi Nicotera

Chemiosmotic Theory; Vol.1 - Pages 405-412, Keith D. Garlid

Chemolithotrophy; Vol.1 - Pages 419-424, Alan B. Hooper

Chlorophylls and Carotenoids; Vol.1 - Pages 430-437, Hugo Scheer

Chloroplast Redox Poise and Signaling; Vol.1 - Pages 438-445, John F. Allen

Chloroplasts; Vol.1 - Pages 446-450, Nicoletta Rascio

Cytochrome b6f Complex; Vol.1 - Pages 521-527, Gunter A. Hauska and Thomas Schodl

Cytochrome bc1 Complex (Respiratory Chain Complex III); Vol.1 - Pages 528-534, Bernard L. Trumpower

Cytochrome c; Vol.1 - Pages 535-538, Hans Tuppy and Gunther Kreil

Cytochrome Oxidases, Bacterial; Vol.1 - Pages 539-543, Peter Brzezinski and Pia Adelroth

Cytochrome P-450; Vol.1 - Pages 544-549, Rita Bernhardt

Energy Transduction in Anaerobic Prokaryotes; Vol.2 - Pages 24-30, Gottfried Unden

ER/SR Calcium Pump: Function; Vol.2 - Pages 56-60, Giuseppe Inesi

ER/SR Calcium Pump: Structure; Vol.2 - Pages 61-65, Chikashi Toyoshima and Yuji Sugita

F1–F0 ATP Synthase; Vol.2 - Pages 73-79, Donata Branca

Ferredoxin; Vol.2 - Pages 104-106, Giuliana Zanetti and Vittorio Pandini

Ferredoxin-NADP+ Reductase; Vol.2 - Pages 107-111, Giuliana Zanetti and Alessandro Aliverti

Free Radicals, Sources and Targets of: Mitochondria; Vol.2 - Pages 134-142, Alberto Boveris and Enrique Cadenas

Friedreich's Ataxia; Vol.2 - Pages 143-145, Paul E. Hart and Anthony H. V. Schapira

Giant Mitochondria (Megamitochondria); Vol.2 - Pages 186-188, Bernard Tandler and Charles L. Hoppel

Glutathione Peroxidases; Vol.2 - Pages 224-228, Fulvio Ursini and Matilde Maiorino

Green Bacteria: Secondary Electron Donor (Cytochromes); Vol.2 - Pages 321-324, Hirozo Oh-oka and Robert E. Blankenship

Green Bacteria: The Light-Harvesting Chlorosome; Vol.2 - Pages 325-330, John M. Olson

Green Sulfur Bacteria: Reaction Center and Electron Transport; Vol.2 - Pages 331-336, Gunter A. Hauska and Thomas Schodl

Heme Synthesis; Vol.2 - Pages 362-366, Gloria C. Ferreira

Intracellular Calcium Channels: cADPR-Modulated (Ryanodine Receptors); Vol.2 - Pages 465-468, Antony Galione

Intracellular Calcium Channels: NAADP+-Modulated; Vol.2 - Pages 469-472, Armando A. Genazzani and Marcella Debidda

IP3 Receptors; Vol.2 - Pages 478-481, Colin W. TaylorEdward Morris and Paula da Fonseca

Iron–Sulfur Proteins; Vol.2 - Pages 482-489, Helmut Beinert, Jacques Meyer and Roland Lill

Ligand-Operated Membrane Channels: Calcium (Glutamate); Vol.2 - Pages 551-561, Elias K. Michaelis

Ligand-Operated Membrane Channels: GABA; Vol.2 - Pages 562-566, F. Minier and Erwin Sigel

Light-Harvesting Complex (LHC) I and II: Pigments and Proteins; Vol.2 - Pages 567-570, Stefan Jansson

Luft's Disease; Vol.2 - Pages 599-601, Salvatore DiMauro

Membrane Transport, General Concepts; Vol.2 - Pages 627-630, Stanley G. Schultz

Membrane Transporters:Na+/Ca2+ Exchangers; Vol.2 - Pages 631-636, Jonathan Lytton

Membrane-Associated Energy Transduction in Bacteria and Archaea; Vol.2 - Pages 637-645, Gunter Schafer

Metabolite Channeling: Creatine Kinase Microcompartments; Vol.2 - Pages 646-651, Uwe Schlattner and Theo Wallimann

Mitochondrial Auto-Antibodies; Vol.2 - Pages 683-688, Harold Baum

Mitochondrial Channels; Vol.2 - Pages 689-692, M. Catia Sorgato and Alessandro Bertoli

Mitochondrial DNA; Vol.2 - Pages 693-696, Gottfried Schatz

Mitochondrial Genes and their Expression: Yeast; Vol.2 - Pages 697-702, Piotr P. Slonimski and Giovanna Carignani

Mitochondrial Genome, Evolution; Vol.2 - Pages 703-708, B. Franz Lang, Dennis V. Lavrov and Gertraud Burger

Mitochondrial Genome, Overview; Vol.2 - Pages 709-715, Douglas C. Wallace

Mitochondrial Inheritance; Vol.2 - Pages 716-719, Eric A. Shoubridge

Mitochondrial Membranes, Structural Organization; Vol.2 - Pages 720-724, Carmen A. Mannella

Mitochondrial Metabolite Transporter Family; Vol.2 - Pages 725-732, Ferdinando Palmieri and Martin Klingenberg

Mitochondrial Outer Membrane and the VDAC Channel; Vol.2 - Pages 733-736, Marco Colombini

Neuronal Calcium Signal; Vol.3 - Pages 16-20, Hilmar Bading

Nicotinamide Nucleotide Transhydrogenase; Vol.3 - Pages 50-56, Jan Rydstrom

Nuclear Genes in Mitochondrial Function and Biogenesis; Vol.3 - Pages 100-104, Alexander Tzagoloff and Carol L. Dieckmann

Oncocytes; Vol.3 - Pages 165-166, Bernard Tandler and Charles L. Hoppel

Oxygenases; Vol.3 - Pages 178-182, Osamu Hayaishi

Periplasmic Electron Transport Systems in Bacteria; Vol.3 - Pages 231-238, David J. Richardson, Gary Sawers and Rob J. M. Van Spanning

Phosphatidylinositol-3-Phosphate; Vol.3 - Pages 272-276, Joseph V. Virbasius and Michael P. Czech

Photosystem I, Structure and Function; Vol.3 - Pages 342-347, Petra Fromme

Photosystem I: FX, FA, and FB Iron–Sulfur Clusters; Vol.3 - Pages 348-356, Mikhail L. Antonkine and John H. Golbeck

Photosystem II Light Harvesting System: Dynamic Behavior; Vol.3 - Pages 357-362, Peter Horton and Alexander Ruban

Photosystem II: Assembly and Turnover of the D1 Protein; Vol.3 - Pages 363-366, Eira Kanervo and Eva-Mari Aro

Photosystem II: Protein Components; Vol.3 - Pages 367-374, James Barber

Photosystem II: Water Oxidation, Overview; Vol.3 - Pages 375-380, Fabrice Rappaport and Pierre Joliot

Plasma-Membrane Calcium Pump: Structure and Function; Vol.3 - Pages 385-389, Emanuel E. Strehler

Plastocyanin; Vol.3 - Pages 390-393, Elizabeth L. Gross

Protein Import into Mitochondria; Vol.3 - Pages 510-515, Johannes M. Herrmann and Walter Neupert

P-Type Pumps: Copper Pump; Vol.3 - Pages 561-564, Ilia Voskoboinik and James Camakaris

P-Type Pumps: H+/K+ Pump; Vol.3 - Pages 565-570, Jai Moo Shin and George Sachs

P-Type Pumps: Na+/K+ Pump; Vol.3 - Pages 571-576, Peter L. Jorgensen

P-Type Pumps: Plasma-Membrane H+ Pump; Vol.3 - Pages 577-581, A. Brett Mason and Carolyn W. Slayman

Purple Bacteria: Electron Acceptors and Donors; Vol.3 - Pages 582-585, Evaldas Katilius and Neal W. Woodbury

Purple Bacteria: Photosynthetic Reaction Centers; Vol.3 - Pages 586-594, C. Roy D. Lancaster

Pyrimidine Biosynthesis; Vol.3 - Pages 600-605, Monika Loffler and Elke Zameitat

Quinones; Vol.3 - Pages 621-627, Giorgio Lenaz and Maria Luisa Genova

Respiratory Chain and ATP Synthase; Vol.3 - Pages 671-675, David G. Whitehouse and Anthony L. Moore

Natriuretic Peptides and their Receptors

Lincoln R. Potter
University of Minnesota, Minneapolis, Minnesota, USA

Natriuretic peptides are an ancient family of hormones/paracrine factors that regulate blood pressure, cardiovascular homeostasis, and bone growth. The mammalian family consists of atrial natriuretic peptide, brain natriuretic peptide, and C-type natriuretic peptide. All three peptides are derived from separate genes, but share a common 17-amino-acid disulfide ring that is required for biological activity. A family of three cell surface receptors mediates their cellular effects: two are receptor guanylyl cyclases, enzymes that catalyze the synthesis of the intracellular second messenger, cGMP, whereas one is a decoy receptor that lacks enzymatic activity. In this article, the structure, function, and regulation of each hormone and receptor are discussed.

Natriuretic Peptides

Atrial Natriuretic Peptide

The first natriuretic peptide to be identified was atrial natriuretic peptide (ANP), which was originally called atrial natriuretic factor (ANF) because of its unknown structure. It was discovered by de Bold and co-workers in 1981. They found that intravenous infusion of atrial, but not ventricular, homogenates into rats caused a rapid and dramatic increase in renal sodium and water excretion that was accompanied by reduced blood pressure. Subsequently, a smooth muscle relaxing activity was shown to cofractionate with the natriuretic activity. The peptide responsible for both blood pressure lowering properties was purified and sequenced from multiple species by several laboratories. The structure of the polypeptide precursor of the mature peptide was derived from cDNA sequence, which like the peptide sequence was obtained from a number of different species by several different laboratories.

All natriuretic peptides are synthesized as preprohormones. Human preproANP is 151 amino acids in length. Proteolytic removal of the amino-terminal signal sequence yields a 126 residue proANP peptide, which is the predominant storage form found in dense atrial granules. Upon secretion, proANP is cleaved by corin, a transmembrane serine protease, to a 98 residue amino-terminal peptide and a 28 residue carboxyl-terminal peptide. Both fragments circulate in the plasma and are elevated under conditions where vascular volume is increased, such as congestive heart failure. The carboxyl terminal 28 amino-acid peptide is the mature biologically active form of ANP that mediates the known biological effects associated with the ANP gene (Figure 1).

The majority of ANP gene expression occurs in the cardiac atria, but there is low-level expression in extra-atrial tissues, e.g., central nervous system, adrenal gland, kidney, and ventricles. Expression in the latter tissue is generally only observed in early life or during ventricular hypertrophy. Hence, ANP mRNA expression has become a universal marker for ventricular remodeling that results from prolonged hypertension or other forms of cardiovascular insult. Differential processing of ANP in the kidney produces a variant containing four additional amino-terminal amino acids called urodilatin. It has been reported to be more potent than ANP, possibly because it is less sensitive to proteolytic degradation by neutral endopeptidases (NEPs). Atrial-wall stretch, reflecting increased intravascular volume, is the dominant stimulus for ANP release. However, several hormones and neurotransmitters – such as endothelin, arginine vasopressin, and catecholamines – also stimulate its secretion.

In addition to stimulating natriuresis, diuresis, and vasorelaxation, ANP also inhibits renin, vasopressin, and aldosterone release. It decreases cell proliferation and hypertrophy as well. Hence, ANP's short-term (natriuresis, diuresis, vasorelaxation) and long-term (antimitogenesis) effects are generally considered beneficial.

Transgenic mice exhibiting lifelong elevated plasma ANP levels display reduced blood pressure and heart size. In contrast, mice lacking ANP are hypertensive. The initial report describing these animals suggested that ANP regulates blood pressure in a salt-sensitive manner, but a subsequent communication indicated that these same mice were also hypertensive when fed a very low

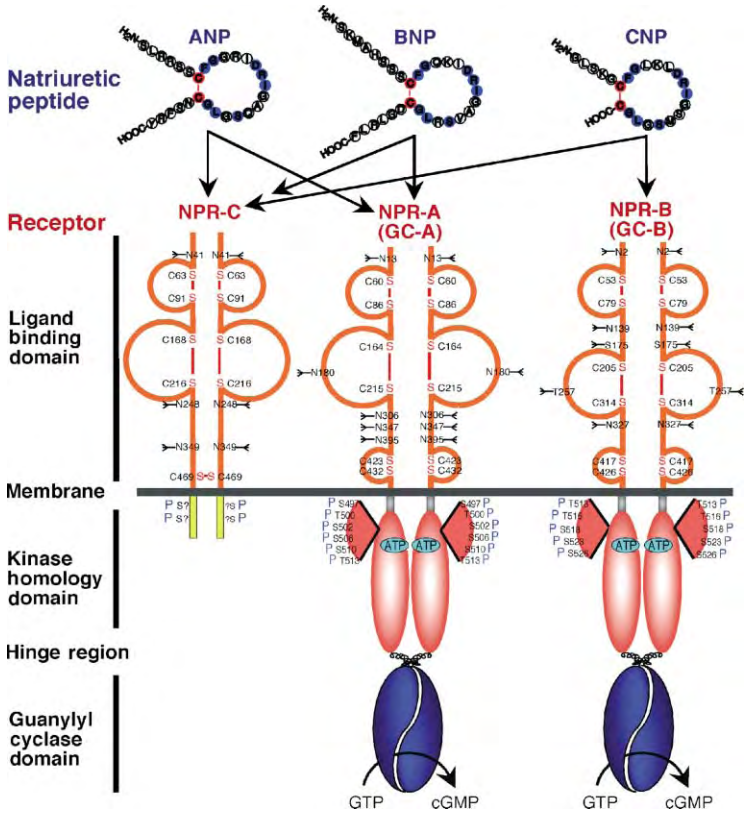

FIGURE 1 Schematic representation of natriuretic peptides and their receptors. Black arrows indicate which receptors each natriuretic peptide binds. Note that each peptide can bind more than one receptor. Blue circles in natriuretic peptide structures indicate conserved residues. Red lines indicate disulfide bonds. Black branched lines indicate N-linked glycosylation sites. Blue Ps indicate phosphorylation sites. ANP, atrial natriuretic peptide; BNP, brain natriuretic peptide; CNP, C-type natriuretic peptide; cGMP, cyclic guanosine monophosphate; GC-A, guanylyl cyclase A; GC-B, guanylyl cyclase B; GTP, guanosine triphosphate; NPR-A, natriuretic peptide receptor A; NPR-B, natriuretic peptide receptor B; NPR-C, natriuretic peptide receptor C.

salt diet (0.008% NaCl), consistent with ANP mediating its effects independently of body sodium chloride levels.

ANP is degraded outside and inside the cell by extracellular proteases and NPR-C-dependent internalization and degradation, respectively. The extracellular NEP 24.11 is a metallopeptidase that degrades all three natriuretic peptides. Recently, compounds have been developed that inhibit both angiotensin converting enzyme (ACE) and NEP. Omapatrilat, the most studied of these so-called vasopeptidase inhibitors, has the combined benefit of prolonging the blood pressure decreasing effects of natriuretic peptides while inhibiting the blood pressure increasing effects of the angiotensin system. Although early indications from clinical trials suggested that these drugs are beneficial to some patients with hypertension and/or congestive heart failure, very recent studies indicate that patients receiving vasopeptidase inhibitors experience more angioedema than patients treated with ACE inhibitors. Therefore, further development is needed before vasopeptidase inhibitors are viable alternatives to current therapies.

Brain Natriuretic Peptide

Although brain natriuretic peptide (BNP) was originally isolated from porcine brain, it was subsequently found to be more abundant in cardiac ventricles. Of all the natriuretic peptides, the amino-acid sequence of BNP varies most among species. For instance, in human, pig, and rat, mature BNP is 32, 26, and 45 amino acids in length, respectively.

Human BNP cDNA encodes a 132 amino-acid preprohormone that is processed to a 105-residue prohormone by removal of the signal peptide. Both corin and the endopeptidase, furin, have been shown to cleave the prohormone into the 32 amino-acid mature peptide. In the myocyte, BNP mRNA levels are regulated transcriptionally and posttranscriptionally in response to increased ventricular filling pressures or mechanical stretch. BNP is functionally similar to ANP

with respect to its vasorelaxant, natriuretic, and diuretic properties, but normal plasma BNP levels are only one-seventeenth of ANP levels. In contrast to ANP, ventricular BNP is not stored in secretory granules, instead it is released in a constitutive fashion following synthesis. Transgenic mice overexpressing BNP exhibited reduced blood pressure and cardiac weight accompanied by an elevation of plasma cGMP concentrations. They also exhibit increased long bone growth that most likely results from cross-activation of NPR-B. BNP null mice have normal blood pressures, but display pressure-sensitive cardiac fibrosis, proliferation of interstitial fibroblasts, and elevated ventricular extracellular matrix proteins. Hence, BNP's main function may be to regulate the cardiac ventricles.

BNP release is directly proportional to ventricular volume expansion and pressure overload. Although ANP is elevated in patients with congestive heart failure, BNP levels correlate more closely with left ventricular pressure, amount of dyspnea, and the state of neurohormonal modulation. Therefore, BNP, more than ANP, is an excellent indicator of heart failure. A rapid, whole-blood BNP assay (Triage BNP Test, Biosite Inc., San Diego, CA) that allows quick evaluation of patient plasma BNP levels was recently approved by the US Food and Drug Administration. Normal human plasma levels of BNP are <40 pg ml^{-1} and levels greater than 100 pg ml^{-1} are highly correlated with congestive heart failure. The high negative predictive value of this measurement suggests that it may be extremely useful in ruling out cardiac abnormalities in patients with dyspnea.

Recombinant B-type natriuretic peptide, whose clinical and trade names are Nesiritide and Natrecor, respectively, mimics the actions of endogenous BNP. It has been studied in more than 1700 patients with acute decompensated heart failure and has been shown to cause potent, dose-related vasodilation that is rapid in onset and sustained for the duration of drug infusion. It was approved for the treatment of acute decompensated congestive heart failure by the Food and Drug Administration in 2001.

C-Type Natriuretic Peptide

Like BNP, C-type natriuretic peptide (CNP) was first isolated from porcine brain. It is the most highly expressed natriuretic peptide in this tissue. Similarly in cerebrospinal fluid, CNP is $\sim$2 pM, which is about tenfold higher than ANP or BNP. BNP is also found at high concentrations in cytokine-treated endothelial cells and bone tissue. Because it is barely detectable in plasma, CNP is expected to signal primarily in a paracrine manner.

The primary structure of CNP is similar to ANP and BNP, but it lacks a C-terminal tail (Figure 1). It has higher amino-acid identity between species than ANP and BNP. For example, the structures of CNP from humans, pigs, and rats are identical. The 103 amino acid CNP propeptide is processed to either 53 or 22 amino acid forms. Furin, but not corin, has been suggested to mediate this final cleavage step. Both the 53 and 22 amino acid forms have been identified *in vivo* and the 22-amino-acid peptide predominates in the central nervous system, anterior pituitary, kidney, vascular endothelial cells, and plasma. Unlike ANP, CNP is not stored in granules. Instead, it is regulated at the level of transcription by various signaling molecules, such as transforming growth factor-β, tumor necrosis factor-α, and shear stress.

CNP relaxes vascular smooth muscle and is a more potent dilator of veins than ANP or BNP. It is not a potent inducer of diuresis and natriuresis. Like ANP, CNP has been shown to inhibit the proliferation of various cultured cell lines. A potential clinical benefit of this antimitogenic property was demonstrated in a rodent model when CNP treatment was shown to dramatically inhibit the normal vascular intimal thickening that accompanies balloon angioplasty.

Homozygous deletion of the gene-encoding CNP in mice caused more than half of the offspring to die during postnatal development. Surviving animals exhibited shortened body length and defects in endochondral bone development, which is analogous to human dwarfism. Importantly, cGMP-dependent protein kinase II (PKGII) knockout mice also develop dwarfism as a result of impaired endochondral ossification, suggesting that PKGII mediates the CNP-dependent skeletal effects. Consistent with a linear CNP/cGMP/PKGII pathway, the targeted expression of CNP in growth plate chondrocytes cannot increase the longitudinal bone growth or chondrocytic proliferation and hypertrophy in PKGII knockout mice.

Natriuretic Peptide Receptors

There are three known natriuretic peptide receptors. Natriuretic peptide receptor A (NPR-A) (also known as guanylyl cyclase A (GC-A)) and natriuretic peptide receptor B (NPR-B) (also known as guanylyl cyclase B (GC-B)) are receptor guanylyl cyclases, whereas the natriuretic peptide clearance receptor (NPR-C) does not possess any known enzymatic activity. Instead, NPR-C controls the local concentration of natriuretic peptides that are available to bind NPR-A and NPR-B through receptor-mediated internalization and degradation.

Guanylyl Cyclase-Linked Natriuretic Peptide Receptors

The ligand selectivity for NPR-A is ANP > BNP ≫ CNP, whereas the ligand selectivity for NPR-B is CNP ≫ ANP > BNP. Mice lacking NPR-A are hypertensive and develop cardiac hypertrophy and ventricular fibrosis. In addition, they are completely unresponsive to the renal and vasorelaxing effects of ANP and BNP, consistent with NPR-A being the sole signaling receptor for these peptides. A promoter mutation resulting in reduced transcription of the human NPR-A gene was recently identified and shown to be highly correlated with essential hypertension or ventricular hypertrophy.

Both NPR-A and NPR-B consist of an ~450-amino-acid extracellular ligand-binding domain, a 21-residue hydrophobic membrane-spanning region, and a 566- or 568-amino-acid intracellular domain, respectively (Figure 1). The latter can be divided into a ~250-amino-acid kinase homology domain (KHD), a 41-amino-acid hinge-dimerization region, and a 250-amino-acid C-terminal guanylyl cyclase catalytic domain. Like adenylyl cyclases and soluble guanylyl cyclases, a dimer is believed to be the minimal catalytic unit for both NPR-A and NPR-B.

The NPR-A extracellular domain contains three intramolecular but no intermolecular disulfide bonds (Figure 1). Similar Cys are conserved in the extracellular domain of NPR-B. Both NPR-A and NPR-B are highly glycosylated, and several studies suggest that glycosylation is required for proper receptor folding and/or transport of the receptor to the cell surface, but is not required for hormone binding. The crystal structure of the glycosylated, unliganded, dimerized hormone-binding domain of NPR-A has been solved at 2.0Å resolution. It reveals that the monomer consists of two interconnected subdomains, each encompassing a central β-sheet flanked by α-helices and the dimerization results from juxtaposition of 2×2 parallel helices that bring the two protruding C termini in close proximity. The crystal structure of an ANP–NPR-A complex has not been solved.

Activation of the guanylyl-cyclase-linked natriuretic peptide receptors is incompletely understood. Both receptors are homooligomers in the absence and presence of their respective ligands, indicating that receptor activation does not simply result from ligand-dependent dimerization. However, ANP binding does cause a conformational change in NPR-A that brings the extracellular juxtamembrane regions of each monomer closer together. In addition to natriuretic peptides, ATP is also required to maximally activate these receptors in broken cell preparations. Since receptors lacking the kinase homology domain are constitutively active and are not further stimulated by ATP, it has been suggested that the ATP binding to the kinase homology domain may relieve the basal repression of the guanylyl cyclase domain. No direct binding data have been presented to confirm this hypothesis, but ATP has been shown to modulate ANP binding and cyclase activity in purified receptor preparations, which is consistent with a direct binding model. On the other hand, the ATP effect observed with purified preparations is significantly less than that seen in crude membranes, which is consistent with a hypothesis where membranes contain an ATP-binding factor that is only partially removed during the purification procedure.

In the resting state, both NPR-A and NPR-B are highly phosphorylated on serines and threonines within their KHD domains. NPR-A isolated from resting 293 cells is phosphorylated on Ser497, Thr500, Ser502, Ser506, Ser510, and Thr513, which are located within a 17-residue stretch that contains the glycine-rich elbow and putative ATP-binding region of its KHD. Mutation of any of these phosphorylated residues to alanine in order to mimic a dephosphorylated serine or threonine results in decreased ANP-dependent guanylyl cyclase activities. Furthermore, receptors containing alanine substitutions at four or more phosphorylation sites are completely unresponsive to hormone. NPR-B is phosphorylated on Thr513, Thr51, Ser518, Ser523, and Ser526 in a similar region of its KHD. Four of these five sites are conserved between NPR-A and NPR-B. Phosphorylation of NPR-B is also required for ligand-dependent activation.

With respect to the mechanism by which an activated receptor is turned off, a process commonly referred to as desensitization, a number of theories have been put forth. Initial *in vitro* data suggested that direct phosphorylation of NPR-A by protein kinase C mediated its desensitization, but subsequent studies conducted in live cells indicated that desensitization in response to chronic natriuretic peptide exposure (homologous desensitization) or activators of protein kinase C results in the loss of phosphate from NPR-A and NPR-B. The role of phosphorylation/dephosphorylation in the regulation of these receptors was later clarified when mutations that mimic phosphorylated or dephosphorylated receptors were shown to be active or inactive, respectively. These experiments revealed for the first time a clear positive correlation between the phosphorylation state and enzymatic activity of NPR-A and NPR-B.

In contrast to the protein phosphorylation, the role of ligand-dependent internalization and degradation of NPR-A is unclear. Pandey and co-workers have reported many times that NPR-A undergoes this process, whereas Maack and co-workers contend that NPR-A is a constitutively membrane resident protein that is not internalized.

The Natriuretic Peptide Clearance Receptor

In addition to NPR-A and NPR-B, all three natriuretic peptides bind to a third receptor called the natriuretic peptide clearance receptor (NPR-C). NPR-C migrates as a 60 and 120 kDa protein when fractionated by reducing or nonreducing SDS-PAGE, respectively. It is found on the cell surface as a disulfide-linked homodimer. NPR-C has a large amino-terminal extracellular ligand-binding domain, a single transmembrane domain, and an intracellular domain that contains only 37 amino acids and possesses no known enzymatic activity (Figure 1). It binds ANP, BNP, and CNP with similar affinities, but it can also bind tightly to several smaller carboxyl-terminal and ring-deleted peptide analogues that do not bind well to NPR-A or NPR-B. C-ANF, the prototypical form of these peptides, is sometimes used to distinguish NPR-C from NPR-A in both binding and cGMP stimulation assays. The crystal structure of both the apo form and CNP bound form of NPR-C has been determined. In contrast to the 2:2 stoichiometry that was suggested for the ANP–NPR-A complex, the stoichiometry of binding of CNP to NPR-C was determined to be 1:2.

NPR-C is the most abundant natriuretic peptide receptor on the cell surface, and its primary function is to remove natriuretic peptides from the circulation via receptor mediated internalization and degradation, thereby controlling the local concentrations of the natriuretic peptides that are available to bind NPR-A and NPR-B. Like many nutrient receptors, NPR-C internalization is constitutive, i.e., it is not increased by natriuretic peptide binding. In addition to its clearance role, NPR-C has also been implicated in signaling, possibly in a G-protein-dependent manner. However, mice lacking NPR-C displayed a reduced ability to clear ^{125}I-ANP from the circulation, but no reduction in known signaling functions. In fact, pathways activated by NPR-A and NPR-B, blood pressure, and bone growth, respectively, are increased in these animals. Nonetheless, it remains possible that NPR-C may signal as yet unidentified processes.

Glossary

cyclic GMP A cyclic mononucleotide of guanosine that acts as an intracellular second messenger for hormones, such as natriuretic peptides, guanylin, and nitric oxide.

guanylyl cyclase An enzyme that catalyzes the synthesis of cyclic GMP and pyrophosphate from guanosine triphosphate.

natriuresis Urinary sodium excretion.

protein phosphorylation Covalent addition of a phosphate molecule to the side chain of an amino acid, usually serine, threonine, or tyrosine in mammalian cells.

Biography

Lincoln Potter earned his B.S. in biology/chemistry from David Lipscomb University in Nashville. He received his Ph.D. under the direction of David Garbers from Vanderbilt University in 1994 and then conducted postdoctoral studies with Tony Hunter at the Salk Institute in San Diego. In the fall of 1999, he joined the Department of Biochemistry, Molecular Biology and Biophysics at the University of Minnesota as a tenure-track assistant professor, which is his current position.

N-End Rule

Alexander Varshavsky
California Institute of Technology, Pasadena, California, USA

The N-end rule relates the *in vivo* half-life of a protein to the identity of its N-terminal residue The N-end rule stems from the activity of a universally present proteolytic pathway called the N-end rule pathway.

Proteolysis

Proteolysis, or protein degradation, is a set of processes that result in the hydrolysis of one or more of the peptide bonds in a protein. Proteolysis is a part of protein turnover, in which the molecules of specific proteins are first made through ribosome-mediated translation, and are eventually destroyed, in ways and at rates that are specific for the protein in question and depend on the state of an organism. The *in vivo* half-lives of intracellular proteins vary from a few seconds to many days. Two major functions of intracellular proteolysis are the selective destruction of damaged or otherwise abnormal proteins, and the regulated destruction of normal proteins whose concentrations must vary depending on the cell's state. Metabolic instability (a short *in vivo* half-life) is a property of many regulatory proteins. These proteins evolved not only to carry out their primary functions, for example, those of a phosphokinase or a repressor of transcription, but also to be rapidly destroyed *in vivo*. A short half-life of a regulator provides a way to generate its spatial gradients and allows for rapid adjustments of its concentration through changes in the rate of its synthesis. A protein can also be conditionally unstable, i.e., long-lived or short-lived depending on the state of molecular circuit of which the protein is a part. This fact, and also a faster (in general) destruction of the newly formed molecules of a protein in comparison to older, conformationally mature molecules of the same protein result in complex degradation kinetics, so that a single "half-life" of specific protein is at best an approximation of its actual decay curve *in vivo* (Figure 1).

The Ubiquitin System

A major set of pathways that target and destroy specific intracellular proteins is the ubiquitin (Ub) system, also called the Ub-proteasome system. In eukaryotes, the N-end rule pathway (Figure 2) is one pathway of the Ub system. Ub, a highly conserved 76-residue protein, is conjugated to ε-amino groups of lysine residues of other proteins (including other Ub molecules) through the action of three enzymes, E1, E2, and E3. The selectivity of ubiquitylation is determined by E3, which recognizes a substrate's degradation signal (degron). The term "Ub ligase" denotes either an E2–E3 complex or its E3 component. A ubiquitylated protein substrate bears a covalently attached poly-Ub chain, which mediates the binding of substrate to the 26S proteasome, an ATP-dependent protease that processively destroys the bound protein, yielding short peptides. The rate of degradation of specific proteins is regulated through modulation of the structure or steric exposure of their degrons, and also through the control of activity of Ub ligases. Physiological functions of the Ub system encompass enormous range: the regulation of cell differentiation, cell cycle, embryogenesis, apoptosis, signal transduction, DNA transcription, replication, repair and recombination, transmembrane and vesicular transport, stress responses (including the immune response), functions of the nervous system, and many other processes.

The N-End Rule Pathway

The multiple proteolytic pathways of the Ub system have in common their dependence on Ub conjugation and the proteasome, and differ largely through their utilization of distinct E2–E3 complexes. The Ub ligase of the N-end rule pathway targets proteins bearing specific (destabilizing) N-terminal residues (Figure 2). The corresponding degron, called the N-degron, consists of a substrate's destabilizing N-terminal residue and an internal lysine residue, the latter being the site of formation of a substrate-linked poly-Ub chain. Because an N-degron must be produced through a proteolytic cleavage that yields a destabilizing N-terminal residue, a nascent N-end rule substrate contains a cryptic N-degron, called pro-N-degron. In the yeast *Saccharomyces cerevisiae*, the two substrate-binding

FIGURE 1 The N-end rules of the prokaryote *E. coli* and the eukaryote (yeast) *S. cerevisiae*. Approximate *in vivo* half-lives of X-β-galactosidase (X-βgal) test proteins in *E. coli* at 36°C and in *S. cerevisiae* at 30°C. The N-end rule pathway is Ub-dependent in eukaryotes, and is also present in prokaryotes, which lack the Ub system.

sites of the 225-kDa Ub ligase UBR1 recognize (bind to) primary destabilizing N-terminal residues of two types: basic (type 1: Arg, Lys, His) and bulky hydrophobic (type 2: Phe, Trp, Leu, Tyr, Ile) (Figure 2B). Several other N-terminal residues function as tertiary (Asn, Gln) and secondary (Asp, Glu) destabilizing residues, in that they are recognized by UBR1 only after their enzymatic conjugation to Arg, a primary destabilizing residue (Figure 2). In the case of N-terminal Asn and Gln, the conjugation of Arg is preceded by enzymatic deamidation, to yield N-terminal Asp and Glu. In animals (but not in fungi such as *S. cerevisiae*), N-terminal Cys is yet another tertiary destabilizing residue, in that the arginylation of Cys is preceded by its oxidation. These covalent modification/conjugation reactions of N-terminal residues are required for the "downstream" step of Ub conjugation to N-end rule substrates that bear N-terminal Asn, Gln, Asp, Glu, or Cys (Figure 2A).

The UBR1 Ub ligase of the N-end rule pathway contains yet another, third substrate-binding site that recognizes a specific internal (non-N-terminal) degron in pathway's substrates. The only physiological substrate of this class that had been identified thus far is the 35-kDa homeodomain transcriptional repressor CUP9 of *S. cerevisiae*. Among the genes repressed by CUP9 is *PTR2*, which encodes a di- and tripeptide transporter. CUP9 is a short-lived protein targeted by the N-end rule pathway through an internal degron near the C terminus of CUP9. Dipeptides with destabilizing N-terminal residues allosterically activate UBR1, leading to accelerated *in vivo* degradation of CUP9 and the resulting induction of PTR2 expression (Figure 3). Through this positive feedback, *S. cerevisiae* can sense the presence of extracellular peptides and react by accelerating their uptake. Thus, the type 1 and type 2 sites of UBR1 function not only as substrate-binding sites, but also as nutritional sensors, making possible the adaptive regulation of peptide import (Figure 3). The mechanism of activation by dipeptides involves a conformational transition in UBR1, induced by the binding of dipeptides, that exposes the previously inactive (sterically inaccessible) CUP9-binding site of UBR1.

Another function of the *S. cerevisiae* N-end rule pathway is the maintenance of chromosome stability. At the metaphase–anaphase transition, the *ESP1*- encoded protease, called separase, cleaves SCC1, a subunit of cohesin complexes that hold together sister chromatids of replicated chromosomes. The resulting 33-kDa C-terminal fragment of SCC1 bears N-terminal Arg and is rapidly degraded by the N-end rule pathway. A failure to degrade this fragment of SCC1 in *ubr1*Δ cells (which lack the pathway's Ub ligase) results in a greatly increased frequency of chromosome loss, presumably because the retention of cohesin's fragment perturbs the assembly of intact cohesin complexes in subsequent cell cycles. Thus, the type 1 binding site of the UBR1 Ub ligase has a dual function of both a dipeptide-binding nutritional sensor (Figure 3) and a site that recognizes proteins with destabilizing N-terminal residues, targeting these proteins for Ub-dependent degradation.

Methionine aminopeptidases (MetAPs), the proteases that are specific for N-terminal Met (every nascent protein bears N-terminal Met), would remove this Met residue if, and only if, the second residue after Met is a stabilizing residue in the N-end rule. The only exceptions, in the mammalian N-end rule, are destabilizing residues Cys, Ala, Ser, and Thr (Figure 2A). Other destabilizing residues can be exposed at the N termini of proteins only through cleavage by proteases other than MetAPs. One such protease is separase, which cleaves the SCC1 subunit of cohesin, as stated before. A large class of proteases that can also produce, *in vivo*, a destabilizing residue at the N terminus of a protein are deubiquitylating enzymes (DUBs). One reaction catalyzed by these proteases is the cleavage of a linear Ub-X-polypeptide fusion at the Ub-X junction; this cotranslational cleavage can take place irrespective of the identity of a residue X at the junction, proline being a single exception. A method, called the Ub fusion technique, that takes advantage of

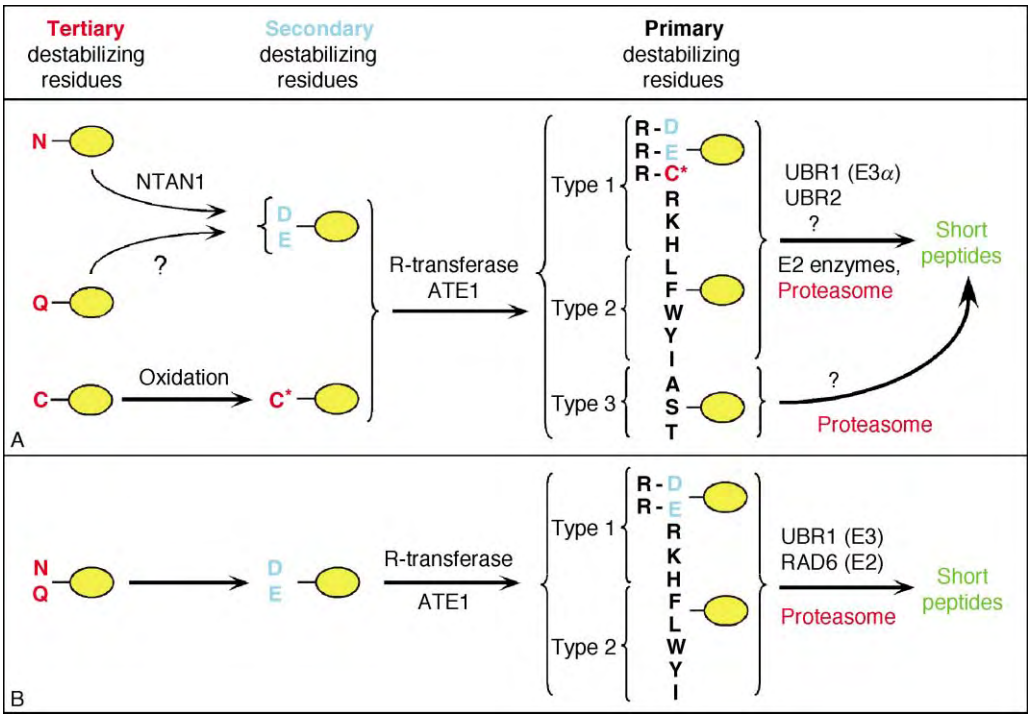

FIGURE 2 The N-end rule pathway in mammals (A) and the yeast *S. cerevisiae* (B). N-terminal residues are indicated by single-letter abbreviations. The ovals denote the rest of a protein substrate. In mammals (A), the Asn-specific N-terminal amidase NTAN1 converts N-terminal Asn into Asp. N-terminal Gln is deamidated by another (unidentified) amidase. N-terminal Asp, Glu, and Cys are conjugated to Arg by Arg-tRNA-protein transferases (R-transferases), encoded by the *ATE1* gene. N-terminal Cys is arginylated after its oxidation to either sulfinic or cysteic acid (A), a reaction that does not take place in yeast (B). The primary destabilizing N-terminal residues Arg, Lys, His (type 1 residues), as well as Phe, Leu, Trp, Tyr, and Ile (type 2 residues) are recognized in yeast (B) by the UBR1 E3, in a complex with the RAD6 E2 enzyme. In mammals (A), the same residues are recognized by UBR1 and UBR2, and by another Ub ligase that remains to be identified. In mammals but not in yeast, Ala (A), Ser (S), and Thr (T) are primary (type 3) destabilizing residues, recognized by a distinct Ub ligase that remains to be characterized.

this property of DUBs, has made it possible to produce different residues at the N termini of otherwise identical test proteins *in vivo*, and led, in 1986, to the discovery of the N-end rule.

Besides CUP9 and SCC1, several other proteins were also found to be substrates of the N-end rule pathway. These proteins include Sindbis virus RNA polymerase (and homologous polymerases of other alphaviruses), the integrase of the human immunodeficiency virus (HIV), a bacterial protein p60, which is secreted by *Listeria monocytogenes* into the cytosol of infected mammalian cells, the mammalian GTPase-activating proteins (GAP) RGS4 and RGS16, the *S. cerevisiae GPA1*-encoded Gα protein, and the encephalomyocarditis (EMC) virus 3C protease. Physiological functions, if any, of the degradation of these proteins by the N-end rule pathway are either unknown or have not been established definitively.

The N-end rule pathway of multicellular eukaryotes is organized similarly to that in *S. cerevisiae*, with several additional features. Among them is the presence of at least three functionally overlapping Ub ligases that target pathway's substrates, in contrast to a single such ligase, UBR1, in *S. cerevisiae* (Figure 2). Molecular genetic analyses in the mouse have demonstrated, through the deletion of *ATE1*, which encodes Arg-tRNA-protein transferases (R-transferases), that the arginylation branch of the mammalian N-end rule pathway (Figure 2A) is essential for cardiovascular development. It was also discovered that the mammalian N-end rule pathway is essential for meiosis in spermatocytes: in the absence of UBR2 (one of the pathway's Ub ligases), spermatocytes fail to form synaptonemal complexes and die, rendering the male *UBR2* $^{-/-}$ mice infertile. The corresponding molecular circuits, as well as physiological N-end rule substrates whose metabolic stabilization causes the cardiovascular and meiotic phenotypes in these mutants are unknown. Yet another function of the N-end rule pathway is regulation of apoptosis (programmed cell death) in the fruit fly *Drosophila melanogaster*. Specifically, the activated caspases (specific proteases that mediate apoptosis) cleave DIAP1, the inhibitor of apoptosis, producing a large C-terminal fragment of DIAP1 that bears Asn, a tertiary destabilizing residue in the N-end rule (Figure 2A). The degradation of this fragment by the N-end rule pathway down-regulates

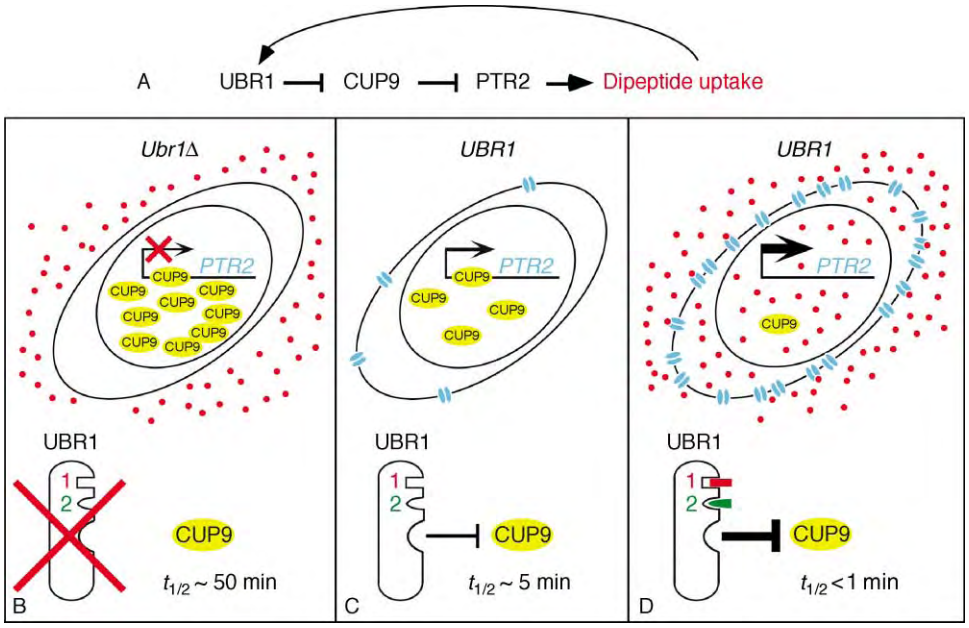

FIGURE 3 Ubiquitin-dependent activation of peptide import in *S. cerevisiae*. (A) Genetic diagram of the peptide transport circuit. (B) UBR1 is required for dipeptide uptake. In the absence of UBR1 (*ubr1*Δ), the transcriptional repressor CUP9 is long-lived, accumulates to high levels, and extinguishes the expression of peptide transporter, encoded by *PTR2*. *ubr1*Δ cells cannot import dipeptides (small dots). (C) In a *UBR1* cell growing in the absence of extracellular dipeptides, UBR1 targets CUP9 for degradation ($t_{1/2}$ ~ 5 min), resulting in a lower steady-state concentration of CUP9 and weak but significant expression of the PTR2 transporter (double ovals). (D) In *UBR1* cells growing in the presence of extracellular dipeptides some of which bear destabilizing N-terminal residues, the imported dipeptides bind to the basic (type 1) or hydrophobic (type 2) residue-binding sites of UBR1. These peptides are denoted as a rectangle and a wedge, respectively. Binding of either type of dipeptide to UBR1 allosterically increases the rate of UBR1-mediated degradation of CUP9. The resulting decrease of the half-life of CUP9 from ~5 min to less than 1 min leads to a further decrease in CUP9 levels, and consequently to a strong induction of the PTR2 transporter.

the apoptosis in *Drosophila*, presumably through the concomitant destruction of DIAP1-associated activators of apoptosis. The set of proteases that produce physiological N-end rule substrates is unlikely to be confined to MetAPs, caspases, and separases. For example, the cleavage specificity of calcium-activated proteases called calpains and the properties of other, less well-characterized cytosolic and/or nuclear proteases suggest that they, too, may function as upstream components of the N-end rule pathway. Although many functions of the N-end rule pathway remain to be discovered, the functions that have already emerged – peptide import, chromosome stability, cardiovascular development, meiosis, and apoptosis – are strikingly diverse. The broad functional range of the N-end rule pathway thus resembles, in a microcosm, the vastly greater span of the Ub system at large.

Glossary

degrons, or degradation signals Features of proteins that confer metabolic instability (short *in vivo* half-lives) on these proteins.

polyubiquitin chain A chain of covalently linked Ub moieties in which the C-terminal Gly residue of one moiety is conjugated to a specific lysine residue (usually, but not always, Lys-48) of adjacent Ub moieties. Protein-linked poly-Ub chains of different topologies (mediated by different, but unique for a given chain, lysine residues of Ub) underlie distinct roles of the Ub system, including its nonproteolytic functions. Poly-Ub can also exist as linear, head-to-tail chains of DNA-encoded Ub repeats produced through the ribosome-mediated translation. Such chains, the natural precursors of mature Ub, are called linear poly-Ub.

spermatocytes Germ cells in the testes of animals that are engaged in meiosis.

synaptonemal complex Two chromosome-length, closely apposed structures that mediate the pairing of two homologous chromosomes in meiosis.

ubiquitin ligase A complex of E2 and E3 enzymes, or an E3 enzyme alone.

ubiquitylation Conjugation of Ub to other proteins, including other Ub molecules. Ub whose C-terminal (Gly-76) carboxyl group is covalently linked to another compound is called the *ubiquityl* moiety.

Biography

Alexander Varshavsky is Smits Professor of Cell Biology at the California Institute of Technology, in Pasadena. He is a member of the US National Academy of Sciences, and has received a number of scientific awards, including the Gairdner Award, the Lasker Award, the Sloan Prize, the Merck Award, the Wolf Prize, the Horwitz Prize, the Max Planck Prize, the Pasarow Award, the Massry Prize, and the Wilson Medal.

Neoglycoproteins

Y. C. Lee and Reiko T. Lee
The Johns Hopkins University, Baltimore, Maryland, USA

The term neoglycoproteins refers to proteins modified with chemical or enzymatic means to acquire structurally defined carbohydrates. The carbohydrates can be monosaccharides, oligosaccharides, or even polysaccharides.

Preparation

Direct Coupling of Oligosaccharides to Proteins

The easiest method is to attach naturally available oligosaccharides to the amino groups of proteins. This process does not require any chemical manipulations other than the conjugation process by reductive amination. Some of the readily available di- and oligosaccharides are: lactose, maltose, cellobiose, melibiose, N-acetyl-lactosamine, di-N-acetyl-chitobiose, and a number of milk oligosaccharides. An example of coupling of lactose by reductive amination to protein using sodium cyanoborohydride or pyridine borane as reducing agent, which preferentially reduces aldimine (Schiffs base) over aldehyde, is shown in Figure 1. This method relies on the fact that reducing sugars in acyclic aldehydo form, although present in a very minor proportion, are in equilibrium with the cyclic forms. As the aldehydo form of oligosaccharide is consumed, more will become available by conversion from the cyclic forms. However, the conjugation by this simple method is a very slow process, requiring several days or longer, because of the low concentration of the aldehyde form of oligosaccharide in solution.

The reductive amination converts the primary amino groups of N terminus and lysine side chains to secondary amines initially, and eventually to tertiary amines (with two sugar groups attached to a single nitrogen), if both oligosaccharide and reducing agent are present in excess. It is important to note that after such a reaction, the reducing terminal sugar of the oligosaccharide will become acyclic, and for this reason, conjugation with monosaccharide is meaningless. The shortcoming of this approach, in addition to long reaction time mentioned above, is the limited availability of suitable oligosaccharides. However, the number of commercially available oligosaccharides that are naturally derived or synthetically prepared has been steadily increasing.

Using Synthetic Carbohydrate Derivatives

Neoglycoproteins prepared by direct conjugation of oligosaccharides sometimes can be disadvantageous, due to sugar residues that are recognition target being too close to the protein surface. Synthetic carbohydrate derivatives would expand the scope of neoglycoprotein considerably both in terms of sugar structure and its disposition on the protein surface. The procedures can be totally synthetic or can be chemical modifications of naturally available glycans either in a free sugar form or linked to a group such as peptide. A few of the popular procedures are presented below.

Aromatic Glycosides

Commercially available *p*-aminophenyl glycosides are convenient derivatives for making neoglycoproteins either by diazo-coupling to tyrosine side chains or via transformation into isothiocyanate (reaction with thiophosgen), which then reacts with amino groups. *p*-Nitrophenyl glycosides, commonly used chromogenic glycosides, are available in even wider variety, and can be easily reduced to the corresponding *p*-aminophenyl glycosides. A shortcoming of these derivatives is that they can increase the hydrophobicity of product neoglycoprotein considerably and consequently may alter the nature of protein and give anomalous results in the probing of carbohydrate function.

Nonaromatic Glycosides

The problem of excessive hydrophobicity can be alleviated by the use of derivatives which do not contain aromatic rings and are not as hydrophobic as aromatic glycosides (e.g., Figure 2). Some of these derivatives are thioglycosides, which have the advantage of being more resistant to most exoglycosidases and also specifically cleavable with mercuric salts. Examples shown in Figure 2 are: (A) sugar imidate reacting with amino groups of protein to produce amidino-type (AI)

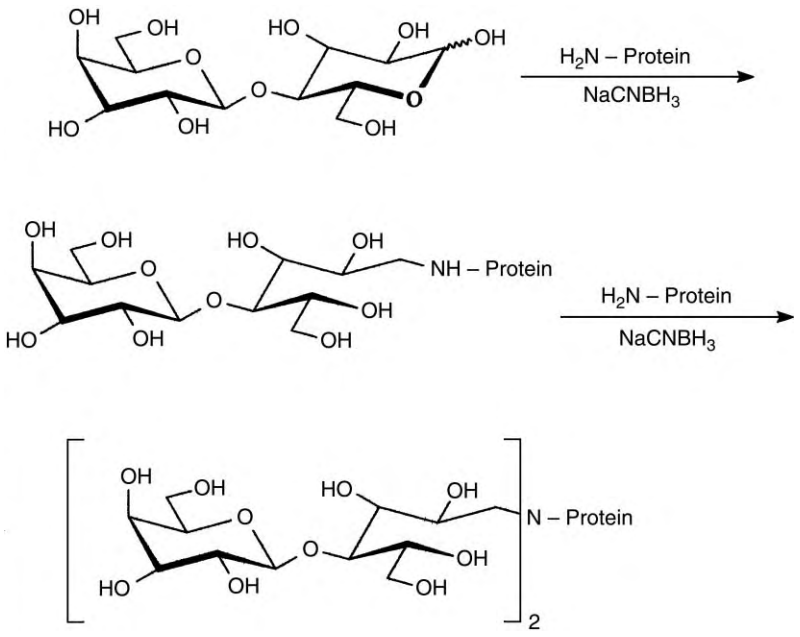

FIGURE 1 Conjugation of lactose via reductive amination.

neoglycoproteins; (B) an ω-aldehydo glycoside being coupled to protein via reductive amination; and (C) an ω-aminoalkyl glycosides converted to squaric acid derivative which can react with amino groups of protein. In both (B) and (C), the length of a glycon can be varied.

Reduced and Periodate-Oxidized Natural Oligosaccharides

Synthesis of oligosaccharides having complex structure is still a tedious and difficult task. Therefore, it is prudent sometimes to utilize naturally isolable oligosaccharides, if the quantity of neoglycoprotein needed is not too large. Natural oligosaccharides, pre-existing or obtained from natural glycoconjugates by enzymatic cleavage, can be made more reactive by first reducing them with sodium borohydride (to convert the reducing sugar residue into acyclic alditol) followed by mild periodate oxidation (e.g., 10 mM $NaIO_4$ for 10 min at room temperature), which will preferentially oxidize acyclic glycols to generate aldehydo group(s) without affecting the rest of the cyclic sugar residues. The newly generated aldehyde can be used in the reductive amination reaction as described above.

Using Other Functional Groups of Proteins

Most of the conjugation methods described above utilize amino groups of proteins for conjugation, which are often abundant and reactive because of the distance from the protein backbone. However, other functional groups such as phenolic, sulfhydryl, and carboxyl groups can also be used for conjugation. Diazo coupling of aryl glycosides to tyrosine side chain has been mentioned earlier. Thiol groups of protein are easy target for oligosaccharide attachment, since chemically mild, thiol-specific reactions are readily available. For example, a heterobifunctional linker with an amino-reacting group on one end and a maleimido or iodoacetamido group on the other end is reacted first to an Asn-oligosaccharide (or other glycopeptide) via its amino terminus, which is then reacted with protein thiol groups to produce neoglycoprotein in high yield. Bovine serum albumin has a single sulfhydryl group which can be utilized in this way to produce a neoglycoprotein carrying a single oligosaccharide chain of defined structure. An interesting approach is to react glycosylthiol with protein thiol group to form a disulfide bond. This will result in a product quite similar in structure to the natural N-glycosylated protein in terms of linkage length.

Use of Glycosyl Transferases

As the number of glycosyl transferases available commercially increases steadily, these enzymes have become a powerful synthetic tool in neoglycoprotein synthesis. The advantage of glycosyl transferases, is their exquisite specificity for anomeric configuration as well as the position of attachment. Thus, these enzymes are especially suited for modifying a pre-existing glycan structure (even a monosaccharide) at a specific position. Attachment of terminal α-L-fucosyl group or sialic acid group is a prime example. The enzymatic reaction can be carried out on the oligosaccharide before conjugation or after the conjugation to proteins.

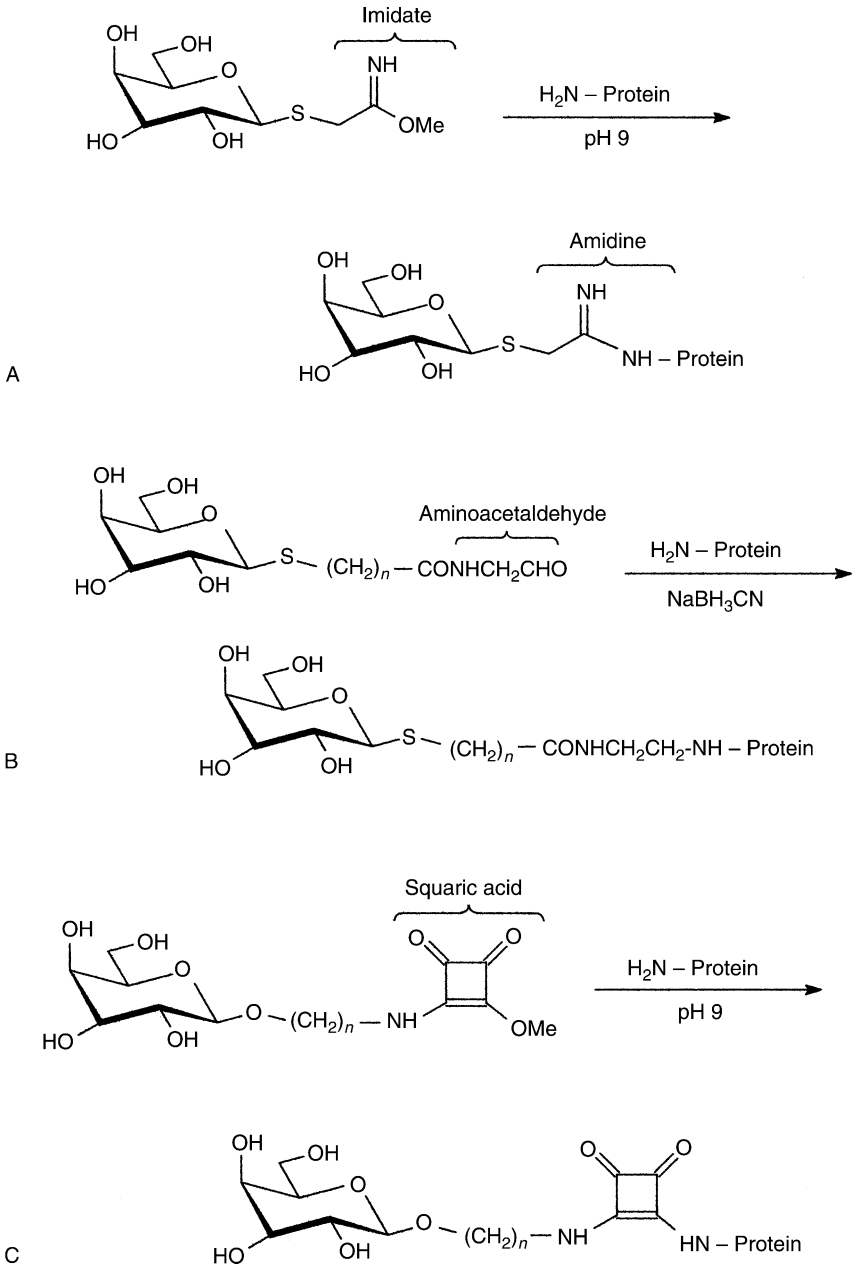

FIGURE 2 Example of synthetic methods for neoglycoprotein preparations.

Conjugation of Glycopeptides

For the conjugation of glycan structures from glycoprotein, sometimes it is easier to generate glycopeptide than to generate reducing oligosaccharide. A heterobifunctional crosslinker with a hydrazide and an acetal groups at two ends of molecule was devised to react first with amino groups of glycopeptide (or any other amino-terminated carbohydrate derivatives) via azide reaction, which is followed by generation of aldehydo function and then coupling to protein via reductive amination.

In all of these reactions, the level of sugars on neoglycoproteins can be controlled either by the ratio of reagent to protein or by the length of reaction. It should be borne in mind that these modifications generally produce a distribution of different sugar substitution in terms of both position and number. However, the ability to vary the degree of substitution turned out to be a great advantage for probing of carbohydrate function in many biological systems that is not readily available in natural glycoproteins. This is because recognition of carbohydrates often requires multivalency (Glycoside Clustering Effect) in order to manifest its function unequivocally. Neoglycoproteins can readily provide multivalency and thus are powerful ligands for carbohydrate binding.

In addition, neoglycoproteins can be radioiodinated (using the tyrosine side chain) or modified with fluorescent groups, such as fluorescein (using available ε-amino group) for easy monitoring.

Applications

Carbohydrate Receptor Analyses

Using neoglycoproteins, one can easily survey sugar-binding receptors (or lectins) in biological specimen. For example, a series of neoglycoproteins have been used to determine that alligator hepatic receptor has binding specificity for mannose and L-fucose. The binding of tagged neoglycoproteins (e.g., ^{125}I-labeled) to receptors can be probed both in solution phase and solid phase. Properly labeled neoglycoproteins can be used as cytochemical markers.

Affinant for Isolation

Neoglycoproteins can serve as effective affinant for isolation of lectins and receptors. For such a purpose, a neoglycoprotein can be conveniently immobilized to a suitable solid phase (e.g., Sepharose). In an alternate case, a protein (such as BSA) is immobilized first and then modified with one of the reagents mentioned above to form neoglycoproteins on solid phase.

Substrates for Enzymes

Neoglycoproteins can be used as convenient substrate for enzymes. For example, GlcNAc-BSA adsorbed on microtiter wells was used conveniently as substrate to assay β-galactosyl transferase with great sensitivity, which in turn can be used to assay α-fucosyl transferase.

Targeting Device

Neoglycoproteins can be used to target drugs and other materials to specific organs. For example, Gal- or GalNAc-containing neoglycoproteins, when properly conjugated to drug or anti-sense materials, can be used to target such materials to mammalian liver.

Examination of Glycoprotein Structure/Function Relationship

Carbohydrate chains of glycoprotein can have biological and biochemical function unrelated to specific sugar–lectin interaction. One of the better documented cases is the glycan in the Fc domain of IgG, which is required for interaction with Fc receptor. Neoglycoproteins were prepared by disulfide formation between Cys (in lieu of Asn) in the Fc domain and glycosylthiols of various structures to examine the effect of glycan structure on Fc receptor binding activity. Moreover, if the amino acid sequence and X-ray structure are known, one can place a Cys at different surface locations by genetic engineering, which would provide more latitude in examination of the role of carbohydrates on glycoproteins.

Biography

Y. C. Lee is Professor of Biology at the Johns Hopkins University in Baltimore, Maryland. He received his Ph.D. from the University of Iowa. His principal research interests are chemistry and biochemistry of glycoconjugates, especially biological interactions involving carbohydrates. He developed the field of neoglycoproteins as well as discovered glycoside clustering effect. He has published nearly 400 papers and book chapters, and received the Claude Hudson Award of the American Chemical Society in 2001.

Reiko Lee also received her Ph.D. from University of Iowa and is a Research Scientist in Biology Department of the Johns Hopkins University. She has coedited several volumes of books on the topics of neoglycoconjugates and recognition of carbohydrates in biological systems.

Neuronal Calcium Signal

Hilmar Bading
University of Heidelberg, Heidelberg, Germany

Neurons initiate many changes in gene expression in response to a synaptic or electrical stimulus. Calcium is the principal second messenger bridging the gap between the synapse and the nucleus. To couple synaptic events to specific genomic responses, neurons exploit the spatial diversity of calcium signals associated with the stimulus. Dendritic calcium signals, activating the MAP kinase (extracellular signal-regulated kinase, ERK1/2) signaling cascade, stimulate gene expression mediated by the serum response element. Calcium signals in the cell nucleus activate the transcription factor CRE-binding protein (CREB) and the coactivator CREB-binding protein (CBP). Nuclear calcium may, in particular, initiate and govern gene-expression-dependent forms of neuronal adaptations, including survival, learning, and memory.

Calcium Ions, Key Regulators of Electrical-Activity-Dependent Gene Expression

The generation of calcium signals following electrical activation is a fundamental property of neurons that controls many processes in the developing and the adult nervous system. Activity-induced increases in the intracellular calcium concentration result from calcium entering neurons from the extracellular space through ligand- and/or voltage-gated ion channels; these calcium transients can be amplified through calcium release from intracellular calcium stores. The N-methyl-D-aspartate (NMDA) receptor, a calcium permeable, glutamate-gated ion channel, plays a particularly important role in the mammalian central nervous system. Calcium entry through NMDA receptors, triggered by electrical activity, stimulates mechanisms that affect synaptic connectivity and neuronal network behavior leading to information storage; NMDA receptor-mediated calcium entry can also promote neuronal survival or cause cell death. For the consolidation of these activity-induced responses it is important that calcium signals, generated initially at the plasma membrane, are transduced to the cell nucleus where they stimulate the expression of particular genes. Thus, neurons use calcium ions to couple electrical signals to specific genomic events. Among the target genes of calcium signaling are neurotrophic factors, cytoskeletal proteins, and transcription factors (see below).

Spatial Calcium Signaling in Synapse-to-Nucleus Communication

The use of calcium as a universal signal mediator raises the issue of specificity: what mechanism allows neurons to use a single second messenger to convert a diverse range of electrical stimuli into distinct gene expression responses? Neurons appear to achieve this by using a calcium code: a given electrical stimulus is transformed into a calcium signal with particular spatial and temporal properties. Thus, an activity-induced neuronal calcium signal is a signature of the stimulus; it functions as its intracellular representation and links the stimulus to a gene expression response. The amplitude and the duration of the calcium signal, two features that transcriptional regulators decode, primarily control the magnitude of the increase in transcription. The site of calcium entry also matters; indeed, calcium entry through synaptic NMDA receptors and through extrasynaptic NMDA receptors has opposing effects on the activation of a crucial transcription factor (see below). However, most importantly, the genomic response depends on which part of the neuron is invaded by the calcium transient (Figure 1). For example, a weak synaptic input may generate a calcium signal that is confined to the submembranous space in the immediate vicinity of the site of calcium entry; following a stronger stimulus, calcium increases may reach further into the dendritic tree. Under certain conditions the calcium signal can invade the cell body and the nucleus. It is important for the specification of the gene expression response exactly which subcellular compartment (i.e., submembranous space, dendritic tree and somatic cytoplasm, and cell nucleus) undergoes a change in the calcium concentration. Thus, the "dialogue between genes and synapses" (to use a phrase from Eric Kandel) exploits the spatial and temporal diversity of calcium

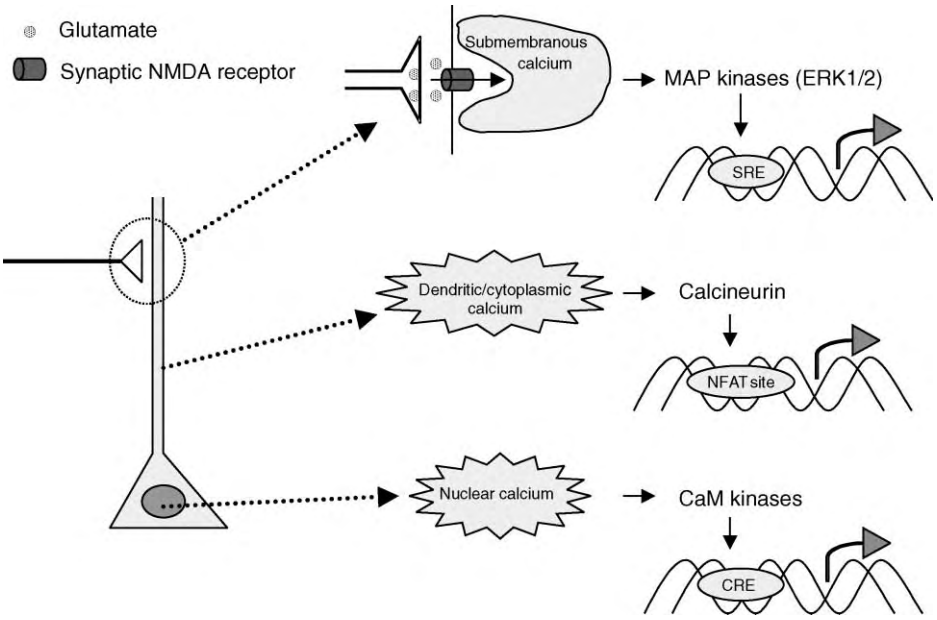

FIGURE 1 Schematic drawing of a neuron and the intracellular signaling pathways that mediate the induction of gene expression following neuronal activity. Three spatially distinct calcium signals (submembranous, cytoplasmic, and nuclear) are illustrated. Each type of calcium signal couples to a specific effector mechanism with distinct genomic targets. The decoding, by transcriptional regulators, of spatial information contained in activity-induced calcium transients allows neuronal impulse patterns to specify gene expression responses.

transients associated with electrical activation. Transcriptional regulation and the neuronal responses depend on how calcium enters the neurons, the amplitude of the signal, how long the signal lasts and what subcellular compartment it invades.

Regulators of Calcium-Induced Gene Expression

Much knowledge of the mechanisms of electrical-activity-dependent gene expression comes from studies of the *c-fos* gene. This gene is induced, without the need for new protein synthesis, within minutes after the stimulation. The *c-fos* gene encodes a DNA binding protein; together with members of the Jun transcription factor family it forms the AP-1 complex that is involved in the regulation of many genes. *c-fos* was the first gene found to be induced by membrane depolarization and calcium influx into excitable cell lines and primary neurons.

SRE AND CRE

Analysis of the *c-fos* promoter revealed that calcium influx-induced gene transcription is mediated by two distinct DNA regulatory elements: the cAMP response element (CRE) and the serum response element (SRE). The CRE and the SRE were previously known to mediate gene induction upon increasing intracellular levels of cAMP or following the addition of serum to serum-starved fibroblasts, respectively. Analysis of calcium regulation of SRE-dependent and CRE-dependent transcription uncovered the importance of the intracellular localization of the calcium signal: an increase in cytoplasmic calcium activates gene expression mediated by the SRE; in contrast, activation of the CRE and the CRE-binding protein (CREB) require increases in the nuclear calcium concentration. Thus, a single second messenger can, depending on its intracellular localization, induce distinct responses.

NFAT AND DREAM

Calcium-responsive regulators of transcription, other than the SRE and CREB, include the Nuclear Factor of Activated T-cells (NFAT) and the downstream regulatory element (DRE)-binding protein, DREAM (DRE-Antagonist Modulator). NFAT is important in the immune system; it mediates in activated T-cells the induction of interleukin-2 expression, a critical step in the response to antigen stimulation. DREAM is a multifunctional calcium-binding protein that can act as a repressor of gene transcription. The importance of spatial calcium signaling in the regulation of the SRE, the CRE, NFAT, and DREAM is outlined in the following section.

Calcium Signals in Different Subcellular Compartments

Calcium brings about biological responses through activating effector molecules such as protein kinases or protein phosphatases. Exactly which calcium-regulated molecule is stimulated depends on the subcellular localization of the calcium transient.

Submembranous Calcium Signals

A calcium microdomain restricted to the submembranous space near synaptic NMDA receptors serves as the "on-switch" of the MAP kinase (ERK1/2) cascade following synaptic activity. This signaling pathway is a major route for intracellular communication. The actions of MAP kinases (ERK1/2), both in the vicinity of calcium entry sites and in the nucleus, are involved in controlling many different brain functions ranging from learning to neuronal survival and light-induced shifts in the circadian rhythm.

One important target of the MAP kinase (ERK1/2) cascade is the nucleus. The MAP kinase (ERK1/2) signal propagates to the nucleus independently of global (i.e., cell-wide) increases in the calcium concentration and stimulates gene expression mediated by the SRE. It can also lead to the phosphorylation of CREB on its activator site, serine 133. Although this phosphorylation is necessary for inducing CREB-mediated transcription, it is not sufficient; a second regulatory event is required that involves stimulation of the activity of the CREB coactivator CBP by nuclear calcium and nuclear calcium/calmodulin (CaM)-dependent protein kinases. Nevertheless, the MAP kinase (ERK1/2) cascade acts as an auxiliary pathway that promotes at least one of several activating steps that control CREB-dependent gene expression. CREB target genes include *c-fos* and the brain-derived neurotrophic factor (BDNF).

Dendritic/Cytoplasmic Calcium Signals

The second calcium pool with a role in transcription regulation by neuronal activity is localized to the dendrites and the cytoplasm of the cell body. One of the targets of dendritic/cytoplasmic calcium is calcineurin (CaN). CaN is a cytoplasmic serine/threonine phosphatase that, upon activation by calcium/CaM, catalyzes the dephosphorylation of NFAT, which unmasks a NFAT nuclear localization signal. The activated CaN/NFAT complex is subsequently imported into the nucleus to activate gene transcription. Possible target genes of the CaN/NFAT signaling module are genes involved in regulating calcium homeostasis; this includes the IP_3 receptor and plasma membrane calcium ATPases (calcium pumps).

Once calcium concentrations have returned to basal levels, the NFAT/CaN complex dissociates, NFAT is exported from the nucleus and transcription is rapidly shut off. Thus, the magnitude of the transcriptional response is a function of the duration of the calcium signal; only prolonged increases in intracellular calcium efficiently activate NFAT-mediated gene expression. In addition, increases in nuclear calcium are required to maintain NFAT in the nucleus and to sustain transcription. Such calcium signals (i.e., elevated calcium plateaus in the cytoplasm and the nucleus) are typically seen in antigen-stimulated T-cells that require NFAT activation for the immune response (see above). In neurons, synaptic activity often generates only transient increases in intracellular calcium that may induce a less robust NFAT activation.

Nuclear Calcium Signals

The third player in electrical-activity-dependent gene expression is nuclear calcium. Synaptically evoked calcium transients can be amplified by calcium release from intracellular stores and are propagated, possibly in the form of a regenerative wave, to the nucleus. Nuclear calcium is a central regulator of neuronal gene expression. It activates nuclear calcium/CaM-dependent protein kinases and is the principal regulator of gene expression by the CREB/CBP complex. Activation of gene expression by CREB/CBP requires at least two regulatory events: phosphorylation of CREB on its activator site serine 133, which allows CBP to be recruited to CREB. The second event is the stimulation of CBP activity. The first regulatory step can be catalyzed by several protein kinases, including kinases of the MAP kinase (ERK1/2) signaling pathway (triggered by submembranous calcium; see above) and nuclear calcium-induced CaM kinases. Induction of CBP activity, however, depends upon increases in the nuclear calcium concentration and the activation of nuclear CaM kinases.

The only other second messenger known to stimulate CBP activity and to increase CREB/CBP-mediated gene expression is cAMP. Global increases in the intracellular concentration of cAMP stimulate the cAMP-dependent protein kinase (PKA); upon binding of cAMP to the PKA regulatory subunit, the catalytic subunit of PKA translocates to the cell nucleus to activate the CREB/CBP complex. A large body of literature suggests that cAMP and PKA are important for certain long-term, gene-expression-dependent forms of plasticity and learning in *Aplysia californica* and *Drosophila melanogaster*. Mammalian neurons are also capable of increasing intracellular levels of cAMP

following synaptic activity through a process that involves calcium/CaM-dependent adenylyl cyclases. However, electrical activity does not appear to elevate global levels of cAMP sufficiently high to stimulate the CREB/CBP complex, although it may increase cAMP and PKA activity locally leading to the phosphorylation of neurotransmitter receptors or other proteins in the post-synaptic space. Thus, the cAMP-PKA system may be important for localized dendritic signaling in the mammalian nervous system, but the stimulation of CREB/CBP-dependent gene expression following synaptic activity appears to be controlled by nuclear calcium signals.

CBP is a coactivator of CREB, but it also interacts with several other DNA-binding proteins, thereby conferring calcium inducibility. One example is the transcription factor c-Jun that can function as a calcium-regulated activator. Thus, control of CBP activity by nuclear calcium and nuclear CaM kinases provides a general mechanism through which electrical activity regulates an entire class of transcription factors and, consequently, many genes. This may be important in activity-dependent neuronal adaptation including information storage and memory that are likely to require up-regulation (or down-regulation) of many genes. Indeed, CREB (presumably as a CREB/CBP complex) has been implicated in synaptic plasticity and learning-related event in *Aplysia californica*, *Drosophila melanogaster*, and mice. Nuclear calcium may be essential for these processes.

A second type of transcriptional regulation by nuclear calcium involves DREAM. Rather than being controlled by calcium/CaM-dependent enzymes, the ability of DREAM to modulate transcription is directly controlled by nuclear calcium. DREAM is a calcium-binding protein that, in the absence of calcium, interacts with the DRE and represses transcription. Increases in nuclear calcium lead to the formation of a calcium/DREAM complex; calcium-bound DREAM dissociates from the DNA, allowing transcription to take place. Potential DREAM-binding sites are present in many different genes; the involvement of DREAM is best documented for the prodynorphin gene.

CREB Shut-Off Pathway

The genomic responses (and their effects on survival and plasticity programs) induced by calcium flux through synaptic NMDA receptors are antagonized by a signaling pathway stimulated by the addition of glutamate to the extracellular medium. Bath glutamate application stimulates both synaptic and extrasynaptic NMDA receptors as well as other types of glutamate receptors. Pharmacological experiments revealed that calcium flux through extrasynaptic NMDA receptors is responsible for this nuclear signaling mechanism that negatively regulates gene expression; this pathway also couples to neuronal cell death. The target transcription factor inactivated following calcium entry through extrasynaptic NMDA receptors is CREB; the CREB shut-off is brought about by a rapid dephosphorylation of CREB on its activator site, serine 133.

Extrasynaptic NMDA Receptors Antagonize Nuclear Calcium Signaling and BDNF Gene Expression

After calcium entry through extrasynaptic NMDA receptors, one of the consequences of the CREB shut-off is the suppression of BDNF gene expression. BDNF, a neurotrophic factor, activates intracellular signaling pathways through binding to TrkB, a receptor tyrosine kinase; BDNF also acts as a fast neurotransmitter and can rapidly depolarize neurons. BDNF has many functions in neuronal plasticity and cell survival. BDNF gene transcription is electrical-activity-dependent and controlled, antagonistically, by two calcium signaling pathways: calcium flux through synaptic NMDA receptors (or through L-type voltage-gate calcium channels) stimulates BNDF gene transcription; in contrast, calcium flux through extrasynaptic NMDA receptors antagonizes increases in BDNF expression. The BDNF gene's promoter is complex and provides binding sites for many transcription factors; however, a key factor is CREB, which may explain the opposing action of synaptic and extrasynaptic NMDA receptors on influencing BDNF gene transcription. Activation of synaptic NMDA receptors (or L-type voltage-gate calcium channels) strongly promotes CREB activity, whereas CREB function is shut off following activation of extrasynaptic NMDA receptors. Thus, the dialogue between the synapse and the nucleus is modulated by extrasynaptic NMDA receptors; those receptors trigger a CREB shut-off signal and antagonize increases in BDNF transcription induced by calcium entry through synaptic NMDA receptors. This underscores the importance of the intracellular localization of the calcium signal for the specification of the neuronal response.

Glossary

calcium Principal second messenger in the control of gene expression by electrical activity in neurons.

CBP (CREB binding protein) Transcriptional coactivator regulated by cAMP and calcium signaling pathway; interacts with CREB and many transcription factors thereby conferring calcium- and cAMP-inducibility.

CRE (cAMP response element) DNA regulatory element present in the promoter of many genes.

CREB (CRE binding protein) CRE-interacting transcription factor that is a target of cAMP and calcium signaling pathways; mediates gene induction upon synaptic activity and nuclear calcium transients.

MAP kinases/extracellular signal-regulated kinases (ERK 1/2) Important intracellular signaling pathway; activated by electrical activity-induced submembranous calcium signals.

spatial calcium signaling Electrical activity can induce calcium signals in different intracellular compartments; submembranous, cytoplasmic, and nuclear calcium activate gene expression through different mechanisms and have distinct genomic targets.

SRE (serum response element) DNA regulatory element regulated by signaling pathway, activated by growth factors, serum, or calcium; nuclear target of MAP kinases (ERK 1/2) signaling pathway.

Biography

Hilmar Bading is Professor of Neurobiology and Director of the Neurobiology Institute at the Interdisciplinary Center for Neurosciences at Heidelberg University, Germany. He holds an M.D. from Heidelberg University, received postdoctoral training at the Max Plank Institute in Berlin and Harvard Medical School, and was a staff scientist at the MRC Laboratory of Molecular Biology, Cambridge, United Kingdom. His principal research interest is neuronal calcium signaling and how this affects gene regulation and plasticity. His work highlighted the spatial aspects of calcium signals and the importance of nuclear calcium in governing activity-dependent gene expression in neurons.

Neuronal Intermediate Filaments

Ronald K. H. Liem
Columbia University College of Physicians and Surgeons, New York, USA

Neuronal intermediate filaments (IFs) are 10–12 nm filaments that are expressed in the nervous system. IF proteins belong to a large gene family and the expression of different IF proteins is tissue specific. In the nervous system, different neuronal IFs are expressed in neuroepithelial stem cells, the central nervous system (CNS) and peripheral nervous system (PNS). In addition, the expression patterns of these neuronal IFs are developmentally regulated. There are six neuronal IFs that will be described in this section. These are the three neurofilament triplet proteins (NFTPs), α-internexin, peripherin, and nestin.

Introduction

The cytoskeleton of most eukaryotic cells is composed of microtubules, microfilaments, and IFs. Microtubules are 25 nm in diameter and are composed of two subunit proteins called α- and β-tubulin, as well as a number of associated proteins, microfilaments are 6–8 nm in diameter and made up of a protein called actin. IFs are intermediate in size between the microtubules and microfilaments. All IF proteins contain a central α-helical rod domain flanked by nonhelical N-terminal head and C-terminal tail domains. The rod domain contains hydrophobic repeats (called heptad repeats) that mediate dimerization by allowing two α-helices to wrap around each other forming a "coiled coil." Subsequent polymerization into filaments involves the formation of tetramers and higher-order structures for which the N-terminal head domain is particularly important. Based on their protein sequence similarities and their gene structure, the IF protein family is separated into six or seven types. In the nervous system, IFs are expressed in both neurons and glial cells. In the CNS, astroglial cells express the glial fibrillary acidic protein (GFAP), whereas oligodendrocytes appear to be one of the few cell types that express no cytoplasmic IFs. In the PNS, Schwann cells express the more ubiquitous IF protein vimentin. Vimentin and GFAP are quite similar in sequence and gene structure and are part of a subfamily of IFs called type III IFs.

Neuronal IFs are the major and most visible filamentous structures in the axons. The number of neuronal IFs is correlated with axon diameter and they are believed to be primary determinants of axonal diameter. The NFTPs are the most ubiquitous IF proteins in neurons; they are present in both central and peripheral nerves. The NFTPs and α-internexin are more closely related to each other than to other IF proteins and are classified together as a subfamily called type IV IFs. The expression of peripherin predominates in the PNS. Although peripherin is expressed exclusively in neurons, based on its protein sequence homologies and its gene structure, peripherin is more similar to vimentin and GFAP and is therefore considered a type III IF. Nestin is the IF protein found in neuroepithelial stem cells, as well as muscle progenitor cells. The protein sequence of nestin is quite unique and nestin is sometimes considered to be a separate type VI IF. However, on the basis of its gene structure, it resembles the other type IV neuronal IFs.

One of the hallmarks of a number of neurodegenerative diseases is the accumulation of neuronal IFs in the form of axonal spheroids. These axonal spheroids have been observed in amyotropic lateral sclerosis (ALS, also called Lou Gehrig's disease) as well as other neuropathies. A number of recent studies from transgenic mice have indicated that the disorganization of neuronal IFs, especially in the forms of axonal spheroids, can lead to neurodegeneration. The relationship between the various neuronal IF proteins and neurodegeneration will be discussed below.

The Neurofilament Triplet Proteins

The NFTPs are composed of three proteins called NFL, NFM, and NFH for neurofilament light, medium, and heavy chain. NFTPs have been identified in all mammals and birds. The identification of the NFTPs was first done on the basis of studies on the transport of proteins in the axon. To study the transport of particular proteins, early studies used radioactive amino acids to label the newly synthesized proteins, and the nerves were then analyzed to determine the rates at which different proteins move. The slowest moving fraction moved at 0.1–1 mm per day and were believed to be the structural components. There were five major proteins, α- and β-tubulin and three

proteins with apparent molecular weights of 68, 145, and 200 kDa. Since actin, the component of the microfilaments, moved somewhat faster than these five proteins, the three unidentified proteins were identified as the subunits of the other structural element, the neurofilaments. Biochemical verification came when neurofilaments were purified and isolated and the contaminating astroglial filaments were removed. Each subunit was purified and the ability of the purified proteins to assemble *in vitro* was determined and assayed by examining the assembled filaments under the electron microscope. These *in vitro* assembly studies showed that the 68 kDa protein, later called NFL, was necessary and sufficient for IF formation. The 145 kDa (NFM) and 200 kDa (NFH) proteins coassembled with NFL and their long C-terminal tails appeared to form the links that can be observed between filaments in the electron microscope. The actual sequences of each of these proteins were determined by protein sequencing and later by cDNA cloning. They are shown schematically in Figure 1. Like all other IFs they contain a central α-helical rod domain flanked by nonhelical N-terminal head and C-terminal tail. The rod domain contains α-helical segments that are represented as cylinders. The rod domain of NFL can be divided into three separate segments (1A, 1B, and 2), whereas those of NFM and NFH are separated into two segments. The NF proteins have variable size C-terminal tails. The lengths of the C-terminal tails determine the ultimate sizes of the three proteins.

The tails of NFM and NFH contain multiple lysine-serine protein (KSP) repeats (shown as yellow circles), which are sites for phosphorylation as described below. As mentioned above, NFL is necessary for filament formation. Using various assays to study protein–protein interactions, it has been demonstrated that NFL can form homodimers and heterodimers with NFM and NFH. These results are consistent with the earlier observations from *in vitro* assembly studies that NFL can form a filament, whereas the other two proteins require NFL to assemble into filaments. Interestingly, transfection studies have shown that rat or mouse NFL needed either NFM or NFH to form a filamentous network *in vivo*, indicating that rodent neurofilaments are obligate heteropolymers. Human NFL can self-assemble in the transfected cells, but this assembly is not very efficient. The other neuronal IF proteins, peripherin, and α-internexin are able to self-assemble into homopolymers *in vitro* and *in vivo*, although NFM appears to have an inhibitory effect on the ability of peripherin to assemble into a filamentous network.

Neurofilaments have been suggested to play a role in regulating axonal caliber and thereby influencing axonal conduction velocity. This role has been confirmed by studies of the Japanese *quiver* quail, which has a premature termination codon in its NFL gene and consequently no neurofilaments in its axons. Normal radial growth is severely inhibited in the large caliber fibers. When the NFL gene was deleted in NFL knockout mice, no visible IFs were observed and there was axonal hypotrophy. There was also a substantial decrease in NFM and NFH in the NFL knockout mice, presumably because they were unstable, since they could not polymerize into filaments. Curiously, in spite of this hypotrophy, the NFL deficient mice developed normally and showed no obvious neurological problems. NFM and NFH knockouts have an even less severe phenotype. NFM knockouts also resulted in some reduction of the caliber of large axons and some axonal loss, whereas NFH knockouts resulted in an even more modest reduction in axonal caliber. Overexpression of NFL and either NFH or NFM in transgenic mice resulted in an increase in the number of neurofilaments as well as axonal caliber, consistent with the role of neurofilaments in regulating axonal calibers.

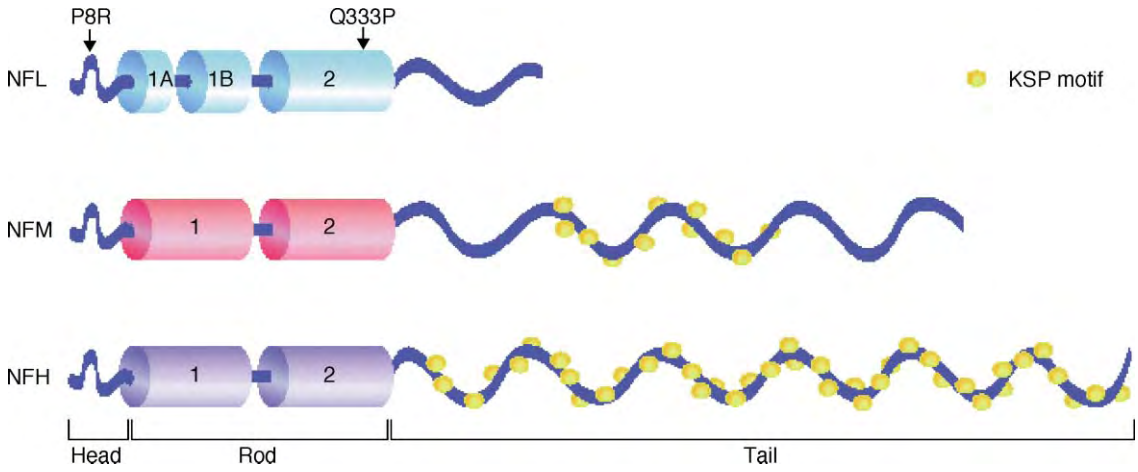

FIGURE 1 Diagrammatic representation of the NFTPs. Note that the size of the proteins are dependent on the lengths of the C-terminal tails. The a-helical rod regions are shown as cylinders. The KSP phosphorylation sites in the tail regions are shown as yellow circles. The first two mutations linked to CMT disease in NFL are indicated.

NFs are characterized by their phosphorylation, a post-translational mechanism that is thought to regulate their functions. NFM and NFH are phosphorylated mainly in the (KSP) repeats located in their C-terminal tail domains. These phosphorylation sites are depicted in the tail domains seen in Figure 1. NFH has 44–51 KSP residues, whereas NFM has 5–14 of these residues, depending on species. Phosphorylation of NFs induces extension of their side arms from the filament backbone, apparently increasing the spacing between individual filaments and ultimately the axonal caliber. Phosphorylated NFs are found in axons, while the nonphosphorylated forms are found in neuronal cell bodies and dendrites. A number of different kinases have been shown to phosphorylate the KSP residues of NFM and NFH. Phosphorylation of the KSP residues has been proposed to be important for the increase of the radial growth of axons by increasing the nearest neighbor distances between the neurofilaments, possibly through electrostatic repulsion between the neurofilament sidearms. The evidence for this proposal came from electron microscopy studies that showed that dephosphorylated neurofilaments were more closely spaced together than phosphorylated neurofilaments. In the dysmyelinated *Trembler* mouse mutant, there is a decrease in neurofilament phosphorylation and smaller axonal diameter. When segments of *Trembler* sciatic nerves were grafted onto control nerves, the *Trembler* segments still maintained their smaller diameters and dephosphorylated neurofilaments, whereas adjacent regions showed normal diameters and neurofilament phosphorylation. These studies were considered as strong evidence that phosphorylation of neurofilaments (especially of NFH) is a determinant of axonal diameter. It therefore came as a surprise that the NFH knockout mice showed only a slight decrease in nearest neighbor spacing of neurofilaments and did not change the axon caliber, indicating that NFH phosphorylation may be less important for the determination of axonal caliber than was predicted. To test this particular property of NFH more rigorously, the NFH gene was replaced in transgenic mice with one deleted in the NFH tail. The results showed that the loss of the NFH tail and all of its phosphorylation sites did not affect the interfilament spacing of the neurofilaments. In contrast, the NFM tail and its state of phosphorylation may be more important for radial growth, even though it contains considerably fewer phosphorylation sites.

As described before, neurofilament proteins are synthesized in the cell body and have been found to move down the axon as part of the slow component of axonal transport with a velocity of $\sim 0.1–1$ mm day^{-1}. The initial hypothesis was that the entire axoplasm moved as a coherent block, but more recent work has shown that the entire axoplasm in its totality does not move. Neuronal IFs are now thought to move as monomeric and polymeric units. Studies using proteins tagged with green fluorescent protein and live-video microscopy have demonstrated that neuronal IFs undergo rapid, intermittent, and nonsynchronous transport in both directions, with predominance of the anterograde transport and long pauses in between movements along the axons. These studies indicate that slow transport is actually the result of fast motions interrupted by long pauses. This fast transport is likely to utilize one of the many motors that have been identified for fast transport. These motor proteins could also be responsible for some of the cross-links observed between IFs and microtubules. Other potential cross-linkers are members of the plakin family of proteins that were first identified in junctions in epithelial cells. Recent studies have indicated that some plakins are also expressed in the nervous system. Plakins have distinct domains that include microtubule, microfilament, and IF-binding domains and could therefore be important in the formation of cross-links between these cytoskeletal elements. The phosphorylation of the side chains of the neurofilaments described above has also been considered to be important for the regulation of transport of neurofilaments through axons. Two recent studies have provided different conclusions regarding the role of NFH side arm phosphorylation in neurofilament transport. In one study, all the potential phosphorylation sites of NFH were mutated either to preclude phosphorylation or mimic permanent phosphorylation of the NFH side arms. These mutants displayed altered rates of transport in a bulk transport assay. The mutant mimicking permanent phosphorylation spent a higher proportion of time pausing than one that could not be phosphorylated, indicating that NFH phosphorylation slows neurofilament transport. In contrast, in transgenic mice, where the endogenous NFH was replaced by a tailless NFH, there were no changes in the rate of bulk transport. These studies indicate that the mouse studies are not always consistent with the studies in cultured cells, in part due to additional compensatory mechanisms that may exist in the mouse. In any case, some of these aspects of neurofilament transport will become clearer when the specific motors that move neurofilaments are identified.

Overexpression of neuronal IFs in transgenic mouse models results in the formation of mislocalized protein aggregates, which affect neuronal function and survival. This has been shown in the case of human NFH, mouse NFL, peripherin, and rat α-internexin. The relationship between misexpression, disrupted transport, and mislocalization of neuronal IFs to neurodegeneration is also apparent from the appearance of axonal neurofilamentous accumulations in a number of neurodegenerative diseases. In particular, aggregation of IFs in motor neurons and alteration in their axonal transport has been reported in amyotrophic lateral sclerosis (ALS).

It appears likely that mutations in neurofilament proteins would also lead to neurodegeneration. When an assembly disrupting NFL mutant was produced in a transgenic mouse model, the mutant NFL caused massive degeneration of motor nerves. Recently, several mutations have been identified in neurofilament proteins that lead to neurodegenerative diseases. Deletions and insertions in the tail domain of NFH have been reported in 1–2% of patients with sporadic ALS. More strikingly, a number of mutations in the NFL gene have now been linked to Charcot-Marie-Tooth neuropathy type 2E. Two of these mutations (P8R and Q333P) are shown in Figure 1. When these same mutations are introduced in an NFL cDNA and the mutant NFL constructs are expressed in cultured cells, defects in assembly and transport of NFL are observed. It appears therefore that these mutations in NFL might alter axonal transport, which in turn would cause neurodegeneration. This notion is consistent with the hypothesis that alterations in axonal transport (in which neuronal IFs could be directly or indirectly involved) play a role in the pathogenesis of other neurodegenerative diseases.

α-Internexin

α-Internexin was first isolated from optic nerve and spinal cord and found to be particularly abundant in the developing nervous system. α-Internexin has an apparent molecular weight of 66 kDa and is therefore a little smaller than the NFTPs. Although it is present in both the CNS and PNS early in development, it is mainly CNS specific in the mature mammalian nervous system. Consistent with its expression early in development in the absence of other IFs, α-internexin has been shown to be able to self-assemble both *in vitro* and in transfected cells. α-Internexin is closely related to the NFTPs and is therefore also classified as a type IV IF protein. α-Internexin is the first neuronal IF expressed in neurons after they are committed to the neuronal lineage. The expression of α-internexin is high early in development and then decreases after the axon matures. In the PNS, the level of α-internexin decreases significantly in adulthood, although it persists especially in thinner unmyelinated axons. In the CNS, α-internexin expression is also lower after the axon matures. Of particular interest is the fact that α-internexin is the only neuronal IF expressed in some neurons, e.g., the granule cell neurons in the cerebellum. The axons of these neurons are thinner in diameter than the ones that express the NFTPs suggesting that α-internexin is not important for maintaining axonal diameter. The early expression of α-internexin led to the suggestion that it might be important for axon outgrowth. Although this idea was supported by antisense inhibition experiments in cultured cells, the α-internexin knockout mice have no obvious phenotype. No compensatory changes in the levels of other neuronal IFs were observed and it appears that α-internexin is not necessary for axon outgrowth in these mice. Unfortunately, these knockout studies tell us little about other potential functions of this protein. Overexpression of α-internexin in transgenic mice results in the formation of cerebellar torpedoes. These torpedoes are swellings in Purkinje cell axons. The presence of these torpedoes results in the degeneration and ultimate death of the Purkinje cell. There is a dysfunction of the cell as determined behaviorally from the transgenic mice before the cells die.

Peripherin

Peripherin was first identified as an IF protein from neuroblastoma and its cDNA was cloned from a cell line that can be induced to grow neuronal processes by the addition of nerve growth factor, called PC12 cells. Peripherin has a molecular weight of 57 kDa and belongs to the type III IF proteins, which also consists of vimentin, the glial specific GFAP, and the muscle specific IF protein called desmin. Peripherin is therefore the only type III neuronal IF protein, since all the other neuronal IFs are in the type IV category. The significance of this difference is not known. Like all the other type III IFs, peripherin can self-assemble into a filamentous network. Peripherin can also coassemble with other neuronal IFs. Peripherin is predominantly found in the PNS (hence its name), but some CNS neurons also express peripherin. As described above, peripherin was identified as a gene that was increased in PC12 cells upon stimulation by nerve growth factor. Peripherin has also been shown to be up-regulated following axonal injury. These studies suggested that peripherin may play a role in axon outgrowth and elongation. Peripherin depletion experiments with anti-sense technologies yielded conflicting results: initial studies showed that anti-sense oligonucleotides did not inhibit neurite outgrowth, whereas more recent studies using small interfering RNAs (siRNAs) showed that peripherin siRNA inhibits the initiation, extension and maintenance of neurites in PC12 cells. The reason for this discrepancy is not clear. Peripherin knock-out mice have normal caliber axons and show no axonal loss. Some interesting observations have led to the possibility that misexpression of peripherin can lead to neurodegenerative disease. Peripherin has been found in axonal spheroids in patients with ALS. Furthermore, overexpression of peripherin by four to seven fold in transgenic mice leads to late onset progressive motor neuron disease, which is accelerated in mice that lack NFL.

Nestin

Nestin was first described as a marker of neuroepithelial stem cells. Subsequent cDNA cloning showed that a large IF protein encoded this marker. Nestin has the basic hallmarks of an IF protein with a α-helical rod, capable of forming coiled coil dimers, a very short head domain and a very long tail domain. Nestin has little homology to the other mammalian IF proteins, but its genomic structure is similar to the NFTPs and α-internexin. As a result, nestin is placed either as a separate type of IF (type VI), or as a type IV IF along with the NFTPs and α-internexin. During early development, nestin is expressed in neuroepithelial cells and muscle progenitor cells. Transgenic mouse studies have indicated that different regulatory elements in the nestin gene are responsible for directing gene expression in developing muscle and neural precursor cells, respectively. Nestin is not able to self-polymerize, but requires vimentin to form a filamentous network. There have been no published reports of a nestin knockout mouse.

Glossary

axonal spheroids Accumulations of protein aggregates in axons, usually containing neurofilamentous structures.

axonal transport The movements of vesicles, mitochondria, and other cytoplasmic structures down the axon, necessitated by the fact that most protein synthesis occurs in the axon and the proteins must sometimes travel long distances to reach the end of the axon. This transport generally occurs by way of motor proteins along microtubules and microfilaments.

Charcot–Marie–Tooth (CMT) disease An inherited neurological disorder that affects the peripheral nerves. It is named after the three physicians who described it. CMT patients slowly lose the normal use of their limbs as the nerves to the extremities degenerate. There are a large number of different causes for the disease, including the recently identified neurofilament mutations.

cytoskeleton A network of interconnected cytoplasmic filaments that consists of microtubules, microfilaments and IFs.

transgenic mouse A mouse that has been genetically altered to express a gene that is not normally expressed or to have a gene deleted (also called a knockout mouse).

Biography

Ronald K. H. Liem is a Professor of Pathology and Anatomy and Cell Biology at Columbia University College of Physicians and Surgeons. Dr. Liem's primary research interest is in the cell and molecular biology of the neuronal cytoskeleton and its involvement in neurodegenerative diseases. His contributions include the biochemical identification of the neurofilament triplet proteins, the first identification and cDNA cloning of α-internexin and the characterization of the plakins, the major cytoskeletal linker proteins in the nervous system.

Neuropeptide Y Receptors

Eric M. Parker
Schering-Plough Research Institute, Kenilworth, New Jersey, USA

Neuropeptide Y (NPY) is a 36 amino acid neuropeptide that is widely distributed in both the central and peripheral nervous systems. NPY is a member of the pancreatic polypeptide family, which also includes the structurally related peptides peptide YY (PYY) and pancreatic polypeptide (PP). Neurons containing NPY typically coexpress and cosecrete classical neurotransmitters and/or other neuropeptides (e.g., norepinephrine, γ-aminobutyric acid, somatostatin, corticotrophin releasing hormone); hence, NPY probably acts in concert with other neurotransmitters and neuropeptides in either a cotransmitter or modulatory role. As expected from its ubiquitous distribution and colocalization with other neurotransmitters and neuropeptides, NPY has been implicated in a wide variety of physiological effects, including the regulation of body weight, neuronal excitability, circadian rhythms, mood, ethanol consumption, nociception, cognition, endocrine function, cardiovascular function, gastrointestinal function, and bone formation. The effects of NPY on energy homeostasis have been most extensively studied in recent years. NPY increases body weight via stimulation of food intake and reduction of energy expenditure and also induces metabolic abnormalities associated with obesity, including hyperinsulinemia, hyperglycemia, and hypercortisolemia.

Neuropeptide Y (NPY) produces its physiological effects by interacting with at least six distinct G-protein-coupled receptors designated Y_1, Y_2, Y_3, Y_4, Y_5, and y_6. With the exception of the Y_3 receptor, genes and/or cDNAs encoding each of these receptors have been cloned. Pharmacological tools that activate (agonists) or inhibit (antagonists) each of the NPY receptors have also been identified (Table 1, Figure 1). Although all the NPY receptors are G-protein-coupled receptors with high affinity for NPY, their primary sequences are not highly related to one another (Figure 2). Site-directed mutagenesis studies suggest that NPY, NPY-related peptides, and nonpeptide NPY receptor antagonists have overlapping (although not entirely identical) binding sites, composed primarily of residues in the extracellular domains and in the extracellular side of the transmembrane domains.

The NPY Y_1 Receptor

The NPY Y_1 receptor is pharmacologically characterized by its high affinity for [Pro^{34}]NPY and [D-Arg^{25}]NPY; its low affinity for N-terminally truncated NPY analogues; and its high affinity for nonpeptide antagonists such as 1229U91, BIBP3226, and BIBO3304 (Table 1, Figure 1). Structurally, the receptor is related to the NPY Y_4 and NPY y_6 receptors (Figure 2). NPY Y_1 receptor mRNA is expressed at highest levels in brain (especially cortex, hippocampus, thalamus, and hypothalamus), vascular smooth muscle, heart, kidney, spleen, skeletal muscle, lung, testis, adrenal gland, placenta, bone marrow, and gastrointestinal tract. NPY Y_1 receptor protein distribution mirrors mRNA distribution fairly closely with the notable exception that low levels of receptor are detected in most hippocampal regions. The NPY Y_1 receptor is coupled to multiple signal transduction pathways via pertussis toxin sensitive G proteins (G_i and/or G_o), including reduction of cyclic AMP (cAMP) formation, an increase in intracellular calcium, an increase in MAP kinase activity, and activation of GIRK K^+ channels and L-type Ca^{2+} channels. The NPY Y_1 receptor mediates several biological effects of NPY, including contraction of vascular smooth muscle, stimulation of food intake and body weight gain, inhibition of insulin secretion, anxiolytic and antidepressant effects, regulation of pituitary hormone secretion (reduction of growth hormone and thyroid stimulating hormone secretion, stimulation of luteinizing hormone secretion), regulation of ethanol consumption, nociception, and neurogenic inflammation. Activation of the NPY Y_1 receptor acutely stimulates food intake and body weight gain, and acute treatment with NPY Y_1 receptor antagonists often has the opposite effect. As expected from acute experiments, mice lacking the NPY Y_1 receptor are hypophagic, hyperinsulinemic and have slightly reduced NPY- and deprivation-induced food intake. However, NPY Y_1 receptor-deficient mice are also obese, perhaps due to hyperinsulinemia, reduced locomotor activity, and/or reduced metabolic rate.

The NPY Y_2 Receptor

The NPY Y_2 receptor is structurally quite distinct from the other NPY receptors (Figure 2) and is pharmacologically characterized by its high affinity for N-terminally truncated NPY analogues, its low affinity for [Pro^{34}]NPY, and its high affinity for the nonpeptide antagonist BIIE0246 (Table 1). The NPY Y_2 receptor is localized primarily in the brain, but is also expressed at low levels in the gastrointestinal tract and peripheral nerve terminals. In the brain, highest levels of NPY Y_2 receptor mRNA are found in hippocampus, piriform cortex, olfactory tubercle, hypothalamus, thalamus, inferior olive, and lateral reticular nucleus. NPY Y_2 receptor protein is detected at highest levels in subfornical organ, thalamus, hypothalamus, substantia nigra, and area postrema. NPY-containing neurons in the brain express the NPY Y_2 receptor and the NPY Y_2 receptor antagonist BIIE0246 increases depolarization-evoked NPY release from brain slices, suggesting that the NPY Y_2 receptor acts as an autoreceptor. Similarly, pharmacological studies have shown that the receptor is localized on sympathetic, parasympathetic, and sensory nerve terminals where it functions as both an autoreceptor and a heteroreceptor to regulate neurotransmitter/neuropeptide release. The NPY Y_2 receptor couples to pertussis toxin-sensitive G proteins (G_i and/or G_o) leading to a reduction of cAMP formation, an increase in intracellular calcium mediated by activation of phospholipase C, an increase in MAP kinase activity, an activation of K^+ channels (e.g., Kv4, GIRK, and Ca^{2+} activated K^+ channels), and an inhibition of voltage-gated (N and P/Q type) Ca^{2+} channels. The NPY Y_2 receptor also apparently increases intracellular calcium via a phospholipase C-independent pathway that utilizes a pertussis-toxin insensitive G protein. The NPY Y_2 receptor is involved in several physiological processes, including reduction of neuronal excitability and seizure activity, regulation of circadian rhythms, regulation of body weight and energy metabolism, improvement in learning and memory, regulation of ethanol consumption, reduction of bone formation, reduction of gastrointestinal motility, intestinal secretory activity and stimulation of angiogenesis and wound healing. The precise role of the NPY Y_2 receptor in the regulation of body weight is currently unclear. Selective NPY Y_2 receptor peptide agonists do not alter food intake, suggesting that this receptor does not mediate the orexigenic effects of NPY. In fact, the NPY Y_2 receptor peptide agonist PYY3-36, which is released postprandially, actually decreases food intake and body weight in humans. Variable effects of genetic deletion of the NPY Y_2 receptor in mice have been reported. Further studies are needed to definitively determine the role of the NPY Y_2 receptor in the regulation of body weight.

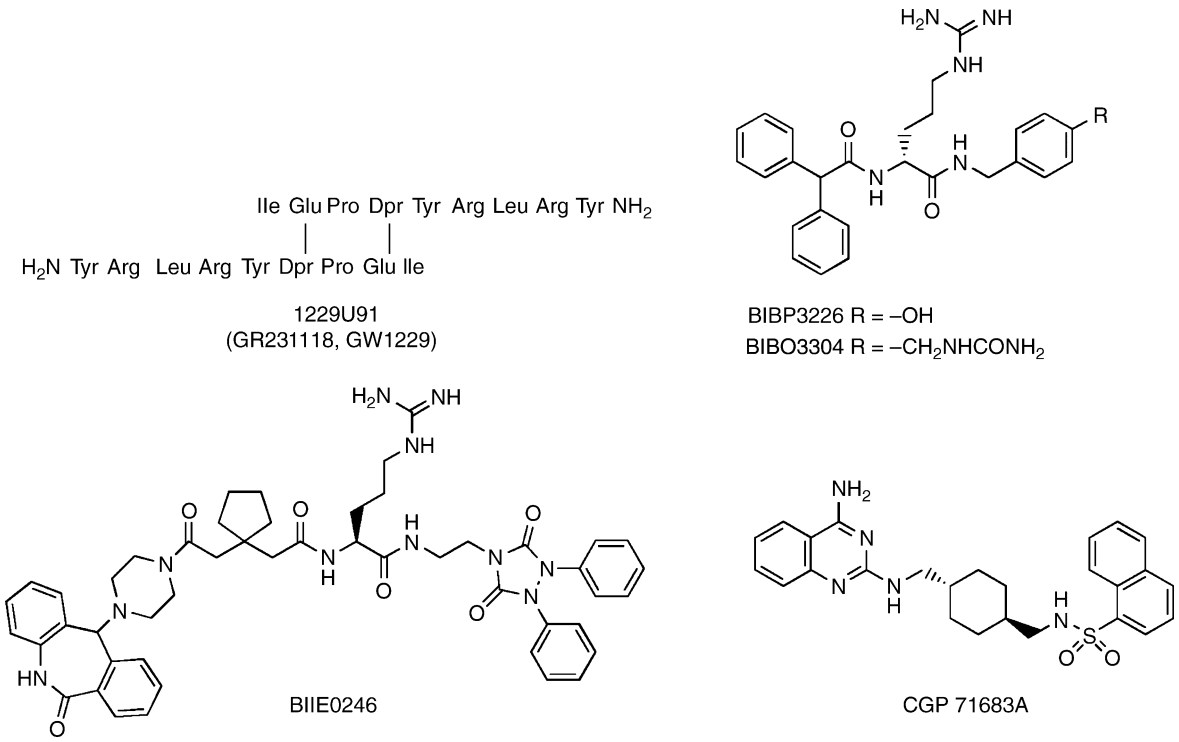

FIGURE 1 Structures of standard NPY receptor antagonists.

The NPY Y_3 Receptor

The NPY Y_3 receptor has been pharmacologically characterized in bovine adrenal chromaffin cells and in the rat heart, colon, lung, hippocampus, and brainstem. The distinguishing pharmacological feature of this receptor is its higher affinity for NPY than for PYY. Activation of the NPY Y_3 receptor has been shown to decrease cAMP formation and increase intracellular calcium concentration. Application of NPY to the brainstem decreases blood pressure and heart rate, effects that may be mediated by activation of the NPY Y_3 receptor. Although pharmacological evidence supports the existence of this receptor in rats and cows, there is no evidence that this receptor exists in humans, and a gene or cDNA encoding the receptor has not been cloned. Molecular characterization of the NPY Y_3 receptor is required to unequivocally validate its existence and determine its physiological role.

The NPY Y_4 Receptor

The NPY Y_4 receptor is structurally related to the NPY Y_1 and NPY y_6 receptors (Figure 2), but has distinct pharmacological properties (Table 1). Specifically, the NPY Y_4 receptor has high affinity for human and rat pancreatic polypeptide (PP), but has low affinity for NPY (Table 1). Indeed, this receptor would be more accurately classified as a PP receptor rather than as an NPY receptor. Interestingly, the rat and human NPY Y_4 receptors display some significant pharmacological differences, perhaps due to the fact that these species orthologues are only 75% identical to one another. Very low levels of NPY Y_4 receptor mRNA are expressed in the brain, primarily in the brainstem and hypothalamus. There are also species differences in the expression pattern of the NPY Y_4 receptor in the periphery. In rat, the receptor is expressed primarily in testis and lung, whereas in human the receptor is expressed primarily in colon, small intestine, prostate, and pancreas. Activation of the NPY Y_4 receptor decreases cAMP formation and increases intracellular calcium. Pharmacological studies have shown that, the NPY Y_4 receptor mediates the ability of PP to increase pancreatic secretion and increase intestinal motility. Mice lacking the NPY Y_4 receptor suggest that this receptor is involved in aggressive behavior and in maintaining sympathetic nervous system activity. In addition, genetically obese *ob*/*ob* mice lacking the NPY Y_4 receptor have improved fertility relative to *ob*/*ob* mice with an intact NPY Y_4 receptor, suggesting that this receptor mediates at least some of the negative effects of NPY and/or PP on fertility and on the hypothalamic–pituitary–gonad axis.

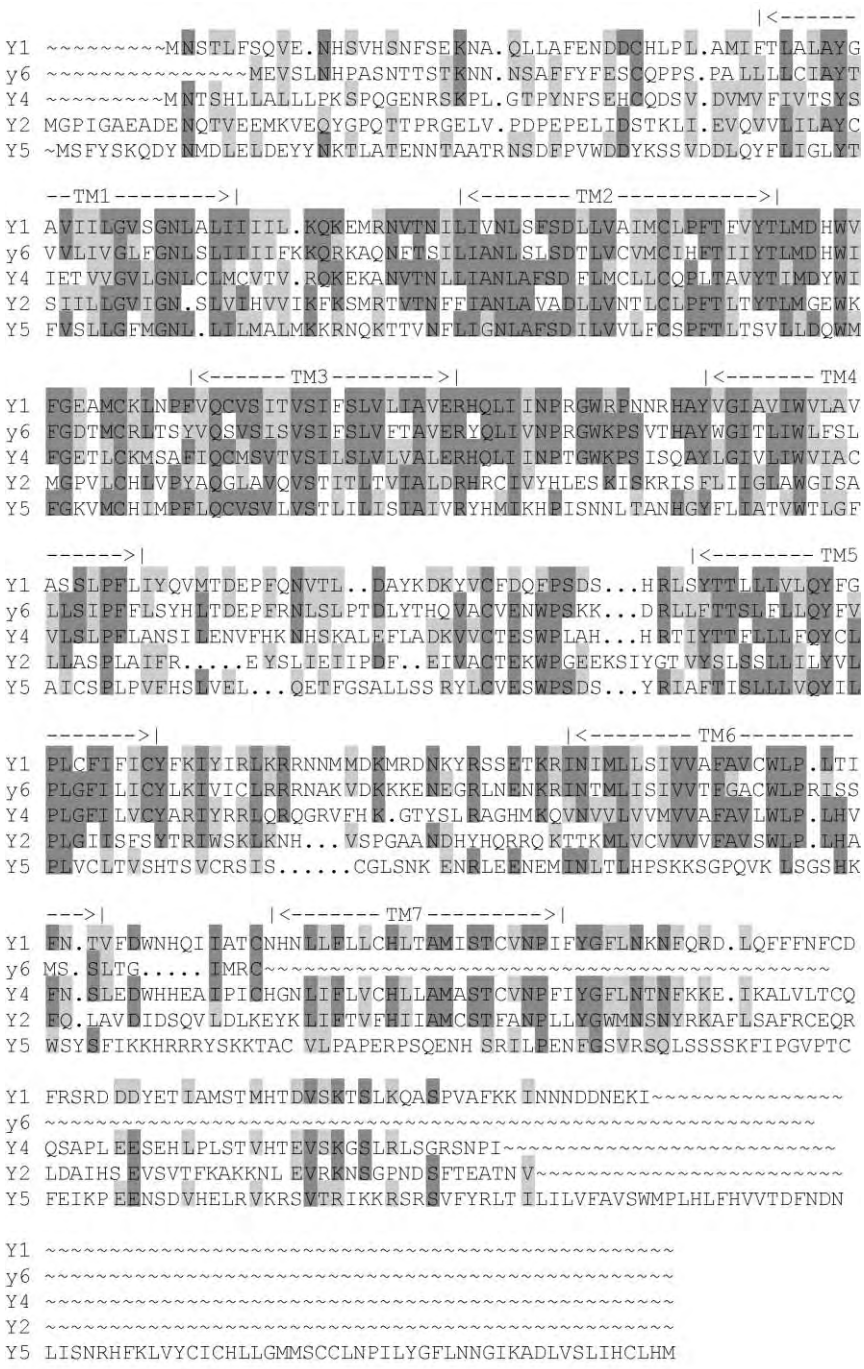

FIGURE 2 Alignment of the primary sequences of the NPY receptors. Amino acids that are identical in ≥3 NPY receptors are shaded dark while conservative amino acid substitutions in >3 NPY receptors are shaded light. The approximate location of the seven transmembrane domains is indicated over the sequences.

The NPY Y_5 Receptor

The NPY Y_5 receptor is a structurally and pharmacologically unique NPY receptor (Figure 2) characterized by high affinity for N-terminally truncated NPY analogues [Pro^{34}]NPY, [D-Trp^{32}]NPY, [D-Trp^{34}]NPY, and [Ala^{31}, Aib^{32}]NPY (Table 1). This receptor also has high affinity for several recently disclosed nonpeptide antagonists such as CGP-71684A (Figure 1). The NPY Y_5 receptor is discretely localized in brain, primarily in hypothalamus, hippocampus, piriform cortex, and olfactory tubercle. Interestingly, NPY Y_5 receptor mRNA is almost always localized in neurons that also express NPY Y_1 mRNA. Since the

genes encoding the NPY Y_1 and Y_5 receptors overlap on chromosome 4q31, this may reflect a regulatory mechanism inherent to this gene locus. In the periphery, NPY Y_5 receptor mRNA has been detected in testis, spleen, pancreas, gastrointestinal tract, vascular smooth muscles, and cardiomyocytes. Like the other NPY receptors, the NPY Y_5 receptor couples to multiple G protein-mediated pathways (primarily pertussis toxin-sensitive G proteins G_i and/or G_o) to decrease cAMP formation, increase intracellular calcium concentration, and activate MAP kinase pathways. There is evidence that the NPY Y_5 receptor utilizes a somewhat different signaling pathway to activate MAP kinase than do the other NPY receptors. Evidence suggests that this receptor is involved in the regulation of body weight (stimulation of food intake and reduction of energy expenditure), control of glucose homeostasis, regulation of pituitary hormone secretion (stimulation of adrenocorticotropin secretion, inhibition of thyroid stimulating hormone secretion, inhibition of luteinizing hormone secretion), regulation of ethanol consumption, control of neuronal excitability and seizure activity, circadian rhythms, diuresis, and natriuresis. Although selective NPY Y_5 receptor peptide agonists have been shown to stimulate food intake and decrease energy expenditure, selective NPY Y_5 receptor antagonists generally do not affect food intake, energy expenditure, or body weight. Furthermore, mice lacking the NPY Y_5 receptor have normal food intake, energy expenditure, and body weight. Thus, the role of the NPY Y_5 receptor in the regulation of body weight remains unclear.

The NPY y_6 Receptor

The NPY y_6 receptor is structurally related to the NPY Y_1 and Y_4 receptors. It is pharmacologically very similar to the NPY Y_1 receptor, although it tends to bind N-terminally truncated NPY analogues with somewhat higher affinity than the NPY Y_1 receptor. The NPY y_6 receptor couples to G_i and inhibits cAMP formation. Interestingly, a functional NPY y_6 receptor is found in mice and rabbits, but not in rats and primates. In the case of rats, a gene encoding the NPY y_6 gene cannot be detected, whereas in primates the gene is a nonfunctional pseudogene. The lack of a functional NPY y_6 receptor in primates has resulted in the adoption of a lower case designation for this receptor. In mice, NPY y_6 receptor mRNA has been detected in kidney, testis, and brain, particularly in the hypothalamus. Although the NPY y_6 receptor clearly does not contribute to the effects of NPY in humans, this receptor must be taken into account when considering the physiological effects of NPY in mice. To date, however, no physiological effect of NPY in mice has been linked to activation of the NPY y_6 receptor.

Regulation of NPY Receptors

As is the case for most G-protein-coupled receptors, NPY receptors are subject to various mechanisms of regulation. The NPY Y_1, Y_2, and Y_5 receptors have recently been shown to exist as homodimers in the plasma membrane, although the extent of homodimerization was not affected by the binding of NPY to the receptors or by the coupling of the receptors to G proteins. NPY receptors have also been shown to be subject to both homologous and heterologous desensitization. These desensitization processes are typically mediated by phosphorylation of the receptor and subsequent association of the phosphorylated receptor with arrestins. Over a longer period of time, receptors can internalize and be recycled or degraded. Changes in receptor gene expression can also occur. NPY Y_1 receptors rapidly desensitize after NPY treatment by phosphorylation of the receptor and rapid internalization of the receptor via clathrin coated pits. Conversely, NPY Y_2 receptors are internalized very slowly. The NPY Y_1, Y_2, Y_4, and Y_5 receptors also associate with β-arrestin 2, with the Y_1 receptor again showing the most rapid association rate and NPY Y_2 receptors showing the slowest association rate. With respect to heterologous desensitization, NPY Y_2 receptors have been shown to desensitize after exposure of LN319 cells to bradykinin.

Glossary

G protein A heterotrimeric GTP binding protein consisting of α-, β-, and γ-subunits. G proteins link G-protein-coupled receptors to a wide variety of effector molecules in signal transduction pathways by alternately binding and hydrolyzing GTP in response to receptor and effector activation.

G-protein-coupled receptors (GPCRs) A family of ~500 neurotransmitter and neuropeptide receptors (as well as several hundred odorant receptors) that are structurally characterized by seven transmembrane domains, an extracellular amino terminus, and a cytoplasmic carboxy terminus. This receptor family is functionally characterized by the ability to bind and activate G proteins upon binding of their cognate ligand.

Neurotensin Receptors

William Rostène, Patrick Kitabgi and Didier Pélaprat
INSERM, Paris, France

Peptides are now well-recognized as important modulators of central and peripheral functions. Among the considerable number of peptides which has been discovered in various species, neurotensin (NT) has been found to play an essential role in specific brain and neuroendocrine functions and more recently in cancer. These effects of NT have been related to an interaction of this 13 aminoacid peptide with receptors belonging to the family of G protein-coupled receptors (GPCRs) with seven transmembrane domains. Very recently a new NT receptor with a single transmembrane domain has been discovered. Cloning of these receptors has permitted to develop agonists and antagonists for NT, the more recent developments being focused on the potential therapeutical usefulness of nonpeptide and peptido-mimetic substances able to cross the blood–brain barrier.

Neurotensin

The discovery of Neurotensin (NT), a 13 aminoacid peptide, occurred during the isolation of another peptide, substance P, from bovine hypothalamus, by Susan Leeman and Robert Carraway in 1973. It was the simple observation of a characteristic vasodilatation occurring around the face and ears after intravenous injection of the isolated material which allowed the purification of NT. Rapidly after its primary structure in aminoacids was known, antibodies were raised, a strategy used for several peptides in order to develop sensitive radio-immunoassays and immunocytochemical approaches which provided useful information on the physiology, content, distribution, and anatomical localization of NT in fluids and tissues. Though NT was first found in the brain, 90% of the peptide is located in the gut.

The main *in vivo* biological activities of NT following peripheral administration include a strong vasodilatation and hypotension, an increase in vascular permeability via histamine released by the mast cells, a hyperglycemia involving glucagon, insulin and histamine, inhibition of gastric acid and pepsin secretion and of gastric motility. Strong neuroendocrine effects on the release of pituitary hormones such as ACTH, LH, FSH, GH, and prolactin have been particularly evidenced. Central injection of NT induced hypothermia, release of the neurotransmitter dopamine (DA), inhibition of feeding in fasted animals, and analgesic effects which are not mediated by opiates. Finally, high-fat meal and drugs affecting the brain DA systems have been reported to produce strong release of NT in plasma and brain, respectively.

Neurotensin Receptors

The relatively simple amino acid sequence of NT allowed structure-activity studies which showed that the C-terminal part (aa 8–13) of the peptide contained the whole activity of NT. Thus, design of small peptide molecules and modifications both in the N- and C-terminal portions of NT rapidly led to NT analogues which could be labeled with tritium or iodine in order to carry out binding studies. Such experiments demonstrated that high affinity NT binding sites could be observed in several tissues and various cell lines including human cancer cells. From these binding studies, it became obvious that NT could bind to several receptors as already shown for other neuropeptides.

Up to now indeed, three NT receptors – NTS1, NTS2, and NTS3 – have been identified and their biochemical and pharmacological properties recently reviewed. We will thus briefly outline their main characteristics (Table I).

NTS1

NTS1 has been cloned from rat and human and belongs to the family of G protein-coupled receptors (GPCRs) with seven transmembrane domains. It seems to be involved in the majority of the physiological effects of NT reported so far. NTS1 is a Gq-preferring receptor suggesting that binding of NT to NTS1 induces activation of phospholipase C, increase in inositol phosphate, and intracellular calcium concentration. In parallel, in transfected cell systems, NTS1 has been also reported to be linked to Gi/o or Gs, leading to inhibition or stimulation of cyclic AMP production, respectively, and to stimulation of more distal transduction pathways such as mitogen-activated protein kinases. Interestingly, the most recent data indicate that different intracellular

[c] Mouse.

domains of the receptor are involved in coupling to the various G-proteins and suggest the existence of multiple agonist-selective conformations, which may lead to the preferential activation of either of the corresponding signaling pathways. These results open the possibility of designing agonists selective for one of the pathways associated with a given NTS receptor.

Although the development of selective NT agonists may be important for a better understanding of the physiological relevances of this peptide, random screening and chemical optimization led to the achievement of nonpeptide antagonists, which have proved extremely useful to study the role of endogenous NT associated with NTS1. The first nonpeptide antagonist, SR 48692, developed by Sanofi-Synthelabo, as well as the recent development of knock-out mice for NTS1 confirmed that most of the NT effects reported above can be attributed to NTS1. More recently, another nonpeptide NTS1 antagonist, SR 142948A, but with less selectivity for NTS1 than SR 48692, has been described.

Elegant strategies of mutagenesis and modeling of NTS1 have provided useful information about the molecular determinants of NT and SR 48692 binding sites on NTS1 demonstrating that on the 424 aminoacid protein sequence of rat NTS1, the third extracellular domain and residues in the sixth and seventh transmembrane domains were essential for both NT and SR 48692 binding. Some residues such as Trp339, Phe344, and Tyr347 (all of them aromatic aminoacids) located in the third extracellular loop of NTS1 are implicated in NT binding, Tyr324, Tyr351, Thr354, Phe358, and Tyr359 are involved in antagonist binding only, and Met208, Phe331, and Arg327 interact with both agonist and antagonist. The third intracellular loop of the NTS1 and the first half of the C-terminal intracellular domain are involved in Gq and Gi/o coupling respectively, whereas the C terminus is essential for NT-induced NTS1 internalization, an observation important for NT targeting, as it will be discussed later (Figure 1).

NTS2

NTS2 which is also a GPCR shares 60% sequence similarity with NTS1. It has been cloned from mouse, rat, and human, and corresponds to the low NT affinity sites originally described and able to bind the nonpeptide histamine H1 antagonist levocabastine. Most of the physiolological implications of NTS2 are unknown, but several arguments suggest that it mediates the analgesic effect of NT reported in the mouse. Surprisingly, depending on the species studied, NT, SR 48692, and levocabastine behave differently on transduction signaling pathway activation. In summary, SR 48692, an antagonist of the NTS1, behaves as a potent agonist on NTS2, whereas NT or levocabastine have no effect or antagonize the effect of SR 48692, for instance, on inositol phosphate production. These results suggest that an endogenous activator for NTS2 other than NT may exist and remains to be discovered. Though mutagenesis studies have not been carried out as extensively for NTS2 as that for NTS1, it was recently reported that a single tyrosine residue in position 237 in the third intracellular loop of the mouse and human NTS2 was responsible for receptor phosphorylation and essential for receptor recycling.

NTS3

In contrast to both NTS1 and NTS2, this more recently discovered NT receptor subtype belongs to the family of proteins characterized by a single-transmembrane domain, a cystein-rich domain, a signal peptide, a furin cleavage site, and a short cytoplasmic C-terminal

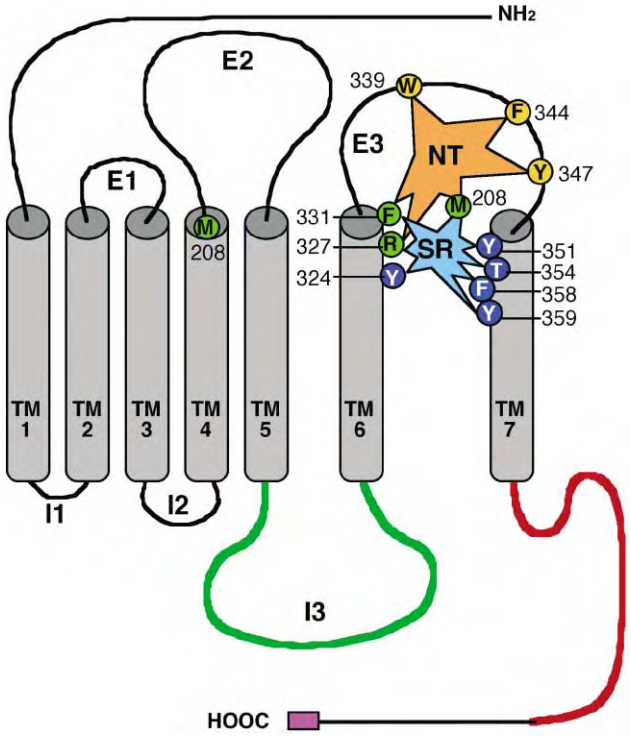

FIGURE 1 Molecular properties of the rat NTS1 (color illustration). The rat NTS1 is a 424 amino acid proteins with seven transmembrane (TM) domains. The SR 48692 (SR, light blue) and NT (orange) binding domains were established by mutagenesis and modeling studies. The residues that play a role in agonist and antagonist binding can be grouped in three categories: Met208, Phe331, Arg327 that interact with both NT and SR 48692 (green); Tyr324, Tyr351, Thr354, Phe358, and Tyr359 that are involved in antagonist binding only (blue); and Trp339, Phe344, and Tyr347 in extracellular loop 3 (E3) that interact with NT only (yellow). The C terminus of the NTS1 (magenta box) is essential for agonist-induced receptor internalization. Intracellular loop 3 (I3, in green) and the first half of the C-terminal intracellular domain (in red) are involved in Gq and Gi/o coupling, respectively.

tail. This 100 kDa protein shares 100% with sortilin, a protein involved in molecule sorting between the cell surface and intracellular compartments. Thus, it was recently observed that NTS3 could interfere with NT-induced intracellular trafficking of NTS1. Brain distribution of NTS3 demonstrates an extensive overlap of NTS3 with NTS1 and NTS2 subtypes, suggesting that NTS3 might interact with the other NT receptors to mediate central effects of NT. Recent evidence suggests that NT3 can mediate the effect of NT on microglial migration.

Receptor-Mediated Physiological Effects of NT

Although NT has been implicated in several central and peripheral effects as reported above, studies have been extensively focused on two main orientations. On the one hand, the brain involvement of NT in the regulation of central dopaminergic systems. On the other hand, in the periphery, its implication in cancer.

The main conclusions of these studies and their potential implication in therapeutics are reported here.

Neurotensin Receptor Implication in Brain Functions

Neurotensin and Dopamine Interaction

More than twenty years ago, it was observed that some behavioral and biochemical effects of centrally administered NT were similar to those exhibited by antipsychotic drugs, and that these drugs stimulated NT expression in brain regions where there are mesocorticolimbic and nigrostriatal DA neuronal projections. These observations led to the hypothesis that NT may act as an endogenous neuroleptic, and stimulated the research on NT–DA interactions. Moreover, autoradiographic binding studies showing that central DA neuronal pathways could be mapped using radiolabeled NT further suggested that NT could regulate DA transmission.

Subsequent studies confirmed that NT compounds targeting NTS1 might represent a new class of antipsychotic drugs. However, there is still a debate as to whether an NTS1 agonist or an antagonist such as SR 48692 would be more suitable as an antipsychotic and have fewer side effects than the antipsychotic drugs used in clinics. Such controversial issue has recently been addressed in two complementary reviews.

Part of the discrepancies is based on the fact that NT exerts opposite effects on DA transmission depending on the site of injection in the brain. Administered into the nucleus accumbens where the mesolimbic DA system projects, NT produced a neuroleptic-like effect. By contrast, injection of the peptide in the ventral tegmental area, the region of the mesolimbic DA cell bodies, elicits psychostimulant-like effects. Similarly, though several data demonstrate that NT facilitates DA synthesis and DA transmission (an effect blocked by SR 48692), suggesting a psychostimulant action of NT, the observation that SR142948A disrupted acquisition of latent inhibition in rat, an animal model of schizophrenia, is in favor of NT mediating the effects of antipsychotic drugs. Finally, a pseudopeptide analogue of NT able to cross the blood brain barrier, NL-69L, was recently reported to exhibit antipsychotic-like effects after peripheral administration in rat.

Overall, final answer to whether an NT agonist or antagonist may be useful for the treatment of psychotic disorders such as schizophrenia will need clear-cut results in human trials.

Another field in which interaction between NT and DA has been proved to be potently and clinically

interesting is the treatment of stress and drug abuse. On the one hand, SR48692 has been shown to blunt stress-induced DA release and stimulation of the hypothalamo-pituitary adrenal axis; on the other hand, very recent data clearly report that NT neurons play a key role in the modulation of DA mesolimbic system in reward, blockade of NTS1 by SR 48692 inducing an inhibition of both amphetamine and cocaine-induced increase in locomotor activity and addiction.

NT and Pain Modulation

Whereas NTS1 seems to be implicated in NT–DA interaction, strong evidence suggests the involvement of NTS2 in the mediation of NT antinociceptive effects. Pharmacological studies have demonstrated that the NT antagonist SR 142948A does not distinguish between NTS1 and NTS2, blocks NT-induced nociception, whereas the NTS1-specific antagonist SR 48692 does not. Recent data on NTS1 and NTS2 knockout mice suggest the implication of NTS2 in the analgesic effects of NT. Supporting this, levocabastine and NTS2 antisense oligonucleotides were both found to inhibit the antinociceptive effects of intracerebroventricular administration of NT. Furthermore, brain structures associated with every single sensory system, in particular those implicated in the descending control of nociceptive inputs (e.g., the periaqueductal gray or raphe nuclei), contain a strong NTS2 immunoreactivity. However, since the distribution of brain NTS2 largely exceeds that of NT terminal fields, it suggests that NT may not be the only endogenous ligand for this receptor subtype. More work has to be done to clarify the pharmacology and physiological relevance of NTS2 in that context.

Neurotensin Receptor Implication in Cancer

Increasing evidence demonstrates that proNT and NTS1 are deregulated in several human cancers such as colon, pancreatic, prostate, and lung cancer, suggesting that NT may exert an autocrine activation of its own NTS1 receptor in cancer. Thus, the use of NT receptor antagonists to block the proliferative effect of NT on cancer cells is one of the promising prospects in cancer therapy. In this respect, it has been recently reported that SR 48692 could inhibit NT-stimulated growth of human colon, pancreatic, and lung cancer cell lines and, when administered alone to nude mice grafted with human NTS1-expressing colon cancer cells, could induce a reduction in tumor volume. It also seems that the proliferative effect of NT can be mediated not only by NTS1 but also by NTS3 since several of the cancer cells coexpressed both receptor subtypes. Selective NTS3 antagonists may thus be of particular interest in cancer therapy.

Not only NT antagonists but also NT agonists may be useful in cancer. Since NT receptors can be overexpressed in cancer tissues, this property can be used positively to target NTS-expressing cancer cells. Like most GPCRs, NTS1 undergoes internalization of the agonist into the target cell. Because NTS1-agonist complexes readily internalize, radiolabeled NT analogues targeting NTS1-expressing cancer cells have been recently developed. Pseudopeptide NT 8–13 stable analogues radiolabeled with 99mTechnecium have been developed for diagnostic purpose in cancer. Recently a strategy using the simultaneous detection of an antigen specifically expressed on cancer cells, carcinoembryonic antigen, with NTS1 using an 111Indium labeled NT hapten-bearing analogue has been shown to be an extremely promising approach to enhance selectivity to target tumor cells as compared to cells only expressing the cell surface receptor. This approach could allow the development of radiopharmaceuticals labeled with isotopes suitable not only for diagnostic but also for radiotherapy.

Glossary

antipsychotic and **psychostimulant drugs** Synthetic molecules which affect brain dopamine transmission. Neuroleptics are antipsychotics and psychostimulant drugs of abuse.

dopamine A neurotransmitter synthesized in specific cells from tyrosine, by means of a rate-specific enzyme, tyrosine hydroxylase. Dopamine is implicated in motor activity, mood behavior, and emotion. It is considered as a "pleasure" molecule.

EISAI, NT-69-L, JMV 449, JMV 431 NT analogues used for the characterization of NTS.

GPCR G protein-coupled receptors, receptor family of heptahelical transmembrane proteins that trigger intracellular signaling cascade via G proteins when stimulated by a variety of stimuli including light, odorant molecules, neurotransmitters, hormones, and peptides. They represent targets for more than 40% of all marketed drugs and around 10% of the human genome.

levocabastine A nonpeptide histamine H1 antagonist that binds NTS2; developed by Janssen Laboratories, Beerse, Belgium.

neuropeptides Peptides that work as neurotransmitters or neuromodulators on brain and neuroendocrine functions. More than 100 have been described so far.

neurotensin A 13 amino acid peptide found mainly in both the brain and the gut. Synthetized as part of a precursor protein (pro-NT) from which it is excised by prohormone convertases in the regulated secretory pathway of neuroendocrine cells. Its primary structure is: pGlu-Leu-Tyr-Glu-Asn-Lys-Pro-Arg-Arg-Pro-Tyr-Ileu-Leu.

SR 48692 and SR 142948A Synthetic molecules which are nonpeptide antagonists of NTS1 and agonists of NTS2 developed by Sanofi Synthelabo, France.

Biography

William Rostène is Research Director at INSERM, France. He was head of the INSERM Unit 339 in Paris (1991–2002). He qualified as a neuroendocrinologist and was President of the French Society for Neuroendocrinology (1997–2000). He is one of the pioneers in the development of autoradiography and image analysis for neuropeptide receptors and has carried out extensive work on two neuropeptides, neurotensin and VIP.

Patrick Kitabgi is Research Director at INSERM, France. He is currently Head of INSERM E0350 in Paris. He has devoted most of his scientific career to the study of neurotensin starting in 1974 in the laboratory of Susan Leeman who discovered neurotensin.

Didier Pélaprat is Research Director at INSERM, France. He qualified as an organic chemist and then a neurobiologist. His work particularly focused on functional consequences of ligand–receptor interactions and modulation of dopaminergic systems by neuropeptides such as cholecystokinin and neurotensin.

Neurotransmitter Transporters

Aurelio Galli, Randy D. Blakely and Louis J. DeFelice
Vanderbilt University, Nashville, Tennessee, USA

Neurotransmitters are chemical messengers that neurons use to communicate with each other. Timely removal of neurotransmitters from the synaptic cleft is critical for synaptic neurotransmission. If released neurotransmitter molecules remain in the synaptic cleft, the synapse would become nonresponsive due to continued exposure of neurotransmitter. Removal of neurotransmitter from the synaptic cleft occurs by three mechanisms: diffusion, enzymatic degradation, and reuptake. Transporter proteins localized in nerve and glial cell membranes mediate high affinity reuptake for the released neurotransmitters, and under many circumstances reuptake is the dominant mechanism for the termination of synaptic signaling. This mechanism not only serves to clear extracellular neurotransmitter, but it also recaptures transmitter molecules for possible reuse. In addition, significant ionic currents are associated with transport, and these may contribute substantially to the excitability of the cell.

Neurotransmitter transporters utilize the electrochemical energy derived from the inward movement of ions, particularly sodium, to drive the intracellular accumulation of neurotransmitter. Neurotransmitter transporters are thus designated as cotransporters. In the early 1990s, several of these membrane proteins were cloned and two broad families have been identified. The first, which includes the norepinephrine (NE), dopamine (DA), γ-aminobutyric acid (GABA) and serotonin (5HT) transporters, shares no significant sequence homology with the second, which includes transporters for glutamate. After the "cloning" decade, several intriguing and exiting questions related to their structure and function are being raised: What is the molecular mechanism of transport? How does the protein structure define these mechanisms? What are the cellular signals and determinants that regulate transporter expression and function? Are there disease states related to neurotransmitter transporter dysfunction? This article will be restricted to GABA transporters and the monoamine transporters; discussion of vesicular transporters, glutamate transporters and sodium-dependent glucose transporters will be omitted.

Mechanisms of Transport

Reuptake

Neurotransmitter transporters operate by coupling the transmembrane translocation of substrate to the movement of driving ions down pre-established electrochemical gradients (cotransport). Members of this family include the membrane carriers for dopamine (DAT), serotonin (SERT), norepinephrine (NET), and γ-aminobutyric acid (GAT1–3). The most widely held concept of how cotransporters function is founded on the "alternating access model," in which the binding sites for substrates and cosubstrates are alternately exposed to extracellular or cytoplasmic environments via conformational changes in the transporter protein. The thermodynamic work of the transporter is accomplished by coupling the flux of substrate to the movement of cotransported ions down their electrochemical gradients. The stoichiometry inferred from radiolabeled transport studies on neurotransmitter transporter-expressing cells and membrane vesicles is two Na^+, one Cl^-, and one molecule of substrate for DAT and GAT1. For NET the proposed stoichiometry is one Na^+, one Cl^-, and one molecule of NE. With the exception of mammalian SERT, which is proposed to be electroneutral due to additional counter ion flow, the neurotransmitter transporter process is electrogenic meaning that the transport cycle moves net charges across the plasma membrane. Indeed, in cell lines stably transfected with the cDNA of neurotransmitter transporters, it is possible to record electrical currents generated by their activity using the patch clamp technique in the whole-cell configuration. However, these currents are generally too large to be explained entirely by fixed stoichiometry models (see Figure 1).

Recent electrophysiological studies of both native and cloned neurotransmitter transporters revealed that transporters can have brief and rare channel-like openings comparable to those generated by ligand-gated ion channels. Models for this exiting mode of the neurotransmitter transporters have been established, in which substrate, Na^+ and Cl^- induce the carrier to transport in the alternating access mode (Figure 1A, 1B), and rarely switching to a channel-like mode (Figure 1C). The alternating access model assumes that the substrate permeation occurs through a state transition (A ↔ B) and results in the transport of a single neurotransmitter molecule (Figures 1A and 1B). The channel-like mode (Figure 1C) is a low probability event that consists of hundreds of ions

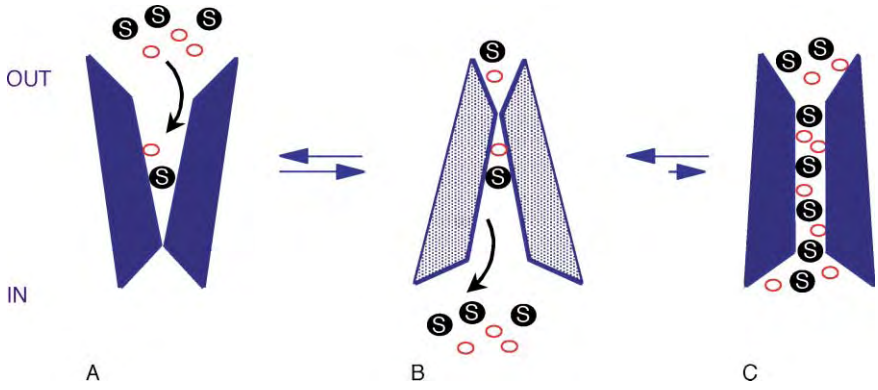

FIGURE 1 Model for neurotransmitter transporter function.

crossing the membrane (using a transporter pore), down their electrochemical gradients. These models have been recently refined and expanded based on new data.

Efflux

In addition to mediating the reuptake of neurotransmitter into nerve terminals, transporters can also cause non-Ca^{2+}-mediated efflux of the transmitter from the nerve terminal. There are essentially two mechanisms by which to elicit reverse transport from neurons: first, by changing the transmembrane ion gradients and voltage; and, second, for monoamine transporters, via the actions of pharmacological compounds such as amphetamine that may stabilize an efflux competent conformation, modulate ion gradients or both. In the case of glutamate transporters, nonvesicular neurotransmitter release is thought to play a role in pathophysiological conditions causing membrane depolarization such as epilepsy, or excitotoxicity such as stroke.

Structure and Function

A milestone in the advancement of knowledge of neurotransmitter transporters was achieved in 1990 when the first cDNAs encoding the GABA transporters were cloned and sequenced. As a consequence neurotransmitter transporters cDNAs for NET and SERT were soon cloned, and the list grew. The gene products of the Na^+/Cl^- neurotransmitter transporter family are highly conserved. Monoamine and GABA transporters show a common structure of a predicted 12 transmembrane (TM) domains with a single large loop in the external side of the plasma membrane with potential glycosylation sites. Each TM domain contains predominantly hydrophobic amino acid residues. The TM domains are connected by extracellular or intracellular loops located on either side of the plasma membrane in which the residues are mostly hydrophilic. Because high-resolution structures, such as the ones obtained by X-ray crystallography, are difficult to gain for integral membrane proteins, most of the structural information for neurotransmitter transporters obtained in recent years has been obtained by chemical modification with labeling reagents. In particular, the cysteine accessibility method (SCAM) has been used to gather information on the topology and the mechanism of transport. With this technique, a particular residue in the sequence is replaced usually with a cysteine residue. Then, chemical modifications of the cysteine are performed to measure its accessibility by evaluating, for example, changes in transporter function induced by the chemical modification. Cysteines are well tolerated as a replacement for a particular amino acid in the sequence of most membrane transporter proteins. By using different types of reagents, and, depending on the reagent used, the accessibility of a residue may provide information about its location and function. Use of these methodologies allowed researchers to measure the level of exposure of predicted extracellular loops in SERT, DAT, and other neurotransmitter transporters. Because the kinetics of reactivity for cysteine substitutions in TM domains and loops are expected to be different, SCAM can also provide information on the location of the end and the beginning of a particular transmembrane domain. Furthermore, cysteine substitutions whose chemical reactions result in a robust modification in transporter activity can elucidate the relationship between structure and function. For example, if the change in transporter activity resulting from the chemical modification of a cysteine can be altered by the presence of an inhibitor or a substrate, there is the possibility that this cysteine is part of the substrate-inhibitor binding site. With this experimental strategy, Rudnick and co-workers suggested that the Ile in position 172 and Tyr in position 176 of the TM domain 3 of the rat

SERT are in proximity to the binding site for 5-HT and cocaine. A relevant transporter (lactose permease of *Escherichia coli*) structure from another gene family has recently appeared.

Regulation

It is not surprising that molecules regulating the spatial and temporal dimension of synaptic events are tightly regulated. Several reports have shown that various signaling molecules can rapidly regulate many of the neurotransmitter transporters. Regulators of neurotransmitter transporter activity include G protein-coupled receptors such as the D_2 and mGluR5 receptors, kinases such as protein kinase C, phosphatidylinositol 3-kinase, tyrosine kinase, and Ca^{2+}/calmodulin kinase, protein kinase B, protein kinase C, and neurotrophic factors. In addition to transporter rates, many studies suggested that the regulation of neurotransmitter transport capacity might originate from a change in their cell surface expression. In this context, it is important to point out that transporter interacting proteins finely control plasma membrane expression level of neurotransmitter transporters. For example, in addition to PKC and other signaling pathways, cell surface expression and activity of GAT1 and NET are regulated by syntaxin 1A, a protein involved in synaptic vesicle fusion to the plasma membrane. Similarly, DAT surface expression can be influenced by its PDZ-mediated protein–protein interaction with PICK1, a PKC-binding protein. Although it is still not clear whether this transporter family shares common regulating factors, it is becoming evident that the trafficking of neurotransmitter transporters represents a new paradigm by which neurons control their ability to reuptake neurotransmitter. Other regulators of DAT and SERT cell surface expression include psychostimulants such as AMPH and cocaine.

The general process of transporter trafficking, that involves endocytosis, intracellular sorting, and exocytosis of these membrane proteins, is acquiring great interest for neuroscientists. Indeed, researchers studying transporter cell surface redistribution are envisioning the possibility of discovering new cellular targets to cure specific neurological disorders.

Relationships Between Disease States and Neurotransmitter Transporters

The ability of the neurotransmitter transporters to regulate normal synaptic signaling implies that functional modification of transporter activity might contribute to the etiology of multiple neurobiological diseases. Indeed, many studies have suggested for years, largely on the basis of pharmacology, that the monoamine transporters NET, DAT, and SERT play an important role in regulating mood, learning, and motor activity, while GABA transporters have been implicated in neuronal excitability dysfunction such as epilepsy. Indeed, a decade of innovative pharmacology resulted in the development of compounds that, by targeting neurotransmitter transporters, alleviate the symptoms of neurological diseases such as drug abuse and attention deficit/hyperactivity disorder. New hopes for the cure of these conditions are coming from studying the gene organization and polymorphisms of these membrane proteins. It has been shown that variations in the human neurotransmitter transporter sequences, known as polymorphisms, may alter transporter expression level, activity, or regulation that ultimately may influence the levels of extracellular neurotransmitter. The cloning of the neurotransmitter transporter genes has provided the tool for examining transporter genetic variations and possibly to correlate them to human diseases. This is particularly true for the monoamine transporters (SERT, DAT, NET) each encoded by a single gene. Therefore, the impact of polymorphisms could have far-reaching consequences due to a limited opportunity for compensation from other genes. Finding an association of a polymorphism with disease is clearly the first of many steps toward understanding how genetics shape the neurobiological diseases. A recent example of such an effort is the identification of a NET coding variant, A457P, in subjects with orthostatic intolerance.

BIOGRAPHY

Aurelio Galli received his Ph.D. from the University of Milan in 1994. He is now a faculty member in the Department of Molecular Physiology and Biophysics at Vanderbilt University in Nashville, Tennessee. His principal research interest is to study the regulation by psychostimulants of neurotransmitter transporter function.

Randy Blakely received his doctorate in Neuroscience from the Johns Hopkins School of Medicine and then pursued postdoctoral studies at Yale University. Following a faculty position at Emory University, he became the Alan D. Bass Professor of Pharmacology at Vanderbilt. His major interest is in the molecular regulation of neurotransmitter transporter.

Louis J. DeFelice received his Ph.D. in Physics in Calgary, Alberta, Canada in 1967. He is now a Professor of Pharmacology and Neuroscience at Vanderbilt University. His principal research interest is the molecular mechanism of ion tansport across membranes, including ion channels and co-transporters.

Neurotrophin Receptor Signaling

Jennifer J. Gentry and Bruce D. Carter
Vanderbilt University, Nashville, Tennessee, USA

The purification of nerve growth factor (NGF) during the 1950s, based on its ability to promote the survival of sensory and sympathetic neurons, led to the discovery of a family of related trophic factors referred to as the neurotrophins. The members of the neurotrophin family include NGF, brain-derived neurotrophic factor (BDNF), neurotrophin 3 (NT3), and neurotrophin 4 (NT4), and each is essential for the survival of specific, but overlapping, populations of neurons during development. Given that nearly half of the neurons generated during mammalian ontogenesis undergo programmed cell death, it is clear that the neurotrophins have a major role in determining the ultimate population size for a given group of neurons. Moreover, the neurotrophins not only promote survival, but also regulate differentiation, axon guidance, synaptogenesis and neurite branching, and elongation; thus, this family of trophic factors has a wide spectrum of actions that are key for the proper sculpting of the mammalian nervous system. In addition to their role in development, this family of proteins also has important effects on maintenance of the nervous system, including such processes as learning and memory, neurogenesis in the adult and response to injury. This article will focus on the molecular-signaling mechanisms activated by the binding of neurotrophins to their receptors, with particular emphasis on the regulation of cell viability.

Introduction

The diversity in neurotrophin function is likely a reflection of the variety of signaling pathways that are influenced by activation of their receptors. The neurotrophin receptors consist of a family of tyrosine kinase receptors, the Trks, and a member of the tumor necrosis factor receptor family, p75NTR. Neurotrophin binding to the Trks promotes survival and differentiation while activation of p75NTR can also enhance cell viability or, paradoxically, induce apoptosis. Although activation of the Trks or p75NTR can initiate discrete signal transduction pathways, the two receptor types are frequently coexpressed on a given cell. Thus, it is the complex interactions between these receptors and crosstalk between their signaling pathways that ultimately determines the fate of the cell. In addition, a number of other receptors are modulated by the neurotrophins or can regulate neurotrophin signaling, either through interaction between receptors or cross talk between signaling pathways.

Neurotrophin Activation of Trk Receptors

The most well-studied actions of neurotrophins are mediated through activation of a family of tyrosine kinase receptors, the Trks. There are three members of the Trk family, TrkA, TrkB, and TrkC. Each receptor binds to specific members of the neurotrophin family preferentially with nerve growth factor (NGF) having the highest affinity for TrkA, BDNF, and NT4/5 for TrkB, and NT-3 for TrkC. Binding of a neurotrophin, which exist as dimers, to a Trk receptor triggers receptor dimerization and activation of intrinsic tyrosine kinase activity. Like other tyrosine kinase receptors, autophosphorylation of specific residues within the intracellular domain of the receptor leads to the recruitment of a wide variety of signaling molecules (Figure 1). In particular, these phosphotyrosines serve as docking sites for proteins containing Shc homolog 2 (SH2) or phosphotyrosine-binding (PTB) domains, including phospholipase C-γ (PLC-γ) and the adaptor proteins Shc, Frs-2, rAPS and SH2-B. These receptor-binding proteins initiate several signal transduction cascades.

Association of Trk with PLC-γ activates this enzyme, resulting in cleavage of phosphatidylinositol (4,5) bisphosphate to release the second messengers inositol-1,4,5-triphosphate (IP3) and diacylglycerol (DAG). DAG activates a number of isoforms of protein kinase C (PKC) while IP3 triggers the release of Ca^{2+} from intracellular stores, which activates a variety of pathways, including calmodulin kinases and Ca^{2+} regulated isoforms of PKC. The maintenance of calcium homeostasis has been well documented as key for regulating neuronal survival. Indeed, a role for PKC in prosurvival effects of the neurotrophins has been suggested; however, recent data suggests that this pathway has a more significant role in regulating spatial learning and

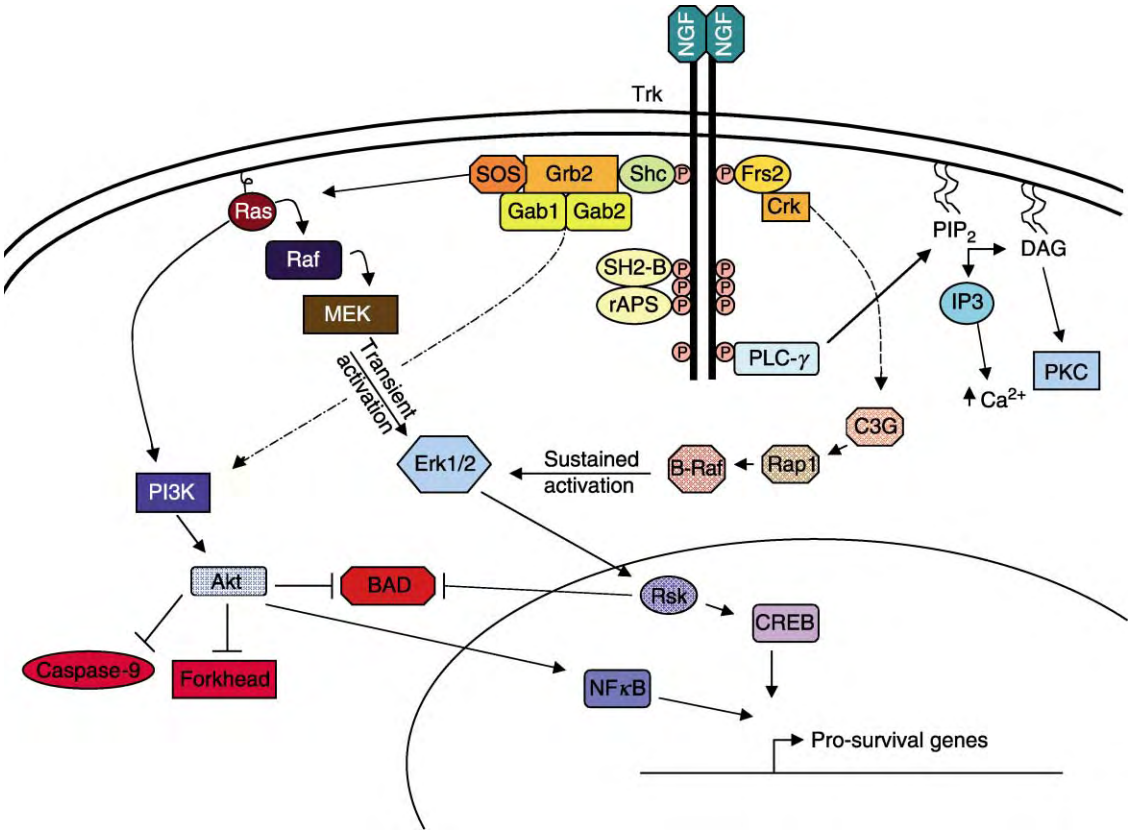

FIGURE 1 Neurotrophin signaling through the Trk receptor.

memory. Analysis of transgenic, knock-in mice lacking the docking site for PLC-γ on the TrkB receptor has not revealed any defects in neuronal survival, but the animals do display deficiencies in hippocampal long-term potentiation (LTP), which is a model for spatial memory.

Another signaling cascade activated by the Trk receptors is the Ras–MAP kinase pathway (Figure 1). The phosphorylation of the membrane proximal tyrosine (Y490 on TrkA) recruits the protein Shc, leading to docking of the adaptor proteins Gab1, Gab2, and Grb2. Grb2 associates with the guanine-nucleotide-exchange factor SOS, which facilitates activation of Ras, an activator of several pathways. The activated, GTP-bound form of Ras recruits the serine/threonine kinase Raf to the plasma membrane, thereby facilitating its activation. Raf then phosphorylates MEK1 and/or MEK2 and these kinases phosphorylate the MAP kinases Erk1 and 2. The activated Erks translocate into the nucleus where they phosphorylate a variety of substrates, including the kinase Rsk, which can phosphorylate and inactivate the proapoptotic protein Bad. Rsk also phosphorylates the transcription factor CREB, resulting in its activation and the subsequent up-regulation of downstream genes such as the prosurvival gene Bcl-2. In addition, the Ras–MAP kinase pathway is also important for neurotrophin mediated differentiation, including the induction of neurite outgrowth. For example, expression of activated Raf, in the absence of neurotrophin, induced neurite elongation in sensory neurons and constitutively active MEK up-regulated p35, leading to cdk5 activation, which increases neurite extension.

The ability of neurotrophins to promote differentiation appears, in part, to depend on prolonged Erk1/2 activation, as opposed to the transient activation of the kinases induced by other growth factors such as EGF. The longer kinetics are a result of phospho-Trk associating with the adaptor, Crk, through interaction with the fibroblast growth factor receptor substrate-2 (Frs2). Crk binds to the nucleotide-exchange factor C3G, thereby stimulating the small GTP-binding protein Rap1. The kinase B-Raf is then activated by Rap1, resulting in sustained Erk1/2 activation (Figure 1).

The activation of Ras also leads to activation of the lipid kinase, phosphatidylinositol 3 kinase (PI3K). In addition, PI3K can be activated independent of Ras through Grb2 binding to the adaptor Gab1/2, which facilitates Trk stimulation of the kinase. PI3K produces phosphatidylinositides phosphorylated on the third position of the inositol and these serve to indirectly

activate the serine/threonine kinase Akt. Akt acts on a number of signaling proteins that are critical regulators of cellular survival. The kinase activity of Akt leads to activation of the transcription factor NFκB, which can serve as a prosurvival factor in the nervous system, and inhibition of the proapoptotic proteins Bad, Forkhead, GSK3β, and caspase 9. Numerous studies have demonstrated a requirement for the PI3K-Akt pathway in neurotrophin mediated survival; however, this pathway also promotes protein translation and neurite branching (Figure 1).

Adding to the complexity of Trk signaling is the presence of several splice variants of all of these receptors. Among these isoforms, both Trk B and Trk C exist as truncated receptors lacking the intracellular kinase domain. While there is evidence that loss of the kinase domain can function to abrogate Trk signaling by competitively binding the available neurotrophin or forming inactive complexes with full length receptor, there is also evidence that these truncated Trks may function to display bound neurotrophin to adjacent cells. In addition, recent findings suggest that the truncated receptors can initiate signaling within astrocytes, leading to IP3-dependent calcium release. A second type of splice variant observed for all of the Trks is a form of the receptor lacking a small portion of the extracellular domain in the juxtamembrane region. Expression of these isoforms more stringently restricts the responsiveness of a given Trk for its cognate neurotrophin and may be one mechanism to insure the elimination of neurons making connections to an inappropriate target tissue.

One important aspect of neurotrophin signaling that needs to be considered is the spatial limitations of a neuron. Typically, it is the axonal tip that encounters the neurotrophins, while the regulation of survival involves transcriptional activity; hence, the signal must be retrogradely transported some distance back to the neuron soma. Although it has long been known that neurotrophins are retrogradely transported, it was only recently demonstrated that it is essential that the factor be transported with the active receptor, although this requirement has been contended by Campenot and colleagues. TrkA and NGF are not transported alone, rather, an entire complex of signaling proteins associated with an internalized vesicle, referred to as a signalosome, has been shown to undergo transport from neuronal endings back to the cell body.

Neurotrophin Activation of the p75NTR Receptor

While p75NTR was the first neurotrophin receptor identified and the founding member of the TNF receptor family, only recently has its importance for neurotrophin action been appreciated. With that appreciation, a wave of research highlighting both the mechanisms and functional consequences of its signal transduction pathway has been generated. p75NTR is important for neuronal development through its regulation of programmed cell death. In addition, accumulating evidence indicates that p75NTR also plays an important role in injury response within the nervous system.

Like many members of the TNF receptor family, p75NTR can activate the transcription factor NFκB and the stress activated kinase JNK (c-Jun N-terminal kinase) (Figure 2). The activation of NFκB by p75NTR has been shown to promote survival, thus providing a mechanism by which this receptor can function together with Trk to keep cells alive. In contrast, the activation of JNK is a proapoptotic signal in many contexts. For example, p75NTR-mediated apoptosis has been demonstrated to play a role in the normal elimination of neurons during development of the mouse retina, spinal cord, basal forebrain, and sympathetic ganglia. One of the major roles for cell death induced by this receptor may be after nerve injury. Following a spinal cord lesion in rodents, oligodendrocytes undergo p75NTR-dependent apoptosis. Similarly, pilocarpine-induced seizures cause mouse hippocampal neurons to die through a process dependent on p75NTR. Given that p75NTR is highly up-regulated following a large number of insults, it is likely that future studies will continue to reveal a role for this receptor in the associated cell death.

In addition to its activation of NFκB and JNK, p75NTR has been shown to regulate the small GTP-binding proteins Rac and Rho (Figure 2). Rac has been suggested as an upstream activator for JNK, thus playing an essential role in the apoptotic signal; however, Rac and Rho are best known for their ability to alter the cytoskeletal architecture. It is through modulation of these G proteins that p75NTR alters neurite extension, either promoting it following binding of neurotrophin, or causing growth cone collapse upon association with ligand-bound Nogo receptor.

Although the downstream signals activated by p75NTR are similar to other members of the TNF receptor family (NFκB and JNK), the receptor-proximal mechanisms used appear to be somewhat different. This is not entirely surprising given that p75NTR is the only member of the TNF receptor family that is activated by a dimeric ligand, rather than the trimeric ligands (e.g., TNFα and Fas ligand) that create trimeric receptor complexes and recruit trimeric adaptor proteins. Recently, much effort has been focused on understanding the transduction mechanism of this unique pathway. This work has resulted in the identification of a large number of p75NTR interacting factors whose sheer

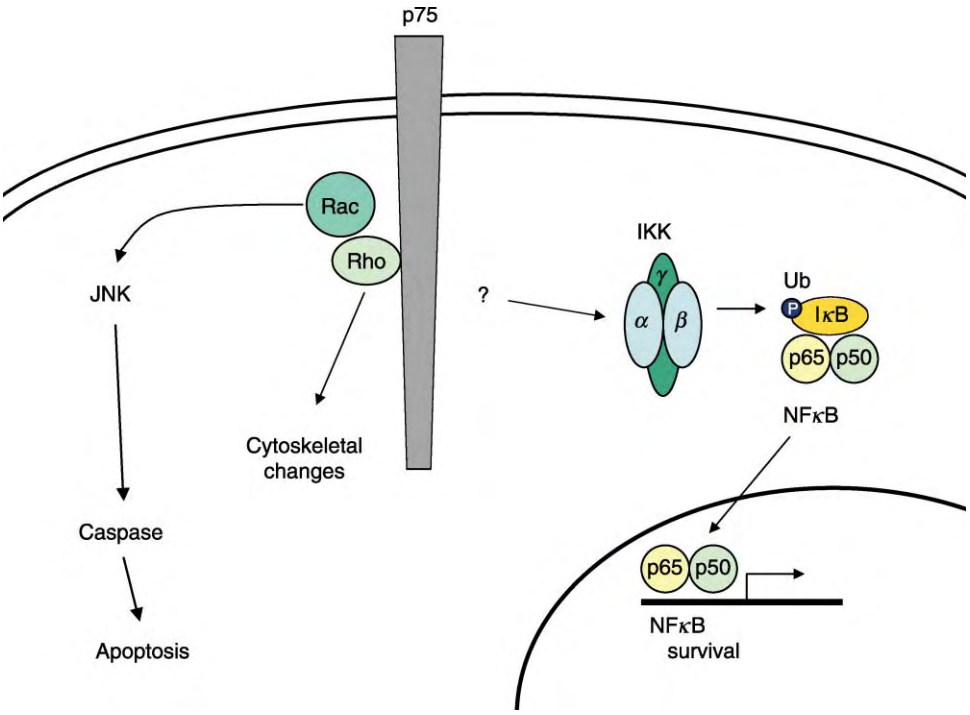

FIGURE 2 Neurotrophin signaling through p75NTR. Neurotrophin binding to this receptor activates the stress kinase JNK, the transcription factor NFκB, and regulates the GTP-binding proteins Rac and Rho. Not depicted are the numerous receptor-binding proteins that have been reported, since how they participate in p75NTR signaling has yet to be elucidated.

numbers will require some time to sort through to understand how they fit into p75NTR signaling under various conditions.

A long-standing conundrum in understanding the physiological role of p75NTR has been the high levels of neurotrophin needed to activate the receptor. *In vivo*, the neurotrophins are typically found at very low levels, usually at or below the K_D for p75NTR. Recently, the group of B. Hempstead made an important discovery that may resolve this dilemma. They found that the unprocessed, proform of the neurotrophins bind p75NTR with high affinity and activate downstream pathways more effectively than the mature neurotrophins. Hence, a mechanism exists for selective activation of p75NTR, since the proneurotrophins do not bind or activate the Trks. This discovery has renewed interest in studying the regulation of neurotrophin processing and release, as these are likely to be key for modulating neuronal survival during development and after injury.

Crosstalk Between p75NTR and the Trks

It is clear that neurotrophin binding to either p75NTR or members of the Trk family of receptors can initiate distinct signal transduction pathways, but these receptors are often coexpressed in the same cells. When both neurotrophin receptors are present, they interact to form a very selective, high-affinity complex. Given the limiting quantities of neurotrophin present in typical target tissues, such a binding site provides neurons expressing both receptors, in the proper ratio, with a competitive advantage during development. Moreover, the interaction between p75NTR and Trk leads to enhanced Trk tyrosine kinase activity and more robust activation of downstream survival signals. The binding of mature neurotrophin to the p75NTR–Trk complex also represses the p75NTR apoptotic signal; for example, Trk activation of Ras has been shown to inhibit p75NTR activation of JNK. Thus, the two receptors synergize to increase neuronal viability. A lack of the p75NTR–Trk receptor interaction has been proposed to explain the significant loss of sensory neurons in the p75NTR −/− mice.

Interaction Between p75NTR and the Nogo Receptor

Although p75NTR responds to binding of the neurotrophins, this receptor can also be activated by an additional group of ligands typically expressed on central nervous system myelin, including Nogo, myelin associated glycoprotein (MAG) and oligodendrocyte

myelin glycoprotein (OMgp). These myelin proteins inhibit neurite outgrowth and are, in part, responsible for preventing regeneration of CNS axons after nerve injury. They all bind to a GPI-linked receptor referred to as the Nogo receptor (NgR), which interacts with p75NTR. Association of NgR with p75NTR results in activation of Rho, which causes changes in the actin-cytoskeleton resulting in growth cone collapse. Interestingly, the association of NgR with p75NTR activates Rho and inhibits Rac, while the binding of neurotrophin to p75NTR has the opposite effects on these G proteins. The mechanisms by which these opposing signals are generated have yet to be fully resolved.

Crosstalk Between Trk and Non-Neurotrophin Receptors

The Trk receptors also interact with a number of non-neurotrophin receptors, although this is primarily an indirect interaction. Several G protein-coupled receptors can transactivate Trk and thereby stimulate downstream signaling pathways. For example, the adenosine receptor and the pituitary adenylate cyclase activating polypeptide (PACAP) receptor can induce phosphorylation of TrkA through a mechanism that does not involve neurotrophins. Such crosstalk is likely involved in the neuroprotective effects of these ligands.

Alternatively, neurotrophin binding to Trk can cross-stimulate the tyrosine kinase c-Ret, a component of the receptor complex for the glial cell line-derived neurotrophic factor (GDNF) family. Although c-Ret is normally activated by GDNF family members, it can also be phosphorylated in mature sympathetic neurons following NGF binding to TrkA. This indirect activation of c-Ret is required for these neurons to maintain their metabolic status and somal size. Similarly, BDNF stimulation of TrkB can transactivate a subunit of the NMDA receptor, which is essential for the formation of LTP. Since BDNF is known to enhance LTP, Trk-NMDA receptor crosstalk may be the mechanism underlying this effect.

Biography

Dr. Bruce Carter is an Associate Professor of Biochemistry in the School of Medicine at Vanderbilt University. His principal area of research is on the mechanisms by which the neurotrophins regulate neuronal survival. He holds a Ph.D. degree from the University of Michigan and received postdoctoral training at the Max Planck Institute in Munich, Germany and at Cornell Medical School.

Dr. Jennifer Gentry received her Ph.D. from Vanderbilt University and is currently a postdoctoral Fellow at Harvard Medical School.

Nicotinamide Nucleotide Transhydrogenase

Jan Rydström
Göteborg University, Göteborg, Sweden

Membrane-bound nicotinamide nucleotide is located in the bacterial plasma membrane and mitochondrial inner membrane and catalyzes the reversible reduction of $NADP^+$ by NADH. The reaction is linked to the electrochemical proton gradient across the membrane, generating NADPH essential for, e.g., detoxification of peroxides. In its isolated form the enzyme is a proton pump where proton translocation is driven by the catalytic reaction, mediated by conformational changes. Extensive investigations of the structure–function relationships especially of the substrate-binding domains have established their structures and roles. The membrane domain, in which the proton channel resides, has been structurally predicted, but remains to be determined structurally at the atomic level. Models for the molecular proton translocation mechanism are therefore beginning to emerge.

Introduction

Proton-pumping nicotinamide nucleotide transhydrogenase (E.C. 1.6.1.2) is an integral membrane protein found in most species except some yeasts, plants, and certain bacteria. It is located in the inner membrane of mitochondria and in the plasma membrane of bacteria. The enzyme catalyzes the reversible reduction of $NADP^+$ by a hydride ion, donated by NADH, which is linked to proton translocation across the membrane according to the reaction

$$H^+_{out} + NADH + NADP^+ \rightleftharpoons H^+_{in} + NAD^+ + NADPH \quad [1]$$

In the absence of an electrochemical proton gradient (Δp), the reaction from left to right (the forward reaction) is approximately fivefold slower than the reverse reaction. Under these nonphysiological conditions, the overall reaction proceeds to an equilibrium constant of close to 1. In the presence of a Δp, i.e., under more physiological conditions, the forward reaction is increased five- to tenfold and the apparent equilibrium constant is increased to ~ 500, with one proton translocated per NADPH formed. The net effect of the transhydrogenase (TH) reaction is therefore probably to provide NADPH at the expense of NADH and Δp. Thus, this suggests important roles of TH in mitochondrial/cellular redox regulation including biosynthesis, detoxication (via the glutathione/thioredoxin systems), and apoptosis. TH is globally expressed in eukaryotes, e.g., human, mouse, and *C. elegans*.

Proton-translocating THs from eukaryotes are homodimeric proteins with a relatively large hydrophilic domain composed of the NAD(H)-binding domain I (dI) and the NADP(H)-binding domain III (dIII); part of dI is homologous to alanine dehydrogenase (Figure 1). The hydrophobic part of the enzyme containing the proton channel, denoted domain II (dII), is composed of a variable number of transmembrane helices depending on species. The *Escherichia coli* TH is composed of an α-subunit and a β-subunit, the former subunit containing dI and helices 1–4 of dII and the latter subunit containing dIII and helices 6–14 of dII. Intact *E. coli* TH has the composition $\alpha_2\beta_2$, i.e., it is a tetramer in which $\alpha+\beta$ corresponds to the mitochondrial single polypeptide. dI and dIII can be expressed separately and purified in an active state and, when combined, show catalytic activity. In order to elucidate the coupling mechanism of TH, the enzyme mainly from bovine, human, and *E. coli* has been extensively studied in the purified forms, in cytosolic (plasma membrane) vesicles, as well as reconstituted in liposomal membranes. dI and dIII from bovine, human, and *Rhodospirillum rubrum*, as well as a complex between dI and dIII, have been structurally determined using X-ray crystallography and NMR.

Structure–Function of the Substrate-Binding Domains

Recent advances in structural resolution of the hydrophilic dI and dIII by X-ray crystallography and NMR spectroscopy have dramatically increased our

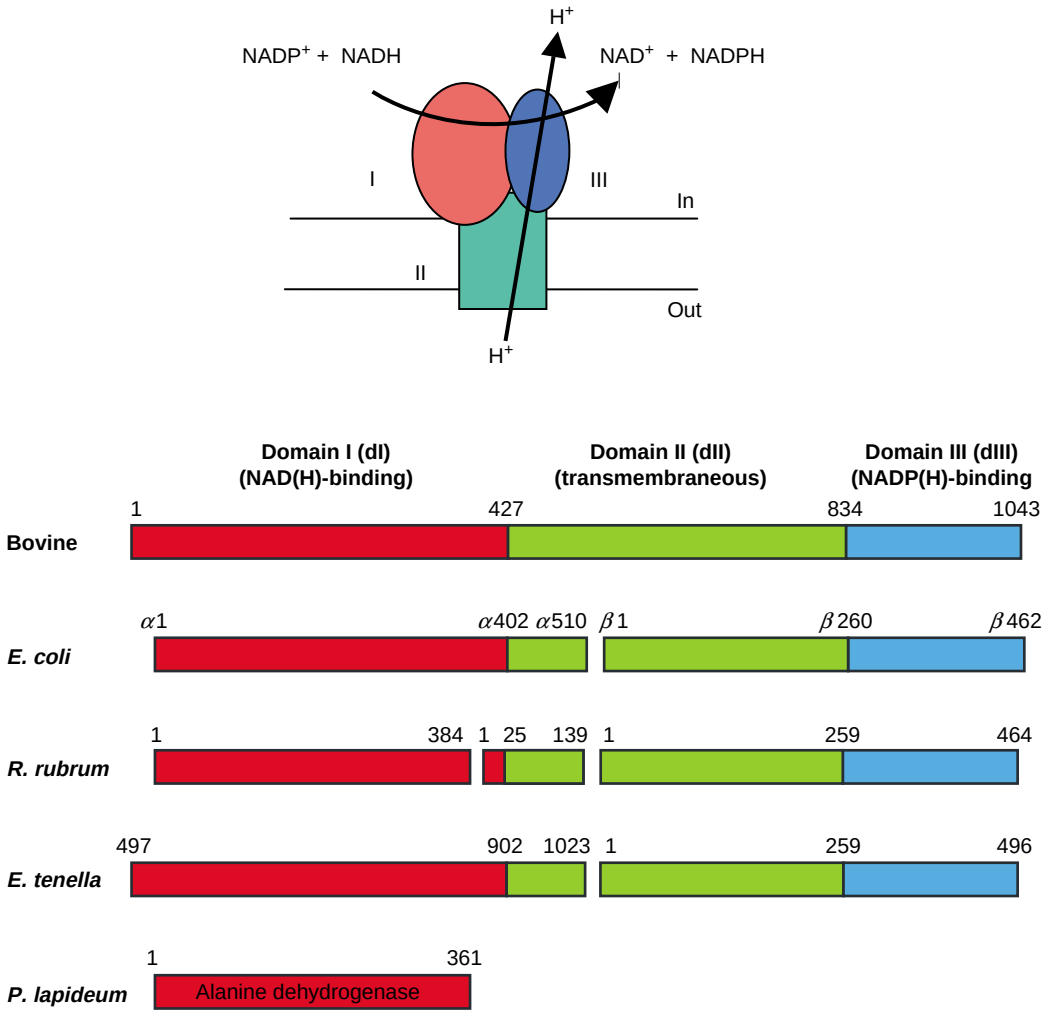

FIGURE 1 Structural organization of proton pumping THs.

knowledge about the structure–function relationships of these domains and their interactions. Thus, the crystal structure of the NAD^+ form of dI from *Rhodospirillum rubrum* solved by Jackson and coworkers and, in the NADH form from the same source later by Hatefi and coworkers, shows that it involves a dimer of a 40 kDa subunit, denoted A and B. Each subunit comprises two subdomains, dI.1 and dI.2, both of which have a Rossmann nucleotide-binding fold composed of a sheet of parallel β-strands flanked by α-helices. The two domains are arranged on the sides of a deep cleft. However, in the crystal structure of the dimer only dI.2(A) contains bound NAD^+ positioned so that its nicotinamide moiety is exposed in the cleft. In contrast, dI.2(B) site contains disordered NAD^+ or no ligand. The arrangement of the monomers in the dimer is such that the nucleotide-binding sites in dI.2(A) and dI.2(B) are pointing away from each other. The potential nucleotide-binding sites in dI.1 (A) and dI.1(B) have no known ligands. It is obvious that in the dI dimer, dI.2(A) and dI.2(B) must have different conformations, since only dI.2(A) contains well-ordered NAD^+. In a dimeric structure of dI with bound NADH, other minor but significant structural changes are observed.

Human and bovine dIII have been structurally resolved by Jackson and co-workers, and Hatefi and coworkers, respectively, using X-ray crystallography. These are structurally close to identical. The structures involve an alternating α/β-structure with a central β-sheet core, and a Rossmann fold in which $NADP^+$ is tightly bound at the C-terminal end of the β-sheet. The molecular mass of dIII is 20 kDa, it is a monomer, and it is isolated with predominantly tightly bound $NADP^+$; the K_d of the NADP(H) bound is in the nM–μM range. A striking difference, however, as compared with other NAD(P)-binding enzymes is that the $NADP^+$ bound to dIII is turned approximately 180°, i.e., the nicotinamide ring is close to α-helix 3 in *E. coli* dIII (corresponding to α-helix B in *R. rubrum* dIII) (Figure 2). A number of

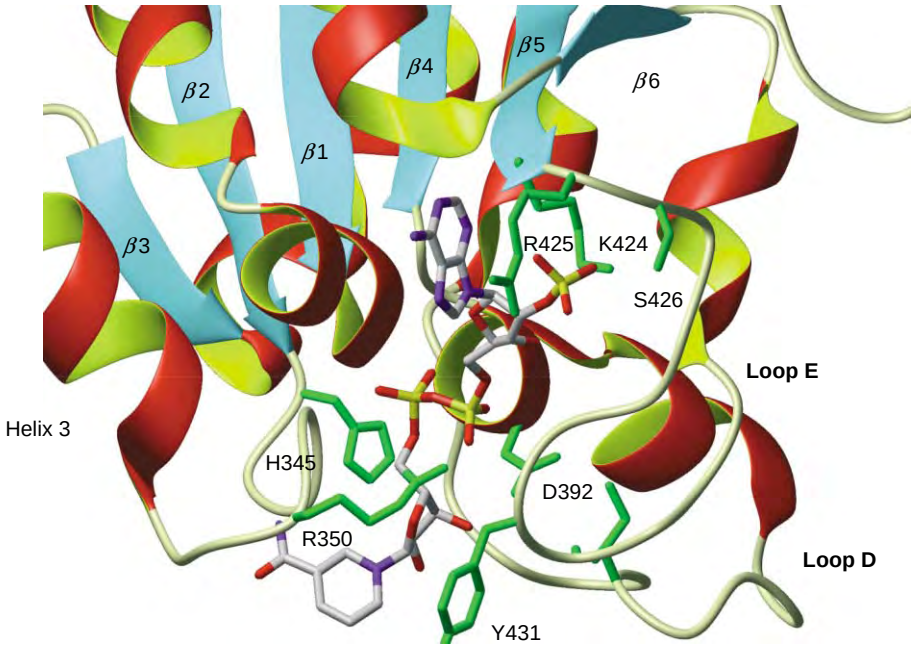

FIGURE 2 The NADP(H)-binding region of dIII. Amino acid residues and loops indicated are directly or indirectly essential in binding NADP(H).

hydrogen bonds stabilize NADP(H) in its binding site, involving, for example, Asp392, Lys424, Arg425, and Ser426. Loops D and E may indeed contribute to the binding and have been proposed to be involved in the Δp-dependent release of NADPH. Interactions between dI and dIII and their regulation by NADP(H)/NAD(H) have been investigated thoroughly by Karlsson and coworkers using NMR spectroscopy.

A crystal structure of a heterotrimer dI_2–dIII complex from *R. rubrum* showed that the dI and dIII structures are essentially identical to those determined separately. However, the dI_2–dIII structure revealed that dIII interacts with the dI.2(B), i.e., the NAD(H)-binding site that contains disordered NAD^+ rather than well-ordered NAD^+. This may be interpreted as indicating that when dIII (with bound $NADP^+$) is interacting with dI_2, it binds the dI.2(B) that has a disorganized NAD^+, not the dI.2(A) that has a well-ordered NAD^+. However, a complicating fact is that, even though an NAD(H) molecule could be modeled in the dI.2(B) site, the two nicotinamide rings are still separated by some 4–6Å, making direct hydride transfer difficult. A possible mechanistic solution to this problem is that the nicotinamide ring of the modeled NAD(H) is changed from an *anti* to a *syn* conformation, leading to a more open exposure of the nicotinamide ring in the cleft, and a direct interaction with the nicotinamide ring of $NADP^+$. Indeed, this rotation may be the very reason why NAD^+ is more mobile in dI.2(B). An additional factor influencing the interaction between dI and dIII, and thus hydride transfer, is the amino acids that make up the interface between the domains. One of these, Gln132 in dI, appears to be essential for activity because it works as a "tether" during the catalytic cycle, holding both NAD(H) and NADP(H) together in the right conformation through H-bonds.

Mechanism of Hydride Transfer

Transfer of the hydride ion between the 4A-hydrogen (*pro-R*) of NADH and the 4B (*pro-S*)-hydrogen of $NADP^+$, while the two substrates are bound to dI and dIII, respectively, occurs directly without any known intermediate and without exchange with bulk protons. Even though NAD^+/NADH are rapidly exchanging with the NAD(H)-binding site in dI throughout the reaction cycle, NADH especially shows different affinities in the open (ordered, high affinity) and closed (disordered, low affinity) states. These affinity changes, and the associated *anti/syn* transitions of NAD(H), are apparently induced by subtle conformational changes in the dI dimer. However, several pieces of evidence together indicate that regulation of hydride transfer by, for example, an electrochemical proton gradient, Δp, occurs mainly at the level of dIII, rather than dI. Essential information in this context was derived from the fact that separately expressed and purified dIII contains tightly bound NADP(H) which, due to a limiting release of the product NADP(H), catalyzes an ~2 orders of

magnitude slower reverse and forward reactions in the presence of purified dI than the wildtype enzyme. Isolated dIII also catalyzes a very fast so-called cyclic reaction, i.e., reduction of 3-acetyl-pyridine-NAD^+ (an NAD^+ analogue) by NADH, mediated by the bound NADP(H). This reaction involves reduction of bound $NADP^+$ by NADH, release of the NAD^+ formed, binding of 3-acetyl-pyridine-NAD^+, reduction of 3-acetyl-pyridine-NAD^+ by the bound NADPH, and release of 3-acetyl-pyridine-NADH. Indeed, it was reasonable to assume that the properties of the isolated dIII reflected an intermediate, the "occluded" state, in the reaction cycle of the intact transhydrogenase (TH). In reaction [1], this is interpreted to indicate that the activity of the forward reaction is limited by NADPH release, a limitation that is alleviated by Δp, allowing the enzyme to be catalytically fully active.

A general reaction scheme for forward reaction catalyzed by the *E. coli* TH may be outlined as follows (Figure 3). Starting with the resting state (state A), $NADP^+$ binds to dIII in the β-subunit generating state B, in which the proton channel and the protonatable group X2 become accessible to the periplasmic space; in state C, the enzyme is protonated at X2, and the β-subunit subsequently changes conformation to state D. In state D the proton moves from X2 to X1 concomitant with hydride transfer from NADH to $NADP^+$, generating state E. States D and E correspond to the "occluded" state. Following a conformational change in dIII, an opening of dIII, and a less tight NAD(H) (state F), the proton dissociates on the cytosolic side generating state G. After dissociation of NADPH, the enzyme returns to the resting state A. During the entire cycle NAD(H) can freely bind to and dissociate from dI. X3 indicates a group on dI that may be regulated by the cytosolic pH.

As further discussed below, at any given time, only half of the sites in the active dimeric enzyme (in the *E. coli* enzyme, $\alpha_2\beta_2$) seem to be available for, for example, NADP(H) binding and reaction with dicyclohexylcarbodiimide. In a recent modification of this principle, an alternating site mechanism has been proposed in which the two dIIIs alternate between an open and a closed ("occluded") state.

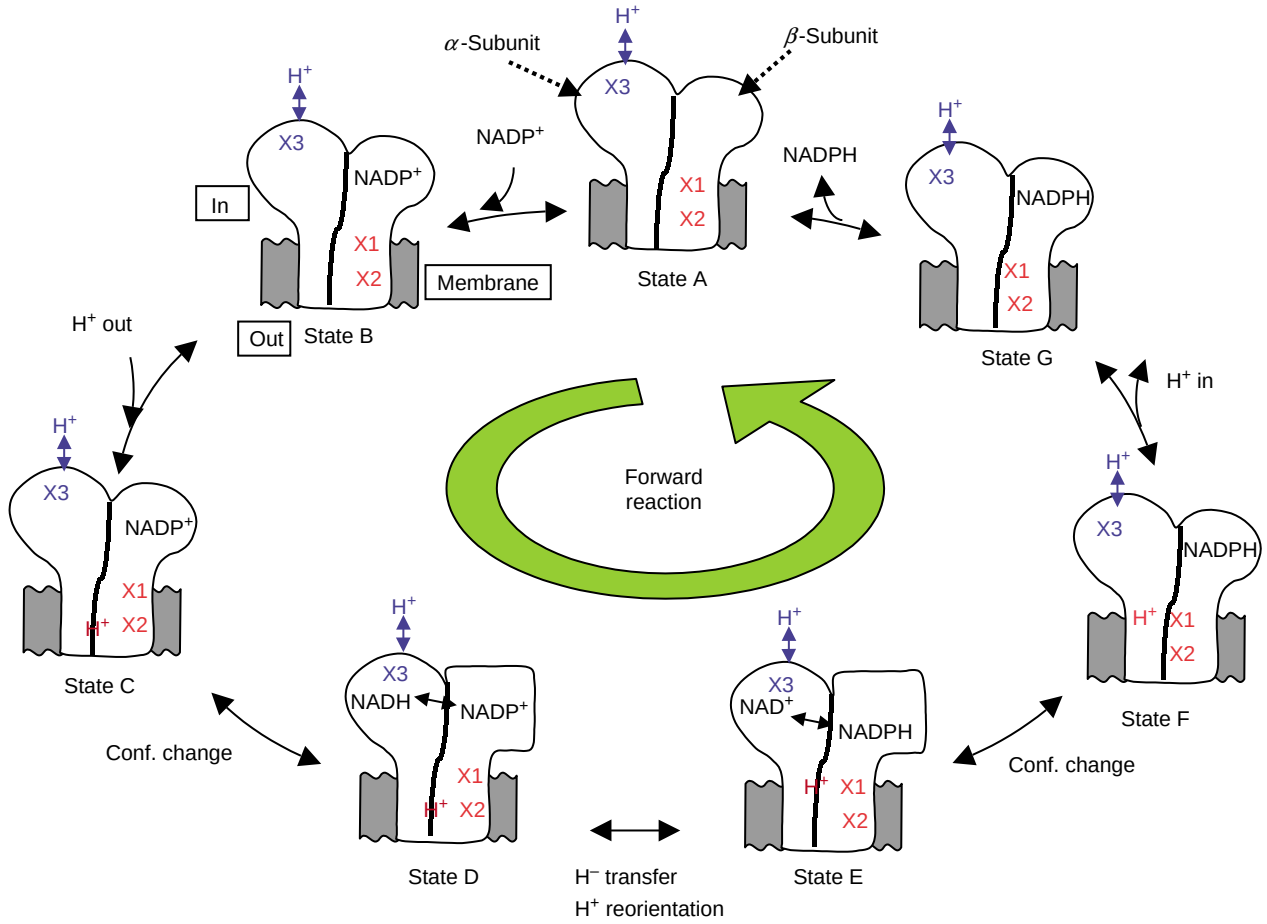

FIGURE 3 Reaction cycle of the forward TH reaction. X1 and X2 denote two protonatable residues in dII, possibly His91 and Asn222, respectively. X3 is a protonatable group in dI unrelated to the proton channel.

Membrane Topology and Helix Packing of the Membrane Domain

dII of the mitochondrial TH was early predicted to be composed of 14 transmembrane α-helices, whereas dII of the *E. coli* TH has been shown to be composed of 13 transmembrane α-helices (Figure 4). However, in contrast to the mitochondrial enzyme, *E. coli* TH consists of two subunits, the α- and β-subunits, which both contribute to dII. For some time, the membrane topology of the *E. coli* enzyme was unclear, especially regarding the region in dII where the two subunits interact. Subsequently, it was shown that the α- and β-subunits can be fused at the gene level, generating a mitochondrial-like TH, provided that the peptide linker is long enough, i.e., as long as the extra helix peptide in the mitochondrial TH; shorter linkers lead to truncated proteins with diminished activities. The C terminus of the α-subunit and the N terminus of the β-subunit are therefore located on different sides of the membrane (Figure 4).

Despite the obvious importance of dII in the overall transhydrogenase reaction, the structure of this domain has subsequently received comparatively little attention. However, a systematic effort to elucidate the packing of dII of the *E. coli* enzyme using cysteine crosslinking of double cysteine mutants in the cysteine-free background has been carried out, with one cysteine located in the α-subunit and the other at various positions in the β-subunit. The results show that, within the $\alpha+\beta$ unit, helices 2 and 4 are close to helix 6, and helix 3 and the C terminus of the α-subunit are close to helix 7. In the $\alpha_2\beta_2$, helices 2 and 4, as well as helix 6, are close to the same helices in the second subunit.

The Proton Channel

Being a proton pump, the membrane domain of THs must contain at least one proton channel, and considering the symmetry of the active $\alpha_2\beta_2$ structure, most likely two identical channels, one in each β-subunit. That the channel resides in the β-subunit is obvious due to the lack of suitable conserved protonatable residues in the α-subunit. However, residues in the α-subunit may contribute to the proton channel. DII of the *E. coli* TH contains few conserved protonatable amino acids, which may form part of a proton channel. Based on the properties of especially the positively charged H91K and N222R mutants (mimicking protonated His91 and Asn222, respectively), located in helix 9 and helix 13 (Figure 4), Bragg and coworkers made the important discovery that these mutants contain tightly bound NADP(H), reminiscent of isolated dIII. Indeed, this was the first piece of evidence indicating that dII not only communicates with dIII, but that the degree of protonation of specific residues, i.e., His91 and Asn222, in dII

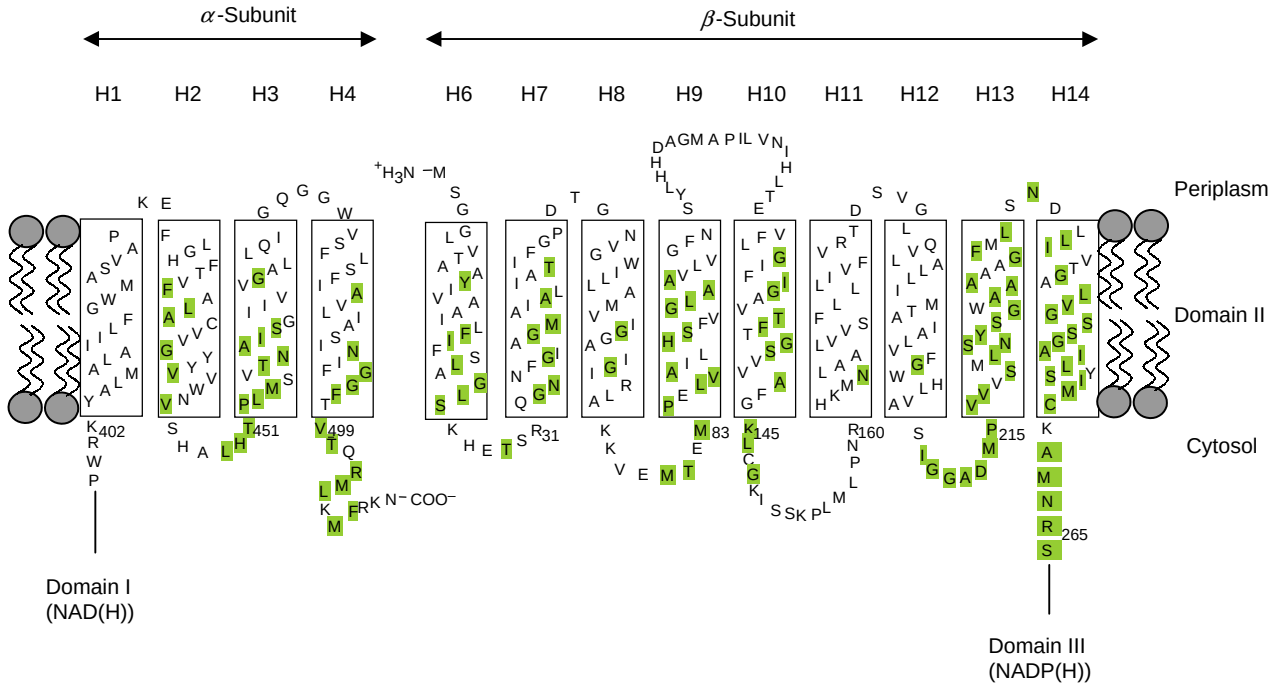

FIGURE 4 Membrane topology of *E. coli* TH. The topology was determined as described by Meuller, J., and Rydström, J. (1999). Residues in green background are at least 80% conserved among 61 THs.

induces conformational changes that affect the dissociation constant for binding of NADP(H) to dIII. Ser139 is another potential component of the proton channel, with Glu85, Asp213, and Glu124 being possible peripheral residues of the channel, located close to the membrane surfaces.

Some mutants of the conserved His91, Asn222, and Ser139 residues still catalyze proton pumping although at reduced rates. This may be due to a compensatory effect of the remaining protonatable residues in the channel. In this context it should be stressed that a proton channel *per se* does not require protonatable residues. It would be sufficient with a chain of bound water molecules in a channel across the membrane to allow protons to "jump" from one water molecule to another. Protonation/deprotonation of protonatable amino acids in the channel induces conformational changes in the channel which link proton passage through the channel to catalytic events in often distantly located domains.

Coupling Mechanism

One of the main mechanistic challenges in past and present TH research is to understand how a Δp can be converted into a high [NADPH][NAD^+]/[NADH][$NADP^+$] ratio and conversely, how a high [NADPH][NAD^+]/[NADH][$NADP^+$] (or a [$NADP^+$][NADH]/[NADPH][NAD^+]) ratio can drive proton pumping. Since the difference in standard redox potential between the NADPH/$NADP^+$ and NADH/NAD^+ pairs is negligible, the main contribution to the redox potential/free energy is derived from the above substrate/product ratios. Because of the water-soluble nature of the TH substrates, and the apparently large distance between the substrate-binding sites and the membrane, it has been generally accepted that some kind of conformational coupling is involved. Such a mechanism is often described as resembling that of ATPase/synthase in which conformationally dependent binding changes are essential. This was also experimentally demonstrated earlier by extensive Δp-dependent changes of Km values for especially NAD(H). As described in the previous section, the single most important finding in this context was that mutating His91 and Asn222 to more positive amino acids lead to tightly bound NADP(H) in the intact mutant enzyme. An important contribution was also the demonstration of tightly bound NADP(H) in isolated dIII, which was assumed to represent an intermediate in the reaction cycle of TH, denoted the "occluded" state, which led to the proposal that both directions of the TH reaction, but especially the Δp-stimulated forward reaction, is limited by dissociation of NADP(H). The term "binding change" mechanism is frequently used in order to stress the role of dissociation/binding of NADP(H).

Despite the known crystal structures of dI, dIII, and the dI–dIII complex, the interface between dII and dI+dIII is unknown, i.e., little is known regarding the communication between dII and dIII. Most cytosolic loops of dII are poorly conserved, which makes it unlikely that dII–dIII signaling occurs via the surfaces of these domains. However, the peptide linking the C-terminal end of dII with dIII is quite conserved, and is highly mobile during catalysis as indicated by the NADP(H)-dependent increased trypsin sensitivity of Arg265 close to transmembrane helix 14 (Figure 4), indicating that this region is potentially important. Subsequently, Arg265 has been suggested to form a functional-salt bridge with Asp213, constituting an essential component ("hinge" region) of a new coupling mechanism. However, communication between this proposed salt bridge and the NADP(H)-binding site remains unknown, although loops D and E close to the NADP(H)-binding site in dIII may be important. Proton-translocating THs, which are all dimers, may work according to an alternate-site-binding change mechanism. According to this mechanism, only half of the intact TH is catalytically active at any given time.

Physiological Role

In 1959 Klingenberg and Slenczka found that the mitochondrial redox level of NADP(H) was at least 90%, and that of NAD(H) ~50–60%. The forward TH reaction (reaction [1]), driven by Δp, is largely responsible for this high redox level of NADPH which, as expected, is sensitive to uncouplers. This also explains the fact that NADPH-dependent detoxification (through glutathione peroxidase) of organic peroxides in intact mitochondria is more effective with NADH-linked substrates than with NADPH-linked substrates. Thus, endogenous $NADP^+$ together with NADH (generated by the added substrate, e.g., β-hydroxybutyrate) provides a higher redox level of NADPH through TH than NADPH-linked substrates. A high level of NADPH is important because it generates reduced glutathione essential for, for example, glutathione peroxidase. NADPH also regulates the redox levels of thioredoxin and protein-bound thiols. Organic peroxides lead to a rapid oxidation of mitochondrial reduced glutathione through the glutathione peroxidase system, which in turn leads to a massive release of Ca^{2+} ions, presumably through the mitochondrial permeability transition pore (MPTP). MPTP may, in turn, contain redox-sensitive protein thiols. Therefore, the high mitochondrial redox level of NADP(H), maintained by TH, is of crucial importance for detoxification, Ca^{2+} homeostasis, cell thiol regulation, and biosynthesis. In liver, but probably not in heart, TH-generated NADPH in the

mitochondrion contributes to cytosolic NADPH through transport in the form of (iso)citrate generated by the NADP-dependent isocitrate dehydrogenase (NADP–ICDH).

A different hypothesis for the physiological role of TH involves a regulation of the citric acid cycle, especially the NAD and the NADP-dependent isocitrate dehydrogenases. The NAD enzyme (NAD–ICDH) is irreversible and strongly regulated by, for example, ADP, whereas NADP–ICDH is reversible and apparently unregulated. Oxidative decarboxylation of isocitrate to α-ketoglutarate, carbon dioxide, and NADH by the NAD–ICDH can be linked to the NADP–ICDH by a reductive carboxylation of α-ketoglutarate, carbon dioxide, and NADPH back to isocitrate. The NADH generated by the NAD–ICDH, together with $NADP^+$, is thus used by TH and Δp to generate NADPH that drives the NADP–ICDH. This nonproductive cycle uses one proton/cycle to slow down or regulate the flux through this step in the citric acid cycle. However, there is no obligatory simultaneous occurrence of TH and NADP-isocitrate dehydrogenase in some species, which casts some doubt on this potentially important regulatory system.

Theoretically, a reversal of reaction [1] can also be used to generate a Δp under, e.g., ischemic conditions. However, it is generally believed that unless a continuous source of $NADP^+$-reducing substrates as well as NAD^+-oxidizing substrates are available, the Δp generated would be transient and short-lived.

Glutathione Peroxidases

Glossary

membrane protein A membrane-associated protein, in this context an integral membrane protein spanning the membrane.

NAD(H) Oxidized (NAD^+) and reduced (NADH) nicotinamide adenine dinucleotide, a common cofactor in cell metabolism, especially catabolism.

NADP(H) Oxidized ($NADP^+$) and reduced (NADPH) nicotinamide adenine dinucleotide phosphate, a common cofactor in cell metabolism, especially anabolism.

proton pump A group of membrane proteins catalyzing a translocation of protons across the membrane, driven either by redox energy, an ion gradient, or ATP.

transhydrogenases A group of enzymes composed of two subgroups: a soluble flavine-containing type and a membrane-bound and proton-translocating type. Both catalyze the transfer of a hydride ion between NAD(H) and NADP(H).

Nicotinic Acetylcholine Receptors

Nivalda O. Rodrigues-Pinguet and Henry A. Lester
California Institute of Technology, Pasadena, California, USA

Ion channels are classified by their gating (opening) mechanisms. Mechano-sensitive channels are activated directly by forces applied to the channel proteins. The superfamily of voltage-gated channels responds to changes in the membrane potential. The ligand-gated or agonist-gated receptors open as they bind specific molecules. The nicotinic acetylcholine receptor (nAChR) is a well-studied member of the superfamily of ligand-gated ion channels (LGICs). The nAChR is the prototype LGIC since its sequence and structure strongly resemble that of glycine, serotonin 5-HT3$_A$, γ-aminobutyric acid (GABA$_A$), and invertebrate glutamate-gated chloride (GluCl) receptors. Since the early twentieth century, researchers have worked to unravel some of the mysteries of this cylindrically shaped macromolecule embedded in the membrane at vertebrate nerve–muscle synapses, at invertebrate nicotinic synapses, and in the vertebrate central nervous system. To date, several nAChR subtypes have been successfully isolated, cloned, purified, imaged, expressed, and unitary currents have been recorded from these channels. There is now a clear picture of the nAChR architecture and function. However, efforts are still underway to understand key functional aspects of this receptor as well as its role in addiction and disease.

Structure

Nigel Unwin and colleagues have resolved the muscle nicotinic acetylcholine receptor (nAChR) structure from *Torpedo* electric organ, which is derived from muscle, to 4Å resolution. The structure of the neuronal nAChR has not been resolved. Yet one expects that many details, certainly including its membrane topology, are identical to the muscle receptor. From Unwin's work, it is now known that the entire muscle nicotinic receptor complex is ~150Å tall (Figure 1A). Biochemical and electron microscopic studies reveal that nicotinic receptors, in peripheral organs (e.g., muscle) and in the central nervous system, are heteromers composed of five subunits that assemble into a barrel-like structure around a central ion pore. The receptor has three main parts: a region found outside of the cell (extracellular), a region located within the membrane (transmembrane), and an intracellular portion (cytoplasmic).

Subunits

Steve Heinemann, Norman Davidson, Shosaku Numa, Jim Patrick, Jim Boulter, and others cloned the nAChR subunits. To date, ten α-subunits and seven β-, γ-, δ-subunits have been cloned. However, additional subunit genes probably await discovery. Each of the five nicotinic subunits is composed of (from N–C terminus) an extracellular domain, four transmembrane domains (referred to as M1–M4) 19–27 amino acids in length, a cytoplasmic loop, and an extracellular C terminus consisting of ~20 amino acid residues (Figure 1A). The fetal or denervated muscle nAChR is a heteromeric pentamer composed of two α-subunits and one β-, γ-, and δ-subunit. In most adult nAChRs, the δ-subunit is replaced with an ε-subunit. Central nicotinic receptors can be either homomeric or heteromeric pentamers composed of α-subunits or, α- and β-subunits, respectively.

The Extracellular Domain

The extracellular domain protrudes ~60Å away from the membrane and has several characteristic structural elements shared by other members of the ligand-gated ion channels (LGICs) superfamily. In 2001, Titia Sixma and co-workers crystallized the acetylcholine-binding protein (AChBP) from a mollusc. Most of the nAChR N-terminal features deduced from X-ray crystallographic, biochemical, and physiological studies have been confirmed with the 2.7Å resolution structure of AChBP. This protein has ~20% homology to the extracellular domain of nicotinic receptors, and it lacks transmembrane, cytoplasmic, and C-terminal domains. Yet Sixma's AChBP crystal structure has given researchers a clearer image of the extracellular region of the nAChR. There are six loops, named with the letters A–F, involved in ligand binding. This region also contains a disulfide bond within loop C and another disulfide bond (the signature loop) located between cysteine residues 123 and 136. Sixma's AChBP crystal structure suggests that the signature disulfide loop present in the nAChR is located at the bottom of the binding domain, where it can interact directly with

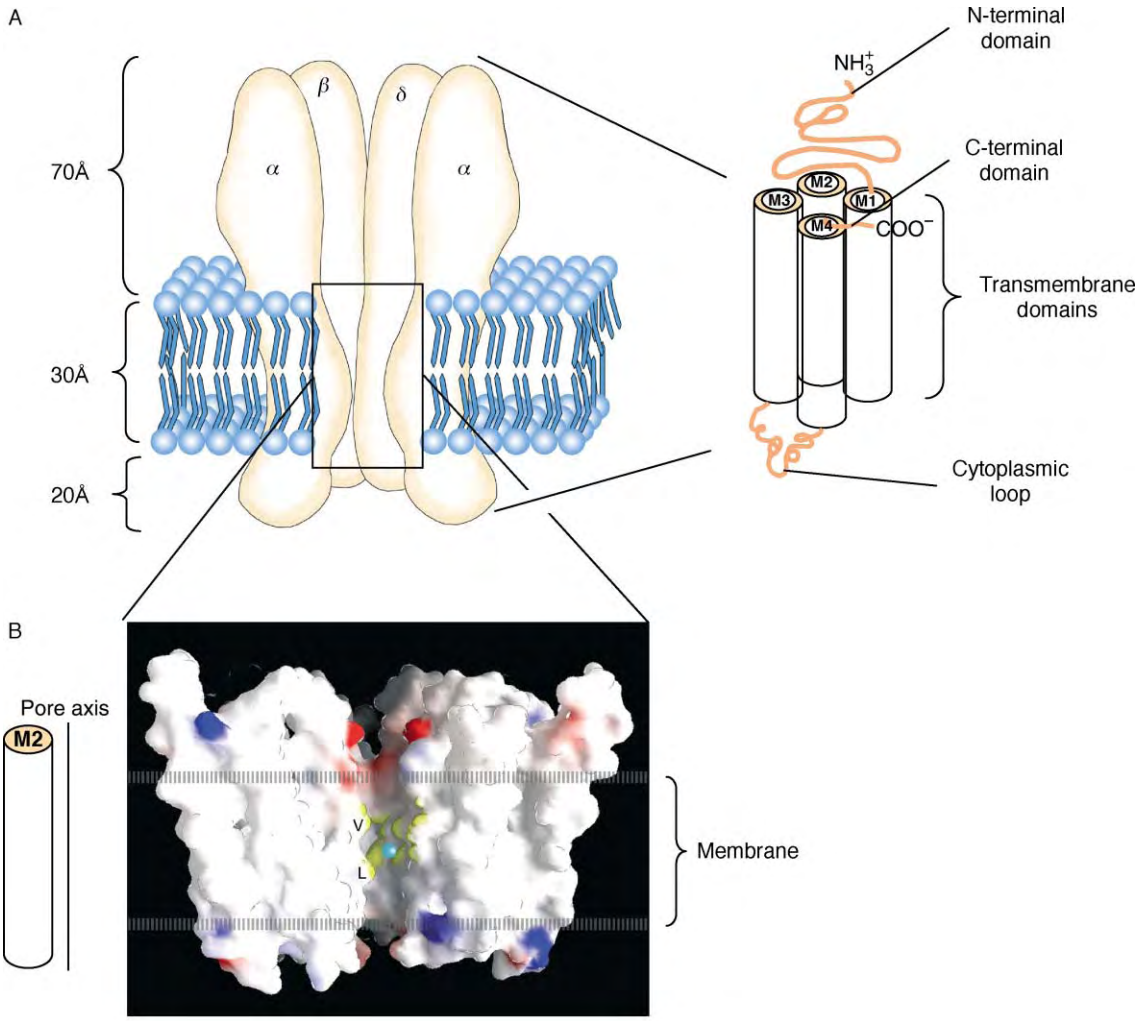

FIGURE 1 (A) The structure of the muscle nicotinic receptor embedded in the plasma membrane (blue), with the front subunit removed. Each subunit is composed of an N-terminal domain, four transmembrane domains (M1–4), a cytoplasmic loop, and a C-terminal domain. (B) The nAChR pore is mostly lined by M2 α-helices. Gray lines represent the plasma membrane, red and blue areas correspond to negative and positive charges, respectively. The channel's gate is expected to be located in hydrophobic regions within the pore (shown in yellow). The blue sphere in the channel represents a sodium ion. other parts that reside within the membrane, possibly coupling agonist binding with channel opening.

The Agonist Binding Site

The endogenous ligand for the nAChR is acetylcholine (ACh). The open state of the channel is much more likely to be associated with two bound agonist molecules than with a single bound molecule. ACh specifically binds to amino acids at the subunit interface of the extracellular region, within loops A, B, and C in the α-subunit and D, E, and F in the non-α-subunit. The binding site resembles a box that is lined by aromatic amino acid residues (tyrosine and tryptophan) (Figure 2). The positively charged ACh molecule binds to its target site partially via cation–π interactions. In this type of interaction the cation (or positively charged moiety) interacts with the electron density at the face of an aromatic side chain.

The Pore

The nicotinic receptor's pore lies within the membrane ~50Å below the ACh binding site. The central ion channel is mostly lined by the M2 α-helices from the five nicotinic subunits (Figure 1B). Parts of the M1 transmembrane domain from each subunit also protrude into the pore. The M2 domains approach each other most closely midway through the membrane creating a gate, which prevents ions from permeating the channel in the closed conformation. Sliding, rotating, and/or tilting of the M2 α-helices during nearly symmetrical transitions of the pentameric bundle remove this constriction. Once the receptor opens, three rings of

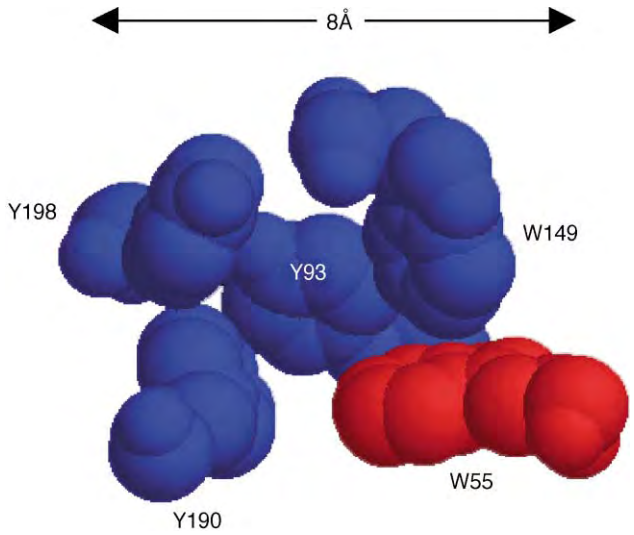

FIGURE 2 The agonist binding site resembles a box lined with five aromatic amino acid residues. Amino acids shown in blue and red are located in the α- and the non-α-subunits, respectively.

negatively charged amino acids within the pore allow the receptor to conduct positively charged sodium, potassium, and calcium ions.

The Cytoplasmic Loop

The M3–M4 cytoplasmic loop in the nAChR varies in both length and sequence among the nicotinic receptor subunits. However, the sequences of the cytoplasmic loops contain consensus phosphorylation sites for various kinases including protein kinase A, C, tyrosine kinase, casein kinase, calmodulin dependent kinase II, and cyclin dependent kinase 5. The M3–M4 loop also contains endoplasmic reticulum retention and export motifs as well as endocytosis motifs. In addition to having phosphorylation sites and targeting motifs, the M3–M4 loop of the muscle nAChR binds to a protein called rapsyn. The muscle nicotinic receptor is anchored to the membrane through its association with this protein.

Channel Activation

The nicotinic acetylcholine receptor has various conformational states including a resting, an active (open channel), and at least two desensitized (non-conducting) states. Upon binding two molecules of ACh in the extracellular region, the receptor undergoes a poorly known conformational change that places the M2 α-helices in the open, cation-conducting state. The channel remains open, or opens several times in succession, for only a few thousandths of a second before one or both agonist molecules dissociate from the binding pocket and the channel closes. If agonist remains present and binds repeatedly, the channel enters a desensitized state.

The Function of nAChRs *in vivo*

Neuromuscular Junction

After the motor nerve muscle is stimulated, the nerve action potential reaches the presynaptic terminal, where it evokes release of prepackaged vesicles containing ACh. The ACh released into the synaptic cleft binds and activates nicotinic receptors located on the postsynaptic muscle membrane. Once the postsynaptic cell is depolarized, voltage-gated sodium channels open, propagating the action potential, and consequently leading to muscle twitches. Presynaptically released ACh remains in the synapse for only about a millisecond before it is broken down by acetylcholinesterase or, more slowly, diffuses away.

Central Nervous System

Researchers have begun by studying the structure and function of the muscle nicotinic receptor. However, the diversity and function of the neuronal nicotinic receptors is being appreciated only now. Despite good efforts, researchers have still not clearly described the various neuronal nAChRs' precise subunit composition, assembly, regulation, and the significance of their heterogeneity.

Neuronal nAChR Composition

Researchers believe that many central nicotinic receptors are heteropentamers composed of at least two α- and three other (α- or β-) subunits. The α7-, α8-, and α9-subunits can form functional homopentameric receptors. There are eight α-subunit (α2–α7, α9, and α10) and three β-subunit (β2–β4) genes expressed in the vertebrate nervous system. An additional α8-subunit gene has been identified in avian species. However, β-, γ-, δ-, and ε-subunits are not expressed in the brain. Although there are literally thousands of different theoretical subunit combinations, only a handful of these produce functional receptors with distinct pharmacological and biophysical properties. Heterologous expression of nAChRs in *Xenopus* oocytes and in mammalian cells has revealed which specific α/β combinations produce functional receptors. The α2-, α3-, and α4-subunits can each form heteropentamers with either β2 or β4. α6β4 receptors express successfully, but similar to the α5- and β3-subunits, α6 expresses best in combination with two other types of subunits. Although the α7-, α8-, and α9-subunits can form functional homopentameric receptors, they can also

form heteropentamers (i.e., $\alpha 7\alpha 8$ and $\alpha 9\alpha 10$ receptors). Evidence for the precise subunit composition of native neuronal receptors is still scant. Although a few major subtypes have been identified (i.e., $\alpha 7$ homopentamers, $\alpha 4\beta 2$, and $\alpha 3\beta 4$), future studies will probably discover other subtypes and perhaps more complex subunit combinations.

The Role of Neuronal nAChRs

Previous work using *in situ* hybridization techniques and radiolabeled ligands shows that nicotinic receptors are present in various brain structures, including the thalamus, cortex, hippocampus, hypothalamus, and cerebellum. Although many neuronal nAChRs are found on the presynaptic terminal, some are located postsynaptically. Brain nAChRs are thought to presynaptically modulate, rather than directly mediate, chemical synaptic transmission. In the retina and striatum, cholinergic (ACh containing) interneurons release ACh and activate nAChRs located on the presynaptic cell. Presynaptic nicotinic receptor activation can positively or negatively affect the release of various neurotransmitters including GABA, glutamate, dopamine, and noradrenaline.

Nicotinic Receptor Agonists and Antagonists

Agonists

In addition to ACh, other compounds can activate nicotinic receptors. In fact, nAChRs are offensive or defensive targets for various organisms. For instance, nicotine, an alkaloid product from tobacco, is the prototypic agonist for nAChRs. Additionally, epibatidine, a powerful analgesic that is purified from the skin of the South American tree frog, *Epipedobates tricolor*, is the most potent nAChR agonist discovered. Other naturally occurring nAChR agonists include choline, cytisine, anabaseine, and (+)-anatoxin A. In an effort to provide greater subtype selectivity and therapeutic efficacy, researchers have also developed a wide range of synthetic compounds that can activate nAChRs. Keep in mind that the muscle and the various neuronal nicotinic receptor subtypes have distinct pharmacological profiles for different natural and synthetic agonists.

Antagonists

Nicotinic receptor inhibitors stabilize the closed-channel conformation and, in the case, of competitive inhibitors, prevent agonist binding. D-tubocurarine (d-TC) is a classic competitive nAChR inhibitor that does not discriminate well between the various types of nicotinic receptors. South American Indians commonly used this poison found in the shrubs of *Chondodendron tomentosum* to coat the tip of their arrows. More selective than d-TC, dihydro-β-erythroidine is an alkaloid that is mostly used to inhibit $\alpha 4\beta 2$ receptors. α-Bungarotoxin (α-Bgt) is a well-established selective competitive nAChR antagonist found in the venom of the Taiwanese banded krait (*Bungarus multicintus*). α-Bgt inhibits muscle nAChRs and $\alpha 7$ homomers, as well as receptors containing $\alpha 8$- and $\alpha 9$-subunits. It does not appear to interact with α/β heteropentamers. Other nAChR noncompetitive inhibitors include α-conotoxins, mecamylamine, steroids, local anesthetics, and such therapeutic agents as MK 801, carbamazepine, buproprion, and chlorpromazine.

Nicotinic Receptors and Disease

Congenital Myasthenic Syndrome

Nicotinic receptors have been implicated in a number of diseases. At the neuromuscular junction, 26 mutations have been identified in the extracellular, transmembrane, and cytoplasmic domains of the nAChR that lead to different forms of congenital myasthenic syndrome (CMS). CMS are presynaptic, synaptic, and postsynaptic in origin. Postsynaptic CMS mutations are divided into two categories, depending on their effects at the endplate region of the muscle membrane. CMS mutations are classified as either slow- or fast-channel syndromes. The slow-channel mutations enhance agonist affinity or gating efficiency. The fast-channel syndrome mutations reduce agonist affinity for the open channel or impair gating. Work from Andrew Engel, Christopher Gomez, Steven Sine and Anthony Auerbach has contributed to the molecular pathophysiology of CMS. Furthermore, their biophysical analyses of the CMS mutations have provided us with some basic insights into the relationship between the structure and function of nAChRs.

Epilepsy

Nicotinic receptors appear to be linked to several forms of inherited epilepsy. Autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE) is a monogenic disease presently linked to three $\alpha 4$ and two $\beta 2$ mutations. All five of these mutations lie within (or immediately adjacent to) M2 and produce similar clinical symptoms. To date, the mechanism(s) by which these mutations lead to the onset of a partial epileptic seizure remains to be elucidated. However, two effects common to all of the mutations have been identified. (1) The ADNFLE mutants reduce the nAChR's sensitivity to changes in extracellular calcium and (2) the mutations enhance the receptor's sensitivity to ACh. Studies on mouse

models of ADNFLE may be the most appropriate tactic for understanding the pathophysiology of these partial seizures.

Alzheimer's Disease (AD)

AD is a neuro-degenerative disease characterized by the progressive deterioration of higher cognitive functions, including memory loss. Since nicotinic receptors play a critical role in learning and memory, it is not surprising that AD patients lose the cholinergic pathways from the basal forebrain to the hippocampus and the cortex. Moreover, the brains of AD patients have a reduced number of cholinergic cells and presynaptic nAChRs. Since low levels of ACh are believed to lead to the cognitive decline observed in patients, cholinesterase inhibitors (such as tacrine, donepezil, and rivastigmine) are currently used to treat AD.

Parkinson's Disease (PD)

Patients with PD, another neuro-degenerative disorder, have difficulty initiating and sustaining smooth muscle movements. Although loss of dopaminergic neurons defines PD, patients also lose cholinergic cells in the basal forebrain and their high affinity nAChRs. In fact, the reduction in cortical nAChRs correlates well with the degree of dementia. Furthermore, researchers have correlated tobacco use with a lower incidence of PD.

Other Diseases

Nicotinic receptors have also been implicated in other diseases such as schizophrenia, Tourette's syndrome, anxiety, and depression. However, the precise role of the nAChR in the pathology of these diseases remains to be determined.

Biography

Nivalda O. Rodrigues-Pinguet obtained her Ph.D. in Biomedical Sciences at the University of California, Riverside. She is currently a post-doctoral scholar with Drs. Bruce N. Cohen and Henry A. Lester at the California Institute of Technology. During her graduate tenure, Dr. Rodrigues-Pinguet studied the functional effects of nicotinic receptor mutations linked to autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE).

Henry A. Lester is the Bren Professor of Biology at the California Institute of Technology. He obtained his Ph.D. in Biophysics from Rockefeller University and pursued his postdoctoral training with Dr. Jean-Pierre Changeux, at the Institut Pasteur in Paris, France. Dr. Lester received formal training in physics but has also embraced biochemistry, molecular biology, and neurogenetics. He has worked on nicotinic receptors for 30 years and is an authority on ion channels and molecular neuroscience.

Nitric Oxide Signaling

Michael A. Marletta
University of California, Berkeley, California, USA

The basic components of nitric oxide (NO) signaling involve nitric oxide synthase (NOS) to synthesize NO and the soluble isoform of guanylate cyclase (sGC) to trap NO. Once activated by NO, sGC converts GTP to guanosine 3′5′-cyclic monophosphate (cGMP), leading to cGMP-dependent physiological responses such as vasodilation. Termination of the cGMP signal involves a cyclic nucleotide phosphodiesterase (PDE). There are multiple PDE isoforms, and selective inhibition of specific isoforms has proven to be clinically useful (for example, sidenifil [Viagra] in the treatment of erectile dysfunction). sGC must also be turned off; however, the *in vivo* mechanism for this remains unknown. Catalytic activity of constitutive NOS isoforms involved in signaling is controlled by Ca^{2+} and calmodulin via receptor-mediated events that trigger Ca^{2+} release from intracellular stores or uptake from external sources.

Biological Processes Controlled by Nitric Oxide

First defined as EDRF (endothelium-derived relaxing factor), the biological effects of nitric oxide (NO) have now been definitively characterized in a number of tissues. Smooth muscle is often the target of NO action, leading to vasodilation in blood vessels (Figure 1) and penile erection via NO synthesis in the corpus cavernosum, two well-established functions. Smooth muscle relaxation in the gut is another important function for NO, playing a key role in gastrointestinal tract motility. NO synthesis in the brain is also well established, though the exact role in learning and memory is still under debate. In the CNS, NO acts as a somewhat atypical neurotransmitter in that it is not synthesized and stored and then released with the appropriate signal, but is synthesized on demand. Constitutive nitric oxide synthases (NOSs) are involved in all of these responses and are under the control of Ca^{2+} and calmodulin. Receptor-mediated events that trigger Ca^{2+} release or uptake turn on the specific NOS isoform in the tissue. NOS has also been found in skeletal muscle, in the myocardium, and in many other cells, suggesting that it will play an even more extensive role in physiological control than is currently established. The function of NO in the myocardium is particularly complex, although it appears that novel therapeutics will be an outcome of sorting out the complexity.

Nitric Oxide Synthase

The catalytic activity of the NOS isoforms (constitutive) involved in signaling is controlled by Ca^{2+} and calmodulin (CaM). After stimulation by the appropriate external signal, an increase in intracellular-free Ca^{2+} occurs, which then leads to a Ca^{2+}–calmodulin complex. Each of the four EF hands of calmodulin binds one Ca^{2+}, and then this Ca^{2+}–CaM complex binds to NOS, thereby activating NOS to synthesize NO. The NOS reaction is shown in Figure 2. The enzyme converts L-arginine to citrulline and NO. Co-substrates for the reaction include NADPH and O_2. NOS is composed of two domains: a reductase domain with homology to cytochrome P450 reductase and a heme domain. The reductase domain contains two bound flavins, FAD and FMN, and with analogy to P450 reductase, the electron transfer route is from NADPH to FAD and then to FMN. The heme domain contains a cytochrome P450-type heme (ferric protoporphyrin IX coordinated to cysteine thiol), one equivalent of 6(R)-tetrahydro-L-biopterin (H_4B), and the L-arginine binding site. Crystal structures of the heme domain show it to be dimeric with a tetra-thiolate zinc center at the dimeric interface using two cysteines from each subunit. Catalytic chemistry at the heme domain is dependent on electron transfer from the flavins in the reductase domain, which is triggered by binding of the Ca^{2+}–CaM complex to NOS.

The catalytic chemistry takes place at the P450 heme site; in fact, structures of the oxygenase domain that have been solved in the presence of L-arginine show the substrate positioned over the heme. H_4B also participates in electron transfer at the heme site, using unprecedented one-electron chemistry. The exact details of the involvement of this required bound cofactor are still emerging. As shown in Figure 2, L-arginine is first converted to NHA (N^G-hydroxy-L-arginine) and then NHA is converted to citrulline

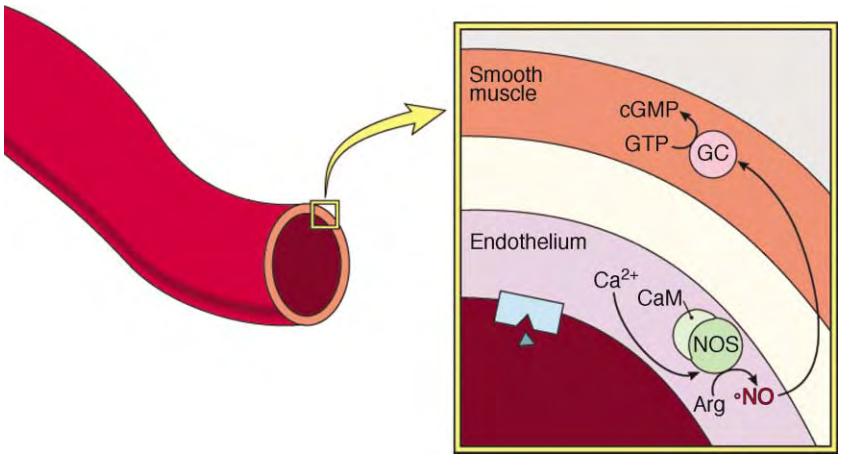

FIGURE 1 Nitric oxide function in blood vessel dilation. In response to a receptor-mediated event (shown schematically), endothelial NOS is activated by Ca^{2+} and calmodulin, leading to the synthesis of NO. NO then diffuses into the adjacent smooth muscle and activates the soluble isoform of guanylate cyclase and the synthesis of cGMP. cGMP, through a signaling cascade, then leads to smooth muscle relaxation.

and NO. NADPH and O_2 are required in both steps of the reactions, as is H_4B. The mechanism of the reaction is complicated and not fully understood, but clearly involves oxidative chemistry at the P450 heme with participation of H_4B.

The Ca^{2+}–CaM complex exerts control over the NOS reaction catalyzed by the constitutive cell-signaling isoforms, eNOS (endothelial NOS) and nNOS (neuronal NOS) by controlling electron transfer from the reductase domain to heme domain. Without this required process, the reaction does not take place, therefore, Ca^{2+}–CaM exerts complete control over the reaction. NO is toxic, and so it is absolutely crucial in NO signaling to strictly control the amount of NO that is made. Tight regulation over Ca^{2+} concentrations in the cell provides this required level of control. In general, nM concentrations of NO are synthesized by the generator cell, and pM concentrations act in the target cell. iNOS (inducible NOS) was first described as a Ca^{2+}–CaM-independent isoform, but subsequent studies showed that Ca^{2+}–CaM co-purified with this isoform. It is, therefore, "constitutively" active. Because the function of iNOS is in the host response to infection, a NOS isoform that is constitutively active and produced at the site of infection conforms to this biological role.

A number of inhibitors of NOS have been developed. The initial molecules were simple derivatives of the substrate L-arginine; however, other non-arginine-related structures were later found that were derived largely from library screens in the pharmaceutical industry, and some demonstrate significant isoform selectivity.

Chemistry of NO

NO is unstable in aqueous, aerobic solution. The stable end products of NO decomposition are nitrite (NO_2^-) and nitrate (NO_3^-). The reaction sequence that leads to these products is shown in Figure 3. This solution chemistry consumes NO as it traverses a path from the generator cell to the target cell, hence the amount that

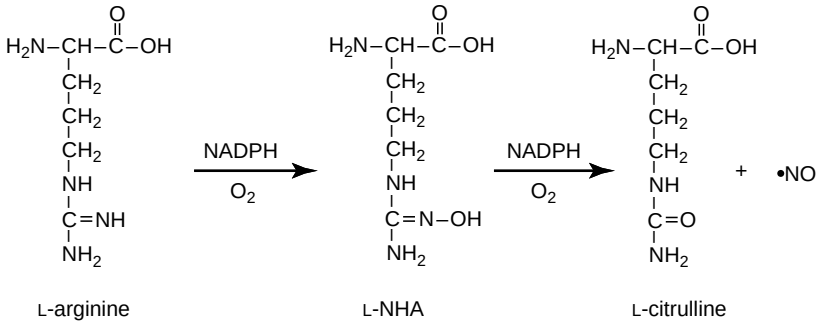

FIGURE 2 The reaction catalyzed by nitric oxide synthase. The substrate for the reaction is the amino acid L-arginine, which is converted to L-NHA and then to citrulline and ·NO. Although it has never been shown, it is assumed that the stereochemistry of citrulline at the α-carbon remains unchanged.

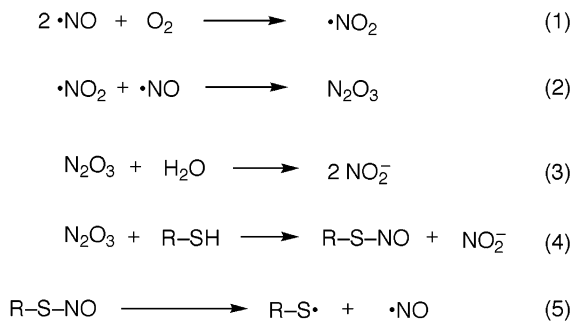

FIGURE 3 Relevant solution chemistry of nitric oxide. NO reacts with O_2 in aqueous solution to produce nitrogen dioxide ($\cdot NO_2$) (Eq. 1). ·NO2 then reacts with another molecule of ·NO to produce dinitrogen trioxide (N_2O_3) (Eq. 2). N_2O_3 can then hydrolyze to yield NO_2^- (Eq. 3) or react with protein or low molecular weight thiols to make the S-nitroso derivative (Eq. 4). The S-nitrosated protein or small molecule is capable of homolytically cleaving to generate the thiol radical and ·NO (Eq. 5).

arrives at the target cell is always lower. An intermediate along the reaction pathway is dinitrogen trioxide (N_2O_3). N_2O_3 can react with water as shown to produce NO_2^- or react with other cellular nucleophiles. The reaction with cysteine residues in proteins or with small cellular sulfur nucleophiles such as glutathione leads to the formation of S-nitrosated species as shown in Figure 3. S-Nitrosated proteins and small molecules are known to decompose to the sulfur radical and NO in a so-called homolytic cleavage (Figure 3); certain biological conditions can accelerate the reaction. The significance of this chemistry is discussed below. NO has 11 valence electrons and, therefore, has one unpaired electron. The radical nature of NO dictates other chemistry, such as the facile reaction of NO with superoxide to give peroxynitrite ($^-$OONO), which then converts very quickly to NO_3^-, and the reaction with oxyhemoglobin to give methemoglobin and NO_3^-, again with the intermediacy of $^-$OONO. Peroxynitrite is a potent oxidant and has been shown to be important in various types of tissue damage associated with the formation of high levels of NO. The decomposition of relatively high concentrations of NO in tissue that occurs under inflammatory conditions leads to nitration chemistry, most frequently seen on tyrosine residues.

Guanylate Cyclase

The soluble isoform of guanylate cyclase (sGC) is the receptor for NO in target cells. Activation of sGC leads to the formation of cGMP, and then through a cascade involving cGMP-dependent kinases, a lowering of intracellular Ca^{2+} occurs, leading to effects such as smooth muscle relaxation (e.g., vasodilation). sGC is a heterodimeric protein composed of two subunits. The best characterized is the physiologically occurring $\alpha1\beta1$ heterodimer, first isolated from lung tissue. The β-subunit contains a unique ferrous heme cofactor that is the receptor for NO. This porphyrin, despite having the same ligation as the globins, does not bind oxygen; rendering it ideally suited to bind NO is the presence of a high competing concentration of oxygen. Upon binding of NO, sGC is activated 300-fold over the basal activity, and a burst of cGMP is produced. cGMP then acts through cGMP-dependent kinases to bring about physiological responses such as vasodilation and other smooth muscle relaxation responses.

Tools to manipulate sGC are emerging and include ODQ (1H-[1,2,4]oxadiazole[4,3-a]quinoxalin-1-one), which inhibits sGC by oxidation of ferrous porphyrin to the ferric oxidation, and a family of activators based on the structure of YC-1 (3-(5′-hydroxymethyl-2′-furyl)-1-benzyl indazole). This compound is a weak activator of sGC; however, YC-1 and CO activate sGC to the same level as NO, and YC-1 acts synergistically with NO. A class of activators based on the YC-1 structure that directly activate and are more potent than YC-1 are entering clinical trials.

Non-cGMP NO-Signaling Pathways

As mentioned previously, N_2O_3 is an intermediate that forms during the aerobic solution decomposition of NO. N_2O_3 is a potent nitrosating agent that reacts with the ω-amino group of lysine and the thiol of cysteine. Formation of S-nitrosated cysteines in proteins can cause a change in the biological activity of the protein. Although increasing studies are directed toward understanding the chemistry and biological activity of the S–NO bond and the formation of these bonds with small molecule thiols and protein thiols, critical aspects remain to be determined. For example, the formation of R–S–NO could occur via the solution reaction of N_2O_3 with the thiol or by an enzyme-catalyzed process. The former path would appear to be too inefficient, and an enzyme to catalyze the latter path has not been isolated. Other hypotheses advanced involve the reversible formation of R–S–NO, where again the R group could be either a low molecular weight species or a protein similar to phosphoryl transfer. The kinase and phosphatase equivalents have yet to be isolated. Confounding all these hypotheses is the chemical reaction of R–SH with N_2O_3, which would be facilitated much beyond what would be expected to occur when nonbiological concentrations of NO are used.

There is another important outcome from the formation of S-nitrosated proteins and low molecular

weight compounds like glutathione. The S-nitroso bond is known to homolytically fragment, forming NO and a thiyl radical. The NO so derived can then function to activate sGC as described above. This mode of generating NO is attractive in that it represents a semi-stable form of this signaling agent and could be a way to store, transport, and deliver NO. There is no question that the decomposition of NO in aerobic aqueous solution will lead to S-nitrosation; rather, the issue is whether the amounts formed *in vivo* are physiologically significant.

Michael A. Marletta is the Aldo DeBenedictis Distinguished Professor of Chemistry in the Department of Chemistry, and Professor of Biochemistry in the Department of Molecular and Cell Biology at the University of California, Berkeley. His research interests on protein structure and function relationships have an emphasis on enzymatic catalysis and redox biochemistry. He holds a Ph.D. from the University of California, San Francisco. He is a Fellow of AAAS and was elected to the American Academy of Arts and Sciences and the Institute of Medicine.

N-Linked Glycan Processing Glucosidases and Mannosidases

Linda O. Tremblay and Annette Herscovics
McGill University, Montréal, Québec, Canada

Endoplasmic reticulum (ER) and Golgi glucosidases and mannosidases trim the asparagine-linked glycans (*N*-glycans) attached to newly formed glycoproteins within the secretory pathway. The sequential action of these enzymes yields the substrate(s) required for the biosynthesis of hybrid and complex *N*-glycans which mediate cell–cell interactions during embryogenesis, development, tumor metastasis, lymphocyte trafficking, leukocyte recruitment in inflammation, and many other biological interactions. In addition, the glycosidases participate in glycoprotein folding and quality control.

Abrogation of mammalian glycosidase functions as a consequence of genetic defects in humans or of targeted gene ablation in the mouse results in developmental and multisystemic abnormalities due to anomalous *N*-glycan biosynthesis. Herein the structure, function, and physiological roles of mammalian ER and Golgi processing glucosidases and mannosidases are reviewed, including pertinent studies of yeast and filamentous fungi enzymes.

Glucosidases

Glucosidase I

Glucosidase I is a type-II ER transmembrane protein of 92 kDa that cleaves the terminal α1,2-linked glucose residue of $Glc_3Man_9GlcNAc_2$ immediately following its transfer to nascent polypeptide chains. This inverting glycosidase has been conserved during eukaryotic evolution and, based on sequence similarity, it belongs to glycosylhydrolase family 63. Recently, missense mutations were identified in the human glucosidase I gene of a severely ill neonate that perished shortly after birth (Table I), showing that removal of the terminal glucose residue of $Glc_3Man_9GlcNAc_2$ is essential for human development and viability.

Glucosidase I is inhibited by castanospermine, 1-deoxynojirimycin and its N-methyl and N-butyl-deoxynojirimycin derivatives. These compounds prevent exit of some glycoproteins from the ER. As a result, they affect processes such as myoblast fusion to myotubes, transformation induced by glycoprotein oncogenes, cell surface expression of glycoprotein receptors, and also act as antiviral agents.

Glucosidase II

ER glucosidase II removes the two inner α1,3-linked residues (Figure 1). This glycosidase (glycosylhydrolase family 31) consists of a soluble catalytic α-subunit ($\sim$110 kDa) and a β-subunit ($\sim$80 kDa) which contains the ER retrieval signal HDEL. Glucosidase II is affected by the same inhibitors as glucosidase I, as well as by bromoconduritol.

Endo α-Mannosidase

Endo α-mannosidase is a 52-kDa enzyme present in the intermediate compartment and in the Golgi. It provides an alternate pathway independent of ER glucosidases for glucose removal from $Glc_{1-3}Man_{4-9}GlcNAc_2$, the preferred substrate being $Glc_1Man_9GlcNAc_2$ (Figure 1). Endo α-mannosidase expression is cell-specific and restricted to the chordate phylum; thus, it is likely to have appeared late in evolution. It does not share homology with any other known proteins. Upregulation of endo α-mannosidase was suggested to partially compensate for the glucosidase I deficiency described in the aforementioned patient.

Classification and Properties of Processing α-Mannosidases

Processing mannosidases have been classified into two distinct groups based on their amino acid sequences, different enzymatic mechanisms, and sensitivity to inhibitors. Class-I α1,2-mannosidases (glycosylhydrolase family 47) are inverting enzymes that have been conserved through eukaryotic evolution. They require calcium for activity and are inhibited by 1-deoxymannojirimycin and kifunensine, but not by

TABLE I

Human Glycosidase Genetic Defects and Mouse Glycosidase Gene Ablation Phenotypes

Glycosidase gene	Phenotype
Human diseases	
Glucosidase I	Generalized hypotonia, hypomotility, dysmorphic features, hepatomegaly, hypoventilation, seizures, neonatal lethality
Mannosidase II	Congenital dyserythropoietic anemia (HEMPAS), jaundice, hepatosplenomegaly, diabetes and gallstones
Mouse gene ablations	
Mannosidase II	Dyserythropoietic anemia, splenomegaly, autoimmune disease similar to systemic lupus erythematosus
Mannosidase IIx	Male infertility, hypospermatogenesis, decreased testis size, diminished spermatogenic cell adhesion to Sertoli cells

swainsonine. In contrast, class-II α-mannosidases (glycosylhydrolase family 38) are retaining enzymes that are inhibited by swainsonine, but not by 1-deoxymannojirimycin or kifunensine. The class-II enzymes are involved in *N*-glycan biosynthesis as well as in degradation, and with the exception of the Drosophila Golgi α-mannosidase II, they do not require divalent cations for activity.

Class-I α1,2-Mannosidases

α1,2-Mannosidase Subgroups

The class-I family consists of three subgroups of proteins sequestered by their sequence similarity and distinguished by their enzymatic activity. Subgroup (1) contains yeast and mammalian ER α1,2-mannosidase I that primarily form $Man_8GlcNAc_2$ isomer B; subgroup (2) includes mammalian Golgi α1,2-mannosidases IA, IB and IC as well as filamentous fungi α1,2-mannosidases that readily form $Man_5GlcNAc_2$ from $Man_9GlcNAc_2$ through $Man_8GlcNAc_2$ isomers A and/or C as intermediates; subgroup (3) consists of a group of proteins with amino acid sequence similarity to α1,2-mannosidases, such as mammalian EDEM and yeast Htm1p/Mnl1p, that have no apparent α1,2-mannosidase activity. This latter subgroup of proteins has been implicated in the degradation of misfolded glycoproteins as described in various articles in this encyclopedia.

ER α1,2-Mannosidase I

ER α1,2-mannosidase I is a type-II transmembrane protein of about 80 kDa that absolutely requires calcium for activity. It is the only processing α1,2-mannosidase in the yeast *Saccharomyces cerevisiae*. X-ray crystallographic studies of the yeast catalytic domain as an enzyme–product complex showed that it consists of a novel $(\alpha\alpha)_7$ barrel with one side of the barrel plugged by a β-hairpin forming a cavity of $\sim$15Å. The active site consisting of essential acidic residues and calcium is located at the bottom of the barrel. The structure of the human enzyme in complex with the inhibitors 1-deoxymannojirimycin and kifunensine was also determined. It shows that calcium coordinates with conserved acidic residues and the O2′ and O3′ hydroxyls of the six-membered rings of the inhibitors stabilized in a $^1C_4$ conformation. Although ER α1,2-mannosidase I primary trims the terminal middle arm α1,2-linked mannose residue of $Man_9GlcNAc_2$ to form $Man_8GlcNAc_2$ isomer B (Figure 1), recent studies revealed that ER α1,2-mannosidase I is capable of removing additional mannose residues from $Man_8GlcNAc$, *in vitro* and *in vivo*.

Class-I Golgi α1,2-Mannosidases

There are three mammalian class-I Golgi α1,2-mannosidases, IA, IB, and IC, derived from different genes on different chromosomes. They are type-II transmembrane proteins of about 70 kDa. These enzymes trim the α1,2-linked mannose residues from $Man_8GlcNAc_2$ isomer B to form $Man_5GlcNAc_2$ (Figure 1). When $Man_9GlcNAc_2$ is used as substrate, they readily form $Man_6GlcNAc_2$, but remove the last α1,2-linked mannose residue much more slowly. Their specificity is complementary to that of ER α1,2-mannosidase I since the last residue cleaved from $Man_9GlcNAc_2$ by the Golgi enzymes is the mannose preferred by ER α1,2-mannosidase I. There are small differences in the order of mannose removal by the different Golgi α1,2-mannosidases. X-ray crystallographic and modeling studies of a fungal α1,2-mannosidase with the same specificity as the mammalian Golgi orthologues revealed that the overall protein fold and topology of the active site is identical to that of ER α1,2-mannosidase I, and that the different specificities of these enzymes is determined by the space within the barrel. The fungal enzyme barrel permits binding of multiple oligosaccharide conformations of all three $Man_8GlcNAc_2$ isomers, whereas only a single conformation of $Man_8GlcNAc_2$ isomer B is accommodated by ER α1,2-mannosidase I.

The major difference between the three mammalian Golgi α1,2-mannosidases is their tissue- and cell-specific expression as determined by Northern blots of murine and human tissues and by immunolocalization studies in the male rat reproductive system.

The organization of the three human and murine Golgi α1,2-mannosidase genes is highly conserved with the location of the intron–exon boundaries being nearly identical. Thus, late evolutionary gene duplication is

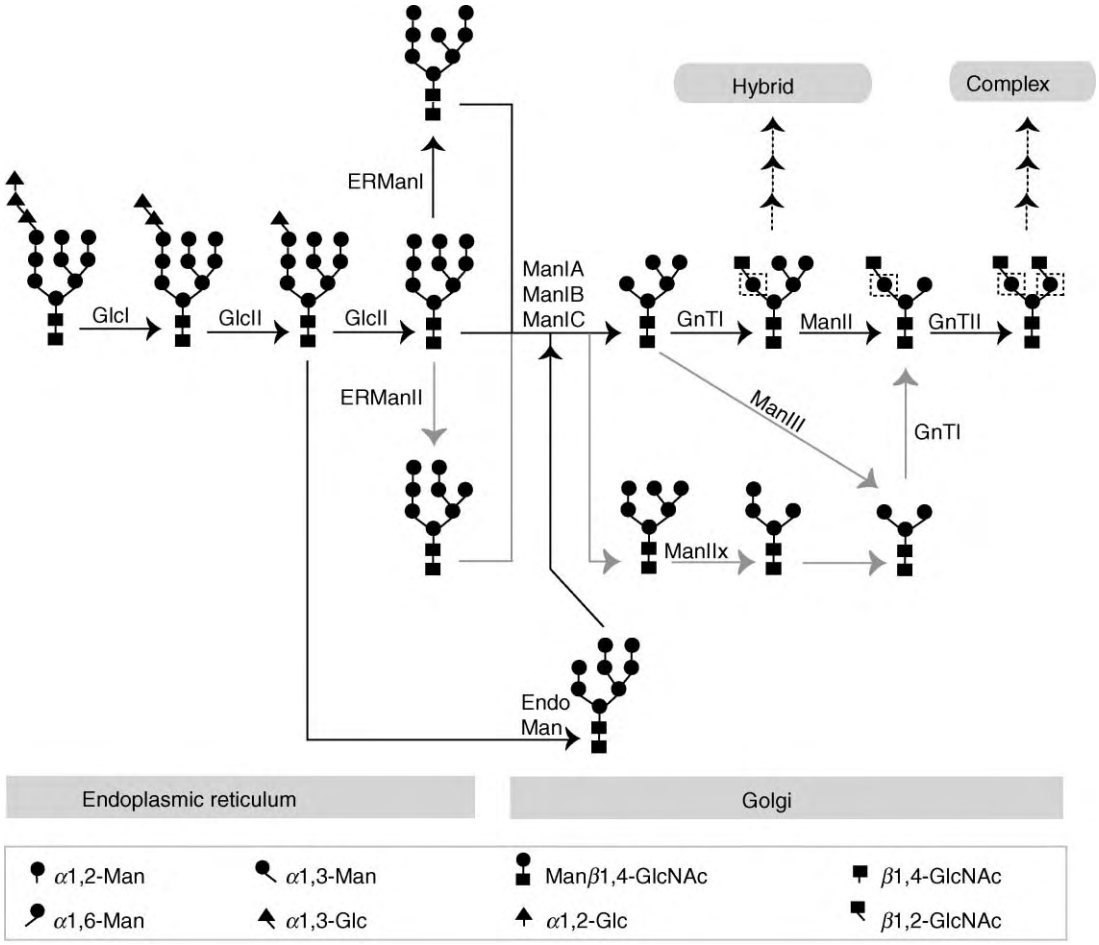

FIGURE 1 Role of glycosidases in mammalian *N*-glycan processing. The $Glc_3Man_9GlcNAc_2$ precursor oligosaccharide attached to asparagine residues of nascent chains (within Asn-X-Ser/Thr where X is any amino acid except Pro) is sequentially modified by processing glycosidases and glycosyltransferases, beginning in the endoplasmic reticulum and continuing in the Golgi. Trimming by α-glucosidases and α1,2-mannosidases is essential for the formation of complex and hybrid *N*-glycans initiated by GnTI. Additional enzymes add other GlcNAc residues to the boxed core mannose residues. Subsequently, glycosyltransferases further elaborate the structures by linking galactose, fucose, and sialic acid. Gray arrows indicate the suggested role of ERManII and the proposed ManIIx- and ManIII-mediated alternate pathways independent of Golgi α-mannosidase II. GlcI, α1,2-glucosidase I; GlcII, α1,3-glucosidase II; ERManI, ER α1,2-mannosidase I; ERManII, ER α1,2-mannosidase II; ManIA, IB, IC, Golgi α1,2-mannosidase IA, IB, IC; Endo Man, endo-α-mannosidase; ManII, IIx, III, α-mannosidase II, IIx, III; GnTI, II, N-acetylglucosaminyltransferase I, II. (Modified from Tremblay, L.O., PhD Thesis, McGill University 2002).

likely to have produced the Golgi α1,2-mannosidase gene family. However, the organization of the Golgi α1,2-mannosidase genes differs from that of the other two class-I α1,2-mannosidase subgroups, suggesting that the genes of the three subgroups may have arisen independently.

Class-II Processing α-Mannosidases

Class II Golgi α-Mannosidases

Golgi α-mannosidase II trims the terminal α1,3- and α1,6-linked mannose residues of $GlcNAc_1Man_5GlcNAc_2$, thus providing the substrate for complex *N*-glycan biosynthesis (Figure 1). It is absolutely dependent upon prior action of N-acetylglucosaminyltransferase I (GnTI) that initiates the first N-acetyllactosamine branch of complex *N*-glycans. The enzyme is a type-II membrane protein of ~130 kDa. The crystal structure of the Drosophila Golgi α-mannosidase II revealed that the active site is on the planar side of the hemi-oval-shaped catalytic domain comprised of an N-terminal α/β-domain, a bundle of three helices, and a C-terminal β-domain. The conformation is stabilized by disulfide bonds and the coordination of a zinc ion. The zinc ion participates directly in the catalytic mechanism and contributes to substrate binding. The terminal GlcNAc of the substrate is anchored in a binding pocket near the active site and is postulated to serve as an anchor

point for substrate rotation within the active site leading to the sequential trimming of the α1,6- and α1,3-linked mannose residues with minimal conformational change.

Ablation of the mouse α-mannosidase II gene indicated that this enzyme plays an important role in the biosynthesis of glycoproteins that maintain erythrocyte membrane integrity. This phenotype resembles congenital dyserythropoietic anemia type II, a rare human disease also known as HEMPAS, caused by a defect in the human Golgi α-mannosidase II gene (Table I). Mice lacking α-mannosidase II also progressively develop autoantibodies indicating that proteins bearing the atypical *N*-glycans produced in these mice can evade self-tolerance. These α1,2-mannosidase II null mice thus provide a model for lupus erythematosus in humans. The fact that complex *N*-glycan biosynthesis occurs in many tissues of mice lacking α-mannosidase II revealed the existence of an alternate biosynthetic pathway mediated by a cobalt-dependent enzyme called α-mannosidase III (Figure 1). However, a gene or cDNA encoding this activity has not yet been identified.

The human and mouse genomes also encode α-mannosidase IIx, a protein that has significant amino acid similarity to α-mannosidase II. The exact specificity of this enzyme remains to be definitively established. However, targeted gene ablation of mouse α-mannosidase IIx indicated that it is required for the biosynthesis of complex *N*-glycans that mediate spermatogenic cell interactions with Sertoli cells in the testis (Table I).

ER α1,2-Mannosidase II

The existence of mammalian ER α1,2-mannosidase II has been proposed from studies with intact cells and membrane preparations, but remains to be confirmed. This activity is distinct from ER α1,2-mannosidase I, since it yields a different $Man_8GlcNAc_2$ isomer (Figure 1) and is inhibited by swainsonine and 1-deoxymannojirimycin but not by kifunensine. Its substrate specificity and sensitivity to inhibitors are similar to those of a class-II cytosolic α-mannosidase involved in glycoprotein degradation. In addition, ER α1,2-mannosidase II cross-reacts with antibodies generated towards the cytosolic α-mannosidase. The existence of a distinct cDNA or gene encoding ER α1,2-mannosidase II has not been described.

In conclusion, the enzymatic specificities and properties of mammalian glycosidases that are involved in *N*-glycan biosynthesis have been well characterized. Current studies are elucidating their functions in glycoprotein folding and in ERAD, but their physiological roles and involvement in genetic diseases remain to be elucidated by further gene ablation studies.

Biography

Dr. Linda O. Tremblay recently obtained her Ph.D. from McGill University. The focus of her dissertation was on the cloning and characterization of mammalian α1,2-mannosidases.

Dr. Annette Herscovics is a Professor at the McGill Cancer Centre and in the Departments of Medicine, Biochemistry, and Oncology at McGill University. Her main research interests are concerned with the structure and function of enzymes required for eukaryotic glycosylation. She holds a Ph.D. from McGill University and is a Fellow of The Royal Society of Canada.

Non-Homologous End Joining

Penny A. Jeggo
University of Sussex, Brighton, UK

The process of DNA non-homologous end joining (NHEJ) is one of several mechanisms that function to repair DNA double strand breaks (DSBs) in DNA. NHEJ represents the major mechanism for DSB repair in G1 phase cells. If unrepaired, a DSB can lead to loss of genomic material which is likely to result in cell death; a misrepaired DSB can cause genomic rearrangements, a potential initiating event for carcinogenesis. NHEJ, therefore, represents an important mechanism for maintaining genomic stability. Paradoxically, NHEJ also functions during immune development to help create genetic diversity.

Nature of the Rejoining Process

Three mechanisms for DSB rejoining have been described. Homologous recombination (HR) uses an undamaged homologue as a template to repair a DSB and to restore any genetic information lost at the site of the break. Single strand annealing (SSA) uses short direct repeat sequences to hold the broken ends together and then rejoins the two closely located DNA nicks. NHEJ, in contrast, requires no homology or, at most, a few base pairs of microhomology to achieve DSB rejoining. HR has the potential to be highly accurate even if sequence information is lost at the break site. SSA annealing is inherently inaccurate leading to deletions at the break site. The level of accuracy achieved by NHEJ is still unclear. However, cells lacking NHEJ components show increased levels of misrepair observable either as chromosomal rearrangements or in specific assays aimed at detecting misrepair.

Proteins that Function in NHEJ

Six proteins required for NHEJ have been identified in mammalian cells (see Table I). The first component identified was Ku, a heterodimer consisting of two subunits, Ku70 and Ku80. Ku has strong double-strand DNA end-binding activity. Once bound to a DNA end, Ku recruits a large protein kinase to form a complex called the DNA-dependent protein kinase (DNA-PK). The catalytic component of this complex is called the DNA-PK catalytic subunit (DNA-PKcs). A complex of two further proteins, XRCC4 and DNA ligase IV, are required for the rejoining step of NHEJ. More recently, "artemis" has been identified as an additional protein required for some aspects of NHEJ. In the yeasts, *Saccharomyces cerevisciae* and *Schizosaccharomyces pombe*, some additional proteins are required for NHEJ but either homologues of these proteins have not been identified in mammalian cells or the identified homologues do not appear to be required for the process (see Table I). It is noteworthy that there are differences in the requirements for these additional proteins even between the two yeasts. The roles of Sir2, 3, and 4 and Nej1p are regulatory.

The Ku Protein

In addition to being a strong DNA end-binding protein, Ku is able to translocate along the DNA, leading to a DNA substrate with multiple bound Ku molecules. The crystal structure of Ku resembles a basket-shaped structure with two pillars and a handle. A double-stranded DNA end is able to fit through the cavity in the structure allowing Ku to encircle the DNA. The C-terminal region of Ku80 is required for interaction with DNA-PKcs.

DNA-PKcs

DNA-PKcs is a member of a subfamily of phosphoinositol (PI) 3-kinases called PI 3-K-like kinases (PIKKs). This subfamily has protein kinase activity, in contrast to the lipid kinase activity of the PI 3-Ks. DNA-PKcs at 460 kDa is one of the largest PIKKs and other family members include ataxia telangiectasia mutated protein (ATM) and ataxia telengiectasia and Rad 3-like protein (ATR). PI 3-Ks have a conserved kinase domain at the C terminus and PIKKs in addition have a small region at the extreme C terminus that is required for protein kinase activity. Although *in vitro*, DNA-PK can phosphorylate many of the proteins phosphorylated by ATM and ATR, *in vivo*, the three PIKKs have distinct functions. The *in vivo* substrates of DNA-PK have not

TABLE I

Proteins Required for NHEJ in Different Model Systems

	Mammalian cells	*S. cerevisiae*	*S. pombe*
Ku70, Ku80	+	+	+
DNA ligase IV	+	+ (Lig4p)	+ (Lig4p)
XRCC4	+	+ (Lif1p)	+ (Lif1p)
DNA-PKcs	+	No homologue identified	No homologue identified
Artemis	+	No homologue identified	No homologue identified
Mre 11/Rad50/Xrs2	Not required	+	+
Nej1p	No homologue identified	+	No homologue identified
Sir 2, 3, and 4	No homologue identified	+	No role identified

been identified although artemis and XRCC4 are likely substrates. DNA-PK also undergoes autophosphorylation, which is essential for its function in NHEJ. It has been suggested that one role of DNA-PKcs is to regulate the process by phosphorylating NHEJ components. In line with this, autophosphorylation of DNA-PKcs results in release of the protein from the Ku–DNA complex.

XRCC4-DNA Ligase IV

DNA ligase IV has a conserved ligase domain at its N terminus and two BRCT domains at its C terminus. The region between the two BRCT domains is required for interaction with its partner protein, XRCC4. The crystal structure of XRCC4 and the interacting region with DNA ligase IV shows that XRCC4 consists of a globular head domain and a helical tail. A single ligase chain binds to an XRCC4 dimer leading to unwinding of the coiled coil that forms in the uncomplexed molecule. XRCC4 stimulates but is not essential for DNA ligase IV's activity. However, XRCC4 is essential for NHEJ and cells lacking either XRCC4 or DNA ligase IV have identical phenotypes. Ku bound to DNA can recruit the DNA ligase IV-XRCC4 complex, thereby stimulating ligation.

Artemis

Artemis is a member of the metallo-β-lactamase superfamily and, when unphosphorylated, has $5'-3'$ exonuclease activity. Artemis forms a complex with and is phosphorylated by DNA-PKcs, which changes the specificity of its nuclease activity so that it acquires endonucleolytic activity as well as the ability to cleave hairpin structures. A hairpin intermediate is generated during the process of V(D)J recombination and artemis cleaves this hairpin allowing V(D)J recombination to proceed. Consequently, cells and patients lacking artemis are unable to rejoin the coding junctions during V(D)J recombination leading to severe combined immunodeficiency.

Model for NHEJ

Figure 1 presents a model for NHEJ based on a range of biochemical, biophysical, cellular, and molecular studies. The first step of the process is the binding of the Ku heterodimer to DNA ends followed by recruitment of DNA-PKcs and activation of DNA-PK activity. Recruitment of DNA-PKcs causes inward translocation of Ku on the DNA molecule and potentially synapsis of the DNA ends. DNA-PK phosphorylates artemis, which activates its hairpin cleavage activity, a step essential for V(D)J recombination. The specificity of artemis nuclease activity may also be modulated by phosphorylation allowing it to cleave ends that are not amenable to direct ligation. DNA-PKcs may also undergo autophosphorylation enabling it to be released from DNA-bound Ku. Ku then recruits the DNA ligase IV-XRCC4 complex to the DNA end. Subsequent rejoining ensues with the release of the DNA ligase IV-XRCC4 complex.

Roles of NHEJ

Rodent cell lines lacking NHEJ components, as well as the SCID mouse and SCID cell line, have provided invaluable tools to evaluate the function of NHEJ. Complementation analysis of the rodent cells led to the classification of the defective genes as X-ray cross complementing (XRCC). This classification was made prior to cloning, resulting in some of the genes having dual nomenclature (for example, Ku80 is also XRCC5). This nomenclature and the rodent cell lines studied are given in Table II. More recently, mice knocked out for each of the NHEJ components have been generated. The phenotypes observed in the cell lines and mice are shown in Table III. Some phenotypes may represent roles of the proteins separate from their role in NHEJ. For example, Ku70 and 80 knockout mice are growth retarded, die early, and show a severe combined immunodeficient (SCID) phenotype. The latter phenotype reflects the role

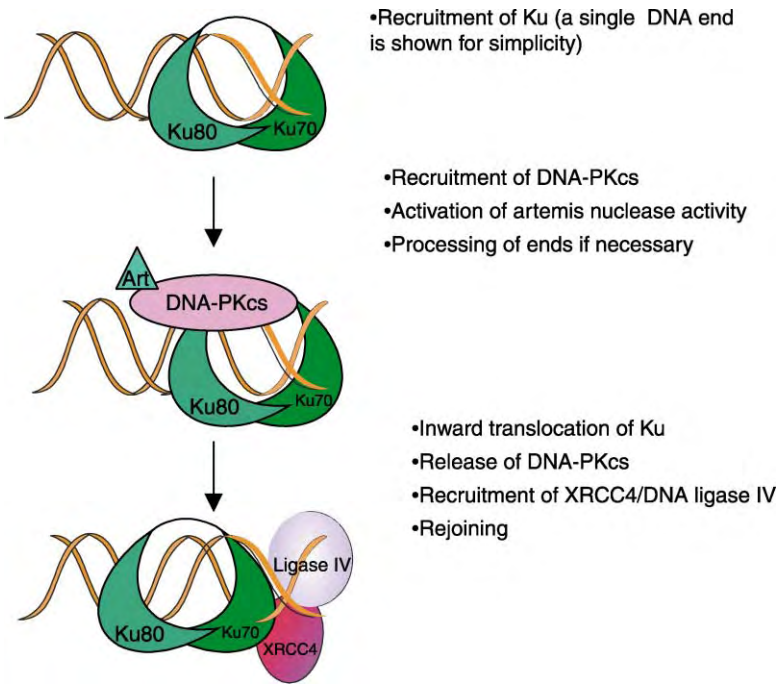

FIGURE 1 Model for DNA NHEJ. Proposed steps involved in the process.

of NHEJ in V(D)J recombination whilst the growth retardation and early senescence are most likely caused by a role of Ku in telomere maintenance, which may be distinct from its role in NHEJ. Mice lacking XRCC4 or DNA ligase IV are embryonic lethal displaying extensive neuronal apoptosis. It is currently unclear whether these differences represent roles for XRCC4 and DNA ligase IV in a process distinct from NHEJ or whether some rejoining can occur in the absence of the other NHEJ components. It has also been suggested that the uncoordinated binding of Ku to DNA ends prevents alternative DSB rejoining mechanisms taking place.

Repair of Radiation Induced DSBs

A DNA DSB is the most biologically significant lethal lesion induced by ionizing radiation. Consequently, all cell lines lacking components of the NHEJ machinery display pronounced radiosensitivity demonstrating that NHEJ represents a major mechanism for the repair of radiation-induced DSBs. Another characteristic feature of Ku, DNA-PKcs, XRCC4, and DNA ligase IV-deficient cells is impaired DSB rejoining monitored by the technique of pulse field gel electrophoresis. Interestingly, artemis-deficient cells repair the majority of their DSBs normally demonstrating that its role is distinct from the other NHEJ components. It is currently unclear if artemis functions downstream of the break rejoining process, for example to relay to the cell that the break has undergone rejoining, or possibly functions to repair a critical subset of breaks that are not detected by the pulse field gel electrophoresis technique. Cytological studies have shown that NHEJ-deficient cells display, not only increased gaps and breaks after irradiation

TABLE II

Nomenclature of Genes Involved in NHEJ and Characterized Cell Lines

Gene	XRCC nomenclature	Rodent cell lines	Human patients
Ku80	XRCC5	xrs 1-6; XRV15-B; XRV9B; sxi-3	None identified
Ku70	XRCC6	sxi-1	None identified
DNA-PKcs/SCID	XRCC7	SCID mouse cell line; V3; M059J glioma cell line; XR-C1; SX9; irs-20	None identified
XRCC4	XRCC4	XR-1	None identified
DNA ligase IV (LIG4)		SX10	LIG4 syndrome
Artemis		None identified	RS-SCID

TABLE III

Phenotypes of Cell Lines and Mice Defective in NHEJ Components

	Cell line deficiency			
Phenotype	**Ku70/Ku80**	**XRCC4/DNA ligase IV**	**DNA-PKcs**	**Artemis**
Cultured cell lines				
Radiosensitivity	Marked sensitivity	Marked sensitivity	Marked sensitivity	Slighly milder sensitivity
DSB rejoining	Defective	Defective	Defective	Normal or mild defect
DNA end-binding activity	Defective	Normal	Normal	Normal
DNA-PK activity	Defective	Normal	Defective	Normal
V(D)J recombination				
Coding joins	Major defect	Major defect	Major defect	Major defect
Signal joins	Major defect	Major defect	Minor defect	No defect
Primary cell lines				
Spontaneous breakage	Increased (also in heterozygotes)	Increased (also in heterozygotes)	Normal	Normal
Mice				
Immunodeficiency	SCID	SCID	SCID	SCID
Growth/viability	Growth retarded senesce early	Embryonic lethal	Normal	Normal
T cell lymphomas	Increase in Ku70−/− mice; no lymphomas in Ku80−/− mice	Mice not viable	Small increase	Increase in patients with hypomorphic mutations

Many of the phenotypes of Ku70-/- and Ku80-/- cell lines and mice are similar and so they have been grouped together. Similarly for XRCC4/DNA ligase IV deficient mice.

indicative of failed rejoining, but also increased chromosomal rearrangements, indicative of misrejoining. Whilst this finding does not address the fidelity of NHEJ, it does suggest that in its absence, there is increased misrejoining. Finally, NHEJ-deficient cells show normal ability to effect cell-cycle checkpoint responses after irradiation demonstrating that the defect lies primarily in the rejoining process rather than in the signalling responses to DSB induction.

Role During Immune Development

In germ line cells, the variable (V), diversity (D), and joining (J) segments are arranged on the DNA as contiguous sequences which become rearranged into distinct V(D)J units during T- and B-cell differentiation via a process called V(D)J recombination. Each V, D, or J segment, termed a coding sequence, is associated with a semi-conserved signal sequence. The initiating event for the recombination process is the generation of a site-specific DSB by two recombination-activating gene proteins (RAG1 and 2). The breaks form between a pair of coding sequences and their adjacent signal sequences and rejoining ensues to create coding and signal junctions from the rejoining of two coding and signal sequences, respectively. A number of additional processes serve to create deletions or insertions at the coding junctions, adding to the diversity of junctions generated. There are distinctions between the rejoining of coding and signal junctions. RAG-mediated cleavage generates hairpin coding ends in contrast to blunt-ended signal ends and the requirements for rejoining of the two ends can be distinguished genetically; coding joint formation requires all six NHEJ components whereas signal joint formation does not require artemis and has only a partial requirement for DNA-PKcs. Current evidence has shown that artemis is the nuclease that cleaves the hairpin end and is activated by DNA-PKcs, providing an explanation for these differences.

Changes in antibody isotype (IgM to IgG/IgA/IgE), an essential feature of the immune response, is achieved by class switch recombination (CSR). Since CSR takes place after V(D)J recombination, it cannot be readily monitored unless V(D)J recombination has taken place. Nonetheless, several novel approaches using transgenes have provided evidence that CSR requires the introduction of a DSB as well as components of the NHEJ machinery.

Role in Maintaining Genomic Stability

Cells constantly incur endogenous DNA damage from reactive oxygen species (ROS) generated as metabolic by-products. DSBs can arise indirectly from ROS following the processing of oxidative damage. DSBs also arise during replication. Current evidence suggests that breaks at the replication fork are repaired

by homologous recombination. Nonetheless, studies of primary cells lacking NHEJ components or even primary cells heterozygous for these proteins have shown elevated chromosome breaks demonstrating that NHEJ also functions to repair endogenously generated damage.

Contribution to Human Disease

Two hereditary syndromes have been shown to be caused by defects in components of the NHEJ machinery. LIG4 syndrome is characterized by pancytopaenia, developmental and growth delay. Hypomorphic mutations in DNA ligase IV have been found in LIG4 syndrome patients, all of which markedly impact upon the protein function. One of the five patients identified developed leukaemia and showed dramatic clinical radiosensitivity. However, the small number of patients precludes an assessment of whether LIG4 syndrome is associated with cancer predisposition.

RS-SCID patients display severe combined immunodeficiency with no additional clinical features. Cell lines derived from the patients show pronounced radiosensitivity. RS-SCID has been shown to be caused by mutations in artemis, many examples of which are loss of function mutational changes. Hypomorphic mutations in artemis have also been described in patients with partial T and B lymphocyte immunodeficiency and a predisposition to EBV-associated lymphomas.

The clinical differences between RS-SCID compared to LIG4 syndrome patients highlights the differing roles of artemis and DNA ligase IV during neuronal development.

Glossary

DNA damage response mechanisms A number of distinct processes that function to maintain genomic stability. They include pathways of DNA repair and signaling mechanisms that effect cell-cycle checkpoint control and/or apoptosis.

DNA-dependent protein kinase A complex involving Ku, the DNA targeting component, and DNA-PKcs, the catalytic component.

DNA end-binding activity A protein that can bind to double-strand DNA ends. This is normally monitored by electrophoretic mobility shift assays (EMSAs).

genomic rearrangement Joining of two genetic sequences that are not linked in a normal genome. Often visualized cytogentically.

hairpin DNA end A DNA molecule that does not have 5′ and 3′ ends but a continuous looped sequence to the opposite strand. Normally the hairpin involves some unpaired bases.

phenotype The characteristic features of a cell or animal. Contrasts to genotype which describes the genetic status of a cell or animal.

V(D)J recombination A process of recombination that occurs during differentiation of immunoglobulin and T cell receptor genes and serves to enhance their genetic diversity.

Biography

Dr. Penny A. Jeggo is a Senior Scientist and Group Leader at the Genome Damage and Stability Centre, University of Sussex, UK. She holds a Ph.D. from the National Institute of Medical Research, London which she undertook in Dr. Robin Holliday's laboratory. Dr. John Cairns was another significant mentor. Dr. Jeggo played a key role in identifying the first components of the NHEJ machinery. She now has broader interests in damage response mechanisms and the contribution of these processes to human disease.

Nonhomologous Recombination: Bacterial Transposons

Bao Ton Hoang and Michael G. Chandler
Laboratory of Molecular Genetics and Microbiology CNRS, Toulouse, France

Transposable genetic elements (TEs) are small functional segments of DNA capable of translocation into DNA sites within and between genomes and play an important role in horizontal gene transfer. A major division between TEs is whether they translocate via RNA or DNA intermediates. Prokaryotic TEs are probably exclusively limited to those that move using DNA intermediates. They are capable of sequestering and transmitting a variety of genes involved in accessory cell functions such as resistance to antimicrobial agents, catabolism of unusual compounds, and pathogenicity, virulence, or symbiotic functions. They also promote deletions and inversions and their insertion can activate or extinguish gene expression. TEs can constitute an important fraction of bacterial genomes (both chromosomes and plasmids). For example, one class of transposon, bacterial insertion sequences, represents ~7% of the 4 Mbp *Bordetella pertussis* chromosome and ~40% of the 220 kbp *Shigella flexnerii* virulence plasmid pWR100.

Structural Similarities and Diversity

All TEs encode a cognate transposase (Tpase) or recombinase, which recognizes their ends and catalyzes the individual DNA cleavages and strand transfer events necessary for transposition. In bacteria the term transposon (Tn) is limited to elements that carry genes specifying additional functions to those involved in transposition. The large number of TEs which do not include a distinct phenotypic trait are known as insertion sequences (ISs).

Definition of Transposases

Different types of elements can be defined by the nature of their cognate recombinases. In transposition reactions, these enzymes are known as transposases (Tpases). The majority fall into a class generally called DDE transposases because of the presence of three key amino acids, two aspartate residues and a glutamate, as part of the active site. Although DDE enzymes represent the majority of known Tpases, at least three additional types of Tpases have been identified. One class is similar to rolling circle replicases used by certain bacteriophages and plasmids. These are known as Y2 transposases since their catalytic mechanism involves two highly conserved tyrosine residues. The other two classes are members of the site-specific recombinase families. However, while these Tpases show site-specificity for the ends of the donor transposon, they appear more flexible than classic site-specific recombinases in the target DNA sequences they recognize and use. They are known as Y-Tpases and S-Tpases to distinguish them from tyrosine and serine recombinases. A fifth class, which catalyzes sequence-specific integration but does not resemble any of the above groups is represented by a newly discovered class of elements.

Types of Transposable Elements

Insertion Sequences

The smallest autonomous elements known are the bacterial ISs. These have been detected in almost all eubacterial and archaebacterial genomes. They are genetically compact, between 750 bp and 2500 bp in length, are generally flanked by two partially identical and inverted sequences (terminal inverted repeats: IRs) and encode only functions involved in their mobility. The Tpase gene is composed of one or two open reading frames (*orf*s) occupying almost the entire length of the IS (Figure 1A). The IR proximal to the Tpase promoter is defined as IRL. In many ISs with two *orf*s, Tpase is produced as a fusion protein using a programmed −1 translational frameshift between the *orf*s similar to that observed in generating the pol polyprotein in some retro-viruses.

Over 1000 bacterial ISs are known. These have been divided into ~20 groups or families defined by their genetic organization, similarities in their IRs and Tpase sequences, and their preference for given target DNA

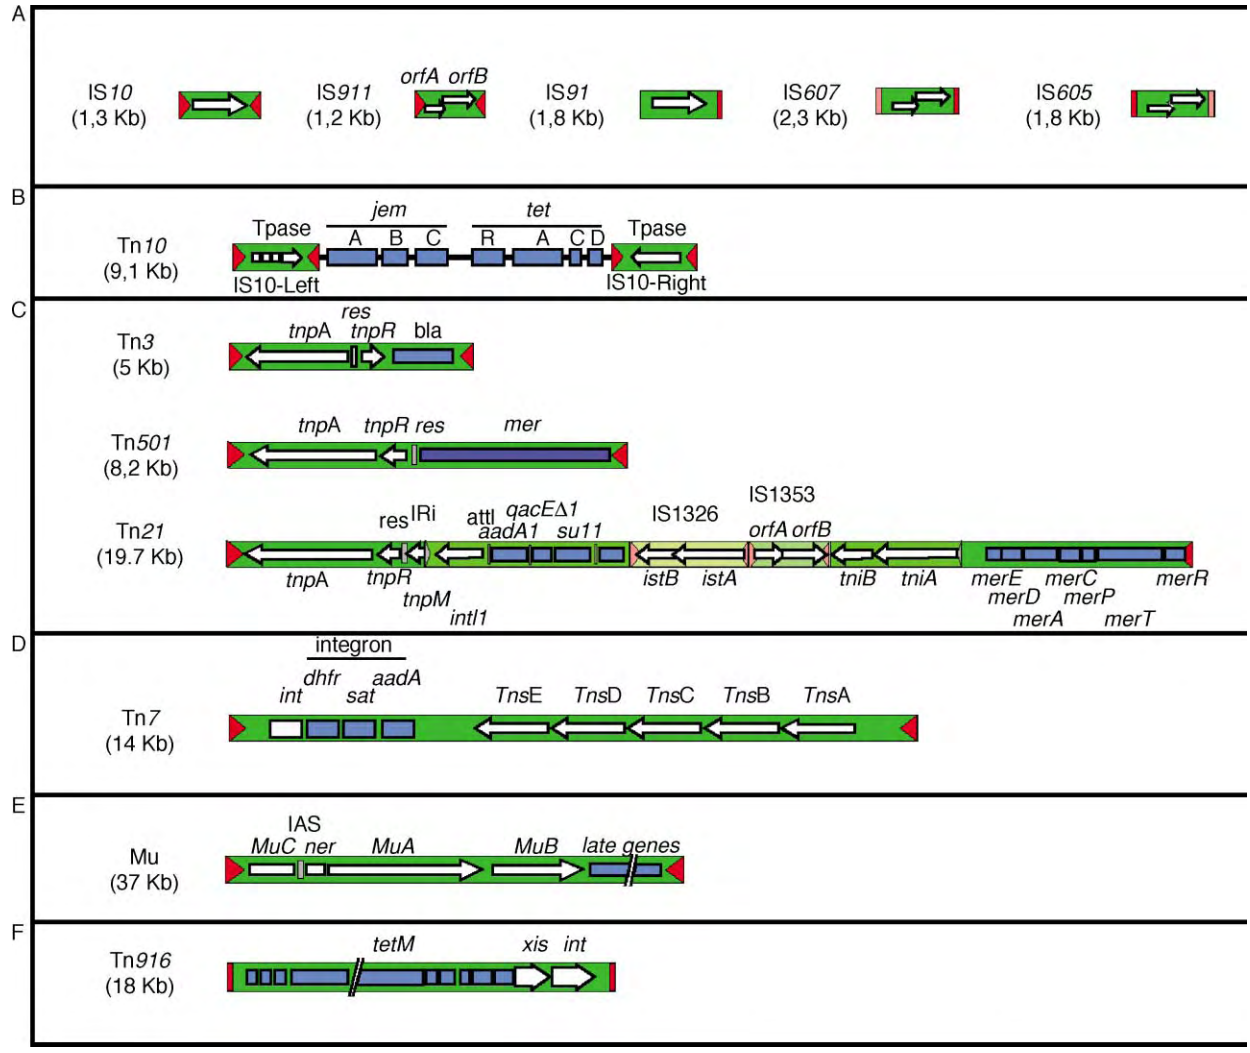

FIGURE 1 Diversity of bacterial transposable elements. The organization of different types of bacterial TE is shown. Terminal repeats (red triangles), transposon ends (red boxes in the case of IS*91*, IS*605*, IS*607* and Tn916 to indicate that they are not inverted repeats), genes whose products are involved in transposition, site-specific integration or recombination (int, xis, R) functions (white boxed arrows), resistance genes and accessory genes (conjugative transfer or phage functions) (blue boxes) are indicated. Grey boxes indicate recombination sites for resolution of cointegrates (*res*) or integron capture of gene cassettes (*att*). *bla*: resistance to β-lactams; *tet*: resistance to tetracycline; *mer*: mercury resistance.

sequences (www-IS.biotoul.fr). The majority (17/20) of these families encode a DDE Tpase, one (IS*91*) encodes a Y2 enzyme, a third (IS*607*) encodes an S-Tpase while a fourth (IS*605*/IS*608*) specifies an enzyme whose mechanism of catalysis is at present unknown (Figure 1A). This classification will undoubtedly continue to evolve as more are characterized.

Miniature Inverted Repeat Transposable Elements

Several bacterial genomes harbor many copies of small DNA segments. Depending on the bacterial species, these are variously called *Rep*, *Box*, *Rup*, or *Correia*. Some resemble ISs, which have been deleted for the transposase. Interestingly, the ends often resemble those of members of the IS*630* family and like these elements are flanked by a directly repeated TA dinucleotide. These were first described in eukaryotic systems.

Compound Transposons

Antibiotic resistance genes in bacteria were often found to be flanked by a pair of similar IS elements. Flanking ISs are capable of mobilizing any interstitial DNA segment. These structures are known as compound transposons. They are widespread and can include resistance to many different antibacterials, to genes involved in bacterial–host interactions as well as to other "accessory" genes, which are important to the host under some conditions of growth. Classical examples are tetracycline resistance transposon, Tn*10*

(flanked by two IS*10* elements in inverse repeat) (Figure 1B), the neomycin resistance transposon, Tn*5* (flanked by two IS*50* elements in inverted repeat) and the chloramphenicol resistance transposon, Tn*9* (flanked by two copies of IS*1* in direct repeat). In some cases the autonomy of the flanking ISs may be reduced in various ways to favor transposition of the entire structure.

Unit Transposons

Another class of bacterial transposons are the unit transposons such as members of the Tn*3* family (Figure 1C). Here, additional genes are contained within the transposable element itself. Large numbers of such transposons have been described carrying antibiotic resistance genes or genes involved in catabolism of unusual substances (including xenobiotics). Tn*3*-family transposons share very similar IRs (~40 bp) and carry highly related DDE transposase genes. They carry a specific site (*res*) and encode a site-specific recombinase (*tnp* R), which promotes recombination in the cointegrate between the two elements at their *res* sites. This leads to separation of donor and target molecules and leaves a single copy of the transposon embedded in each. Many variations on this basic structure have been observed. They include derivatives, which encode only the Tpase with no additional genes and therefore might be included within the IS group.

Tn*3*-family elements can accommodate and accumulate additional genes. For example Tn*21* (Figure 1C) evolved by insertion of a now defective transposon into an ancestral mercury resistance transposon, which has additionally acquired two ISs. Tn*21* also carries a genetic trap, which permits the acquisition of additional genes: the integron system. Integrons include an integrase gene, related to the Y-recombinase of bacteriophage λ. It also carries a flanking site equivalent to the λ attachment site, *att*, at which integration occurs. The acquired genes are generally promoterless and are located on small cassettes, which integrate site-specifically into the *att* site where a resident promoter is appropriately located to drive expression.

Tn*7*

Transposon Tn*7* (Figure 1D) is unusual in that it encodes five proteins necessary for its transposition and uses two transposition pathways: a site-specific insertion pathway and a more random pathway, which recognizes aspects of DNA structure in the target. One of the transposition enzymes (TnsB) is a DDE transposase while a second (TnsA) shows similarity to restriction endonucleases. Two additional proteins (Tns D and E) are involved in target choice for each of the two pathways while the fifth (TnsC) provides a bridge between target protein and the transposase. Tn*7* also carries an integron system, which has permitted it to acquire resistance to trimethoprim among other antibiotic resistances. Other members of this group including different resistance genes have also been described.

Transposable Bacteriophage

The first example of this type to be described was the temperate mutator phage Mu (Figure 1E), so-named because it inserts in a relatively random way and generates mutations during infection. Many different examples of mutator phages have been identified either as phage particles or during annotation of bacterial genome sequences. They are extremely large (>40 kbp) and relatively complex since they must encode for the enzymes and structural proteins involved in the bacteriophage lifestyle. They transpose using DDE enzymes.

Conjugative Transposons

These were first discovered in gram-positive bacteria as elements capable of transmitting tetracycline resistance from cell to cell and between bacterial species. Although they have been called transposons (Ctns for conjugative transposons), they use a site-specific recombination reaction for integration and excision. The enzymes are generally Y-transposases, similar to the site-specific recombinases used by phage λ or the integrons. However, whereas λ and integrons show pronounced sequence specificity for integration, conjugative transposons are much less exacting in their choice of integration sites. They are large and, in addition to the genes involved in integration and excision and in antibiotic resistance, they carry genes required for conjugative transfer. Tn*916* (Figure 1F) and Tn*1545* are the best-characterized transposons of this type. Several examples of Ctns encoding S-transposases have also been described.

Mechanism

DDE Enzymes

Transposition requires precise cleavage at the transposon ends and their coordinated transfer into a target molecule. This is achieved through the assembly of a nucleo-protein complex of defined architecture: the transpososome. This structure involves the Tpase, the transposon ends and target DNA. The signals for recognition and processing by Tpase are located in the transposon ends. Most bacterial ISs carry relatively simple IRs with a single Tpase-binding site. Other transposons show a complex constellation of sites often arranged differently at each end (e.g., phage Mu and Tn*7*).

The majority of known Tpases are structurally related and carry a conserved triad of acidic amino acids, the DDE motif, which coordinate two divalent metal ions central to catalysis. Cleavage at the 3′ ends of the element by an attacking nucleophile (generally H_2O) occurs to expose a free 3′OH group (Figure 2A). This nucleophile then attacks a 5′ phosphate group in the target DNA in a single-step transesterification reaction

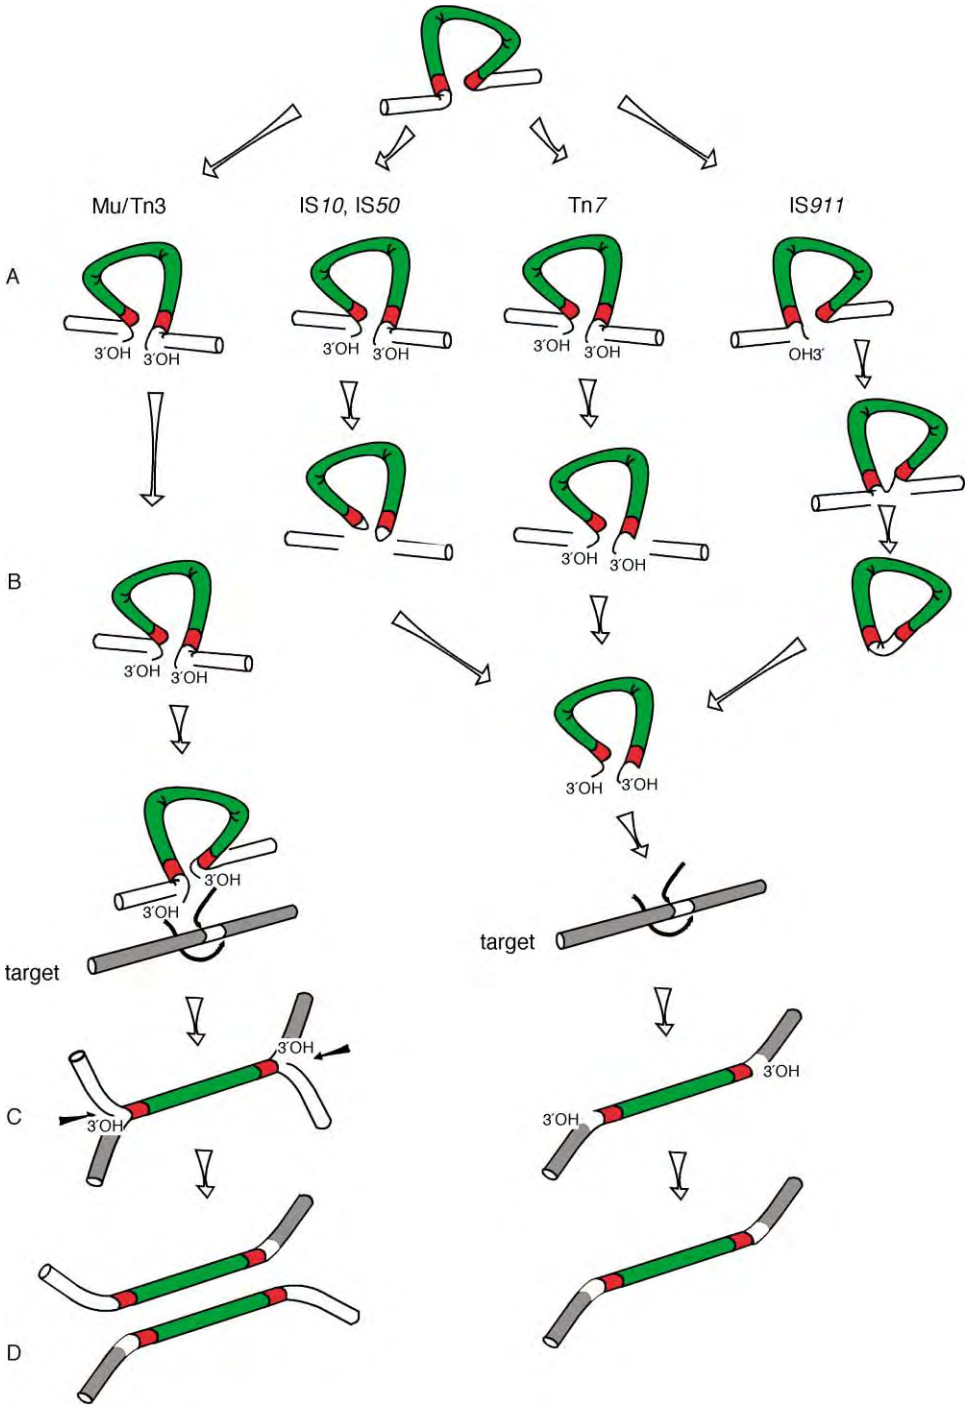

FIGURE 2 Transposition mechanism of DDE elements. Transposon, inverted repeats, and flanking sequences are shown as green, red, and white respectively. In target DNA (grey), direct repetitions (DR) are shown in white. Liberated 3′OH groups involved in subsequent strand joining reactions are shown (A and B). Left column: Replicative transposition as the result of single strand cleavage and transfer to create a replication fork (C). 2nd column: In the IS*10* (IS*50*) reaction pathways the 3′OH liberated in the initial hydrolysis attacks the opposite strand to generate a hairpin intermediate, liberating the transposon from its flanking donor DNA (A). A second hydrolysis regenerates the 3′OH (B). 3rd column: Double strand cleavage using two enzymes (e.g.Tn*7*). 4th column: For members of the IS3 family (e.g., IS*911*), the 3′OH from a single-end hydrolysis directs a strand transfer reaction to the same strand to the other end of the element (A). The branched single-strand circle is resolved into a transposon circle by the host. Single-strand hydrolysis at each 3′end (B) generates a linear transposon, which can integrate in a target.

(Figure 2B). The reaction, analyzed in detail for bacteriophage Mu, HIV, and IS*10*, has been shown to occur as an in-line nucleophilic attack with chiral inversion of the phosphate group. The two metal ions are thought to act respectively as a Lewis acid and base in the reaction.

Concerted transfer of both transposon ends into the target site, while maintaining the correct strand polarity, results in joining each transposon strand to opposite target strands. Since the position of attack in target DNA is generally staggered, this generates short, complementary single strand regions flanking the newly inserted element (Figure 2C). Repair by the appropriate host machinery generates a short duplication (direct repeat or DR) of defined length in the flanking target DNA (Figure 2D). The reactions do not require an external energy source nor do they involve a covalently linked enzyme-substrate intermediate. The donor transposon strand performs the cleavage-ligation steps in the target DNA and no cleaved target molecule is detected in the absence of strand transfer.

DDE enzymes cleave only one of the two DNA strands. An important feature of the transposition reaction is therefore the way in which the 5′ end (second strand) is processed. Some transposons do not process the second strand and are therefore not separated from the donor molecule. Strand transfer generates a structure, which can be used as a replication fork. "Replicative integration" generates cointegrates or replicon fusions where the donor and target replicons are fused and separated at each junction by a directly repeated copy of the element (e.g., bacteriophage Mu, the Tn*3* family; Figure 2 left column). Other elements shed their donor DNA prior to insertion. For some elements, the 3′OH generated by the first hydrolysis attacks the second strand to generate a hairpin form which then undergoes hydrolysis to regenerate an active 3′OH (e.g., IS*10* and IS*50*; Figure 2 second column). Others possess a second enzyme dedicated to cleavage of the second strand (e.g., Tn*7*; Figure 2 third column). For members of several bacterial IS families (e.g., IS*3*, IS*21*, and IS*30*) the 3′OH liberated at one end of the IS attacks the other end on the same strand generating a form in which one IS strand is circularized. The entire transposon is then resolved into a free transient circular form by replication or recombination of the second strand. The transposon circle then undergoes efficient integration after single-strand cleavage at each end (Figure 2 fourth column).

Non-DDE Transposases

The mechanism of transposition mediated by the other classes of transposase is less well detailed than that of the DDE transposases.

Y2 Transposases

The Y2 transposases, at present limited to the IS*91* family, show significant identity to the rolling circle replicases of phage and plasmids in the regions covering their active sites. The characteristics of transposition are strikingly different from those of DDE-mediated events. ISs of this type do not exhibit terminal IRs, do not generate flanking direct repeats and insert into a conserved tetranucleotide, which is required for further transposition events. The right (but not the left) end and the tetranucleotide are essential for transposition. Moreover, deletion of the left end can result in one-ended transposition. In this case, the inserted fragment of donor DNA is flanked at one end (constant end) by the right end and at the other end by a conserved tetranucleotide sequence present elsewhere in the donor plasmid (variable end). In addition, circular single-stranded derivatives of IS*91* have been observed and may represent transposition intermediates. While these data clearly support a polarized rolling circle mechanism, little is known about the strand transfer, which would assure transfer from donor to target site.

Y- and S-Transposases

Again, although site-specific recombination reactions directed by S- and Y- recombinases are known in exquisite detail, the activities of the corresponding transposases remain largely uninvestigated. By analogy, and in contrast to the DDE enzymes, it is assumed that catalysis involves the formation of a covalent enzyme substrate intermediate (Figure 3). In both cases, the element is excised precisely from the donor molecule.

For the Y-transposases, this would involve nucleophilic attack of the target phosphodiester bond by the active site tyrosine to generate a 3′-phosphotyrosyl bond exposing a 5′OH (Figure 3A, left column). In a second step, the 5′OH attacks the phosphotyrosine bond at the opposite end to promote strand exchange (Figure 3B, left column). Note that the reaction of only one strand is shown here. Sequential reactions of cleavage and transfer on the opposite strand would then generate a circular intermediate (Figure 3C, left column). Insertion is thought to occur by reversal of these reactions (Figure 3D, left column).

For the S-transposases recombination occurs by a concerted four strand cleavage (Figure 3A, right column) in which a catalytic serine residue attacks the target phosphodiester bond to generate a 5′ phosphoserine bond and to expose a 3′OH (Figure 3B, right column). Strand transfer to generate a circular intermediate would occur by nucleophilic attacks of the covalent DNA-enzyme bonds by the 3′ hydroxyl ends generated by cleavage (Figure 3C, right column). A second round of similar recombination reactions (Figure 3D, right column)

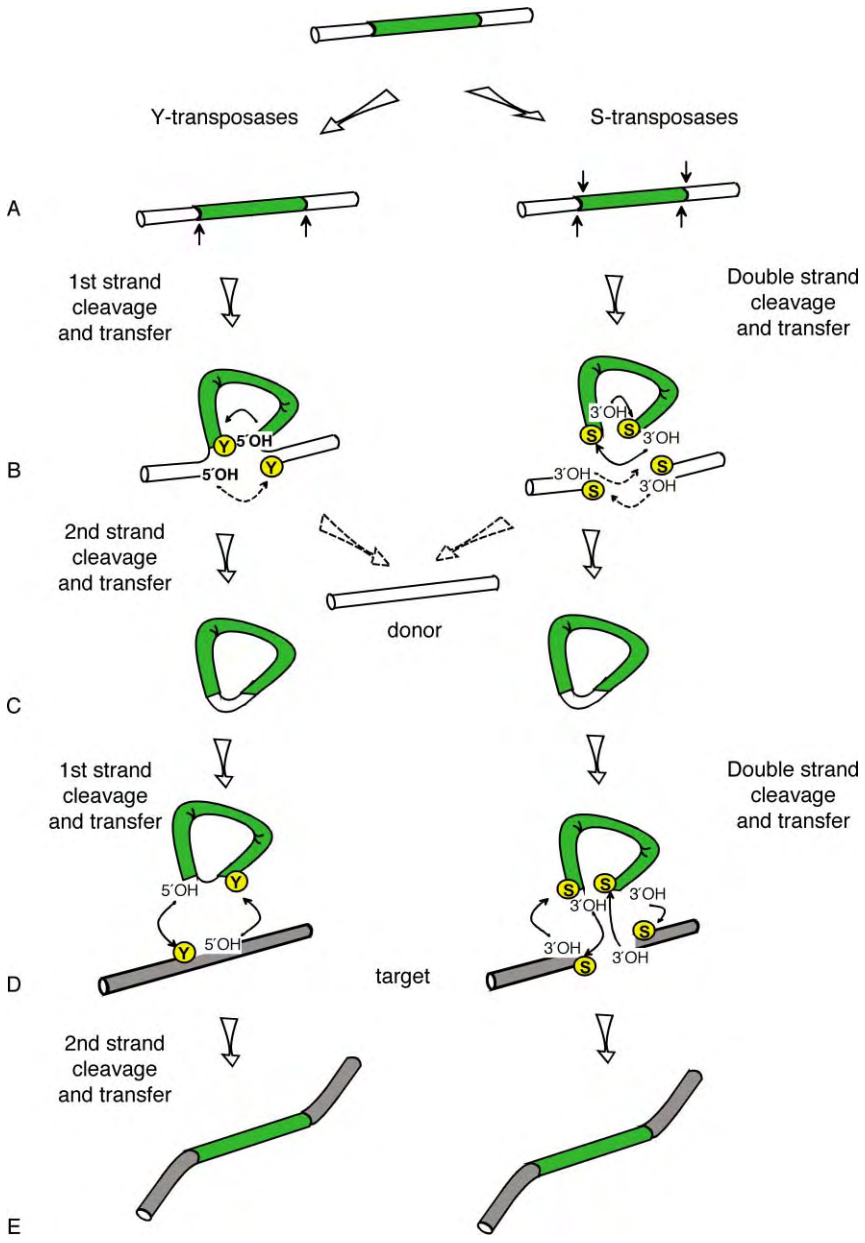

FIGURE 3 Reaction mediated by Y- transposase and S-transposases. Left column: Transposon and flanking sequences are shown as green and white respectively. The active site residue Y or S is shown within a yellow circle. Y-transposase nicks one transposon strand (here on bottom strand) at both ends (A) and forms covalent 3′ phosphotyrosine intermediates (B). The liberated 5′ OH attacks the phosphotyrosine linkage at the other end (arrows) to circularize one transposon strand (B). The same reaction is performed on the top strand to regenerate the donor and a circular intermediate (C). Further cleavage and transfer (D) is presumed to result in an insertion into target DNA (E). In contrast to site-specific recombination, the Y-transposase exhibits low sequence specificity for the target site. Right column: S-transposase catalyzes concerted double-strand breaks at both ends (A), forming covalent 5′ phosphoserine intermediates (B). After a switch of strands, the 3′ OHs attack the phosphoserine bonds in the opposite end (B), resulting in a circular intermediate (C). The same process (D) permits insertion of the element in a target (E). For both pathways, strand transfers reconstituting donor molecule (B and C) are shown by dotted arrows.

would then lead to insertion of the circular transposition intermediates (Figure 3E).

Target Choice

The choice of an insertion site can have important implications both for the transposon and for the host. Insertion into a specific target DNA sequence can provide a secure refuge for the transposon. For example, by using a specific sequence in a highly conserved gene in such a way that insertion does not disrupt the gene, transposon Tn*7* is assured an insertion site, which does not affect the fitness of the host and occurs in many bacterial species. On the other hand, in excluding insertions into other DNA sequences, this strategy precludes the capacity of

the element to generate mutations or to activate or sequester genes and thus to generate genetic diversity. Different transposons exhibit a variety of different strategies for selecting a target. On a genome scale, most transposons appear to insert "randomly". However, when analyzed at the nucleotide level, most show some degree of target preference. Insertion can be sequence-specific, with target sequence lengths varying from a few to many nucleotides, or show regional preferences, for example GC or AT rich DNA segments, probably reflecting more global parameters such as local DNA structure. Other factors which have also been implicated are: the degree of supercoiling, DNA replication, transcription, direction of conjugative transfer, and protein-mediated targeting to, or exclusion from, transcriptional control regions. In addition, some transposons show a preference for insertion close to sequences resembling the transposon end. Others exhibit the converse behavior: exclusion of insertions close to a resident end. This phenomenon, transposition immunity, can act over many kilobases of DNA. For Tn*7* and Mu it has been shown that this is accomplished by a second transposon-encoded protein (in both cases a DNA dependant ATPase), which binds target DNA. Briefly, for phage Mu, the transposase MuA, is capable of stimulating dissociation of the DNA-dependent ATPase, MuB from DNA. Thus, MuA bound to a transposon end resident in the target molecule is thought to provoke disassembly of MuB from neighboring DNA with a probability, which decreases as the distance increases.

Clearly, many insertion preferences must reflect constraints in the architecture of the synaptic complexes formed between the transposon ends, the target DNA and the transposase.

Regulation

Transposable elements are very highly regulated and have evolved a variety of perspicacious regulatory mechanisms. Apart from the temperate transposable bacteriophages, which possess a highly efficient transposition mechanism during their lytic development, transposition is not an efficient event. A given transposable element generally possesses an ensemble of regulatory mechanisms, which can differ in detail from even closely related elements.

Regulation can be at the gene expression level or at the level of Tpase activity. A combination of weak promoters and poor ribosome-binding sites can limit transcription and translation while secondary structures, which sequester translation initiation sites and involve RNA sequences upstream and downstream of the Tpase promoter can be present to prevent accidental activation by impinging transcription (IS*10*, IS*5*). Some elements produce a small antiRNA also capable of sequestering translation initiation signals, which acts as a negative control component (IS*10*). Another mechanism to control transposition activity has been documented in elements whose transposition involves a circular or a dimeric intermediate (IS*911*, IS*2*, IS*30*, IS*21*). Here, the weak endogenous promoter can provide low levels of transposase to enable low frequency formation of the transposon circle. However, the IR–IR junction formed in both transposon dimers and circles creates a strong promoter by virtue of a -10 promoter element oriented inward at one IR and a -35 element oriented outward in the other. This boosts transposase synthesis resulting in cleavage, disassembly of the junction promoter and insertion of the transposon, which then again assumes a low level of Tpase expression from the indigenous promoter. Transcription termination signals within the Tpase *orf* or posttranslational processing might also regulate Tpase expression, although these mechanisms have not been investigated in detail. Another relatively common regulatory mechanism involves programmed translational frameshifting (IS*1* and IS*3* families). Here, the Tpase is distributed over two consecutive *orf*s and frameshifting serves to generate a fusion protein including the products of the upstream *orf*, which generally carries DNA-binding and multimerization functions, and the downstream *orf*, which can include the catalytic site. The product of the upstream frame in these cases generally serves a regulatory role. For certain elements, posttranslational proteolysis might also be used to generate small regulatory proteins. IS*50* also generates a protein, Inh, using a second promoter located downstream from the Tpase promoter and representing an N-terminal truncated derivative of the Tpase. Inh acts as a transposase inhibitor.

Regulation can also occur at the level of transposase activity. The differential arrangement of Tpase-binding sites at each of phage Mu and Tn*7* (and perhaps members of the IS*21* family) permits a functional distinction and presumably favors the use of one left and one right end *in vivo*. Moreover, in many cases, Tpase bound at one end catalyzes strand cleavage at the partner end. This "trans" cleavage assures that the correct complex has been assembled before transposition can take place. For Tn*7*, the cleavage and strand transfer reactions require the presence of the target DNA molecule.

An additional level of control of Tpase activity is reflected in the observation that these enzymes often prefer to act on the copy of the element from which they are synthesized. In other words, they exhibit a preference for activity *in cis*. Several nonexclusive explanations for this behavior are apparent and *cis* activity is likely to involve a combination of different effects. One invokes a, yet untested, cotranslational-binding model in which a nascent Tpase protein is

capable of correctly folding its DNA-binding domain and binding to transposon ends before synthesis of the entire protein is accomplished. A second model invokes Tpase stability and it has been demonstrated in at least one case, IS*903*, that the ion protease plays a crucial role *in cis* activity.

Other host factors can also intervene at different regulatory levels. DAM methylase is involved in regulating Tpase expression and the recombination activity of the ends both IS*10* and IS*50*. DNA architectural proteins such as IHF, Fis and Hu have also been implicated in assuring the correct assembly of the transpososome. Moreover, IHF has been implicated in driving the molecular transitions leading to strand cleavage in IS*10*. Other factors such as RecBC, DnaA, Acyl carrier protein, and ribosomal protein L29 have also been implicated in the transposition behavior of various elements but the exact details remain to be elaborated.

Eukaryotic Transposons

Although this section is devoted to prokaryotic elements, it is important to note that eukaryotes generally carry large numbers of both intact and truncated transposable elements. These constitute over 40% of the human genome and somewhat less in Arabidopsis. There are many similarities between prokaryotic and eukaryotic elements. A major group is the Tc/mariner superfamily whose members are similar to bacterial ISs. They carry terminal inverted repeats and encode a DDE, or in this case, a DDD group transposase and resemble the IS*630* family of bacterial elements. Many eukaryotic genomes, especially those of plants, harbor extremely high numbers of truncated derivatives, similar to those found in bacteria, in which the transposase gene appears to have been deleted leaving both IRs. These elements have been also called miniature inverted repeat transposable elements (MITES) and can presumably be mobilized by the full length copies of the elements located elsewhere in the genome.

Another major group, which is limited to eukaryotes are the retro-viruses and LTR-retro-transposons, which pass through an RNA intermediate during their (viral) life cycle. Integration into the host genome occurs through a double-stranded cDNA intermediate and uses DDE group integrase (IN).

The immunoglobulin V(D)J recombination system represents another important element in vertebrates. Here, rearrangements involve two host proteins, RAG1 and RAG2. The RAG1 recombinase is related to DDE transposases. An interstitial DNA segment (signal sequence) is excised to permit the rejoining of two flanking sequences (coding sequence). In a similar way to IS*10* and IS*50*, recombination involves the formation of a hairpin intermediate. In this case, however, the hairpin is generated on the flanking DNA rather than on the excised fragment.

A third large family of eukaryotic elements is the hAT superfamily. Although the nature of their transposase is not clear and little work has yet been undertaken concerning their transposition (which includes *hobo* and *Hermes* from insects, Ac and Tam3 from plants) it seems probable that they have adopted a V(D)J-type of recombination mechanism.

Eukaryotes also harbor other families of IS-like elements including the P element of *D. melanogaster* whose mode of transposition has received much attention due to its use in mutagenesis, the CACTA family, which includes the plant transposons Tam1 and Tam1, and the En/Spm family.

Other newly recognized classes of eukaryotic elements are the helitrons, which resemble rolling circle transposons of the IS*91* family, and Cryptons, DIRS1, and kangaroo elements, which appear to encode Y-transposases.

In addition to eukaryotic elements, which transpose using a DNA intermediate including the retro-viruses, a large class of transposons, which transpose by a completely novel mechanism have also been identified. These are the target-primed (TP) retro-transposons in which an RNA intermediate is copied into its DNA target via reverse transcription.

Biography

Bao Ton Hoang is a Research Scientist with the Centre National de Recherche Scientifique (CNRS) in Toulouse, France. She obtained her Ph.D. from the Université Paul Sabatier and received her postdoctoral training at the Institut National de Recherche Agronomique, Auzeville and the Ecole Veterinaire, Toulouse, France.

Michael Chandler is a Research Director with the CNRS in Toulouse. He obtained his Ph.D. from the University of Leicester (England) and received his postdoctoral training at the University of Geneva (Switzerland). The principal interest of both authors is in genome plasticity and horizontal gene transfer.

Nonhomologous Recombination: Retrotransposons

Siew Loon Ooi and Jef D. Boeke
The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Transposons are segments of DNA that can move from one chromosomal locus to another locus on the same or different chromosomes within one cell. DNA transposons transpose via a DNA intermediate, while retrotransposons transpose via an RNA intermediate. Retrotransposons use its own reverse transcriptase protein to make a copy of its DNA from RNA, and the newly-made DNA is then inserted into a new chromosomal location. In this sense, the life cycle of retrotransposons closely resembles that of HIV virus. DNA transposons exist in both prokaryotes and eukaryotes, while retrotransposons are only found in eukaryotes. Interestingly, retrotransposons make up a significant portion of our genome and may play a role in shaping our genome by providing plasticity for evolution.

Genes are typically considered static entities that stably reside at identical loci of chromosomes in the same species. For the most part, this assumption is correct. However, in the 1940s, while studying the genetic basis of variegated pigmentation pattern of maize (Indian corn) kernels (Figure 1), Barbara McClintock proposed that some genes can change position and move from one locus to another locus on the same or different chromosomes, changing the pigmentation patterns of the kernels. She termed these genetic entities that could move into and back out of genes "controlling elements". When a controlling element moves into a gene required for pigment color formation, it disrupts the function of the gene, thus giving rise to a cell that has no color. McClintock's discovery of transposable sequences was ~30 years ahead of its time and was largely ignored mainly because it contradicted the then accepted concept that genes resided at fixed spots on chromosomes. It was not until the 1970s, when transposons were discovered in bacteria, that the general scientific community became more receptive to the concept of transposons.

Transposons

Transposons exist in all forms of life ranging from simple unicellular prokaryotes (e.g., the gut bacterium *Escherichia coli*) and eukaryotes (e.g., yeast *Saccharomyces cerevisiae*) to more complex multicellular eukaryotes including worms, insects, and mammals. Transposons are defined as segments of DNA that can move from one chromosomal locus to another locus on the same or different chromosomes within one cell, without any sequence homology to the insertion site. Transposons are also known as transposable genetic elements, insertion sequences (IS), mobile elements, jumping genes, and nomadic elements. For clarity, the parental copy of the transposon, located in one site of the host genome, is defined as the donor copy (Figure 2A). The new chromosomal site into which the transposon transposes is termed the target site and the new copy of transposon at the target site is termed the newly transposed copy (Figure 2A).

Almost all transposons acquire their abilities to mobilize themselves from the gene(s) encoded in their DNA such as transposase, integrase, and reverse transcriptase. The bacterial IS*50* element is a simple bacterial DNA transposon. IS*50* elements encode transposase required to carry out the transposition reaction and a repressor protein that represses transposition. IS*50* is flanked by a 9 base pair (bp) inverted repeat sequence required for protein binding and recognition by its transposase. Retro transposons are a type of transposon that makes a new copy of itself by copying or "reverse transcribing" an RNA copy of itself. In this way, the life cycle of retro transposons closely resembles that of retro-viruses. Yeast *Ty1*, a long terminal repeat (LTR) retro transposon, is an example of retro transposon (Figure 3A). *Ty1* contains ~340 bp direct LTR repeat that flanks both ends of the retro transposon and its two open reading frames (ORFs) or genes (Figure 3A). The first ORF encodes *GAG*, a structural protein that packages the *Ty1* RNA into a virus-like particle. The second ORF encodes *POL*, a catalytic protein containing activities such as integrase, protease, and reverse transcriptase required for transposition.

FIGURE 1 The discovery of transposons. By studying genetic entities important for pigment formation in maize, Barbara McClintock discovered maize DNA transposons, which can transpose into and out of genes involved in pigment formation and cause corn kernels to have segments with different colors.

Features of Transposons

The size and orientation of repeat elements and the size of the target site duplication are characteristic of individual types of transposons.

Direct Versus Inverted Repeat Elements

Most transposons are flanked by repeat elements ranging in length from a few to more than 300 bp. The 9 bp near-perfect inverted repeat in IS*50* serves as a binding site for the IS*50*-encoded transposase while in *Ty1*, the 340 bp repeat element is required for proper reverse transcription and integrase binding. Repeat elements can exist in either the direct or inverted orientations (Figure 2B). The orientation of the repeat elements is significant because it affects the type of chromosomal rearrangement product resulting from recombination of the repeat sequences. Interestingly, even those transposons flanked by direct repeats such as LTRs are also flanked by short inverted repeats. That is, each LTR itself contains a terminal inverted repeat sequence – in the case of *Ty1* this sequence is TG … CA. Inverted repeat sequences are also known as palindromes. However, palindromes in the "language" of DNA differ from the English palindromes (Figure 2B).

Target Site Duplication

The target site duplication (TSD) is the short "host" DNA sequence that flanks the transposon (Figure 4). For each individual copy of a transposon, the sequence of the TSD will be different, but typically its length is the same. During transposition, the target site is cleaved on both strands by transposase (or for LTR retro transposons, the integrase) followed by insertion of the transposon, resulting in a transposition intermediate structure that must be repaired by DNA synthesis. These repaired gaps that flank both ends of the transposon are identical in sequence, and form the new TSD. Note that TSD is a direct repeat sequence. The size of the TSD is defined by the distance between the two cleavage sites created by the transposase and is unique to each transposon.

"Cut-and-Paste" versus "Copy-and-Paste" Transposition

During conservative transposition, practiced by many but not all DNA transposons, the transposon excises

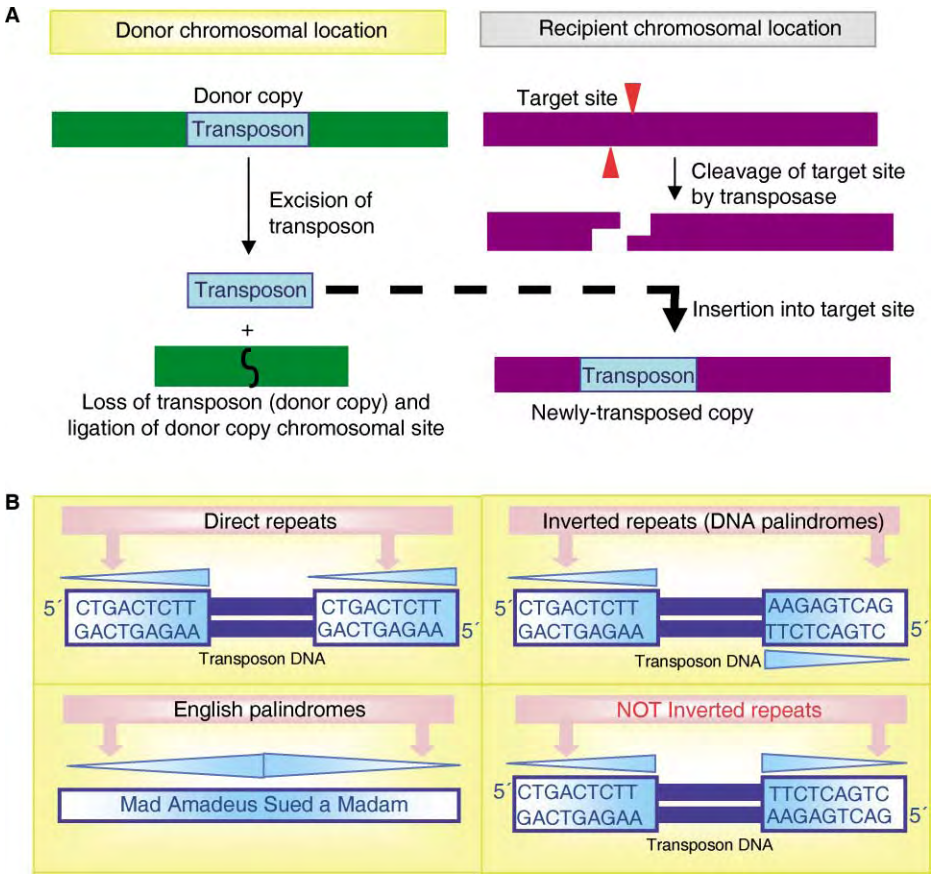

FIGURE 2 (A) Transposition. During transposition, the transposon (donor copy) is first excised from its donor chromosomal location by transposase. Next, transposase cleaves both strands of the DNA at the target site, defined as the chromosomal location into which the transposon will transpose. The transposon inserts itself into the target site, creating a "newly-transposed copy" of the transposon. The yellow background depicts events occurring at the donor chromosomal location while the gray background events occurring at the target site. In this case, the transposon transposes via the "cut-and-paste" mechanism, thus the donor copy of the transposon is lost at the donor chromosomal location. (B) Direct versus inverted repeats. Due to the double-stranded nature of DNA, direct repeats have the same DNA sequence encoded on the same strand, while inverted repeats have the same DNA sequence encoded on opposite strands. Inverted repeats are DNA palindromes, which differ from English palindromes (Reprinted by permission of David R. Godine, from "Mad Amadeus Sued A Madam," by Allan Miller).

itself from the donor site and reinserts itself into the target site. This is also known as "cut-and-paste" transposition. In contrast, retro transposons do not cut themselves out of the donor site. Rather, they copy themselves into RNA (using the cellular RNA polymerase) and then copy that RNA sequence back into DNA using reverse transcriptase. The newly made DNA copy is then inserted into a new site and this process is known as "copy-and-paste" transposition.

RNA- versus DNA-Mediated Transposition: Retro- versus DNA-Transposon

DNA transposons transpose via a DNA intermediate. Transcription of DNA transposons is only needed as a means of expressing the transposon-encoded proteins. In contrast, retro transposons transpose via an RNA intermediate, and transcription of retro transposon is important both for (1) the translation of the retro transposon-encoded proteins and (2) making a full-length RNA copy of its own genome to serve as the template for retro-transposition.

Retrotransposons

In summary, retro transposons differ from DNA transposon mainly because retrotransposons transpose via an RNA intermediate and the "copy-and-paste" mechanism. In addition, retro transposons are only found in eukaryotes including microbes, plants, and animals. Retro transposons can be categorized into long terminal repeats (LTRs) and non-LTR types (Figure 3). They differ primarily in the 5′ and 3′ end structure and in their transposition mechanisms.

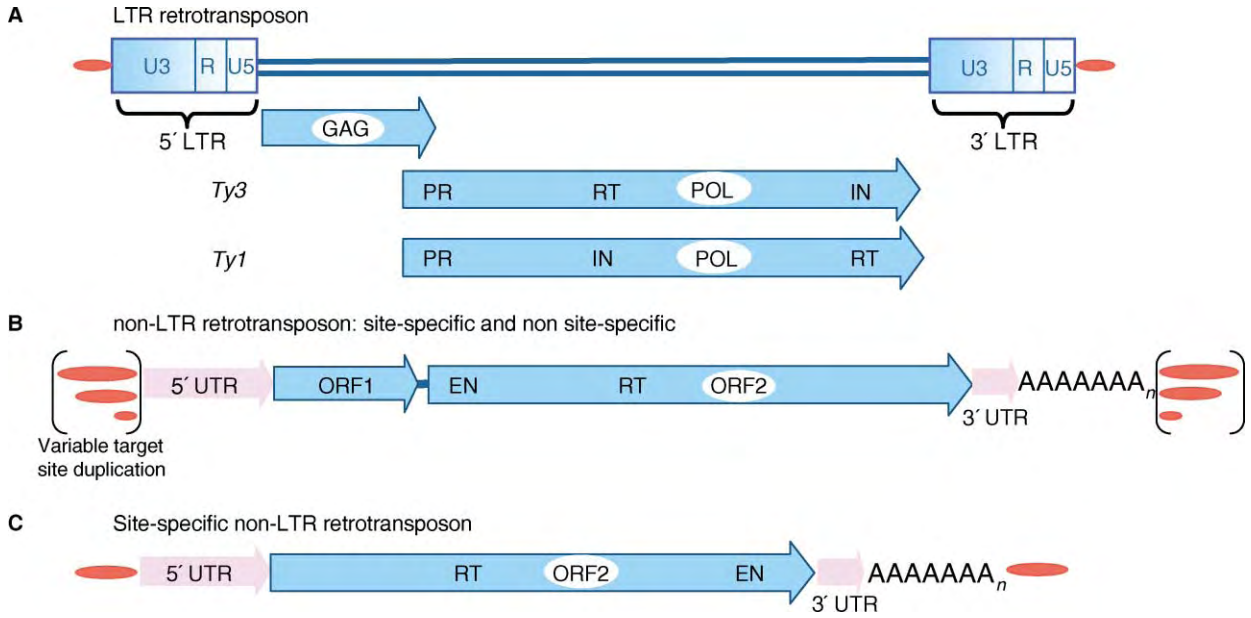

FIGURE 3 Structure of retrotransposons. (A) The long terminal repeat (LTR) of LTR retrotransposon is a few hundred base pair in length and is made up of three distinct segments termed U3, R, and U5. The transposon encodes two ORFs: GAG and POL. In *Ty3*, POL encodes protease (PR), reverse transcriptase (RT) followed by integrase (IN). In *Ty1* POL, the IN domain precedes the RT domain. (B) Non-LTR retrotransposon lacks repeat elements, instead, its 3′ end always ends in stretches of polyA sequences. Non-LTR retrotransposons encode two ORFs: ORF1 and ORF2. ORF1 contains RNA binding activity, while ORF2 encodes for endonuclease (EN), reverse transcriptase (RT) and other unknown functions. (C) Some site-specific non-LTR retrotransposons encode for only one ORF. The red oval denotes the target site duplication, which is variable in length for non-LTR retrotransposons.

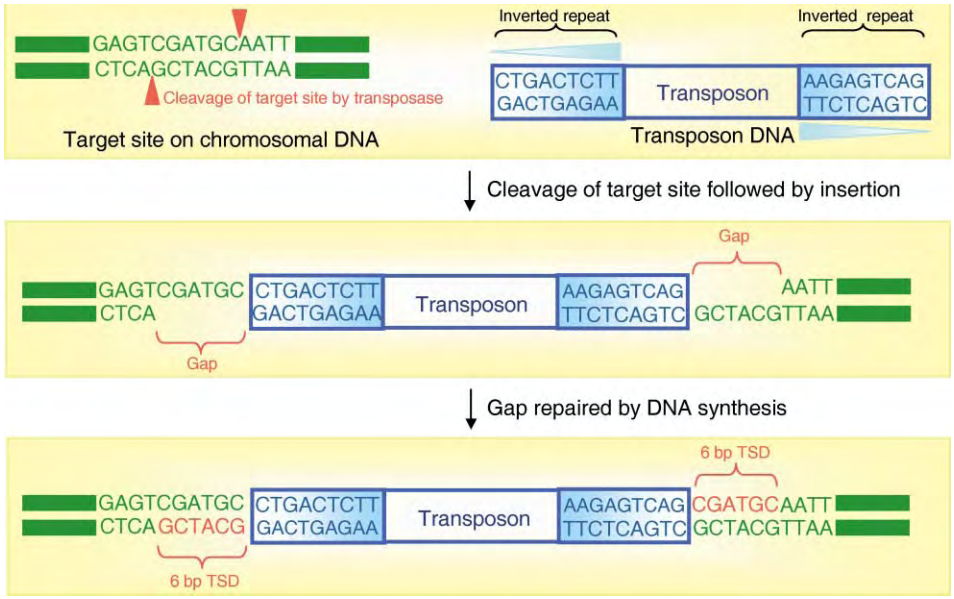

FIGURE 4 The generation of target site duplication (TSD). During transposition, transposase cleaves both strands of the DNA at the target site. The transposon, together with its terminal inverted repeats (arrows) can then insert itself into the new genomic locus. The insertion creates a gap that is usually repaired by DNA synthesis. Once repaired, the 6 bp flanking the transposon is identical in sequence, and is thus termed target site duplication (TSD). The distance between these two cleavage sites defines the size of the TSD. Genomic sequence, transposon and newly synthesized DNA are depicted in green, blue and red respectively.

Long Terminal Repeat (LTR) Retrotransposons

LTR retro transposons resemble retro-viruses such as HIV both in their basic structure and life cycle (Figure 5). Both their DNA structures begin and end with long terminal repeats several hundred bp long and they have similar *Gag* and *Pol* gene structures. The *Pol* gene encodes protease, reverse transcriptase, and integrase (the integrase functions similarly to the transposase of DNA transposons, effecting the reaction outlined in Figure 4). The major difference between LTR retro transposons and retro-viruses is that retro-viruses have a retro-virus-specific *Env* gene, encoding an envelope protein that can bind to receptors on host cells, conferring on retro-viruses the ability to shuttle from cell to cell and thus their infectivity. Retrotransposon life cycles take place within a single host cell, and they are not infectious. Retro-viruses are believed by most scientists to have evolved from the simpler LTR retro transposons.

Non-LTR Retrotransposons

Mammalian genomes contain an additional class of retro transposons that do not have LTRs, suggesting that these retro transposons are quite different from retro-viruses. In human cells for example, the long-interspersed nuclear element (LINE-1 or L1) element is a 6 kilobase (kb) long non-LTR retro transposon. LINE-1 retro transposon consists of a 900 bp 5′ untranslated region (UTR) containing an internal promoter; ORF1, encoding an RNA-binding protein; ORF2, encoding a large protein containing endonuclease, reverse transcriptase and possibly other functions, and a 3′ UTR (Figure 3B). In contrast to LTR retro transposons, the 3′ end of LINE-1 (and similar elements found in other host species) ends in a polyA tail ranging in size from a few nucleotides to ~100 bp long. LINE-1 and related elements lack not only LTRs, but any type of terminal repeats, suggesting a fundamentally different type of insertion mechanisms. Finally, the target site duplication length is variable rather than fixed in LINE-1 retro transposon.

Site-Specific Non-LTR Retrotransposons

Some non-LTR retro transposons such as the insect R1, R2, TRAS1, and SART1 elements are defined as site-specific retro transposons, because they have preferred target sites in the genome. For non-LTR retro transposons, the target site preference is usually defined by a specific host DNA sequence that is repetitive in nature and one that can be recognized and cleaved by the endonuclease encoded by each type of element. R1 and R2 elements target different sequences in ribosomal

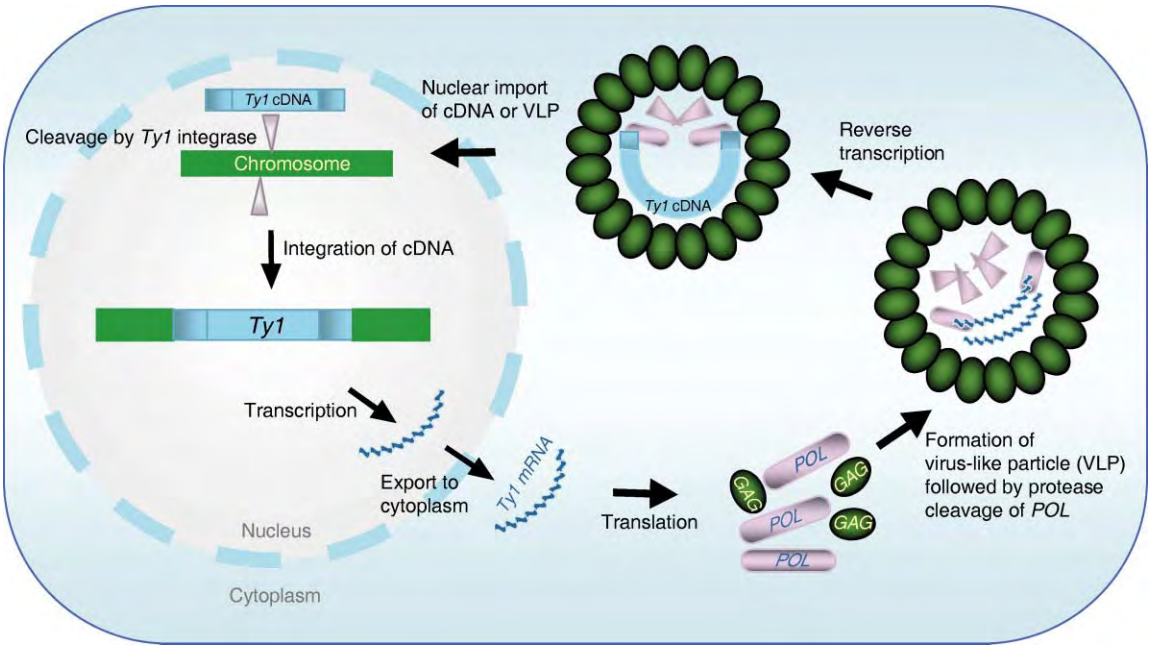

FIGURE 5 The life cycle of *Ty1*. The *Ty1* full length RNA is transcribed in the nucleus and exported to the cytoplasm, which leads to translation of Ty1 protein: *GAG* and *POL*. Full length *Ty1* RNA, together with *GAG* and *Ty1* reverse transcriptase and integrase, is then packaged into a virus-like particle (VLP). *Ty1* protease cleaves *POL* protein into the RT and IN peptides within the VLP. Reverse transcription most likely occurs within the VLP. The newly made *Ty1* cDNA is then imported into the nucleus, and with the help of integrase, which nicks the DNA at the target site, is inserted into a new chromosomal locus to create a new copy of the *Ty1* retrotransposon.

DNA (hundreds of copies per host genome) and TRAS and SART elements target opposite strands of the telomeric repeat sequence (present in hundreds to thousands of copies per host genome). Since the targets are repetitive in nature, such retro transposon insertions are unlikely to harm the host.

Alu Elements

Alu elements are ~300 nucleotide long interspersed elements found only in primate genomes, including the human genome. There are ~1.4 million copies of *Alu* in the human genome, comprising more than 10% of the human genome. Like LINE-1 elements, *Alu*s have 20–100 base pair long polyA tails. *Alu*s elements are too short to encode for proteins required for their transposition. *Alu*s most likely use the transposition machinery of LINE-1 for mobilization, as their 3′ end structures resemble those of LINE-1. Thus, *Alu*s are considered nonautonomous retrotransposons.

Significance

Retrotransposons Make up a Significant Portion of the Human Genome

DNA encodes genetic information required to specify an organism, however, surprisingly, only 2% of the human genome encodes for protein sequences. About 36% of the human genome is comprised of repetitive DNA, of which ~17% are LINE-1 retro transposons and 10% are *Alu* elements. About 8% are LTR elements, and the rest are DNA transposons or unclassified. The genome of multicellular organisms such as primates, fly, and worms contains a very high percentage of noncoding DNA, while the genome of unicellular organism such as yeast and bacteria has a higher percentage of coding DNA. This raises the question of why so much of our genome encodes DNA that does not seem to do anything obvious for the organism.

Are Retrotransposons Selfish DNA or are they One of the Shapers of our Genomes?

Transposon DNAs are often disparaged as junk or selfish DNA since it is not clear what they are doing in our genome. Transposons may have spread simply because they can multiply independently of the host genome. In this view, transposons are purely genomic parasites, selfish DNA that often has detrimental effects on the host. Deleterious insertions are removed from the host species by selection. Elements required for the survival of a species will be selected for. Transposons could play positive evolutionary roles by shaping the genome of host organisms, including our genome, serving as a source of plasticity. LINE-1 sequences sometimes move "chunks" of host genes around in the genome, shuffling gene segments to form new combinations. Their ability to transpose, copy, and rearrange DNA sequences allows the host opportunities to restructure their genome to survive and to adapt to a new environment. There is good evidence that transposons can spread because they confer selective advantages to the cells. Perhaps an organism's ability to evolve and compete effectively directly depends on the flexibility provided by "junk" DNA.

Transposons are Agents of Mutation

If left unchecked, in theory, transposons can colonize an entire genome. To survive, an organism needs to have mechanisms to down-regulate transposition. Full-length human LINE-1 RNA is expressed at very low levels. Worms apparently use RNA interference (RNAi) as one mechanism to defend their genome from transposon invasion by down-regulating transposon RNA expression. Other organisms including mammals may use similar mechanisms. Most of the time, transposons do not cause any detectable phenotypic changes. However, if a transposon inserts itself into coding regions, it can have detrimental effects on the host. There are examples of hemophilia A and other human diseases caused by insertion of LINE-1 sequences into human genes. In *Drosophila*, many spontaneous mutations with visible phenotypes result from insertions of transposable elements.

Glossary

coding DNA DNA sequence that encodes for protein: the exons of mRNA.

host The organism in whose genome a transposon or retro transposon resides.

integrase A protein required for retro-transposition, in order to make a cleavage in the template DNA so that transposon can insert itself into a new chromosomal locus; analogous to transposase in DNA transposons.

noncoding DNA DNA sequence that does not encode for proteins or any functional RNAs. This includes the promoter element, introns and 3′ untranslated region of mRNAs as well as intergenic regions, which can be extensive.

protease An enzyme that recognizes specific amino acid sequences within a protein and cleaves the protein via hydrolysis of the peptide bonds.

retrotransposon Transposon that transposes via an RNA intermediate using reverse transcriptase.

reverse transcriptase A protein required for retro-transposition and retro-virus multiplication, which uses single stranded RNA as

template to make a double stranded DNA termed complementary DNA (cDNA).

RNA interference (RNAi) A mechanism used by eukaryotes to degrade mRNA via a double stranded RNA intermediate.

target site The DNA sequence in the host genome that the transposon inserts into.

target site duplication (TSD) A short host sequence flanking a transposon that was duplicated during the insertion process.

transposition Movement of a transposon to a new, nonhomologous target site.

transposon Segment of DNA that can move from one chromosomal locus to another locus on the same or different chromosomes within one cell without having any sequence homology to the insertion site.

Biography

Jef D. Boeke is a Professor of molecular biology and genetics, Professor of oncology, and Director of the High Throughput Biology Center at the Johns Hopkins University School of Medicine in Baltimore, Maryland. His principal research interests are in retro-transposition, chromatin structure, and yeast genetics and genomics. He holds a Ph.D. from the Rockefeller University and received his postdoctoral training at the Whitehead Institute at the Massachusetts Institute of Technology.

Siew Loon Ooi was a graduate student with Dr. Boeke.

Nuclear Compartmentalization

Kelly P. Smith and Jeanne B. Lawrence
University of Massachusetts Medical School, Worcester, Massachusetts, USA

The eukaryotic nucleus must somehow accommodate diverse tasks ranging from DNA replication to the selective transcription, processing, and transport of different classes of RNA, each requiring its distinct macromolecular machinery. On a gross morphological level the nucleus is composed of a bilayered nuclear envelope, separating the nuclear contents from the cytoplasm, the nucleolus, devoted largely to rRNA metabolism, and the nucleoplasm, which contains the bulk of the genome and the myriad factors essential to its maintenance, replication, and expression. It has now become evident that the nucleoplasm is further differentiated into a number of non-membrane bound "compartments" in which distinct subsets of macromolecules concentrate, presumably for a common function. Despite the significant amount of investigation into these compartments, their functions remain elusive and controversial. Although the list of nucleoplasmic compartments or bodies is incomplete, this article elucidates the current state of knowledge of the most studied of these nucleoplasmic structures, the splicing factor domains, PML nuclear bodies, Cajal bodies and Gemini of Cajal bodies.

Splicing Factor Compartments, "Speckles," or SC35 Domains

In the eukaryotic nucleus, the distribution of pre-mRNA splicing factors is not uniform, but is markedly concentrated at 20–40 sites, with lower levels of factors diffuse throughout the nucleoplasm (Figure 1). Variously referred to as "speckles," "SC35 domains," or "splicing factor compartments (SFCs)," these irregular but discrete domains are most frequently visualized with an antibody directed against the spliceosome assembly factor SC35. Each domain, 0.5–3.0 μm in diameter, corresponds largely, if not entirely, to ultrastructures termed interchromatin granule clusters (IGCs). In addition to spliceosome assembly factor SC35, these domains contain numerous splicing factors and SR proteins, as well as poly(A) RNA, poly(A) RNA-Binding Protein II, hyperphosphorylated RNA polymerase II, lamins, and factors implicated in RNA export. These components are also more diffusely distributed throughout the nucleus. Although the positions of the domains themselves are relatively immobile, they are dynamic structures in that factors within them are in rapid flux dependent upon their phosphorylation state. It is likely that ~150 different proteins localize, at least transiently, to these domains.

As they show relatively little label with uridine incorporation, one hypothesis is that they do not contain mRNA or pre-mRNA but are storage sites of excess splicing components. These components are then "recruited" to nearby active genes, where splicing occurs. However, several active genes have been shown to position directly at the periphery of domains, and RNAs from highly expressed genes have been found within them. The organization of these genes with domains is locus specific and cell-type specific. Evidence now suggests that most, if not all, splicing factor domains associate with numerous genes and contain mRNAs derived from them. The placement of specific genes near these concentrated domains of RNA metabolic factors suggests a specific nuclear organization to the gene relative to the domain which would facilitate the rapid reassembly and use of large RNA metabolic complexes for highly expressed and complex genes (see Figure 2).

PML Nuclear Bodies, ND10

Mammalian nuclei contain 10–30 spherical structures termed PML nuclear bodies (PML NBs) (also termed PODs, ND10 or Kremer bodies) (Figure 3). These 0.3–1 μm bodies were first observed by electron microscopy (EM) and later found to contain the PML protein. Interest in this nuclear body, and nuclear structure in general significantly increased with the discovery that the gene encoding PML is fused to the retinoic acid receptor gene in the t(15;17) translocation of acute promyelocytic leukemia (APL). The resulting PML-retinoic acid receptor fusion protein causes a breakdown of PML domains, a major hallmark of APL. PML bodies are also targeted by many DNA viruses in early infection, and are the site of viral transcription initiation. Subsequently, the viral early proteins localize to and eventually disrupt PML NBs.

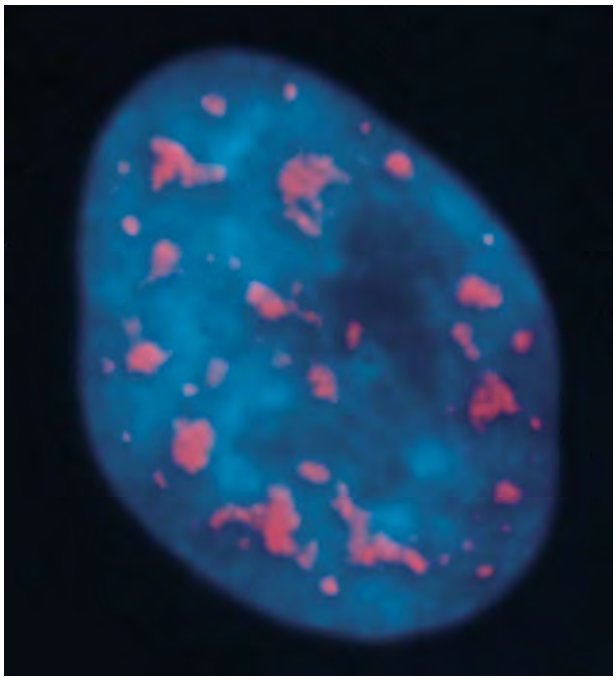

FIGURE 1 Splicing factor rich SC35 domains. Human fibroblast nucleus immunostained using an antibody to the spliceosome assembly factor SC35 (red). The nucleus is stained blue using the DNA stain 4′,6-diamidino-2-phenylindole (DAPI).

FIGURE 3 PML Nuclear Bodies. Human fibroblast nucleus stained with DAPI (blue) has numerous PML nuclear bodies visualized with an anti-PML antibody (red).

The lynchpin of the PML NB is the PML protein, essential for PML body formation. The PML protein occurs in numerous alternatively spliced isoforms and contains a RING finger, B-box coiled coil (RBCC) motif. This domain allows PML to interact with many of the PML NB proteins (Table I), as well as some proteins such as HDAC that are not concentrated in the PML body, some in an isoform specific manner. The PML NB proteins are involved in a number of different cellular processes including tumor suppression, growth control, apoptosis, immune response, and transcription regulation. A few of the over 40 proteins found within PML NBs are present under all conditions, but many others localize under a variety of conditions such as cell cycle and transient overexpression (see Table I). All of these factors are found at lower levels in the nucleoplasm in addition to the concentrations in PML NBs. Some proteins do not colocalize with all PML NBs or in all cell types, suggesting that different PML NBs may have distinct functions.

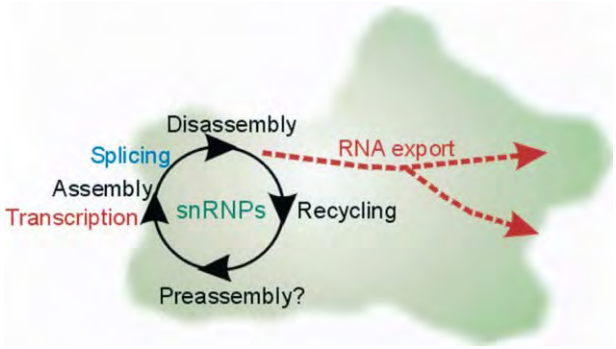

FIGURE 2 SC35 domain model. Domains may function by coupling the completion of mRNA maturation and release for mRNA export with the recycling/preassembly of factors. Because the RNA metabolic machinery requires interaction of such a large number of different factors, their concentration at a site would facilitate recycling and a rapid rate of reuse for expression of adjacent genes. Adapted from Johnson, C. V., Primorac, D., McKinstry, M., McNeil, J., Rowe, D., and Lawrence, J. B., (2000). Tracking COL1A1 RNA in osteogenesis imperfecta. Splice-defective transcripts initiate transport from the gene but are retained within the SC35 domain. *J. Cell Biol.* **150**, 417–431 with permission.

The sheer variety of proteins found in PML bodies has made attribution of a single function almost impossible. The dynamic and diverse nature of these bodies has led to the theory that PML NBs are "nuclear depots" in which numerous proteins are recruited and/or released in response to stimuli such as viral attack or other cell stress. Additionally, PML NBs could be sites for degradation of some nuclear proteins. However, PML NBs may also play a more specific, though indirect, role in transcription, by sequestration and/or modification of transcription factors. Recently, reports have asserted that PML NBs can associate with specific genes such as the p53 locus TP53. Other evidence suggests that, contrary to earlier reports, PML NBs contain newly synthesized RNA. These results are suggestive of a more direct role for PML NBs in gene expression.

TABLE I

Partial List of PML Nuclear Body Components

Component	Function	PML interaction[a]	Conditional association[b]
PML	Essential for NB formation; transcription activator? repressor?	Y	
Transcription			
pRB	Tumor suppressor, transcription factor	Y	Y
p53	Tumor suppressor, transcription factor	Y	Y
CBP	Histone acetylase	Y	Y
Daxx	Transcription regulation, apoptosis	Y	
Sp 100	Transcription factor		
Sp 140	Transcription factor		Y
Sp 110	Transcription factor		
Translation initiation			
eIF-4	Recruits ribosomes to mRNA	Y	Y
INT-6	Promotes ribosomes binding to mRNA		Y
Protein modification			
SUMO-1	Protein modifier	Y	
HAUSP	De-ubiquitination		Y
Ubiquitin	Protein modifier, not with all PML NBs		
Immune response			
PA28	Activates immunoproteasome		
ISG20	Exonuclease, antiviral activity		Y
DNA repair			
BLM	DNA helicase, genome stability		

[a] Factors known to interact with the PML protein.
[b] Factors shown to interact with PML NBs under certain conditions such as cell cycle or interferon treatment.

Cajal (Coiled) Bodies and Gems

First described in 1903 as nucleolar accessory bodies, the Cajal (coiled) bodies (CBs) are usually seen as roughly spherical 0.1–2.0 μM structures numbering one to five per nucleus (see Figure 4A), varying in number and size during the cell cycle and in different cell types. The Cajal bodies are not seen in all cells or tissues, but are especially prominent in highly proliferative cells such as cancer cells or metabolically active cells like neurons. The neuronal CBs, as originally identified, are not round nucleoplasmic bodies, but are found capping the nucleolus as seen in Figure 4B. This localization illustrates the close association between the nucleolus

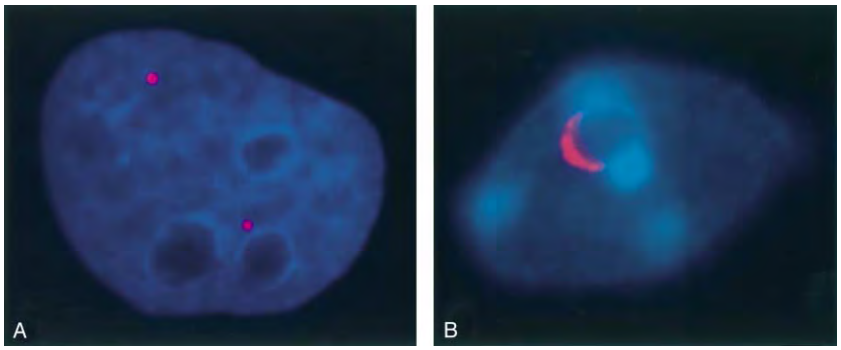

FIGURE 4 Heterogeneity of Cajal Bodies. Cajal bodies, seen using an anti-coilin antibody (red) can appear as round nucleoplasmic bodies in highly proliferative cultured cells like the cervical carcinoma cell HeLa (A) or can be found to cap the nucleolus in mouse brain neurons (B). DNA in nuclei is stained with DAPI.

and the CBs. Whether the CBs capping the nucleolus are functionally distinct from the nucleoplasmic bodies most often seen in cultured cells is unknown.

The coilin protein was first identified using human autoimmune serum and has become the marker most often used to visualize CBs. Although relatively little is known about the function of coilin, studies have indicated that it is the link between CBs and the nucleolus. In addition to coilin, numerous snRNAs and proteins of both nuclear and nucleolar origin are enriched in the CBs. These include factors involved in transcription and/or processing of mRNAs, snRNAs, histone mRNAs, and rRNA (see Table II). CBs have been shown to spatially associate with several U snRNA and histone gene loci, all of which have unusual 3′ processing, suggesting that CBs could have relationship to expression and nuclear metabolism of specific types of RNAs. The CBs contain U7RNA involved in histone RNA processing and have been shown to contain pre-U2RNA, implicating them in snRNA modification or transport. More recent studies have found small Cajal body-specific RNAs (scaRNAs) which catalyze the methylation and pseudouridylation of snRNAs within Cajal bodies.

Like PML bodies, recent work has linked loss of CBs to leukemia. ELL is an RNA polymerase II (pol II) transcriptional elongation factor that interacts with a protein called EAF1. Both ELL and EAF1 are components of Cajal bodies. In acute myeloid leukemia, the (11;19) (q23;p13.1) translocation results in the formation of a chimeric MLL-ELL fusion protein. This fusion mislocalizes ELL and causes the disruption of the Cajal bodies in leukemic cells. The role of ELL in CB formation is unknown.

TABLE II

Reported Coiled Body Components

Component	Function
p80-coilin	Shuttling protein? Interacts with many CB components
mRNA splicing factors	
snRNAs	
U1, U2, U4, U5, U6	General pre-mRNA splicing
U11, U12	Splicing of minor class of introns
U7	3′ processing of histone pre-mRNAs
Sm core proteins	pre-mRNA splicing
U2AF	Splice site selection
SART3/p110	snRNP reassembly after splicing
snRNA modification	
scaRNAs: U85 U93	Modification of spliceosomal snRNAs
Nucleolar factors	
Fibrillarin	rRNA processing, pre-rRNA modification
Nopp 140	Transcription regulation? Nucleolus-cytoplasmic shuttling
Ribosomal protein S6	Ribosome function
Gar1p	pre-rRNA processing
NAP 57	rRNA processing, ribosome assembly
snoRNAs	
U3	Processing of pre-18S ribosomal RNA
U8	Cleavage of pre-rRNA to 5.8S and 28S rRNAs
Transcription factors	
ELL, EAF1	RNA pol II transcription elongation factors
cdk7, cyclin H, MAT1, p62	Subunits of general transcription factor TFIIH
p220(NPAT)	Histone gene transcription factor
PTF	snRNA transcription factor

SMN "Gems" and CBs

Modification of snRNAs may not be the sole function of CBs. The disease Spinal Muscular Atrophy results from deletion of a gene encoding the "survival of *m*otor *n*euron" (SMN) protein. This protein is consistently enriched in foci termed SMN gemini of Cajal bodies (gems), since in the cell line in which they were discovered, gems were often very closely associated or even coincident with CBs (see Figure 5A). However, subsequently in many cultured cells studied, SMN and coilin staining appear to be coincident in CBs (Figure 5B). The SMN protein complexes with a number of other factors, termed gemins. Currently there are six identified geminus, 2–7, in this complex. The SMN complex has been implicated in snRNP assembly, supporting the idea that gems and CBs may be involved in the recycling and/or biogenesis of splicing factors. An extension of this hypothesis is that CBs are sites of preassembly of pols I, II, and III transcription/RNA processing complexes or "transcriptosomes."

The Compartmentalized Nucleus

While this article has focused on some of the most-studied non-nucleolar compartments in the nucleus, there is evidence for the existence of numerous other compartments about which little is known. These include the perinucleolar compartment, Sam68 bodies, cleavage bodies, paraspeckles, and OPT domains. In addition to these compartments, some portions of the genome can form dense, transcriptionally inert regions in the nucleus, often referred to as the heterochromatic compartment. While the nuclear compartments described here all have different components and seemingly different functions, they all do seem to have certain traits in common. First, they are all dynamic structures, varying in composition in different conditions. Additionally, they all appear to associate with specific gene loci. Lastly, PML bodies, CBs, and splicing

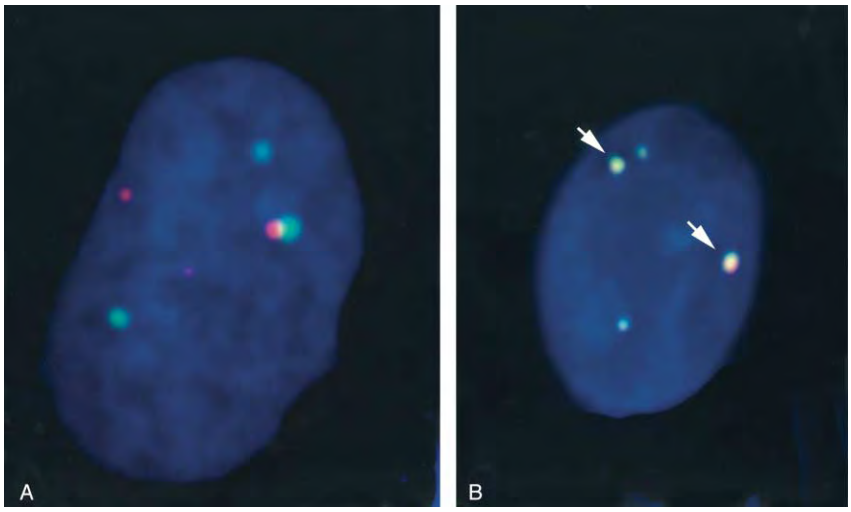

FIGURE 5 SMN gems differ in their association with CBs. By dual staining with anti-SMN antibody (red) and anti-coilin antibody (green), we see that SMN gems are separate from, but often associated with, CBs in some cells such as HeLa (A), but are most often found to be completely coincident with CBs (arrows) as seen in the breast cancer cell HCC1937 (B). Nuclei are stained with DAPI.

factor compartments appear to associate with one another. These commonalities reveal a compartmentalized, functionally integrated nucleus.

Glossary

Cajal bodies Spherical nuclear bodies (1–5/nucleus) enriched in mRNA, rRNA, and snRNA processing factors.

nuclear compartment A non-membrane-bound subnuclear structure in which a variety of factors accumulate to facilitate specific nuclear processes.

nucleus A membrane-bound cellular structure containing DNA which controls the cell's growth, metabolism, and replication.

PML nuclear bodies Spherical nuclear structures (10–30/nucleus) rich in a variety of factors, many of which are involved in transcription regulation.

SC35 domains 20–40 irregular "speckles" in the nucleus in which numerous factors required for mRNA metabolism accumulate.

SMN gems Nuclear bodies enriched in survival of motor neurons (SMN) protein and other factors involved in snRNP assembly. Gems often associate or coincide with Cajal bodies.

Dr. Lawrence is a pioneer in the development of fluorescence *in situ* hybridization technology for detection of individual genes and nuclear RNAs.

Nuclear Envelope and Lamins

Bryce M. Paschal
University of Virginia, Charlottesville, Virginia, USA

The nucleus is a prominent cytological feature of eukaryotic cells that is enclosed within a specialized double membrane termed the nuclear envelope. Because of this arrangement, the nuclear envelope provides a physical boundary that separates nuclear processes such as DNA replication and RNA synthesis from cytoplasmic processes such as protein synthesis. Other important functions of the nuclear envelope are mediated by macromolecular structures that are physically integrated into the membrane. Nuclear pore complexes, which are elaborate channels that span the double membrane, provide the passages for transport between the nucleus and the cytoplasm. The nuclear lamina, a meshwork of proteins just beneath the membrane, acts as a scaffold that contributes to nuclear architecture and to the regulation of gene expression. The importance of the nuclear lamina in human biology is underscored by the discoveries of genetic disorders that are caused by mutations in lamina proteins.

Structure of the Nuclear Envelope

The first descriptions of the nuclear envelope were provided by 19th century biologists, notably Fleming, who used light microscopy to examine the nuclei of plants and protozoa. A century later, the application of electron microscopy to the analysis of a variety of intracellular organelles revealed the unique structure and organization of the nuclear envelope. The nuclear envelope consists of two membranes, an inner membrane and an outer membrane, each of which is a bilayer of lipids and proteins (Figure 1). The intermembrane space, or lumen, is a site of calcium storage in the cell, and special channels in the membrane facilitate calcium release and re-uptake upon physiological stimulation. Since the outer nuclear membrane is continuous with the rough endoplasmic reticulum membrane, there is continuity between the lumen of the nuclear envelope and the rough endoplasmic reticulum.

Structure of the Nuclear Lamina

In 1966, Fawcett published a seminal electron microscopy study showing the presence of a "fibrous lamina on the inner aspect of the nuclear envelope" in several cell types. The organization of the lamina as a meshwork of 10 nm diameter filaments adjacent to the inner nuclear membrane was later revealed in samples prepared from frog oocyte nuclei (Figure 1).

Composition of the Lamina

The development of biochemical procedures for isolating nuclei from cells and for preparing the lamina-nuclear pore complex fraction from nuclei set the stage for identifying proteins that comprise the lamina.

Lamins

The major proteins of the nuclear lamina, termed lamins, are members of the intermediate filament protein superfamily. The molecular weights of lamins range from 60–70 kDa depending on the isoform, and all lamins have related primary and secondary structures. The amino- and carboxyl-terminal domains of lamins are globular, the latter encoding a nuclear localization signal. Like other members of the intermediate filament superfamily, lamin proteins contain a central rod domain composed of four α-helical segments that mediate coiled-coil interactions resulting in the formation of lamin dimers (Figure 2). Lamin dimers assemble into tetramers, which, in turn, assemble into 10 nm diameter filaments that comprise the nuclear lamina. The approximately orthogonal arrangement of lamin filaments observed by electron microscopy implies the presence of proteins that mediate inter-filament crosslinks, however, the proteins and interactions that establish and maintain this higher order structure have not yet been identified.

Lamin Genes

Lamins are classified as A-type and B-type. The B-type lamins are expressed in most cell types, whereas A-type lamins, which include lamin C, are generally expressed in differentiated tissues. There is a single lamin A gene (*LMNA*) in mammals that, through alternative

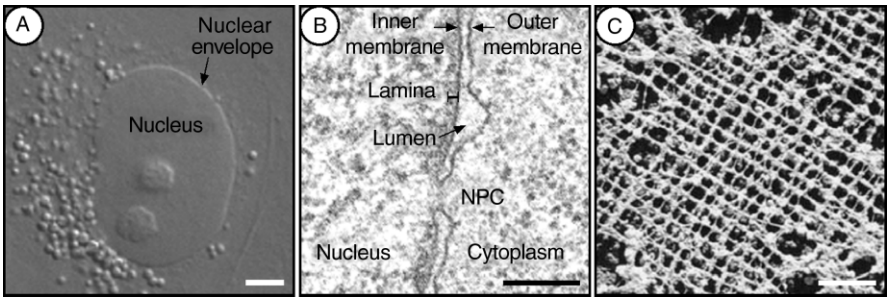

FIGURE 1 The nuclear membrane viewed by light and electron microscopy. (A) Differential interference contrast microscopy of a cell showing the nuclear envelope (scale bar, 5 μm). (B) Thin section electron microscopy showing a small region of the nuclear envelope and associated structures (scale bar, 0.2 μm). (C) Metal-shadowed nuclear lamina from a frog oocyte viewed by electron microscopy (scale bar, 0.5 μm). (Part (C) is modified from Aebi, U., Cohn, J., Buhle, L., and Gerace, L. (1986). The nuclear lamina is a meshwork of intermediate-type filaments. *Nature* **323**, 560–564.

splicing, produces transcripts for two lamin A isoforms and two lamin C isoforms. There are two lamin B genes (*LMNB1* and *LMNB2*) that together encode three lamin isoforms. The phylogenetic distribution of lamins extends to invertebrates, but lamins are absent from plants and fungi.

Lamin-Associated Proteins

A group of integral membrane proteins, which are unique to the inner nuclear membrane, bind directly to nuclear lamins and play critical roles in modulating lamina structure and function. This group includes LAP2, Emerin, Man1, and LBR. These proteins are anchored in the inner nuclear membrane by hydrophobic, membrane-spanning segments, while the rest of the protein projects into the nucleoplasm, where it contacts the lamina. Lamin-associated proteins also interact with DNA-binding proteins such as BAF and GCL that mediate chromatin-attachment to the nuclear membrane.

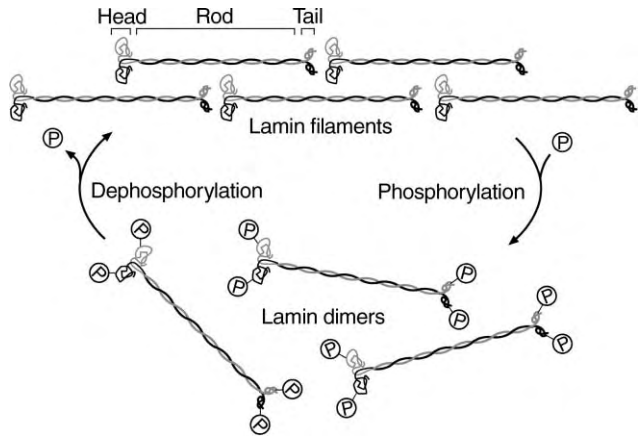

FIGURE 2 Structure of the nuclear lamina is regulated by phosphorylation. Lamin filaments undergo phosphorylation by kinases in mitosis, causing disassembly into lamin dimers. At the end of mitosis, the lamins are dephosphorylated by phosphatases, which return the lamins to an assembly competent state.

Functions of the Lamina

The nuclear lamina performs both structural and regulatory functions. These functions are not mutually exclusive, since alterations in structure can change the capacity of the nuclear lamina to regulate nuclear functions. Characterization of the regulatory functions of the nuclear lamina is a relatively recent area of investigation, and this knowledge base should expand dramatically in the next several years.

Nuclear Envelope Assembly after Mitosis

Disassembly of the nuclear envelope and lamina occurs at prometaphase, a period of the mitotic cell cycle that precedes chromosome segregation. The nuclear envelope fragments into membrane vesicles, and the lamin filaments are disassembled into lamin dimers. Near the end of mitosis in late anaphase, the nuclear envelope-derived vesicles and lamin proteins are reassembled around the chromosomes of the two new daughter cells. The reassembly pathway involves multiple steps, beginning with the binding of lamins and vesicles to the surface of chromosomes. The vesicles then fuse to generate membranes. The incorporation of lamins into the lamina continues after membrane formation by virtue of nuclear import of lamins through newly formed nuclear pore complexes.

Nuclear Size

Experimental manipulation of the nuclear reassembly pathway has shown that lamins and lamina-associated proteins are necessary for the several-fold increase in volume of the nucleus during the cell cycle. The lamina is, therefore, a critical regulator of nuclear size.

Nuclear Shape and Rigidity

The lamina forms a cage-like structure within the nucleus and is tethered to the inner nuclear membrane. As such, the lamina plays a major role in defining nuclear shape. A striking example of how lamins determine the shape of the nucleus is lamin B3, a lamin isoform that was shown by Furukawa and Hotta in 1993 to be responsible for the unusual hook-shape of nuclei in spermatocytes. The lamina also provides rigidity that resists deformation and aids in restoration of shape following deformation. Nuclei from the nematode *Caenorhabditis elegans,* rendered lamin-deficient, show little resistance to deformation, and a failure to restore nuclear shape.

Positioning of Nuclear Pore Complexes

Nuclear pore complexes span both the inner and outer nuclear membranes. Integration of nuclear pore complexes into the membrane is mediated by GP210, an integral membrane protein. The relative spacing of nuclear pore complexes in the two-dimensional plane of the nuclear envelope is maintained by the nuclear lamina. B-type lamins mediate this spacing through direct interactions with nuclear pore complexes. Loss of this functionality results in a failure to maintain the proper distribution of nuclear pore complexes in the nuclear envelope.

Regulation of Gene Expression

Lamins can have a positive or negative influence on gene expression, depending on the context. Lamins and lamina-associated proteins bind to chromatin, resulting in the attachment of a subset of chromatin to the inner nuclear membrane which can be observed by microscopy. Because there is a strong correlation between localization of chromatin at the nuclear periphery and gene silencing, the nuclear lamina has historically been viewed as a scaffold for anchoring transcriptionally inactive heterochromatin. Lamin B is highly concentrated at the inner nuclear membrane, and, together with several DNA-binding proteins that repress transcription, mediates the negative influence on transcription at the nuclear periphery. In contrast, it has been shown that lamin A can turn on expression of muscle-specific genes, a clear indication of positive effects on transcription. Lamin A is found at both the inner nuclear membrane and throughout the nucleoplasm, and the latter pool is thought to promote transcription. Thus, whether lamins influence transcription positively or negatively is dependent on the particular lamin protein, and its subnuclear distribution.

Regulation of DNA Replication

Lamins play an important role in DNA replication by facilitating the recruitment of proteins needed for initiation of replication. The original link between lamins and DNA replication was made by Newport and colleagues in 1990, using a system that reconstitutes nuclear assembly *in vitro*. Depletion of lamin B from the system resulted in small nuclei that failed to initiate DNA synthesis. Subsequent experiments have implicated lamina-associated proteins in DNA replication as well.

Posttranslational Modification of the Lamina

The lamin proteins are subject to modifications that profoundly affect function.

Phosphorylation

Gerace and Blobel showed in 1980 that phosphorylation is used as a molecular switch to control the assembly properties of lamins. Disassembly of lamin filaments at prometaphase is driven by lamin phosphorylation (Figure 2). Lamin disassembly occurs specifically at prometaphase because the kinase that mediates lamin phosphorylation is activated during the mitotic phase of the cell cycle. The phosphorylated lamins are subsequently dephosphorylated by phosphatases, rendering them competent for reassembly into filaments in late anaphase and telophase.

Isoprenylation

A cysteine-containing motif in the carboxyl terminus of lamin B, called a CaaX box, is the site for attachment of an isoprenyl group. This lipid moiety inserts into the inner nuclear membrane, and mediates the stable membrane attachment of lamin B. During mitosis, lamin B remains stably associated with nuclear-envelope-derived vesicles. The isoprenylated carboxyl terminus is cleaved from Lamin A, and Lamin C protein lacks this modification altogether because the CaaX box is not encoded in Lamin C transcripts.

Proteolysis

Lamins are regulated by proteolysis in two functionally distinct pathways. After translation, the carboxyl-terminal 18 amino acids of lamin A are removed by proteolytic cleavage. This cleavage reaction removes the site of isoprenylation and the capacity of lamin A to associate directly with membranes.

During apoptosis, lamins are cleaved by a group of proteases called caspases. Lamin cleavage is a critical step in disassembly and fragmentation of the nucleus, and is commonly used as a biochemical indicator of apoptosis.

Lamins in Human Disease

Certain mutations in lamin A, or in the lamin-associated protein Emerin, cause Emery-Dreifuss muscular dystrophy. Patients display tendon contractures, degeneration of skeletal muscle, and electrical conduction problems in cardiac muscle. Lamin A mutations are also linked to familial partial lipodystrophy, which causes partial loss of fat tissue and late-onset insulin-resistant diabetes. These and other human disorders caused by mutations in the lamin A gene are referred to as laminopathies.

The clinical severity of a particular lamin A mutation often varies, even among members of a given family. This indicates that penetrance of the phenotype can be highly dependent on the genetic background. A major unanswered question is how laminopathies are manifest in specific tissues since lamins are expressed in all cell types. Currently there are two hypotheses addressing the tissue-specific basis of laminopathies. The structural hypothesis proposes that muscular dystrophies result from fragile nuclei that are susceptible to muscle contraction-induced physical damage. The gene expression hypothesis is based on the concept that lamin deficiencies alter nuclear architecture in a manner that changes the pattern of gene expression.

Biography

Bryce M. Paschal is an Associate Professor of Biochemistry and Molecular Genetics in the Center for Cell Signaling at the University of Virginia in Charlottesville. His principal research interests are the mechanisms of transport through the nuclear pore complex. He holds a Ph.D. from the University of Massachusetts Medical School and received his postdoctoral training at The Scripps Research Institute in La Jolla, California. Using biochemical and cell biological approaches, Dr. Paschal has identified several proteins that play major roles in intracellular transport.

Nuclear Factor kappaB

Thomas D. Gilmore
Boston University, Boston, Massachusetts, USA

Nuclear factor kappaB (NFκB) is a family of structurally related DNA-binding proteins that act as transcription factors to regulate the expression of a wide variety of genes involved in many key cellular and organismal processes. The discovery of mammalian NFκB is generally attributed to Ranjan Sen and David Baltimore, who were studying the regulation of expression of a specific immunoglobulin gene; however, it is now clear that earlier researchers studying a viral oncoprotein (v-Rel) and a protein (Dorsal) required for the establishment of *Drosophila* embryonic polarity were also studying an NFκB activity. This entry focuses primarily on the vertebrate NFκB system, although most of the discussion is also applicable to the NFκB system in insects. NFκB activity is controlled by a multicomponent signal transduction pathway, such that in most cells. NFκB is inactive until any of several inducers initiates the signaling pathway that ultimately activates NFκB as a nuclear, DNA-binding protein. Misregulation of NFκB activity has been implicated in a number of human diseases, including several chronic inflammatory diseases and cancer, and the NFκB pathway is modulated by or used by several viruses as part of their pathology or replication. As such, the NFκB pathway is the subject of intense focus for pharmacological intervention.

NFκB Proteins and Protein Structure

The nuclear factor kappaB (NFκB) family is comprised of several evolutionarily conserved proteins that are related through a domain, usually called the Rel homology domain (RHD), which has sequences required for DNA binding, dimerization, and nuclear localization (Figure 1A). In *Drosophila*, there are three known NFκB proteins (Dorsal, Dif, and Relish), whereas in vertebrates, the NFκB protein family is comprised of five proteins: p50/p105, p52/p100, c-Rel, RelA (also called p65), and RelB. There is also an avian retroviral oncoprotein, v-Rel, that is a member of this family. All NFκB proteins contain the ~300 amino acid RHD towards their N termini; however, NFκB proteins can be subdivided into two distinct groups based on sequences C terminal to the RHD. One group (including p50/p105, p52/p100, and Relish) contains C-terminal sequences that fold back to inhibit the RHD, and thus these C-terminal sequences must be removed to release the active DNA-binding protein (i.e., p50 or p52 from the precursors p105 and p100, respectively). A second group (c-Rel, RelA, RelB, Dorsal, Dif) contains C-terminal sequences that are not cleaved and that activate transcription.

NFκB proteins bind to 9–10 bp DNA sites, usually called κB sites, located in the regulatory regions of many cellular and viral promoters. To bind DNA, NFκB proteins must form dimers. These dimers can, with few exceptions, be any combination of homodimer or heterodimer, although the most common NFκB dimer in many cells is a p50–RelA dimer (Figure 1B). The affinity of the various NFκB subunits for one another and the affinity of the various dimers for specific target DNA sites can vary greatly. These considerations provide an array of diversity in the NFκB dimers that are found in different cells, in the DNA sites that can be recognized by different NFκB dimers, and in the genes (and consequently cellular responses) that these dimers regulate.

Regulation of NFκB Activity

In most cells, NFκB is present in the cytoplasm in an inactive state, due to interaction with a family of inhibitor proteins, termed inhibitor of κB (IκB) proteins. IκB proteins include IκBα, IκBβ, IκBϵ, Bcl-3, and the C-terminal sequences of the NFκB precursor proteins p105 and p100. Through a series of ~30 amino acid repeats (called ankyrin repeats), a single IκB protein binds directly to sequences in the RHD of an NFκB dimer. Binding of an IκB to NFκB inhibits the activity of the dimer in two ways: it causes NFκB to be in the cytoplasm and it blocks NFκB DNA binding.

A variety of inducers (Table I), including many cytokines, cell stress, and viral or bacterial infections, can activate NFκB. In almost all cases, NFκB activity is induced through activation of a cellular kinase complex called IκB kinase (IKK). IKK is composed of three subunits: two related kinases (IKKα and IKKβ) and a

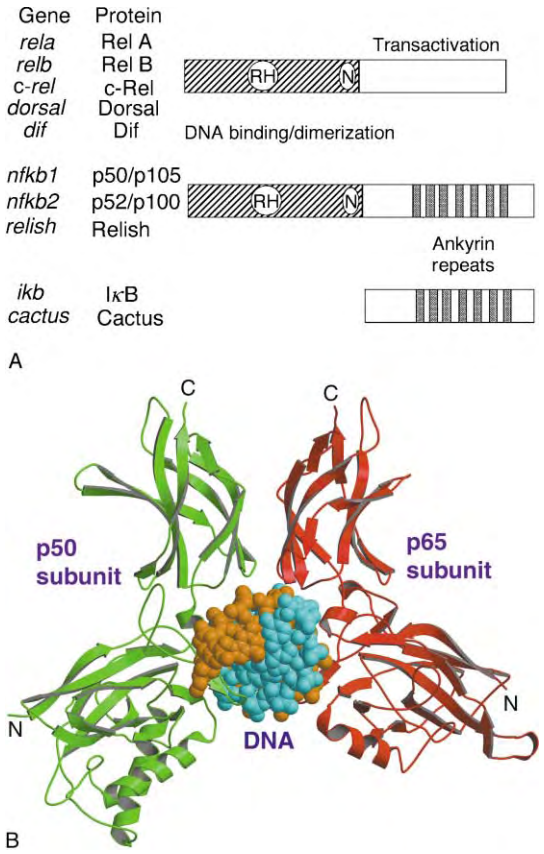

FIGURE 1 NFκB proteins. (A) Shown are the generalized structures, protein names, and genes encoding the two classes of NFκB proteins and the IκB proteins. sensing or scaffold protein called IKKγ. Activation of the IKK complex generally requires phosphorylation of residues in the activation loop of the IKKα or IKKβ kinase, and probably also phosphorylation of IKKγ. Activated IKK then phosphorylates the IκB protein, which in turn signals the IκB sequences for degradation by the ubiquitin–proteasome pathway. The liberated NFκB complex can then enter the nucleus, bind to DNA, and activate specific target gene expression. In many cases, activation of NFκB is transient (perhaps lasting no more than 30 min) primarily because one of the target genes for NFκB is the gene encoding IκB. Therefore, newly synthesized IκB can cause NFκB to be resequestered in an inactive form in the cytoplasm, thus returning the pathway to its original state.

Although the overall pathway of activation is similar (as in Figure 2), there are actually two distinct pathways to activation of NFκB, depending on the nature of the IκB protein and IKK involved. In one pathway, a separate IκB molecule, such as IκBα bound to p50–RelA, is phosphorylated by the IKKβ subunit, which leads to the complete proteolysis of IκBα. In a second activation pathway involving a complex such as p100–RelB, a C-terminal site in p100 is phosphorylated by IKKα, which then leads to the partial proteolysis of the C-terminal ankyrin repeat sequences of p100, ultimately yielding an active p52–RelB dimer, which can also translocate to the nucleus to regulate gene expression.

However, a variety of recent evidence suggests that the NFκB pathway is regulated by mechanisms in addition to interaction with IκB proteins. For example, NFκB proteins can undergo posttranslational modifications

TABLE I

Some Inducers of NFκB Activity

General category	Examples
Bacteria	*Salmonella*, *Staphylococcus*, Lipopolysaccharide
Viruses	HTLV-1, Epstein–Barr virus, hepatitis B virus
Cytokines	Interleukins, tumor necrosis factor
Oxidative stress	Hydrogen peroxide, reperfusion ischemia
Growth factors/ hormones	Platelet-derived growth factor, epidermal growth factor, insulin, transforming growth factor
Drugs	Various chemotherapeutic agents

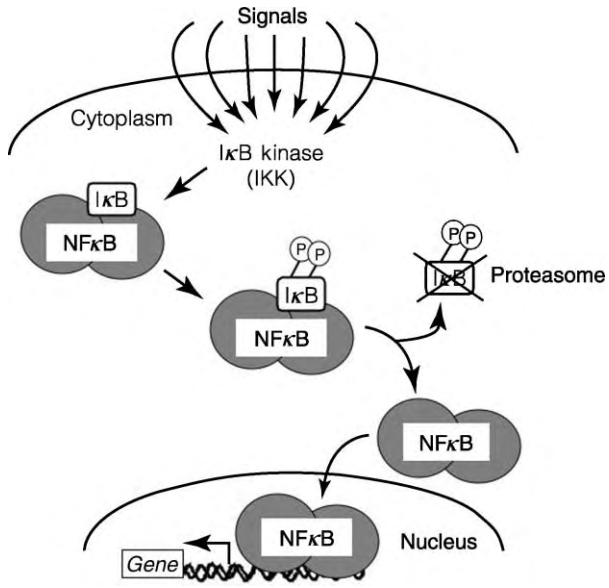

FIGURE 2 The NFκB signal transduction pathway. Under most circumstances, NFκB dimers (e.g., p50–RelA) are located in the cytoplasm of cells bound to inhibitory IκB proteins. Upon receiving an inducing signal, an IκB kinase (IKK) is activated. Active IKK phosphorylates IκB, and phosphorylated IκB then serves as a substrate for the ubiquitin–proteasome degradation pathway. Free NFκB can then enter the nucleus to increase or decrease specific target gene transcription. The system is eventually returned to its resting state through an auto-regulatory system, in that NFκB turns on expression of the gene encoding IκB, and newly synthesized IκB then resequesters NFκB in the cytoplasm.

(such as phosphorylation and acetylation) that affect their activity, they can interact with a variety of other proteins (including many other transcription factors), and the IKK proteins may also have effects on chromatin-binding proteins to affect gene expression from κB site-containing promoters.

Genes and Biological Processes Regulated by NFκB

Normal Biological Roles for NFκB

There are over 300 genes whose transcription is known to be regulated by NFκB activity, and these genes are involved in a multitude of biological processes (Table II). However, a variety of genetic and cellular studies have established that one of the key roles of NFκB is in regulating the innate immune response. In *Drosophila*, the activities of Dorsal, Dif, and Relish are induced to enter the nucleus by bacterial and fungal pathogens. These fly NFκB proteins then bind upstream and increase the expression of a family of genes called cecropins, which encode antifungal and antibacterial peptides. In mammals, it is also clear that many genes that encode antibacterial peptides, cytokines, and interferons are rapidly induced after infection with various pathogens. Moreover, mice in which individual genes for c-Rel, RelB, p50, and p52 are disrupted ("knockout mice") have severe defects in T- and B-cell-mediated immune responses. For example, c-*rel* knockout mice have B cells with greatly reduced survival and proliferation in response to antigen stimulation.

NFκB proteins are, however, also involved in the control of several other genes and processes that are not directly related to immunity. These include certain developmental processes, apoptosis, cell growth, and cell stress. In terms of development, NFκB activity (as directed by Dorsal) is required for the proper establishment of dorsal-ventral polarity in the early *Drosophila* embryo. In mammals, NFκB activity appears to be involved in proper limb development, due to the regulation of a gene called *Twist*.

NFκB transcription factors also regulate cell survival in many contexts, either by promoting or, more often, by inhibiting apoptosis. For example, RelA is required to protect liver cells from apoptosis induced by tumor necrosis factor, and RelA knockout mice die embryonically due to massive liver degeneration. Thus, the genes encoding several inhibitors of apoptosis are activated by NFκB.

TABLE II

Some Biological Processes and Relevant Genes Regulated by NFκB

Biological process	Relevant NFκB target genes
Angiogenesis	Vascular endothelial growth factor (VEGF)
Apoptosis	Bcl-X1, Bfl/A1, Bcl-2, IAP, TRAF, Fas
Cell adhesion	ICAM-1, VCAM-1
Cell growth	Cyclin D1, c-Myc
Stress	Cyclooxygenase, superoxide dismutase, nitric oxide synthetase
Innate immunity	Interleukins, interferon, tumor necrosis factor
Viral promoters	HIV-1, cytomegalovirus

NFκB and Disease

Aberrant NFκB activity has been implicated in several human diseases (Table III), most notably certain cancers and chronic inflammatory diseases, such as inflammatory bowel disease, asthma, and arthritis.

Many cancer cells have constitutively active, nuclear NFκB activity. In certain B-cell lymphomas, notably diffuse large B-cell lymphomas and Hodgkin's lymphomas, NFκB activity is dysregulated due to either amplification of the c-*rel* gene or mutations that inactivate the gene encoding Iκ B. Furthermore, several oncogenic human viruses, such as Epstein-Barr virus (lymphomas, nasopharyngeal carcinomas), HTLV-1 (T-cell leukemias), and Hepatitis B virus (liver cancer), encode proteins that activate NFκB. However, in many other cancers one finds chronic nuclear NFκB activity, which is usually made up of p50–RelA dimers, in the apparent absence of mutations in the NFκB signaling pathway or associated viral infection. That increased NFκB activity is important for the growth and survival of several cancers is emphasized by studies showing that inhibition of NFκB activity often either causes the tumor cells to die (undergo apoptosis) or to become more sensitive to apoptosis-inducing agents.

Because NFκB controls the expression of many cytokines, it is also consistently active in many situations involving acute or chronic inflammation. Moreover, in several animal model systems inhibition of NFκB activity can reduce inflammation. Furthermore, mice with knockouts in the genes encoding p50 or c-Rel are resistant to experimentally induced arthritis.

TABLE III

Some Diseases Associated with Chronic NFκB Activation

Arthritis
Asthma
Cancer
Diabetes
Inflammatory bowel disease
Ischemia/reperfusion damage
Sepsis

Pharmacological Regulation of NFκB Activity

Because of the role played by NFκB in inflammatory diseases and cancer, it has received much attention as a molecular target for pharmacological intervention. As a multicomponent pathway, NFκB activation can be inhibited at a variety of levels, including activation of IKK, IKK-mediated phosphorylation of IκB, ubiquitination and proteasome-mediated degradation of IκB, nuclear translocation of NFκB, and DNA-binding and transactivation by NFκB. Indeed, NFκB inhibitors that act at each of these steps have been described (partial list in Table IV). Nevertheless, to date, most research effort has focused on identifying NFκB inhibitors that target the IKK complex, due to its central role in controlling the NFκB pathway and to successes in identifying specific kinase inhibitors in other systems.

Several natural products with anticancer or anti-inflammatory activities have been shown to inhibit activation of NFκB. Among many others, these natural NFκB inhibitors include gold compounds (anti-arthritis), green tea (anticancer), curcumin (anticancer, anti-inflammation), and various plant extracts (anti-inflammation). In addition, some commonly used anti-inflammatory compounds, such as glucocorticoids, ibuprofen, and aspirin, have been reported to have anti-NFκB activity in experimental model systems. However, in these cases, it is not clear if their biological effects in people are exerted through inhibition of NFκB, due to the fact that doses lower than those required to inhibit NFκB are often still effective in reducing inflammation in humans.

Because NFκB is constitutively active in many cancers, clinical trials are underway with several compounds known to inhibit NFκB. Early clinical trials have reported promising results in the use of a small-molecule inhibitor of the proteasome for the treatment of multiple myeloma, an NFκB-dependent B-cell cancer. Such compounds inhibit activation of NFκB by blocking proteasome-mediated degradation of IκB.

TABLE IV

Some Inhibitors of NFκB Signaling

Inhibitor	Molecular target
Aspirin (high doses)	IKK
Curcumin	IKK
Glucocorticoids	Re1A
Green tea compounds	IKK
PS-341	Proteasome
Sulindac	IKK

Glossary

apoptosis A programmed cell death pathway that is used by an organism to eliminate unwanted cells or maintain organ size.

cytokines Factors that regulate the growth and activity of blood cells and lymphocytes.

proteasome A cellular complex composed of several proteases that degrades ubiquitinated proteins.

protein kinase An enzyme that can add a phosphate group onto specific residues in a target protein, which then affects the activity of the target protein.

signal transduction A molecular process by which a signal (often an extracellular compound) effects a cellular response. Often this is a multicomponent step-wise intracellular pathway that involves binding of a ligand to a cell-surface receptor, which initiates a cascade of cytoplasmic enzymatic activities that ultimately leads to the activation of a transcription factor that then regulates the expression of a biologically-relevant set of target genes.

transcription factor A protein or protein complex that binds to specific DNA sequences to regulate (increase or decrease) the rate of transcription of a gene.

ubiquitin A small (~8.6 kDa) polypeptide chain that can be conjugated to substrate proteins, which often targets them for degradation by the proteasome.

Thomas D. Gilmore is a Professor in the Department of Biology at Boston University. His general research area is in the molecular basis of cancer. He holds a Ph.D. from the University of California (Berkeley) and received postdoctoral training at the University of Wisconsin (Madison). He has authored many research papers and review articles on the role of Rel/NF-κB transcription factors in leukemia and lymphoma, and recently his laboratory was the first to show that human c-Rel has oncogenic activity.

Nuclear Genes in Mitochondrial Function and Biogenesis

Alexander Tzagoloff
Columbia University, New York, USA

Carol L. Dieckmann
University of Arizona, Tucson, Arizona, USA

Only a small fraction of the protein constituents of mitochondria are encoded in the small vestigial genome of the organelle. Most of the genes governing the biogenesis of mitochondria reside in the chromosomal DNA of the nucleus. Referred to as *PET* genes, they represent a sizeable fraction of the total genetic information in the nucleus. *PET* genes code for the enzymes making up the different metabolic pathways housed in mitochondria, for the substrate and protein transport systems, and for the transcriptional and translational machineries involved in expression and regulation of mitochondrial genes.

Historical Background

All life depends on ATP, the universal currency of biological energy. The chemical energy inherent in the structure of this molecule is used to support a large variety of phenomena including chemical, osmotic, electrical, and mechanical work. Most of the ATP in eukaryotic organisms is supplied by the mitochondrion, a complex cellular organelle composed of two membranes (outer and inner) and two soluble compartments (intermembrane space and matrix). Biogenesis of mitochondria occurs by replenishment and addition of newly synthesized proteins and phospholipids to the preexisting organelle. In dividing cells there is a net increase of mitochondrial mass, which is distributed among the progeny. This process is aided by the ability of mitochondria to undergo fusion and fission. Mitochondria, therefore, are not synthesized *de novo* but rather serve as a template for their own faithful replication. The genetic determinants of mitochondria are located in two physically separate compartments of the cell. Most of the information is provided by the *PET* genes of the nucleus, but a small number of genes present in mitochondrial DNA (mtDNA) also play an important role.

The discovery of an extranuclear genetic element (*rho*) in yeast by Boris Ephrussi, and the later demonstration by Gottfried Schatz that this factor corresponds to a unique DNA present in mitochondria, were the foundations for much of the subsequent work aimed at understanding the function of this genome. Despite large variability in the organization, mode of expression, and gene compositions of mtDNA among different members of the plant and animal kingdoms, some general statements can be made nonetheless. More than 100 different mtDNAs have so far been sequenced. In all instances, at least some components of the mitochondrial translational apparatus, such as the genes for the endogenous ribosomal RNAs and tRNAs, are encoded in mtDNA. Another important attribute of this genetic system is that it codes for a small number of mitochondrial proteins that are important for the respiratory and ATP-generating capacities of the organelle. In most organisms, the protein-coding genes of mtDNA specify several subunits of cytochrome oxidase, cytochrome *b*, and one or more subunits of the proton-translocating ATP synthetase/hydrolase. The *rho* zero mutants lacking this set of genes produce mitochondria that are defective in respiration and oxidative phosphorylation because they lack the genes for catalytically important components of the respiratory chain, ATP synthetase, and the ribosomal RNA and tRNAs needed for translation of the endogenous mRNAs.

A much larger share of the information essential for maintaining the structural and functional integrity of mitochondria is contributed by *PET* genes, which are located in the chromosomal DNA of the nucleus.

Origin of Nuclear Gene Products with Functions in Mitochondria

The endosymbiont hypothesis, first proposed by Lynn Margulis in 1968, was a landmark advance in our thinking about how cells evolved in response to major changes in their environment. According to this

hypothesis, many organelles of modern-day eukaryotic cells, including mitochondria and chloroplasts, are stripped down products of what originally were free-living bacteria. In the case of mitochondria, a nucleated cell dependent on glycolysis as its sole source of ATP was invaded by a bacterium with an aerobic mode of energy metabolism. Such a union was advantageous to the host and became fixed during evolution. There is compelling evidence to support the bacterial origin of subcellular structures that inhabit eukaryotic cells. Most notable is the presence in mitochondria and chloroplasts of autonomously replicating genomes, and of all the enzymatic machinery needed to transcribe the organellar genes and translate the resulting RNAs into the encoded protein products. Significantly, the transcriptional and translational machineries of mitochondria and chloroplasts are more closely related to their bacterial counterparts than to those operating in the cytoplasm of eukaryotic cells.

The extent to which the mitochondrial genome contributes towards the propagation of the organelle has been severely reduced due to a continual transfer of genetic information to the host's nuclear DNA. Today, the existence of mitochondria relies in large measure on the expression of gene products encoded in nuclear DNA. The loss of mitochondrial autonomy is clearly evident from the properties of cells that have been depleted of mtDNA. Such genome-less variants termed *rho* zero mutants have been created in yeast and mammalian (e.g., human) cells. Despite the complete absence of mitochondrial DNA, *rho* zero mutants contain subcellular structures with the characteristic morphology and most of the metabolic pathways of mitochondria. These observations point to the nonessentiality of mtDNA for the perpetuity of mitochondria, but do not minimize the importance of this genome for their functional competence.

Number of Mitochondrially Related Nuclear Genes

The number of distinct proteins in mitochondria is still not known precisely but based on currently available data of the unicellular yeast, *Saccharomyces cerevisiae*, a reasonable estimate is in the range of 700–800. This corresponds to ~10–12% of the different proteins known to exist in this organism. Of course, this number will vary in more complex eukaryotes, where depending on their tissue of origin, mitochondria may have specialized and have less complex functions. For example, in mammals, mitochondria of organs like heart and muscle have simpler metabolic profiles than those of liver and consequently are simpler in their protein composition.

Yeast as a Model for Mitochondrial Studies

For practical reasons, *S. cerevisiae* has become an important model for the study of *PET* genes. A vast arsenal of genetic and biochemical tools is directly applicable to the analysis of mitochondria in this organism. Also available are the complete sequences of the 16 nuclear chromosomes and of mtDNA. Finally, because of its status as a facultative anaerobe, this yeast is able to tolerate most mutations that impair mitochondrial function as long as it is supplied with a fermentable source of carbon and energy.

Most of what we presently know about *PET* genes stems from three different sources. An important body of information has been derived from traditional studies of the intermediary metabolism carried out by mitochondria. In some instances, such studies have predated the discovery of mitochondria as the cellular repository of the pathways in question. Genetic analysis has played an equally important role. Respiratory defective mutants of yeast have been instrumental in defining many nuclear genes that impinge on all aspects of mitochondrial function and biogenesis. More recently, the high-throughput proteomic approach has further augmented the list of mitochondrially related gene products, whose functions are yet to be understood.

Gene Functions

Based on the phenotype of the respective mutants, *PET* genes can be either essential or nonessential. Nonessential genes, which make up the larger class, are defined by *pet* mutants. Such strains are viable, but because of their genetic lesions are unable to produce ATP by means of oxidative phosphorylation. The products of *PET* genes have functions that are related either directly or indirectly to mitochondrial metabolism, but not to the continuity of mitochondria as a structural compartment of the cell. The second, less abundant, class consists of essential genes needed for the survival of the cell. Their products provide functions relevant to the structural integrity of mitochondria or to some essential aspect of metabolism. Mutations in the latter prevent growth on both fermentable and nonfermentable substrates.

Nonessential *PET* Genes

These genes encompass a wide range of mitochondrial functions. The most important, from a quantitative point of view, are involved in the expression of the products encoded in mtDNA (Figure 1). They consist of proteins that function in replication of mtDNA, transcription and processing of mitochondrial RNA.

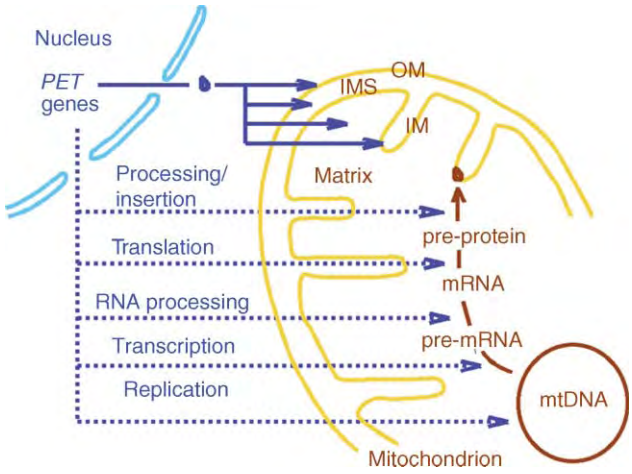

FIGURE 1 Dependence of mitochondrial gene expression on products of *PET* genes. The dashed blue arrows show some of the functions contributed by nuclear DNA for expression of the mitochondrially encoded subunits of the ATPase and respiratory enzymes. In yeast, the pre-mRNAs can be multi-genic transcripts that are matured by excision of intronic sequences and endonucleolytic cleavages. Some proteins are synthesized as precursors (pre-protein) with amino-terminal sequences that are removed by specific proteases. The solid blue arrows denote *PET* gene products targeted to the outer membrane (OM), intermembrane space (IMS), inner membrane (IM), and internal matrix compartment.

They also code for all except one of the mitochondrial ribosomal proteins, as well as most of the tRNA synthetases and translation initiation, elongation, and termination factors. A second important group of genes code for proteins that catalyze most of mitochondrially based metabolism. This includes enzymes of the tricarboxylic acid cycle (TCA cycle), fatty acid metabolism, some aspects of amino acid biosynthesis, and a number of other pathways needed for the synthesis of important cofactors such as hemes A and B, coenzyme Q, and lipoic acid.

The ATP synthetase/hydrolase as well as the enzymes making up the respiratory chain (Figure 2) are all hetero-oligomeric proteins, with more than a dozen different subunit polypeptides in most cases. Assembly of the subunits into the final holoenzymes is a complex process that requires the assistance of nuclearly encoded factors. Some of the chaperones act by facilitating a topologically correct insertion of specific subunits into the inner membrane, by preventing nonproductive interactions of hydrophobic proteins, or by still other unknown mechanisms. Because these chaperones target specific subunits, they represent a substantial fraction of the total number of mitochondrial proteins. For example, some dozen nuclear mutants have been reported to be cytochrome oxidase deficient due to mutations in proteins that affect late events in assembly of this single enzyme. Finally, many *PET* genes, coding for novel proteins still lack functions that can be assigned at this time.

Essential *PET* Genes

The highly regulated metabolism of eukaryotic cells depends on the sequestration of the enzymes making up the various pathways in their appropriate compartments. Proteins translated in the cytoplasm but destined to function in one of the internal compartments of mitochondria are imported and sorted by means of complex

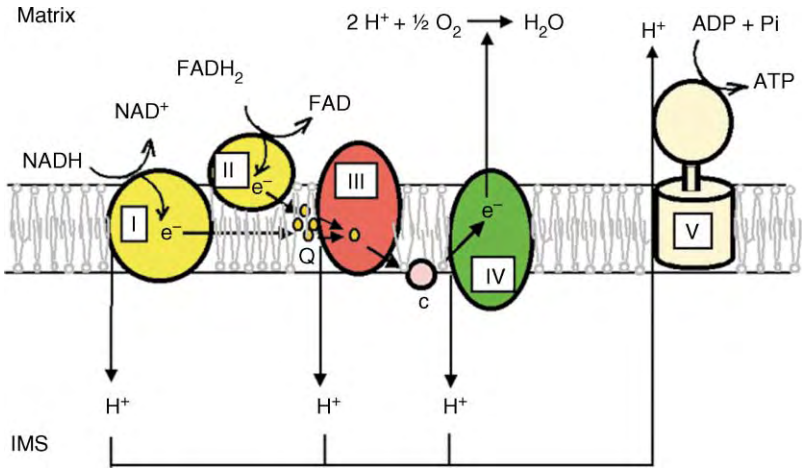

FIGURE 2 Schematic representation of the respiratory complexes and ATP synthetase in the mitochondrial inner membrane. The four complexes of the respiratory chain are: NADH-coenzyme Q reductase or complex I (yellow), succinate-coenzyme Q reductase or complex II (yellow), coenzyme QH_2-cytochrome *c* reductase or complex III (red), and cytochrome *c* oxidase or complex IV (green). Coenzyme Q is denoted by the small orange circles and cytochrome *c* by the pink circle. The ATP synthetase/hydrolase or complex V is shown with the F_1 ATPase protruding into the matrix compartment. In addition to catalyzing the transfer of electrons from NADH and $FADH_2$ to oxygen, three of the complexes promote the vectorial transfer of protons from the matrix to the intermembrane space (IMS). Protons are recycled by the ATP synthetase during synthesis of ATP from ADP and inorganic phosphate.

machines such as the TOM and TIM translocases of the outer and inner membranes, respectively. Mutations in components of either of these protein transport systems are lethal to the cell for several reasons. An immediate effect of the transport defect is a mislocalization of proteins in the cytoplasm. This abrogates the accretion of newly synthesized material by mitochondria, resulting in their eventual disappearance.

Mitochondria house proteins that function in pathways essential for the overall economy of the cell. For example, certain steps of heme B biosynthesis occur in mitochondria. Since heme B is a prosthetic group of enzymes (e.g., P450 hydroxylases) other than those involved in respiration, cells unable to produce heme B are not viable. This also applies to certain enzymes of amino acid biosynthesis located in mitochondria. In animals, carbamoyl synthetase and ornithine transcarbamylase, two important enzymes of arginine biosynthesis, catalyze their respective reactions in the mitochondrial matrix.

In certain instances, nuclear genes may code for proteins that are apportioned in the cytoplasm and mitochondria. This is true for some tRNA modification enzymes and for aminoacyl-tRNA synthetases. In yeast, six mitochondrial aminoacyl-tRNA synthetases are expressed from nuclear genes that also code for the same cytoplasmic enzymes. Therefore, mutations in these essential genes result in cell lethality.

Regulation

Many *PET* genes of yeast are regulated at the level of transcription by oxygen and carbon source. Oxygen stimulates the synthesis of heme in mitochondria mainly at later steps of the pathway catalyzed by oxygenases. Heme activates the binding of the Hap1 transcriptional activator to the upstream activation sites of some genes for respiratory chain proteins such as cytochrome *c*, thereby activating their transcription. Glucose has the opposite effect. It suppresses transcription of genes involved in alternative fuel usage by means of a complex regulatory pathway called catabolite repression. In the absence of glucose, repression is relieved and transcription of glucose-responsive genes is enhanced by the Hap2/3/4/5 transcriptional activator complex.

Mitochondrial gene expression is regulated primarily at the posttranscriptional level by products of *PET* genes. Mitochondrial RNA polymerase recognizes a simple promoter and there is little regulation of its activity except that it is more abundant in the absence of glucose and the presence of oxygen. Most mitochondrial genes are transcribed as long multigenic RNAs. Points of regulation include processing of 5′ and 3′ ends of RNA to the mature length, excision of introns and RNA stability. Initiation of translation is regulated by factors that attract ribosomes to the correct internal translational start sites of mitochondrial mRNAs. Posttranslation modification and assembly of the constituent subunits of the respiratory and ATP synthetase complexes also depend on the intervention of factors encoded by *PET* genes subject to these regulatory systems.

Human Disorders

A growing list of human pathologies has been related to mitochondrial defects and the responsible mutations mapped to RNA and protein-coding genes of mtDNA. Such mutations manifest a wide range of clinical phenotypes including encephalomyopathies, cardiomyopathy, deafness, diabetes, optic neuropathy, and dystonia. Similar presentations are elicited by mutations in nuclear DNA that affect mitochondrial metabolism either directly through lesions in the structural genes for enzymes of the TCA cycle, fatty acid oxidation, and mtDNA integrity; or indirectly by interfering with metabolite and protein import, assembly of respiratory chain complexes, metal homeostasis, and protein turnover. In view of their central role in oxidative metabolism, the list of currently known mitochondrially related diseases will undoubtedly be increased in the future.

Glossary

ATP synthetase/hydrolase An enzyme of the inner membrane able to form ATP from ADP and inorganic phosphate by utilizing the energy of the proton gradient generated during the oxidation reactions catalyzed by the respiratory chain complexes. It can also form a proton gradient by hydrolyzing ATP to ADP and inorganic phosphate.

chaperones Proteins that promote the folding or unfolding of proteins. In the present context they also facilitate association of subunit polypeptides into hetero-oligomeric proteins.

eukaryotes Organisms with cells having a nucleus enclosed by a membrane.

organelle A structure or membrane enclosed compartment of a cell.

***pet* mutants** Viable mutants able to derive ATP from glycolysis but not from oxidative phosphorylation.

proteome Term used to denote all of the proteins of an organism or compartment of the cell.

respiration In the biochemical sense, the process by which the electrons and protons extracted from reduced fuels such as carbohydrates, fats, and proteins are transferred to oxygen.

***rho* zero mutants** Mutants devoid of mitochondrial DNA.

TIM complex An organized assembly of proteins that mediates the translocation of proteins from the TOM complex to the inner membrane or matrix of mitochondria.

TOM complex An organized assembly of proteins that mediates the translocation of a protein from the cytoplasm to the intermembrane space of mitochondria.

Biography

Alexander Tzagoloff is a Professor in the Department of Biological Sciences at Columbia University. He received a Ph.D. from Columbia University and postdoctoral training at the Enzyme Institute of the University of Wisconsin. He has used genetics and biochemical approaches to study the roles of mitochondrial and nuclear genes in biogenesis of yeast mitochondria.

Carol L. Dieckmann is a Professor in the Department of Biochemistry and Molecular Biophysics at the University of Arizona. She received a Ph.D. from the University of California, San Diego, and did postdoctoral training at Columbia University. She has used a combination of genetics, molecular biology, and biochemistry to study the regulation of mitochondrial gene expression.

Nuclear Organization, Chromatin Structure, and Gene Silencing

Lori L. Wallrath, John R. Danzer, Oya Yazgan and Pamela K. Geyer
University of Iowa, Iowa City, Iowa, USA

Gene silencing is the process whereby a gene is inactivated due to its chromosomal position. Chromosomal rearrangements that move a gene from a transcriptionally permissive location to a transcriptionally nonpermissive location result in gene silencing. This loss of gene expression is not due to a mutation in a gene itself, but due to the placement of a gene into a chromatin environment that is not favorable for transcription. Chromatin packaging influences whether a chromosomal location will support transcription or result in gene silencing. Eukaryotic genomes are packaged into two types of chromatin, euchromatin and heterochromatin. Euchromatin is represented by single copy, gene-rich DNA sequences located between centromeres and telomeres. These regions are packaged with acetylated histones that foster gene expression. In contrast, heterochromatin is represented by repetitive, gene-poor DNA sequences located near centromeres and telomeres. These regions are packaged with hypoacetylated histones and can cause gene silencing.

The regulation of gene expression involves complex interactions between DNA sequences and protein factors. One mechanism for regulating access of transcription factors to DNA is through chromatin packaging. Double-stranded DNA is wound twice around a histone octamer, forming the fundamental packaging unit, the nucleosome. Nucleosomal DNA is further folded into higher-order chromatin structures that differentiate euchromatin from heterochromatin. A second mechanism for regulating access of transcription factors to DNA involves the spatial positioning of genes within the nucleus. Increasing evidence supports the notion that the nucleus is not a homogenous mixture of DNA and proteins, but is a highly organized environment. For example, chromosome labeling techniques show that certain chromosomes reproducibly localize to specific positions within the nucleus, termed chromosome territories (Figure 1). Thus, a given gene might have a specific address within the nucleus.

Nuclear zones are superimposed on chromosome territories (Figure 1). A zone is defined as a region of the nucleus that is enriched in a particular class of transcription factors. There are two types of zones, those enriched for silencing factors that do not support transcription (inactive zones), and those enriched for activating factors that do support transcription (active zones). Entire chromosomes can be located within a zone, such as the case for the inactive X chromosome (Barr body) of mammalian females that localizes to an inactive zone along the nuclear periphery. Alternatively, smaller regions along a chromosome can attract transcription factors and form a local zone (Figure 1). In addition, regions of similar transcription activity on different chromosomes can come together to form a zone. Thus, regulation of gene expression can occur at many levels involving the local chromatin environment, chromosomal territories, and the nuclear zones.

Establishing a Zone

Zones are established by increasing the local concentrations of transcriptional regulatory factors within an area of the nucleus. This nonuniform distribution of factors occurs by mechanisms involving protein–protein and protein–DNA interactions. As an example, heterochromatin protein 1 (HP1) can direct silent chromatin into the inactive zone at the nuclear periphery. The amino terminal chromo domain of HP1 interacts with a histone modification that is enriched in heterochromatin and the carboxy chromo shadow domain of HP1 interacts with a component of the nuclear envelope. These protein–protein interactions promote the accumulation of heterochromatin and HP1 at the nuclear periphery. The role of protein–DNA interactions is illustrated by studies of yeast telomeres. Repetitive DNA sequences found at yeast telomeres attract the DNA-binding protein Rap1. This protein interacts with Sir proteins that are involved in gene silencing. Through this interaction, the concentration of Sir proteins increases at the nuclear periphery relative to the interior of the nucleus. The concentration gradient of Sir proteins within the nucleus can be "sensed" by reporter transgenes containing Sir-responsive DNA sequences. When such a reporter transgene is

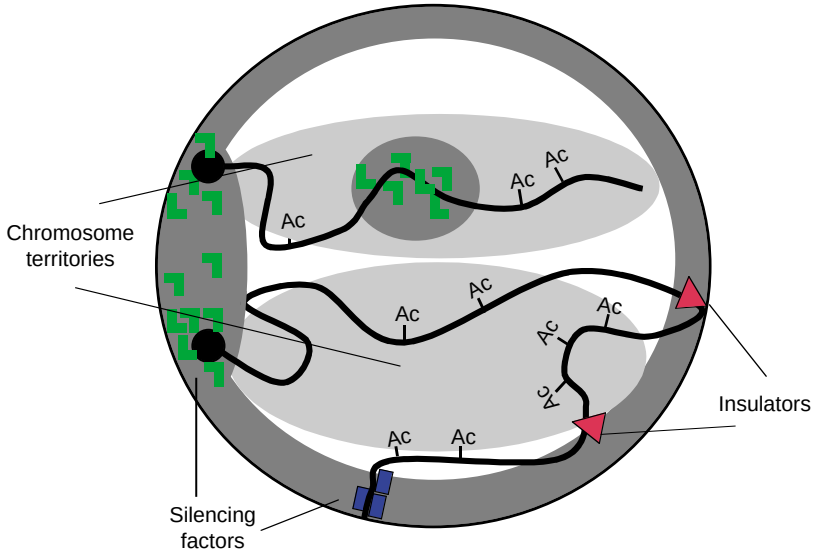

FIGURE 1 Diagram of organization within the nucleus. A nucleus is depicted with chromosome territories (light gray) and silencing zones (dark gray). Histone acetylation (Ac) is shown over active chromatin. Hypoacetylation is associated with inactive chromatin, such as that found at centromeres (black circle) and telomeres. Small domains within a chromosome can acquire properties similar to heterochromatin and form a silencing zone (shaded circle). Silencing factors (green and blue shapes) are involved in chromatin compaction, gene silencing, and tethering to the nuclear periphery. Insulator elements (red triangles) partition chromosomes into transcriptonally related domains and assist in organizing chromatin into zones.

placed at positions close to the telomere, gene silencing is strong. When the same transgene is positioned further from the telomere, gene silencing is weak. Overexpression of Sir proteins produces silencing at internal sites, presumably due to increased levels of Sir proteins within the interior of the nucleus. These studies demonstrate that gene silencing can be modulated by the position of a gene within the nucleus, as well as, the local concentration of regulatory factors.

Organizing DNA into Zones

What mechanisms ensure that chromosome domains remain independent? Specialized DNA elements called insulators may be responsible for maintaining domain autonomy. These DNA elements, 0.2–3 kb in length, associate with specific proteins that limit the scope of regulatory interactions. An insulator located between an enhancer and promoter blocks activated gene expression. Insulator elements flanking a gene "insulate" it from neighboring positive and negative regulatory elements. Several models have been proposed to explain the mechanism of insulator action. One model states that attachment of insulators to the nuclear envelope could result in the formation of looped domains that compartmentalize gene activity (Figure 1). Physical associations with architectural components of the nucleus could serve to anchor chromosomal sites leading to spatial positioning of insulated domains within a zone.

Changes in Gene Expression Correlate with Shifting Zones

The nucleus is a highly dynamic environment in which protein factors and chromosomal domains can change positions within seconds. This mobility allows gene expression to be regulated by shifting zones. Studies on the expression and localization of lymphocyte specific genes demonstrate this point. A set of lymphocyte-specific genes in mice associate with Ikaros, a zinc-finger DNA-binding protein that also associates with centric heterochromatin. When these genes are silenced they localize to discrete foci within B-cell nuclei that correspond to the location of centromeres. Expression of these genes correlates with movement away from the centric foci. A direct role for Ikaros in this process was demonstrated by examining cells that had low levels of Ikaros. In such cells, these genes do not colocalize with centromeres when silenced. These data suggest that Ikaros is not required for silencing but plays a critical role in directing silent genes to an inactive zone. However, it appears that in these examples movement into an inactive zone is not the cause of gene silencing. Therefore, positioning a gene within a silent zone might be a consequence of silencing or assist in the maintenance of the silent state.

Additional studies correlating nuclear position with gene expression have focused on the *brown* gene in the fruit fly *Drosophila*. The *brown* gene is normally positioned at a site distant from centric heterochromatin.

A mutant allele designated *brown*^{Dominant} contains an insertion of a large block of heterochromatin (>1 Mb) in the coding region. Heterochromatin proteins associate with the insertion and are involved in positioning *brown*^{Dominant} near centric heterochromatin. Surprisingly, the wild-type brown allele also becomes silenced. This occurs due to a process called "*trans*-silencing" that results from homologous pairing along the length of *Drosophila* chromosome arms. Silencing of the wild-type *brown* gene demonstrates the impact of positioning within an inactive zone.

In some cases it appears that localization within an inactive zone occurs as the default state. Studies using a mouse *β-globin* transgene demonstrate that a complete enhancer element is required for both gene expression and localization away from inactive zones. Point mutations within the enhancer element that disrupt binding of a transcription factor eliminate gene expression and cause the *β-globin* transgene to localize to inactive zones near centromeres. Interactions between factors bound at enhancer elements and the transcriptional machinery housed within the interior of the nucleus might be responsible for localization within an active zone. Alternatively, factors that bind to enhancer elements might recruit chromatin remodeling machines and/or histone acetyltransferases, generating a chromatin environment that disrupts interactions with silencing proteins in the inactive zone.

Multiple Determinants for Establishing the Activity State of a Gene

The emerging picture is that both nuclear zones and local chromatin structure play essential roles in establishing the transcriptional state of a gene. Silencing at the yeast mating type locus *HMR-E* is dependent upon the recruitment of specific *trans*-acting factors. Deletion of some of their binding sites generates a defective silencer, leading to transcriptional derepression. Tethering an *HMR-E* with a defective silencer to the nuclear periphery restores gene silencing. However, tethering an *HMR-E* in which all binding sites had been removed has no effect on gene expression. These experiments demonstrate that the local chromatin structure, not just the position within a nuclear zone, is necessary to establish the transcriptionally inactive state.

Effects of local chromatin structure and nuclear positioning were further demonstrated by studies involving chromosomal translocations in *Drosophila*. A stock possessing a reporter gene inserted within a region associated with heterochromatin-silencing factors was subjected to X-rays and translocations were recovered. The degree of silencing of the reporter gene was dependent on the location of the translocation breakpoints. Rearrangements that placed the transgene closer to centric heterochromatin showed increased levels of gene silencing. In contrast, rearrangements that placed the transgene at sites distant from centric heterochromatin resulted in decreased gene silencing. Contrasting observations were made when a stock containing the same transgene inserted within a chromosomal region that normally does not associate with heterochromatic silencing factors was subjected to X-rays. Resulting translocations did not alter the expression of the reporter gene, even when the transgene localized near centric heterochromatin. The transgene appeared to be insensitive to positioning in the nucleus. These data suggest that local chromatin structure can influence the response of a gene to placement within a particular nuclear zone.

Nuclear Zones and Human Disease

Studies in model organisms, such as yeast and fruit flies, have clearly demonstrated that nuclear positioning affects gene expression. There is growing evidence in humans that some diseases might result from misregulation of gene expression due to translocations that place a disease-causing gene into an inappropriate zone. Examples include cases of aniridia (absence of the iris), autism, and Burkitt's lymphoma. In these cases the disease-related gene is not damaged by the translocation, in fact, the breakpoints of the translocation map several kilobases or megabases from the gene affected. It is hypothesized that altered expression of the disease gene is due to placement in an inappropriate nuclear zone as a consequence of the translocation. Therefore, understanding the rules of gene regulation has become a three-dimensional problem that will require sophisticated detection of gene expression coupled with high-resolution nuclear imaging.

Glossary

boundary elements DNA elements that bind specialized nuclear complex that attach to nuclear substructure to delimit chromosome domains.

chromosome territory An area within the nucleus that is occupied by a specific chromosome.

euchromatin Regions of the genome that contain mostly single copy DNA sequence and are relatively gene-rich. These regions replicate early in S phase and decondense during interphase.

heterochromatin Regions of the genome, frequently located near centromeres and telomeres, that contain repetitive DNA sequences and are relatively gene-poor. These regions replicate late in S phase and remain condensed throughout the cell cycle.

histones Small, highly conserved, basic proteins that form a nucleosome.

insulators Specialized DNA sequences that block the effect of enhancers or silencers when placed between a promoter and the regulatory element. When flanking both ends of a gene, they block position effects that arise from neighboring regulatory elements.

nucleosome The fundamental unit of chromatin packaging containing eight histones and ~165 bp of double stranded DNA.

somatic pairing Pairing of two homologous chromosomes during interphase in somatic cells.

Biography

Lori L. Wallrath and Pamela K. Geyer are faculty members in the Department of Biochemistry at the University of Iowa. Their principal research interest is chromatin structure and gene expression. Dr. Wallrath's research is focused on the molecular mechanisms of gene silencing. Dr. Geyer's research is focused on the role of genomic insulators in gene expression.

John Danzer is a senior Ph.D. student in the Molecular Biology Program, working on the molecular mechanism of heterochromatin spreading.

Dr. Oya Yazgan is a Postdoctoral Fellow researching the role of proteins that associate with insulators.

Nuclear Pores and Nuclear Import/Export

Anita H. Corbett
Emory University School of Medicine, Atlanta, Georgia, USA

The hallmark of a eukaryotic cell is the presence of the nucleus, which separates the chromosomes that encode the genetic information from the protein translation machinery in the cytoplasm. This physical separation requires nuclear transport (import and export) machinery, which is capable of moving macromolecules such as proteins and RNAs rapidly but selectively into and out of the nucleus. There are many processes in eukaryotic cells that require macromolecular exchange between the nucleus and the cytoplasm. The most obvious example is the expression of a gene where the DNA is transcribed to messenger RNA (mRNA) within the nucleus and this mRNA must be transported to the ribosomes, the cytoplasmic protein translation machinery, to be decoded and translated into protein. In addition, many proteins that are created by the cytoplasmic translation machinery enter the nucleus to function in essential nuclear processes such as DNA replication, transcription, DNA repair, and many others. Thus, there is a great deal of traffic between the cytoplasm and the nucleus and these transport events are critical for the proper functioning of a eukaryotic cell.

Nuclear Pores

All transport between the nucleus and the cytoplasm occurs through large protein channels that are embedded in the nuclear membrane. These channels, which are called nuclear pore complexes (NPCs), are composed of proteins referred to as nucleoporins.

Structure

NPCs are large (~30 MDa in yeast and ~60 MDa in vertebrates) structures that span the double membrane, which surrounds the nucleus to provide a transport channel for very large macromolecular cargoes. Many different studies have led to a model for the structure of the NPC (Figure 1). The core of the NPC consists of a cylinder with eightfold rotational symmetry, which spans the nuclear envelope and surrounds a central channel. In addition to this central channel, there are filaments that extend into the cytoplasm and a basket structure that extends into the nucleoplasm. Cargoes that move through the nuclear pores probably interact first with the peripheral structures, move through the central channel, and are then released into their target compartment.

Composition

Sophisticated biochemical studies have revealed the identity of the nucleoporin proteins that make up the NPC. Surprisingly, these studies reveal that both the yeast and vertebrate nuclear pores are composed of only approximately 30 distinct proteins. The pore is large because most of these pore components are present in 16–32 copies per NPC. Many of these nucleoporins contain a characteristic repeat sequence of phenylalanine glycine repeats (FG). These FG-repeat nucleoporins line the central channel of the pore and probably provide the conduit for movement of macromolecules through the pore complex.

Transport Mechanisms: Protein Trafficking

Transport through nuclear pores occurs in both directions, from the nucleus to the cytoplasm and from the cytoplasm to the nucleus. The desired direction of transport generally depends on the cargo to be transported. The cell has developed sophisticated mechanisms to mark cargoes for transport and regulate the direction of the transport processes.

Targeting Signals

As with most intracellular targeting mechanisms, trafficking between the nucleus and the cytoplasm depends on amino acid sequences within the protein cargoes to be transported. However, unlike other targeting mechanisms, such as mitochondrial and ER targeting, nucleocytoplasmic trafficking signals are not

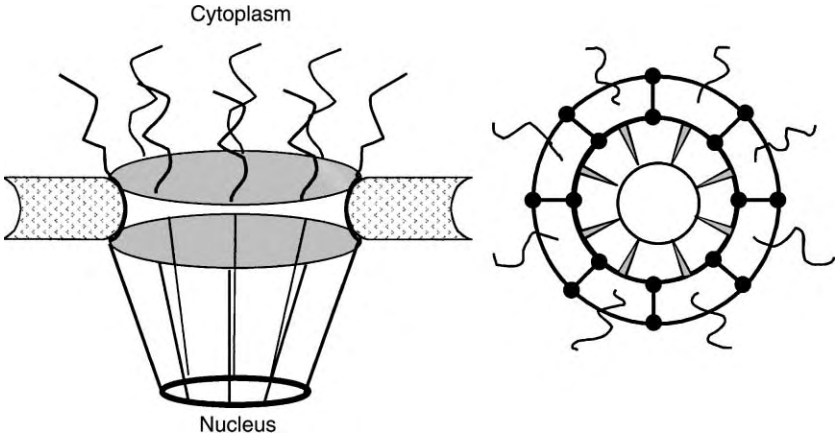

FIGURE 1 Schematic of the nuclear pore complex (NPC). Left: A schematic of the pore in the plane of the membrane is shown. The schematic shows the cytoplasmic filaments and the nuclear basket. Right: A schematic view of the pore looking down from the cytoplasmic face. The eightfold rotational symmetry of the pore is evident.

cleaved and remain an integral part of the protein. This mechanism can allow the cargo proteins to undergo multiple rounds of import and/or export. The nuclear targeting signal within the cargo protein generally mediates a physical interaction with a soluble nuclear transport receptor, which targets the cargo to the nuclear pore for transport.

Canonical signals for both nuclear protein import and nuclear protein export have been identified and studied in some detail. Nuclear import signals are generally termed nuclear localization signals (NLS), while signals that target proteins for export from the nucleus are termed nuclear export signals (NES). The classical NLS consists of either a single cluster of basic amino acid residues (monopartite) or two clusters of basic amino acid residues separated by a 10–13 amino acid linker sequence (bipartite). The monopartite NLS sequence is typified by the NLS found in the simian virus 40 (SV40) large T antigen (PKKKRKV), whereas the bipartite NLS is typified by the nucleoplasmin NLS (**KR**PAATKKAGQA**KKKK**). The classical NES is comprised of a series of hydrophobic amino acids, generally leucine, isoleucine, or valine. Numerous variations on this theme have been identified and thus far the best consensus sequence for an NES is LxxxLxxLxL, where the spacing between the leucines can vary, and, in fact, the leucines can be substituted with virtually any hydrophobic amino acid. Although classical NLS and NES signals are typically identified through computer searches of proteins sequences, it is essential that their function be verified through experimental methods.

Transport Receptors

Targeting signals within cargo proteins are recognized by soluble receptors that direct those cargoes to the nuclear pore for transport. These receptors form a family of structurally related molecules that are generally referred to as importins (for import receptors), exportins (for export receptors), or generally as transport receptors or karyopherins. The family of related receptors is generally referred to as the importin β or karyopherin β-family. One feature of these transport receptors is that they are modulated in such a way that they bind tightly to their cargo in the compartment where the cargo needs to be picked up. However, following the translocation through the NPC to the compartment where the cargo needs to be delivered, the transport receptor undergoes a conformational change that leads to the efficient release and delivery of the cargo. This switch in binding to the cargo is regulated by the small GTPase Ran.

Although most transport cargoes bind directly to their cognate transport receptor, there are examples where an adaptor protein mediates this interaction. The best example of this occurs in nuclear protein import of cargoes that contain a classical NLS sequence. The NLS within these cargoes is recognized by an adaptor protein called importin α or karyopherin α. The importin/karyopherin α recognizes and binds to the cargo and then binds directly to the transport receptor to form a trimeric import complex. This complex is then translocated through the nuclear pore into the nucleus and the NLS cargo is delivered.

Once cargo is released from the transport receptors within the delivery compartment, all the receptors are recycled for another round of transport. Import receptors are recycled back to the cytoplasm and export receptors are recycled back to the nucleus. This recycling of receptors assures that a single receptor can mediate multiple rounds of transport.

The Ran GTPase Cycle

The small GTPase Ran, serves as a molecular switch that modulates the directionality of nuclear transport. As with other GTPases, Ran can exist in two forms, either bound to GDP (RanGDP) or bound to GTP (RanGTP). It is the compartmentalization of these two distinct forms of Ran that regulates cargo/receptor interactions to impart directionality on nuclear transport. This compartmentalization is achieved through the intracellular separation of the two important regulators of the Ran GTPase cycle. The Ran GTPase-Activating Protein (RanGAP), which enhances Ran-mediated GTP hydrolysis, is located in the cytoplasm and the Ran Guanine Nucleotide Exchange Factor (RanGEF), which facilitates exchange of GDP for GTP on Ran, is located in the nucleus. As shown in Figure 2, with the RanGAP in the cytoplasm, any RanGTP that enters the cytoplasm is rapidly converted to RanGDP. Thus, in the cytoplasm the level of RanGDP exceeds the level of RanGTP. In contrast, within the nucleus in the presence of the RanGEF, RanGDP is rapidly converted to RanGTP. Thus, in the nucleus the level of RanGTP is high compared to the level of RanGDP. Due to the asymmetric localization of the Ran regulators, high levels of RanGTP serve as a marker for the nucleus and high levels of RanGDP serve to identify the cytoplasmic compartment.

The different nucleotide bound states of Ran regulate the flow of protein cargoes into and out of the nucleus by regulating the assembly of the import and export complexes (Figure 3). Cargoes to be transported into the nucleus bind to their cognate import receptors in the cytoplasm. These complexes are translocated into the nucleus through NPCs. Once they reach the nucleus, where levels of RanGTP are elevated, RanGTP binds to the import receptor causing a conformational change that releases the import cargo into the nucleus. In contrast, export cargoes bind to their export receptors only in the presence of RanGTP. Export complexes are trimeric complexes that consist of the export receptor, the export cargo, and RanGTP. As with import, the export complex is translocated through NPCs to the cytoplasm. In the cytoplasm, the export complex encounters the RanGAP and the bound RanGTP is converted to RanGDP. This disassembles the export complex and leads to the release of the export cargo into the cytoplasm.

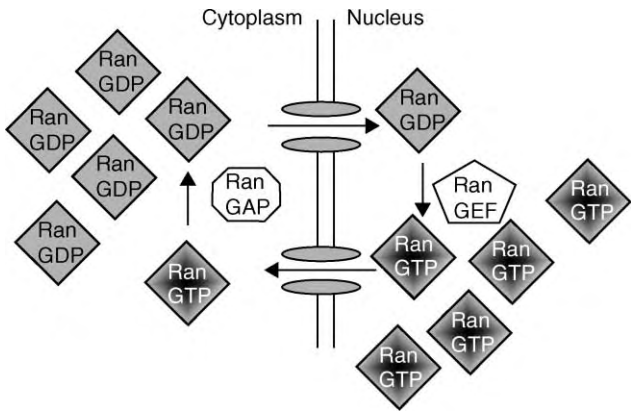

FIGURE 2 The RanGTP gradient. The compartmentalization of the RanGAP to the cytoplasm and the RanGEF to the nucleus results in localized concentrations of RanGDP and RanGTP. In the cytoplasm where the RanGAP enhances the Ran-mediated GTP hydrolysis, levels of RanGDP are high. In the nucleus where the RanGEF facilitates the exchange of GTP for GDP on Ran, the levels of RanGTP are high. This compartmentalization is critical for the identification of the nuclear and cytoplasmic compartments in nuclear transport and in other cellular processes.

Classical NLS-Mediated Protein Import

The best understood nuclear transport process is the import of protein cargoes that contain a classical basic NLS (Figure 4). Thus, this process can be used most readily to illustrate the steps that occur when a transport cargo is moved into or out of the nucleus. Historically, nuclear protein import was divided into two steps, docking at the nuclear pore, an energy-independent step, and translocation into the nucleus, an energy-dependent step. Advances in our understanding of the process and the players now lead us to define at least five distinct steps for import of a cargo that contains a classical NLS: (1) recognition and binding of the NLS cargo to the α/β heterodimeric-import receptor in the cytoplasm; (2) targeting to the nuclear pore through interactions between the importin/karyopherin β nuclear transport receptor and the nuclear pore; (3) translocation through the pore through transient interactions between importin/karyopherin β and the FG-repeat containing nucleoporins; (4) delivery into the nucleus where RanGTP binds to importin/karyopherin β to cause a conformational change that releases α and the NLS cargo; and (5) recycling of importin/karyopherin α to the cytoplasm in a heterotrimeric complex with an importin/karyopherin α export receptor and RanGTP and importin/karyopherin β presumably in complex with RanGTP. Note that the only energy expenditure in this process occurs when the karyopherin proteins are recycled to the cytoplasm and the accompanying RanGTP is hydrolyzed.

Transport Mechanisms: RNA Trafficking

Multiple classes of RNAs, including mRNAs, tRNAs, and U snRNAs are transcribed and processed within

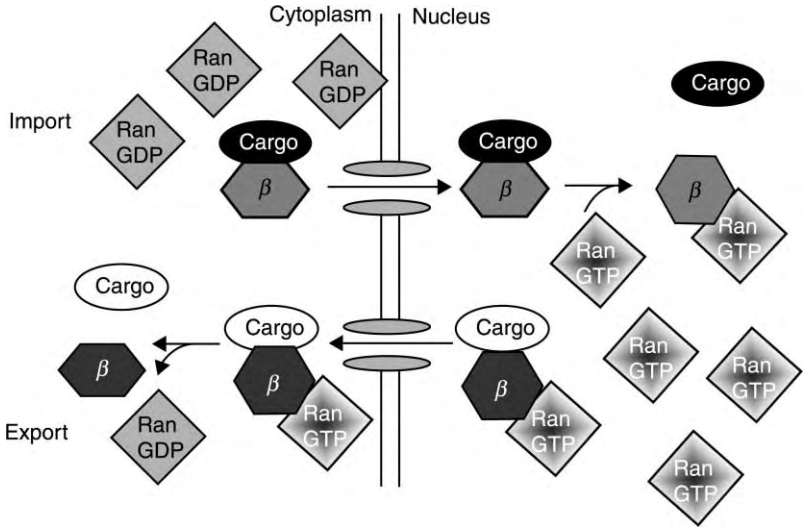

FIGURE 3 Ran regulates the assembly of import and export complexes. Top: For transport into the nucleus (Import), cargoes are recognized in the cytoplasm by an importin/karyopherin β receptor to form an import complex. Once this complex is translocated into the nucleus, it encounters the nuclear RanGTP, which binds tightly to the importin/karyopherin β receptor and causes a conformational change that releases the import cargo. Bottom: For transport out of the nucleus (Export), cargoes are recognized in the nucleus by an importin/karyopherin β receptor. However, in contrast to the import complex, the export complex can only form in the presence of RanGTP. Thus, export complexes are obligate trimeric complexes that consist of the export cargo, the importin/karyopherin β export receptor, and RanGTP. Once the export complex is translocated to the cytoplasm, it encounters the RanGAP. In the presence of the RanGAP, the RanGTP within the complex is converted to RanGDP and the complex dissociates resulting in the release of the export cargo into the cytoplasm. Hence, by controlling complex assembly and disassembly, the different forms of Ran confer directionality on the nuclear transport machinery.

the nucleus and then transported to their sites of action in the cytoplasm. As compared with proteins, RNAs require extensive processing before they reach their mature form and are ready to exit the nucleus. This means that RNA export is intimately linked to RNA processing within the nucleus.

Export of RNA via Classical Nuclear Transport Receptors

The export of tRNA, U snRNA, and rRNA follows pathways analogous to nuclear protein export. For example, tRNA is recognized directly by the importin/karyopherin β family nuclear transport receptor, exportin-t/Los1p and is exported as a complex with RanGTP. As for any classical export process, this trimeric complex is disassembled in the cytoplasm when RanGTP is hydrolyzed to RanGDP. Preferential export of mature tRNAs seems to be achieved at least in part by the specificity of exportin-t for the mature processed, modified, and appropriately aminoacylated tRNAs. U snRNAs are synthesized in the nucleus, transported to the cytoplasm where they associate with protein components of mature small nuclear ribonucleoproteins (snRNPs), and are then reimported to the nucleus where they function in mRNA splicing. Although this export depends on Ran, it is controversial whether Ran plays a direct role in export or whether its activity may be essential for the import of components required for RNP assembly.

mRNA Export

Export of poly (A)+ mRNA remains the least well understood of the RNA export mechanisms. mRNAs are not exported to the cytoplasm as naked nucleic acids, but rather as RNP complexes, and it is generally agreed that the export machinery recognizes signals within the proteins of these complexes rather than the RNA itself. For example, export of intron-containing HIV transcripts from the nucleus is mediated by the HIV protein Rev through its binding to the classical NES receptor, CRM1/exportin. While the HIV virus exploits this mechanism, none of the classical nuclear transport receptors play a central role in cellular mRNA export.

Although the mechanistic details of mRNA export have not yet been fully elucidated, it appears that there are two classes of proteins that are required to achieve export of mature messages. First, there is a family of evolutionarily conserved heterogeneous nuclear ribonucleoproteins (hnRNPs) that interact with poly (A)+ RNA *in vivo*. A number of these hnRNP proteins shuttle between the cytoplasm and the nucleus and escort the poly(A)+ RNAs as they are exported through the NPC. Current models suggest that at least some of the hnRNP proteins may be involved in RNA processing steps that occur cotranscriptionally. The hnRNPs that remain bound to the maturing messages may serve as markers that the different processing steps have been successfully accomplished. The second class of proteins consists of

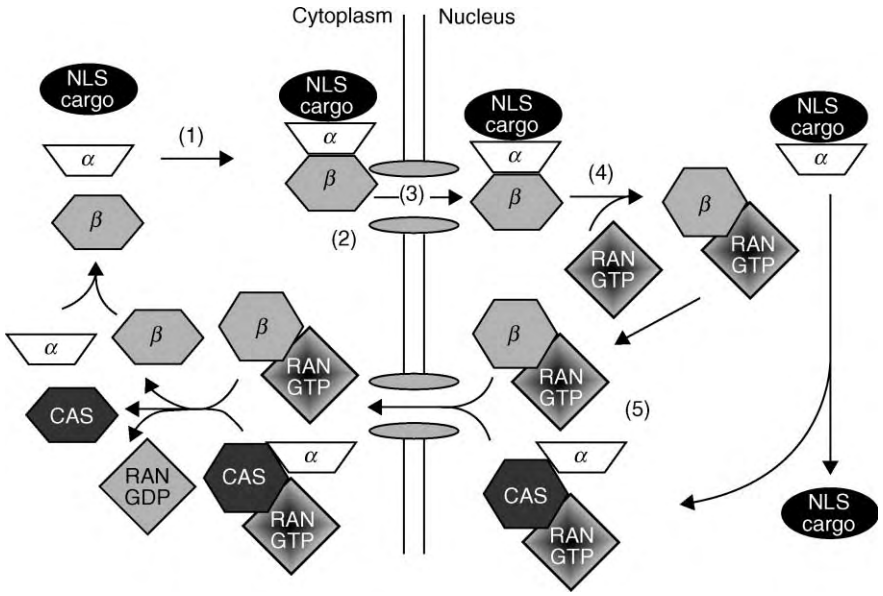

FIGURE 4 Model for classical NLS-mediated protein import into the nucleus. The best-understood transport mechanism is that of classical nuclear protein import mediated by importin/karyopherin β and the NLS binding adapter, importin/karyopherin α. This process can be divided into at least five distinct steps as shown in the model: (1) recognition and binding of the NLS cargo to the α/β heterodimeric import receptor in the cytoplasm; (2) targeting to the nuclear pore through interactions between the importin/karyopherin β nuclear transport receptor and the nuclear pore; (3) translocation through the pore through transient interactions between importin/karyopherin β and the FG-repeat containing nucleoporins; (4) delivery into the nucleus where RanGTP binds to importin/karyopherin β to cause a conformational change that releases α and the NLS cargo; and (5) recycling of importin/karyopherin α to the cytoplasm in a heterotrimeric complex with an importin/karyopherin α export receptor and RanGTP and importin/karyopherin β presumably in complex with RanGTP.

those proteins that have been implicated more directly in the export process; including a helicase, Sub2p/UAP56, and the heterodimeric-export receptor, Mex67p/Mtr2p (TAP/p15 in humans). TAP/Mex67p shuttles between the cytoplasm and the nucleus, and in complex with p15/Mtr2p, binds both to mRNA and to nucleoporins. Thus, it could potentially target bound RNAs directly to the NPC for export.

Glossary

cargo Macromolecular substrate to be transported between the nucleus and the cytoplasm.

GTPase Protein that binds to and hydrolyzes the nucleotide GTP.

heterogeneous nuclear ribonucleoprotein (hnRNP) Abundant non-specific poly(A)+ RNA binding protein.

HIV Human immunodeficiency virus.

messenger RNA (mRNA) Class of RNA that carries the information from the DNA to the cytoplasm and serves as the informational blueprint for protein synthesis.

nuclear export signal (NES) An amino acid sequence within a protein that targets that protein for export from the nucleus.

nuclear localization signal (NLS) An amino acid sequence within a protein that targets that protein for import into the nucleus.

nuclear pore complex (NPC) The large proteinaceous channel through which macromolecular cargoes are transported in and out of the nucleus.

nucleoporins Proteins that make up the NPC.

Ran A small GTPase that regulates the directionality of nuclear transport.

RanGAP Cytoplasmic protein that enhances the GTPase activity of Ran.

RanGEF Nuclear protein that facilitates the nucleotide exchange on Ran.

ribosomal RNA (rRNA) Class of RNA that serves as a structural and catalytic component of ribosomes.

transfer RNA (tRNA) Class of RNA that is charged with amino acids to decode the mRNA for protein synthesis.

transport receptor/karyopherin/importin/exportin The receptors that bind to and recognize protein and RNA cargoes that are transported into or out of the nucleus.

U snRNA Small RNAs that participate in splicing.

Biography

Anita H. Corbett, Ph.D., is an Associate Professor of biochemistry at the Emory University School of Medicine. Her principal research interest is in the area of macromolecular trafficking between the cytoplasm and the nucleus. She utilizes the budding yeast, *Saccharomyces cerevisiae* as a model system for most of her studies. Dr. Corbett holds a Ph.D. in biochemistry from Vanderbilt University. She completed a postdoctoral fellowship at Harvard Medical School before moving to Emory in 1997.

Nucleoid Organization of Bacterial Chromosomes

Charles J. Dorman
Trinity College, Dublin, Ireland

Bacteria do not possess a nuclear membrane, and so have no clearly defined nucleus in the eukaryotic sense. It is for this reason that they are classed as prokaryotes. The term nucleoid is used to describe that part of the bacterial cytoplasm that is occupied by the genetic material. This has been the subject of investigation for several decades now, yet despite intensive study, many details of nucleoid structure and function remain obscure. It seems ironic that our understanding of these so-called "simple" organisms continues to lag behind that of cells in higher organisms in this respect. This article will describe those features of the bacterial nucleoid over which there is general agreement. Much of the material comes from work with *Escherichia coli*, the best-studied prokaryote, and encompasses the organization of the genetic material within the nucleoid and its interactions with those DNA-binding proteins that are thought to impart structure to it.

Organization of DNA in the Nucleoid

When considering the nucleoid, one of the first issues to be confronted concerns the problem of how to package a circular DNA molecule measuring ~1.5 mm in circumference within a cylindrical container with hemispherical ends (the cell) that measures 2 μm in length × 1 μm diameter. Any solution to this problem must take into account the persistence length of the molecule, which for B-DNA is 50 nm (150 bp). This imposes on the circular chromosome a tendency to adopt a disordered globular configuration, resulting in a ball of DNA measuring 10 000 nm in diameter. This structure is at least 10 times too large to fit in the cell. Since bacterial chromosomes clearly do fit in cells, organization at some level must be imposed on this otherwise chaotic arrangement. Organization is also required so that the DNA can participate in transactions such as gene transcription. It seems that this organization occurs at least on two levels. The first concerns an effect on the shape of the DNA itself that is imparted through negative supercoiling, whereas the second involves the interaction of the DNA with so-called nucleoid-associated proteins. Each of these aspects will be considered in turn.

DNA Supercoiling

As with DNA in other types of cells, bacterial DNA is maintained in a negatively supercoiled state. This arises because the double helix in the cell has a deficiency of helical turns; in other words, it is in an under-wound state. The molecule is thus placed in a thermodynamically unfavorable state due to torsional stress. This difficulty is resolved by a structural transition to an energetically more favorable form. In practice, this involves adopting a shape (or topology) that we call supercoiled, in which an already-coiled molecule (the DNA duplex) itself becomes coiled (Figure 1). Supercoiling creates writhing of the DNA helical axis and this results in a more compact molecule. The compaction can arise due to adoption by the DNA of a plectomenic (braided) or a toroidal (doughnut-like) configuration. Depending on how supercoiled the DNA becomes, the structure can also form branches, leading to further compaction. This reduces the diameter of the DNA ball to a value that can be accommodated within the confines of the cell.

The foregoing description of DNA supercoiling and its effects on DNA compaction is highly qualitative. It is possible to treat DNA supercoiling in a quantitative manner, making accurate measurements of how supercoiled DNA molecules are under particular conditions. This is desirable since it allows one to calculate the energetic consequences for DNA of different levels of supercoiling. The under-winding of the DNA duplex that is a characteristic of negatively supercoiled molecules imparts free energy to the DNA, and this energy is available to drive the major transactions in which DNA participates, such as gene transcription. Knowledge of the minimum energy requirements of a particular transaction can be used to estimate the level

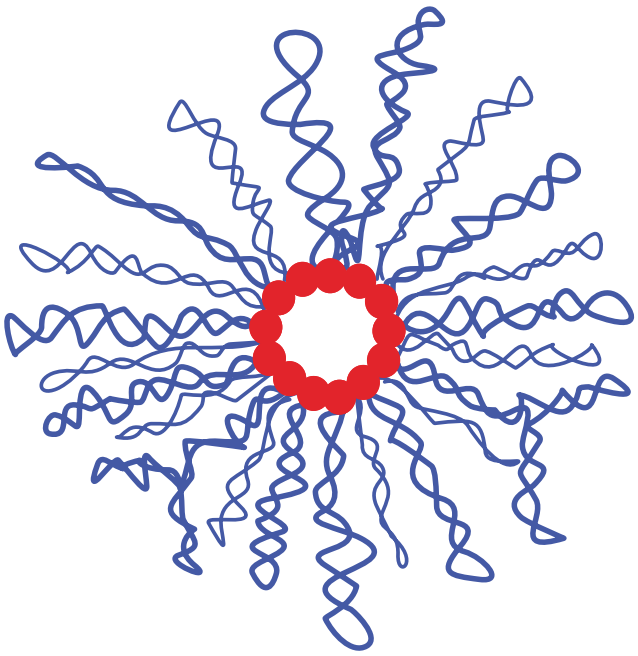

FIGURE 1 Organization of the bacterial nucleoid. A representation of the nucleoid liberated from the cell is shown. The red spheres at the core represent the nucleoprotein complexes that define the ends of the supercoiled domains. These complexes are thought to be composed of nucleoid-associated proteins and possibly topoisomerases. The blue ribbons represent the DNA making up the supercoiled domains. A typical nucleoid from *E. coli* has between 50 and 100 of these.

to which DNA has become supercoiled. When used in conjunction with physical methods based on electrophoretic mobility of covalently closed circular DNA or its sedimentation rates, one can obtain robust measurements of DNA supercoiling.

DNA can be described in terms of three topological parameters: linking number (L), twist (T), and writhe (W). The linking number is a measure of the number of times the two strands of the DNA duplex link with one another. Twist measures the turning of the DNA strands about the helical axis, whereas writhe measures the winding of the helical axis about itself. These properties are related as follows: $L = T + W$ and $\Delta L = \Delta T + \Delta W$. This means that a change in linking number is distributed between the other two parameters, resulting in a change that is manifest: (1) only as altered twist, (2) only as altered writhe, or (3) as a change in both twist and writhe. For very large DNA molecules, such as bacterial chromosomes, measurements of L are cumbersome and largely impractical. Here one employs a parameter such as the superhelical density, σ. This is the average number of superhelical turns per helical turn of DNA:

$$\sigma = 10.5\tau/N$$

where τ is the number of measurable supercoils, N is the number of base pairs in the molecule, and 10.5 refers to the number of base pairs per helical turn in B DNA. The importance of the energetics of supercoiling for DNA-based processes was referred to above. The free energy of supercoiling is related to the change in DNA linking number as follows: $\Delta G = (1050\ RT/N)\ (\Delta L)^2$, where R is the gas constant, T is the temperature in kelvin, and N is the size of the molecule in base pairs. The important point to note about this relationship is that the free energy varies in proportion to the square of the change in the linking number (L). Put qualitatively, this means that even modest changes in the linking number can result in significant variances in the energy imparted to the DNA.

Control of DNA Supercoiling

The level of DNA supercoiling in the bacterial nucleoid is established and maintained largely by the action of specialist enzymes called topoisomerases (Table I). Bacterial DNA gyrase is a type II ATP-dependent topoisomerase that introduces negative supercoils into DNA, reducing its linking number in steps of two. It can also remove positive supercoils using the same enzymatic mechanism. The activity of gyrase is opposed in the cell by DNA topoisomerase I, a type I topoisomerase that removes supercoils from negatively supercoiled DNA by a "swivelase" mechanism, increasing the linking number of the molecule in steps of one. It acts independently of ATP, using the energy stored in the supercoiled DNA molecule to drive the reaction. *E. coli* has two other topoisomerases, III and IV (Table I) that can relax negatively supercoiled DNA, although their main role *in vivo* seems to be to act as decatenases. The promoters of the genes coding for gyrase (*gyrA*, *gyrB*) and topoisomerase I (*topA*) are controlled, *inter alia*, by DNA supercoiling. This provides a useful feedback loop that controls the supply of these proteins. The *gyr* promoters are activated by DNA relaxation (loss of negative supercoiling), whereas the *topA* promoter is repressed by negative supercoiling. An important link between gyrase activity and cellular physiology concerns the dependence of this enzyme on ATP and the fact that gyrase is inhibited by ADP. In this way the major source of negative supercoiling is directly responsive to the energy charge of the cell.

The Domain Structure of the Nucleoid

Physical analysis has indicated that the chromosome within the cell is subdivided into ~50–100 independently supercoiled domains (Figure 1). Evidence comes from experiments in which chemical agents were used to

TABLE I

DNA Topoisomerases of *E. coli*

Enzyme	Gene	Molecular mass (kDa)	Remarks
Topoisomerase I	*topA*	97	Type I enzyme; relaxes negatively supercoiled DNA; cuts one strand of DNA and binds to cut site via a 5′-phospho-tyrosine covalent bond; Mg^{2+} dependent
DNA gyrase (Topoisomerase II)	*gyrA* *gyrB*	105 (GyrA) 95 (GyrB)	Type II enzyme; negatively supercoils relaxed DNA (requires ATP); relaxes positively supercoiled DNA; makes a transient double-stranded cut in DNA and binds via a 5′-phosphotyrosine bond Mg^{2+} dependent
Topoisomerase III	*topB*	73.2	Type I enzyme; can relax negatively supercoiled DNA; decatenase; Mg^{2+} dependent
Topoisomerase IV	*parC* *parE*	75 (ParC) 70 (ParE)	Type II enzyme; with strong sequence homology to gyrase; decatenase; relaxes negative supercoils but cannot create them; requires ATP and Mg^{2+}

nick the DNA. If the chromosome consisted of one continuous domain, a nick anywhere along its length would allow all supercoils to be lost through DNA relaxation. Since 50–100 nicks must be introduced to relax the DNA fully, it has been concluded that subdomains must exist. The possibility that these domains might be supercoiled to different values of σ is an attractive idea since it would allow gene promoters at different locations on the chromosome to experience different degrees of negative superhelicity. This in turn might contribute to differential expression of genes at different locations. However, experiments in which supercoiling-sensitive promoters were placed at different locations in the genome provided no support for this proposal. Therefore, it seems likely that on average each domain of the nucleoid is supercoiled to a similar value of σ.

An important and unresolved issue concerns the nature and locations of the boundaries of the chromosomal domains. Some evidence obtained by promoting long-range interactions in the genome leading to DNA recombination indicates that these boundaries are not fixed in their locations. They may have a transient existence, being dismantled to permit processes such as replication of the DNA to proceed. A favorite hypothesis to explain the nature of the boundaries envisages a role for nucleoid-associated DNA-binding proteins, perhaps acting in combination with topoisomerases (Figure 1).

Nucleoid-Associated Proteins

Bacteria possess DNA-binding proteins that have been described both as "histone-like" and "nucleoid-associated." The former term reflects their function rather than any strong structural similarity to the histones of eukaryotes. The latter name implies that they have a role to play in the organization of the nucleoid. These proteins typically have a low molecular mass, are basic in amino acid composition, and have DNA-binding activity. Depending on the protein, on binding to DNA it can bend or wrap the DNA around itself. DNA wrapping results in the constraining of supercoils. If the DNA is nicked in the absence of the protein, the supercoils are lost; if the protein has wrapped the DNA around itself, the DNA in association with the protein has its supercoils preserved. Measurements of σ for *E. coli* indicate that at any given time ~50% of the DNA in the cell is associated with such proteins while the remainder is in the form of plectonemic supercoils. This is in sharp contrast to the situation in eukaryotes where interaction with histones is the norm. It means that in the bacteria the impact of changes in σ can have more immediate consequences for DNA transactions in these protein-free regions.

The bacteria possess a wide array of histone-like proteins. In *E. coli* the most important include HU, IHF, H-NS, and Fis (Table II). Of these, HU and H-NS are characterized by a lack of a consensus sequence for DNA binding. Instead, they interact with structures in the DNA, such as four-way junctions (HU) or intrinsically curved DNA (H-NS). IHF has a similar amino acid sequence to HU (Fis, HU, and H-NS are structurally distinct) but binds to a clearly defined consensus sequence where it introduces a DNA bend of up to 180°. This gives it a powerful role in local structural organization within the nucleoid, although its action is confined to regions that contain a copy of its binding site. It may also act in conjunction with DNA gyrase to maintain supercoiling at strategically important sites. Fis binds to a rather degenerate consensus sequence and is characterized by having an expression profile that is

TABLE II

Major Nucleoid-Associated Proteins of *E. coli*

Protein	Gene	Molecular mass (kDa)	Remarks
Fis	*fis*	11.2	Fis: factor for inversion stimulation; homodimeric DNA-binding protein; binds to degenerate consensus sequence; bends DNA by between 40° and 90°; organizes local DNA topology; multifunctional and is involved in transcription, DNA replication, recombination, and transposition. Strong growth phase regulation varies protein number/cell over 200–100 000 range
H-NS	*hns*	15.6	H-NS: histone-like nucleoid structuring; oligomeric DNA-binding protein; lacks a consensus sequence for DNA binding but has an affinity for curved DNA; compacts DNA and constrains supercoils; important transcription regulator (usually a repressor); estimated to be 20 000–60 000 H-NS monomers/cell
HU	*hupA* *hupB*	9.5 9.5	HU: heat unstable; abundant heterodimeric DNA-binding protein; 60 000 dimers/cell; lacks a consensus sequence for DNA binding; can constrain DNA supercoils
IHF	*ihfA* *ihfB*	11.2 10.6	IHF: integration host factor; heterodimeric DNA-binding and -bending protein; homologue of HU but binds to well-conserved consensus sequence; bends DNA by up to 180°; between 17 000 and 34 000 monomers/cell

tightly linked to the growth phase of the cell. It is highly abundant in cells exiting lag phase but is present in miniscule amounts in cells in late logarithmic growth. The Fis protein plays a direct role in nucleoid organization by acting as a transcription repressor at the promoters of *gyrA* and *gyrB*, the genes coding for gyrase. It also binds preferentially to DNA with intermediate values of σ and preserves their topology in the face of attempts by topoisomerases to alter σ. Finally, DNA supercoiling controls the supply of Fis at the level of *fis* gene transcription, providing a feedback loop linking expression of this protein to the topological state of the nucleoid. In *E. coli*, the subunit composition of HU and its activities vary with growth phase as the relative amounts of each subunit change in the cell. H-NS is expressed roughly at a constant level throughout growth, but it forms hetero-oligomers with a paralogous protein called StpA at certain periods in the growth cycle and this may alter its properties. IHF also shows a growth-phase-dependent pattern of expression, being most abundant as the cell approaches the stationary phase of growth. This dynamism in the expression of the nucleoid-associated proteins can be expected to have an impact on the structure of the nucleoid as the cell grows and may be reflected in the location and number of domain boundaries and the compactness of the nucleoid.

Nucleolus, Overview

Thoru Pederson
University of Massachusetts Medical School, Worcester, Massachusetts, USA

Nucleoli are specialized structures within the nuclei of most eukaryotic cells and are the sites of ribosomal RNA synthesis and the assembly of ribosomes. Nucleoli form around the genes for ribosomal RNA (rRNA), and their structural organization is thought to be a manifestation of ongoing rRNA synthesis and ribosome assembly. The nucleoli are not separated from the rest of the nuclear interior by a membrane, and there is a rapid and diverse traffic of various RNAs and proteins in and out of nucleoli (in addition to the overall export of new ribosomes). There is increasing evidence that nucleoli are involved in functions in addition to ribosome synthesis.

Background

The nucleolus was one of the earliest intracellular structures (and the first within the nucleus) to be observed by microscopy, around 1860. Throughout the early twentieth century, cytologists were struck by the consistent presence of nucleoli inside the nuclei of virtually all cells examined, although the number and shape of nucleoli were quite variable (Figure 1). In the 1930s, it was discovered that the formation of the nucleolus is determined by a distinct genetic locus. This genetic element, termed "the nucleolus organizer," was found in the 1960s to consist of repeated genes for rRNA. It is an interesting historical fact that the rRNA genes were not only the first ones from eukaryotes to be observed at high resolution in the electron microscope, but also they were the first genes to be physically isolated, well before the advent of recombinant DNA techniques.

Although a considerable amount of cytochemical and ultrastructural research had been done on nucleoli up through the 1950s, a major advance occurred when they were first isolated by cell fractionation in the mid-1960s. This opened the door to the investigation of their protein and RNA components, and accelerated the study of rRNA synthesis and processing.

Structure

Although the ultrastructural (electron microscopic) appearance of nucleoli is highly variable, a tripartite organization is generally observed. Fibrillar centers (FCs) are one or more rather small foci within a nucleolus that have a distinctive appearance. Each of these FCs is surrounded (in three dimensions) by a typically much larger zone, called the "dense fibrillar component" (DFC). The remainder of the nucleolus, or at least most of the remainder, displays a distinctly more granular appearance, and is thus called the granular component (GC).

Functional Organization

The tripartite ultrastructural landscape of the nucleolus has been functionally defined (Figure 2). The FCs are the zones where the active rRNA genes themselves are located. The nascent transcripts of pre-rRNA extend out into the juxtaposed DFC, which also contains intermediate RNA species in the rRNA processing pathway. Also present in the DFC are numerous (100–200 or more) small RNA species (and their associated proteins) that serve as guide RNAs for the site-specific modification (2′-*O*-ribose methylation and pseudouridine formation) of many internal nucleotides in pre-rRNA. The GC consists of more mature, assembled ribosomal particles. It is not yet entirely clear whether certain stages of ribosome maturation are sharply restricted to the DFC or the GC or instead have some degree of overlap between them.

Amplified Nucleoli and Missing Nucleoli

One of the most dramatic aspects of the biology of the nucleolus is its selective amplification in the oocytes of certain organisms. In these cells, the rRNA genes are amplified into a large number (typically thousands) of extrachromosomal copies, which form supernumerary nucleoli. Through their activity, the growing oocyte builds up a large reservoir of maternal ribosomes to sustain early embryonic development. Amplified nucleoli are found in the oocytes of several phyletic

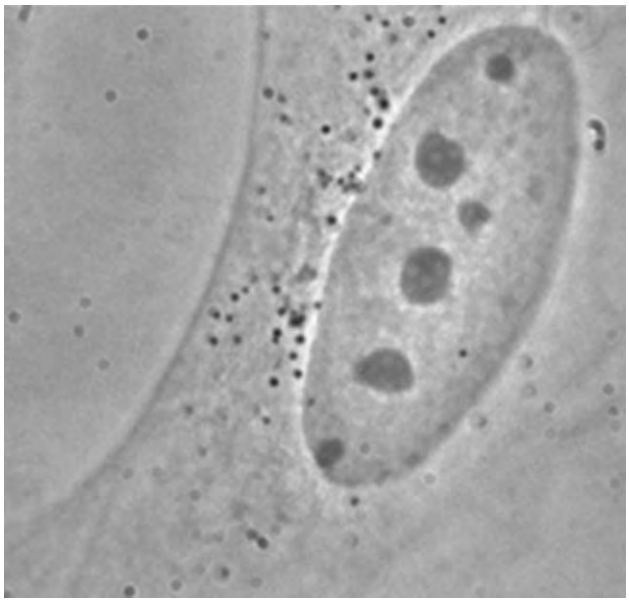

FIGURE 1 Phase contrast micrograph of a portion of a living HeLa (human cervical carcinoma) cell. The dark, spherical objects within the nucleus are the nucleoli. This micrograph was taken by Laura Lewandowski in the author's laboratory. Magnification approx. 3,000x.

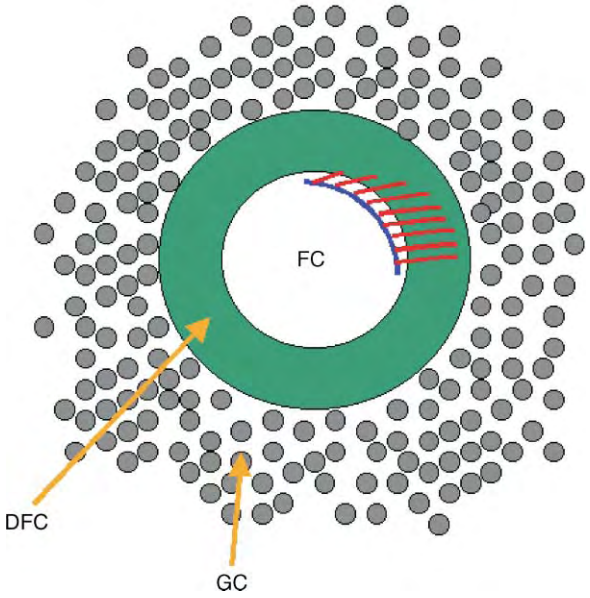

FIGURE 2 A schematic diagram illustrating the relationships of the three major components of the nucleolus. An FC contains the active rRNA genes (blue) with the nascent transcripts of pre-rRNA (red) extending into the surrounding DFC, embedded in the GC. See text for further details. Cell Biol.* **157**, 739–741, with copyright permission from the Rockefeller University Press and with the kind consent of the author.

groups, but have been most extensively studied in urodele and anuran Amphibia (salamanders and frogs).

One of the ways the function of the nucleolus in ribosome synthesis was first revealed was by an elegant experiment that involved a frog mutant in which one chromosomal set of rRNA genes is missing. Half the oocytes of females that are heterozygous for this mutation have no rRNA genes whatsoever and, consequently, cannot form amplified nucleoli, nor can anucleolate embryos descended from them synthesize new ribosomes. Accordingly, these embryos die at a time during development when the maternal supply of ribosomes becomes limited. This experiment is one of the classics in the field of eukaryotic gene expression.

Clinical Connections

Two aspects of the nucleolus are significant clinically. For many years pathologists have used nucleolar morphology and number as an important guide in the diagnostic classification of certain malignancies. In addition, a specialized structure called the perinucleolar compartment (PNC) sits as a cap-like disk on the surface of the nucleoli in most malignant cells (both tumor cell lines and actual patient biopsies). The PNC seems to be involved in RNA metabolism, and contains a set of small RNAs that are transcribed by RNA polymerase III. However, its relationship to malignancy is not known.

The Plurifunctional Nucleolus

Since the 1990s a number of clues have begun to suggest that the nucleolus may have functions beyond ribosome synthesis. One line of evidence consists of the observation in nucleoli of various molecules that have no known connection with ribosome biosynthesis. For example, several proteins related to mitogenic cell signaling and cell cycle progression have been found in nucleoli, although these various observations have not yet been drawn together into a coherent framework. In budding yeast, the nucleolus of interphase cells contains a complex that is released and promotes a late stage of mitosis after the nucleolus breaks down, but whether this complex has some role within the interphase nucleolus as well is not known. The RNA subunit of the ribonucleoprotein enzyme telomerase appears to shuttle between the chromosomes and the nucleolus in some cells but, again, the functional meaning of this observation is not clear. The fact that so many of the various ribosome-unrelated molecules and complexes that are increasingly being observed in the nucleolus are related to cell growth is quite intriguing, and this is an important area for future work.

It has also become clear that the life cycle of certain viruses involves the nucleolus in some way. For example, in the replication of the human immunodeficiency virus, certain forms of viral messenger RNAs are associated with the nucleolus during a particular stage in the infectious cycle. However, the functional significance of this and other observations of viral connections with the nucleolus is not presently known.

A third nonribosomal function of the nucleolus is its likely participation in the biosynthesis of the signal recognition particle (SRP). The SRP is an RNA–protein complex that ensures the topologically correct synthesis of membrane and secreted proteins. Both the RNA component of the SRP and some of the SRP's protein components are present in the nucleolus in yeast, amphibian oocytes (i.e., in the amplified nucleoli), and

mammalian cells, suggesting that this translation-related RNA–protein complex originates in the nucleolus, as do the ribosomes themselves.

Current Trends and Conclusion

At the present time, studies on the nucleolus are being conducted by nucleolar specialists on the one hand, and by an increasing number of cell biologists on the other, who are encountering a nucleolar connection in their work. A nucleolar protein has been implicated in the biology of embryonic stem cells, and a reorganization of the nucleolus in donor somatic cell nuclei appears to be a key factor in the cloning of mammalian animals. Meanwhile, on the analytical front, proteomics studies of purified human nucleoli have identified ~350 proteins that are highly enriched in the isolated fraction (Figure 3). Many of these proteins have no obvious relationship to ribosome biosynthesis. One interesting possibility is that perhaps all of these apparently nonribosome related nucleolar components are indeed related to ribosome biosynthesis after all, not in the constitutive pathway of ribosome synthesis itself (the classical model), but as regulatory components of cellular growth control circuits that intersect in the nucleolus and thus with the biogenesis of the protein synthesis machinery (a neoclassical model).

Biography

Thoru Pederson is the Vitold Arnett Professor in the Department of Biochemistry and Molecular Pharmacology at the University of Massachusetts Medical School. He received his Ph.D. from Syracuse University and was a Postdoctoral Fellow in Cell Biology at the Albert Einstein College of Medicine. He was at the Worcester Foundation for Biomedical Research throughout his initial career. His research is centered on RNA processing, RNA–protein interactions, and the functional organization of the cell nucleus.

Nucleotide Excision Repair and Human Disease

James E. Cleaver
University of California, San Francisco, California, USA

Nucleotide excision repair, the mechanism of repair of large DNA adducts, has a key role in the development of every organism. This article discusses the types and mechanisms of nucleotide excision repair, and the clinical consequences associated with its deficiencies.

Introduction

DNA repair is an important set of cellular processes that maintain the integrity of the genomes of every organism. Repair genes are found in every sequenced genome, and repair systems are dynamically interrelated to each other and with normal cell metabolism. The mechanism of repair of large DNA adducts especially those produced by ultraviolet (UV) light, known as nucleotide excision repair (NER), plays an important part in the development of the subject. The first connection between repair, specifically NER, and human disease has been found in xeroderma pigmentosum (XP) and details of the disease are in the website – www.xpmutations.org (Table I). XP is predominantly due to a failure of NER in cells that contain UV-induced photoproducts in their DNA (Figure 1). When these photoproducts are unrepaired-replication errors and cytosine deamination leads to characteristic C to T mutations, including especially CC to TT mutations, that are found at very high frequencies in sun-exposed skin and UVB (between 280 and 320 nm wavelength)-induced skin cancers.

Transcribed genes and their transcribed strands are more rapidly repaired than the rest of the DNA in a cell. A specific branch of NER has therefore been named "transcription coupled repair (TCR)" to distinguish it from repair of the remainder of the genome, called "global genome repair (GGR)" (Figure 2). Several components of the basal transcription factor, TFIIH, are also NER enzymes, indicating close integration of the transcription apparatus with repair.

Although in prokaryotes many DNA repair enzymes are inducible in response to damage, in eukaryotes a different strategy appears to predominate. Most of the eukaryotic repair genes are constitutively expressed, except for a small number in human cells that are p53-responsive such as *XPC*, *DDB2*, and *GADD45*. Modification of enzyme activity by phosphorylation, however, represents a major strategy by which eukaryotic cells regulate their response to cellular and DNA damage.

Types of Damage Repaired by NER

The NER system recognizes and repairs DNA damage that consists of UV-induced photoproducts and large DNA adducts. These include the cyclobutane [5–5], [6–6] pyrimidine dimers (CPDs) and the [6–4] pyrimidine pyrimidinone dimers ([6–4]PDs) that can involve T and C pyrimidines (Figure 1). The [6–4]PD can further photoisomerase to the Dewar photoproduct at longer UV wavelengths. Cytosine in dimers has an increased propensity to deaminate causing C to T mutagenesis. Chemical adducts include those produced by N-acetoxy-N-acetyl aminofluorene (AAAF), benzo[a]pyrene, 7,12-dimethyl-1,2-benz[a]anthracene (DMBA) aflatoxin, photoactivated psoralens, and *cis*-platinum. An oxidative purine product, 5′,8-purine cyclodeoxynucleoside, also requires the NER system for repair. The NER system can even recognize DNA triplexes formed by the binding of short oligonucleotides to double-stranded DNA.

Other kinds of damage involving smaller modifications to DNA bases (radiation and oxidative products, alkylations) or DNA breakage require a different suite of enzymes, some of which are involved with immunoglobulin rearrangements and developmental processes. The distinctions between the various repair systems are not absolute, however, and there are overlaps in the substrate specificity of these various repair systems and variations in the efficiencies and sites of action on DNA in differing metabolic states.

TABLE I

The Main Genes and Functions of the NER System

Gene	Chrom location[a]	Protein	Function	Partner(s)	CNS[b]
XPA	9q34.1	273aa	DNA damage binding	RPA	+
XPB	2q21	782aa	3′-5′ helicase	TFIIH	+
XPC	3p25.1	940aa	DNA damage binding	HR23B	−
XPD	19q13.2	760aa	5′-3′ helicase	TFIIH	+
XPE	11p11-12	427aa	DNA damage binding (DDB2)	DBB1(p127)	−
XPF	16p13.3	916aa	Endonuclease 5′ to damage	ERCC1	−
XPG	13q32-33	1186aa	Endonuclease 3′ to damage	Thymine glycosylase (nth)	+
XPV	6p21	713aa	Low fidelity DNA polymerase (pol η)	PCNA	−
CSA	5q11.2	396aa	WD protein, ubiquitination of RNA pol II		+
CSB	10q23	1493aa	DNA dependent ATPase, ubiquitination of RNA pol II		+

[a] For further details on chromosome locations and sequence see www.ensembl.org and for mutations in the genes see www.xpmutations.org.
[b] The presence of central nervous system (CNS) disorders in the majority of the patients in the group is indicated by a " + ," complete absence by a " − ".

Recognition of Damage in Transcriptionally Inactive and Active Regions of the Genome

The initial damage recognition factors uniquely required for GGR are the XPC and XPE DNA binding proteins (Figure 2). XPC is found in association with a cofactor HR23B, one of the two human homologues of the yeast Rad23 gene product. The XPC/HR23B complex is the earliest damage detector to initiate NER in nontranscribed DNA with highest affinity for the [6–4]PD. In XP-C cells that lack this complex, repair is confined to small transcriptionally active islands of the genome, where repair occurs at normal rates, surrounded by oceans of unrepaired transcriptionally silent DNA. The constitutive level of expression of *XPC* is controlled by p53, and the protein can be induced by UV irradiation.

The *XPE* gene product involves a dimeric protein having subunits of 127 kDa (DDB1) and 48 kDa (DDB2) and mutations that are diagnostic for XP-E patients are located in the DDB2 subunit. The XPE protein is mainly involved in repair of mutagenic UV-induced photoproducts.

CPDs are excised more rapidly from actively transcribed genes, especially from the DNA strand used as the template for transcription. The initial damage recognition mechanism for TCR may be the stalled RNA Pol II, itself, although a potentially large number of gene products play a role in mediating the increased rate of repair. Excision can be slow where binding proteins interact with the promoter but increases immediately after the ATG start site for transcription.

Two genes, *CSA* & *CSB*, are involved specifically in TCR. CSA contains WD-repeat motifs that are important for protein–protein interactions. CSB contains an ATPase, helicase motifs, and a nucleotide binding domain, but only the latter is essential for TCR, and CSB does not function as a helicase. Cells lacking either CSA or CSB are unable to ubiquitinate the C-terminal domain of RNA Pol II, that may influence its ability to dissociate or back away from stalling lesions.

The Core Excision Process Common to GGR and TCR

The individual factors of NER associate sequentially and independently on UV photoproducts, *in vivo*, without preassembly of a "repairosome" complex (Figure 2).

Damage Verification

After damage recognition, the initial proteins are replaced by another damage binding complex, XPA and replication protein A (RPA) that acts as a foundation on which many of the other components of the NER process assemble.

DNA Unwinding

The damaged site is unwound by the 3′-5′ (XPB) and 5′-3′ (XPD) helicases of TFIIH and stabilized by the XPA–RPA binding complex.

Excision of the Damaged Strand

An oligonucleotide, 27–29 nucleotides long, containing the photoproduct is excised by enzymatic cleavages, 5 nucleotides on the 3′ side of the photoproduct, and

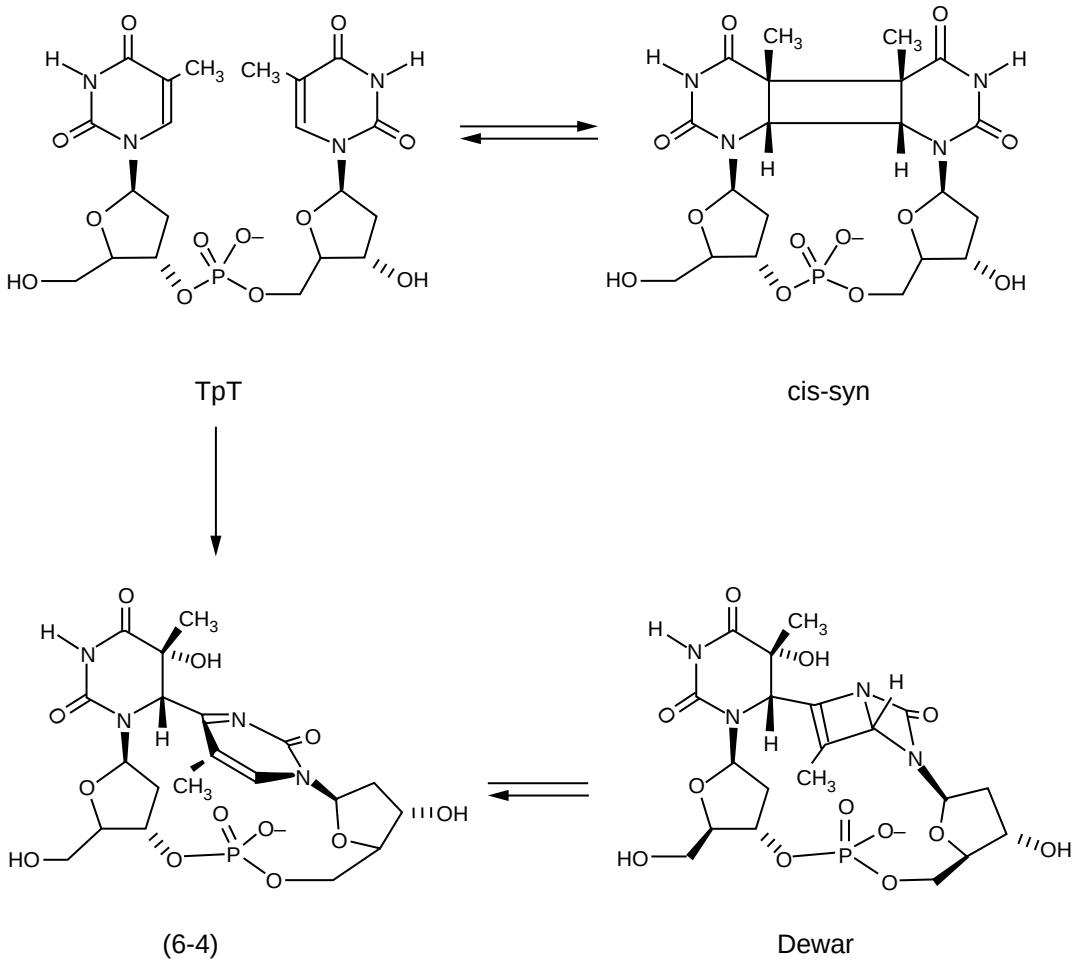

FIGURE 1 Photochemical reactions in a dipyrimidine DNA sequence leading to the formation of a cis-syn CPD (top right) or a [6–4]PD (bottom left) and its photolytic derivative, the Dewar pyrimidine (bottom right). (Reproduced from Cleaver J. E., and Mitchell D. L. (2003). Ultraviolet radiation carcinogenesis. In *Cancer Medicine*, 6th edition, Chap. 20, with permission of B. C. Dekker, London.)

24 nucleotides on the 5′ side. The structure-specific cleavage pattern is determined by binding of RPA to the unwound damaged site, and the excised fragment is close in size to the footprint of RPA on DNA. The XPG nuclease cleaves first on the 3′ side of the damage and interacts with the XPC–HR23B complex and with TFIIH; the XPF–ERCC1 heterodimer then binds to XPA through ERCC1 and cleaves on the 5′ side of the damaged site.

Synthesis of the Repair Patch

The excised region is replaced by the action of a complex similar to that involved in normal DNA replication. Proliferating cell nuclear antigen (PCNA) is loaded onto the DNA by the 5 subunit replication factor C (RFC) complex which then anchors the replicative DNA polymerases, Pol δ or Pol ε. The final closure of the repaired site occurs with DNA ligase I.

Replication of Damaged DNA

NER can remove DNA damage before DNA replication begins, and consequently plays a major role in reducing the amount of damage that becomes fixed as mutations during replication. DNA photoproducts, however, are blocks to the replicative DNA polymerases – alpha, delta and epsilon (Pol α, δ, ε, respectively). Replicative bypass of these photoproducts is achieved instead by damage-specific polymerases with relaxed substrate specificity, now defined as the low-fidelity class Y polymerases. These polymerases have larger active sites that allow them to read-through noninformative sequence information resulting from DNA damage. One adverse consequence of this relaxed specificity is that these polymerases have high error rates of the order of 1% when assayed *in vitro*, and this property must be controlled *in vivo*, otherwise the results would be catastrophic to the cell.

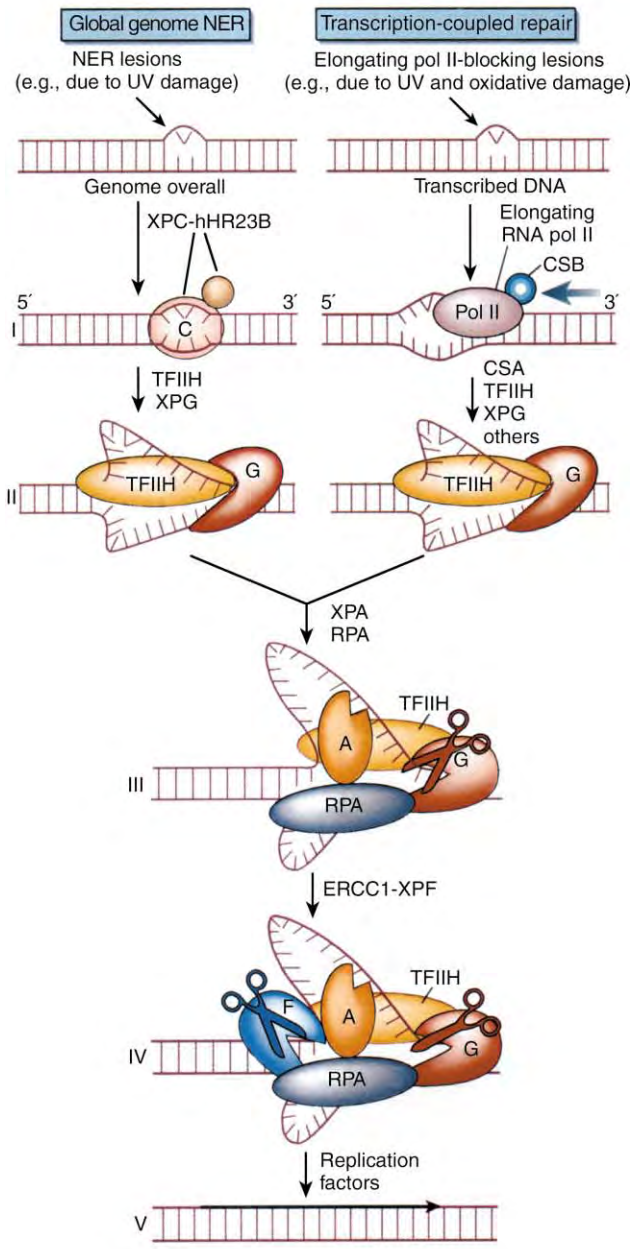

FIGURE 2 The sequence of steps involved in nucleotide excision repair (global genome repair and transcription coupled repair) from damage recognition, verification, unwinding, excision, polymerization and ligation. I, damage recognition; II, DNA unwinding; III, cleavage 3′ to the damaged site; IV, cleavage 5′ to the damaged site; V, repair replication. (Reproduced from Hoeijmakers J.H.J. (2001) Genome maintenance mechanisms for preventing cancer, with permission of Nature.)

Three class Y polymerase genes have been identified in the mammalian genome, *Pol* η, ι, and κ. *Pol* η and ι are close homologues, unique to mammalian cells, and only a single *Pol* η gene is found in yeast. Mutations in *Pol* η result in similar clinical symptoms to those seen in the NER-defective XP patients. Pol η and ι are involved in replication of UV damage but Pol κ replicates other kinds of damage or extends a DNA strand from mis-matched 3′ termini. Pol η preferentially inserts adenines across from thymine-containing photoproducts, resulting in accurate replication of a T-T CPD. Pol ι preferentially inserts guanines across from cytosine-containing photoproducts, resulting in accurate replication of a T–C CPD or [6–4]PD.

Pol η acts distributively to extend nascent DNA chains by one or two bases across from CPDs, and there may be a role for editing by a separate exonuclease. Chain extension then requires the activity of Pol ζ or Pol κ. Pol η is uniformly distributed in the nucleus, and excluded from the replication fork until replication is stalled by UV damage. Pol η then traffics into the nucleus and accumulates with a large number of other proteins in microscopically visible foci at the replication fork. This requires specific sequence motifs in the protein for translocation and for binding to PCNA.

Clinical Consequences of NER Deficiencies – Cancer

Mutations in NER genes are found in XP, and in other cancer, developmental or neurodegenerative diseases such as Cockayne syndrome (CS), trichothiodystrophy (TTD), and Cerebro-Oculo-Facio-Skeletal (COFS) syndrome. These represent only about 10 of the possible 30 genes involved in NER. The other genes are probably essential and mutations are likely to be inconsistent with viability, as has been demonstrated for *ERCC1* and *HR23B*.

XP manifests as a multigenic, multiallelic autosomal-recessive disease but heterozygotes are unaffected. The frequency in the United States is about 1:250 000, but higher in Japan and the Mediterranean, and possibly Central American areas. The disease begins in early life with the first exposures to sunlight, the median age of onset being 1–2 years of age, with skin rapidly exhibiting the signs associated with years of sun exposure. Pigmentation is patchy, and skin shows atrophy and telangiectasia with progressive degeneration of sun-exposed regions of the skin and eyes, usually leading to various forms of cutaneous malignancy (melanoma and nonmelanoma). Cancer incidence for those individuals under 20 years of age is 2000 times that seen in the general population. There may be a reduction in life span associated with the progression of cancer or neurologic degeneration, but a specific effect on aging itself has not been observed. In areas with poor health care, malignant disease may compound other life-threatening conditions (malnutrition, infections etc), but stringent protection from sun-exposure can minimize the development of symptoms dramatically.

The nonmelanoma skin cancers that develop in XP patients contain mutations in the *p53* gene (squamous carcinomas) or *patched* (basal cell carcinoma) that are mainly C to T transitions at dipyrimidine sequences, characteristic of the UV photoproducts that are the substrates for NER (Figure 1). Melanomas are also found at higher frequency in XP patients with a similar body distribution to those in non-XP patients, but UV-specific mutations in relevant genes (*p16*, *BRAF*) have not yet been found.

Clinical Consequences of NER Deficiencies – Neurodegeneration

Progressive neurologic degeneration occurs in a significant number of patients, with NER deficiencies (Table I). Most of these patients have mutations in subset of XP and CS genes, especially those associated with TCR. These include *XPA*, *XPB*, *XPD*, and *XPG*, and the *CSA* and *CSB* genes. Several of these also regulate repair of oxidative damage in transcriptionally active genes. Whether the neurodegeneration and other developmental disorders are due to defects in transcription of critical genes, or defects in repair of oxidative damage in these genes is therefore debatable. Both possibilities may have an element of truth.

In Japan a large fraction of the *XPA* mutations occur at the same splice site, and patients present a fairly uniform neurological disorder involving loss of walking ability and sensoneural deafness.

Patients with one of their *XPA* mutations in exon VI outside the DNA binding region of the gene have much less neurodegeneration. Tunisian patients have a common mutation in this region and have relatively mild symptoms despite their sun exposure. Some neurological dysfunction may, however, appear late in life.

XPD is a particularly complex gene in which mutations can give rise to various diseases and mixed symptoms that correspond to either XP, XP/CS syndrome, XP/TTD, or COFS. Many of these mutations occur in the DNA or RNA helicase "box" regions of the gene or in the 3′ terminal region. Inactivating mutation are lethal, hence all patients so far studied have at least one missense mutation resulting in a change of function, and occasional haplo-insufficiency. Similar XP/CS symptoms are seen in the small number of patients reported with mutations in *XPB*.

TTD is a rare autosomal-recessive disorder characterized by sulfur-deficient brittle hair and ichthyosis. Hair shafts split longitudinally into small fibers, and this brittleness is associated with levels of cysteine/cystine in hair proteins that are 15–50% of those in normal individuals. The hair has characteristic "tiger-tail" banding visible under polarized light. The patients often have an unusual facial appearance, with protruding ears and a receding chin. Mental abilities range from low normal to severe retardation. Several categories of the disease can be recognized on the basis of cellular responses to UV damage and the affected gene. Severe cases have low NER and mutations in *XPB* or *D* as described above. A third category involves another unidentified gene called *TTDA* and lacks major UV sensitivity, but has an unstable TFIIH.

COFS is a particularly severe developmental and neurological expression of mutations in *XPD*, *XPG*, and *CSB*. The disease leads to brain microcephaly and atrophy with calcifications, cataracts, microcornea, optic atrophy, progressive joint contractures, and growth failure.

The XPG nuclease has a particularly complex range of activities, and mutations in *XPG* are often associated with both XP and CS diseases. One patient with a mutation that permits a significant level of repair has been reported who is much milder and has no neurological dysfunction. XPG is an endonuclease in the FEN-1 family that is capable of strand-specific cleavage of a range of DNA substrates that may arise during DNA replication, repair, and recombination. The XPG gene product also interacts with RNA Pol II and facilitates efficient transcription elongation, thereby providing an explanation for the complex symptoms of some XPG patients that show both XP and CS symptoms. XPG is also a cofactor required for the activity of thymine glycosylase (*nth* gene) and is thereby linked to repair of oxidative damage that may also be important in maintaining neural functions that fail in CS.

CS is an autosomal-recessive disease characterized by cachectic dwarfism, retinopathy, microcephaly, deafness, neural defects, and retardation of growth and development after birth. They have a typical facial appearance with sunken eyes and a beaked nose and projecting jaw. CS patients are sensitive to the sun but do not develop cancers, setting this disease apart from XP. Patients who only have CS have mutations in one of two genes, *CSA* and *CSB*, the former being the more common. Cells from CS patients are only defective in TCR. The excision of DNA photoproducts from total genomic DNA of CS cells is normal, but repair of transcriptionally active genes is reduced. Clinically, however, the disease has been classified into type I, II, and others, but no detailed correlation has been made between these classifications and the mutations in *CSA* and *CSB*.

Mouse Models of NER Deficiencies

A series of mouse strains have been developed in which the *XP* or *CS* genes have been knocked out (http://webpath.swmed.edu/mutation/). The knockouts,

in general, exhibit increased cancer rates from treatment with UVB or chemical carcinogens, as expected from their human counterparts.

Xpa and Xpc knockouts, for example, are very sensitive to skin cancer induction. Strikingly, though, mouse knockouts have tended to exaggerate the cancer risks and minimize the neurodegeneration as compared to the corresponding human patients. $Xpa^{-/-}$, $Csa^{-/-}$, $Csb^{-/-}$ mice, for example, show increased skin carcinogenesis from UV light or chemical carcinogens, but have negligible neurodegeneration, whereas the corresponding patients are often severely affected neurologically. Mice that are $Xpa^{-/-}$ or $Csb^{-/-}$ are very sensitive to toxic effects of DMBA, but $Xpc^{-/-}$ survive much better, even though they show increased mutation rates. The severity of the neurological phenotype is greatly enhanced in crosses between Xpa and Csb knockouts, and the double homozygote shows early postnatal ataxia and abnormal cerebellar development.

Homozygous knockouts of the *Xpb* and *Xpd* genes are lethal very early in embryonic cell division because these genes are part of the essential transcription factor TFIIH. Mice with a human TTD mis-sense mutation in the *Xpd* gene are viable and have many of the same symptoms as TTD patients. These TTD mice show increased UVB-induced skin cancer and age prematurely, although TTD patients do not exhibit a corresponding increase in cancer.

Mice lacking Xpg are very severely affected, and exhibit postnatal growth failure and neurological dysfunction especially loss of purkinje cells and early death. Although both Xpg and Xpa mice lack repair completely, Xpa knockouts have a near normal lifespan suggesting important differences in Xpa and Xpg during development.

These studies indicate important differences between the clinical presentation of human patients and corresponding mouse models. One obvious cause is that patients have a variety of mis-sense, chain-terminating, splice site, and deletion mutations, which would not necessarily lead to the same phenotypes as complete knockouts. Another cause may be the difference in NER between human and rodents in the function of the XPE heterodimer. A consensus DNA-binding site for p53 is present in the promoter region of human p48 (DDB2) but the sequence has diverged in the mouse homologue, and is methylated in the hamster. UV-induced expression of DDB2 consequently occurs through p53 transactivation in human, but not mouse or hamster cells. The inactivation of the p53 response element provides a partial explanation for early observations that excision repair was low in some mouse strains and hamster cell strains. Therefore re-expression of DDB2 in mice might confer a phenotype that more closely resembles the human disorders.

Differentiation and Tissue-Specific Expression of DNA Repair Genes

As cells differentiate to a nondividing state their capacity for NER of UV damage declines. The major loss is in the capacity for repair of transcriptionally inactive genes or regions of the genome. Specific down-regulation of repair has been described in the testis due to reduced expression of XPA, rendering testicular tumors more sensitive to cis-platin chemotherapy. In the basal layer of the skin, a small fraction of cells seem to be specifically defective in repair of UV and carcinogen damage and retain photoproducts for long times after irradiation. This represents down-regulation of repair in a few cells distributed among a large population of repair-competent cells.

Polymorphisms in DNA Repair Genes

Polymorphisms that are not directly associated with the XP disease phenotype have been described for many of the NER and other repair genes. Polymorphisms have been found in the *XPA*, *XPC*, and *D* genes. Many of these polymorphisms result in nonconservative amino acid changes that could have an impact on NER function and disease. A large number of alleles present at low frequency individually could combine to create variation in disease frequency in the overall population.

Glossary

DNA damage Any chemical or radiation damage to the bases, deoxyribose and phosphodiester bonds in DNA that interferes with its normal functions.

helicase An enzyme that can unwind double-stranded RNA or DNA in a strand-specific direction.

nucleotide excision repair The process of recognition, removal and resynthesis of a damaged region of DNA.

polymerase An enzyme that copies DNA into RNA (RNA polymerase) or duplicates DNA (DNA polymerase).

polymorphisms Different nucleotides in one position of a gene that give rise to changes in sequence without major alterations in function.

ubiquitin A short peptide that is enzymatically attached to a protein by a set of conjugating enzymes to modify its function or mark it for degradation.

ultraviolet light The wavelengths of solar and artificial light between 240 and 280 nm (UVC), and 280 and 320 nm (UVB) that are strongly absorbed in nucleic acids.

xeroderma pigmentosum A human disease in which hereditary mutations in nucleotide excision repair result in a very high incidence of sunlight-induced skin cancers.

Biography

James E. Cleaver is a Professor of dermatology and pharmaceutical chemistry, former Associate Director in the Laboratory of Radiobiology and Environmental Health, and presently Head of the Cutaneous Oncology Program of the UCSF Cancer Center, University of California, San Francisco. His principal research interest is in the field of DNA repair, and he is best known for discovering the repair defect in the human disease xeroderma pigmentosum that linked repair to human cancer. He holds a B.A. and Ph.D. from the University of Cambridge, UK. He has authored over 350 publications and was elected to the National Academy of Sciences in 1999.

Nucleotide Excision Repair in Eukaryotes

Laura A. Lindsey-Boltz and Aziz Sancar
University of North Carolina School of Medicine, Chapel Hill, North Carolina, USA

Eukaryotes possess several repair mechanisms to provide defense against a large variety of DNA alterations. One of these mechanisms, nucleotide excision repair, is responsible for repairing bulky DNA lesions, which if left unrepaired, can result in oncogenesis, developmental abnormalities, and cellular lethality. Humans with hereditary defects in nucleotide excision repair suffer from diseases including xeroderma pigmentosum, Cockayne syndrome, and trichothiodystrophy, with symptoms including elevated sun sensitivity and skin cancers, neurological degeneration, and developmental delays.

Substrates

Two major carcinogens produce the bulky, DNA helix-distorting lesions which are repaired by the nucleotide excision repair system. UV light produces cyclobutane pyrimidine dimers and (6-4) photoproducts, and cigarette smoke produces benzo[a]pyrene-guanine adducts. However, the nucleotide excision repair system is not limited to the repair of bulky DNA lesions. It removes virtually all base lesions tested, including thymine glycols and 8-oxoguanine which are not bulky. Because of the wide substrate range, it is unlikely that the nucleotide excision repair system recognizes the specific chemical groups that make up the lesion, but rather recognizes the changes in the conformation of the phosphodiester backbone created by the damage.

Nucleotide Excision Repair Factors

In eukaryotes, nucleotide excision repair is carried out by six repair factors containing eighteen polypeptides (Table I). The six human nucleotide excision repair factors are RPA, XPA, XPC, TFIIH, XPG, and XPF-ERCC1. With the exception of XPA and XPG, each repair factor consists of 2–9 polypeptides that are in tight complexes, and these complexes are considered to be the subunits of the nucleotide excision repair enzyme (excision nuclease). All eukaryotic organisms whose genomes have been sequenced to date have homologues of the six nucleotide excision repair factors. However, only in the case of human and the budding yeast, *S. cerevisiae*, the excision nuclease has been reconstituted with the purified factors.

The nucleotide excision repair factors were primarily identified by genetic studies in cell lines derived from humans with xeroderma pigmentosum (XP) and UV-sensitive rodent cell lines. Thus, the repair genes have been named *XPA*, *XPB*, etc. or excision repair cross complementary group 1 (*ERCC1*), etc., depending on whether they were cloned by complementing human XP mutants or repair-defective rodent cell lines. In addition to the seven XP proteins, two multifunctional, multi-subunit factors, RPA and TFIIH, have been shown to be required for nucleotide excision repair. Replication protein A(RPA) is a complex of three proteins, and was originally identified and named for its role in replication. TFIIH, a complex of nine proteins, was originally identified as one of the six general transcription factors required for optimal transcription by RNA polymerase II. TFIIH consists of a core complex of proteins containing XPB, XPD, p62, p52, p44, and p34; and the cdk-activating kinase (CAK) subcomplex, consisting of cdk7, cyclinH, and Mat1 (Table I). Only the TFIIH core complex is required for nucleotide excision repair *in vitro*.

Mechanism of Nucleotide Excision Repair

The three basic steps of nucleotide excision repair in eukaryotes are: (1) dual incisions bracketing the lesion in a 24–32 nt-long oligomer; (2) repair synthesis to fill in the resulting gap; and (3) ligation of the newly synthesized DNA (patch) to the old DNA (Figure 1). Of these three steps, the last two are carried out by replication and recombination enzymes, and thus the dual incision (excision) step might be considered the repair reaction proper. Assays for detecting DNA–protein complexes (gel mobility shift and DNAaseI and

permanganate footprinting) have led to the identification of three high-specificity and high-stability intermediates along the assembly pathway of the excision nuclease. These three intermediates are called preincision complexes (PIC) 1, 2, and 3 and are described in detail below.

Preincision Complex 1

PIC1 consists of DNA, RPA, XPA, XPC, and TFIIH. ATP is required for the formation of this complex. It is hydrolyzed by two helicases in TFIIH, XPB and XPD, which have 3′ to 5′ and 5′ to 3′ helicase activities, respectively. These helicases unwind the DNA by about 20 bp around the lesion in an asymmetric manner with about 15 bp unwound on the 5′ side and 5 bp unwound on the 3′ side of the damage. The overall direction of unwinding with respect to the damaged strand was determined to be 5′ to 3′ based on data with substrates containing an interstrand cross-link.

Preincision Complex 2

XPG enters to form the second complex, which is much more stable than PIC1. As in the case of PIC1, the formation of PIC2 is also dependent on ATP hydrolysis by the XPB and XPD subunits of TFIIH. Interestingly, when the composition of PIC2 was analyzed by gel mobility shift assays it seemed to lack XPC. It appears that XPC leaves the complex after helping to recognize the damage and unwind the duplex, which then enables XPG to enter. The replacement of XPC in PIC1 by XPG in PIC2 is consistent with the findings that TFIIH makes relatively tight complexes with XPC and XPG. Apparently, the binding surfaces of these two factors on TFIIH overlap and therefore the entry of one into the complex is concomitant with the exit of the other. Thus, the composition of PIC2 is RPA XPA XPG TFIIH-DNA.

Preincision Complex 3

Finally, with the entry of XPF ERCC1 into PIC2, the PIC3 forms the complex composed of RPA XPA XPG TFIIH XPF ERCC1-DNA. Within this complex the 3′ incision is made by XPG and the 5′ incision is made by XPF-ERCC1. Following the dual incisions, the excised 24–32 nt-long oligomer carrying the damage is released, and the excision nuclease is dissociated. Replication Factor C (RFC) loads the PCNA trimeric circle onto the DNA, and PCNA recruits DNA Pol δ or Pol ε to fill in the gap in the DNA. Repair is completed by ligation by DNA ligase I.

Damage Recognition and Transcription-Coupled Repair

Recognition of the DNA damage is most likely the rate-limiting step in nucleotide excision repair. The DNA

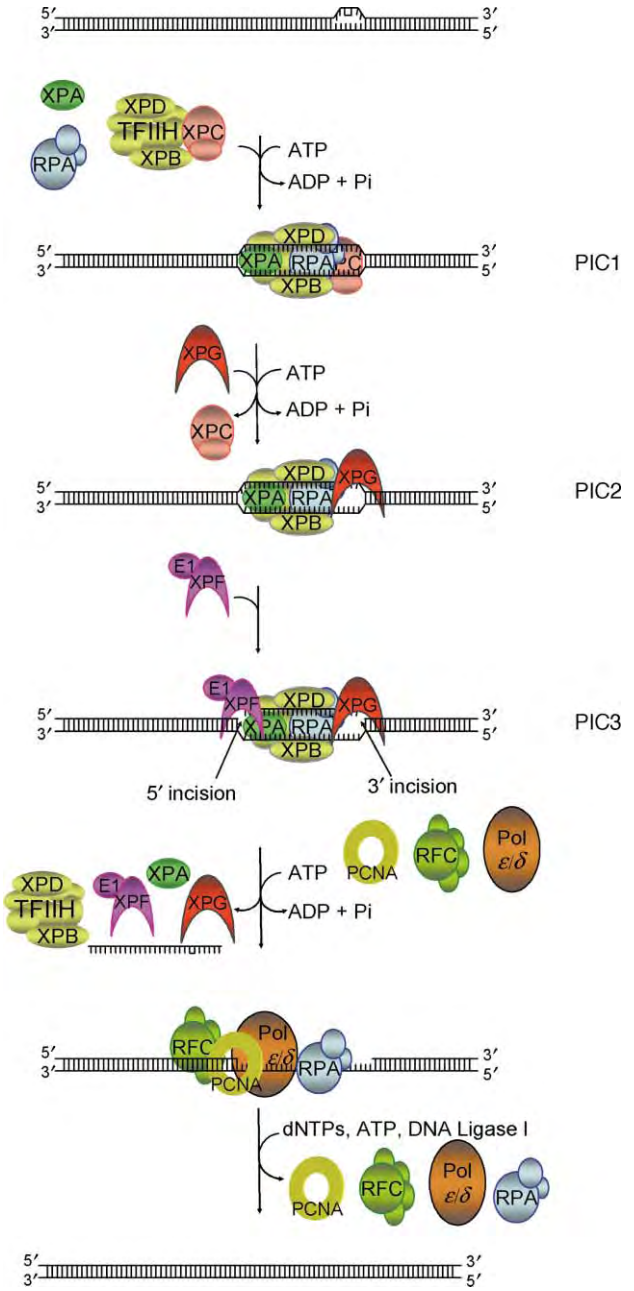

FIGURE 1 Model for nucleotide excision repair in humans. The DNA lesion is bound by RPA, XPA, and TFIIH XPC to form preincision complex (PIC) 1. ATP is hydrolyzed by the XPB and XPD helicase subunits of TFIIH to locally unwind the DNA. XPG enters and XPC exits in the next step which requires ATP hydrolysis by XPB and XPD to form PIC2. After XPF enters to form PIC3, the two endonucleases make incisions in the strand containing the lesion; the 3′ incision is made by XPG and the 5′ incision is made by XPF-ERCC1. Repair synthesis then fills in the single-stranded gap.

lesions must be located among the 3 billion base pairs present in the human genome. The damage recognition factors of the human excision nuclease are RPA, XPA, and XPC. All three proteins are DNA-binding proteins with some preference for damaged DNA, and all three apparently play a role in low-discriminatory damage recognition independent of ATP. However, the precise order of assembly has been difficult to establish with kinetic experiments, resulting in conflicting studies wherein one study concluded that RPA and XPA are the repair factors which make the initial contact, and another study found that XPC makes the initial contact. Nucleotide excision repair appears to operate somewhat differently on DNA that is transcriptionally active (transcription-coupled repair) from that which is transcriptionally silent (global genome repair). Transcribed DNA is repaired at a faster rate than nontranscribed DNA, and this is most likely due to recognition of the RNA polymerase stalled at the damage. In addition to the nucleotide excision repair factors, transcription-coupled repair depends on the CSA and CSB gene products in humans. *In vivo* data indicate that in humans, but not in yeast, XPC is dispensable for transcription-coupled repair. It is thought that the transcription bubble 3′ to the lesion which impedes the progression of RNA polymerase creates a unique damaged DNA structure which can be recognized in the absence of XPC. Indeed, when a cyclobutane thymine dimer is placed adjacent to a 10 nt bubble in a synthetic substrate, it is recognized and excised efficiently in the absence of XPC. Transcription-coupled repair has not been reconstituted *in vitro*, and therefore the mechanism in eukaryotes is currently not known.

Glossary

Cockayne's syndrome (CS) Human disease caused by defects in proteins involved in coupling transcription to nucleotide excision repair; symptoms include mental retardation, dwarfism, neurological defects, and moderate sensitivity to UV light.

endonuclease Protein that cleaves bonds within a nucleic acid chain, e.g., XPF and XPG.

excision nuclease Enzyme that removes damaged bases by dual incisions bracketing the lesion in the damaged strand.

helicase Protein that uses the energy of ATP hydrolysis to unwind a nucleic acid duplex, e.g., XPB and XPD.

trichothiodystrophy (TTD) Human disease caused by mutations in XPB and XPD which results in defects in both transcription and nucleotide excision repair; symptoms include brittle hair and nails, mental retardation and skeletal abnormalities.

xeroderma pigmentosum (XP) Human disease caused by reduced level of nucleotide excision repair; symptoms include mental retardation, ataxia, deafness, and predisposition to skin cancer caused by sunlight exposure.

Laura Lindsey-Boltz is a Postdoctoral Fellow in Dr. Aziz Sancar's laboratory, and she holds a Ph.D. from Duke University.

Aziz Sancar is a Kenan Professor in the Department of Biochemistry and Biophysics at the University of North Carolina, Chapel Hill. His principal research interests are in the fields of DNA repair, DNA damage checkpoints, and circadian photoreceptors. He holds an M.D. from Istanbul University School of Medicine and a Ph.D. from the University of Texas at Dallas.

Nucleotide Excision Repair, Bacterial: The UvrABCD System

Bennett Van Houten
National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina, USA

Lawrence Grossman
The Johns Hopkins University, Baltimore, Maryland, USA

DNA repair is intrinsic to the evolution of life, and organisms have evolved a large number of complex systems to ensure the integrity of their heredity material. DNA constantly undergoes chemical modification as a result of its intrinsic chemical instability, as well as, endogenous and environmental stresses. The most versatile DNA repair mechanism is nucleotide excision repair (NER), first discovered in *Escherichia coli* in 1964 independently by Setlow and Carrier and Boyce and Howard-Flanders. This bacterial system, like its eukaryotic counterpart, has a very broad spectrum of damage recognition and operates according to the same basic principles in all organisms: (1) repair proteins form macromolecular assemblies in order to locate and activate damage utilizing a number of ATP-hydrolysis-driven nucleoprotein rearrangements; (2) the DNA is incised on both sides of damage; and (3) the incised fragment is displaced with concomitant resynthesis followed by ligation. NER is coupled to other cellular processes, notably, transcription. The sequencing of the complete genomes of over 20 different bacterial species indicates that the NER system is a highly conserved process.

UvrABC Endonuclease

The nucleotide excision repair (NER) pathway consists of five basic steps: damage recognition, incision, excision, repair synthesis, and ligation. In most bacteria the first steps of this process are carried out by an ensemble of three proteins encoded by the *uvrA*, *uvrB*, and *uvrC* genes in an ATP-dependent series of reactions. During the initial characterization of these proteins, the name of this system was shortened to "UvrABC endonuclease" which makes both the 5′ and 3′ incisions to a lesion in a "dual incision" reaction (Figure 1). The UvrABC endonuclease possesses a broad spectrum of substrate specificity and is capable of acting on a wide variety of unrelated DNA damage (Table I).

Genetics and Evolutionary Conservation of *uvr* Genes

It was photobiologists who discovered NER from analyses of ultraviolet radiation (UV) survival curves in some bacterial, most notably *E. coli*. Rather than observing a first-order decline in survival of cells as a function of UV dose there was a shoulder in the survival curves at lower doses. Some *E. coli* mutants, which lacked this shoulder, were sensitive to low doses of UV, and were isolated. All these mutants map at one of three loci on the *E. coli* chromosome designated *uvrA* (92 min), *uvrB* (17 min), and *uvrC* (41.5 min), and are hence, unlinked genes. In species of *Bacillus*, the *uvrA* and *uvrB* genes are within 50 bp of each other on the chromosome.

The *uvr* genes were first cloned, sequenced, and amplified from *E. coli*, which led to a greater understanding of the roles of three proteins in the process of damage recognition and incision. Subsequently, large-scale sequencing efforts have revealed that *uvr* genes are highly conserved among the bacterial species

uvrA

uvrA is one of a series of genes collectively referred to as SOS genes, which are induced to increased levels of transcription by agents that cause DNA damage. A specific binding site for the LexA repressor protein specific for the operator promoter region of the *uvrA* gene (the so-called LexA box or SOS box) has been identified. Sequence analyses reveal that the *uvrA* gene (2.82 kbp) translates into 940 amino acids (Mr = 103,874 Da) and contains two ATP-binding motifs, two zinc-finger motifs and a helix-turn-helix motif.

uvrB

The *uvrB* gene is also a member of the SOS regulon and is inducible by DNA damage. The gene is transcribed

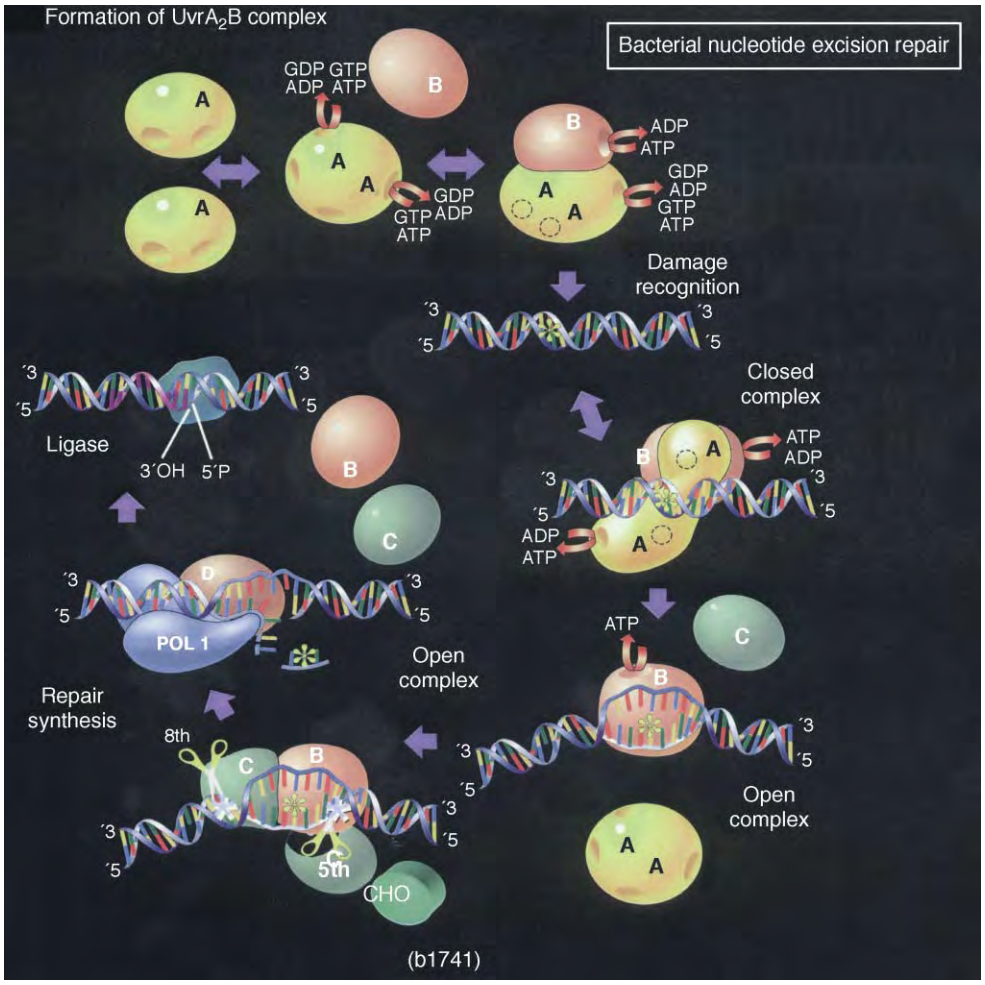

FIGURE 1 Nucleotide excision repair pathway in bacteria. $UvrA_2$ interacts with UvrB, and this $UvrA_2B_1$ complex translocates to the damaged sites. UvrA dissociates and UvrC binds to the UvrB—DNA complex at a damaged site. Dual incision is catalyzed by UvrC. The N-terminal domain is involved in the 3′ incision and the C-terminal domain performs the 5′ incision. UvrD displaces UvrC and an oligonucleotide containing the damage. DNA polymerase I fills the single stranded gap, and DNA ligase seals the nick.

from two overlapping promoters called P1 and P2. A LexA protein-binding site is present in the P2 promoter region. Transcription from P2 is inhibited by LexA repressor protein while that from P1 is unaffected. Sequence analysis revealed that the *uvrB* gene is 2,019 bp, which translates into 673 amino acids (76.6 kDa). The *uvrB* gene product has a consensus Walker-type A nucleotide-binding motif, helicase motifs II–VI as well as coiled-coils consensus sequences.

uvrC

In contrast to *uvrA* and *uvrB*, *uvrC* is not inducible by DNA damage and is not a member of the SOS regulon, although its cellular location is altered during SOS. The sequence analysis shows that the size of *uvrC* is 1,830 bp encoding a polypeptide of 610 amino acids (66 kDa).

Cho

It was quite surprising that a new uvrC homologue, Cho, could be discovered in an organism for which the complete genome sequence was known since 1997. The gene encoding Cho was found to be UV-inducible by Hanawalt and Brown using a high density DNA microarray. Careful inspection of this gene revealed homology to the Tev-homing endonucleases and also the N terminus of uvrC. Goosen and co-workers cloned and overexpressed the Cho protein, and found that the Cho protein will incise a DNA adduct at the tenth phosophodiester bond 3′ to the damaged site. This cutting at a distance was shown to help incise at bulky lesions, which might otherwise block the normal uvrC 3′ incision. They also found that uvrC can complete the incision process by efficient cleavage 5′ to the 3′ incised adduct. Cho is rather rare in the bacterial kingdom (Figure 2).

TABLE I

Range of Substrates of the Bacterial NER UvrABC System

Type	Lesion	UvrABC	ΔM_r	Properties
Single base modification	Thymine glycol	++	+34	
	Dihydrothymine	0	+2	
	Benzo[*a*]pyrene adduct	+++	+171	T_M lowered
	Anthramycin adduct	+++	+191	T_M elevated
	Cross-linked triple strand	+ [72]	~ + 3000	
	O^4-alkyl thymine	+	+14

A selection of DNA lesions illustrates the lack of a single common property that determines the response of UvrABC to DNA damage. The relative rate of incision for a particular lesion (neglecting the influence of sequence context) by the UvrABC system is indicated by +, ++, and +++; 0 indicates no incision, − indicates inhibition. ΔM_r, change in molecular weight due to the modification.

Properties of UvrA, UvrB, and UvrC Proteins

UvrA

The UvrA protein is a DNA-independent ATPase that binds DNA and is a member of the ABC transporter superfamily characterized by dual ATP binding sites. Soon after UvrA was sequenced, it was noticed that the gene probably arose through multiple duplication events in which a four-cysteine zinc finger was placed between the Walker type A and B nucleotide-binding motifs. Site-directed mutagenesis studies show directly that UvrA has an ATPase activity located in a region centered at lysine residues of two Walker type A nucleotide-binding motifs. UvrA also hydrolyzes GTP. ATPase activity of UvrA is modulated by DNA. High concentrations of UvrA protein and the binding energy of ATP (or poorly hydrolyzable ATP-γ-S) favor dimerization of the protein. UvrA dimers are DNA-binding species. The binding of UvrA to undamaged DNA is $10^3 \sim 10^4$-fold weaker than to the damaged one. The specificity for damaged DNA is abolished by ATP-γ-S, while it enhances nonspecific binding. The dissociation rate for UvrA from damaged sites is fast in the presence of ATP. ATP hydrolysis increases the specificity of binding to the damaged DNA, but lowers the equilibrium binding constant by stimulating dissociation. UvrA contains two zinc atoms per molecule, at least one of which is required for DNA binding. Consistently, C-terminal zinc-finger of UvrA is absolutely essential for nonspecific DNA binding, while N terminal is dispensable. The helix-turn-helix motif as well as C-terminal glycine-rich region appears to contribute into damage recognition by UvrA.

UvrB

The purified protein has no detectable ATPase activity, although it binds ATP with a $K_d \sim 1$ mM. However, ATPase activity is observed when UvrB interacts with UvrA in the presence of DNA. This dramatic appearance is due to activation of the cryptic ATPase when UvrB forms an UvrAB–DNA complex. When UvrB is proteolyzed in a specific region of the C terminus, the resulting ~70 kDa protein is referred to as UvrB*. The "cryptic UvrB ATPase" functional in UvrB*

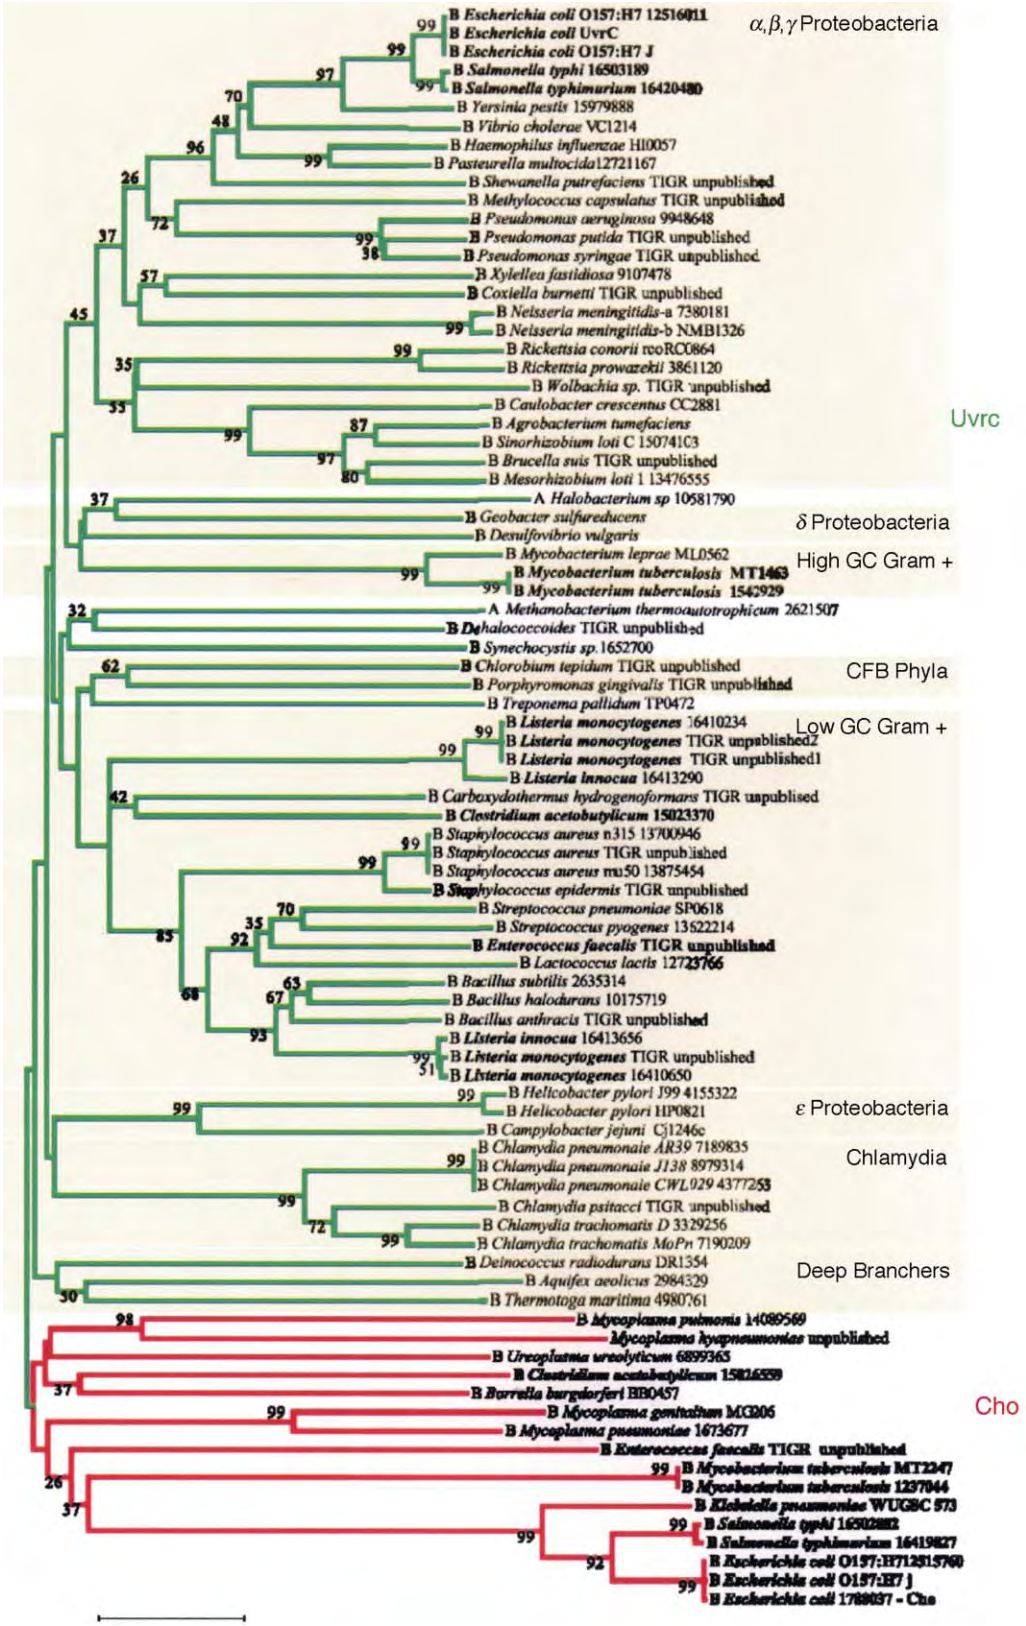

FIGURE 2 Phylogenetic tree of UvrC and Cho in various bacterial species. Phylogenetic tree of UvrC and Cho homologues. Homologues were identified in complete or nearly complete genomes by blastp or blastx searches. Protein sequences were aligned using clustalx. Boostrap values, a measure of statistical support for particular groupings of genes to the right of the number, are shown on the tree when greater than 40%. Reprinted from Van Houten, B., Eisen, J. A., and Hanawalt, P. C. (2002). A cut above: discovery of an alternative excision repair pathway in bacteria. *Proc. Natl Acad. Sci. FIGURE 3 Structure of UvrB. Domains 1a, 1b, 2, and 3 are shown in yellow, green, purple and red, respectively. The β-hairpin bridging the gap between domains 1a and 1b is shown in cyan. The ATP molecule bound at the interface between domains 1 and 3 is indicated. (Reprinted from Theis, K., Chen, P. J., Skorvaga, M., Van Houten, B., and Kisker, C. (1999). Crystal structure of UvrB Provides insight into the mechanism of nucleotide excision repair. *EMBO J.* **18**(24), 6899–6907, with permission of Oxford University Press.)

is activated by single stranded DNA or chaotropic salts. UvrB can bind to double stranded DNA only in the presence of UvrA, and binds to single-stranded DNA with a K_d in the micromolar range. The amino acid sequence of the UvrB protein shows homology with two limited stretches of the sequence of the UvrC protein. Three groups have independently solved the crystal structure of UvrB. The structure has revealed that UvrB is folded into four separate domains (Figure 3). Domain 1a includes four helicase motifs: Ia, Ib, II, and III that are required for ATPase activity. Domain two is important for UvrA interaction and domain 3 contains helicase motifs, IV, V, and VI. Sandwiched between domains 1a and 1b is an important β-hairpin motif which is believed to provide important DNA contacts. Further details of the UvrB structure and how it provides function is discussed below.

UvrC

UvrC is a single-strand DNA-binding protein and binds to it with a relatively high affinity. UvrC is a catalytic subunit of the UvrABC endonuclease. Mutations in the C-terminal region of UvrC are extremely sensitive to UV and defective in 5′-incision activity. The 314 C-terminal amino acids of UvrC are sufficient to support dual incision of damaged DNA by the UvrABC endonuclease. UvrC protein associates with a UvrB–DNA complex at damaged site. Recently, the C-terminal part of UvrC was solved by multidimensional NMR and shown to consist of two helix-hairpin-helix (HhH) motifs as predicted previously. Kaptein and co-workers found that this C-terminal region of the protein bound avidly to double-strand/single-strand junctions like those found in bubble substrates containing more than six unpaired bases. Interestingly this is exactly the number of base pairs believed to be unwound during the formation of the UvB–DNA complex.

Damage Recognition and Incision

The broad substrate specificity of the UvrABC endonuclease is achieved through a complex molecular mechanism (Figure 1) identifying some general changes in DNA conformation and dynamics rather than chemically modified bases *per se*.

Molecular Mechanism of Damage Recognition

Molecular recognition proceeds through a series of coordinated Uvr protein–protein and nucleoprotein intermediates characterized by different composition and architecture.

UvrA Dimerization

UvrA forms a dimer in solution with apparent $K_d \sim 10^{-8}$ M. Nucleotide (ATP) binding to UvrA drives UvrA dimerization, whereas the hydrolysis of ATP or the presence of ADP drives monomerization. The UvrA dimer is the active form in binding to undamaged or damaged DNA. Formation of a dimer results in a conformational change of the UvrA protein. UvrA is believed to recognize overall changes in the structure of the DNA helix.

$UvrA_2B_1$ Complex in Solution

The purified UvrA protein associates in solution with UvrB protein (domain 2) in an ATP-dependent manner. The N-terminal 230 amino acids of UvrA are involved in this interaction. UvrB has two UvrA-binding sites: one within amino acids 115–250 and another within C-terminal amino acids 573–673. However, $UvrB^*$ which lacks these C-terminal amino acids can also bind UvrA in solution. The apparent stochiometry of the UvrA–UvrB complex in solution is $UvrA_2UvrB_1$.

$UvrA_2$–DNA Binding

The UvrA dimer binds both damaged and undamaged DNA. ADP decreases the UvrA-binding affinity two- to

threefold and ATP is not required for the specific binding to a damaged site. ATP-γ-S quantitatively inhibits the specific binding while enhancing nonspecific binding. The equilibrium constant for nonspecific binding of UvrA is $(0.7–2.9) \times 10^5\ M^{-1}$. The apparent binding affinity of $UvrA_2$ to damaged DNA is in the range $0.07 \sim 1.0 \times 10^9\ M^{-1}$, depending on the damage type. However, affinity of $UvrA_2$ to damage does not generally correlate with the efficiency of the entire incision reaction.

$UvrA_2B_1$–DNA Complex

This complex provides for more productive damaged DNA-binding intermediates than UvrA dimer. Binding of $UvrA_2B_1$ to DNA results in locally unwound undamaged-DNA between 180° and 220°. Furthermore, it has been proposed that the DNA is wound around the UvrB molecule. The formation of the $UvrA_2B_1$–DNA complex results in a multifold stimulation of ATPase activity apparently through activation of a "cryptic" ATPase of UvrB. Using atomic force microscopy, Goosen and co-workers have recently suggested that UvrA and UvrB can form $UvrA_2UvrB_2$ complex on DNA. Once the UvrAB complex actively engages the damage, UvrA (and possible one molecule of UvrB) dissociate leaving a long-lived salt stable UvrB–DNA complex.

Formation of the UvrB–DNA Intermediate

Previous work by Grossman and co-workers have suggested that the UvrAB complex can track along the DNA helix using a limited helicase activity to create waves of negative and positive supercoiling behind and in front of the damaged site, respectively. This is consistent with the helicase fold of UvrB (shown in Figure 3). However, work from both the Rupp and Van Houten laboratories have argued that the UvrAB complex cannot dissociate damaged DNA strands even as small as 26 bases, and that formation of the UvrB–DNA complex leads to a destabilization of the DNA helix. However, neither UvrB by itself or in complex with UvrA can unwind long tracks of DNA, which is a typical property of proteins with true helicase activity.

Damage-Sensing Mechanism: Padlock Model of Damage Recognition by UvrB

The UvrABC endonuclease does not recognize a specific chemical group or structure in the damaged nucleotide nor does it, in all likelihood, solely recognize a specific backbone deformity in the duplex induced by the varied and unrelated genotoxic chemicals (Table I). Initial damage recognition may occur through direct UvrA–DNA interactions. This triggers structural changes of the preceding $UvrA_2B_1$–DNA complex, so that $UvrA_2$ dissociates, while UvrB is loaded onto a damaged site. Even though the cocrystal structure of the UvrB–DNA complex has not yet been solved, this complex has been observed in footprinting experiments by electron microscopy and gel mobility shifts and the complex is isolated by gel filtration. The formation of this complex requires ATP hydrolysis by both UvrA and UvrB and occurs after the recognition of a damage site by the UvrAB complex. As noted above, Goosen and co-workers have shown that the formation of the UvrB pre-incision complex at damaged sites results in a conformational change of both UvrB and DNA. The DNA molecule in this complex is kinked and the DNA wrapped around the UvrB molecule. Helicase motifs and the β-hairpin motif of UvrB seem to play a role in UvrB–DNA binding at damaged sites (Figure 4). The rate of UvrB loading to DNA is low ($k_{on} = 6–10^{-4}\ M\ s^{-1}$), suggesting that this step may be limiting for damage-specific incision of DNA. Kisker and co-workers have proposed a padlock model of UvrB binding to DNA to help reconcile the earlier helicase-unwinding model of Grossman with the known helicase fold of UvrB. In this model the UvrAB complex uses the UvrB ATPase to make limited motion along the DNA, causing transient opening and closing of the DNA, in which it is believed that the β-hairpin is inserted through the helix. If a DNA lesion is encountered by UvrB, there is a conformational change in the protein–DNA complex leading to the release of UvrA. In this precision complex, UvrB is believed to lock down the nondamaged between the β-hairpin and the wall of domain 1B (Figure 4). In this locked padlock model, the damaged strand wraps in front of the β-hairpin and the hydrophobic tyrosine side-changes at the base of the β-hairpin are believed to bind to or facilitate the damaged nucleotide to flip out of the DNA helix. In this locked down conformation, ATP binding is believed to lead to a large motion of domain 3 which clamps down on the DNA resulting in further deformation of the DNA helix leading to strained structure that is recognized by UvrC.

Dual Incision

The binding of UvrC to the pre-incision UvrB–DNA complex results in the incision of DNA on both sides of the lesion in the damaged strand. DNA sequence context and the type of damage affect the precise location of the 5′ and 3′ incision sites. Usually, it occurs at the 8th phoshodiester bond 5′ to the damage and 4th or 5th phoshodiester bond 3′ to the damage. The C-terminal coiled-coil motif of UvrB (amino acids 636–668) and the N-terminal homologous regions of UvrC (amino acids 214–239) are required for the

formation of UvrBC complex. Site-directed mutagenesis of the UvrC and UvrB proteins has led to the conclusion that the incision process is not a concerted one. The 3′ incision is affected by the N terminus of the UvrC protein, and this incision precedes the 5′ nicking, catalyzed by the C terminus of UvrC protein. There is a conformational change of UvrBC–DNA complex following 3′-incision. The C-terminal region of UvrC (amino acids 555–610) is involved in DNA binding and 5′-incision. Dual incision *per se* does not require ATP hydrolysis; ATP-γ-S can substitute ATP during this step.

Postincision Steps

Following dual incision, the UvrBC complex remains bound to damaged DNA. As a result of the stability of the postincision complex, UvrABC endonuclease does not turnover in an *in vitro* system, which is biochemically reconstituted with only Uvr proteins. Restoration of the DNA primary structure and integrity as well as turnover of the Uvr proteins is accomplished in a series of postincision steps, which require products of two additional genes, uvrD and polA.

UvrD

Its gene maps at 84 min of *E. coli* chromosome. UvrD + is a part of the SOS regulon and is induced by DNA damage. The product of this gene is a 3′–5′ DNA helicase II – a 75 kDa protein which is a DNA-dependent ATPase. DNA helicase II is required for removal of incised damage as a 12–13-mer oligonucleotide fragment. It also effects release of UvrC protein, but not UvrB from the postincision complex.

PolA

Its gene maps at 85 min of *E. coli* genetic map. It encodes a 109 kDa protein, DNA polymerase I. The UvrB protein is not displaced by DNA helicase II and remains bound to gapped DNA. In the presence of deoxyribonucleoside-5′-triphosphates, DNA polymerase I catalyzes repair synthesis, resulting in the filling in of the gap and displacement of the UvrB protein. The size of *in vitro* repair patch is usually ~12 nucleotides in length. Molecular interactions of Uvr proteins, DNA helicase II, and DNA polymerase I during postincision events are not presently known. *E. coli* strains, deficient in uvrD + and polA + are usually significantly less sensitive to the killing effects of UV radiation than Uvr-deficient strains, indicating their auxiliary role in repair. DNA ligase completes NER by catalyzing joining of the last 3′-nucleotide of the patch with the rest of polynucleotide chain.

Transcription-Coupled Repair

Transcription-repair coupling (TRC) allows cells to select some regions of the genome for NER in preference to others. In *E. coli*, as a consequence of a 436-fold induction of β-galactosidase operon, 70% of the UV-induced pyrimidine dimers are removed from the transcribed strand of the induced operon within 5 min, whereas only 50% of dimers are removed from the nontranscribed strand after 20 min of repair. This selective removal of pyrimidine dimers from the transcribed strand of a gene is abolished in the absence of significant levels of transcription. The mechanism of TRC in *E. coli* is a complex one, and may include several subpathways. In one of them, TRC is achieved through the action of transcription-repair coupling factor (TRCF). TRCF is a product of mfd + (for mutation frequency decline) gene, which maps at 25 min on the *E. coli* chromosome. The cloned mfd + gene is translated into a 1148 amino acids protein of ~130 kDa. The Mfd protein has consensus Walker type A nucleotide-binding motif, and, indeed, is a relatively weak ATPase. The Mfd protein can nonspecifically bind dsDNA (and less efficiently ssDNA) in an ATP binding-dependent manner, the ATP hydrolysis promoting its dissociation. The amino acid sequence of Mfd reveals motifs, which are characteristic of a number of DNA and RNA helicases. However, *in vitro* purified Mfd does not show either DNA or RNA helicase activity. The N-terminal 1–378 residues of Mfd, having 140 amino acid region of homology with UvrB, bind UvrA protein. The Mfd protein can also bind different forms of *E. coli* RNA polymerase (RNAP). Amino acids 370–571 of Mfd are involved in this binding. *In vitro*, transcription inhibits NER of damage in a transcribed strand, while it has no effect on the coding strand. This inhibition is thought to result from RNAP stalled at the site of damage. Mfd is able to release stalled RNAP in an ATP hydrolysis-dependent manner. Moreover, Mfd actually stimulates NER on the transcribed strand, so that it becomes faster than on the nontranscribed one. Based on all these observations, it is concluded that TRCF-Mfd carries out preferential repair of the transcribed strand by (1) releasing RNAP stalled at damaged site, and (2) recruiting the $UvrA_2B_1$ complex to damaged site through the high-affinity interaction with UvrA protein. The TRC in *E. coli* is influenced by the rate and conditions of growth as well as the level of gene

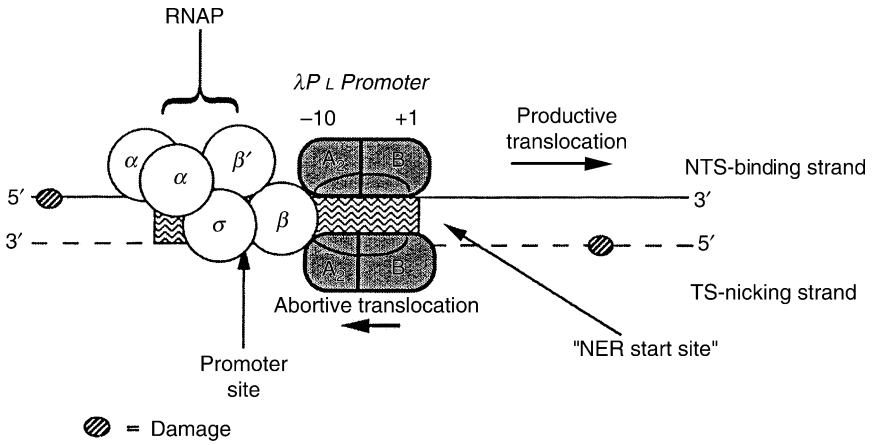

FIGURE 5 Model for strand selectivity by UvrAB helicase. RNA polymerase provides the UvrAB complex a preferred binding site at transcription bubble region via the physical interaction of RNAP with the UvrAB complex. Once the UvrAB complex binds to the promoter region, a competent nucleoprotein complex for helicase action is formed. The UvrAB complex may translocate along the non-transcribed strand in an ATP hydrolysis-dependent reaction. During tanslocation, the DNA damage recognition domain of the UvrA subunit of the UvrAB complex senses damaged sites on the complementary strand. (Reprinted from Ahn, B., and Grossman, L. (1996). RNA polymerase signals UvrAB landing sites. *JBC.* **271**(35), 2153–2161, with permission of The American Society for Biochemistry and Molecular Biology.)

transcription. In the LacZ gene the Mfd-dependent mechanism of preferential repair dominates at basal levels of transcription, while Mfd-independent mechanisms prevail at induced transcription levels. It was shown that in the presence of RNAP, $UvrA_2B_1$ complex is able to specifically bind promoter regions and translocate unidirectionally along coding strand while sensing damage in a transcribed strand. This strand specificity is dictated by the $5'-3'$ directionality of the $UvrA_2B_1$ helicase which can translocate only on the coding strand because the RNAP interferes with that directionality on the transcribed strand (Figure 5). Nicking occurs only on the strand opposite to the strand, along which the $UvrA_2B_1$ complex translocates. Hence, it is the transcribed strand, which is initially repaired. This mechanism could account for the observed Mfd-independent TRC *in vivo*. The Mfd-dependent mode of preferential repair seems to operate at those RNAP molecules which escaped binding of $UvrA_2B_1$ complex at the promoter region and was subsequently stalled at a damaged site.

Conservation of Nucleotide Excision Repair from Bacteria to Man

Nucleotide excision repair (NER) of bacterial, yeast, and mammalian cells have been reconstituted *in vitro* with purified proteins and defined damaged DNA substrates. While it would appear that it takes some 25 proteins in a human cell to complete the process achieved by six bacterial proteins, there is a high degree of conservation of function from bacteria to eukaryotes. Thus NER system of bacteria will certainly serve as a primary model for structure–function studies for years to come.

Biography

Bennett (Ben) Van Houten works at the National Institute of Environmental Health Sciences. His principle research interest is in the structure and function of DNA repair enzymes, and the consequences of mitochondrial DNA damage. He holds a Ph.D. from the University of Tennessee and completed postdoctoral training at the University of North Carolina, and has received the Burroughs Wellcome Toxicology Scholar award.

Lawrence (Larry) Grossman is the University Distinguished Service Professor of Biochemistry in the Department of Biochemistry and Molecular Biology in the Johns Hopkins Bloomberg School of Public Health. His research interests included the chemistry, biochemistry, and enzymology of damaged nucleic acids. He holds a Ph.D. from the University of Southern California and has been a Guggenheim Fellow as well as a Commonwealth Fund Fellow.

Nucleotide Excision Repair: Biology

Errol C. Friedberg
University of Texas Southwestern Medical Center, Dallas, Texas, USA

Nucleotide excision repair (NER) is a fundamental DNA repair process that is ubiquitously distributed from bacteria to man. The process is essential for the enzyme-catalyzed removal of various types of base damage from the nuclear genome, typically those that result in significant distortion of the helical structure of DNA. This article discusses the overview and biology of NER.

The name nucleotide excision repair derives from the fact that during this process damaged bases are excised from the genome as oligonucleotide fragments. This distinguishes nuclear excision repair (NER) from other types of excision repair such as base excision repair (BER), during which damaged bases are excised as free bases, and mismatch excision repair (MMR), during which mismatched nucleotides are removed from the genome as mononucleotides. The oligonucleotide fragments are generated by specific incision of the damaged DNA strand on either side of sites of base damage (bimodal incision) (Figure 1). The gaps (~30 nucleotides in length) generated by oligonucleotide excision are filled in by repair synthesis (Figure 1), using the intact opposite strand as an informational template. When the last nucleotide is inserted, the remaining nick is sealed by DNA ligase (Figure 1).

Modes of Nucleotide Excision Repair

Nucleotide excision repair (NER) transpires in cells in various subforms. Its operation on transcriptionally silent regions of the genome and on the non-transcribed strand of transcriptionally active genes is often referred to as global NER, to distinguish it from NER that specifically operates on the transcribed strand of transcriptionally active genes, so-called transcription-coupled NER (TC-NER). Additionally, both global NER and TC-NER are characterized by incision of the affected DNA strand on either side of sites of base damage (Figure 1), some lower eukaryotes support a form of NER that involves a single incision 5′ to the site of base damage. This process is referred to as specialized NER.

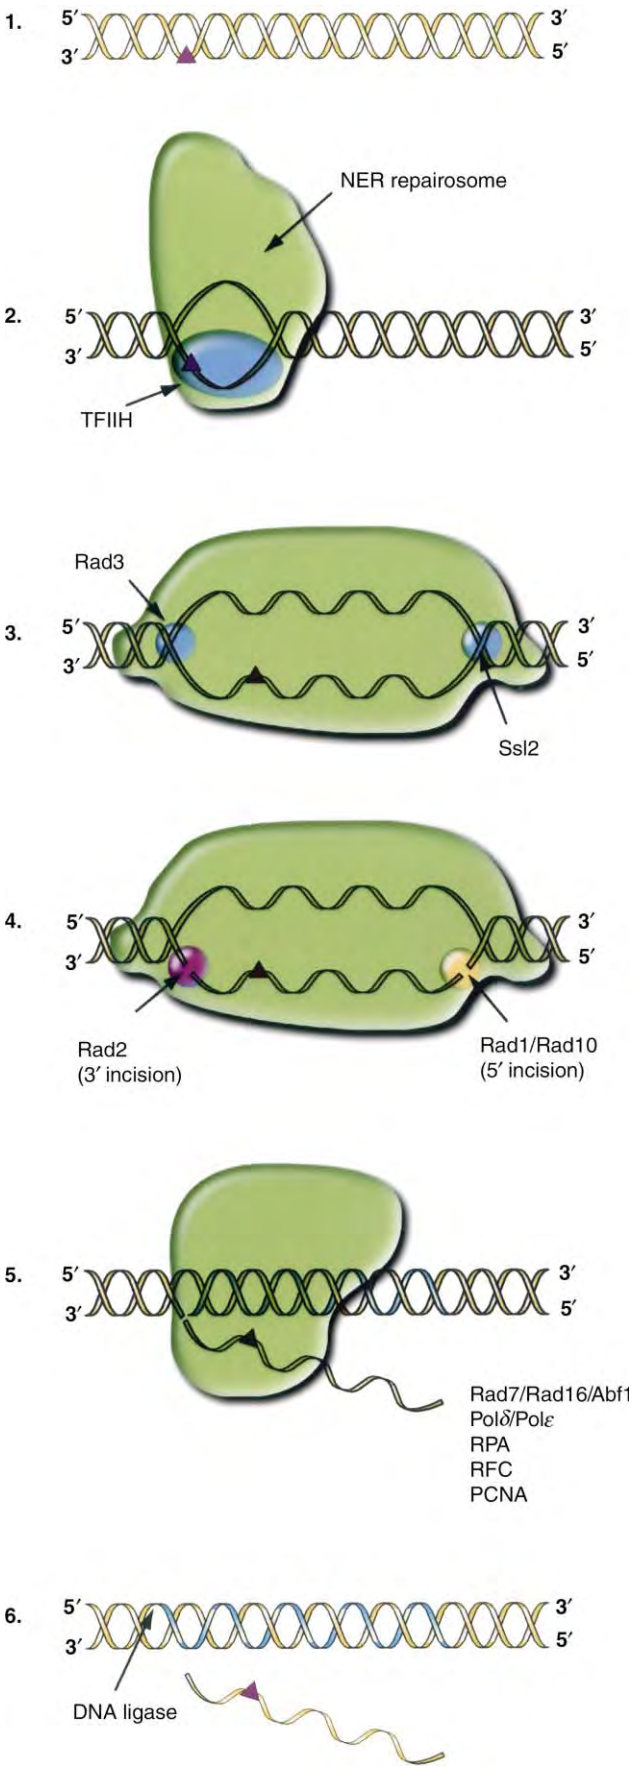
The Biology of NER

Distribution in Nature

As we ascend the evolutionary ladder and encounter increasingly more complex organisms, our information about the cellular biology of NER becomes less precise, even though paradoxically our biochemical understanding has taken leaps and bounds in recent years. Several aspects of the cell biology of higher cells contribute to this paucity of information. Perhaps most importantly, both the structure and organization of the eukaryotic genome is much more complex than that of prokaryotes. Eukaryotic genomes are considerably larger, and the requirements for packaging such large amounts of DNA into the limited confines of the cell nucleus have led to a complex structural organization. A consideration of the distribution of DNA damage in eukaryotes must take into account that nuclear DNA exists in intimate association with both histones and nonhistone chromosomal proteins, and that the structure of chromosomes reflects various levels of folding and coiling of the basic chromatin structural unit, the nucleosome.

Our present understanding of how chromosome structure and nucleosome conformation influence the enzymology of DNA incision and of postincision events during NER in eukaryotes is still scanty. It is certain that structural elements do in fact limit the access of repair enzymes to sites of base damage, and that specific perturbations of chromatin structure are necessary to facilitate NER.

Conventional NER involving the bimodal incision of damaged DNA is operationally and fundamentally similar in all organisms, from bacteria to man. However, there are significant biochemical differences between NER in prokaryotes and eukaryotes. Additionally, the biochemistry of global NER and TC-NER differ in important details during the initial stage of the process. Specifically, during global NER particular proteins are required for the recognition of base damage in DNA. In contrast, during TC-NER the process of arrested RNA polymerase II transcription is believed to provide the mechanism of damage recognition.



The NER Machinery

NER operates through the assembly of a multiprotein complex. In bacteria this complex comprises about six polypeptides. However, in both lower and higher eukaryotes as many as 30 proteins are required for NER. These comprise proteins that participate in (1) the recognition of base damage, (2) bimodal incision of DNA, (3) oligonucleotide fragment incision, (4) repair synthesis of the gap generated in DNA, and (v) DNA ligation. (Figure 1). In eukaryotes the RNA polymerase II, basal transcription factor IIH (TFIIH) is an integral component of the NER machinery. As noted below, mutations in some of the genes encoding TFIIH subunits can result in disease states with transcription defects.

Substrate Specificity

NER operates primarily on types of base damage that generate conformational distortion of the DNA helical structure. The so-called (6–4) photoproduct, a highly distortive type of base damage in DNA that results from exposure to UV light (Figure 2), as well as cyclobutane pyrimidine dimers (Figure 2), are premier examples of substrates for NER. The NER machinery does not recognize small loops or mismatches in DNA, and small chemical adducts such as those produced by methylation and the oxidation of bases are preferentially recognized by the BER process. The precise mechanism of substrate recognition during NER in eukaryotes remains to be determined.

Detection of NER *in vivo* and *in vitro*

Studies on NER in mammalian cells have historically utilized a variety of increasingly refined experimental strategies and techniques, many of which have been adapted from methods initially developed for studies

FIGURE 1 The general mechanism of nucleotide excision repair (NER) in eukaryotes. In the figure yeast is used as an example. The red triangle represents some type of base damage that is recognized by the transcription-independent NER system. The binding of multiple proteins at or near the site of base damage in an ordered step-wise fashion generates a large multiprotein complex, the NE repairosome, that includes the RNA polymerase II basal transcription factor TFIIH. Two DNA helicase subunits in TFIIH (Rad 3 and Ssl2 in yeast) facilitate the generation of a bubble in the DNA that is ~30 nucleotides in length and that flanks the site of base damage. The double-stranded/single-stranded DNA junctions are then recognized by two structure-specific endonucleases (Rad2 and Rad1/10). These cut the DNA duplex only on the damaged strand, generating an oligonucleotide fragment ~30 nucleotides in length. The Rad7/Rad16/Abf1 protein complex then facilities displacement of the oligonucleotide as a free DNA fragment carrying the damaged base. Replicative DNA polymerases (d and/or e) together with accessory proteins (RPA, RFC, PCNA) fill in the gap formed and DNA ligase seals the damaged DNA strand to restore complete covalent integrity.

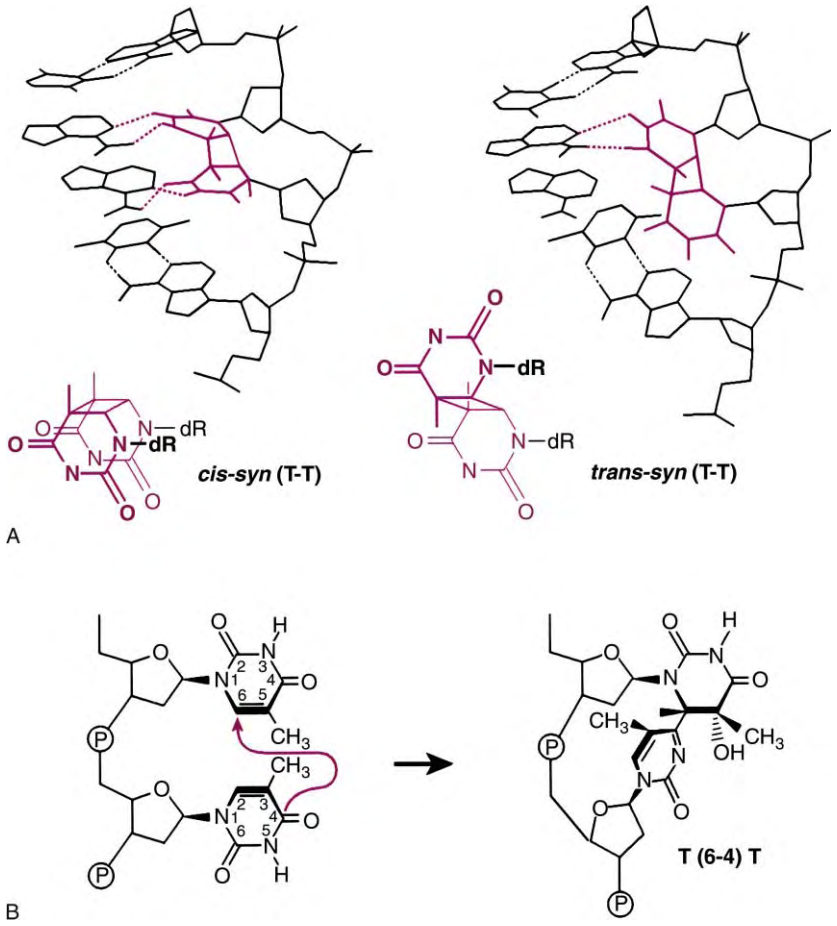


FIGURE 2 Chemical structures of cyclobutane pyrimidine dimers (CPD) (A) and [6–4] photoproducts (B). Both of these photoproducts are generated in large amounts when DNA is exposed to UV light, including sunlight.

with bacteria. Some of these procedures measure the damage-specific incision of DNA, either directly or indirectly. Others measure the physical excision of damaged nucleotides, repair synthesis of DNA, or the rejoining of strand breaks (DNA ligation). A particularly widely used technique for monitoring NER in living cells is referred to as the unscheduled DNA synthesis (UDS) assay, that identifies repair synthesis of DNA. In this procedure cells in monolayer culture are exposed to a DNA damaging agent such as UV radiation and the medium is supplemented with a radiolabeled precursor for DNA synthesis. Repair synthesis of DNA associated with NER is identified by a delicate autoradiographic stippling of nuclei in cells that are outside the S phase of the cell cycle (hence UDS) (Figure 3).

Kinetics of NER

While the application of many of the experimental procedures mentioned above supports the existence of NER in higher organisms, the relative kinetics of specific events associated with NER, such as DNA incision, the excision of specific lesions from high-molecular-weight DNA, and repair synthesis in mammalian cells, are still controversial. In part these controversies have arisen from the use of different experimental procedures, which, though designed to measure the same biological end points, sometimes have optimal reliabilities at different extents of DNA damage and under different experimental conditions, and hence may not be strictly comparable. Nonetheless, some of these apparent "experimental inconsistencies" may actually reflect real distinctions in NER associated with different cell types, different functional states of cells, particular regions of the genome, and different types of DNA damage. It is generally acknowledged that (6–4) photoproducts are removed from the genome of human, and in particular rodent cells, more rapidly than are pyrimidine dimers. It can take many hours before the latter lesions are fully cleared from the genome.

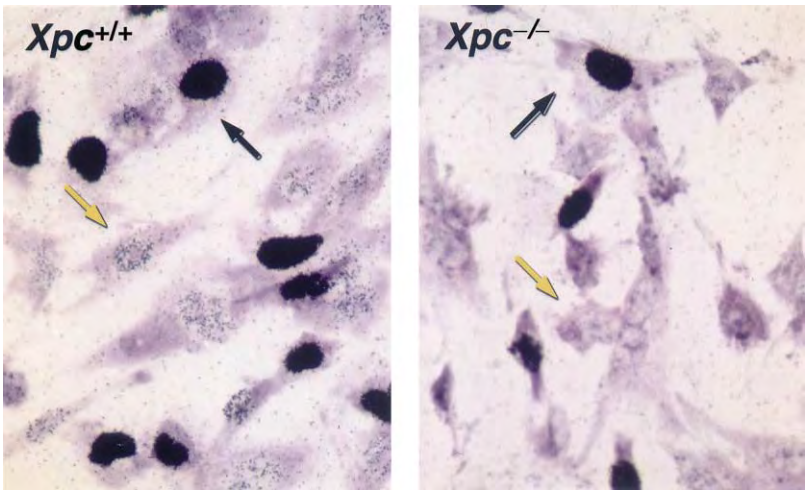

FIGURE 3 The identification of repair synthesis during NER in mammalian cells. The repair synthesis step shown in Figure 1 can be monitored in mammalian cells in monolayer culture. Mouse wild-type ($Xpc^{+/+}$) and NER-defective ($Xpc^{-/-}$) cells are exposed to UV radiation and allowed to incubate in the presence of [^{3}H] thymidine. Cells in S phase of the cell cycle undergo intense autoradiographic labeling by incorporating the radiolabled thymidine (black arrows). However, cells undergoing repair synthesis during NER incorporate much less label which can be identified as a delicate autoradiographic stippling (yellow arrow, $Xpc^{+/+}$). These grains are greatly reduced or absent in the NER-defective $Xpc^{-/-}$ cells.

Defective NER and Human Disease

Several human hereditary diseases have been identified that result from defective NER. The so-called classical xeroderma pigmentosum (XP) is an autosomal-recessive disease that results from defects in both global NER and TC-NER. Affected individuals are extremely sensitive to sunlight and have a markedly increased risk of developing skin cancers. A clinically indistinguishable form of XP called the XP variant form, derives from mutations that affect a different biological response to UV radiation-induced DNA damage. Individuals with mutations in genes required for both NER and RNA polymerase II transcription can develop the clinical features of both XP and a different disease called Cockayne syndrome (CS). Pure CS (unaccompanied by XP) arises from defects in the *CSA* or *CSB* genes that encode proteins required for TC-NER. Unlike XP, CS does not lead to an increased risk of skin cancer in human subjects. Defects in subunits of TFIIH can result in a spectrum of diseases characterized by developmental and neurological defects with or without defective NER, the disease trichothiodystrophy (TTD) being a notable example.

Mouse Models for Defective NER

Mouse models for each of the human hereditary diseases mentioned above have been generated by conventional targeted gene replacement, and sometimes by more refined strategies. In general these mice have proven to mimic the human disease well and have provided much valuable information about the relationships between defective NER and cancer predisposition and pathogenesis.

Olfactory Receptors

Sigrun I. Korsching
University of Cologne, Germany

Olfactory receptors mediate the primary interaction of the olfactory brain with the external world. Any odor stimulus is initially represented as activation of one to many different olfactory receptors. Vice versa, anything that binds and activates an olfactory receptor, is as per definition an odor, or odorant, as the single compounds are often called. Olfactory receptors constitute one of the largest families of G protein-coupled receptors. Many large and small clusters of olfactory receptors are distributed throughout the genome. Olfactory receptors are expressed in a highly specific manner and monogenic expression is the general rule, i.e., one neuron–one receptor. The molecular receptive range has been analyzed for several olfactory receptors. Generally, olfactory receptors have been found to exhibit a somewhat relaxed specificity towards ligands. However, some receptors, in particular those for pheromones, show very high specificity. Olfactory receptors signal through specialized trimeric G proteins to open calcium-permeable nonspecific cation channels.

Olfactory Receptors are G Protein-Coupled Heptahelical Receptors

From a modest origin in simple eukaryotes like yeast, G protein-coupled heptahelical receptors (Figure 1) have evolved into the largest superfamily known. As the name indicates, signaling occurs through (trimeric) G proteins, with particular families making use of different G proteins. These receptors transmit biological effects of many hormones, neurotransmitters, chemokines, and diverse sensory stimuli. Chemosensation constitutes an ancient function for this family. Already in yeast a dichotomy between sensing nutrients and sensing pheromones is found.

Whereas simple animals like nematodes possess a single chemosensory sense, in higher animals several specialized systems have evolved, using olfactory and gustatory receptors, respectively. Olfactory receptors may recognize volatile or water-soluble odorants, depending on the species (e.g., mammals versus fish), and the defining difference to taste receptors appears not to be the nature of the ligand, but the outreach of the system. Taste is generally considered to be a contact sense, whereas olfaction delivers long-range information.

Olfactory Receptors Segregate in Several Highly Divergent Groups

Thirteen years ago, the first higher eukaryote chemosensory receptors – mammalian odorant receptors proper (OR) – have been identified. Linda Buck, then a postdoctoral fellow in Richard Axel's laboratory, used short motifs conserved in previously known heptahelical receptors to amplify a group of rat odorant receptors from nasal cDNA via polymerase chain reaction. Like all heptahelicals, odorant receptors exhibit the canonical seven-transmembrane domain structure (Figure 1) and the G protein-interaction motif. Peculiar are the relatively short N and C termini. OR are a highly divergent group, and amino acid homologies below 20% have been reported within one species. Between phyla, homologies have been so low as to be undetectable. Thus, insect and nematode chemosensory receptors have not been identified via homology searches, but by looking for orphan heptahelical receptors in either single cell libraries or genomic databank searches.

Two classes of distantly related receptors have been found in the mid-1990s. They are designated V1R and V2R family, after their occurrence in the mammalian vomeronasal or accessory olfactory system. V1R receptors share the short N and C termini with the OR receptors, whereas the V2R exhibit a large extracellular N-terminal domain, and show some sequence homology to the Ca^{2+}-sensing receptor and the metabotropic glutamate receptor, a neurotransmitter receptor. In mice the V2R family comprises ~100 genes and the V1R family contains ~150 genes, which segregate into 12 subfamilies designated V1Ra, V1Rb etc. Humans and other hominoids have nearly no VR receptors as their accessory olfactory system is derelict and their VR genes suffer ongoing pseudogenization. No intact human V2R is remaining and less than a handful of intact *V1R* genes have been identified in extensive genome searches.

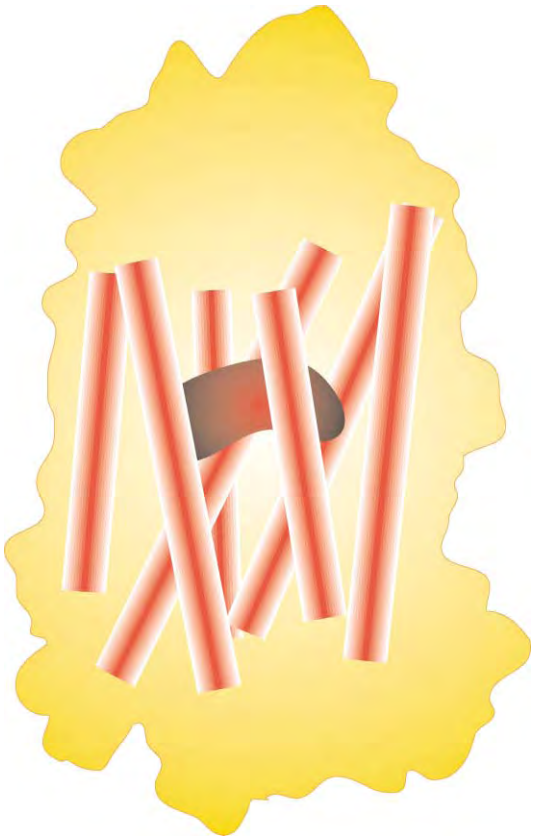

FIGURE 1 Schematical representation of an olfactory receptor. No crystallographical data are available for olfactory receptors. It is assumed that their structure is analogous to that of rhodopsin and the adrenergic receptor, which are more extensively studied. This is supported by some mutational analysis and molecular dynamics modeling. The scheme shown here is based on the structure of rhodopsin, whose crystal structure has been solved in 2000. Seven-transmembrane regions are depicted as cylinders. The binding site for ligands is centrally situated, between several transmembrane domains.

It is commonly assumed but not rigorously shown that OR deal with common odors whereas VR are specialized for detecting pheromones – odors which are relevant in a social context as in kin recognition and mating.

It should be mentioned that there may be another, radically different group of olfactory receptors, a type of membrane-bound guanylate cyclases with a single transmembrane domain. Members of this family are expressed in specific subsets of olfactory receptor neurons. However, no ligands have been identified for them so far.

Gene Structure and Genomic Arrangement of Olfactory Receptors

Vertebrate OR and V1R feature an intronless coding region of ~1 kb that may be preceded by one to several noncoding introns. Alternative splicing is a frequent phenomenon for odorant receptors. Insect olfactory receptors and vertebrate V2R contain several introns within the coding region, as is common for other G protein-coupled receptors.

The OR family size approaches 1300 identified genes in mouse, a species with a completely sequenced genome. About one-fifth are pseudo-genes, a high percentage, which has people speculating about a putative role of the pseudo-genes in the evolution of the gene family. The human OR gene family is of similar size; however, the percentage of pseudo-genes is much higher, so that only ~350 odorant receptors appear functional in humans. Clusters of related genes are a frequent feature and indicate recent expansions of the respective gene lineages. Sometimes other genes may be interspersed, a notable example being the intercalation of MHC genes with odorant receptors reported for the mouse (but not for the human) genome. Overall, olfactory receptors are widely spread throughout the genome, asserting the ancient origin of this gene family.

Family sizes are smaller for lower vertebrates and insects – for *Drosophila* 60 receptor genes have been identified in the complete genome, mosquitoes possess ~80 olfactory receptor genes. For fish estimates range ~100 different OR. However, the occurrence of (smaller) clusters and the overall widespread distribution of receptor genes are equivalent to higher vertebrates. Surprisingly, the nematode *Caenorhabditis elegans* boasts ~1100 different chemosensory receptor genes (including 30% pseudogenes).

Monogenic and Monoallelic Expression of Olfactory Receptor Genes

Nematode chemosensory neurons, like taste receptor cells, express many different receptor genes per cell. Such bundling of receptors may be efficient if many different chemicals should lead to very few behavioral outcomes – mainly the choice between "stay here" and "get out of here" or "swallow this" and "spit it out," respectively. As soon as a chemical sense is used for more sophisticated distinctions, it is imperative that more selective means of expression are used.

Accordingly, the expression of vertebrate and insect olfactory receptors is highly regulated. One particular olfactory receptor neuron expresses only a single type of OR gene or VR gene (Figure 2). This very restricted expression has been christened monogenic expression. In fact, for rodents it has been shown that expression is restricted even to one allele of a particular *OR* or

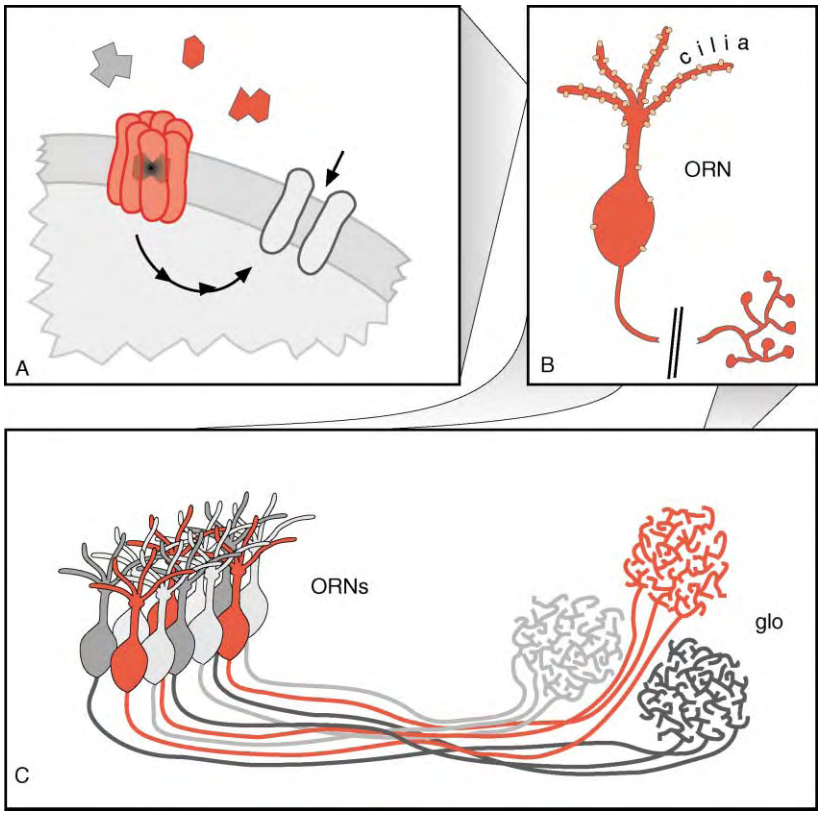

FIGURE 2 Olfactory receptors are part of the olfactory information processing pathway. (A) Olfactory receptors bind odorants and initiate a several step signal processing cascade. As endpoint various channels are opened, leading to depolarization of the olfactory receptor neuron. (B) The olfactory receptors are mainly expressed on the cilia (or microvilli, not shown) of olfactory receptor neurons. These neurons generate action potentials in their axons and propagate them towards their terminals in the so-called glomeruli (glo). Glomeruli are neuropil structures and constitute the first relay station (synapse) in the olfactory processing pathway. (C) Ciliated olfactory receptor neurons expressing the same odorant receptor are distributed within the sensory surface, but converge onto a common glomerulus. Microvillar receptor neurons such as those expressing the *V1R* and *V2R* genes converge onto several microglomeruli (not depicted here).

*VR*gene, reminiscent of the monoallelic expression of immunoglobulin genes.

Some exceptions occur to the rule of one neuron–one gene. Notably a particular insect olfactory receptor, OR83b, has been found to be coexpressed in about two-thirds of all olfactory receptor neurons. This receptor is also highly unusual in that it is strongly conserved between many insect species. It is suspected that such atypical receptors may not have a role in odor detection, but serve another, so far unknown function.

Olfactory Receptor Gene Expression is Regulated by Proximal and Distal Control Regions

A stringent test for specificity of expression relies on the convergence of olfactory receptor neurons expressing the same receptor gene into a single glomerulus at a roughly fixed position (Figure 2). In several cases such a restricted expression pattern could be reproduced faithfully by reporter gene constructs containing variable segments of DNA flanking the coding region. It has been possible to narrow-down control elements to regions of one to a few kilobases, but specific enhancer sites, transcription factors, or combinations thereof are just beginning to be identified. In some cases all control elements appear to be situated close to the gene, whereas for other OR essential regulatory elements have been found in distances of ~100 kb from the coding region.

Selection of an odorant receptor gene for expression is a multilevel process. First, a choice is made for a particular subgroup of genes. Such subgroups feature spatially or temporally limited expression. In a second step, a particular odorant receptor is selected in a stochastic manner and then exerts negative feedback regulation onto all other OR. Thus, monogenic expression of odorant receptors is ensured.

Ligand Spectra have been Established for a Handful of Olfactory Receptors

Although hundreds of olfactory receptors have been cloned to date, ligands are only known for a small percentage of them. The difficulty of guessing potential ligands from among the enormous pool of potential odorants has been a major problem. Also, correct expression in heterologous systems has turned out to be unusually complicated, and has only been possible for some receptors. Most of the receptor molecules synthesized in heterologous systems are not transported to the plasma membrane, but remain in the endoplasmatic reticulum, possibly because some unknown auxiliary molecules are missing. Indeed, for nematode chemosensory receptors a chaperone has been shown to be essential for proper protein translocation and V2R receptors are coexpressed with MHC class 1b molecules that appear to serve as escort molecules. For two OR genes it has been possible to use a viral transfection method to express the recombinant odorant receptor in olfactory receptor neurons. In several cases knockouts of particular olfactory receptors have served to identify receptor ligands, as first shown for the *C. elegans* ODR10 diacetyl receptor. The binding of ligands is not measured directly, but evaluated by a downstream parameter such as a change in membrane potential, or, more commonly, a rise in intracellular calcium levels.

Usually olfactory receptors respond best to a small group of highly related compounds and with lower sensitivity to further odorants. Often a particular functional group is preferred, but in some cases ligands with other functional groups may also activate the same receptor. Many strong ligands identified so far contain an aldehyde or keto group. The most extensive ligand analysis has been performed for the rat odorant receptor I7, which has *n*-octanal as main ligand. Hydrocarbon chain length is another molecular feature that influences ligand efficacy. In the vast majority of cases longer hydrocarbon chains result in more avid binding. From psychophysical experiments it is known that also the shape and rigidity of the ligand molecule determine the olfactory sensation. Enantiomers of known ligands often, but not always, show differential responses. Taken together, a particular olfactory receptor requires a particular combination of molecular features in its cognate ligand/s.

Combinatorial versus Monospecific Representation of Odorants

Due to the monogenic expression of olfactory receptors, the ligand specificity of the olfactory receptor determines the odor responses of the corresponding olfactory receptor neurons (Figure 2). Due to the convergence of olfactory neurons expressing the same receptor in single glomeruli (Figure 2) the ligand specificity of the olfactory receptor determines the odor responses in these glomeruli. This results in a rather direct map of the ligand specificities of the olfactory receptor repertoire on a two-dimensional surface in the corresponding brain region (the olfactory bulb in mammals, the antennal lobe in insects). Interestingly mammalian odorant receptors influence the choice of a target glomerulus of olfactory receptor neurons as shown by gene swap experiments. Insect olfactory receptors, on the other hand, appear not to be involved in selection of the proper target site.

Two complementary principles of odorant representation emerged from ligand binding studies *in situ* and in heterologous systems. Firstly, many odorants activate a small subset of the large repertoire of odorant receptors. Vice versa, any particular OR gets activated by a handful of different compounds, not just by a single compound. This results in a unique combination of activated receptors for each individual odor compound (Figure 3). The theoretical coding capacity of such a combinatorial representation is immense and much higher than needed – even for millions of different odors. In fact, the neuronal representation is sparse – the large majority of receptors does not respond to any given odorant – and thus suboptimal with respect to coding capacity. Nevertheless, humans (trained perfumers, that is) can distinguish and identify several thousand different odors, more than tenfold the number of the functional human OR repertoire.

An alternative principle of neuronal representation seems to be realized for a smaller group of chemicals, including many pheromones. The high sensitivity and specificity of several such olfactory receptors (observed in mammals, fish and insects) appears to indicate a monospecific interaction. A well-known example is the male/female attraction in silk moth, *Bombyx mori* (Figure 3). To integrate labeled line coding with hard-wired behavior appears straightforward. The coding capacity of such a system is low – it equals the number of different olfactory receptors devoted to this strategy – but sufficient for the limited number of potential pheromones. An example for a receptor/ligand pair is the mouse V1Rb2 receptor that specifically recognizes 2-heptanone.

Signal Transduction of Olfactory Receptors

All heptahelical olfactory receptors signal through trimeric G proteins. A controversy surrounding the

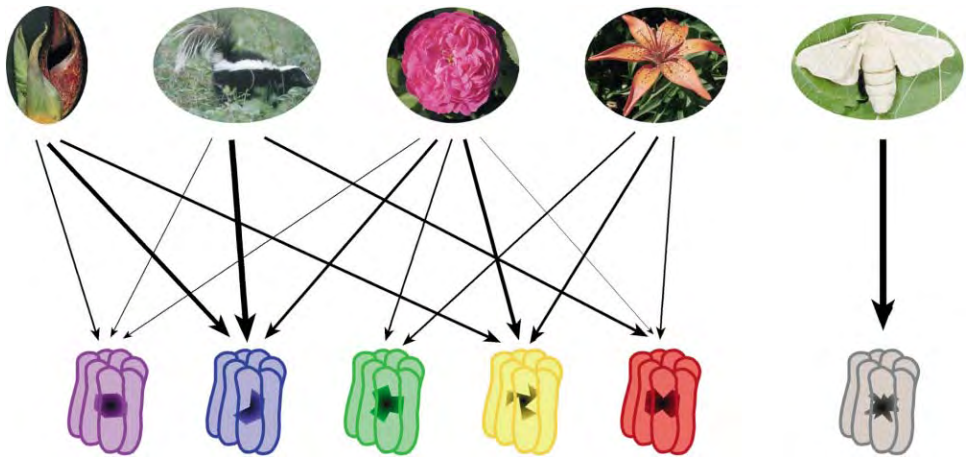

FIGURE 3 Two types of olfactory processing: combinatorial versus monospecific. To the left the combinatorial representation of odorants is depicted. Different odors – here symbolized by various odor sources (skunk cabbage, skunk, rose, lily) – activate overlapping, but distinctive combinations of olfactory receptors. This is also valid for the individual odor components, the odorants. Each odorant activates a particular subset of all olfactory receptors and thus each odorant generates a unique, if overlapping "fingerprint" of olfactory receptor activation. To the right monospecific representation of odorants is shown. A single compound activates a highly specific receptor very selectively, as is often observed for pheromones. Depicted here is a female silk moth, source of an attractive pheromone that is detected with extremely low threshold by the male of that species.

signal transduction by OR has been more or less resolved. Vertebrate OR signal through G_{olf}, a specialized α-subunit, which in turn activates adenylate cyclase type III (Figure 4). The resulting cAMP activates a cyclic nucleotide-gated channel that is a rather nonselective cation channel. Such channels are widespread in the nervous system, their particular gating properties are set by the subunit composition (A2A4B1b in the case of the mammalian olfactory channel). A considerable portion of inward current is carried by calcium (Figure 4). The resulting influx of calcium opens a calcium-gated chloride channel, resulting in chloride efflux, i.e., in further depolarization and thus amplification of the signal (mammals, amphibians, and fish). Finally, the odor-induced signal is switched off by G protein-coupled receptor kinase 3 (GRK3) and binding of arrestin-related molecules to the phosphorylated odorant receptor (Figure 4). Even with a constant odor stimulus the olfactory sensation is down-regulated within seconds, in part due to the peripheral mechanisms mentioned here.

The signal transduction cascade has not been worked out as well in invertebrates. Insects appear to also use cAMP as second messenger. Lobster may additionally employ IP3 as a second signal transduction system that

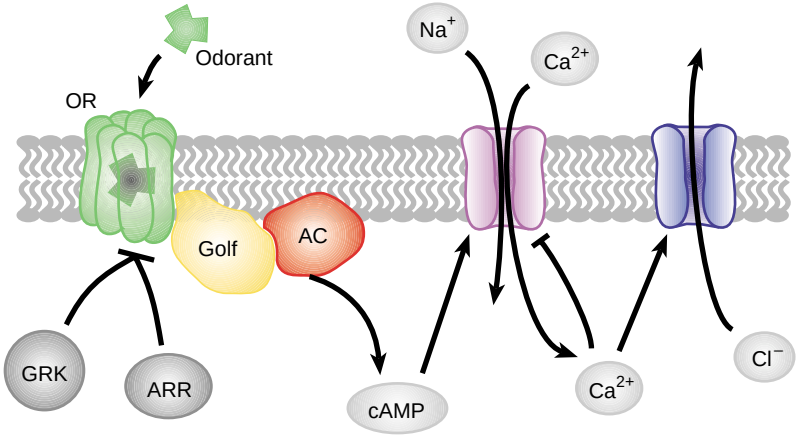

FIGURE 4 Signal transduction and termination of odor responses. A schematical representation of the main signaling pathway. AC, adenylate cyclase type III; ARR, β-arrestin-related molecules; G_{olf}, an α-subunit somewhat specific for the olfactory nervous system; GRK, G protein-coupled receptor kinase; OR, odorant receptor. The cyclic nucleotide-gated channel is permeable for sodium and calcium, but gets blocked by calcium. GRKs phosphorylate the odorant receptor, which subsequently binds β-arrestin, leading to a complete stop of the signal transduction cascade.

opens IP3-gated channels situated in the plasma membrane. Such channels have been described in olfactory receptor neurons of many species, including fish and rodents, but appear to be a minor constituent compared to the number of cyclic nucleotide-gated channels. The effects described for IP3 on olfactory signal transduction in mammals and fish may reflect a modulatory role of this second messenger, conceivably in setting the basal activity level of olfactory receptor neurons. When all the evidence is weighed, a completely independent second signaling pathway for odorant receptors appears not plausible.

Signal transduction for olfactory receptors of the VR type differs both from OR and between V1R and V2R. The emerging picture is that V1R signal via the G_{i2} α-subunit and V2R via the G_o α-subunit. Finally, a transient receptor potential channel, TRP2, is activated by diacylglycerol and allows the influx of cations including calcium.

Glossary

chemosensation Any chemical sense, such as olfaction or taste. Very ancient, occurs already in bacteria where it is used for chemotaxis.

glomeruli Globular neuropil, comprises synapses of olfactory receptor neurons.

heptahelical A receptor with seven-transmembrane helices, often, but not exclusively a G protein-coupled receptor.

odorant A chemically pure odor, i.e., a single compound that activates an odorant receptor.

olfactory code The neuronal representation of odors insofar as it is relevant to the encoding of these odors. Often confused with the neuronal representation, which is more commonly studied.

pheromone An odorant that mediates intraspecies communication, eliciting neuroendocrine changes and stereotyped behavioral repertoires.

Biography

Sigrun Korsching is a Professor at the Institute of Genetics at the University of Cologne in Germany. Her principal research interest is in the field of sensory neurobiology, in particular the sense of smell. She holds a Ph.D. from the Ludwig-Maximilian-Universität in Munich, Germany and received her postdoctoral training at the California Institute of Technology, California. She has authored influential texts in the fields of neurotrophic interactions and olfactory encoding.

Oligosaccharide Analysis by Mass Spectrometry

Andrew J. Hanneman and Vernon N. Reinhold
University of New Hampshire, Durham, New Hampshire, USA

Glycosylation is important for cellular regulation and recognition activities and oligosaccharide structural details are essential determinants of function. In contrast to other biopolymers that are joined by identically positioned functional groups, an oligosaccharide chain is commonly branched, with multiple positions for linkage. The monomer units themselves may exist as isomeric ring conformers (pyrans, furans), with differing spatial orientation of hydroxyl groups. When these hydroxyl groups are involved in linkage between residues (anomers), additional isomeric complexity is introduced. As a consequence, oligosaccharide structure elucidation can be a complicated problem requiring a number of different analytical approaches. Most of the techniques currently available for oligosaccharide analysis are based on mass spectrometry (MS) and we summarize in this report the details of composition, sequence, branching, and inter-residue linkage that can be obtained using small amounts of sample material.

Important Classes of Oligosaccharides

Glycoprotein Glycans

Glycoprotein glycans are branched oligomers having ~5–20 monosaccharides that are added to proteins co- or posttranslationally. Protein glycosylation is primarily based upon two main structural motifs: (1) *N*-linked glycans are linked through the amide bond of asparagine at an amino acid sequence called the consensus site: asparagine-x-serine/threonine (where x can be any amino acid except proline); and (2) *O*-linked glycans, which have no known consensus sequence and are linked through glycosidic bonds to serine and threonine residues on the protein. For both glycan types there are constant core structures proximal to the protein backbone, although numerous variations are known.

Glycosphingolipid Glycans

Glycosphingolipids represent a diverse set of amphipathic molecules comprised of an outer glycan portion linked to a ceramide lipid tail. In glycosphingolipids the ceramide lipid serves as an anchor to the cell membrane and the carbohydrate can present a hydrophilic surface for cell–cell recognition.

Glycosaminoglycans

Glycosaminoglycans (GAGs) are linear carbohydrate chains consisting of repeating disaccharide units, often rich in sulfate groups (e.g., heparin), that make up the carbohydrate portion of high molecular weight protein/carbohydrate assemblages known as proteoglycans. Tissue-specific proteoglycans are inserted into plasma membranes, excreted into the extracellular matrix, or stored in intracellular compartments where they are involved in adhesion, lubrication, and regulatory functions.

Methods and Instrumentation

Obtaining and Preparing Glycans for Mass Spectrometry

Carbohydrates, being less polar, are generally more difficult to ionize than other classes of biological molecules, a feature that is compounded when in the presence of salts and peptides. Consequently, judicious purification steps are required for effective MS analysis of carbohydrates. Purification, including desalting, is often accomplished online using high pressure liquid chromatography (HPLC) prior to electrospray mass spectrometry (ESI). Changing the physical characteristics by derivatization has also proven to be successful, and this is discussed below.

Glycan Release and Purification

Prior to mass spectrometry glycoproteins can be enzymatically cleaved using trypsin or other proteases

resulting in a peptide/glycopeptide mixture; however, glycopeptides ionize poorly within such mixtures and subfractionation is usually advantageous. Consequently, glycans are often enzymatically or chemically released from proteins first and then purified. This approach, however, loses an important feature of structure: the location of the glycan and its consensus sequence on a peptide. Most *N*-linked glycans are conveniently released from proteins using the endoglycosidase enzymes PNGase F or PNGase A. Analogous enzymes for general release of *O*-linked glycans, however, are not known and *O*-linked glycans are typically released using chemical methods including base-release (beta-elimination) and anhydrous hydrazine at low temperature. Hydrazinolysis at higher temperatures is well suited for *N*-linked glycan release, however, at high temperature significant degradation of *O*-glycans is observed.

Glycolipids are obtained from biological materials by extraction with organic solvents, including chloroform: methanol:water (CMW). Glycolipids can be isolated from other lipids using ion exchange or silica gel chromatography and may then be analyzed directly or the oligosaccharide chains are enzymatically or chemically released and extracted.

GAGs are chemically released from proteoglycans and subjected directly to MS analysis or may first be broken down into smaller subunits using GAG-chain-specific enzymes including chondroitinases and heparinases.

Derivatization and Adduction for Ionization

Lacking very polar functional groups many oligosaccharides are not easily ionized. In the positive ion mode naturally occurring oligosaccharides are typically observed as adducts with cations such as sodium or potassium, although numerous cations can be used. Derivatization is another strategy for improving ionization to enhance MS signal. Some of the common derivatization strategies were originally developed to improve the volatility of carbohydrates for gas chromatographic analysis. Complete methylation of hydroxyl groups improves volatility and also assists purification by organic solvent extraction, providing sensitivity enhancement when analyzed by electrospray ionization (ESI) or matrix-assisted laser desorption ionization (MALDI)-MS. Permethylation is also advantageous when structural details are pursued. Other procedures involve covalent attachment of an ionizable functional group such as an amine to the oligosaccharide-reducing end. Some aminated derivatives may include a chromophore or fluorophore to enhance UV/vis or fluorescence detection.

Instrumentation for Glycoconjugate Mass Spectrometry

Mass spectrometry is a gas-phase analytical technique originally limited for use with small molecules that had to be thermally vaporized prior to ionization. The molecular weight obstacle has since been overcome by techniques that combine vaporization and ionization in a single step; these include ESI and MALDI. Both techniques have been interfaced with a variety of mass analyzers, and high-molecular-weight samples now provide no barrier using these techniques.

Gas-phase ions are a long way from detailed structural understanding, thus the recent challenges in mass spectrometry relate to disassembly of large structures within the mass spectrometer. Notwithstanding recent developments, composition analysis of depolymerized oligosaccharides by GCMS has remained an important tool for structure determination.

Ionization Methods for Mass Spectrometry

Electron Impact and Chemical Ionization Electron-impact ionization (EI) and chemical ionization (CI) were the first ionization methods to be widely applied to carbohydrate samples. EI and CI are gas-phase techniques that are readily interfaced with a gas chromatograph (GC) enabling complex mixtures to be efficiently separated by GC with subsequent component identification by MS. EI imparts high energy to the sample resulting in extensive fragmentation. The fragments serve to guide structure determination. Excessive energy and resultant fragmentation in EI often precludes molecular weight determination leaving structural ambiguity if the parent ion is lost from the spectrum. This limitation led to the development of the softer ionization technique CI. CI is an extension of EI wherein energetic electrons are initially directed toward ionizing a gaseous molecule such as methane. The gas-phase analyte is ionized by interaction with the gas (by proton transfer in the case of methane). CI generates a robust molecular ion signal but lacks the information that can be obtained following fragmentation. Modern MS approaches are tailored toward soft ionization to obtain a molecular ion followed by fragmentation step(s) for subsequent structural characterization.

Electrospray Ionization (ESI) Electrospray induces vaporization concurrent with soft ionization making it an extremely useful technique for analysis of biopolymers in solution, including HPLC eluates. Electrospray exploits a high electric field to aerosolize analyte-containing solutions creating a fine mist of charge-dense droplets. A bath gas at ambient pressure serves to vaporize solvent from droplet surfaces reducing their

size and increasing the surface charge density. Electrostatic repulsion ultimately disrupts the droplet surface leading to production of small charged droplets and eventual ejection of gas-phase analyte ions into a high vacuum region for mass analysis.

Matrix-Assisted Laser Desorption Ionization (MALDI) MALDI is a solid-state ionization method that, like ESI, combines ionization and vaporization into a single step thereby providing another convenient interface for biopolymer analysis. In MALDI the sample is dissolved in a matrix solution, spotted onto a stainless steel "target" and dried. The matrix molecules provide a UV-chromophore with an absorbance spectrum tuned to the laser-irradiation source. Laser ablation of the target spot under vacuum results in flash vaporization and ionization of the matrix and embedded sample molecules that can be subsequently directed into the mass analyzer region. In contrast with ESI, which may produce multiply charge ions, MALDI ions are typically singly-charged.

Mass Analyzers

In a mass spectrometer the ionization sector (e.g., ESI, MALDI) is coupled to a mass analyzer. The earliest mass analyzers used magnetic and/or electric sectors to separate ions by their mass-to-charge ratio (*m/z*); more recent instruments use a variety of new designs to accomplish the same task; these include the ion trap (IT), quadrupole mass filter, time-of-flight (TOF) tube, as well as hybrid instruments consisting of a combination of mass analyzers arranged in series for tandem or sequential mass spectrometry.

Complete Structure Elucidation by Mass Spectrometry

Oligosaccharide structure elucidation generally follows an approach consisting of determining the monosaccharide composition, defining monomer sequence and branch points, identifying inter-residue linkage positions, and specifying the anomeric configuration of glycosidic bonds.

Obtaining an MS Profile

After using a specific release, extraction, and cleanup procedure, an oligosaccharide sample is typically profiled by single-stage MS (MALDI, ESI, or HPLC-ESI) to profile the molecular weight(s) of constituent oligosaccharides. With molecular weight in hand, a general composition of monomers may be assigned to each oligosaccharide, i.e., hexose, deoxyhexose, N-acetyl hexosamine, but without indication of specific isomers. When combined with knowledge about the source material, release and purification method, and a composition analysis, a significant component of sequence information can be hypothesized based on the MS profile; however, it remains fraught with holes for potential incorrect assignments. Further characterization is mandatory to accurately assign sequence, branching, and linkage details.

Composition Analysis by GCMS

MALDI and ESI allow most oligosaccharides to be analyzed intact; however, GCMS-based composition analysis has remained a useful method for quantitative determination of monosaccharide composition, offering valuable complementary information. GCMS involves depolymerization into constituent monomers by hydrolysis or methanolysis, followed by volatility-enhancing derivatization. Both the GC retention time and the mass spectrum are used to identify and quantify the constituent monomers. A variety of derivatization or combined depolymerization/derivatization schemes, involving methylation, acetylation, and/or trimethylsilylation are used in composition analyses.

Linkage Analysis

Linkage analysis is used to determine inter residue linkage and branch points. This methodology is an extension of composition analysis wherein the oligosaccharide is permethylated prior to hydrolysis. Following hydrolysis the partially methylated monomers are reduced and acetylated, placing acetyl groups at all the positions opened by hydrolysis and reduction. The resulting alditol acetates have mixed methylation/acetylation substitution patterns depending upon their position in the original polymer, and reduction decreases anomeric heterogeneity in the gas chromatograms. The GC retention times and electron impact fragmentation patterns of partially methylated alditol acetates (PMAA) are used to indicate the type of linkages associated with specific monomers. Because the method involves depolymerization, however, the information that connects one monomer with another is lost making it challenging to use linkage analysis with mixtures.

Tandem Mass Spectrometry (MS/MS) and Sequential Mass Spectrometry (MS^N)

When collision-induced dissociation (CID) is performed on isolated parent ions the fragments produced provide an important strategy for understanding structure. Tandem mass spectrometry is commonly

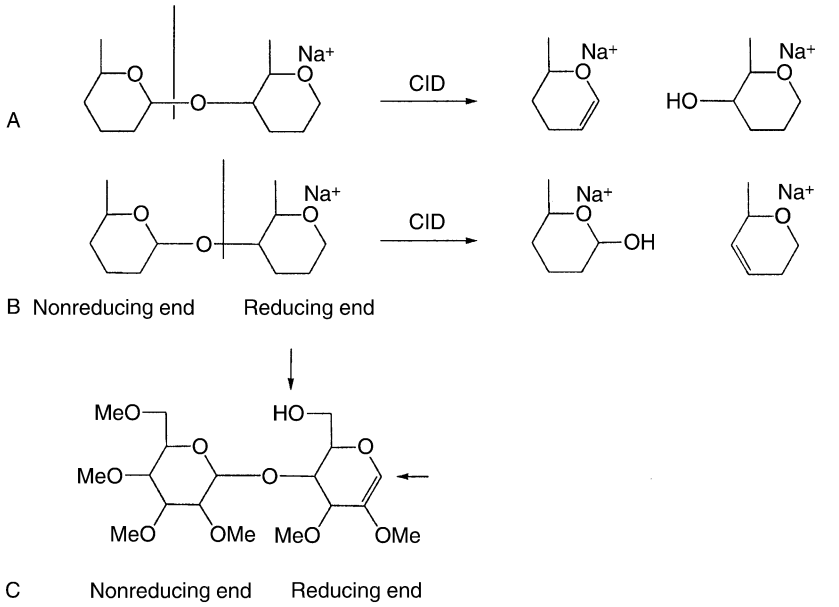

FIGURE 1 (A) and (B) Glycosidic bond cleavages for sodium adducted oligosaccharides. Sodiated fragments representing the reducing and nonreducing ends are observed for breaks on both sides of the glycosidic bond. (C) A branch point fragment; arrows identify the broken bonds.

used in this manner to sequence linear polymers. This straightforward approach has been applied with remarkable success to characterization of peptides but is limited when applied to oligosaccharides. Oligosaccharides are replete with isomeric possibilities that require further decomposition not available by tandem MS.

In order to fully characterize branching and obtain complete understanding of sequence and linkage, sequential steps of collision-induced dissociation must

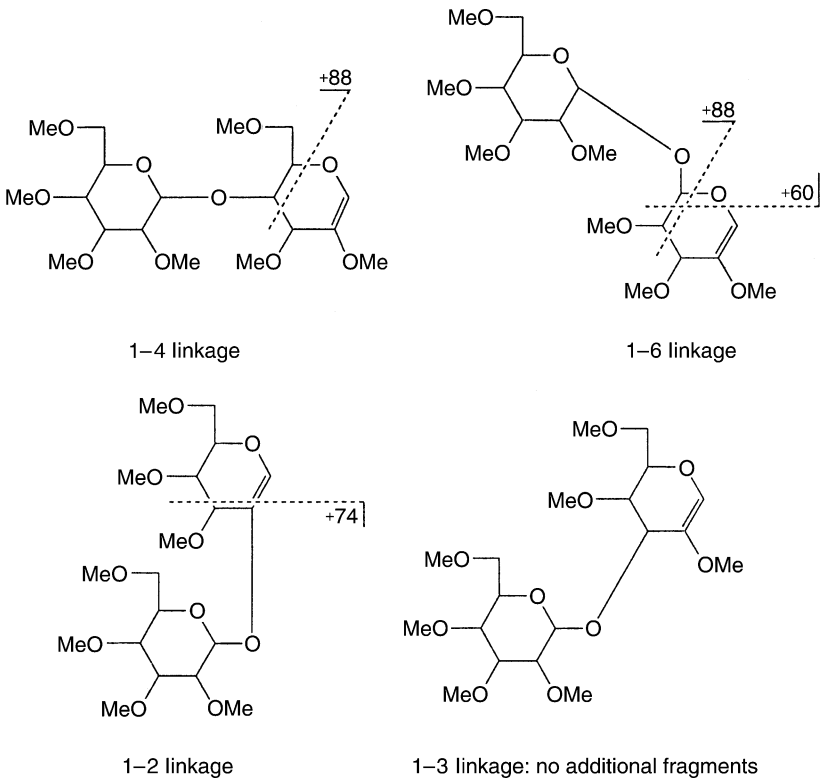

FIGURE 2 Use of cross-ring cleavages in MS^n to identify linkage position on hexoses in permethylated glycans.

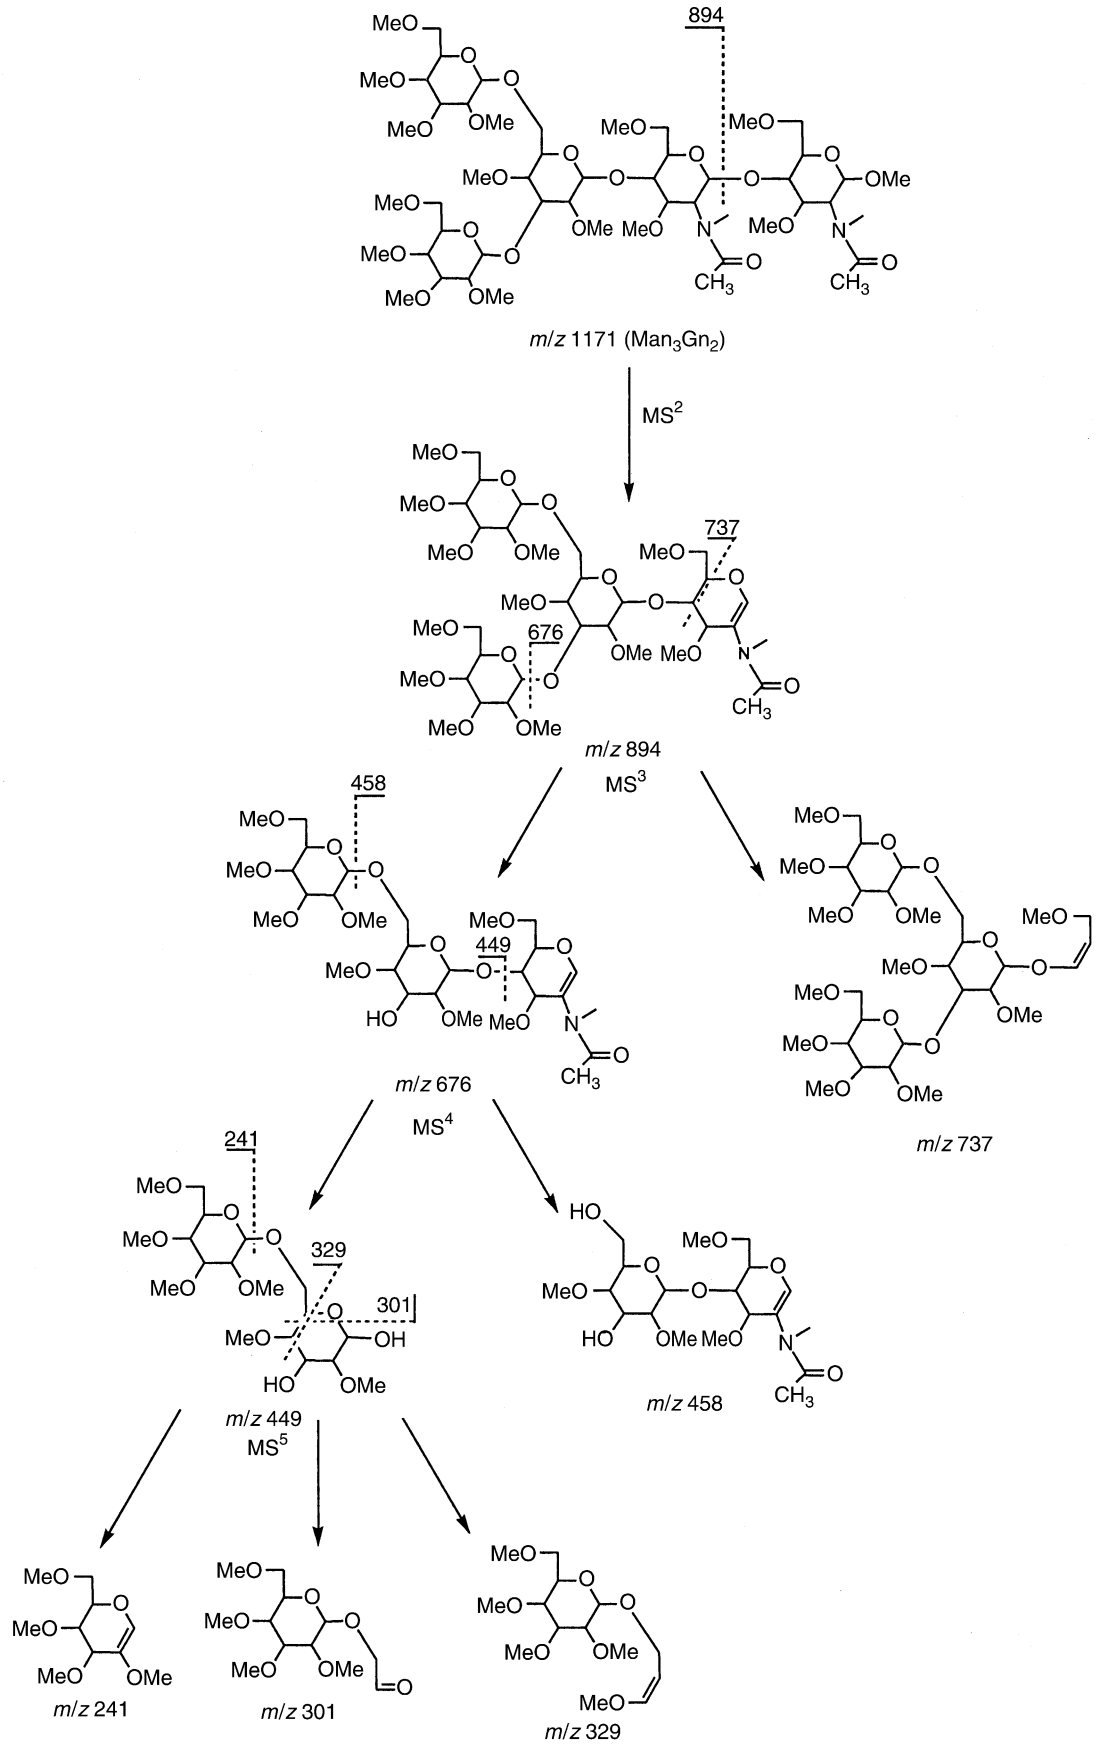

FIGURE 3 Use of MS^n to dissect a typical *N*-linked glycan. Selected CID pathways are shown through MS^5.

be performed using ion trap mass spectrometry (IT-MS). In ion trapping the molecular ion is maintained in a stable oscillatory trajectory within an ion trap via application of electrical fields. Ion trap instruments are programmed to perform sequential rounds of ion isolation sweeping the trap free of all other products. The generated fragments are released from the trap by resonance activation and mass measured, or single product ions may be re-isolated in the same manner and fragmented again. Fragmentation on any isolated ion is accomplished by low-energy collision-induced dissociation (CID) using a neutral gas.

Using MS^n to Identify Oligosaccharide Branching: Glycosidic Bond Rupture

Glycosidic bonds are easily ruptured by CID and fragments representing a single cleavage on either side of the glycosidic oxygen are observed with a mass difference of 18 Da (Figures 1 (A) and 1(B)). Methylation prior to MS analysis uniquely provides identity to reducing and nonreducing termini, as well as an indication of branching when MS peaks appearing at 14 Da lower intervals indicate hydroxyl group exposed during CID (Figure 1 (C)).

Using MS^n for Linkage Analysis: Cross-Ring Cleavages

Monomers within an oligosaccharide sequence are linked through C-1 of a nonreducing end monomer to any one of four hydroxyl groups (2, 3, 4, or 6) on the adjoining reducing end monomer. These subtleties in structure can be identified in an MS/MS spectrum through minor fragment ions in the mass spectrum appearing above the abundant ions indicating glycosidic ruptures. The increment is a consequence of cross-ring fragmentation around the linkage position (88 Da, 4-linkage; 74 Da, 2-linkage; 88 & 60 Da, 6-linkage), (Figure 2). Cross-ring cleavages are not typically observed for 1–3 glycosidic linkages. Diagnostic cleavages observed during MS^n for the *N*-linked glycan Man_3Gn_2 are shown in Figure 3.

Complementary Techniques

Mass spectrometry is typically used to define all oligosaccharide features except for the configuration of anomeric glycosidic bonds. When used in conjunction with MS, anomericity can be approached using enzymes with known activity for specific glycosidic bonds. The enzymes may be employed sequentially or in parallel array and MS and MS^n spectra from before and after treatment are compared to indicate which monomers were lost.

Oligosaccharide Chains: Free, *N*-Linked, *O*-Linked

Tadashi Suzuki
Osaka University, Osaka, Japan

There is growing evidence that *N*-linked glycans play pivotal roles in protein folding and intra- and intercellular trafficking of *N*-glycosylated proteins. It has been known that during the *N*-glycosylation of proteins, significant amounts of free oligosaccharides (free OSs) are generated in the lumen of the endoplasmic reticulum (ER), possibly by the action of oligosaccharyltransferase. Free OSs are also formed in the cytosol by enzymatic deglycosylation of misfolded glycoproteins, which are destined to be destroyed by a cellular system called ER-associated degradation. Although the precise fate of intracellular free OSs remains obscure, recent biochemical studies have revealed that a novel cellular machinery enables them to be catabolized in a sophisticated manner that involves pumping free OSs from the ER to the cytosol where further processing occurs, followed by their entry into the lysosomes.

Free Oligosaccharides Formed in the Endoplasmic Reticulum

N-Glycosylation is one of the most common co- and posttranslational modifications of eukaryotic proteins occurring in the lumen of the endoplasmic reticulum (ER). During the translocation of proteins in the ER, an enzyme complex called oligosaccharyltransferase (OST) transfers an oligosaccharide (OS) moiety from the dolichol-linked donor substrate to asparagine residues located within the consensus sequence -Asn-Xaa-Ser/Thr- (where Xaa is any amino acid except Pro) to form *N*-linked glycans on the nascent polypeptide chains. Although the biosynthesis of lipid-linked OSs, as well as processing of *N*-linked glycan chains on glycoproteins, is understood in outline, certain aspects of phenomena occurring during *N*-glycosylation reaction remain largely unknown. For instance, biochemical studies have shown that a significant pool of free OSs does occur in the lumen of the ER. It has been proposed that, in the absence of sufficient acceptor sequences, the OST exhibits hydrolytic activity and transfers OSs ($Glc_3Man_9GlcNAc_2$ in most organisms) on dolichol to water, presumably to control the amount of donor substrates when fewer acceptor molecules are around. The OSs formed by OST bear di-*N*-acetylchitobiose (GlcNAcβ1-4GlcNAc) at their reducing termini. Whether there are any other enzyme activities responsible for the release of free oligosaccharides in the lumenal side of the ER is still controversial and has not been unequivocally demonstrated in any organism.

Free Oligosaccharide Transport System from the Endoplasmic Reticulum to the Cytosol

Although it is not known whether free OSs have a physiological role in the ER, one could easily envisage that the accumulation of vast amount of free OSs in the ER could interfere with the quality-control system involving the recognition of the folding state of proteins, export of misfolded lumenal and transmembrane proteins into the cytosol, and degradation of them by the 26S proteasome (see later discussion). Therefore, it is not surprising that cells have machinery to eliminate free glycans from the ER lumen. Using permeabilized mammalian cells, it has been demonstrated that free OSs formed in the ER are, after rapid deglucosylation, exported from the ER into the cytosol. A transporter responsible for the export of free OSs from the ER membrane has not been identified, although biochemical studies show that the export is an ATP- and Ca^{2+}-dependent process. The OS export is also effectively blocked by the addition of low concentrations of mannose and its derivatives, but not by other sugars, suggesting that the transport machinery for free OSs recognizes the mannosyl residues at the nonreducing end, but not the GlcNAc residues at their reducing termini. The main structure of free OSs released from the ER to the cytosol has been shown to be $Man_{8\sim9}GlcNAc_2$ (Figure 1).

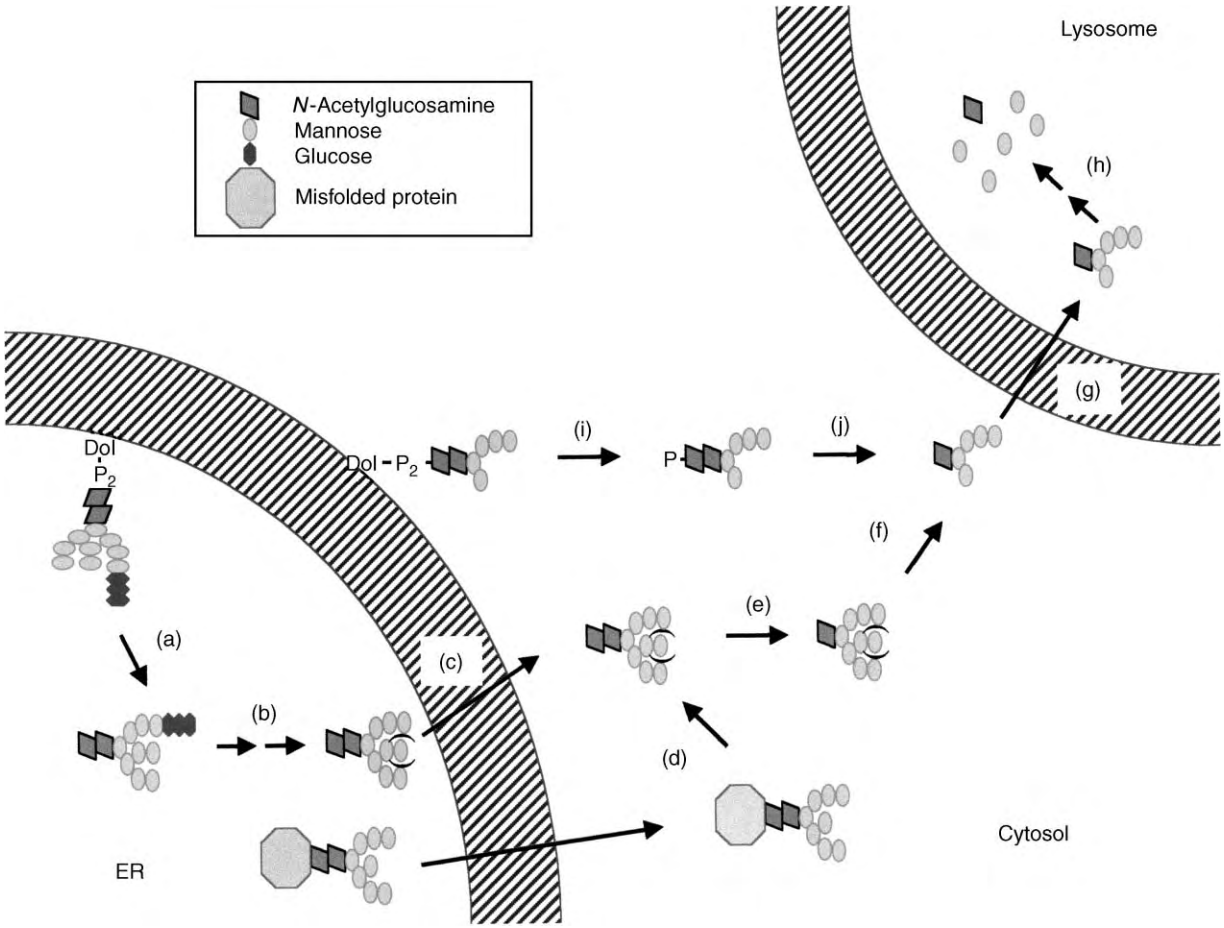

FIGURE 1 Model for the fate of free oligosaccharides generated in and outside of the ER in mammalian cells. Step (a), Free OSs generated in the lumen of the ER by the hydrolytic activity of OST bear di-*N*-acetylchitobiose (two GlcNAc residues) at their reducing termini. Step (b), After quick deglucosylation by α-glucosidase I and II (and sometimes ER α-mannosidase I), (c) $Man_{8\sim9}GlcNAc_2$ is transported into the cytosol by a putative transporter. Step (d), In the cytosol, PNGase removes *N*-linked glycan (most likely a $Man_8GlcNAc_2$ structure because action of an ER α-mannosidase I is prerequisite for the efficient export of misfolded glycoproteins from the ER to the cytosol) from misfolded glycoproteins and thereby releases free OSs bearing di-*N*-acetylchitobiose. Step (e), Once in the cytosol, ENGase (or, in some cases, a chitobiase) forms a free OS with a single GlcNAc at the reducing termini ($Man_{8\sim9}GlcNAc$). Step (f), The free OS with a single GlcNAc is now susceptible to the action of a cytosolic α-mannosidase, giving rise to a $Man_5GlcNAc$ structure. This structure is identical to the last dolichol intermediate present in the cytosolic face. Step (g), The $Man_5GlcNAc$ is transported into the lysosomes by a specific transporter. Step (h), In lysosome, the $Man_5GlcNAc$ is hydrolyzed into monomers (Man and GlcNAc) by lysosomal α- and β-mannosidases. Step (i), Putative pyrophosphatase, whose activity is reported in the cytosolic face of the ER membrane, can also release free OSs from the dolichol-linked OSs (presumably with the structure of $Man_5GlcNAc_2$) in the cytosol. Step (j), probably, this OS-phosphate will be processed by ENGase to give rise to $Man_5GlcNAc$, which is readily transported into lysosome. Note that this scheme cannot be applied to other organisms; for example, *Saccharomyces cerevisiae* does not possess ENGase, so there must be a distinct path.

Free Oligosaccharides Formed in the Cytosol: Its Connection with Endoplasmic-Reticulum-Associated Degradation

Recent evidence clearly shows that the ER has quality-control machinery that differentiates between misfolded (glyco)proteins and correctly folded ones, so that only the latter move from the ER to the Golgi. In this system, proteins that fail to fold or form subunit structures are retained in the ER and interact with various lumenal chaperones that allow them to mature into their native structure before they exit the ER. When proteins consistently fail to acquire the correct state, they eventually are degraded by the mechanism called ER-associated degradation(ERAD). It is now clear that this degradation process involves the retro-translocation of the defective (glyco)proteins from the ER to the cytosol, followed by their degradation in the cytosol by the action of proteasome. Recent growing

evidence shows that glycan chains on glycoproteins play critical roles in monitoring the folding state of glycoproteins in the ER that involves various intracellular lectins.

When the misfolded glycoproteins are retrotranslocated to the cytosol for degradation, protein is ultimately degraded by the action of the 26S proteasome. However, it is reasonable to assume that for glycoproteins to be degraded efficiently by the proteasome, bulky modifications of polypeptide side chains such as *N*-glycan chain may be removed prior to precessive proteolysis by the proteasome. The removal of glycan is achieved by the action of peptide:*N*-glycanase (PNGase), releasing free OSs in the cytosol (Figure 1). PNGase cleaves the amide bond between glycosylated asparagine residues and the proximal GlcNAc residues (Figure 2), and under physiological pH ammonia is released, generating free OSs bearing a di-*N*-acetylchitobiose unit at the reducing termini. The cytosolic PNGase occurs widely from yeast to mammalian cells, and the gene encoding this enzyme has been identified.

Another enzyme that can generate free OSs in the cytosol is a pyrophosphatase that releases OS-phosphate moieties from dolichol-linked OSs (Figure 1). Such cytosol-oriented enzyme activity has been detected in mammalian cells. Another possibility is the action of endo-β-*N*-acetylglucosaminidase (ENGase), which cleaves the glycoside bond in the di-*N*-acetylchitobiose structure, giving rise to free OSs with a single GlcNAc remaining at the reducing termini (Figure 2). This cytoplasmic enzyme is also known to occur widely, but not in yeasts such as *Saccharomyces cerevisiae* or *Schizosaccharomyces pombe*. It is not known whether the cytoplasmic ENGase can directly generate free OSs either from dolichol-linked OS or from glycoproteins *in vivo*.

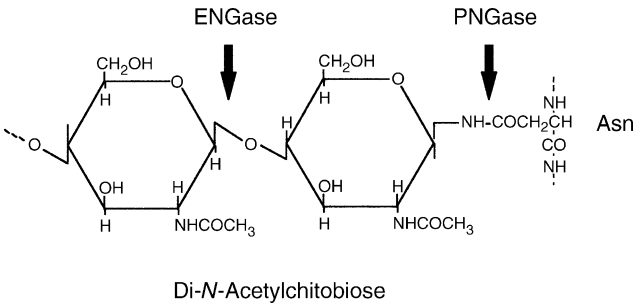

FIGURE 2 Reaction sites for two deglycosylating enzymes acting on *N*-glycosylated peptide. PNGase hydrolyzes the asparaginyl amide bond to give an aspartic acid-containing polypeptide chain and 1-amino-*N*-acetylglucosaminyl oligosaccharide; the latter is subsequently hydrolyzed under neutral pH to *N*-acetylglucosaminyl oligosaccharides and ammonia. On the other hand, ENGase hydrolyzes the glycoside bond in the di-*N*-acetylchitobiose moiety of the core region of *N*-linked glycan, leaving a single *N*-acetylglucosamine on the core peptide.

Cytosolic Processing of Free Oligosaccharides

Irrespective of their source, cytosolic OSs must be further catabolized, possibly to maximize the reuse of the component sugars. In the cytosol, two enzymes mainly contribute to the catabolism of free OSs: β-*N*-acetylglucosaminidase and α-mannosidase. For β-*N*-acetylglucosaminidase, so far two distinct enzyme activities have been reported; one is ENGase and the other is a cytosolic, neutral chitobiase. Although a chitobiase catalyses the same reaction with ENGase, it acts only if the reducing termini of the free OSs are di-*N*-acetylchitobiose, releasing a single GlcNAc from their reducing termini. Therefore, the chitobiase can be called a reducing-end exoglycosidase. Although the gene encoding cytoplasmic ENGase has been identified quite recently, the molecular nature of the cytosolic chitobiase is not known.

It has been shown that the action by a cytosolic α-mannosidase requires that free OSs bear only a single GlcNAc at the reducing ends. The trimming of free OSs by the cytosolic α-mannosidase (α1-2,3,6 mannosidase) results in a different Man_5 structure, yielded by the action of Golgi α-mannosidase I (α1-2 mannosidase), but in the same isomeric conformation with that is present in the dolichol-OS intermediate (Figure 1). The end product of ENGase (or chitobiase) and α-mannosidase in the cytosol, $Man_5GlcNAc$, is then transported into the lysosomes, where further degradation by α- and β-mannosidase can occur (Figure 1). The transporter on the lysosomal membrane seems to be specific to $Man_5GlcNAc$ structure, is ATP-driven, and is inhibited by *N*-acetylglucosamine but not by mannose. The last observation suggests that the reducing terminal structure of free OSs, in sharp contrast to the ER transporter, is crucial for recognition of free OSs by the lysosomal transporter. The molecular nature of the transporter remains to be identified.

Concluding Remarks

Cells possess a variety of enzymes and transporters to handle free OSs generated by several distinct mechanisms. Free OSs collected in the cytosol are processed by ENGase (or a chitobiase) and α-mannosidase before being incorporated into the lysosomes for degradation into monomeric sugars. Why this rather complicated pathway (ER to cytosol to lysosome) is

used for free OS catabolism is a mystery. One notion is that this trafficking route enables them to be removed quickly from the ER, thereby preventing them from interfering with the efficient glycan-dependent quality-control machinery for newly synthesized glycoproteins in the ER. However, it is still possible that a particular free OS itself may play a role in certain cellular processes. Indeed, intracellular free OS derivatives of *N*-glycan chains are known to play a role in the growth, senescence, and ripening of fruits in plants. Although similar bioactivity in other organisms still remains to be detected, the identification of molecules involving the formation, modification, and transport of free OS should provide us with more insight into the mechanism and function of this novel pathway.

Biography

Tadashi Suzuki is Visiting Assistant Professor in the Department of Biochemistry, Graduate School of Medicine, Osaka University. His principal research interest is the biological functions of deglycosylating enzymes, including cytoplasmic peptide:*N*-glycanase (PNGase) and endo-β-*N*-acetylglucosaminidase (ENGase) in eukaryotes. He received a D.Sc. degree from the University of Tokyo and served as a Postdoctoral Fellow and Research Assistant Professor at the Department of Biochemistry and Cell Biology, State University of New York at Stony Brook.

Oncocytes

Bernard Tandler and Charles L. Hoppel
Louis Stokes VA Medical Center, Cleveland, Ohio, USA

Oncocytes, first described by H. Hamperl, are large cells possessing a granular, eosinophilic cytoplasm that are present in many glands and various epithelial linings, particularly in humans; they rarely are found in other mammalian species. In humans, they increase in number with age and may come to constitute a sizeable portion of particular organs; e.g., the oxyphil cells of the parathyroid gland are oncocytes. Oncocytes can occur in neoplastic tissues as well as in normal tissues. Oncocytes in normal tissues can themselves undergo neoplastic transformation and, because they are capable of division, result in a tumor composed wholly or partially of oncocytes, e.g., oncocytoma and Warthin's tumor. These generally are benign, but occasionally various oncocytic neoplasms can be malignant, e.g., Hürthle cell carcinoma and malignant oncocytoma. It is clear that oncocyte formation and neoplasia are independent processes that can occur in either sequence.

Structure of Oncocyte Mitochondria

The fundamental morphological nature of oncocytes was firmly established from the earliest examination of these cells by electron microscopy. They are filled with an abundance of mitochondria, which are responsible for the eosinophilic granularity of the cytoplasm as seen by optical microscopy. Other cytoplasmic organelles are inconspicuous, but sparse lysosomes can be revealed by cytochemistry. Special features normally found in specific precursor cell types, such as folded plasma membranes, microvilli, or secretory granules, are reduced or entirely absent. The mitochondria can be regular in form and are usually ovate, but occasionally are discoidal, rod-shaped, or pleomorphic. In some oncocytic cells, various mitochondrial forms co-exist side by side.

The ovate mitochondria frequently contain an unusual number of cristae, which often are arranged in a central stack where they are closely applied to one another (Figures 1 and 2). With transmission electron microscopy (TEM), the cristae appear to be merely simple infoldings of the boundary membrane, but scanning electron microscopy (SEM) reveals that at least some lamelliform cristae are connected to the boundary membrane by several short tubules, the so-called crista junctions. In certain oncocyte mitochondria in Hürthle cell carcinomas, individual cristae may have a lattice-like form. Despite their altered morphology, oncocyte mitochondria are capable of division by medial partition formation.

Those oncocyte mitochondria that are flattened disks often are aggregated like a stack of pancakes. In such organelles, the cristae occasionally are oriented in a longitudinal pile or may appear to be vesicular. Although conventional matrix granules have not been detected in oncocyte mitochondria, these organelles sometimes include in their inner compartment amorphous densities ranging from small to large. Certain mitochondria contain inclusions filled with either α- or β-glycogen; such inclusions are delimited by a single membrane, showing that they truly are intramitochondrial, rather than being cytosolic glycogen aggregates that merely have been engulfed by intact mitochondria. In oncocytes of the parotid gland in the vampire bat, adjacent mitochondria are linked by periodic cross-bridges measuring 10 nm, separated by a 12.5 nm interval. Such linked organelles have not been observed in human oncocytes.

Mitochondrial Biochemistry

The physiological capacity of oncocyte mitochondria is not well established. Histochemical studies of oncocytes and oncocytomas, irrespective of their site of occurrence, invariably show an increase in mitochondrial oxidative enzymatic activity. At the same time, biochemical studies show an increase in the amount of mitochondrial DNA per cell. Both of these phenomena can be accounted for by the increased number of mitochondria (up to 10-fold) in oncocytes. There are no gross alterations in the mitochondrial DNA. A biochemical study of mitochondria isolated from Warthin's tumor of the parotid gland found them to be partially uncoupled. Analysis of mitochondria from thyroid oncocytic tumors showed significant decrease in ATP synthesis, whereas in renal oncocytomas the

mitochondrial ATPase activity is normal. These data suggest site-specific differences in oncocytic metabolism. The nuclear factor responsible for the increase in mitochondrial number in oncocytes has not been identified. However, this factor does not change in response to decreased respiratory chain activity, decreased ATPase activity, or mitochondrial DNA abnormalities. Study of the biochemistry and genetics of oncocytes is hampered by the comparative rarity of metaplastic or neoplastic aggregates of such cells and by the fact that they occur mostly in humans.

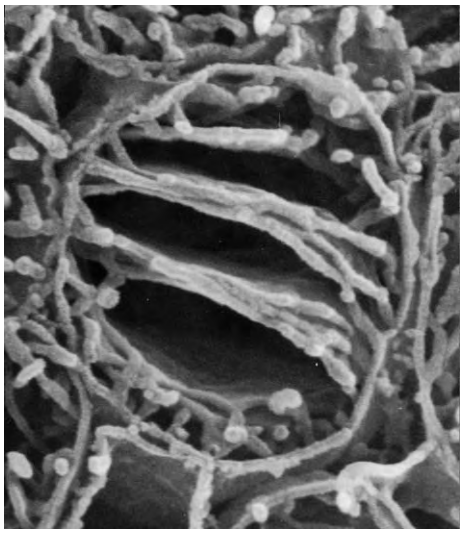

FIGURE 2 A scanning electron microscope micrograph of a mitochondrion from a human oncocyte of submandibular gland origin. All soluble material has been extracted from this specimen, leaving only membranes. A portion of the outer and boundary membranes has been removed from this organelle, allowing the internal sheaf of cristae to become apparent. Original magnification, ×25,000. Biography

Bernard Tandler was a long-time Professor of Oral Biology and of Anatomy at the Case Western Reserve University Schools of Dentistry and Medicine, where he currently is a Visiting Professor of Oral Diagnosis, as well as a Consultant at the VA Medical Center in Cleveland. He also served as Visiting Professor of Anatomy at Kyushu Dental College and of Biological Sciences at Texas Tech University. His major research interests concern the biogenesis, structure, and physiology of giant mitochondria, as well as the structure, function, and evolution of mammalian salivary glands and of secretory cells in general.

Charles L. Hoppel graduated from Gonzaga University and St. Louis University School of Medicine. He is Professor of Pharmacology, Medicine and Oncology at Case Western Reserve University, Co-Director of the Center for Inherited Disorders of Energy Metabolism at CWRU, and Associate Director, Research in the Geriatric Research, Education, and Clinical Center at the Louis Stokes VA Medical Center, Cleveland. His research interests are in mitochondrial structure and function, mitochondrial fatty acid oxidation, and regulation of carnitine palmitoyltransferase-I.

Opioid Receptors

P.Y. Law and Horace H. Loh
University of Minnesota, Minneapolis, Minnesota, USA

Opioid receptors are transmembrane proteins located at the synaptic membranes that serve as targets of an efficacious pain relief drug: morphine. The identification of these binding sites at neural membrane for plant alkaloids has led to the discovery of the first class of endogenous drug molecules, i.e., the enkephalins and endorphins. These opioid receptors belong to the superfamily of G protein-coupled receptor, and upon activation, the activities of multiple cellular effectors are modulated, leading to inactivation of the ascending and activation of the descending pain pathways. Eventually, pain perception is altered. Unfortunately, with the "good" therapeutic actions of morphine, there are also "bad" side effects of the drug, e.g., tolerance and addiction. Thus, the molecular mechanism in the cellular regulation of these opioid receptors, and the designs of specific agonists for these opioid receptors to be ideal analgesic agents are of great interest in pain medicine development.

Historical Perspectives

For centuries, extracts from the opium poppy, *Papaver somniferum*, have been prescribed for pain relief, to control cough, and to treat diarrhea. However, in addition to its medicinal uses, due to its psychological effects, man has abused opium since the time of the ancient Greeks. The isolation of the principal alkaloid by the German pharmacist, Friedrich W. Serturner in 1805, which he named morphine after the Greek god of dreams, Morpheus, has enabled pharmacologists to determine the relationships between structures and their analgesic activities. From the relatively low concentration of morphine needed to relieve pain in 70% of the patients (10 mg/70 kg body-weight), to the stereoselective requirement for analgesic action of the drug, it is apparent that morphine acts by high-affinity binding to proteins, or specific receptor, located in the central nervous system (CNS). The presence of specific morphine receptor was not demonstrated until 1973, when three research groups: Lars Terenius, Soloman Snyder, and Eric Simon, following the guideline established by Avram Goldstein, independently reported the presence of high affinity and stereoselective binding sites at the synaptic membrane preparations of rodent brain. The affinities of various opiate analgesics for these binding sites and the location of these sites correlated well respectively with the *in vivo* potencies and sites of action of the drug. Thus, the era of the opiate receptor is launched. Immediately, it is apparent that these mammalian CNS binding sites could not be evolved for plant alkaloids. This dichotomy was resolved by the isolation of the endogenous opioid peptide, enkephalin, by John Hughes and Han Kosterlitz in 1975 followed later by the identification of the proenkephalin A gene. The subsequent identification of two other gene products, β-endorphin deriving from the pro-opiomelanocortin gene, and dynorphin deriving from the *prodynorphin*or *proenkephalin B* gene suggests that the *in vivo* actions of morphine and its congeners must be a reflection of these endogenous opioid peptides actions. The presence of multiple endogenous opioid peptides genes also suggests the probable existence of multiple opioid receptors.

Discovery of Multiple Opioid Receptors

In 1976, Bill Martin and his colleagues hypothesized the presence of multiple opioid receptors. Concluding from the physiological responses such as blood pressure and respiration, Martin and co-workers coined the multiple opioid receptors terminology based on the prototypic ligands within each group, with morphine being the mu (μ) agonist, ketocyclazocine being the kappa (κ) agonist, and SKF10 047 being the sigma (σ) agonist. The existence of multiple opioid receptors was further demonstrated by measuring the amount of an opiate antagonist to reverse the agonist effect in two *in vitro* bioassay systems, the guinea pig (GP) ileum and the mouse vas deferens. These bioassays were responsible for the identification of the fourth type of opioid receptor, the delta (δ) with enkaplin being the prototypic agonist. Additional studies such as the cross-tolerance measurements also supported the existence of multiple opioid receptors. In the cross-tolerance studies, animals or the *in vitro* GP ileum were treated with an opioid

receptor-selective agonist. Chronic exposure to the agonist resulted in a loss in response, or tolerance development. However, activities of agonists that are selective for other opioid receptors remained unaltered, or no cross-tolerance was developed. These *in vivo* and *in vitro* experiments support the original hypothesis of multiple opioid receptors.

The implication of the existence of multiple opioid receptors by the animals' studies and bioassays was supported initially by the direct receptor-binding experiments reported by Law and Loh, K.J. Chang, Hans Kosterlitz, and their colleagues. The development of receptor-selective antagonists, such as naltrindole (δ) and nor-binaltorphimine (κ), and the development of ligands that would alkylate receptor selectively, such as β-funaltrexamine (μ), have enabled investigators to characterize the properties of these multiple opioid receptors biochemically further by generating membrane preparations that contain single-receptor type. Only after the molecular cloning of the δ-opioid receptor, concurrently by the groups of Chris Evans and Brigitte Kieffer in 1992, followed by the cloning of μ- and κ-opioid receptors in 1993 by others, is the hypothesis of multiple opioid receptors firmly established. These multiple opioid receptors are products of three separate receptor genes and with high amino acid sequence homology (>60%). Although subtypes of these opioid receptors have been postulated, various gene products that exhibit the reported ligand selectivity of the various opioid receptor subtypes have not been identified. Also, from additional pharmacological and the molecular cloning studies, the sigma (σ) receptor does not belong to the opioid receptor family. Hence, the μ-, κ-, and δ-opioid receptors are the sites that endogenous opioid peptides and exogenous opiate alkaloids exert their actions.

Distribution and Pharmacology of Multiple Opioid Receptors

Prior to the cloning of the opioid receptors, the distribution of the receptors within various brain regions or tissues, was determined with autoradiographic studies using radioactive ligands selective for a specific receptor. These autoradiographic results were later substantiated and extended with the *in situ* hybridization studies using the cloned receptor mRNA and with the histochemical or immunofluorescence studies using the receptor-specific antibodies. In general, these data indicate that the location of the multiple opioid receptors coincides with the pharmacological actions of the drugs. These opioid receptors are mainly localized in the limbic system that are involved in the control of emotion and reward behaviors, the ascending and descending pain pathways that include the different laminae layers of cortex, thalamus, periaqueductal gray, midbrain median raphae and the dorsal horn of the spinal cord, and specific brain regions that are known to control locomotion, emesis, cough, and temperature.

The distributions of the μ- and δ-opioid receptor are very similar but distinct. Although these receptors do not co-localize in the pre- or post-synaptic membrane of the same neuron, they are observed to be located in the same components of the limbic systems such as the nucleus accumbens and the amygdala. Their locations at the cortex, the 4th ventricle and at the substantia gelatinosa of the spinal cord are the reasons why both μ- and δ-opioid receptor selective drugs have strong spinal and supraspinal analgesic effects. Similarities in the distribution of these two opioid receptors suggest the μ- and δ-opioid receptors have similar pharmacological profile (Table I). There are reports using δ-opioid receptor selective antagonist or using mice that the δ-opioid receptor has been genetically deleted that implicate the role of δ-opioid receptor in modulating both the acute and chronic effects of the μ-opioid receptor selective agonist.

On the other hand, distribution of the κ-opioid receptor in the central nervous system is distinct from that of μ- and δ-opioid receptors. The most striking difference is the uniform pre-synaptic location of the κ-opioid receptor in the caudate putamen area. Such location could be the explanation for the observed κ-opioid agonist induced decrease in locomotion and the decrease of dopamine release in this brain area. The inhibition of dopamine release is the basis for the dysphoric effects of the κ-opioid agonists. The brainstem and spinal cord distribution of the κ-opioid receptor resemble that of μ-opioid receptor. Hence, κ-opioid agonists could produce spinal analgesia (Table I).

The multiple opioid receptors are not confined to the central nervous system. The presence of the receptors in the gastrointestinal tract accounts for the constipative

TABLE I

effect of μ- and δ-opioid agonists. The presence of the κ-opioid receptor in the cardiac myocytes could be the reason for the bradycardia effect observed with the κ-opioid agonists, though the bradycardia effect of the opioid agonists is mainly associated with the agonist actions at the brainstem medulla. Opioid receptors have been reported also to be present in the immune cells. The true identities of these receptors are yet to be identified, whether they are the μ-, δ-, or κ-opioid receptor types or the "non-classical" opioid receptors. Nevertheless, the pronounced effects that morphine has in the immune responses of animals, and the fact that intravenous drug users are one of the high risk groups for HIV have led to many studies, and the effects of various opioid agonists and antagonists on the functions of immune cells cannot be ignored.

Opioid Ligands Selectivity for the Multiple Opioid Receptors

With the cloning of the opioid receptors and the subsequent generation of mice in which the transcription of selective opioid receptor gene could be disrupted, it is possible now to delineate the opioid receptor types that various opioid ligands could activate. By expressing the three cloned receptors individually into cells that do not express opioid receptor endogenously, it is possible to generate models that could determine the affinities of the opioid ligands to a specific receptor type accurately. Likewise, by genetically eliminating the *in vivo* expression of an individual opioid receptor type, the loss or gain in functions of a specific opioid agonist can be evaluated *in vivo*. These data in combination with the receptor-selective antagonists studies have determined the selectivity of various opioid ligands and their functions, as summarized in Table II.

It is apparent that morphine and its congeners are agonists in the μ-opioid receptor. Although in the *in vitro* cell line models that express the δ-opioid receptor morphine has partial agonist activities, morphine does not exhibit measurable analgesic activities in mice that do not express the μ-opioid receptor. Since these animals have intact δ- and κ-opioid receptor systems, it is unequivocal that morphine pharmacological effects are mediated via the activation of μ-opioid receptor.

Other opiate alkaloids have been shown to exhibit nonselectivity toward these three opioid receptors. The oripavine derivatives (etorphine and diprenorphine) and the benzomorphans (ketocyclazocine and bremazocine) have been shown by many to have similar affinities for all three opioid receptors. This is surprising since ketocyclazocine was used by Bill Martin to define one of the multiple opioid receptors, the κ-opioid receptor. Such dichotomy may be resolved by the fact that some opiate alkaloids have different activities in different opioid receptor types. For example, nalorphine exhibits antagonistic properties in the μ-and δ-opioid receptors but possesses agonistic activities in the κ-opioid receptor. Another example is pentazocine that possesses both κ-agonistic and μ-antagonistic properties. The mixed agonist-antagonist properties of various alkaloids are being exploited in the clinic so as to minimize the side effects of the drug, most noticeably, the addictive liability of the opiate analgesics.

The endogenous ligands, noticeably the products of the three peptides genes – enkephalin, β-endorphin, and dynorphin do not appear to have specificity toward these multiple opioid receptors. Initially, enkephalin and β-endorphin have been considered to be the prototypic ligands for the δ- and μ-opioid receptors respectively. Dynorphin, with the positively charged amino acids arginine and lysine, has been shown to preferentially interact with the κ-opioid receptor. Since then, it has been shown that Met^5-enkephalin has equal affinity for the μ- and δ-opioid receptor, and that dynorphin has high affinity for the δ-opioid receptor. Only when the peptides are restricted in their rotation is receptor selectivity observed, e.g. the D-penicillamine derivatives of enkephalin, DPDPE. This peptide has been shown

in vitro to be selective for the δ-opioid receptor and with minimal activity in the μ-opioid receptor. Hence, the *in vivo* effect of DPDPE has been the hallmark for the δ-opioid receptor activation. However, recent *in vivo* studies using mice lacking the μ- or the δ-opioid receptor, clearly suggest that the DPDPE analgesic effect is mediated by activation of μ-opioid receptor. This conflicting *in vitro* and *in vivo* receptor selectivity of the endogenous peptides and their derivatives requires further detailed investigation.

Molecular Mechanism of Multiple Opioid Receptor Function

A general feature of the opioid agonist is the inhibition of neurotransmitter release. Although there are instances that opioid agonist could increase the neurotransmitter release, it is due to the location of the receptor and the disinhibition of the neurotransmitter release. An excellent example is the dopamine release within the nigrostriatal loop. κ-Opioid agonist inhibits dopamine release by acting directly at the presynaptic dopaminergic terminals, whereas μ- and δ-opioid agonists increase the release by inhibiting the GABAergic interneurons that inhibit the dopamine release. Thus, in either case, the activation of opioid receptor results in the direct inhibition of synaptic transmission.

From the cloning studies, it is unequivocal that the opioid receptors belong to the superfamily of proteins, the G protein-coupled receptors (GPCR) and the subfamily of rhodopsin-like receptors. One common feature of these receptors is that they contain hydrophobic regions that would span the membrane 7 times. Thus these receptors are commonly known as seven-transmembrane receptors. Another common feature is that their signals are mediated by promoting the dissociation of the nucleotide GDP from the α-subunits of the heterotrimeric proteins. The dissociation of GDP allows the association of GTP to the α-subunits resulting in the dissociation of the heterotrimeric proteins into α- and βγ subunits. These subunits will then control the activities of various intracellular or membrane bound proteins and enzymes. For the multiple opioid receptors, the GTP/GDP-binding proteins involved in their actions are the pertussis-toxin-sensitive Gi/Go proteins.

In order for opioid receptors to regulate the neurotransmitter release, two of the proteins that the receptors regulate are the voltage-dependent Ca^{2+} channels and the inward rectifying K^+ channels. By inhibiting the Ca^{2+} channels and thus reducing the influx of Ca^{2+}, opioid agonists could regulate the fusion of vesicles containing the neurotransmitters with the synaptic membrane. Also opioid agonists could activate the voltage-dependent inward rectifying K^+ channels and thus hyperpolarizing the synaptic membrane. By controlling these two ions channels, activation of the opioid receptors would reduce the excitability of the membrane and reduce the transmitter release.

Other prominent proteins and enzymes that are regulated by the multiple opioid receptors are the enzymes responsible for cAMP synthesis, adenylyl cyclase, and that which is involved in the long-term cellular adaptational events, the mitogen-activated protein kinase (MAP kinase). Opioid receptors inhibit the adenylyl cyclase activity, thereby reducing the intracellular cAMP content. This second messenger could control the activities of a protein kinase that, in turn, could regulate the activities of other proteins, such as the ion channels. The MAP kinase has been known to participate in the cellular proliferation and apoptotic events. Thus, it is probable that MAP kinase activation by the multiple opioid receptors could signify their involvement in long-termed potential and learning, two of the probable mechanisms for the basis of chronic drug actions.

Summary and Future Direction

The similarities in the sequence and the molecular action of these multiple opioid receptors are striking. Hence, it is unclear why nature would evolve three different genes coding for three different proteins from the same ancestral gene so as to carry out the same functions. To complicate the picture, there are three endogenous peptides that exhibit selectivity but not specificity among these multiple opioid receptors. It is still unresolved why an endogenous opioid peptide such as Met^5-enkephalin that exhibits *in vitro* agonistic properties in μ-opioid receptor would not produce analgesic effect *in vivo*. There is no debate that endogenous peptides and opiate alkaloids have different recognition motifs within these opioid receptors, and that the cellular regulations of the peptide- and alkaloid-receptor complexes are different. Whether such differences could contribute to the differences in the pharmacological responses of these drugs or simply the spatial distribution of the receptors, remains to be investigated.

In the past, the approach to eliminate the undesirable side effects of the opiate alkaloids was to design drugs that would have selectivity toward one specific opioid receptor. A classic example is the development of drugs that would have κ-opioid receptor selectivity, because the dysphoric effect of κ-opioid receptor activation would reduce the addictive liability of the drug. Unfortunately, drugs marketed thus far do not exhibit the ultimate property of opiate analgesic, i.e., efficacious pain relief with no side effects. The problem lies mainly with the presence of multiple opioid receptors and the selectivity of the drugs for these receptors. Hence new approaches should be taken in

the future for development of pain-management paradigms. With the advent of gene therapy, one could envision the use of receptor engineering in the treatment of pain. If an opioid-receptor mutant could be identified that exhibits distinct phenotype from that of the endogenous receptors, and that this receptor mutant could be delivered to the site of action, e.g., substantia gelatinosa of the spinal cord, then activation of such mutants by a drug that normally would not activate the endogenous receptors, e.g., an opiate antagonist, would result in pain relief. Such an approach would not only provide specificity, but also would eliminate the side effects of the opiate drugs; but this approach could only be accomplished when the molecular basis for the action of the multiple opioid receptors is fully elucidated.

Ornithine Cycle

Malcolm Watford
Rutgers University, New Brunswick, New Jersey, USA

The ornithine cycle, also known as the urea cycle and the Krebs–Henseleit cycle, is the pathway in mammalian liver that allows the detoxification and excretion of excess nitrogen as urea. Flux through the cycle is driven by the demand to remove excess ammonia derived from the degradation of amino acids that arise either from the diet or from endogenous proteolysis. In a healthy individual, consuming a typical western diet, flux through the ornithine cycle produces some 30–35 g of urea per day but as much as 25% of this can be recycled via hydrolysis to ammonia and bicarbonate by colonic bacteria.

History

Three major systems have evolved for the elimination of excess nitrogen from the body, and animals may be classified according to their major nitrogenous excretion product. Thus most fish are ammoniatelic (ammonia excretion), reptiles and birds are uricotelic (uric acid excretion), and mammals are ureotelic (urea excretion). In addition, urea excretion is seen in some teleost fish, and urea synthesis is also present in elasmobranchs (sharks and rays) where urea functions primarily in an osmotic role, not in nitrogen excretion.

Urea was first described as "substance savoneuse," that yielded ammonia on hydrolysis, isolated from urine by Roulle in 1773 and was obtained in pure form by Proust in 1820. There is evidence that Davy synthesized urea from cabonyl chloride and ammonia in 1812 but he failed to recognize the product. Thus Wholer is credited for achieving the synthesis, in 1828, of urea from ammonia and lead cyanate in what is best remembered as the first synthesis of an organic compound from inorganic substrates. Over the next century many theories were developed to explain urea synthesis but the true pathway was not discovered until 1932. Working with liver slices in incubation Krebs and Henseleit found that the addition of small amounts of ornithine greatly accelerated the synthesis of urea from ammonia and furthermore, that the ornithine could be recovered at the end of the incubation. From this they formulated the idea that ornithine was acting as a "catalyst." They also identified citrulline as an intermediate and described the ornithine cycle as ammonia (together with bicarbonate) and ornithine combining to give citrulline that was then converted to arginine. The final step was hydrolysis of the arginine to urea and with the concomitant regeneration of ornithine. This was the first description of a cyclic biochemical pathway again illustrating the central role urea synthesis has had in the history of biology and chemistry.

Chemistry of the Cycle

Since Krebs and Henseleit's original discovery, the chemistry of the cycle has been completely described and although the ornithine cycle consists only of four enzymes, the need for carbamoyl phosphate means that carbamoyl phosphate synthetase 1 is usually considered an ornithine cycle enzyme.

The complete cycle (Figure 1) is only expressed in liver parenchymal cells with highest activity in those cells near the portal inlet (periportal cells). The substrates for the cycle are ammonia, bicarbonate, aspartate, and three ATP equivalents. In this text the term ammonia refers to the sum of NH_4^+ plus NH_3, and where a specific molecular species is important, it is shown in parentheses. Beginning in the mitochondria ammonia (NH_3) combines with bicarbonate to form carbamoyl phosphate involving 2 ATP and releasing 2 ADP plus inorganic phosphate, through the action of carbamoyl phosphate synthetase 1 (EC 6.3.4.16). The carbamoyl group is then transferred to ornithine via ornithine transcarbamoylase (EC 2.1.3.3) to yield citrulline that leaves the mitochondria in exchange for ornithine on the ORN 1 transporter. In the cytosol, citrulline condenses with aspartate in a reaction, requiring ATP and the formation of a citrulline-AMP intermediate, to give argininosuccinate, AMP, and pyrophosphate via the action of argininosuccinate synthetase (EC 6.3.4.5). The carbon skeleton of the aspartate is then cleaved from argininosuccinate by argininosuccinate lyase (EC 4.3.2.1) to yield fumarate and arginine. The final step is hydrolysis of arginine by arginase (EC 3.5.3.1) to give the end product urea with the regeneration of ornithine that can enter the mitochondria on the ORN 1 transporter and begin another round of the cycle.

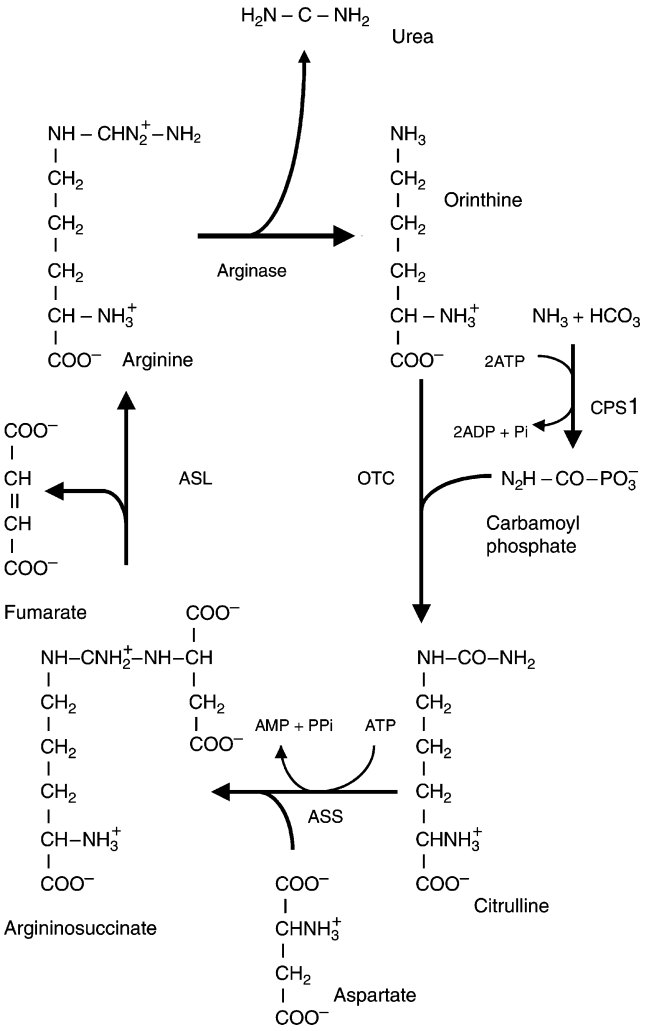

FIGURE 1 The chemistry of the ornithine cycle. CPS 1, carbamoyl phosphate synthetase 1, OTC, ornithine transcarbamoylase, ASS, argininosuccinate synthetase, ASL, argininosuccinate lyase.

Channeling in the Cycle

Although carbamoyl phosphate synthetase 1 and ornithine transcarbamoylase are mitochondrial matrix enzymes, they are localized in very close proximity to the cristae of the inner membrane. This would favor direct transfer of intermediates along the pathway and tracer experiments have shown that extra-mitochondrial ornithine is preferentially utilized for citrulline synthesis over ornithine generated within the mitochondria. Such findings indicate that the ORN 1 transporter, carbamoyl phosphate synthetase 1 and ornithine transcarbamoylase are working efficiently as a unit without free mixing of the intermediates within the mitochondria. In addition, there is evidence of similar channeling within the cytosolic section of the cycle. In permeabilized hepatocytes incubated with ^{14}C labeled bicarbonate, the formation of labeled urea is not significantly diluted by the addition of large amounts of cycle intermediates (arginine, argininosuccinate, or citrulline), again showing no mixing with exogenous intermediates. Therefore all intermediates of the cycle appear to be carefully channeled along the pathway which may be related to the need to ensure removal of the highly toxic substrate, ammonia.

Physiological Aspects of the Cycle

The function of the ornithine cycle is to detoxify excess ammonia in the mammalian body and as such the source of the ammonia must be considered whenever the cycle is discussed in more than simple chemical terms. There are two types of condition when the delivery of ammonia within the liver is high and thus require high rates of urea synthesis. The first is in response to dietary (exogenous) protein when excess amino acids are degraded and the second is in response to increased catabolism of endogenous amino acids, arising from proteolysis, during early starvation and in hypercatabolic states such as those that arise from sepsis and injury. A quantitative analysis of the fate of a typical daily load of dietary amino acids showed that, if those amino acids that must be catabolized within the liver were to undergo complete oxidation then, this would produce more ATP than the liver uses in a day. Since the liver oxidizes other fuels in addition to amino acids, it is evident that the carbon skeletons of the amino acids cannot undergo complete oxidation in the liver. In practice the amino acid carbon skeletons are conserved as either glycogen (indirect pathway of synthesis) or released into the circulation as free glucose. In the case of starvation and hypercatabolic states, the reason the amino acids are being degraded is to provide glucose for the body, and urea synthesis is simply coincidental. Thus the synthesis of urea from amino acids is always linked to the hepatic pathway of gluconeogenesis.

There is currently some debate about how much of the ammonia and aspartate for the cycle are taken up from the circulation directly and how much are synthesized within the liver from ammonia and/or other amino acids. Within the liver however, glutamate dehydrogenase and the major aminotransferases catalyze reactions close to equilibrium which allows the maintenance of a balanced substrate supply to the cycle (Figure 2).

By following the fate of a single amino acid, alanine, through hepatic metabolism, the integrative nature of the ornithine cycle with gluconeogenesis can be seen (Figure 3). Alanine undergoes transamination with α-ketoglutarate in the cytosol and both the pyruvate and glutamate formed enter the mitochondria where the pyruvate is carboxylated to oxaloacetate via the action of pyruvate carboxylase. The glutamate then transaminates with this oxaloacetate to give aspartate and α-ketoglutarate. The latter can then recycle via the

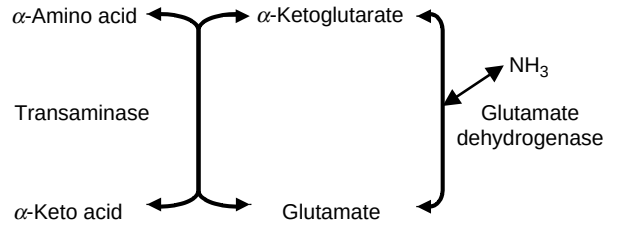

FIGURE 2 The equilibrium nature of glutamate dehydrogenase and the transaminases. Amino acids can transfer their amino group to α-ketoglutarate to produce glutamate via transamination. Glutamate can yield ammonia and α-ketoglutarate through glutamate dehydrogenase. Since glutamate dehydrogenase and the major transminases catalyze reactions close to equilibrium the entire system is freely reversible and thus ensures a balance of substrates, NH3 and aspartate (produced through aspartate aminotransferase) for the ornithine cycle.

cytosol to transaminate with another alanine. The aspartate leaves the mitochondria to be incorporated into the cycle by argininosuccinate synthetase in the cytosol. At the subsequent lyase step the carbon skeleton is released as fumarate. Since fumarate is unable to re-enter the mitochondria, it is metabolized to malate which is oxidized to oxaloacetate with the concomitant generation of NADH in the cytosol. The oxaloacetate is then converted to phosphoenolpyruvate, through the action of cytosolic phosphoenolypyruvate carboxykinase, and enters the gluconeogenic pathway with the utilization of the NADH at the glyceraldehyde 3-phosphate dehydrogenase step. Thus the transport of aspartate out of the mitochondria brings not only the nitrogen required for urea synthesis but also the carbon and the reducing power necessary for gluconeogenesis.

Regulation

In 1905 Otto Folin, carrying out experiments on himself and others, described how urea excretion fluctuated with dietary protein, in particular, he showed how it reached a minimum within two days of consuming a zero protein diet. Thus it is clear that flux through the cycle is highly regulated and as with many biochemical pathways, this involves both short-term (changes in enzyme activity with no change in the amount of enzyme) and long-term (changes in the amount of enzyme) mechanisms. The need for the ornithine cycle is driven solely by the need to remove substrate (ammonia arising from amino acid catabolism), there is never a need for the end product (urea) and thus the cycle is not subject to product feedback regulation. Instead, flux through the cycle must increase rapidly whenever the substrate load increases.

Short-Term Regulation

Quantitative control analysis for the cycle has indicated that carbamoyl phosphate synthetase 1 plays a major regulatory role. In experiments *in vitro* however, where amino acid levels are held constant, the stimulation of carbamoyl phosphate synthetase 1 results in a fall in ammonia levels. This does not occur *in vivo* where the supply of amino acids varies, and at times of increased flux through the cycle, the concentration of ammonia shows little change or even a slight increase. Therefore the role of carbamoyl phosphate synthetase 1 is not to control flux through the cycle, rather it acts to maintain ammonia levels within a very limited range. The intrahepatic concentrations of the intermediates of the cycle are below the K_m for all of the enzymes which means that any increases in the concentration of intermediates, increase flux through the remainder of the cycle. From a teleological viewpoint a possible regulatory scheme would be the simple stimulation of carbamoyl phosphate synthetase 1 by increasing ammonia levels. Since carbamoyl phosphate synthetase 1 shows Michaelis–Menten kinetics towards ammonia

this would mean that a threefold increase in flux through the cycle would require a threefold increase in ammonia concentration. Ammonia levels however, must be held within a very narrow range. If intra-hepatic ammonia levels rise, some will escape from the liver and cause hyperammonemia and neurological toxicity. Conversely, if intra-hepatic ammonia levels decrease, this would disturb the equilibrium nature of the glutamate dehydrogenase and transaminase reactions with resultant dysregulation of non-essential amino acid levels.

Carbamoyl phosphate synthetase 1 has an absolute requirement for an allosteric effector, N-aceyl glutamate, which is made in the mitochondria from glutamate and acetyl CoA by N-acetyl glutamate synthetase (EC 2.3.1.1), and is degraded by an acylase in the cytosol. The synthesis of N-acetyl glutamate is stimulated by arginine and there is evidence that glucagon can increase N-acetyl glutamate levels through inhibition of transport out of the mitochondria thereby decreasing the rate of degradation. The major mechanism responsible for changing N-acetyl glutamate levels however, is substrate supply. Anytime there is an increase in amino acid catabolism this results in increased glutamate supply and a concomitant increase in N-acetyl glutamate levels. This allows carbamoyl phosphate synthetase 1 activity to increase and so prevent the ammonia levels from rising to toxic levels. Thus increased amino acid supply results in not only increased delivery of the direct substrates, ammonia and aspartate of the cycle, but also in the glutamate, and consequently the N-acetyl glutamate, required to allow flux through the cycle to increase and buffer intra-hepatic ammonia levels.

Long-Term Regulation

The urea cycle enzymes are not expressed in mammals until quite late in gestation since there is no need for the fetus to make urea, as the mother can dispose of any potentially toxic waste products. Such changes are also seen in other species, for example, as ammoniatelic tadpoles change to ureotelic frogs there is a dramatic increase in expression of the cycle. In non-carnivorous mammals the levels of all five enzymes can also change with diet and physiological/pathological conditions. Feeding high protein diets, early starvation, and hypercatabolic states are all accompanied by higher amounts of the enzymes, while low protein diets result in lower levels of the enzymes, and Schimke used the kinetics of these responses to develop the quantitative basis of protein turnover. Most of the changes are due to control at the level of gene transcription but the changes in arginase, seen during starvation, also involve changes in the rate of degradation of the arginase protein, and there is evidence that carbamoyl phosphate synthetase 1 expression is also regulated at the translational level. The agents responsible for the changes are predominantly glucagon (cAMP) and glucocorticoids acting to increase expression, with minor roles played by growth hormone, adrenergic hormones, and thyroid hormones. Insulin may act to downregulate expression but the importance *in vivo* is not clear. In addition, transcription of the gene encoding argininosuccinate synthase is suppressed by arginine, but this is likely to be of importance only in non-hepatic cells where the enzyme functions in arginine synthesis.

The half-lives of ornithine cycle enzyme proteins are relatively long, of the order of days, and thus any changes in the amount of protein would take some time to become significant. This means that the long-term changes do not play a role in the acute regulation of the cycle, rather they are adaptive in nature, preparing the body for long-term changes in substrate supply. This fits well with the time course of changes in amino acid catabolism within the body. Excess amino acid supply from a single meal can be readily detoxified through the cycle or temporarily buffered by synthesis of non-essential amino acids such as alanine. However, if the protein content of the diet has undergone a consistent increase then the capacity of the cycle increases to deal with it. Similarly, increased catabolism, of endogenous amino acids in starvation and hypercatabolic states, occurs over the course of days again allowing the cycle time to adapt. Conversely, at times of low protein feeding, expression of the cycle is decreased in order to conserve as much nitrogen as possible. This means that, in retrospect, the experiments of Folin (q.v.) involving the consumption of high protein diets after 14 days of a zero protein diet were potentially highly dangerous. The capacity of the cycle would have been very low and not able to deal with the sudden influx of ammonia. Thus it is important that subjects accustomed to very low protein diets be re-fed relatively small increments of dietary protein until the cycle has increased sufficiently in capacity to avoid hyperammonemia.

Long-term changes in the capacity of the ornithine cycle are always accompanied by similar changes in the expression of a number of genes encoding related hepatic enzymes and transporters. These include, the ORN 1 transporter, various plasma membrane amino acid transporters, tyrosine aminotransferase, glutaminase, and phosphoenolpyruvate carboxykinse. The last is a gluconeogenic enzyme, again illustraing the integrative nature of the entire process of amino acid catabolism.

Extra-Hepatic Expression of Ornithine Cycle Enzymes

The complete ornithine cycle is only found in the liver but some of the enzymes are expressed in other tissues where they function in arginine synthesis. Arginine is not an essential amino acid in non-carnivorous mammals

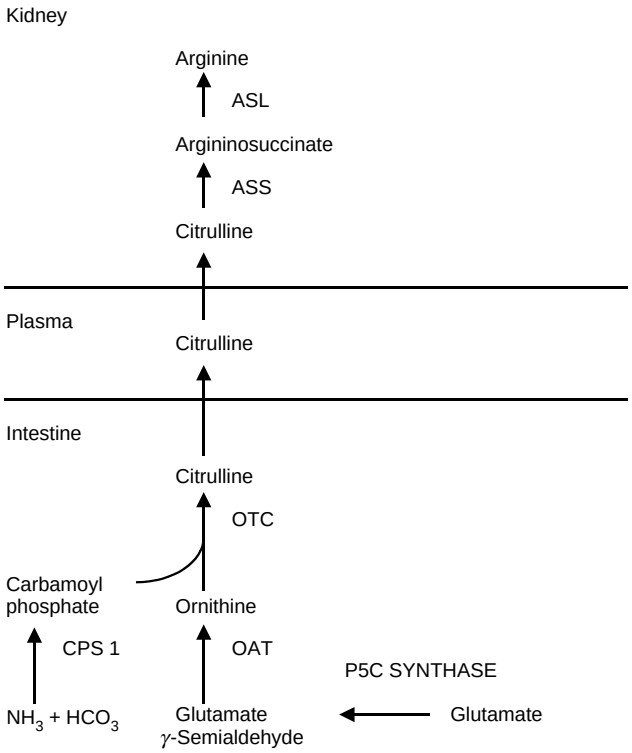

FIGURE 4 Extrahepatic arginine synthesis. ASL, argininosuccinate lyase, ASS, argininosuccinate synthetase, CPS 1, carbamoyl phosphate synthetase 1, OTC, ornithine transcarbomylase, OAT, ornithine aminotransferase, P5C, pyrroline 5-carboxylate.

but the very high arginase activity of the liver means that both dietary arginine and arginine synthesized within the liver are rapidly hydrolyzed and not available to the body. Thus the arginine required for the synthesis of protein, nitric oxide, polyamines, etc. is made in extra-hepatic tissues (Figure 4). The mucosa of the small intestine expresses both carbamoyl phosphate synthetase I and ornithine transcarbamoylase, and together with pyrroline 5-carboxylate synthase and ornithine aminotransferase, this allows the synthesis of citrulline from glutamate and ammonia. This citrulline is released into the circulation to be taken up by the kidney, which expresses both argininosuccinate synthase and argininosuccinate lyase, and used for arginine synthesis. Thus by restricting expression of four enzymes of the ornithine cycle to these two extra-hepatic tissues the body is able to obtain sufficient arginine. Strict carnivores, such as cats and ferrets, lack the intestinal part of this pathway and therefore arginine must be provided in the diet. This is not usually a problem but if, experimentally, they are fed an arginine-free diet, they are unable to generate sufficient ornithine in the liver to allow increased flux through the cycle. This results in hyperammonenia and is one of the very few known cases of acute toxicity arising from a nutritional deficiency.

Inborn Errors of the Ornithine Cycle

As detailed above, the ornithine cycle is not required in utero and thus the genes encoding the cycle enzymes are not expressed until very late in gestation. Therefore it is possible to develop to full term with a misfunctional ornithine cycle gene (inborn errors may arise from a complete lack of a protein, changes in V_{max} or K_M, or the ability to bind cofactors or regulators). Inborn errors for all five cycle enzymes, plus some of the ancillary proteins such as N-acetyl glutamate synthetase and the ORN 1 transporter, have been described. All are characterized by hyperammonemia that is usually accompanied by very high levels of the non-essential amino acids alanine and glutamine. Other intermediates of the cycle accumulate according to the specific enzyme defect. The severity is usually more pronounced with deficiencies of the first two enzymes, carbamoyl phosphate synthetase 1 and ornithine transcarbamoylase, especially if there is a complete lack of activity. The gene encoding ornithine transcarbamoylase is located on the X chromosome and thus boys are most severely affected, however due to Lyonization different alleles are expressed in different cells and some female carriers of a defective gene will present with very low ornithine transcarbamoylase activity. This was traditionally believed to be benign since these women often exhibit protein intolerance and simply self limit their protein intake. It is now recognized however, that times of increased endogenous proteolysis, such as occurs in hypercatabolic states or even pregnancy, can represent a risk for hyperammonemia in such individuals. In classic cases of ornithine transcarbamoylase deficiency, some of the excess carbamoyl phosphate in the mitochondria escapes to the cytosol where it enters the pyrimidine synthesis pathway. This causes production of relatively large amounts of orotic acid which is lost in the urine and the presence of significant orotate excretion is considered definitive evidence for ornithine transcarbamoylase deficiency.

A defect in argininosuccinate synthase results in citrullinemia and excretion of citrulline in the urine. To a limited extent, this lessens the need for urea synthesis and threrefore the ammonemia is not as severe as seen with defects in the first two enzymes. Similarly, with defects of argininosuccinate lyase and argininase, there is excretion of argininosuccinate and arginine, again lowering the need for urea synthesis and the severity of the condition.

The treatment for all inborn errors of the ornithine cycle begins with a limited protein diet to lower the need for urea synthesis. However, depending on the severity of the condition, patients will still encounter periods of hyperammonemia, and additional treatments have been developed. Most commonly, oral benzoic acid or

phenylacetate (or phenylbutyrate) are given since these are detoxified in the liver by conjugation with glycine or glutamine respectively. The amino acid conjugates are excreted which effectively removes nitrogen from the body, again lessening the need for urea synthesis. Recently a number of liver transplants have been carried out and gene therapy trials have been initiated. With inborn errors of the ornithine cycle, except arginase deficiency, arginine becomes an essential amino acid. In cases of argininosuccinate synthase and lyase deficiences, very large amounts of dietary arginine are required to replace the arginine equivalents lost as citrulline and argininosuccinate in the urine. Similarly, while liver transplantion or liver-specific gene therapy will correct the defect in urea synthesis, they do not change the defect in the extra-hepatic arginine synthesis pathway and thus, arginine remains an essential amino acid after such treatments.

Oxygenases

Osamu Hayaishi
Osaka Bioscience Institute, Suita, Osaka, Japan

Oxygenases are a group of oxidative enzymes that catalyze the direct addition or fixation of molecular oxygen into various substrates. The terms "mono" and "di" oxygenases are generally assigned to the enzymes catalyzing the incorporation of either one or two atoms of oxygen per mole of substrate, respectively. Prior to the discovery of "oxygenases" in 1955, the essential characteristics of biological oxidation processes was believed to be the removal or transfer of electrons or hydrogen atoms from a substrate to an appropriate acceptor. These enzymes were termed "dehydrogenases" and when oxygen molecules serve as the immediate electron acceptor, the enzymes have been called "oxidases." Functionally, dehydrogenases and oxidases are mainly involved in energy metabolism whereas oxygenases play major roles in the anabolism and catabolism of biological materials as well as synthetic compounds.

Background

In 1932, Professor Heinrich Wieland, a German Nobel laureate, authored a book entitled "On the Mechanism of Oxidation," in which he proposed the famous "dehydrogenation theory." According to this theory, the principle of biological oxidation processes is the activation and transfer of hydrogen atoms, or their equivalent, from the substrate molecule to an appropriate acceptor such as coenzymes and various dyes. Oxygen molecules may, in some instances, serve as the immediate electron acceptor, and if so, then these enzymes are termed "oxidases." Thus, according to Professor Wieland, molecular oxygen accepts hydrogen atoms and is reduced to water or hydrogen peroxide. However, it is never incorporated into the substrate. When the overall reaction is envisaged as the addition of oxygen, the oxygen atoms are always derived from water molecule rather than from atmospheric oxygen. For example, when aldehydes are converted to acids, aldehydes are hydrated first and then dehydrogenation occurs so that the sum is the addition of oxygen to the substrate X to form XO, but this oxygen atom is derived from water rather than from molecular oxygen. Thus, the direct addition of molecular oxygen to a substrate was considered completely irrelevant to biological oxidation.

In 1955, a set of experiments was performed in which pyrocatechase from a pseudomonad was incubated with its substrate catechol and a heavy oxygen isotope, ^{18}O (oxygen-18), the latter being in its molecular form in air in one flask or in the form of water in the other. The product, muconic acid, was isolated and analyzed for its ^{18}O content by mass spectrometry. Contrary to the then generally held belief, the results clearly demonstrated that the oxygen atoms incorporated into the product molecules were derived exclusively from molecular oxygen and not from the oxygen of the water molecule. Concurrently and independently, the phenolase complex of the mushroom was shown to incorporate 1 atom of molecular oxygen into a substrate, 3, 4-dimethylphenol, to form 4, 5-dimethylcatechol; whereas the other atom of oxygen was reduced to water. These findings together with subsequent work by others established that "oxygen fixation" did occur in biological systems, and revealed a new biological role of molecular oxygen, thus, the new concept of "biological oxygenation" was introduced. These enzymes that catalyze the direct incorporation of molecular oxygen were then named "oxygenases." At first, these oxygenase reactions were generally thought to be rather unusual and were limited to only primitive living organisms such as soil bacteria or mushrooms. It took several years before the ubiquitous existence of oxygenases was confirmed in many laboratories; and during that time a large number of oxygenases were isolated from animals, plants, and microoganisms and were shown to play important roles in the metabolism of various nutrients, hormones, and neurotransmitters as well as synthetic compounds.

Nomenclature, Classification, and General Properties of Oxygenases

Dioxygenases

Dioxygenases are defined as enzymes catalyzing reactions in which both atoms of molecular oxygen are incorporated into substrates. In the many instances where one substrate can act as the oxygen acceptor, the term "intramolecular dioxygenase" may be used.

Pyrocatechase (catechol 1, 2-dioxygenase) (EC 1.13. 11.1) is a typical example. The dioxygenases acting upon two acceptor substrates may be referred to as "intermolecular dioxygenases." One of the two substrates for the latter type has so far been invariably 2-oxoglutarate. Hypoxia-inducible factor 1 (H1F1) is a global regulator of cellular and systemic O_2 homeostasis in animals. Prolyl hydroxylase, also known as procollagen-proline: α-ketoglutarate 4-dioxygenase (EC 1. 14. 11. 2), the enzyme that hydroxylates specific prolyl residues of the collagen chains during their translation and requires 2-oxoglutarate as a cosubstrate in addition to ascorbate and Fe^{2+}, serves as an oxygen sensor. More recent evidence indicates that asparaginyl hydroxylase that hydroxylates the asparagine residues by a similar mechanism also serves as a direct oxygen sensor. A third class of dioxygenases include various enzymes that require NADH or NADPH as an electron donor. Although it is quite possible that reactions of this class may involve a simple dioxygenation reaction followed by a reductive step, these two processes may be coupled in such a way as to justify a separate category. The formation of catechol from anthranilate is an example of this type of reaction.

Prostaglandin endoperoxide synthase (EC 1. 14. 99. 1) is a unique intramolecular dioxygenase catalyzing the sequential addition of two oxygen molecules to a substrate molecule arachidonic acid to produce prostaglandin G_2 followed by the peroxidase reaction to generate prostaglandin H_2. This enzyme is also called cyclooxygenase, abbreviated as COX, and is of great clinical significance as will be discussed.

Some dioxygenases, such as tryptophan 2, 3-dioxygenase, contain heme as the sole prosthetic group; whereas others, such as pyrocatechase, contain nonheme iron, or like quercetinase, contain copper as the prosthetic group.

Monooxygenases

Monooxygenases are defined as a group of enzymes that catalyze the incorporation of one atom of molecular oxygen into a substrate, with the other being reduced to water. Therefore, these enzymes are some times referred to as mixed function oxidases or mixed function oxygenases. The electron donors that serve as coenzymes for these enzymes include reduced forms of pyridine nucleotides, flavin nucleotides, cytochromes, ascorbic acid, and pteridine derivatives. In some cases, the substrate itself may serve as an electron donor.

Internal Monooxygenases

The simplest type of monooxygenase catalyzes the incorporation of a single atom of molecular oxygen concomitant with the reduction of the other oxygen atom by electrons derived from the substrate. Since the reducing agent is internally supplied, these enzymes may be referred to as internal monooxygenases. The first of these enzymes to be crystallized was the lactate oxidative decarboxylase from *Mycobacterium phlei*. This enzyme catalyzes the conversion of lactate to acetate with the incorporation of one atom of oxygen into acetate, the evolution of one mole of CO_2, and the reduction of one atom of oxygen to water.

External Monooxygenases

While the internal monooxygenases do not require external reducing agents, more common types of monooxygenases require various kinds of electron donors. The electron donor (DH_2) serves as a basis for the subclassification of external monooxygenases. Some examples are as follows:

1. Flavoprotein monooxygenases with reduced pyridine nucleotides as DH_2. Salicylate 1-monooxygenase, a flavoprotein, is an example of this type of enzyme and catalyzes the formation of catechol from salicylate.
2. Heme-containing monooxygenases. Aryl 4-monooxygenase (liver microsomal cytochrome p-450) catalyzes the hydroxylation of a variety of substrates with reduced flavin as DH_2.
3. Heme-containing monooxygenases with a reduced iron-sulfur protein as DH_2. Camphor 5-monooxygenase is a typical example of this type of enzyme.
4. Pteridine-linked monooxygenases. Phenylalanine-4-monooxygenase catalyzes the formation of tyrosine from phenylalanine. Nitric oxide (NO) is a ubiquitous bioactive substance and a unique messenger molecule. It is synthesized from L-arginine by NO synthase (NOS), (EC 1, 14, 13, 39) a unique monooxygenase that catalyzes two consecutive monooxygenase reactions and that requires NADPH, tetrahydrobiopterine (BH_4), heme and Ca^{2+}/calmodulin and contains FAD and FMN. The product of the reaction is L-citrulline.
5. External monooxygenases with ascorbate as DH_2. Dopamine β-monooxygenase is an example of this type of enzyme.
6. External monooxygenases with another "substrate" as DH_2. Monophenol monooxygenase is an example of this type. In this case, dopa may be considered as the electron donor in the reaction.

Chemistry of Oxygen Fixation Reactions

Molecular Oxygen as a Substrate

Oxygenases utilize two different species of substrate, namely, molecular oxygen and the oxygen acceptor,

which is called the substrate and may be either an organic or an inorganic compound. It has not yet been clarified whether gaseous oxygen or oxygen dissolved in water is utilized by these enzymes. It is generally believed that the latter type of oxygen is different from the former. In water, oxygen is considered to exist largely in a dimerized form, $O_2{-}O_2$ because of its biradical nature, and probably forms a charge transfer complex with a water molecule. Whatever form is taken by the oxygen dissolved in water, the type of oxygen that serves as a substrate for oxygenases is in rapid equilibrium with gaseous oxygen under normal experimental conditions and can be clearly distinguished through the use of $^{18}O_2$ from the oxygen in water molecules or other compounds in the reaction mixture.

Role of the Substrate that Acts as Oxygen Acceptor

As for the acceptor for molecular oxygen, a great variety of both organic and inorganic compounds can be oxygenated. In general, oxygen-rich and/or hydrophilic compounds such as carbohydrates are not favorable substrates for oxygenases since these usually have many reactive groups containing oxygen, such as the hydroxyl, carbonyl, or formyl, and their biochemical function does not require further oxygenation. On the other hand, hydrophobic compounds such as lipids and aromatic compounds are often metabolized by oxygenases. These oxygen-deficient compounds generally require oxygenation in order to become biologically active or more soluble in water. In contrast, purines and pyrimidines with their hydrophilic ring systems are usually hydroxylated by the addition of water, followed by dehydrogenation.

Reaction Mechanisms and the Nature of Active Oxygen

Evidence generated from a number of laboratories has indicated that the enzyme binds oxygen only in the presence of substrate to form the ternary complex, ESO_2, in which oxygen and substrate interact to form a product. Such a ternary complex was postulated in 1964 on the basis of binding experiments, but more direct experimental evidence was not available until 1967 when a ternary complex of tryptophan 2,3-dioxygenase · tryptophan · O_2 was demonstrated by spectrophotometric experiments. Since that time similar oxygenated intermediates have also been observed, such as those with protocatechuate 3,4-dioxygenase (an iron-sulfur protein dioxygenase), lysine monooxygenase (a flavoprotein), and cytochrome P-450. In each case, the enzyme must bind the organic substrate first, before it can be oxygenated, in contrast to oxygen-carrying pigments such as hemoglobin and hemoerythrin, which are freely and reversibly oxygenated in the absence of any effector or substrate. In fact, several lines of evidence indicate that the substrate tryptophan binds specifically to the heme coenzyme of tryptophan 2,3-dioxygenase; as a consequence, the state of the heme is altered in such a way that its reactivity toward ligands is increased by several orders of magnitude.

The nature of the so-called active form of oxygen in the above-mentioned ternary complexes has been one of the most difficult questions in this field. All oxygenase-catalyzed reactions are exothermic and are therefore irreversible. Nevertheless, molecular oxygen is a rather inert compound and at room temperature reacts slowly with the substrate compounds in the absence of enzymes. This low kinetic reactivity is usually explained on the basis that molecular oxygen is in a triplet ground state. The direct reaction of a triplet molecule with organic molecules in the singlet state is electronically spin forbidden, and therefore a substantial activation energy is required. For this reason singlet oxygen has been suggested as a likely intermediate in many oxygenase-catalyzed reactions; however, definitive evidence is so far unavailable. It has recently been discovered that during enzymic hydroxylation of aromatic substrates the substituent (deuterium, tritium, chlorine, bromine, etc.) displaced by the entering hydroxyl group migrates to an adjacent position in the aromatic ring. On the basis of extensive studies of this phenomenon, called the "NIH shift," the active oxygen species involved in certain monooxygenases was postulated to be oxenoid.

On the other hand, evidence has appeared indicating that $O_2^{\cdot-}$, i.e., the superoxide anion, may be the active form of oxygen in the case of indoleamine 2,3-dioxygenase, and also in the hydroxylation reactions catalyzed by hepatic cytochrome P-450. It is, however, uncertain whether or not the superoxide anion is the general form of active oxygen in all oxygenase-catalyzed reactions or whether these enzymes represent a new class of enzyme that utilizes the superoxide anion rather than molecular oxygen as an oxygenating agent.

Biological Function of Oxygenases

While oxidases and dehydrogenase are mainly involved in energy metabolism, namely, the generation of ATP, oxygenases play important roles in biosynthesis, transformation, and degradation of essential metabolites such as amino acids, lipids, sugars, porphyrins, vitamins, and hormones. They also play a crucial role in the metabolic disposal of foreign compounds such as drugs, insecticides, and carcinogens. Furthermore, they participate in the degradation of various natural and synthetic compounds by soil and airborne microorganisms in

nature and are therefore of great significance in environmental sciences. Therefore, the significance of biological oxygen fixation in medicine, agriculture, and microbiology, and also in food technology, cosmobiology, public health problems, and biochemistry in general, has now been well established.

For example, certain oxygenases fulfill exceptionally important biological functions as exemplified by prolyl and asparaginyl hydroxylases as oxygen sensor as well as NO synthase as already mentioned. Several other examples are being briefly described.

Ribilose 1,5-bisphosphate carboxylase/oxygenase (EC 4. 7. 1 39), also known as "rubisco," catalyzes the CO_2 fixation as well as dioxygenase reaction and is the most abundant naturally occurring catalyst in nature. The global fixation of O_2 by rubisco can be estimated to be $\sim 10^{11}$ metric ton (t) per year.

Tryptophan 2,3-dioxygenase (EC 1. 13. 11. 11), also known as tryptophan pyrrolase, catalyzes the pyrrole ring cleavage by the insertion of two atoms of oxygen to produce L-formylkynurenine. This enzyme is present in the liver and is highly specific for L-tryptophan.

On the other hand, indoleamine 2,3-dioxygenase (EC 1. 13. 11. 42), also known as IDO, shows broad substrate specificity including L- and D-tryptophan, L- and D-5-hydroxytryptophan, serotonin, and so forth and is widely distributed in almost all organs and tissues except in the liver. IDO is induced by interferon and has been implicated in the defence mechanism against infection by depleting tryptophan from the infected tissues and cells. More recently, allogenic fetal rejection was reportedly prevented by tryptophan catabolism by IDO.

The prostaglandin endoperoxide synthases I and II (COX-1 and COX-2) are the major targets of nonsteroidal anti-inflammatory drugs (NSAIDs) including aspirin, indomethacin, ibuprofen, and the new COX-2 inhibitors. These drugs reduce inflammation, pain, and fever and also fatal thrombotic events, colon cancer, and Alzheimer disease.

Another common dioxygenase involved in lipid metabolism and widely distributed in both animals and plants is lipoxygenase (EC 1. 13. 11. 12), which is also known as LOX, lipoxidase, lipoperoxidase, or carotene oxidase. It is a nonheme iron-containing dioxygenase and catalyzes the formation of hydroperoxy derivative of unsaturated fatty acids. Of particular interest is the 5-LOX that catalyzes the dioxygenation of arachidonic acid to produce corresponding cis, trans-diene hydroperoxide followed by the dehydration to generate leukotrien (LT) A_4, another biologically important lipid mediator.

Unspecific monooxygenase is a heme-thiolate enzyme commonly known as cytochrome P450, hepatic microsomal monooxygenase, xenobiotic monooxygenase or aryl-4-monooxygenase (EC 1. 14. 14. 1), and catalyzes hydroxylation of a wide variety of both aromatic and aliphatic compounds. Monooxygenases also catalyze a seemingly diverse group of reactions including epoxide formation, dealkylation, decarboxylation, deamination, and N- or S-oxide formation. Although the overall reactions catalyzed by various monooxygenases appear grossly unlike one another, the primary chemical event is identical, since these processes are all initiated by the incorporation of one atom of molecular oxygen into the substrate.

Oxygenases in Evolution

Primitive Earth is believed to have started with an oxygen-free anaerobic environment. Therefore, the minimum manifestation of life is capable of occurring in the absence of molecular oxygen, as exemplified by the strictly anaerobic microorganisms, which survive and grow solely in the absence of molecular oxygen. With the appearance of oxygen in the Earth's atmosphere, molecular oxygen became a more useful and efficient tool as the terminal electron acceptor. Oxygenases then appeared gradually with the subsequent development of extensive and complicated metabolic pathways for essential components of cell structures and of regulatory mechanisms of metabolism and growth. The appearance of aerobic form of life paved the way for oxygenase-catalyzed reactions by which complicated messengers and structural compounds such as sterols, prostaglandins, and neurotransmitters are efficiently synthesized, while cytochrome P450 plays an essential role in the metabolism of thousands of drugs, carcinogens, and other synthetic compounds and is probably the largest family of proteins that has been cloned and characterized to date. In an evolutionary sense, oxidases preceded oxygenases but the latter appears to be a more advanced oxygen-utilizing catalyst associated with the most advanced and highly specialized life processes.

Glossary

dehydrogenase The enzyme that catalyzes electron transfer from a substrate to an acceptor.

E.C. numbers and trivial names Enzymes are classified and numbered by the international Enzyme Commission. In this list, the names of the enzymes are formal names whereas trivial names are more common names or informal names. For example, catechol 1, 2-dioxygenase is a formal name while pyrocatechase is a trivial name.

oxidase The dehydrogenase that utilizes molecular oxygen as an immediate electron acceptor.

oxygenase The enzyme that incorporates molecular oxygen into substrates.

Biography

Osamu Hayaishi is a Professor Emeritus of Kyoto University and Osaka Medical College and a Director Emeritus of Osaka Bioscience Institute. His principal research interests are oxygenases and molecular mechanisms of sleep and wakefulness. He is a member of the Japan Academy, the National Academy of Sciences USA, and several other academies and served as President of the International Union of Biochemistry from 1973 to 1976.

P2X Purinergic Receptors

Annmarie Surprenant
University of Sheffield, Sheffield, UK

Inside the cell, adenosine triphosphate (ATP) is the major source of energy for all cellular processes. Outside the cell, ATP has quite distinct actions as a neurotransmitter at nerve–smooth muscle and nerve–nerve synapses, as a chemical stimulant at primary afferent terminals, and as a pro-inflammatory stimulus at immune and endothelial cells. Extracellular ATP acts on two types of membrane receptors: G protein-coupled "metabotropic" P2Y purinergic receptors and "ionotropic" P2X purinergic receptors. They are termed purinergic because ATP is a purine nucleotide. Ionotropic P2X receptors are ion channels opened within ms by extracellular ATP. There are seven members of the P2X receptor family ($P2X_1$–$P2X_7$) which are not related to any other known protein. They show widespread tissue distribution; functional responses to activation of these receptors occur in neurons, glia, endothelia, epithelia, bone, smooth muscle, cardiac muscle, red blood cells, and cells of the immune system.

P2X Receptor Genes

There are seven genes encoding P2X receptor subunits (Figure 1A). In the human genome, $P2X_4$ and $P2X_7$ are adjacent to each other on chromosome 12, an occurrence that probably represents gene duplication. $P2X_1$ and $P2X_5$ receptor genes are also very closely associated on chromosome 13. The remaining genes are located on separate chromosomes. The genes have 11–13 exons and all share a common structure with conserved intron/exon boundaries. Many spliced forms of these receptors have been observed, most due to splicing out of one or more exons. Several non-mammalian homologues of P2X receptors have been identified but no homologous sequences from invertebrates have yet been identified.

P2X Receptor Proteins

P2X receptor proteins range from 384 amino acid residues ($P2X_4$) to 595 amino acids ($P2X_7$). Each subunit comprises a large extracellular domain, two transmembrane domains, and relatively short intracellular amino and carboxy terminal regions (Figure 1B). There are ten cysteines in the extracellular region of the P2X receptor subunit which are conserved through all members of the family. Amino acid residues in the second transmembrane region are involved in ion flux through the channel. The carboxy terminal regions show very little homology among individual P2X receptors, but the remaining amino acids show 40–55% identity with each other among the seven receptors (Figure 1A). There is no amino acid sequence homology between P2X receptors and any known ATP-binding protein, any other ion channel, or any known protein: this places the P2X receptors into their own unique gene/protein family. The receptors assemble in multimeric combinations of subunits, either as homomeric channels (all one subtype) or as heteromeric channels (two or more subtypes). $P2X_1$, $P2X_2$, $P2X_3$, $P2X_4$, and $P2X_7$ exist as homomeric channels but $P2X_2$ and $P2X_3$ also exist as a functionally important heteromeric channel ($P2X_{2/3}$). The current evidence suggests these channels are composed of three, or possibly six, subunits.

P2X Receptor Localization

While other ionotropic ion channels are found mainly on excitable cells (i.e., nerve and muscle), P2X receptor channels are unusual in showing a very widespread distribution in both excitable and nonexcitable cells. There is considerable overlap with multiple receptor subunits found in a single cell, particularly in neurons. However, it is possible and biologically useful to generalize the distribution of these receptors (Table I).

Physiology of P2X Receptors

Release of ATP onto P2X Receptors

Cells release ATP in various ways: ATP is coreleased with noradrenaline from sympathetic nerve endings, or with aceytlcholine from parasympathetic or brain cholinergic neurons. It is rapidly released from vascular endothelial cells during hypoxia which is likely to be present under conditions such as angina or myocardial infarction. ATP is released from red blood cells upon

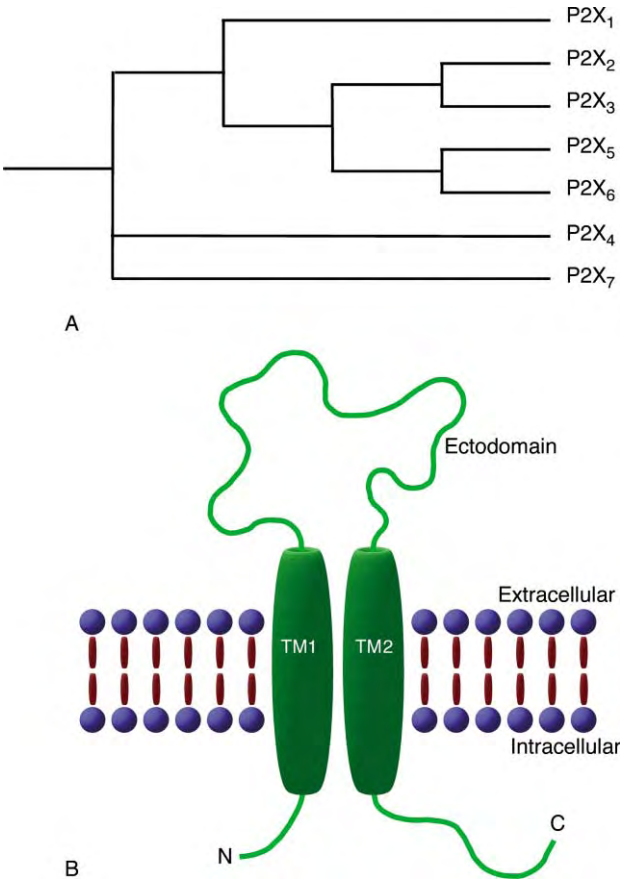

FIGURE 1 Molecular features of purinergic P2X receptor family. In (A) a dendrogram depicts the similarity in amino acid residues among the seven members of the P2X receptor family. $P2X_4$ and $P2X_7$ are the least similar while the pairs of $P2X_2/P2X_3$ and $P2X_5/P2X_6$ are most similar to each other. In (B) a cartoon representation of the likely membrane topology of a P2X receptor subunit shows the receptor protein crossing the lipid bilayer of the cell membrane at two regions (transmembrane TM1 and TM2). The large ectodomain contains the ATP-binding site and the TM2 region forms at least part of the ion channel structure. N and C refer to the intracellular amino (N) and carboxy (C) terminal amino acids.

mechanical distortion. Mechanical deformation of epithelial cells lining the bladder, lung, intestines, and ureter also causes rapid release of ATP. The mechanism by which ATP is released during mechanical displacement of these structures is unclear, but it may be transported from inside to outside by specific ATP transporter proteins or it may be released from storage vesicles by the process of exocytosis. Finally, high concentrations of ATP are released from damaged or dying cells at sites of inflammation and infection.

Activation of P2X Receptor Ion Channels ($P2X_1$ through $P2X_6$)

Although the molecular architecture of P2X receptors (see above) sets this family apart from all other ion channels, their functional properties are generally similar to the other two classes of "fast excitatory neurotransmitter receptors"—the nicotinic and the glutamate receptors. When extracellular ATP binds to specific amino acid residues in the ectodomain of the P2X receptor, a change in the conformation of the protein occurs within milliseconds and this structural alteration allows the influx of sodium ions from the outside concomitant with efflux of potassium ions from the inside. However, chloride or other anions are excluded; thus, the term cation-selective ion channel. This cation flux leads to plasma membrane depolarization and consequent excitation of nerve and muscle, or initiation of other signaling processes in nonexcitable cells. There is also appreciable influx of calcium ions with each P2X receptor allowing different levels of calcium to enter the cell; calcium entry through the $P2X_7$ receptor is several-fold higher than occurs at any other ionotropic (P2X, nicotinic or glutamate) receptor. When a continuous supply of ATP is presented to a cell expressing $P2X_1$ or $P2X_3$ receptors, the cation flux

TABLE I

Overview of Tissue Localization and Functional Role of Individual P2X Purinergic Receptors

Purinergic receptors	Tissue localization	Physiological role	Potential disease involvement
$P2X_1$	Vascular, visceral smooth muscle	Arteriolar vaso-constriction and genito urinary contractility	Male fertility
$P2X_2$	Autonomic neurons	Sympathetic drive	None implicated
$P2X_3$	Afferent neurons	Sensory perception	Neuropathic and visceral pain; bladder dysfunction
$P2X_4$	Epithelia and brain neurons	None identified	
$P2X_5$	Embryonic muscle spinal motor neurons	None identified	
$P2X_6$	Similar to $P2X_4$	None identified	
$P2X_7$	Immune cells	Release of IL-1β	Arthritis, irritable bowel syndrome

(or ionic current) fades away very rapidly (within a few hundred milliseconds) by a process termed desensitization. Desensitization does not occur, or is much slower at the other P2X receptors.

Activation of $P2X_7$ Ion Channels

The $P2X_7$ receptor is a most unusual ion channel in that it not only opens to allow bidirectional flux of cations in a manner similar to that described above for typical ionotropic receptors. However, it also dilates over several seconds to minutes to a size that allows the passage of molecules of either charge with size up to 900 Da. It is not known whether this is due to a true dilatation of the ion-passing pore region within the $P2X_7$ receptor protein itself, or whether the $P2X_7$ receptor couples to another protein which then transports the larger molecules. A further signaling event that is uniquely associated with $P2X_7$ receptor activation includes dramatic, rapid alterations in the cell cytoskeleton due to re-arrangement of the actin filaments within the cell. This causes dynamic membrane blebbing of the cell, visually appearing as though bubbles are continuously forming and retracting. The physiological significance of these membrane blebs are unknown but they have been associated with "programmed" cell death, or apoptosis. The intracellular carboxy-terminal amino acids of the $P2X_7$ receptor are required for the large pore formation and the membrane blebbing but not for its cation-selective ion channel function.

P2X Receptors and Sympathetic Neurotransmission ($P2X_1$ and $P2X_2$ Receptors)

$P2X_1$ receptors are highly expressed on vascular smooth muscle in the gastrointestinal (GI) tract and on visceral smooth muscle of the urogenital system, particularly the bladder, vas deferens, and ureter (Table I). $P2X_2$ receptors are equally highly expressed in the neurons that innervate these tissues, the sympathetic autonomic nerves. The functional role for $P2X_2$ receptors in autonomic neurotransmission is not understood, but $P2X_1$ receptors are now known to be

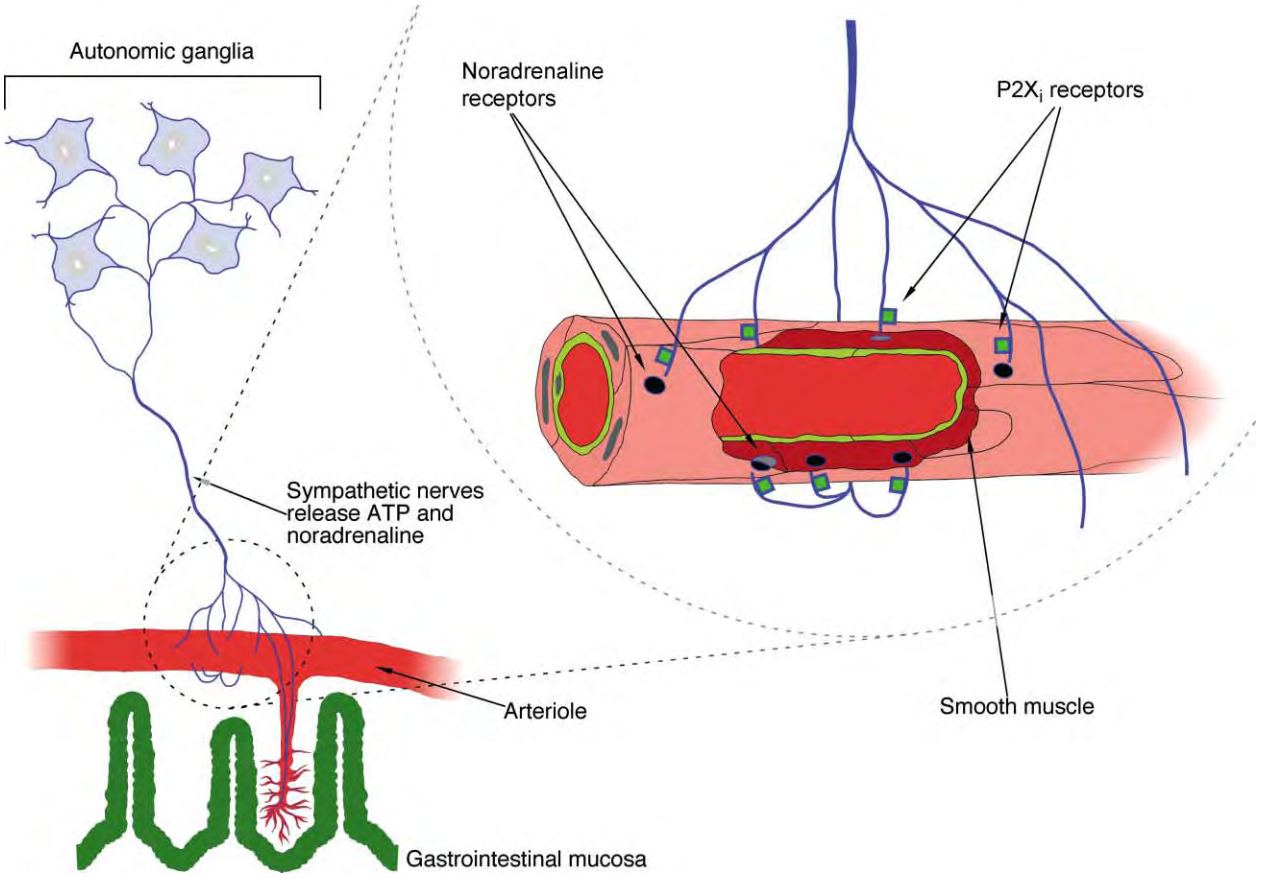

FIGURE 2 Sympathetic innervation to GI blood supply requires P2X receptors. Diagram illustrates the sympathetic nerves supplying the GI vasculature; the sympathetic nerves corelease noradrenaline and ATP. ATP activates postsynaptic $P2X_1$ receptors on the arteriolar smooth muscle to cause vasoconstriction. Noradrenaline released from these nerves acts only on presynaptic noradrenaline receptors which are present on the sympathetic nerve endings; the presynaptic action of noradrenaline alters the subsequent release of ATP.

the primarily, and in some cases, solely responsible for vasoconstriction or visceral smooth muscle contractions caused by sympathetic nerve activity. For example, male mice in which the $P2X_1$ receptor gene has been deleted are infertile, because the sympathetic nerve activity no longer causes smooth muscle of the vas deferens to contract. Thus, no sperm is released from the vas although all other aspects of ejaculation are unaltered. Similarly, in the GI vasculature, the vasoconstriction produced by sympathetic nerve activity is due to the release of ATP onto $P2X_1$ receptors on the vascular smooth muscle. In both of these cases, noradrenaline, which is the cotransmitter along with ATP, continues to be released and act effectively on its receptors. However, the noradrenaline released from these nerves acts on presynaptic noradrenaline receptors to alter the release of both noradrenaline and ATP, but it does not act on postsynaptic noradrenaline receptors present on the smooth muscle (Figure 2).

P2X Receptors and Sensory Pathways ($P2X_3$ and $P2X_{2/3}$)

Pain Pathways

ATP applied to sensory nerve terminals in the skin or tongue has long been known to elicit pain, specifically a tingling or burning sensation in humans. The molecular cloning and subsequent receptor localization studies revealed that the $P2X_3$ receptor subunit is preferentially localized to a specific subset of sensory afferent fibers which innervate skin and viscera. Most of these sensory fibers are nociceptors, i.e., they are activated by noxious stimuli. Both homomeric $P2X_3$ receptors and heteromeric $P2X_{2/3}$ receptors are found at presynaptic and postsynaptic sites in this pathway (Figure 3). When ATP is released as a result of tissue injury, gross visceral distention, or even excess sympathetic activation, it activates the $P2X_3$ and $P2X_{2/3}$ receptors on the nociceptor terminals and initiates excitatory flow to the dorsal horn neurons in the spinal cord. Here, P2X receptors play modulatory roles in further processing of painful stimuli. Presynaptic $P2X_2$ receptors are present on excitatory (glutamate) and inhibitory (glycine or γ-aminobutyrate, GABA) interneurons and can be activated by ATP released from the incoming primary afferents and also when it is coreleased with GABA from GABA interneurons. Activation of these presynaptic P2X receptors increases the further release of transmitters onto the doral horn neurons. There are also postsynaptic P2X receptors on the dorsal horn neurons which can be activated by the release of ATP from the GABA interneurons. These inhibitory and excitatory effects contribute to the "spinal" processing of pain information prior to transmission to central perception areas of the brain (Figure 3).

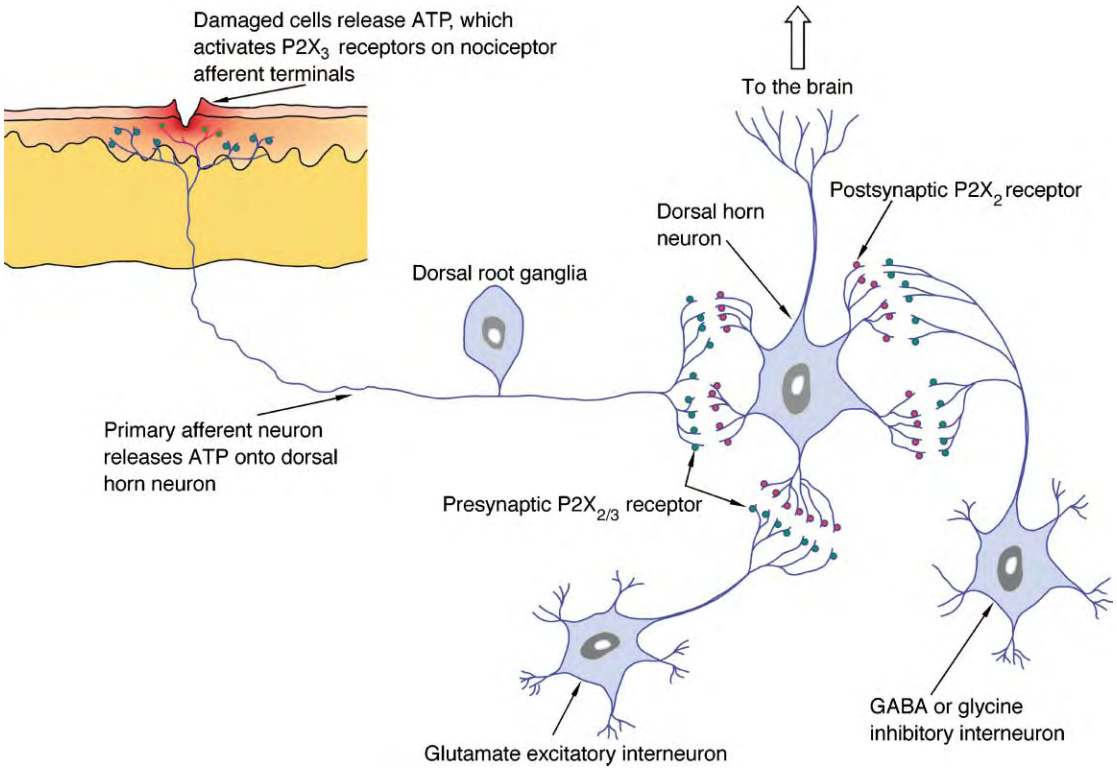

FIGURE 3 P2X receptors and pain pathways $P2X_2$, $P2X_3$, and $P2X_{2/3}$ receptors play a role in pain perception. See text for further description.

Afferent Reflex Pathways

P2X receptors are involved in the proper functioning of several visceral afferent reflexes; the micturation reflex is the best studied. The micturition reflex is initiated by bladder distention and subsequent contraction of the bladder and ureter smooth muscle. This distension releases ATP from the uroepithelium where it activates $P2X_3$ and/or $P2X_{2/3}$ receptors on the urothelial afferent nerve terminals to evoke neural discharge into spinal cord regions which, in turn, activate efferent parasympathetic nerves to bladder and ureter smooth muscle to complete the reflex loop.

P2X Receptors and Immune Cell Function ($P2X_7$)

$P2X_7$ receptors are most abundantly found on immune cells which become activated by tissue damage, inflammation, or infection, i.e., the so-called antigen-presenting cells of the immune system, primarily monocytes, and macrophage. Their synthesis and expression is increased in these cells when the immune response is triggered. Activation of $P2X_7$ receptors by ATP released from damaged cells at sites of inflammation or infection leads to the release of pro-inflammatory mediators (cytokines); the most important of these pro-inflammatory cytokines is interleukin-1β (IL-1β). IL-1β can produce fever, further inflammation, cell, and tissue death. Agents that may block its release are highly sought after with regard to treatment or prevention of diseases such as rheumatoid arthritis and inflammatory bowel disease, and intensive research efforts are currently underway to identify antagonists which selectively target $P2X_7$ receptors.

Glossary

cytokine A protein (usually interleukins or interferons) secreted by lymphoid cells that affects the activity of other cells and is important in controlling inflammatory responses.

dendrogram A diagram showing the relationships of items arranged like the branches of a tree.

exocytosis The release of a substance contained in a small sac (vesicle) within a cell by a process in which the membrane surrounding the vesicle fuses with the membrane forming the outer wall of the cell.

exon A discontinuous sequence of DNA that codes for protein synthesis and carries the genetic code for the final messenger RNA.

intron A length of DNA that is not expressed as an amino acid or messenger RNA.

ionotropic receptors Membrane receptors which are integral ion channels not requiring coupling via intracellular G proteins.

metabotropic receptors Membrane receptors which couple to heterotrimeric G proteins in order to produce an effect.

nociceptor A sensory nerve which subserves the perception of pain.

Biography

Annmarie Surprenant is currently a Professor of Cellular Physiology at the University of Sheffield, United Kingdom. She has a long-standing history of research in the area of ion channel physiology. Her lab was the first to demonstrate that extracellular ATP is a synaptic transmitter in the nervous system and that ATP, not noradrenaline, was the neurotransmitter responsible for sympathetically mediated vasoconstriction in arterioles. These sets of findings led to her work over the past decade: the cloning and functional characterization of the ATP-gated P2X receptor-ion channels.

P2Y Purinergic Receptors

George R. Dubyak
Case Western Reserve University, Cleveland, Ohio, USA

P2Y receptors are intrinsic plasma membrane proteins that mediate functional responses of intact cells to extracellular nucleotides, including ATP, ADP, UTP, UDP, and UDP-glucose. P2Y receptors belong to the superfamily of G protein-coupled receptors (GPCR), an exceptionally large group of structurally and functionally related gene products that play critical roles in the transduction of signals between and among different types of cells. In response to the binding of extracellular nucleotides, P2Y receptors undergo conformational changes that facilitate their direct interaction with, and activation of, G proteins. In turn, the activated G proteins couple P2Y receptors to the regulation of enzymes and ion channels that facilitate generation of "second messengers" and intracellular signaling cascades used for the acute or chronic regulation of specific cellular functions. Appreciation of the physiological or pathological functions of P2Y receptors requires some understanding of the general mechanisms by which nucleotides are used as extracellular signaling molecules.

Extracellular Nucleotides as Signaling Molecules

In addition to their critical roles in intracellular energy metabolism and nucleic acid synthesis, nucleotides, such as ATP, and nucleosides, such as adenosine, play important roles as extracellular signaling molecules. Burnstock and his colleagues generated many of the initial hypotheses regarding the roles of purines in nonadrenergic, noncholinergic neurotransmission. They proposed that extracellular nucleotides and nucleosides are utilized for signal transduction at nerve endings in diverse tissues. Implicit in this concept of "purinergic" transmission or signaling was a requirement that ATP (or other nucleotides) be released and metabolized in a highly localized manner at sites of cell-to-cell communication. Given the emphasis on the role of purines in this neuronal signaling, initial characterization focussed on describing the release of nucleotide/nucleosides at neuron-to-neuron synapses, neuron-to-tissue varicosities, or the immediate locale of neuroendocrine cells. Such studies verified that neurons and neuroendocrine cells can release ATP via standard mechanisms involving exocytosis of nucleotides copackaged with biogenic amines or other neurotransmitters in specialized vesicles or granules.

However, subsequent research has resulted in the cloning and characterization of at least 15 distinct ATP/nucleotide receptor genes (including the P2Y receptors), four adenosine receptor genes, and a dozen different ectonucleotidase genes. Analysis of the expression of these genes revealed that most vertebrate cell types express one or more subtypes of nucleotide or nucleoside receptor along with one or more of the ectoenzymes used for metabolizing extracellular nucleotides. Because most cells lack direct proximity to nerve synapses or neuroendocrine cells, the identification of additional sources of extracellular nucleotides is a current area of investigation and speculation. Recent studies indicate that stressed or damaged cells in many tissues can locally release nucleotides via a variety of pathways ranging from irreversible cytolysis to nonlytic export through nucleotide-permeable channels. In turn, the released nucleotides activate autocrine or paracrine signaling cascades that permit those tissues to adapt to the particular stress or injury that precipitated release of the cellular nucleotides.

Regardless of the mechanisms by which ATP or other nucleotides are released from cells, their half-life within extracellular compartments is generally brief due to rapid catabolism by ectonucleotidases. Some of these ectoenzymes serially convert released nucleoside triphosphates (e.g., ATP) to their diphosphate (e.g., ADP) and monophosphate (AMP) forms. Other ectonucleotidases dephosphorylate the nucleoside monophosphates (e.g., AMP) to their corresponding nucleosides (e.g., adenosine). These nucleosides can be reaccumulated and reconverted to intracellular nucleotides via highly conserved nucleotide salvage pathways. In the case of adenosine, nucleosides can additionally function as agonists for G protein-coupled nucleoside receptors that are distinct from the P2Y nucleotide receptors. Thus, the local release of ATP may initially activate ATP-selective P2Y receptor subtypes. Although this hydrolysis of ATP to ADP by ecto-ATPases would act to terminate signaling by these particular P2Y subtypes,

this same extracellular metabolic reaction would result in activation of ADP-selective P2Y receptor subtypes. Further metabolism to adenosine might result to activation of G protein-adenosine receptors in same or adjacent cells. In these ways, ATP release in intact tissues can trigger the serial activation of multiple P2Y and adenosine receptor subtypes to generate complex patterns of positive or negative feedback among the various cell types that comprise the tissue. As a further complication, many cells export nucleoside diphosphokinases that catalyze transphosphorylation reactions between the various extracellular nucleoside tri- and diphosphates. Thus, released ATP may additionally drive the phosphorylation of ambient UDP to locally generate UTP that is a selective agonist for yet other P2Y receptor subtypes.

General Structure of the P2Y Receptors

As members of the GPCR superfamily, all P2Y receptors are intrinsic membrane proteins that consist of a single polypeptide chain with certain invariant structural domains. These include: (1) an extracellular amino terminal tail; (2) seven transmembrane-spanning segments (usually α-helices); (3) three short extracellular loops and three variably sized intracellular loops that connect transmembrane segments; and (4) an intracellular carboxyl terminal tail. The exact protein domains of P2Y receptors that facilitate selective recognition and binding of the extracellular nucleotide agonists have not been identified as yet. Significantly, no single P2Y domain contains amino acid sequences similar to the well-defined nucleotide-binding sites of the many intracellular proteins that interact with ATP (e.g., ATPases, protein kinases, nucleic acid polymerases).

Functional Classification of the P2Y Receptors

Genes encoding P2Y receptors have been identified in the genomes of all vertebrate species examined thus far. In contrast, no obvious P2Y receptor orthologues are apparent in the completely sequenced genomes of the insect, *Drosophila melanogaster*, or the nematode worm, *Caenorhabditis elegens*. At present, genes encoding eight distinct P2Y receptor subtypes have been characterized in a broad range of tissues and cell types from vertebrate organisms. These subtypes can be classified based either on their selective pharmacological recognition of different nucleotides or on their selective functional coupling to particular classes of heterotrimeric G proteins. Table I summarizes both the pharmacological and functional properties of the eight P2Y receptor subtypes.

Based on their functional coupling to G proteins, effector proteins, and second messenger cascades, P2Y receptors can be broadly subdivided into three major groups. The P2Y1, P2Y2, P2Y4, and P2Y6 receptor subtypes predominantly couple to G_q-family G proteins with consequent activation of phosphatidylinositol-specific phospholipase C effector (PI-PLC) enzymes resulting in accumulation of inositol trisphosphate, diacylglycerol, Ca^{2+} as second messengers. The P2Y12, P213, and P2Y14 subtypes activate G_i-family G proteins. As a result, stimulation of these latter receptors most often leads to inhibition of adenylyl cyclase effector enzymes and reduced intracellular levels of cyclic AMP. However, depending on cellular

TABLE I

Receptor subtype	G protein–effector cascade	Selectivity for physiological nucleotide agonists	Tissue/cellular expression
P2Y1	Gq → PI-PLC	ADP > ATP ≫ UDP, UTP	Platelets, Blood Vessels, Brain
P2Y2	Gq → PI-PLC	ATP = UTP ≫ ADP, UDP	Airways, Exocrine Glands, White Blood Cells, Blood Vessels, Brain
P2Y4	Gq → PI-PLC	UTP ≫ ATP, UDP, ADP (human) UTP = ATP ≫ UDP, ADP (rat, mouse)	Small Intestine, Inner Ear
P2Y6	Gq → PI-PLC	UDP > UTP > ADP ≫ ATP	Gallbladder, Airway
P2Y11	Gq → PI-PLC *and* Gs → AC	ADP > ATP ≫ UDP, UTP	Exocrine Glands, Kidney, White Blood Cells
P2Y12	Gi → AC/others	ADP > ATP ≫ UDP, UTP	Platelets, Brain Astrocytes
P2Y13	Gi → AC/others	ADP > ATP ≫ UDP, UTP	Brain Astrocytes
P2Y14	Gi → AC/others	UDP-glucose ≫ UTP, ATP, UDP, ADP	White Blood Cell Precursors, Stem Cells

background, these Gi-coupled P2Y receptor subtypes may also stimulate the activity of G protein-regulated K^+ channels and/or inhibit activity of N-type voltage-gated Ca^{2+} channels. Finally, the P2Y11 receptor represents a subtype that can couple to both G_q- and G_s-dependent signaling pathways; the activation of G_s allows P2Y11 receptors stimulate adenylyl cyclase effector enzymes and thereby induce accumulation of cyclic AMP. Thus, activation of the different P2Y receptor subtypes can variously trigger rapid changes in Ca^{2+}, cyclic AMP, lipid second messengers, and plasma membrane potential. In turn, these acute signals can be integrated within cell-specific transduction networks to regulate particular protein kinases, protein phosphatases, proteases, and transcription factors.

Pharmacological Classification of P2Y Receptors

P2Y receptors can also be categorized by their pharmacological selectivity for particular nucleotide agonists. The P2Y1, P2Y12, and P2Y13 receptors exhibit very high selectivity for ADP over ATP and are virtually insensitive to non-adenine nucleotides. The P2Y2, P2Y4, and P2Y6 subtypes can be effectively activated by uridine nucleotides albeit with subtype-selective preferences. P2Y2 receptors show high affinity for UTP and ATP, but not the corresponding diphosphates. P2Y4 receptors are most potently stimulated by UTP over ATP (but this is species-dependent), while P2Y6 receptors exhibit a preference for UDP. In general, P2Y11 receptors are activated by ADP or ATP, and less effectively by non-adenine nucleotides. The P2Y14 subtype, the most recently identified member of the P2Y family, exhibits a very high selectivity for sugar-conjugates of UDP, such as UDP-glucose. Given the complex and overlapping affinities of the P2Y subtypes for naturally occurring nucleotides, considerable effort is being directed toward generation of synthetic nucleotide agonists and non-nucleotide antagonists that selectively target particular P2Y subtypes. Such subtype-selective reagents may have high potential utility as therapeutic agents in diseases that involve hyperfunctional or hypofunctional P2Y receptors.

Important Physiological or Pathological Functions of P2Y Receptor Subtypes

Understanding of the most important physiological roles for P2Y receptors has been limited by: (1) the relatively recent identification of most P2Y receptor subtypes (post 1995); (2) the current paucity of subtype-selective drugs; and (3) the rather broad expression of P2Y receptors in most tissue types. However, gene-targeting approaches have been recently used to generate "knock-out" mice that lack the expression of P2Y1, P2Y2, P2Y4, or P2Y12 receptors. These mice (or tissues from the mice) exhibit significant deficits in several critical biological responses.

Mice lacking either the P2Y1 or P2Y12 receptor are characterized by abnormalities in the blood-clotting response (also known as hemostasis) that result in prolonged bleeding times. This reflects the synergistic roles of the P2Y1 and P2Y12 receptors in mediating the aggregation of platelets (the key blood cell type in the clotting reaction) in response to ATP/ADP released from damaged blood vessels. Because platelets also release large amounts of ATP/ADP during aggregation induced by other hemostatic factors (such as thrombin), P2Y1 and P2Y12 play additional roles in amplifying and extending the overall blood-clotting response. However, inappropriate platelet aggregation (thrombosis) can lead to interruption of normal blood flow (ischemia) to critical organs, such as the brain or heart, and thereby contribute to acutely life-threatening conditions including stroke and heart attack. For this reason, drugs that specifically block or antagonize P2Y1 and/or P2Y12 receptors are currently being tested for the treatment of thrombotic diseases in humans.

Analyses of other knockout mice strains have revealed important roles for the P2Y2 receptors that are highly expressed in airway cells and the P2Y4 receptors expressed in the jejunal section of the small intestine. Multiple P2Y receptor subtypes are expressed in the epithelial cells from organs such as the airways, lungs, kidneys, and intestines. The major function of epithelial cells and tissues is to act as both a barrier and selectively permeable interface between very different biological compartments. For example, airway epithelial cells comprise an interface between the inspired air compartment (which contains microbes, small particles, and volatile compounds from the outside environment) and the blood compartment. In addition to physically blocking the entry of these airborne particles, microbes, and compounds into the blood, airway epithelial cells secrete water, salt, mucus, and other protective proteins onto their extracellular surface that directly faces the inspired air compartment. While the secreted mucus solution acts to trap the microbes and particles, ciliated protrusions that extend from the epithelial cells beat in a synchronized manner to push the mucus solution – plus the entrapped microbes and particles – back to the nose and upper throat for eventual removal by sneezing or coughing. Activation, by ATP or UTP, of the P2Y2 receptors in different airway epithelial cells can coordinately regulate: (1) the secretion of the water, different salts, and mucus in sufficient amounts to generate

mucus solutions with appropriate viscosity, fluidity, and composition; and (2) the frequency and direction of the ciliary beating required for the appropriate retrograde flow of the mucus back to the upper airways. In airways from the P2Y2 receptor knockout mice, these important epithelial functions are not appropriately regulated. Analysis of small intestine function in P2Y4 receptor–receptor mice has indicated a similar role for this P2Y subtype in the regulation of salt and fluid secretion by intestinal epithelial cells.

Future studies of additional organ- and tissue-specific functions in mice lacking these and other P2Y receptor subtypes will undoubtedly reveal other important *in vivo* roles for these receptors. Insights from these animal studies, coupled with the development of subtype-selective antagonists, should facilitate delineation of how these receptors function in human physiology and pathology.

Glossary

agonist A molecule that binds to a receptor resulting in functional activation of the receptor.

antagonist A molecule that binds to a receptor and keeps the receptor in a functionally inactive state.

effector protein An intracellular protein, such as an enzyme or ion channel, whose activity is regulated by interaction with G proteins. Effector proteins regulate the production of second messenger signals.

G protein An intracellular protein that becomes active when it binds GTP and becomes inactive when it hydrolyzes the bound GTP to GDP. G proteins act as signal transduction proteins that couple cell surface receptors to the regulation of intracellular effector proteins.

G protein-coupled receptor (GPCR) A cell surface receptor protein for an extracellular signaling molecule; GPCR reversibly interact with G proteins to activate intracellular signal transduction pathways. There are thousands of different GPCR that selectively bind a wide variety of extracellular signaling molecules including many hormones and neurotransmitters.

P2Y receptors A family of related G-protein coupled receptors that become active when bound to extracellular nucleotides such as ATP, ADP, or UTP.

second messenger A small intracellular molecule that is transiently formed in response to the activation of an effector protein by a cell surface receptors, such as a GPCR. Formation of the second messenger acts to relay the signal from the cell surface receptor to the interior of the cell.

Biography

George R. Dubyak is a Professor in the Department of Physiology and Biophysics at the Case School of Medicine of Case Western Reserve University, Cleveland. His broad research interest is in the field of signal transduction biology with particular focus on the roles of extracellular nucleotides in signal transduction during inflammation and regulation of cardiovascular function. He holds a Ph.D. in physiology from the University of Pennsylvania and received post-doctoral training in biophysics at that university.

p53 Protein

Jamie Hearnes and Jennifer Pietenpol
Vanderbilt University, Nashville, Tennessee, USA

p53 is a tumor suppressor gene that is mutated in over half of all human cancers. The tumor suppressive functions of p53 are dependent, in part, upon its activity as a transcription factor. This protein binds DNA in a sequence-specific manner to regulate the expression of select genes involved in a range of cellular processes including growth arrest, apoptosis, DNA repair, senescence (irreversible growth arrest), and angiogenesis (new blood vessel formation). The p53 protein is activated in response to various cellular stresses, and functions to suppress the transformation of a normal cell to a cancer cell. The p53 protein will continue to be a focus of cancer-based research as it plays a pivotal role in suppressing tumorigenesis.

p53 Functional Domains

The p53 protein was originally identified in 1979, and its name is derived from the apparent molecular weight of the protein (p53 = protein of 53 kDa). This protein consists of 393 amino acids and is divided into three functional domains (Figure 1).

Transcriptional Activation Domain

The transactivation domain is located at the amino terminus of the protein sequence (amino acids 1–73). Numerous proteins can bind to this region of the protein to regulate the function of p53. This region of the protein is constitutively and inducibly phosphorylated, which affects the protein's stability and activity.

DNA-Binding Domain

The central region of the p53 protein is the DNA-binding domain (amino acids 100–293). A majority of tumor-derived p53 mutations occur in the DNA-binding domain. The residues most commonly mutated in the DNA-binding domain either directly contact the DNA or are required for the structural integrity of the protein. Since p53 primarily functions as a transcription factor, these mutations result in a loss of function of the protein.

Oligomerization Domain

The carboxy terminus of the p53 protein (amino acids 293–393) contains an oligomerization domain, which is required for the formation of transcriptionally active dimers and tetramers. The oligomerization domain also contains nuclear localization and export sequences that are required for transport into and out of the nucleus, respectively. The carboxy terminus is also post-translationally modified in a regulatory manner.

p53-Mediated Signaling

p53 functions as a sequence-specific transcription factor regulating select genes (target genes) that are involved in numerous signaling pathways, including cell cycle progression, apoptosis, senescence (irreversible growth arrest), DNA repair, and angiogenesis (new blood vessel formation) (Figure 2). These are the same pathways that become deregulated during cancer progression. The p53 consensus DNA-binding site consists of 2 copies of the DNA sequence RRRCWWGYYY which are separated by a 0–13 base spacer region (R = A/G, W = A/T, Y = T/C). This binding site is present in a majority of p53 target gene regulatory regions. The degeneracy of the consensus DNA-binding site at 8 of the 10 bases is thought to contribute to the selectivity of p53 towards certain genes in response to various stresses. p53 can serve as a transcriptional activator or repressor, depending on the specific gene being regulated.

Growth Arrest and Apoptosis

Human cells are continuously exposed to external agents as well as internal agents that can induce cell damage. Eukaryotic cells have evolved a series of surveillance pathways termed cell-cycle checkpoints to ensure that cells copy and divide their genomes with high fidelity during each replication cycle. These checkpoint signaling pathways execute several tasks: rapid induction of cell-cycle delay, activation of DNA repair, maintenance of cell-cycle arrest until repair is complete, reinitiation of cell cycle progression after completed

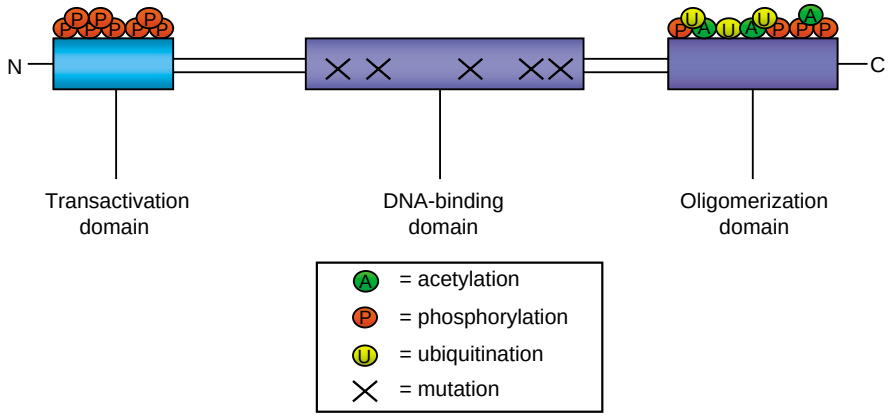

FIGURE 1 Functional domains of p53 are affected by post-translational modifications and mutations. The amino terminus contains the transactivation domain, which becomes phosphorylated in response to certain types of cell damage. The central region of the protein contains the DNA-binding domain that is very commonly mutated in human tumors. The oligomerization domain, which mediates the formation of p53 dimers and tetramers, is present at the carboxy terminus of the protein, and can be modified post-translationally by phosphorylation, acetylation, and ubiquitination.

repair or initiation of apoptosis if the damage is irreparable. These checkpoints provide a fail-safe mechanism by which cells are repaired or eliminated before the damaged DNA is transferred to the daughter cells. Loss of normal cell-cycle checkpoint signaling is a hallmark of tumor cells, and p53 is the most frequently altered cell-cycle checkpoint signaling molecule. One of the major functions of the p53 tumor suppressor protein is to modulate cellular responses to stress and induce cell-cycle arrest or death, as appropriate (Figure 2). Once a cell has been stressed or damaged, p53 initiates cell cycle arrest allowing time for the damage to be repaired or for the stress to dissipate. p53 halts cell growth by selectively activating certain target genes, including $p21^{Waf1/Cip1}$, a protein that inhibits molecules required for cell-cycle progression. If cell damage is extensive and cannot be repaired or the stress is prolonged, the cells may undergo p53-dependent apoptosis. p53 is responsible for both the activation of proapoptotic genes as well as the repression of antiapoptotic genes, and the array of p53-regulated genes involved in apoptosis is quite extensive. Although a given cell in the human body would not benefit from undergoing apoptosis, this process is sometimes necessary for the benefit of the whole organism, to prevent the development of cancer.

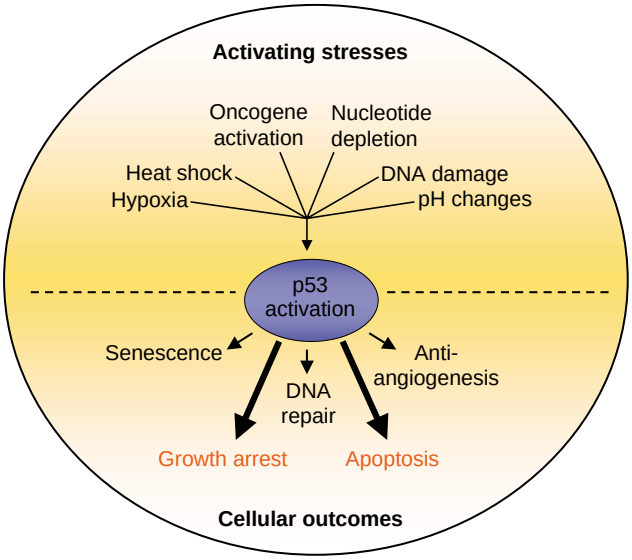

FIGURE 2 p53 signaling pathways. p53 is responsive to many cellular insults (activating stresses) that affect numerous pathways yielding various cellular outcomes. The two primary most well-characterized outcomes of p53 activation are growth arrest and/or apoptosis (thick arrows). However, p53-regulated genes also take part in numerous other signaling pathways (thin arrows).

Other Pathways Regulated by p53

p53 function is not limited to growth arrest and apoptosis. p53 also regulates genes involved in DNA repair, senescence, and angiogenesis (Figure 2). Although the relationships between p53 and these various pathways are not completely understood, future discoveries of novel p53 target genes and protein interactions will further elucidate the signaling networks in which p53 is involved.

p53 Regulation

p53 acts immediately after cell stress occurs, and thus, it is critical that the regulatory mechanism for this protein be fast acting. Following stress, the levels of many proteins in the cell are dictated by transcriptional regulation of the genes encoding the proteins; however, this is not the primary mechanism for p53. Instead, p53

regulation occurs predominantly at the protein level, which allows for rapid induction of p53 activity.

Activating Stresses

In a normal unstressed cell, the p53 protein is present at low levels due to the short half-life of the protein. However, p53 protein levels increase if the cell experiences a stress. There are numerous types of cellular stress and damage that can activate the p53 protein including lack of oxygen (hypoxia), elevated/lowered temperatures (heat/cold shock), DNA damage, metabolic changes, nucleotide depletion, pH changes, and oncogene activation (Figure 2). Cellular stresses trigger signaling pathways that converge on p53, resulting in stabilization and activation of the protein.

Post-translational Modifications

Post-translational modification events are dynamic processes that change protein stability and activity by altering protein–DNA and protein–protein interactions. Depending on the stress, p53 is post-translationally modified with various moieties resulting in diverse effects on the protein's stability, activity, and specificity of DNA binding (Figure 1).

Ubiquitination

Ubiquitination is the addition of ubiquitin molecules to lysine residues of a protein. Following ubiquitination, most proteins are targeted to the 26S proteosome for degradation. This is the mechanism used to rapidly turn over the p53 protein. The ubiquitination system involves numerous proteins, but the specificity of the system depends on the specific E3 ubiquitin ligase enzyme employed, which attaches an ubiquitin molecule to the correct substrate. The mouse double minute 2 (Mdm2) protein is the ligase used to ubiquitinate p53.

Phosphorylation

Phosphorylation of proteins at serine, threonine, and/or tyrosine residues is a common regulatory mechanism in the cell. p53 is phosphorylated at select serine and threonine amino acids in the amino- and carboxy-terminal regions of the protein in response to select cellular stresses. These stresses include exposure of cells to byproducts of cellular metabolism, ultra-violet (UV) radiation, and drugs used in cancer therapy. Numerous kinases have been identified that phosphorylate p53. The specific kinase activated is dependent upon the stress, and each kinase is responsible for phosphorylating a distinct residue(s) on the protein. Phosphorylation of the p53 protein can yield numerous outcomes including protein stabilization, increased transcriptional activity, and alterations in subcellular localization.

Acetylation

Acetylation is a modification that can occur on lysine residues of a protein. Acetylation of a transcription factor can affect the protein's transcriptional activity, either positively or negatively, depending on the specific factor. In response to DNA damage, known transcriptional coactivators acetylate p53 at certain carboxy-terminal lysines, however, the exact role of this modification on p53 activity is not well established.

Protein–Protein Interactions

There are numerous proteins that regulate p53 through a physical interaction. Many of these proteins are involved in post-translationally modifying the protein, but there are also other mechanisms of p53 protein regulation that involve protein–protein interactions. These interactions can both positively and negatively regulate p53.

Mdm2 is a protein that can bind to and ubiquitinate p53, as mentioned above. This p53–Mdm2 interaction results in two outcomes. The first is that Mdm2 inhibits the transcriptional activity of p53 by binding to the amino-terminal transactivation domain of the p53 protein, blocking other interactions that are necessary for p53 activity. The second outcome is p53 ubiquitination, export from the nucleus, and degradation. Mdm2 is responsible for maintaining p53 at low levels in a normal unstressed cell, as well as attenuating the p53 response after stress. Interestingly, Mdm2 is up-regulated by p53 in response to cellular insults, forming an autoregulatory negative feedback loop, which is the primary mechanism of negative regulation for p53.

Viral proteins can also interact with the p53 protein to affect its activity. For instance, the human papilloma virus (HPV) E6 proteins (type 16 and 18) negatively regulate p53 in a manner similar to Mdm2. The E6 protein binds to a protein complex containing p53, which leads to p53 ubiquitination and subsequent degradation.

In addition to protein interactions that negatively regulate p53 activity, there are interactions that have a positive impact on the protein as well. One example of this is the human $p14^{ARF}$ protein. This protein is a tumor suppressor activated in response to oncogenic stimuli. Once activated, $p14^{ARF}$ binds to the p53–Mdm2 complex, which disables Mdm2. This protects p53 from Mdm2-mediated degradation, resulting in p53 activation and subsequent growth suppression or apoptosis of cells that contain activated oncogenes.

p53 Family Members

p53 is a member of a newly identified family of related proteins that includes p73 and p63. p73 was discovered in 1997, with p63 quickly following in 1998. The three family members exhibit a high degree of sequence similarity and conserved functional domains. However, unlike p53 it appears that the functions of p73 and p63 are not restricted to tumor suppression. p73 is involved in neuronal signaling, immune cell apoptosis, and inflammation. p63 is involved in maintaining regenerative cells, and is essential for the normal development of numerous human tissues including the skin, breast, and prostate.

Cancer Therapeutics Involving p53

Since p53 is mutated in over 50% of all human tumors, many therapeutic strategies have been devised to target the p53 signaling pathway, including: (1) transfer of normal p53 genes into mutant p53-containing cancer cells, (2) introduction of small molecules that convert mutant p53 proteins to proteins that are structurally normal in function, (3) identification of small molecules that mimic the function of p53 target genes, and (4) disruption of protein–protein interactions that negatively regulate p53 activity. Due to its central role in preserving genetic stability, deciphering p53 function, regulation, and signaling pathways will continue to be a major focus of cancer-based research.

Biography

Jennifer A. Pietenpol, Ph.D., is a Professor of Biochemistry at Vanderbilt University and Associate Director for Basic Research Programs of the Vanderbilt-Ingram Cancer Center. Pietenpol received her Ph.D. in cell biology from Vanderbilt University and pursued postdoctoral studies at Johns Hopkins University. Pietenpol's research is focused on tumor suppressor signaling pathways, with particular focus on p53. A goal of her research is to define molecular changes in tumor cells that can be used as targets for therapeutic intervention.

Jamie Hearnes is a graduate student at Vanderbilt University and will receive her Ph.D. from the Department of Biochemistry. Her research in the Pietenpol Laboratory focuses on the identification of novel p53 target genes.

p70 S6 Kinase/mTOR

Christopher G. Proud
University of Dundee, Dundee, UK

p70 S6 kinase is a protein kinase that is activated by insulin and other stimuli, and which phosphorylates ribosomal protein S6, a component of the small (40S) ribosomal subunit in animal cells. Mammalian target of rapamycin (mTOR) is involved in regulating p70 S6 kinase, and other proteins, and serves to integrate hormonal and nutritional signals.

p70 S6 Kinase

This family of enzymes phosphorylates a series of seryl residues in the C-terminus of S6. It was identified in the 1980s following early work showing that insulin, and a range of other stimuli, led to increased phosphorylation of S6. The p70 S6 kinases were some of the earliest insulin- and mitogen-stimulated kinases to be studied in any detail, largely because the relatively high abundance of S6 means that it appears as a major insulin-stimulated phosphoprotein.

p70 S6 kinases are now believed to be the physiologically relevant S6 kinase. Confusion is possible here however, as a second type of kinase, $p90^{RSK}$, can also phosphorylate S6 *in vitro*. This gives rise to the abbreviation RSK (ribosomal protein S6 kinase) although it is generally thought that $p90^{RSK}$ is not a physiologically relevant S6 kinase. An important reason for favoring the p70 S6 kinases is that their activation and the phosphorylation of S6 are both blocked by rapamycin, while this drug has no effect on $p90^{RSK}$.

Different Isoforms of p70 S6 Kinase Exist in Mammals

In mammals, there are two genes encoding closely related kinases, both of which phosphorylate S6. Here, they are termed p70α S6 kinase (also called S6K1) and p70β S6 kinase (alternative name, S6K2). The overwhelming majority of studies have concerned the α-isoform, which was discovered much earlier than the β. However, the recent studies on S6K2 suggest that it is regulated in a way broadly similar to S6K1. Further diversity in this family is created by alternative splicing: in the cases of p70α and p70β S6 kinases, this gives rise to additional isoforms (p70α1 and p70β1) which are extended at the N-termini (see Figure 1: the shorter versions are termed p70α2 and p70β2). This extension contains a likely nuclear localization signal, which could mediate the transfer of the longer isoforms into the nucleus.

All four isoforms contain a catalytic domain near the N terminus and a regulatory domain towards the C terminus. Phosphorylation within the catalytic domain and at several sites in the C terminus leads to the activation of the S6 kinases (see Figure 1).

p70 S6 Kinase is Activated by a Variety of Stimuli

p70 S6 isoforms are activated by insulin, serum and mitogens, and also by a range of other stimuli including ones that work through G-protein-coupled receptors. A common feature of these stimuli is that they increase the cell's overall rate of protein synthesis. In all cases, activation of p70α S6 kinase involves increased phosphorylation of the protein (Figure 1), and is blocked by rapamycin, indicating a key role for mTOR in activation.

Less effort has so far been devoted to studying the more recently discovered p70β S6 kinase, but the available information suggests that it is also likely to be activated by a wide range of stimuli.

Roles of Nutrients and mTOR in Regulating p70 S6 Kinase

In a number of types of cells, p70α S6 kinase cannot be activated if the cells are deprived of amino acids. Amino acid starvation also results in a fall in the basal activity of the kinase. Readdition of amino acids results, within minutes, in increased basal activity and restoration of the ability of insulin, for example, to activate p70α S6 kinase. This suggests that amino acids provide an important input into the regulation of p70α S6 kinase, and this is discussed further below. The branched-chain amino acid leucine is the most effective amino acid in most cell types tested.

In some cell types, such as hepatoma cells and primary fat cells, the presence of external amino acids

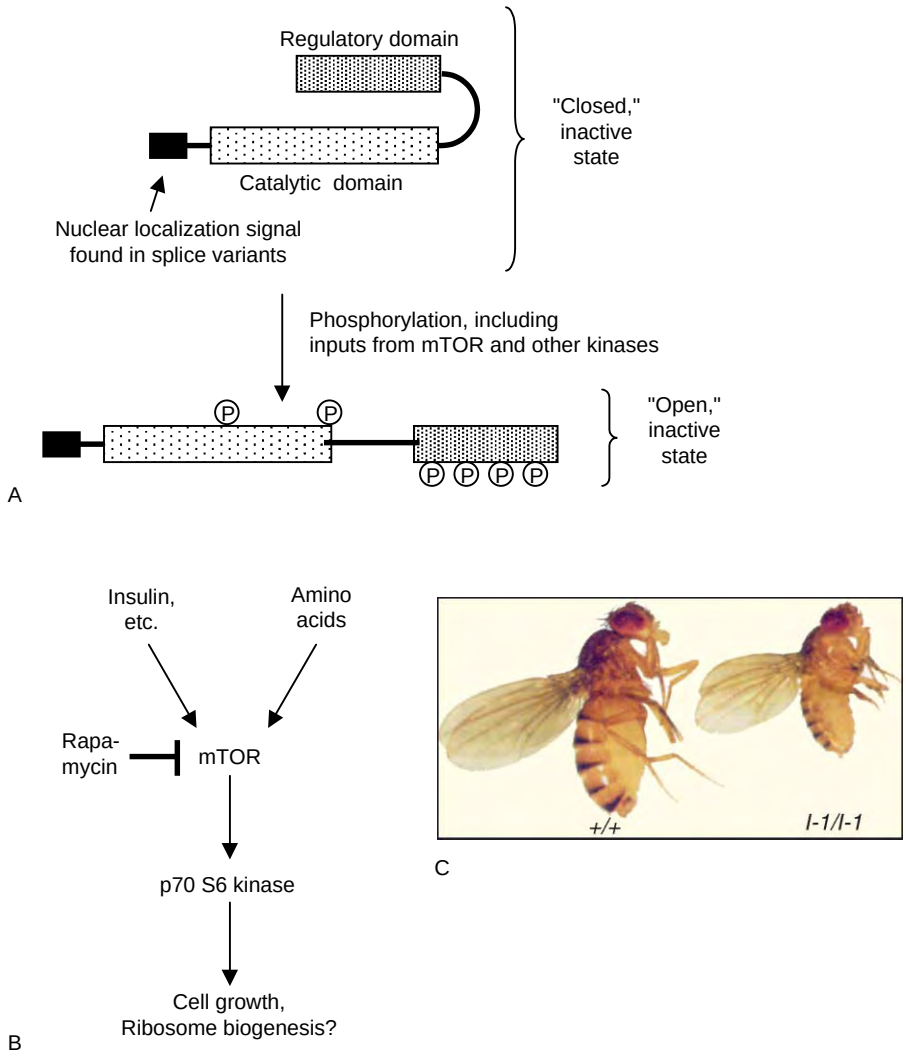

FIGURE 1 p70 S6 kinase. (A) This schematic figure indicates the arrangement of the enzyme into catalytic and regulatory domains. Phosphorylation of the regulatory domain allows the catalytic domain to be phosphorylated too, leading to activation of the enzyme. Phosphorylation involves several kinases and input from mTOR. For further details, see text. (B) Hormones, such as insulin (also growth factors), and amino acids positively regulate p70 S6 kinase via mTOR (its activation is therefore prevented by rapamycin). It has a clear role in regulating cell size, possibly through the control of ribosome biogenesis. (C) Genetic knockout of S6 kinase in *Drosophila melanogaster* dramatically decreases the size of the animals, with all body parts apparently affected to a similar degree: + /+ indicates a wild-type fly, while l-1/l-1 denotes one in which the S6K gene has been disrupted. Reproduced from Montagne, J., Stewart, M. J., Stockes, H., Hafer, E., Kozma, S. C., and Thomas, G. (1999). Drophila S6 kinase: a regulator of cell size. *Science* 285, 2126–2129. Copyright 1999 American Association for the Advancement of Science.

in the medium is not required for regulation of p70α S6 kinase. It is likely that this reflects the presence, within these cells, of sufficient amino acids to support regulation of this enzyme, rather than a fundamental difference in its control in these cells.

Mechanisms Involved in the Activation of p70 S6 Kinase

As noted above, the activation of S6 kinase involves its phosphorylation at several positions. One lies within the catalytic domain and most of the others lie in the C-terminal regulatory domain. It is possible that the C-terminal region blocks access to the catalytic domain, and that this block is alleviated by phosphorylation of the C-terminal sites. The kinases acting at these sites have not been conclusively identified. Since rapamycin blocks the phosphorylation of many sites in p70α S6 kinase, it is conceivable that the relevant kinases are regulated through mTOR, or that mTOR directly phosphorylates p70α S6 kinase, although other explanations are also possible. The proposed mechanism by which p70α S6 kinase is activated is illustrated in Figure 1.

p70 S6 Kinase Plays a Key Role in Growth Control

Genetic studies have revealed a key role for p70 S6 kinases in growth control. The fruit fly, *Drosophila melanogaster*, has just a single p70 S6 kinase gene. Disruption of this gene, to create flies lacking S6 kinase activity, has a dramatic effect on the growth of the flies. S6 kinase-deficient flies are markedly (~50%) smaller than wild-type flies (Figure 1C) and strikingly, this is due primarily to a defect in cell size rather than a reduction in cell number. The mutant flies contain the same number of cells as wild-type flies, but the sizes of these cells are decreased proportionately so that the mutant flies are morphologically very similar to the wild-type flies. This demonstrates a decoupling of cell size from cell proliferation, and implies a key role for S6 kinase in the poorly understood processes that determine cell size. This is discussed further below. A similar effect is observed in mice in which the p70α S6 kinase gene is disrupted, but the magnitude of the reduction in size is smaller, probably because the existence of the second mammalian gene (p70β S6 kinase) compensates to some extent.

Does p70 S6 Kinase Regulate Ribosomal Protein Synthesis?

It has been observed that insulin and serum increase the phosphorylation of ribosomal protein S6 that leads to the identification of the S6 kinases. What role, then, does S6 phosphorylation play? Since it is a ribosomal protein, one would suppose that its role lies in regulating some aspect of mRNA translation (protein synthesis).

In higher animals, the mRNAs encoding the ribosomal proteins all share an unusual feature, a run of pyrimidine nucleotides at the extreme 5′-end of the mRNA. This acts to suppress their translation under basal conditions (e.g., in cells starved of serum or of amino acids). In response to stimulation of cells with serum or amino acids, these mRNAs bind to ribosomes and undergo translation so that ribosomal protein synthesis is switched on. It clearly makes good sense for the production of ribosomes to be stepped up in response to agents that stimulate protein synthesis or cell proliferation, and in parallel with the availability of amino acids, important precursors for ribosome production and for general protein synthesis.

Initial studies showed that rapamycin blocked the activation of the translation of these mRNAs and pointed to a role for p70 S6 kinase in this. However, some more recent studies have questioned the links between p70 S6 kinase/S6 phosphorylation and the activation of the translation of this subset of mRNAs.

Regulation of Other Processes by p70 S6 Kinase

In addition to S6, p70α S6 kinase has also been shown to phosphorylate certain other proteins involved in regulating gene expression. These include a protein involved in the control of gene transcription (the cyclic AMP-response element (CRE) modulator, CREM) and a protein kinase that regulates the elongation stage of protein synthesis (elongation factor 2 kinase). The latter may allow insulin and amino acids to accelerate the rate at which proteins are synthesized. Further substrates for the p70 S6 kinases may, of course, also exist.

mTOR

mTOR is a protein that is implicated in the intracellular signaling events that control a variety of processes in eukaryotic cells. All eukaryotic organisms that have been studied so far contain proteins related to mTOR, and work on the yeast orthologues, TOR1 and TOR2, has been especially fruitful in helping understand TOR signaling.

mTOR Signaling is Inhibited by the Immunosuppressant Drug, Rapamycin

mTOR, and indeed orthologues in many (but perhaps not all) species, are inhibited by rapamycin. Rapamycin is produced by a soil microorganism, *Streptomyces hygroscopicus*, which originates from Easter Island (the indigenous name for this island is Rapa Nui, hence rapamycin). The finding that rapamycin blocks the activation of T-lymphocytes, and thus suppresses the immune response, led to a high level of interest in its mechanism of action. Screening of yeast mutants for strains that are insensitive to the growth-inhibiting effects of this drug led to the identification of TOR1 and TOR2, and to the subsequent identification of related proteins in other organisms, such as mTOR in mammals.

Rapamycin appears to be completely specific for mTOR and its orthologues. Rapamycin binds to mTOR as a complex with a small protein called FKBP12 (FK506-) and rapamycin-binding protein 12: FKBP12 has prolyl *cis/trans* isomerase activity which is inhibited by both rapamycin and FK506, an immunosuppressant (FK506 does not, however, inhibit mTOR). The fact that the binding of the FKBP12/rapamycin complex to mTOR involves contacts with both the drug and the protein probably explains the high specificity. The normal physiological role of FKBP12 is unknown.

mTOR Is a Multidomain Protein

mTOR is a very large protein (about 2500 residues, Figure 2A). Inspection of its sequence reveals a number of potential domains. Its N-terminal section contains multiple "HEAT" domains—such domains are known to be important in protein–protein interactions. Towards its C terminus lies a domain that resembles the catalytic domain of kinases that phosphorylate lipids such as the phosphoinositide (PI) 3-kinases.

The kinase domain of mTOR appears critical to its function since mutants designed to cripple the catalytic domain are not functional *in vivo*. The region with which the FKBP12/rapamycin complex binds and inhibits mTOR function is N-terminal to the kinase domain.

mTOR (and TOR) Regulate Multiple Processes in Eukaryotic Cells

Treatment of cells with rapamycin reveals roles for mTOR/TOR in many important cellular processes such as gene transcription, protein synthesis and degradation, RNA breakdown, nutrient transport, the cell cycle and the organization of the actin cytoskeleton. Recent work with yeast suggests that, in fact, rapamycin may not affect all the functions of yeast TOR2, so that it may have additional roles not revealed by studying the effects of rapamycin. In contrast, the data suggest that all the functions of the other TOR protein in yeast, TOR1, may be blocked by this drug. It was already known that TOR1 and TOR2 had similar, but distinct, functions in yeast.

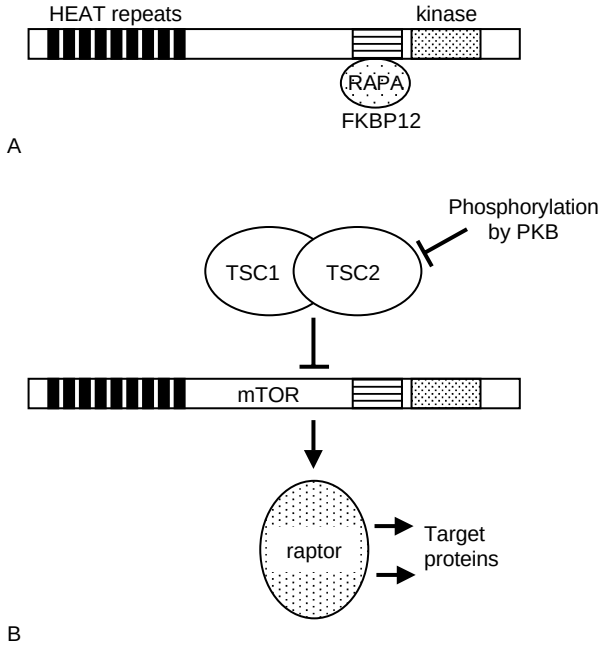

FIGURE 2 mTOR. (A) The figure depicts the principal domains found in mTOR. The complex of rapamycin with FKBP12 binds to and inhibits the function of mTOR. For other details, see text. (B) The complex of TSC1 and TSC2 binds to and inhibits mTOR: inhibition may be removed by phosphorylation of TSC2 by PKB. mTOR also binds a molecular scaffold, raptor, which appears to mediate the regulation of target proteins by mTOR.

The mechanisms by which mTOR/TOR regulates its downstream targets remain unclear. Since, where it has been studied, such regulation often involves changes in the phosphorylation of regulatory proteins, it is likely to be mediated by alterations in the activities of specific protein kinases and phosphatases, and there is evidence for both. In mammals, few of the target proteins that are controlled by mTOR have yet been identified. The best-understood ones are all involved in protein synthesis—they include the p70 S6 kinases, an elongation factor (eEF2) and a repressor of translation initiation, the initiation factor 4E-binding protein, 4E-BP1.

mTOR Interacts with Several Other Proteins

Very recent work has shed important new light on the ways in which mTOR may be regulated and how it signals to its target proteins. The key findings here were that mTOR (and the yeast TOR proteins) interact with other proteins. These interactions may involve the HEAT domains mentioned above. One type of interacting protein ("raptor") appears to be involved in the regulation of targets of mTOR signaling such as 4E-BP1 and the p70 S6 kinases. Others are probably involved in its upstream control.

Like mTOR, raptor is a large protein (1300 amino acids) that contains many motifs that may mediate protein–protein interactions. Related proteins are found in all eukaryotic species studied. Raptor binds to mTOR and also to its target 4E-BP1, and thus appears to act as a molecular scaffold (Figure 2B). The available evidence suggests that it is also required for the regulation of p70α S6 kinase by amino acids. Aspects of mTOR signaling such as raptor are currently a very active area of investigation and further important developments are likely.

Yeast TOR1 and TOR2 have been shown to bind the raptor orthologue in yeast and also to other proteins, although their roles are so far unknown.

mTOR Signaling Is Regulated by Hormones and Nutrients

Recent work has also identified proteins that bind to mTOR and act to regulate it, in response, for example, to insulin. TSC1 and TSC2 are components of the tuberous sclerosis complex, and appear to bind as a complex to mTOR, thereby inhibiting it (Figure 2B).

TSC1 and TSC2 were first identified as the genes that are mutated in tuberous sclerosis, an autosomal dominant disorder, that can lead to the occurrence of benign tumors characterized by excessively large cell size. This is accompanied by increased activity of p70α S6 kinase, consistent with the role described above for p70 S6 kinase in cell growth regulation. The effects of mutations appear to arise because they alleviate the normal inhibitory effect of the TSC1/2 complex on mTOR. The TSC1/2 complex is now also implicated in the normal regulation of mTOR: phosphorylation of TSC2 by a protein kinase B (PKB), which is activated by insulin, is thought to lead to the disruption of the TSC1/2 complex and activation of mTOR. The TSC1/2 complex acts to promote the hydrolysis of GTP on the small G-protein Rheb, which in its GTP-bound state promotes mTOR function. Much remains to be learned about how Rheb activates mTOR, and how other signaling inputs (such as amino acids) activate mTOR.

mTOR Displays Protein Kinase Activity

Although the kinase domain of mTOR resembles those of lipid kinases rather than of protein kinases, mTOR can phosphorylate certain proteins *in vitro*. These include p70α S6 kinase and the translational repressor protein 4E-BP1. However, the activity is weak and requires quite non-physiological conditions, so it is not clear whether this is really a physiological function of mTOR. It is quite conceivable that some of mTOR's partner proteins enhance its kinase activity *in vivo*.

Clinical Implications of mTOR Signaling

As noted above, rapamycin blocks the activation of cells of the immune system and thus acts as an immunosuppressant. As a consequence, rapamycin has found medical applications in combating graft rejection, particularly for recipients of kidney transplants. Very recent work also points to the potential for using rapamycin to treat certain types of cancer. These arise from mutations that inactivate the tumor suppressor protein PTEN and thus lead to unbridled activity of the PI 3-kinase signaling pathway that activates mTOR in response to insulin and many growth factors. Since the mTOR pathway clearly plays a central role in cell and animal growth, it will be of substantial importance for studies on clinical situations characterized by tissue atrophy or hypertrophy.

Biography

Christopher Proud is a Professor of Biochemical Physiology in the Faculty of Life Sciences at the University of Dundee. He holds a Ph.D. from the University of Dundee and did his postdoctoral training in Germany and England. His principal research interests are in the regulation of protein synthesis in mammalian cells by hormones and nutrients, and the roles of defects in protein synthesis and its control in the pathogenesis of human diseases.

Parathyroid Hormone/Parathyroid Hormone-Related Protein Receptor

Thomas J. Gardella
Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, USA

The parathyroid hormone (PTH)/PTH-related protein (PTHrP) receptor (PPR) is a 593 amino acid, class 2 G protein-coupled receptor that mediates the actions of PTH, the major regulator of blood ionized calcium levels, and PTHrP, a key developmental protein. The PPR is abundantly expressed in bone osteoblasts and in renal tubule cells, the target cells of PTH, and in mesenchymal cells of developing tissues (e.g., skeleton, heart, teeth, and mammary glands), smooth muscle cells, and neurons, the target cells of PTHrP. The PPR binds PTH and PTHrP ligands via a bipartite mechanism involving binding interactions to the amino-terminal extracellular domain of the receptor and signaling interactions to the extracellular loops and seven transmembrane helices. The PPR couples strongly to the adenylyl cyclase (AC)/3′,5′-cyclic-adenosine monophosphate (cAMP)/protein kinase (PK)A signaling cascade, and can also activate the phospholipase (PL)C/inositol triphosphate (IP_3)/intracellular calcium (iCa^{2+})/PKC; PLD/phosphatidic acid/PKC; PLA_2/arachidonic acid/PKC; and MAP kinase pathways. Jansen's metaphyseal chondrodysplasia and Blomstrand's chondrodysplasia are rare diseases of skeletal development and calcium ion homeostasis that are caused by activating and inactivating mutations in the PPR gene, respectively. PTH(1–34) has anabolic effects on bone and is now used to treat osteoporosis.

Background and Physiology

Molecular Cloning of the PPR

The complementary (c)DNA encoding the parathyroid hormone (PTH)/PTH-related protein (PTHrP) receptor (PPR) was first isolated in 1991. This work revealed the classical seven transmembrane domain architecture of the G protein-coupled receptor (GPCR) superfamily (Figure 1). It also revealed that the PPR, along with the receptors for secretin, calcitonin, and several other peptide hormones, form a distinct subgroup – the class 2 GPCRs – which has been well-conserved, evolutionarily, with representatives present in *Drosophila* and *C. elegans*. The cloned PPR expressed in COS-7 cells binds PTH and PTHrP with equal affinities, and, in response to these ligands, activates both the AC/cAMP and PLC/IP_3/iCa^{2+} signaling pathways. It thus appears that the cloned receptor can account for all, or most, of the biological actions of two distinct ligands, PTH and PTHrP.

PTH

Discovery of PTH

Parathyroid hormone was identified as a key calcium-regulating hormone in the 1920s, when it was demonstrated that extracts of the parathyroid glands could modulate blood calcium levels and correct the tetany induced by parathyroid gland removal. The active hormone was purified from glands in 1959 and the complete 84 amino acid sequence of bovine PTH was determined in 1970. In 1971, the N-terminal PTH(1–34) fragment was synthesized and showed to be equipotent to native PTH in *in vitro* and *in vivo* assay systems. Physiological studies performed during this period established that PTH is the most important regulator of ionized calcium (Ca^{2+}) in the blood and extracellular fluids, and that it acts on bone, where it stimulates Ca^{2+} release from the mineralized matrix, and kidney, where it stimulates Ca^{2+} reabsorption from the glomerular filtrate. Related studies established that the secretion of PTH from the glands is regulated in a negative feedback fashion by the levels of extracellular Ca^{2+}; thus increases in blood Ca^{2+} result in decreased PTH secretion and decreases in blood Ca^{2+} result in increased secretion. This Ca^{2+}-mediated regulation of PTH secretion is determined by the actions of the calcium-sensing receptor expressed on the plasma membrane of parathyroid cells, and it is highly sensitive, such that blood Ca^{2+} levels are strictly maintained within the range of 1.1–1.3 mM. PTH is also a key regulator of blood phosphate, the principal Ca^{2+} counter ion, and suppresses the reabsorption of phosphate in the kidney.

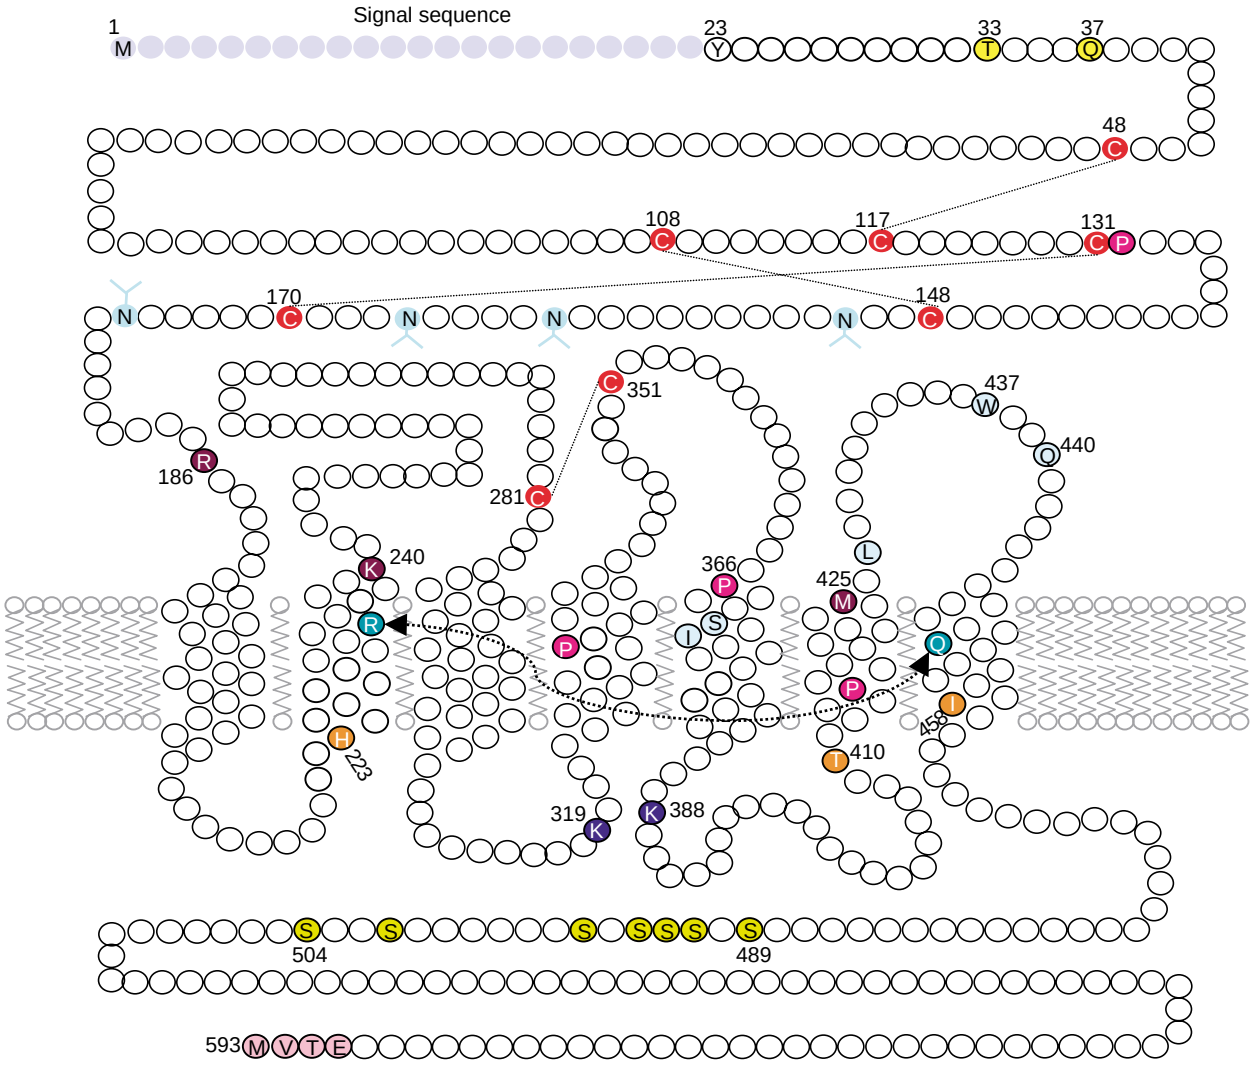

FIGURE 1 The human PTH/PTHrP receptor. Shown is a schematic of the PPR embedded in the lipid bilayer with selected features identified, including the conserved extracellular cysteines and their predicted disulfide linkages; the glycosylated asparagines (N); Thr33 and Gln37, which contribute to PTH(15–34) binding affinity; the probable cross-linking sites for ligand residues 13 (Arg186), 19 (Lys240) and 1 and 2 (Met425); conserved prolines (P), including Pro132, which is mutated to Leu in Blomstrand's chondrodysplasia; a putative inter-helical interaction between Arg233 and Gln451; Ser370, Ile371, Leu427, Trp437, and Gln440, at which mutations alter responsiveness to position 2-modified PTH(1–34) antagonist ligands (also includes Met425); His223, Thr410, and Ile458, which are mutated in Jansen's chondrodysplasia to result in constitutive signaling activity; Lys319 and Lys388, at which mutations impair G_q and G_s/G_q coupling, respectively; serines (S) that are phosphorylated upon agonist activation, and four C-terminal residues (Glu590–Met593) involved in NHERF binding.

PTH Effects in Bone

In bone, the PPR is expressed by osteoblast cells. These bone-forming cells display a variety of responses to PTH, including alterations in the rates of cell proliferation, apoptopsis, and changes in the expression patterns of a number of transcription factors, cytokines and bone-matrix factors. These effects can result in increased rates of bone formation. PTH however, also stimulates the bone-resorbing activity of osteoclastic cells, which are thought to be largely responsible for the calcium-releasing effects of PTH in bone. Osteoclasts, however, do not express the PPR but respond to the hormone via osteoclastogenic factors, such as RANK-ligand, that are expressed by PTH-stimulated osteoblasts. By modulating the activities of both osteoblasts (directly) and osteoclast (indirectly), PTH plays a major role in the continuous process of bone remodeling in the process of bone-remodeling. The mechanisms that control the balance between the anabolic and catabolic effects of PTH on bone are complex and not fully understood; however, it is well documented that intermittent exposure to PTH (once-daily injection) results in net bone formation, whereas continuous exposure (infusion) results in net bone resorption. Consistent with the anabolic effect of intermittent PTH on bone, a large clinical study

completed in 2001 showed that daily administration of PTH(1–34) significantly reduces the risk of bone fracture in patients with osteoporosis. As a result, the peptide is now used in the treatment of this common disease.

PTH Effects in the Kidney

In the kidney, the PPR is expressed by proximal and distal tubule cells. In the distal tubule, PTH stimulates the reabsorption of calcium from the urine, most likely by affecting calcium channel activity. In the proximal tubule, PTH stimulates the synthesis of 1,25-dihydroxy-vitamin D3, which in turn, promotes calcium absorption by the intestine and calcium release from bone. These calcium-regulating effects of vitamin D_3 occur on a longer time scale (days to weeks), than do those of PTH, which occur within seconds to minutes. Also in renal proximal tubule cells PTH suppresses the surface expression of the type II sodium-phosphate co-transporter and thereby decreases the re-uptake of phosphate from the urine.

PTHrP

Discovery of PTHrP

In the late 1980s, much effort was devoted to identifying the hypercalcemia-causing factor that is released by many tumors, and in 1987, the protein factor responsible, PTHrP, was purified from tumor extracts and partially sequenced. This sequence data, in turn, led to the cloning of the corresponding complementary(c) DNA, which revealed a protein of 141 amino acids that has clear N-terminal homology to PTH, as, 8 of the first 13 residues of the two proteins were found to be identical (Figure 2). PTHrP(1–34) peptides were shown to mimic the calciotropic actions of PTH on bone and kidney cells. It seemed clear, however, that PTHrP was not normally a calcium-regulating hormone, as its concentration in the normal circulation was too low (barely detectable). Furthermore, its mRNA was found in a wide variety of tissues (e.g. brain, lung, heart, adrenals, spleen, liver, bladder, skin, stomach, breast, placenta, ovaries, testes), in both adult and fetal life. These observations suggested that PTHrP acts in a paracrine manner, possibly in development.

Genetic Manipulations of PTHrP in Mice

The above hypotheses regarding PTHrP action were largely confirmed in 1994 when mice having homozygous deletion of the *PTHrP* gene were generated and found to die at birth with defects in endochondral bone formation, namely, premature mineralization and short limbs. Subsequent genetic studies in mice determined that PTHrP also plays a role in the development of the mammary glands, hair follicles, and the heart. In 1996, mutant mice lacking the PPR gene were generated, and this established that the PPR mediates the developmental actions of PTHrP. Thus, PPR-deficient mice exhibit nearly the same perinatal lethality and developmental defects as those lacking the *PTHrP* gene.

PTHrP Actions in the Growth Plate

Extensive studies on the cartilaginous growth plates of the fetal tibia and femur in mice vividly demonstrated that PTHrP indeed acts in a paracrine fashion to control the program of events in tissue development. PTHrP is expressed by cells in the periarticular region of the growth plate and acts on prehypertrophic chondrocytes of the central zone to delay their terminal differentiation into hypertrophic chondrocytes. This action of PTHrP in the growth plate is further regulated by at least several other morphogenetic proteins, including Indian hedgehog (Ihh), which is produced by the prehypertrophic chondrocytes and stimulates chondrocyte proliferation. Ihh also induces, as part of a feedback regulatory network, the expression of PTHrP by the periarticular cells. Similar paracrine actions of PTHrP on PPR-expressing cells are also likely to operate in the mesenchyme of other developing tissues (e.g., heart, mammary glands, and hair follicles).

Structure–Activity Relationships in PTH and PTHrP

Functional Domains of PTH(1–34) and PTHrP(1–34)

Both PTH(1–34) and PTHrP(1–34) bind to and activate the PPR with affinities and potencies in the nanomolar range, and the two ligands interact with overlapping sites in the receptor. For both (1–34) ligands, the major determinants of PPR-signaling potency and binding affinity reside within the N-terminal and C-terminal portions, respectively. Based on this physical separation of functional domains, N-terminally truncated analogues, such as [Leu^{11},$DTrp^{12}$]PTHrP(7–34), have been developed as PTH receptor antagonists. The PTH(15–34) fragment represents the minimum-length binding fragment ($K_{dissociation} \sim 1\ \mu M$), and within this

domain, Trp-23, Leu-24, Leu-28, and Val-31 function as key determinants of binding affinity. These residues form the hydrophobic face of a predicted amphipathic α-helix that may contact the receptor. Within the N-terminal signaling domain of PTH, the highly conserved Val-2, plays a key role in PPR activation, as its deletion or replacement by bulky amino acids (e.g., Arg or Trp) confers antagonist behavior to PTH(1–34) analogues. Short amino-terminal fragments, such as PTH(1–14), exhibit little or no binding or signaling activity; however, recent studies have resulted in N-terminal fragment analogues with considerably enhanced binding and signaling capacities. For example, [Aib^{1,3},Gln^{10},Har^{11}, Ala^{12},Trp^{14}]PTH(1–14)NH_2 is ~100 000-fold more potent than native PTH(1–14) for stimulating cAMP formation (EC_{50}s = 2 nM versus 200 μM) and is thus as potent as PTH(1–34) in cell-based assay systems.

Structural Studies of PTH and PTHrP

Solution-phase NMR studies performed on PTH(1–34) analogues suggest that the peptide in solution adopts a bi-helical conformation in which a short N-terminal helix (residues ~3–10) is joined via a turn or flexible linker to a longer more stable C-terminal helix (residues ~17–31). In some studies a U-shaped structure has been proposed for the bi-helical peptide. In 2001, however, the X-ray crystal structure of PTH(1–34) was determined and this revealed a single, slightly bent α-helix that extended from Val-2 to His-32. What is needed now is a direct assessment, by physical methods, of the conformation of the ligand in the receptor-bound state; until this is accomplished, the true bioactive conformation of PTH will likely remain uncertain.

Structure Activity Relationships in the PPR

Molecular Architecture of the PPR

The Amino-Terminal Domain

The PPR contains an amino-terminal extracellular (N) domain of ~167 amino acids (excluding the 23 amino acid signal sequence) (Figure 1). This N domain is Asn-glycosylated at four sites and contains six cysteine residues. These six cysteine residues are very highly conserved among the class 2 GPCRs and they are predicted to form a network of three disulfide bonds that defines a tertiary fold common to the N domains of each of the class 2 receptors. At present, the three-dimensional structure of the N domain of any class 2 GPCR is unknown, but it is clear that for each receptor, the N domain contributes importantly to ligand-binding affinity. For the PPR, the isolated N domain protein, purified and refolded from an *E. coli* expression system, binds PTH(1–34) with micromolar affinity. Protease digestion and mass-spectrometry analysis of this protein reveled the probable disulfide bond arrangement for the PPR N domain (Figure 1), and the same disulfide bond pattern has also been determined for several other class 2 receptor N domain proteins.

The Juxtamembrane Domain

The juxtamembrane (J) region of the PPR is comprised of the heptahelical bundle and the interconnecting loops. The structure of this domain is likely to bear at least some similarity to the heptahelical core region of rhodopsin, the only GPCR for which an X-ray crystal structure is available. Computer models of the PPR J domain have been generated using the rhodopsin X-ray structure as a template, but because there is almost no amino acid sequence homology between rhodopsin, a class 1 GPCR, and the PPR, the accuracy of such models is uncertain. One structural feature that is predicted for the PPR J domain, and for nearly all GPCRs, is a disulfide bond between extracellular loop (ECL)-1 and ECL-2 (Figure 1). Within the transmembrane helices of the PPR there are residues that are well-conserved in the class 2 GPCR family and are likely to help define the topology and functionality of the J domain. These include the prolines in TMs 4, 5, and 6, expected to induce kinks in the helices, and polar residues, such as Arg233 in TM2 and Gln451 in TM7, that are likely to contribute to networks of inter- and intra-helical side-chain interactions. The connecting loops and carboxy-terminal tail (CT) of the PPR also contribute importantly to PPR function, but the structures of these domains are unknown.

The Ligand Interaction Mechanism in the PPR

The Two-Site Model

The ligand-binding mechanism for the PPR has been extensively analyzed by the complementary approaches of photochemical cross-linking and receptor mutagenesis, and the overall results suggest a two-site model. According to this model, the C-terminal binding domain of PTH(1–34) interacts with high affinity with the PPR N domain and this interaction enables the amino-terminal domain of the ligand to interact with lower affinity with the PPR J domain. Thus, the N domain interaction provides the major component of binding energy, while the J domain interaction provides the interactions that induce receptor activation and G protein coupling (Figure 3).

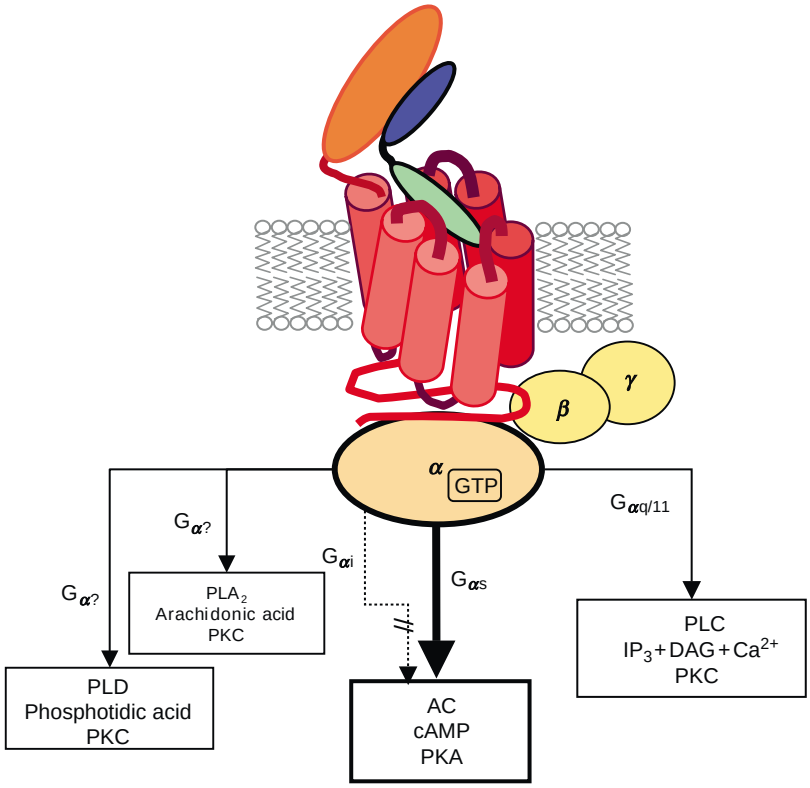

FIGURE 3 Ligand-binding and G protein-coupling mechanisms for the PTH/PTHrP receptor. The ligand, PTH(1–34) or PTHrP(1–34), is shown to interact with the PPR via a bipartite mechanism in which the ligand's C-terminal portion (blue) interacts with the receptor's amino-terminal extracellular domain (orange) to provide binding affinity, and the ligand's N-terminal portion (green) interacts with the receptor's extracellular loops and heptahelical portion (red) to induce receptor activation. The activated PPR can couple to multiple signaling pathways via several different heterotrimeric G proteins. It couples most strongly and in most cells to $G_{\alpha s}$ to stimulate the AC/cAMP/PKA pathway. It can also couple to $G_{\alpha q}$ to stimulate PLC/IP_3/Ca^{2+}/PKC signaling and to a pertussis toxin-sensitive G_i protein to inhibit AC/cAMP activity, but the magnitude of these response are generally less than that of the stimulatory AC/cAMP response. In some cells, the PPR can activate the PLD/phosphotidic acid/PKC and/or PLA_2/arachidonic acid/PKC pathways, but the G proteins involved are unknown.

N Domain Interactions

Cross-linking studies have identified proximities between specific sites in PTH and PTHrP ligands and the PPR. Thus, PTHrP(1–36) analogues modified with the photo-labile amino acid analogue, benzoylphenylalanine (Bpa), at positions 23, 27, 28, and 33 and cross-link to distinct segments of the PPR N domain: (33–40), (96–102), (64–95) and (151–172), respectively. The locations of the important functional contact sites within these N domain regions still need to be determined, but the large segment, residues (61–105), which corresponds precisely to exon E2 of the PPR gene, is not likely to contain such sites, as it can be deleted without affecting ligand-binding affinity. Two possible interaction residues in the N domain of the PPR include Thr33 and Gln37 (Figure 1), as mutation of these residues to alanine results in decreased affinity for PTH(15–34). These two residues are near the Bpa-23 contact site and thus could provide contacts for Trp-23 in the ligand.

J Domain Interactions

Other cross-linking studies identified Met425 at the extracellular end of TM6 as the probable contact site for PTH(1–34) or PTHrP(1–36) ligands modified with Bpa at position 1 or position 2. Interestingly, the Bpa-1-modified analogue (an agonist) and the Bpa-2-modified analogue (a partial antagonist/inverse agonist) cross-linked to overlapping, but not identical, sites at or near Met425, suggesting that the analogues could be used to distinguish between active and inactive receptor conformational states. In further studies, the mutation Met425 → Leu was shown to specifically increase the agonist efficacy (and reduce the inverse agonist efficacy) of [Bpa^2]PTHrP(1–36). These data, combined with earlier data showing that point mutations at the extracellular ends of TM5 (Ser370 → Ala, Ile371 → Val) and, TM6 (Leu427 → Thr) modulate the antagonist properties of [Arg_2]PTH(1–34), and that mutations in ECL-3 (Trp437 → Ala, Gln440 → Ala) impair binding of PTH(1–34) but not that of PTH(3–34), suggest

that residues in the TM5/TM6/ECL-3 region mediate interactions with Val-2 in the ligand that are involved in receptor activation.

Two other contact sites in the PPR J domain identified by cross-linking analyses include Arg186 at the N domain/TM 1 boundary, the probable contact site for ligand residue 13, and Lys240 at the extracellular of TM2, the probable contact site for ligand residue 19. The results of these cross-linking studies, combined with those above for the N-terminally modified ligand analogues, suggest that the portion of the ligand that interacts with the PPR J domain extends from residue 1 to residue 19. Consistent with this, the potencies of PTH(1–20) analogues on a PPR mutant construct (PPR-delNt) that lacks most (residues 23–181) of the N domain are the same as they are on the intact PPR. These studies using the PPR-delNt construct also suggest that the PPR N domain is not required for receptor activation. The PPR N domain is clearly required, however, for achieving full potency and affinity with PTH(1–34), as this ligand is 100-fold weaker on P1R-delNt, as it is on the intact PPR.

PPR Signaling and Regulation

Conformational Changes

As for all GPCRs, it is presumed that PPR activation involves movements in the TM helices and intracellular loops (ICLs), and that these movements result in increased accessibility of the receptor's cyctoplasmic surface to G proteins. The precise conformational changes involved are likely to be complex and are largely unknown. Inter-TM domain movements in the PPR have been analyzed using the Zn(II)-chelation strategy, and these studies have revealed that a movement of TM3 and TM6 away from each other, blocked by the addition of Zn(II), is required for Gs activation. In parallel experiments, a similar movement was also detected in the β2 adrenergic receptor, and has also been observed by this method of analysis in rhodopsin. The activation mechanisms used by the class 1 and class 2 GPCRs may, therefore, be similar. Using conventional mutational methods, specific residues in the IC loops of the PPR have been identified that modulate Gs and/or Gq coupling. These include Lys388 in ICL-3, at which mutations impair both AC/cAMP (G_s) and PLC/IP_3 (G_q) signaling and Lys319 in ICL2, at which mutations selectively impair PLC/IP_3 (G_q) signaling.

The Carboxyl-Terminal Tail

Classical pharmacological studies on PTH action in bone and kidney cells revealed that the PPR desensitizes and internalizes in response to hormone stimulation. More recent molecular studies have shown that the PPR carboxyl-terminal tail plays a major role in this regulation. Upon agonist activation, seven serines within the N-terminal-proximal portion of the tail (Figure 1) are rapidly phosphorylated, most likely by G protein-specific receptor kinase-2. This phosphorylation promotes the binding of β-arrestin and the internalization of the ligand–receptor complex, via clatherin-coated pits, to endosomal vesicles. At least some of the PPR recycles back to the cell membrane in a de-phosphorylated form, resulting in receptor resensitization. The PPR CT also mediates interaction with cytoskeletal scaffolding proteins, including members of the NHERF (Na^+/H^+ exchanger regulatory factor) family of proteins, which were identified in a yeast two-hybrid selection for proteins that bind the PPR CT. The C-terminal four amino acids (Glu-Thr-Val-Met) of the PPR mediate this interaction by binding to one of the PDZ domains of NHERF. The binding of NHERF to the PPR can alter the signaling pathways utilized, resulting in increased PLC signaling and diminished AC/cAMP signaling, and, as suggested by recent data, the internalization properties of the receptor, enabling the internalization of antagonist ligands.

The PPR in Human Disease

Jansen's Metaphyseal Chondrodysplasia

This rare autosomal dominant disease is characterized by short-limbed dwarfism (reflecting the role of PTHrP in the growth plates) and hypercalcemia (reflecting the role of PTH in bone and kidney). In 1995, a mutation in the *PPR* gene that changed His223 at the base of TM2 to Arg was identified in an affected individual. This mutation was then shown to confer high basal cAMP-signaling activity to the receptor expressed in COS-7 cells. Since this time, three other activating mutations in this disease have been identified, each of which alters a residue located near the intracellular termini of a TM helix: Thr410 → Pro and Thr410 → Arg in TM6 and Ile458 → Arg in TM7. In studies performed in transfected COS-7 cells, the antagonist [Leu^{11},$DTrp^{12}$]PTHrP(5–36) was shown to behave as an inverse agonist with the PPRs bearing either the His223Arg or Thr410Pro mutation, while the antagonist [Bpa^2]PTHrP(1–36) behaved as a selective inverse agonist, depressing cAMP signaling only with the His223Arg mutant. These findings with [Bpa^2]PTHrP(1–36) suggest that there may be variable conformational states of the active PPR.

Blomstrand's Chondrodysplasia

This rare perinatal lethal condition is characterized by a severely over-calcified fetal skeleton and short limbs.

Three different PPR-inactivating mutations have been identified in this recessive disorder: a messenger RNA splicing mutation that results in an eleven-amino acid deletion in TM5; a frameshift mutation in ECL-2, and a missense mutation (Pro132 → Leu) in the N domain. The phenotype seen in Blomstrand's chondrodysplasia mirrors that seen in mice having homozygous deletion of the *PPR* gene.

Conclusions

The PPR mediates the biological actions of two key proteins – PTH (calcium and phosphate homeostasis) and PTHrP (development). Disruptions of the PTH/PTHrP/PPR system result in a number of diseases of calcium ion homeostasis and tissue development (Figures 2 and 3). Further unraveling of the molecular mechanisms by which the PPR interacts with PTH and PTHrP is of fundamental biochemical interest and could lead to new therapies for diseases of bone and mineral metabolism.

Biography

Thomas J. Gardella, Ph.D., is an Associate Professor in Medicine with appointments at the Massachusetts General Hospital and Harvard Medical School. He has been a member of the Endocrine Unit of the M.G.H. since 1988, and his research interests focus mainly on the structure–activity relationships of PTH and the PTH receptor. He received his Ph.D. degree in molecular genetics and microbiology from the University of Massachusetts Medical School, Worcester, Massachusetts and a B.S. degree in biochemistry from the University of Massachusetts, Amherst, Massachusetts.

PCR (Polymerase Chain Reaction)

Michael J. Brownstein
National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland, USA

The polymerase chain reaction (PCR) is used to amplify DNA – i.e., to make millions of copies of a particular DNA segment. Invented by Kary Mullis in 1983, the process is simple, fast, and robust. It relies on synthetic oligonucleotide "primers," DNA polymerase(s), nucleotide bases, and a thermal cycler (a programmable instrument that varies and controls the temperature of the solution in which PCRs occur). The enzymes used, among them Taq, Pfu, and Vent polymerases are derived from *Thermus aquaticus*, *Pyrococcus furiosus*, and *Thermococcus litoralis*, respectively. These are bacteria that live in hot springs or undersea vents where the ambient temperature is high. Consequently, the enzymes they synthesize are thermostable. They differ in important ways, however. Taq polymerase, for example, is quite processive. That is, it copies DNA strands very efficiently, but it lacks 3′–5′ exonuclease activity, and is more error prone than Pfu and Vent polymerases, which have exonuclease activity and "proofread" their products. For this reason, enzyme mixtures are sometimes used to catalyze PCR reactions.

The Reaction Cycle

A polymerase chain reaction (PCR) cycle is illustrated in Figure 1. Step one is to melt or unzip the double-stranded DNA templates that will be copied. A thermocycler is used to increase the temperature of the reaction vessel to 90°C or more. At such temperatures most mammalian or bacterial enzymes would be inactivated, but they are well tolerated by the thermostable polymerases described above.

After the DNA strands have been separated, the temperature is dropped to permit short DNA primers to bind (anneal) to complementary sequences on the templates. The polymerases will not copy DNA in the absence of primers, and two are used – one for each of the two template strands that were liberated in step one.

Once they have found their specific target sequences, the polymerases can begin adding bases to the 3′ ends of the primers. Since this process is inefficient at the relatively low annealing temperature, the reaction temperature is increased to ~75°C. Now both of the DNA strands are quickly replicated, beginning at the priming site and ending, in theory, at the end of each template. As the figure shows, there are four DNA strands at the end of the first PCR cycle, instead of the original two. In subsequent cycles, products primed by the two oligonucleotides preferentially accumulate. The length of the "amplicons" is defined by the primers, which form their flanks. After about five PCR cycles have been completed, these amplicons predominate over longer species. It is important to note that at the beginning of a PCR, all of the reagents except for the template are present at high concentrations. Therefore, primer binding is favored over product renaturation, and the amplification is exponential. After many cycles have been completed, this may no longer be the case; product formation becomes linear and finally grinds to a halt. In practice, it is uncommon to use more than 30 reaction cycles.

Applications

PCR can be employed to amplify both DNA and RNA templates. In the latter case, reverse transcriptase (an RNA-directed DNA polymerase) is first used to make complementary DNA from the RNA of interest. DNA produced in this way can be substituted for the double-stranded DNA that served as the starting material in the scheme shown in Figure 1. This process is referred to as reverse transcriptase-PCR (RT-PCR). It allows much smaller amounts of RNA to be measured than can be detected with Northern blotting or RNase protection assays. In fact, real-time RT-PCR has become the method of choice for measuring changes in RNA when large numbers of samples have to be studied. This technique combines PCR with cycle-by-cycle detection of amplicons during the exponential phase of product buildup. Quantitation is based on the fact that many PCR cycles are needed to detect the products of rare targets, while few cycles are required to detect those of abundant ones. The dynamic range of the method spans 6–7 orders of magnitude. It is possible to amplify more than one product at a time with two or more primer pairs (multiplex PCR), and to detect the products with different dyes.

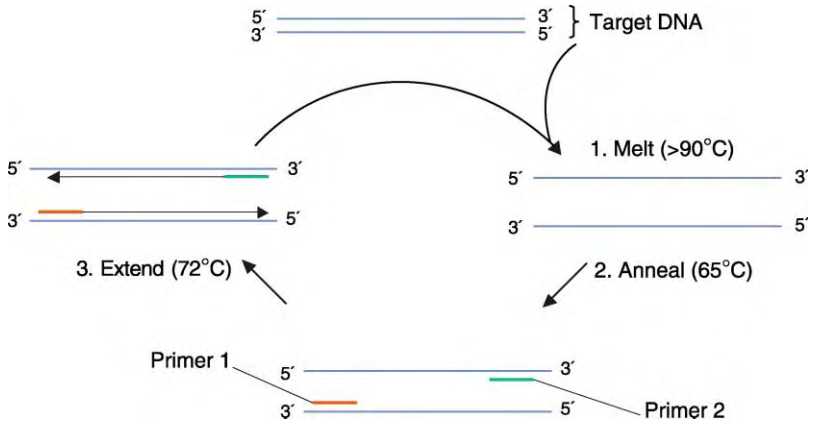

FIGURE 1 The PCR cycle.

It should already be clear that many PCR-based methods have been invented. Some are used for cloning, modifying, and/or sequencing amplicons; others are used for detection or measurement of RNA or DNA. To appreciate these methods, it is important to understand that many sorts of oligonucleotides can be used to prime PCR reactions. Thus, even though it is essential for the primers to be complementary to their targets on their 3′ ends, they can be quite different from the targets on their 5′ ends, where noncomplementary sequences, free amino groups, fluorescent dyes, or molecules like biotin can be added without adversely affecting the amplification process.

One of the earliest uses of PCR was in characterizing families of gene products, e.g., the rhodopsin-like G protein-coupled receptors. In humans there are more than 200 such proteins, exclusive of odorant receptors. After cDNA encoding the first few of these were cloned, it became clear that they were structurally similar, that they shared certain amino acid motifs. "Degenerate" PCR primer mixtures were designed on the basis of the conserved domains and used to amplify fragments of new family members from cDNA templates. Since these fragments lacked the 5′ and 3′ ends of the receptors' open reading frames, another PCR method called rapid amplification of cDNA ends (RACE) was used to identify and isolate the missing 5′ and 3′ termini. Once the sequences of the ends were determined, long-range PCR could be used to amplify the entire open reading frame, using primers with convenient restriction sites on the 5′ ends to facilitate "pasting" the inserts into vectors.

Some scientists were interested in studying the relationship between the structures of receptors (and other proteins) and their functions. To do this, they used PCR to introduce mutations into the receptors or to construct chimeric proteins – half one receptor, and half another, or tagged receptors, which could be used to study protein trafficking in cells. The constructs were sequenced before they were expressed in cells to be sure that no errors were made in producing them. The sequencing reactions were also PCR based. In fact, it is safe to say that the much-heralded sequencing of the human and mouse genomes could not have been accomplished without the method, and DNAs from living species are not the only templates that have been analyzed. PCR has allowed DNA from ancient samples (e.g., insects embedded in amber, tissue from mummies and extinct species like the Quagga) to be characterized.

The instruments used for DNA sequencing can be employed for genotyping as well. To do this, fluorescent PCR primers are used to amplify variable number tandem repeats or single nucleotide polymorphisms that serve as markers for inherited segments of chromosomes. The resulting data are used for linkage analysis, permitting scientists to determine the chromosomal location of disease-causing genes. Once these genes are known, robust screening methods – also based on PCR – can be developed to screen for carriers of deleterious mutations and even to look for mutations in pre-implantation embryos.

Genotyping has other potential uses too. It permits livestock and plants to be improved, and identity, paternity, or culpability of subjects to be determined by forensic scientists.

Finally, PCR is used to detect pathogens in clinical samples, food, and water, and to search for mutations in cancer-causing genes in tumors, or polymorphisms in drug metabolizing enzymes and transporters that affect efficacy/toxicity. It is not unlikely that it will play an important role in the development of personalized medicine in the future. In fact, its use may not be limited to assays of DNA and RNA. PCR-ELISA is an

exquisitely sensitive way to detect any molecule to which an antibody can be raised.

Pentose Phosphate (Hexose Mono Phosphate) Pathway

Bernard R. Landau
Case Western Reserve University, Cleveland, Ohio, USA

The pentose phosphate pathway is the major source of NADPH for reductive biosynthesis and is the source of ribose-5-P for nucleotide and nucleic acid synthesis. Its reactions are usually viewed in two segments. In the first, glucose-6-P is irreversibly oxidized, generating NADPH and pentose-5-P. In the second, the pentose-5-P is reversibly converted through a series of rearrangements to intermediates of the glycolytic pathway. The pathway is in the cytosol.

History

In 1931, Warburg demonstrated glucose-6-P's oxidation to 6-phosphogluconate with the formation of NADPH. In the following decade, Warburg, Lipmann, Dickens, and others found that the gluconate was decarboxylated to CO_2 and to a pentose phosphate that could then be reconverted to hexose-6-P. Details of the pathways were elucidated in the 1950s by Cohen, Racker, Horecker, and their associates. Figure 1 shows the pentose phosphate pathway.

Reactions

Oxidative Segment

Glucose-6-P oxidation is catalyzed by glucose-6-P dehydrogenase, yielding 6-phosphogluconolactone and NADPH (Figure 2). The spontaneous hydrolysis of the lactone, forms 6-phosphogluconate, catalyzed by a specific lactonase. The gluconate is oxidatively decarboxylated to yield another NADPH and ribulose-5-P. The overall reaction of this segment is then glucose-6-P $\rightarrow$ CO_2 + 2NADPH + ribulose-5-P.

Nonoxidative Segment

The ribulose-5-P is isomerized to ribose-5-P and also epimerized to xylulose-5-P (Figure 3). Transfer of the top 2 carbons as a unit from the xylulose-5-P to ribose-5-P, catalyzed by transketolase, yields seven carbon containing sedohepulose-7-P and glyceraldehyde-3-P. Transfer of the top 3 carbon unit as a unit from the sedohepulose-7-P to the glyceraldehyde-3-P, catalyzed by transaldolase, yields fructose-6-P and 4 carbon containing erythrose-4-P. Transfer of the top 2 carbons as a unit from another xylulose-5-P to the erythrose-4-P, again catalyzed by transketolase, yields fructose-6-P and glyceraldehyde-3-P. Thus, the overall reaction of this segment is 3 pentose-5-P $\leftrightarrow$ 2 fructose-6-P + glyceraldehyde-3-P.

Transketolase requires thiamine pyrophosphate as a cofactor. The 2 carbon unit is transferred via its addition to the thiamine ring of the vitamin. The mechanism is similar to that in the oxidative decarboxylation of pyruvate, catalyzed by the thiamine pyrophosphate containing E_1 subunit of the pyruvate dehydrogenase complex. In the transfer of the 3 carbons unit, catalyzed by transaldolase, a Schiff base is formed between the ketone group of the sedohepulose-7-P and a lysine residue at the active site of the enzyme. The mechanism is similar to that in fructose-1, 6-bisphosphatase aldolase catalysis.

Overall Balance and Carbon Fate

On balance, 3 glucose-6-P (18 carbons) are decarboxylated to yield 3 CO_2 and 3 pentose-5-P (15 carbons) (Figure 4). The rearrangements, catalyzed by transketolase and transaldolase produce 2 fructose-6-P (12 carbons) and glyceraldehyde-3-P (3 carbons). The CO_2 contains carbon 1 of the glucose-6-P (Figure 5). The origin of the top 3 carbons of the 2 fructose-6-P are carbons 2 and 3 of the glucose-6-P.

Mode of Operation

Shunt or Cycle

Since glucose-6-P is converted to fructose-6-P and glyceraldehyde-3-P, the pentose phosphate pathway has been viewed as an alternate route for the conversion

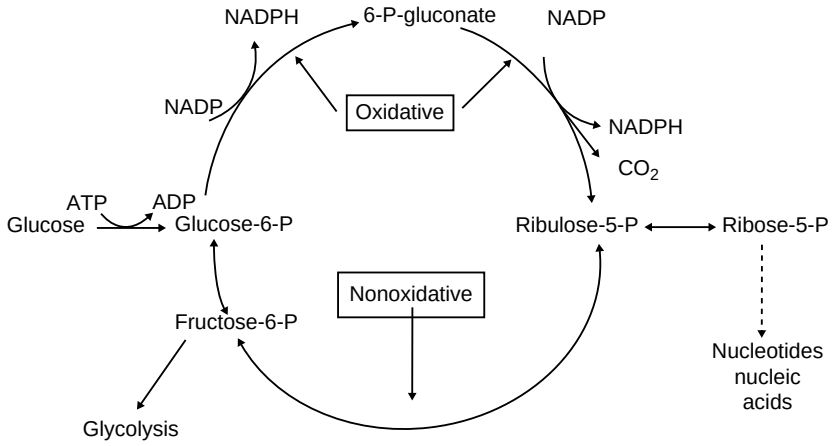

FIGURE 1 Depiction of the pentose phosphate pathway as a cycle composed of oxidative and nonoxidative segments.

of glucose-6-P to intermediates of the glycolytic pathway. Therefore, the pathway has also been called the hexose monophosphate shunt. Since the fructose-6-P can be isomerized to glucose-6-P that can re-enter the pentose phosphate pathway, the pathway has also been viewed as a cycle and called the pentose cycle.

Regulation

The dehydrogenation of glucose-6-P, the first step, is considered to be the rate-limiting step in the oxidative segment. Control is through the activity of glucose-6-P dehydrogenase regulated by the concentration of NADP. NADPH competes with the NADP for binding to the enzyme, thus tightly coupling NADPH production to utilization. When NADPH is utilized (e.g., in fatty acid synthesis), the NADPH is oxidized, increasing NADP and stimulating flux through the oxidative segment. Flux through the nonoxidative segment is determined by the concentration of pentose-5-P. The activity of the pathway is coordinated with that of the pathways utilizing its products. Recent studies identify xylulose-5-P in the pathway as mediating the effect of carbohydrate feeding on the glycolytic pathway and regulating the enzymes required for fatty acid and triglyceride synthesis.

Other Functions

The pentose phosphate pathway is the route by which pentose from food is metabolized. Erythrose-4-P in some organisms is used as an intermediate in the synthesis of the aromatic ring of the amino acids. D-xylulose formed in the glucuronic acid pathway, is further metabolized via the pentose phosphate pathway.

Quantitation

Methods

Estimates of the activity of the pathway rest on measurements of the activities of its enzymes, particularly of glucose-6-P dehydrogenase, and of concentrations of intermediates in the pathway, as well as yields

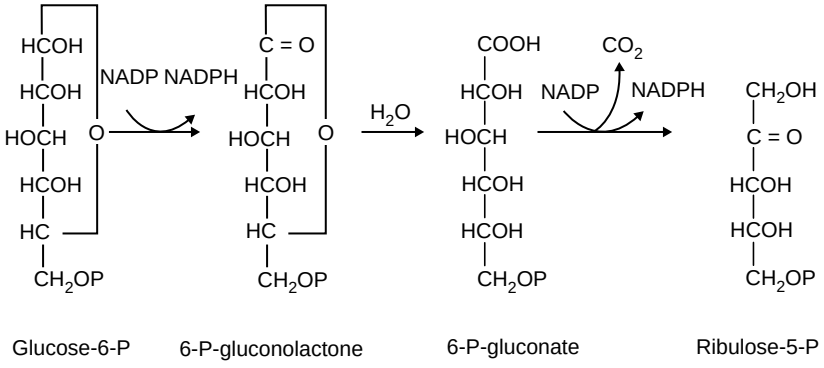

FIGURE 2 Reactions of the oxidative segment of the pentose phosphate pathway.

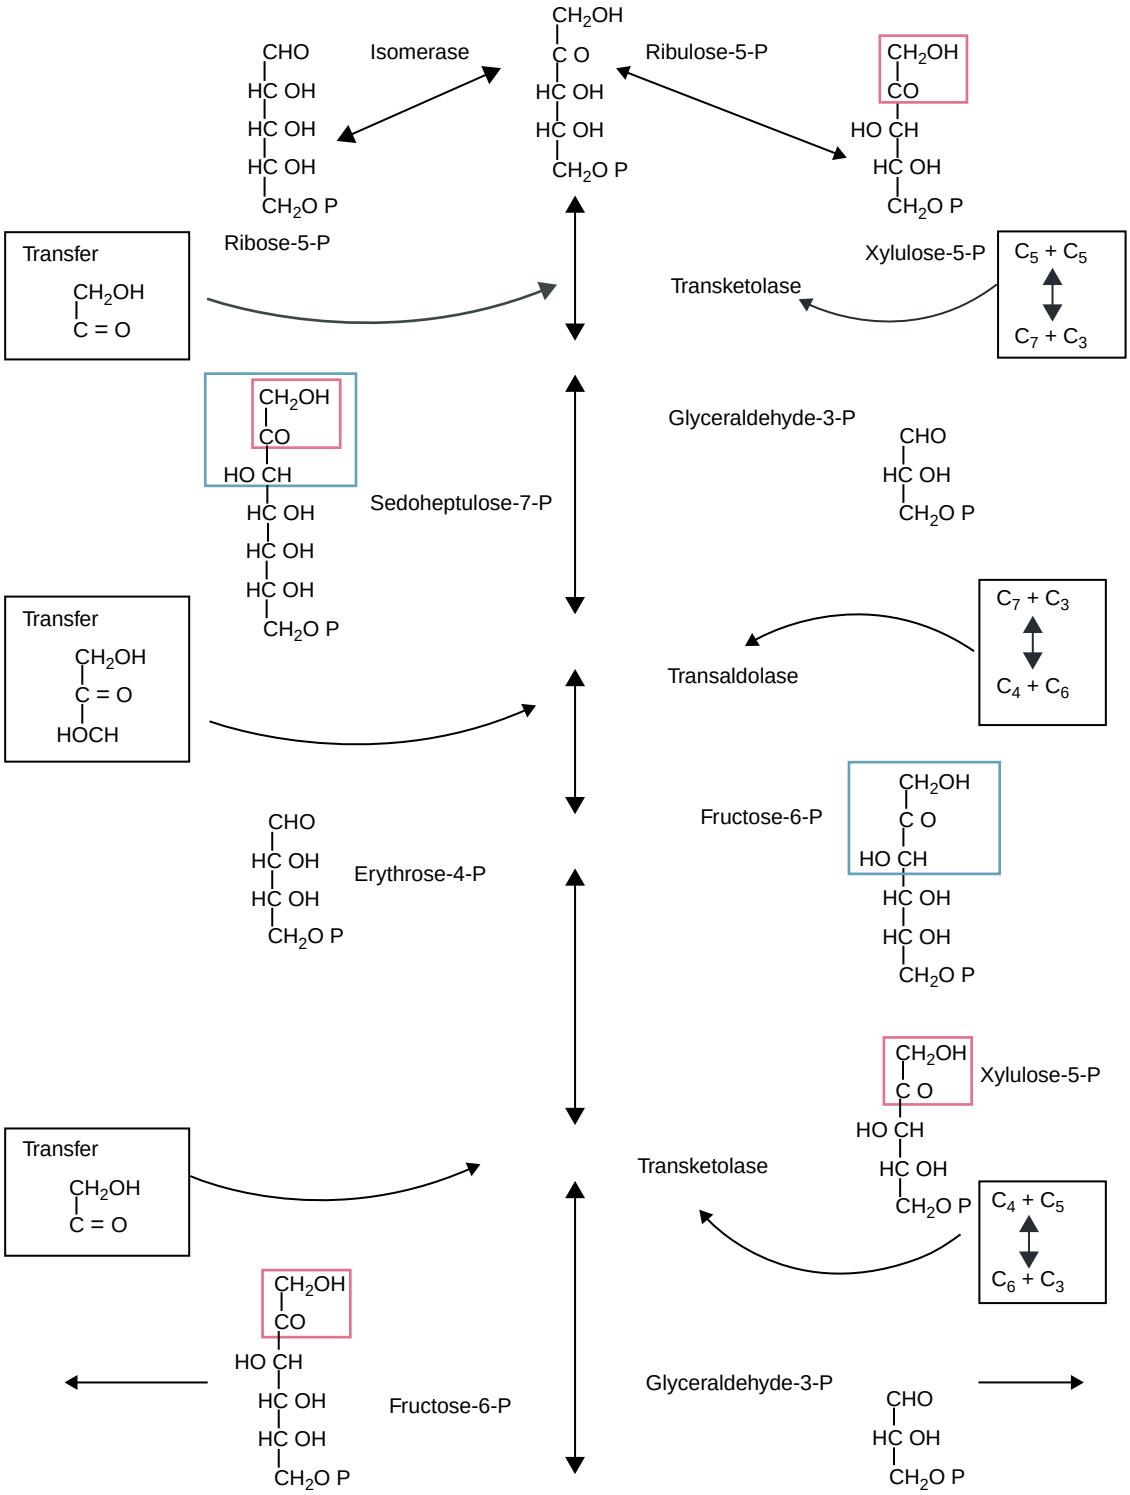

FIGURE 3 Reactions of the nonoxidative segment of the pentose phosphate pathway.

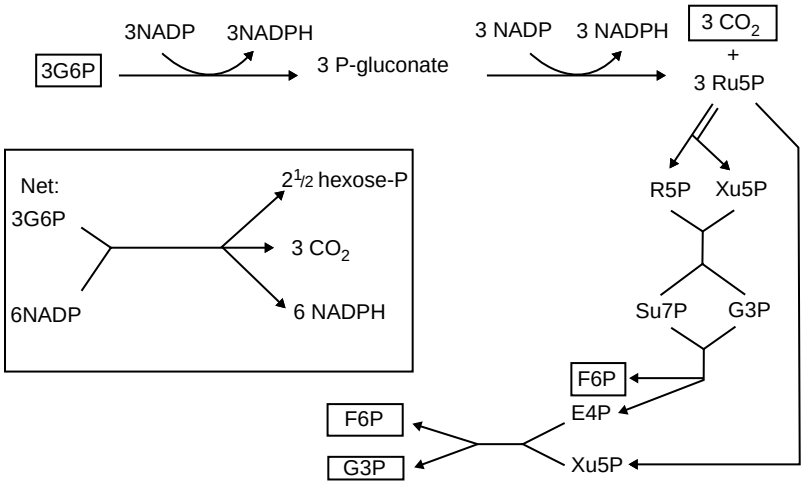

FIGURE 4 Chemical balance in the reactions of the pentose phosphate pathway.

of labeled products after administering labeled substrate and intermediates of the pathway. Specifically, carbon-labeled glucoses have been used to quantitate the amount of glucose utilized by the pathway relative to other pathways utilizing glucose. The quantitations depend on (1) the fact that carbon 1 of every molecule of glucose-6-P entering the pathway is oxidized to CO_2, while via glycolysis and the tricarboxylic acid cycle, carbons 1 and 6 are oxidized to CO_2 to essentially the same extent, or (2) the randomization of carbons 2 and 3 of glucose-6-P occurring in the nonoxidative segment (Figure 5).

The amounts of glucose oxidized and that utilized by the pathway are different. Thus, while the three molecules of glucose-6-P that enter the pathway (Figure 4) are oxidized, and 2 glucose-6-P equivalents are reformed, only a net of 1 glucose-6-P is utilized. It is converted to CO_2 and glyceraldehyde-3-P. If, as can occur in the liver, 2 glyceraldehyde-3-P that are formed are converted to 1 glucose-6-P, the balance becomes 6 glucose-6-P → 12 NADPH + 6 CO_2 + 5 glucose-6-P. Hence, 6 glucose-6-P are oxidized, but only 1 glucose-6-P is utilized (completely oxidized to CO_2).

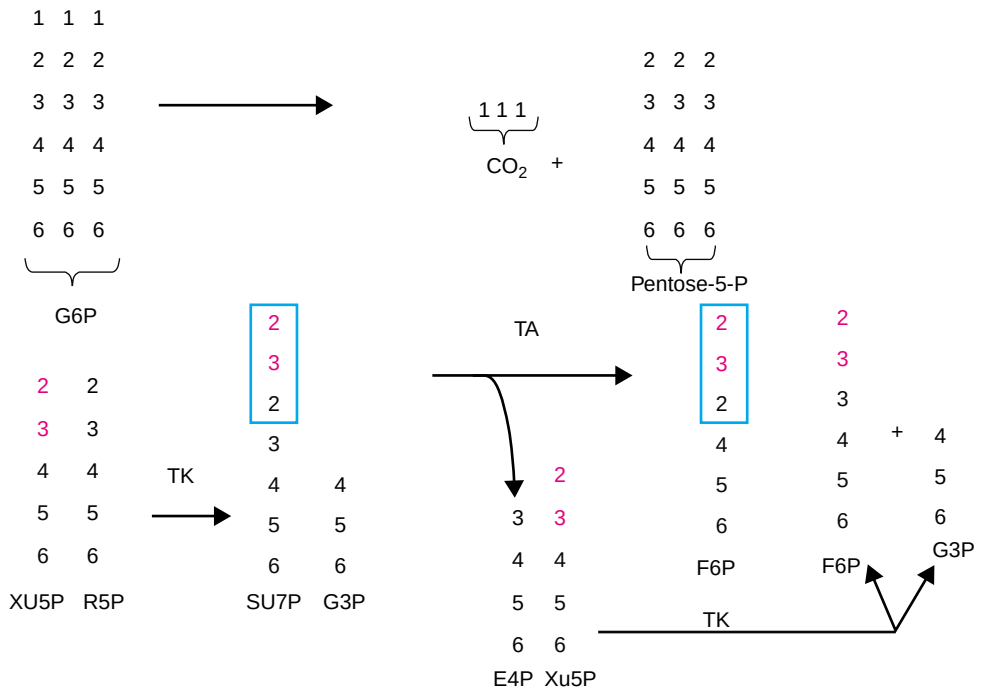

FIGURE 5 Fate of the carbons of the glucose-6-p (g6p) in its metabolism via the pentose phosphate pathway.

Estimates

The pathway is present in all cells. The highest activities are found in tissues where lipogenesis is prominent, e.g., liver, mammary gland, particularly during lactation, and adipose tissue. The pathway is also active in the reproductive glands, adrenal gland, and red blood cells. In those tissues 10–20% of glucose utilization may be via the pathway. The pathway has relatively high activity in growing tissue, e.g., in fetal and newborn tissues and tumors.

Clinical Importance

Maintaining the integrity of the red blood cells depends on having an adequate supply of reduced glutathione to protect the cells from toxic peroxides, as well as maintain hemoglobin in a reduced state. Several hundred million people, mainly in Africa, Asia, and the Mediterranean, have a genetic deficiency of glucose-6-P dehydrogenase. Drugs which increase the formation of peroxide, infections, and other causes of oxidative stress can induce acute hemolysis and hence anemia in those individuals.

The Wernicke–Korsakoff syndrome is a neuropsychiatric disorder occurring in individuals with a dietary deficiency of thiamine. Findings are eyeparalysis, abnormal gait, confabulation, and loss of memory. A genetic defect in transketolase has been suggested as the reason the syndrome is only observed in a small portion of those with thiamine deficiency. A genetic abnormality in transketolase has recently been found in a man with liver cirrhosis.

Biography

Bernard R. Landau is a Professor of Medicine and Biochemistry at Case Western Reserve University and former Director of the Division of Endocrinology at University Hospitals of Cleveland. His research has focused on carbohydrate and lipid metabolism using radioactive and staple isotope tracer technology. He received a Ph.D. in chemistry from Harvard School of Arts and Sciences and an M.D. from Harvard Medical School.

Pentose Phosphate Pathway, History of

John F. Williams
Australian National University, Canberra, Australia

In this article the oxidative and non-oxidative segments of the pentose pathway (PP) of glucose metabolism are defined. The discovery in 1931–1935 by the German biochemist, Otto Warburg, of the oxidative division of the pathway and of the chemistry and role of a new pyridine nucleotide co-enzyme in its reactions is deliniated.

Background

The successful revelation of many of the reactants and enzymes of the non-oxidative PP was largely achieved by two American biochemists, Bernard L. Horecker and Ephraim Racker who, during 1950–1955, independently accomplished our current text-book knowledge of the classical reaction scheme of PP. A precise reaction order and metabolic map depiction of PP reactions was published by Horecker in 1955 from results of prediction labeling experiments that used variously labeled ^{14}C-ribose 5-phosphate dissimilation by liver and plant tissue extracts. Many PP reactions were also assigned roles in the path of carbon in photosynthesis that was unraveled by Calvin and colleagues during 1945–1954. The above accomplishments briefly terminated fundamental research on the nature of PP which was then replaced by an era (1958–1979) of metabolic pathway measurement.

Joseph Katz and Harland G. Wood were the pioneers who developed theory and methods for quantitative measurement of the contributions of pentose cycle (PC) and other pathways to total glucose metabolism. All of these methods depended on the metabolism of ^{14}C-labeled substrates. PC was measured to a significant level in many animal tissues but made its most notable contribution in adipose tissue, which resulted in the PP being renamed the (fat) F-type PP. Contrary to all expectation, many attempts to quantify PC in liver, the major tissue used by Horecker to establish the reaction scheme for the F-type PP, showed it measured a negligible and therefore puzzling contribution to glucose metabolism.

Based on these latter findings the reaction mechanism of PP was reinvestigated during 1965–1992 by Williams and colleagues in Australia. Liver featured in the investigations because it is a rich source of the enzymes and individual reactions of PP. New octulose and heptulose phosphate reactants and new enzyme activites were discovered. Using specifically ^{14}C-labeled substrates, a revised (liver) L-type PP was identified which quantitatively accounted for 25% of total glucose metabolism. These results aroused criticism and polemic by those defending F-type PC theory and measurement practice. This unsettling state was put to rest in 1993 when the Williams group, using ^{13}C-NMR spectrometry showed that the three group transferring enzymes of the PP, namely transketolase, transaldolase and aldolase catalyzed simultaneous mass transfer and group exchange reactions and in all cases the exchange rates exceeded the mass flux rate. As an example it was found that Transketolase exchange rates in normal and regenerating liver, four different neoplasms, spinach chloroplasts and adipocytes exceeded PP flux rates by 5–600 times. Since the groups being transferred by the above enzymes are ^{14}C-labeled in all of the unraveling investigations that involved F-type and L-type pathways, it is concluded that carbon isotope prediction labeling data are useless for the investigations of the reaction order and measurement of PP. Thus metabolic maps of PP in textbooks of biochemistry are erroneous. A concluding statement that best describes how the PP should now be viewed is given.

All or at least a substantial selection of the reactions of the pentose phosphate (PP) pathway of glucose metabolism occur in the cytoplasmic compartment of most cells. The reaction scheme is in two parts and consists of oxidative (Figure 1) and nonoxidative segments (Figure 2). The reactions of the oxidative segment are few and involve the decarboxylation of glucose-6-phosphate (Glc 6-P) to ribulose 5-phosphate (Ru 5-P) via 6-phosphogluconolactone and 6-phosphogluconate (6-Pg). There is concomitant production of two moles each of reduced nicotinamide-adenine dinucleotide phosphate (NADPH) and proton for each mole of Glc 6-P converted to Ru 5-P by oxidative decarboxylation. The non-oxidative reactions (Figure 2) are classically

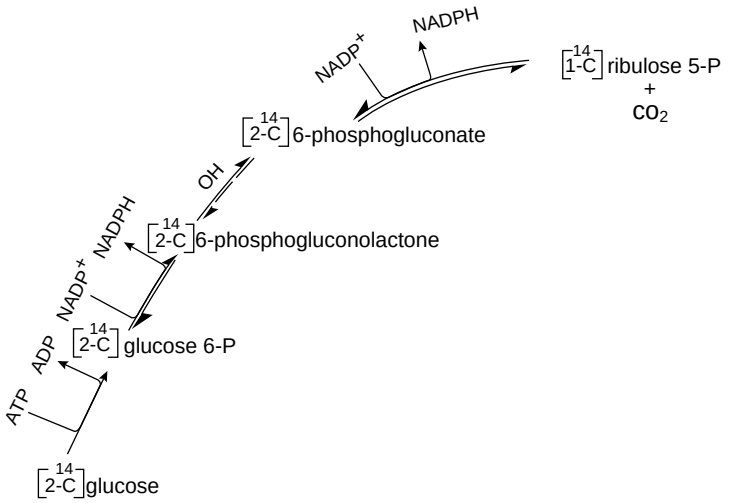

FIGURE 1 Reactions of the oxidative segment of the pentose pathway showing the conversion of [2-^{14}C]-glucose to CO_2 and [1-^{14}C]-ribulose 5-phosphate. Glucose is phosphorylated by hexokinase and oxidatively decarboxylated by the concerted actions of glucose 6-phosphate dehydrogenase, water at pH 7.4 or lactonase and 6-phosphogluconate dehydrogenase (see glossary for equation).

depicted as a diversity of reversible steps for the interconversion and linkage of other pentose phosphate products that arise from Ru 5-P, with triose and hexose phosphates that are also common intermediates in cytoplasm of the higher flux glycolytic pathway of glucose metabolism. The reactions of Figure 2 also show sugar phosphate intermediates (glycolyl units) with 3, 4, 5, 6, and 7 carbon atoms that are generated by the reversible reactions of the nonoxidative segment. There are thus three biosynthetic functions of PP reactions that relate to cellular energetics, growth, and repair: (1) the contribution by the oxidative segment to the provision and maintenance of a high NADPH/$NADP^+$ redox potential and thereby the supply of electrons for some reductive anabolic processes; (2) the formation of ribose 5-phosphate (Rib 5-P) for all nucleotide and nucleic acid biosynthesis; and (3) a storage pool of diverse phosphorylated glycolyl units that may be used in biosynthetic and energy-yielding reactions by other pathways. Finally, selected reactions of the nonoxidative segment are also part of the most extensive synthetic and life-sustaining event on the planet, namely, the photosynthetic reductive path of CO_2 assimilation in all C-3 plants.

Early Discoveries

A summary of the biochemistry of the reactions, enzymes, methods, distributions, and quantitation of the pathways of Figures 1 and 2 in tissues, together with all references cited in this article that relate to the history of the "unraveling" events of the pathway, are given in a comprehensive review of the PP by Williams J. F. *et al.* in 1987. Discoveries which led to the formulation of the classical depiction of the PP (Figures 1 and 2) commenced in 1931 with the discovery of glucose 6-phosphate dehydrogenase (Glc 6-P DH) by Otto Warburg, a German biochemist and a Nobel laureate of extraordinary distinction and influence. Warburg named the enzyme *Zwischenferment* (intermediate enzyme) in order to designate the branching of Glc 6-P away from the pathway of fermentation (glycolysis). In 1935 a second enzyme, 6-phosphogluconate dehydrogenase, was isolated together with a new pyridine nucleotide coenzyme (*Wasserstoffübertragendes*: hydrogen-carrying coferment), which is now called $NADP^+$. Warburg recognized that $NADP^+$ was chemically and functionally different from the NAD^+ coenzyme of glycolysis. With these discoveries Warburg had opened the way into an alternate path of glucose dissimilation. Warburg believed that the NADPH product of these reactions was the substrate of cellular respiration and was thus a prime chemical source of aerobic cellular energy. This view was strongly held and disseminated for the next 20 years, such that the PP was first called the "direct oxidative pathway" in order to distinguish it from the path of fermentation of glucose and lactic acid formation in muscle.

The proposition linking NADPH and respiration (eqns. [1]–[3]) was shared by Erwin Haas, who was a member of Warburg's Berlin-Dahlem laboratory. (Haas fled Germany in 1938 and proceeded to the University of Chicago, where he was joined by Bernard Horecker, a fresh Ph.D. graduate, who was already exhibiting a flair for enzymology.) Haas possessed much of Warburg's data, understood his methods very well, and had a plan of research to test the proposed role of NADPH in respiration. Haas and Horecker set out to isolate a putative NADPH-cytochrome *c* reductase (eqn. [1]) in order to demonstrate the existence and nature of an

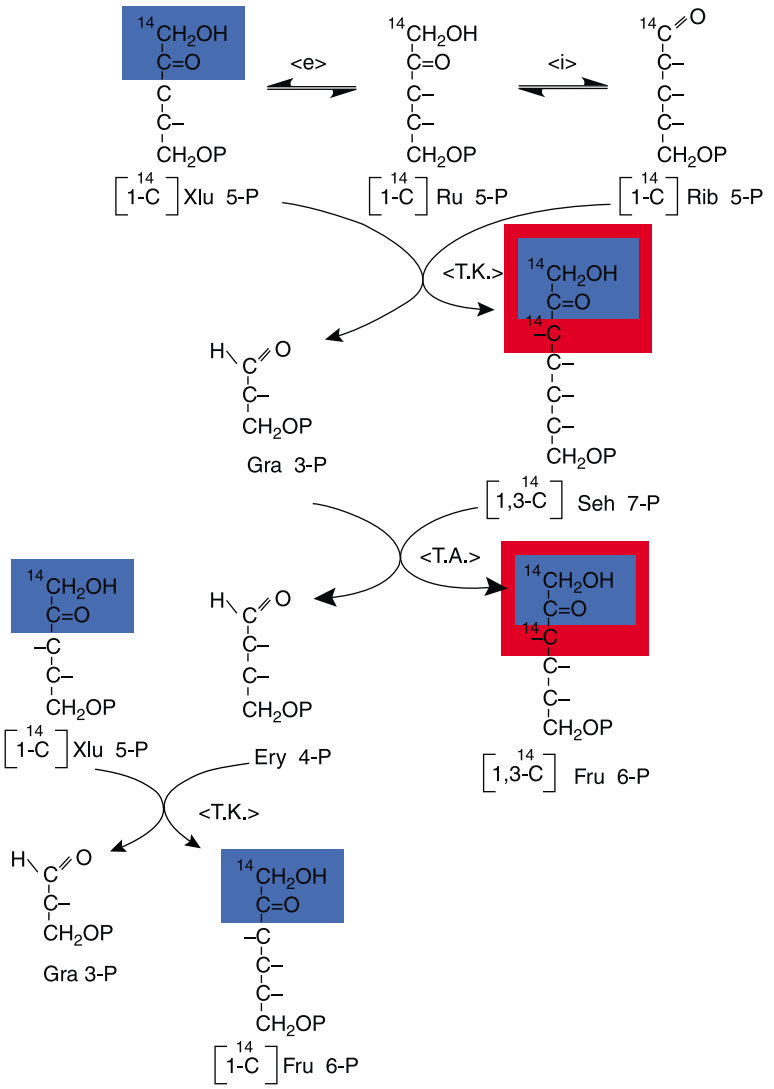

FIGURE 2 The proposed reaction sequence of the non-oxidative segment of the *classical* F-type pentose pathway *in vitro*. The [1-^{14}C]-ribulose 5-P substrate is the labeled product of the Figure 1 reaction scheme and the reactions display the theoretical distributions of ^{14}C-isotope from pentose 5-P into the carbon atoms of labeled intermediates and products. The enzymes catalyzing the reaction steps are: e, ribulose 5-phosphate 3-epimerase, i, ribose 5-phosphate isomerase; TK, transketolase; TA, transaldolase. The blue panels show the two-carbon active *glycolaldehyde* group that is conveyed by TK mass transfer and group exchange. The red panels show the three-carbon *dihydroxyacetone* group that is carried by TA mass transfer and exchange (see text and glossary for other detail).

enzyme that was hypothesized to be the "missing link" in a respiratory pathway between reduced pyridine nucleotide and oxygen via the cytochrome system (eqn. [3]):

$$\mathrm{NADPH + H^+ + Cyt\text{-}cFe^{3+} \xrightarrow{\text{NADPH cytochrome } c \text{ reductase}} NADP^+ + Cyt\text{-}cFe^{2+} + 2H} \quad [1]$$

$$\mathrm{2H + Cyt\text{-}cFe^{2+} + 0.5\ O_2 \xrightarrow{\text{Cytochrome oxidase}} H_2O + Cyt\text{-}cFe^{3+}} \quad [2]$$

Sum reaction:

$$\mathrm{NADPH + H^+ + 0.5\ O_2 \longrightarrow NADP^+ + H_2O.} \quad [3]$$

The search for an enzyme activity was successful and a reasonably pure flavoprotein, NADPH-cytochrome *c* reductase, was isolated from yeast in 1940. Research was interrupted and not taken up again until the end of the Second World War. By 1948, Horecker had returned to the project and soon extensively purified the enzyme from liver. However, by that time, there was growing evidence that the oxidation of NADPH was not the source of reducing equivalents for respiration and the entire proposal was abandoned in 1951, when Albert Lehninger showed that NADH was the "low-redox" respiratory chain substrate for oxidative phosphorylation in mitochondria.

The understandable disappointment with the realization that NADPH-cytochrome *c* reductase had no role in respiratory energy production (it is now known to be part of the cytochrome P-450 hydroxylation-detoxification scheme) directed Horecker's interest to a larger problem, namely, an inquiry into the nature, fate,

and metabolic role of the pentose product of 6-Pg decarboxylation (Figure 1). It is also noteworthy that the British biochemist Frank Dickens (Courtauld Institute, UK) had been making pioneering investigations on this topic since 1936. However, a solution of the problem was made in the USA, where metabolic biochemistry and enzymology were flourishing in the 1950s. The dominant contributions came from the laboratories of Bernard Horecker, Ephraim Racker, and Seymour Cohen. Moreover, a further stimulus was the spectacular investigation made in Melvin Calvin's laboratory at UC Berkeley, which led to a Nobel prize and an understanding of the path of carbon fixation in photosynthesis (PS). Calvin's progress was heavily dependent on success in research by the aforementioned biochemists to resolve the enzymology and chemical problems posed by the reactions of Figure 2.

By 1950 all investigators possessed strong clues which served as signposts for an ultimate elucidation of a PP reaction scheme. (1) There was clear evidence that an alternate path of Glc 6-P dissimilation existed in yeast, red cells, and other animal tissues. (2) Dickens had confirmed that 6-Pg was oxidatively decarboxylated at carbon 1, to yield pentose 5-phosphate and other sugar phosphate products including a putative tetrose-P. He also demonstrated that Rib 5-P was oxidized at 5 times the rates of arabinose 5-phosphate (Ara 5-P) and xylose 5-P (theoretical products of 6-Pg decarboxylation). (3) Finally, as early as 1938, Zacharias Dische, using red cell lysates, found that inosine and inorganic phosphate (P_i) were converted to triose and hexose phosphates. This last important finding of the possible end products of Rib 5-P dissimilation was confirmed in 1946 by Schlenk and Waldvogel, who showed Glc 6-P formation from Rib 5-P using rat liver extracts.

Post Second World War Discoveries of Reactions in the Nonoxidative Segment of the Pentose Pathway

With the above background, between 1950 and 1955, very significant discoveries of enzyme and substrate reactivities followed, which were incorporated into a reaction scheme (mechanism) for the "classical" nonoxidative PP (Figure 2). The diagram in the figure is also designated the F-type (for fat-cell) PP, because it was later shown to uniquely measure a quantitatively large contribution to metabolism when Glc was converted to fatty acid and triglyceride in insulin-stimulated adipocytes. The findings may be summarized in the following temporal conjunction. In 1951 Cohen's group showed that Rib 5-P and Ara 5-P were formed from 6-Pg oxidation. Horecker and his collaborators confirmed Rib 5-P formation and unequivocally established that Ru 5-P was the first pentose-P formed from 6-Pg decarboxylation. They also identified a new enzyme, ribose 5-phosphate isomerase, which catalyzed the interconversion of the two pentose phosphates (see Figure 2). In 1952, Horecker and Smyrniotis, using a liver enzyme preparation, reported the important observation that Rib 5-P was metabolized to sedoheptulose 7-phosphate (Seh 7-P). This seven-carbon ketosugar ester was also found by Andy Benson, in Calvin's laboratory, and was identified as an early product of PS carbon fixation. Seh 7-P was formed by the action of transketolase (TK) (see Figure 2). TK was discovered by Racker and his collaborators in 1951, and it was demonstrated that it catalyzed the transfer of a two-carbon fragment (an active glycolaldehyde group) from appropriately structured ketulose-sugar donors to a wide selection of aldo-sugar acceptors. Two of its donor transfer actions, using different aldo acceptors, are shown as blue rectangular panels in Figure 2. The enzyme requires Mg^{2+} and thiamine pyrophosphate to be active and the list of 15 of its glycolaldehyde acceptor substrates is tabulated. Horecker's group discovered another broad-specificity group transferring enzyme, namely, transaldolase (TA), which catalyzed the reversible transfer of a dihydroxyacetone-enzyme-bound moiety (shown as red panels in Figure 2) from Seh 7-P to glyceraldehyde 3-phosphate (Gra 3-P), thereby forming Fru 6-P and a tetrose phosphate, which was neither isolated nor identified. The availability of synthetic erythrose 4-phosphate (Ery 4-P) enabled Kornberg and Racker to demonstrate the reversal of the TA reaction (eqn. [4]), thus satisfying the reason for its specific inclusion as an intermediate in the reaction scheme of Figure 2. Ery 4-P probably only exists in exceedingly low concentrations in any tissue and to date there is no evidence that it has ever been correctly measured in, or isolated from, any preparation carrying out PP metabolism.

$$\text{Fru 6-P} + \text{Ery 4-P} \longleftrightarrow \text{Seh 7-P} + \text{Gra 3-P}. \quad [4]$$

Finally, in 1954, a third ketopentose ester, xlulose 5-phosphate (Xlu 5-P), was isolated as a product of Rib 5-P metabolism by Ashwell and Hickman. Racker showed that this new intermediate, rather than Ru 5-P, was a definitive substrate of TK. The ribulose 5-phosphate-3′-epimerase (see Figure 2) that catalyzed the formation of the ketosugar imparted the *trans*-configuration to the hydroxyl at C-3, which is the necessary stereochemical condition for substrate reactivity. The 3′-epimerase was simultaneously purified in 1956 by Stumpf and Horecker at NIH and by Dickens and Williamson in the UK (Williamson later became the lifelong collaborator of Hans

Krebs) in the UK. In summary, the above research had uncovered an array of substrates and enzymes that could possibly satisfy the minimum requirements for a new pathway that connected the product of 6-Pg decarboxylation with the formation of hexose and triose phosphates.

Finding a Reaction Sequence for the Nonoxidative Pentose Pathway

It is possible to draw various theoretical schemes that oblige the arithmetic conjunction of five carbon sugars with a summary outcome of sugar products that contain six and three carbon atoms, respectively. That variety is greatly enhanced if reactions by aldolase (Ald) are included. Aldolase occupies the same cellular compartment as the PP; it is a dihydroxyacetone 3-phosphate (DHAP) group transferring enzyme, with a catalytic capacity that is usually much greater than TK or TA (a notable exception is adipose tissue where Ald activity is low and only approximates the activity of TK and TA). Ald also has a broad substrate array of aldo-sugar phosphate acceptors, most of which are the same substrates as those involved in TK and TA reactions. (It has never been clear why the pioneering investigators of the nonoxidative PP assigned aldolase a role of catalytic "silence.")

The results of the two experiments that aimed to identify the reaction sequence (mechanism) of the PP were published by the Horecker group in 1954. Briefly, Horecker adopted a prediction-labeling technique using [1-^{14}C]- and [2,3-^{14}C]-Rib 5-P as substrates and enzyme preparations from rat liver, pea leaf, and pea root tissues to catalyze the formation of ^{14}C-labeled hexose 6-P. It was assumed that the position and degree of any ^{14}C- labeling in Glc 6-P formed from these variously labeled substrates would indicate the nature and order of the reactions involved in Fru 6-P formation (see Figure 2). The enzyme preparations were made from acetone-dried powders of the above tissues. They were therefore free of all nucleotides and thus confined the reactions to a hexose 6-P end point by preventing any possibility of its recycled return through the oxidative segment, with consequent further scrambling of a "predicting" isotope-labeling pattern. Mg^{2+} was also omitted from the reaction mixture in order to inhibit the activity of fructose bisphosphatase and thus the formation of a contaminating Fru 6-P resulting from aldolase manufactured Fru 1,6-P_2 using the triose-P products of TK-catalyzed reactions.

The experiments with liver enzyme preparation were of 17 h duration. Ribose 5-P was rapidly utilized during the initial 3 h and Seh 7-P also accumulated during this early period. Only with the slow decline in Seh 7-P at 6 h was there an increased linear production of Glc 6-P, which was harvested after 17 h and degraded carbon atom by carbon atom to produce the ^{14}C distribution pattern of the whole molecule. The results, using [1-^{14}C]-Rib 5-P as substrate showed that the Glc 6-P product was labeled with ^{14}C isotope in carbons 1 and 3 (see Figure 2) with a C-1/C-3 ratio of 3 (74% of the ^{14}C isotope in C-1 and 24% in C-3). Horecker "tentatively" proposed that the reaction scheme of Figure 2 was consistent with the above isotope distribution. Clearly the consistency is not there, because the pooled [1,3-^{14}C]-Fru 6-P formed in the TA and second TK-catalyzed reactions in Figure 2 impart a ^{14}C content in C-1 and C-3 with a ratio of 2 (twice as much in C-1 as C-3). The difference is serious and the isotope distributions cannot be reconciled with the Figure 2 reaction scheme, nor can the difference be attributed to the tedious analytical and degradative procedures, since the percentage errors in the determination of C-1 are only 2%; C-2, 2.7%; and C-3, 1% with a cumulative percentage error of 12% for the estimate of all carbons of the molecule. The results of the companion experiment conducted by Gibbs and Horecker in1954 used [2,3-^{14}C]-Rib 5-P as substrate and liver, pea root, and pea leaf enzyme preparations made from the acetone-dried powders of these tissues. The results deviated even more radically from the predictions imposed by the sequences of Figure 2 than the above data using [1-^{14}C]-Rib 5-P. It is emphasized that in the publications of these two studies, an ordered series of chemical equations for the nonoxidative PP was only "tentatively" proposed and a metabolic map was not shown. However, in 1955, Horecker authored two important and substantial reviews of carbohydrate metabolism and presented for the first time the diagram illustrating the new metabolic pathway (still with the "tentative" caveat). This illustration (Figure 2) is still the chart of the PP or pentose cycle (PC)—a pathway that has featured in textbooks of general biochemistry since 1956. It is astonishing that such a profound disagreement between practice and theory was so uncritically ignored by the general community of biochemists and glossed over by the very few who drew it to attention in the review literature. This indifference resulted in the prompt inclusion of the scheme of Figure 2 into the canon of metabolic biochemistry without further inquiry. It is also ironic that the participation of a large number of PP reactions into the path of carbon in PS added confidence and prestige to the status of the PP. However, there were two other comprehensive investigations of the mechanism of the PP, one by Joseph Katz and co-workers in 1955 using [1-^{14}C]-Rib metabolism in liver slices and the other by Howard Hiatt in 1957 using the same labeled substrate in mouse liver *in vivo*. These workers did not find ^{14}C distributions in the labeled glucose product with twice as much isotope in C-1 as C-3, but

instead found the carbons equally labeled. These independent early failures to confirm the predictions of Figure 2 were also ignored.

Other than valuable research by Patricia McLean and her collaborators at the Courtauld Institute (UK), who investigated the enzymology, endocrinology, and occurrence of PP reactions in many animal tissues, all fundamental research on the mechanism of the pathway essentially ceased in 1957 and was not taken up again for another decade. Instead the era of the quantitative measurement of pathways of carbohydrate metabolism had dawned and PP measurements featured hugely. This emphasis on quantitation is best summarized in the following statement by Harland G. Wood in 1955. "The determination of the relative role of different pathways in normal living cells is without doubt of the greatest fundamental importance to our understanding of life processes and will in the future require more attention in all fields of metabolism." Wood (Western Reserve University Medical School, Ohio) collaborated with Joseph Katz (Cedars of Lebanon Hospital, Los Angeles) over the next eight years in the development and elaborations of measurement theory for an entity denoted by H. G. Wood and later defined by Wood and Katz as the pentose cycle (PC).

The Quantitation of the Pentose Cycle: Theory and Practice

Between 1958 and 1979 a dozen elegant theoretical papers were published that provided the mathematical basis and formulas for measuring the F-type PC using ^{14}C-labeled substrates. All of these methods depended on a quantitative solution of the problem posed by the recycling of ^{14}C isotope distributions that emerge by the metabolism of the substrates [2-^{14}C]- or [3-^{14} C]-glucose in PC. Calculating the different distributions of labeled carbon to infinite cycles, for all percentage contributions of PC, is a difficult mathematical problem, which was solved by Joe Katz. Katz is not only a gifted biochemist but also an equally talented mathematician and innovative metabolic theorist. The acceptance of a PC definition imposed agreement that all ^{14}C-labeled Fru 6-P formed by the Figure 2 reaction sequence is converted to Glc 6-P and recycled again through the oxidative segment reactions. The quintessence of all measurement methods has involved the development of mathematical expressions describing the rhythmical and ordered redistributions of either carbon 2 or 3 from labeled substrate glucose, into positions 1, 2, and 3 of the hexose 6-P products for any percentage contribution of PC. Such a theoretical distribution is a unique property of the PC. Experimental data for the C-1/C-2 and C-3/C-2 ratios, that have definite limits and values imposed by Katz and Wood theory, measure the degree of redistribution of ^{14}C from the above labeled substrates into the top three carbons of the Glc 6-P product, which is isolated and analyzed for ^{14}C distribution following labeled substrate metabolism. The ratios, in their appropriate measurement equations, express the PC contribution relative to the total metabolism of glucose. The above statements cannot be qualified. They derive from the reaction sequence of Figure 2, which is the mechanistic basis for all the formulas of all the "measurement" papers. The precise values for C-1 and C-3 and the ratio of their isotopic labeling are the "identity" badge of the classically defined PC reaction sequence, which is the foundation of its theories of existence and quantitation. It was therefore intriguing to note, that notwithstanding the initial ambiguities in the establishment of the Figure 2 scheme and the failed efforts of the Katz and Hiatt experiments to support it, that no less than ten independent efforts, over nearly 30 years, have failed to find any significant level of PC in liver using the Katz and Wood method. Liver is a rich source of the enzymes of the PP and it can provide *inter alia* a ready display of the reactions of Figures 1 and 2. Thus, the failure by all measurement investigations to find an F-type PC in liver was mystifying.

The Search for a New Reaction Scheme for the Pentose Pathway

A solution to the mystery was sought in the author's laboratory, with investigations that began in 1965 at the University of New South Wales and later at the Australian National University. Work commenced with the propositions that the scheme of Figure 2 may be an erroneous interpretation of the PP and the coupling of Figures 1 and 2 reactions into a metabolic cycle (PC) was possibly ill-conceived. The following three sets of findings summarize selected aspects of progress in the unraveling of a new PP reaction sequence in liver that does significantly contribute (20–30%) to glucose metabolism.

First, the original experiment performed by Horecker in 1954 was repeated using [1-^{14}C]-Rib 5-P and exactly the same preparation of liver enzymes. However, reaction mixtures were sampled for the labeled Glc 6-P product at a series of much shorter time intervals and right up to the 17 h termination point described in the original work. The results showed a patterned assortment of label distributions in Glc 6-P, that drifted from 8 to 17 h towards the isotope composition in C-1 and C-3 that was originally reported by Horecker. Notably in this study, the C-1/C-3 ratio at 17 h, was the much-sought value of 2. Moreover, in the seven-time

samples, which commenced at 1 min, Glc 6-P was heavily labeled in C-2, C-4, and C-6, while C-1 and C-3 only began to accumulate ^{14}C-isotope after 3 h of reaction. Although this was a study *in vitro*, it is obvious that liver cells *in vivo* do not take between 3 and 17 h to elaborate a path of metabolism and that more enlightening events were being revealed by the isotope distributions in the samples analyzed between 1 and 30 min of reaction. A carbon balance analysis of all compounds in the various reaction mixtures showed that the intermediates of Figure 2 only accounted for 80% of the carbon in the Rib 5-P substrate. The compounds comprising the missing 20% were identified as sugar phosphates, mostly ketuloses (see Figure 3). They were isolated, identified, and shown to be radioactive. These keto-ester sugars were Seh 1,7-P_2, D-*manno*-Heptulose 7-P; D-*glycero*-D-*altro*-octulose 1,8-P_2(D-*g*-D-*a*-Oct); D-*glycero*-D-*ido*-octulose 1,8-P_2(D-*g*-D-*i*-Oct); and a small amount of Ara 5-P (see Figure 3). Octulose (Oct)-, mono- and bisphosphates, and Seh 1,7-P_2 were also isolated and measured in fresh liver. Figure 4 shows the structures and reactions of these sugar esters in a new and much modified reaction scheme for the PP in liver. The new intermediary compounds were easily isolated from all incubations from 30 min to 17 h. The scheme of Figure 4 shows the new PP with prediction ^{14}C-labeling patterns in the intermediates and products of the reactions. The reaction scheme for Figure 4 was initially formulated from the distributions of ^{14}C in the labeled Glc 6-P and D-*g*-D-*i*-Oct 1,8-P_2 formed from [1-^{14}C]-Rib 5-P during the early intervals of the repeat experiment performed by Horecker and co-workers in 1954. The new pathway, called L (liver)-type PP, is distinguished from depictions of the classical F-type PP by the inclusions of Seh-1,7-P_2 and octulose (Oct)-, mono-, and bisphosphates together with Ara 5-P as new intermediates. Aldolase, phosphotransferase (PT), and arabinosephosphate isomerase are new enzymes. Mass transfer catalysis by TA was omitted, but the effects of active TA-exchange reactions (TA_X), which accounted for the 4,6-^{14}C labeling of Glc 6-P, were encountered in all samples. The second TK reaction forming hexose 6-P products in the L-type PP (Figure 4) used D-*g*-D-*i*-Oct 8-P as a substrate and TK was also found to catalyze very active exchange reactions as does aldolase. A clear demonstration that aldolase is a mandatory catalyst in liver PP involved the immunochemical evidence of Bleakly and co-workers in 1984, who showed the cessation of all hexose 6-P formation when liver aldolase antibody titrated the removal of aldolase from the system where Rib 5-P was reacted with the rat liver enzyme preparation that was used to establish the scheme in Figure 2. Irrespective of the other contrary data, this evidence alone showed that there was another reaction mechanism involving Ald in liver PP. The claim that aldolase is an essential enzyme in the PP was also supported by data of Cori and Racker, who, in an *in vitro* "construction" of a PP preparation for the complete oxidation of Glc, noted the formation of Oct-P and the need to include aldolase and sedoheptulose 1,7-bisphosphatase for the construction system to work.

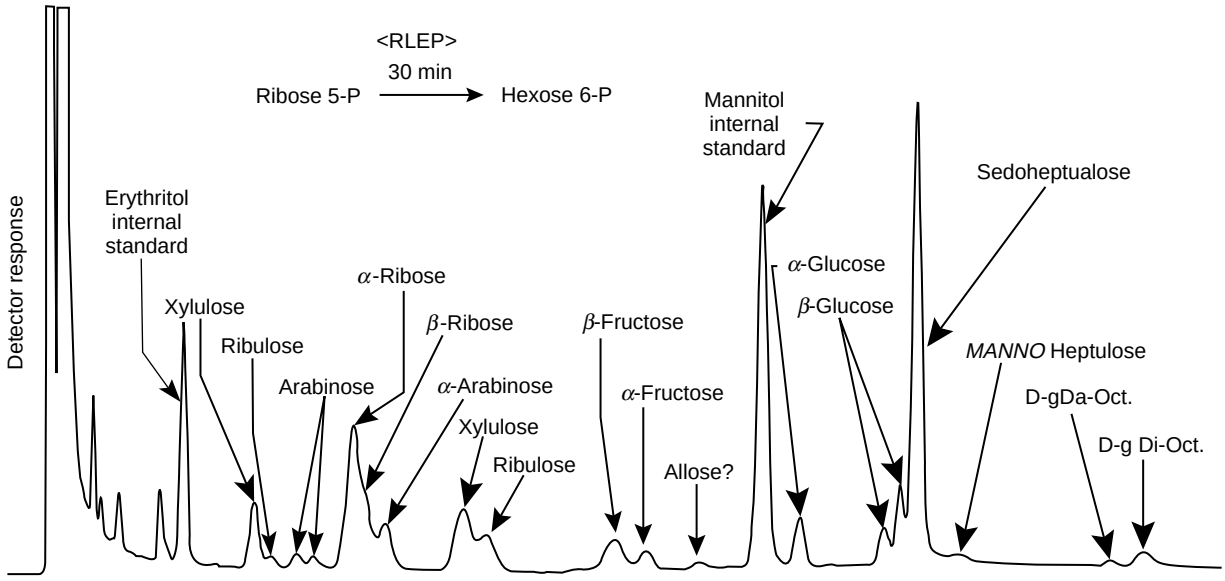

FIGURE 3 Gas liquid chromatogram (GLC) of the dephosphorylated derivatized sugars formed after 30 min reaction of rat liver enzyme preparation with ribose 5-phosphate. The procedures for sample processing and GLC are given in Williams, J. F., Clark, M. G., Arora, K. K., and Reichstein, I. C. (1984) Glucose 6-phosphate formation by L-type pentose pathway reactions of rat liver in vitro: Further evidence. *Seyler's Zeit. Physiol. Chem.* **365**, 1425–1434.

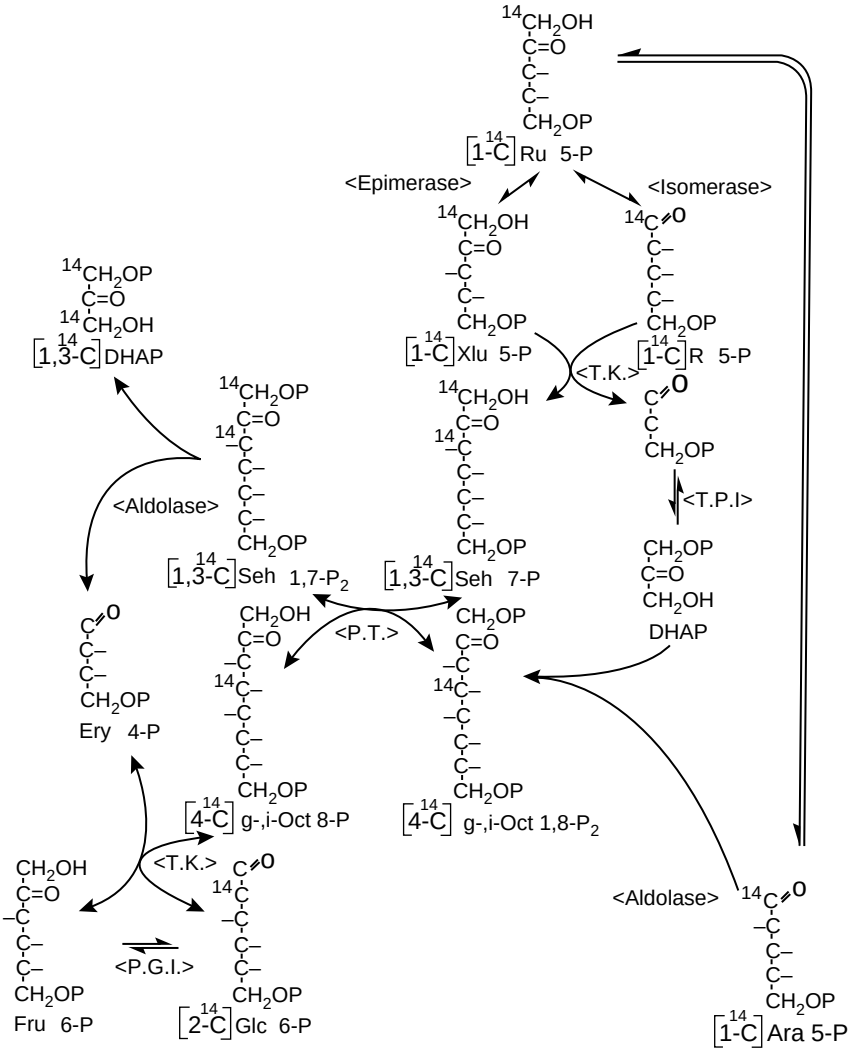

FIGURE 4 The proposed reaction sequence of the nonoxidative segment of the L-type pentose pathway. The [1-^{14}C]-ribulose 5-P substrate is the labeled product of the Figure 1 scheme and the reactions display the theoretical and the found distributions of ^{14}C-isotope from pentose 5-P substrate into labeled Glc, triose and Oct intermediates, and products. The epimerase, isomerase, and TK enzymes are the same catalysts that operate in the F-type pathway. New enzymes are arabinosephosphate isomerase that interconverts arabinose and ribulose 5-phosphates, aldolase, triosephosphate isomerase (EC 5.3.1.1), glucosephosphate isomerase and D-*glycero*-D-*ido*-octulose 1,8-bisphosphate: D-*altro*-Heptulose 7-phosphotransferase, called phosphotransferase (PT) (see Arora, K. K., Cortis, P. A., Bleakley, P. A., and Williams, J. F. (1985) Identification and measurement of D-glycero-D-ido-octulose 1,8-bisphosphate: D-altro heptulose 7-phosphotransferase enzyme in tissues with L-type pentose phosphate pathway activity. *Int. J. Biochem.* **17**, 1329–1337). Besides new enzymes and intermediates, the L-type pathway is distinguished from the F-type pathway by the formation of Glc 6-P labeled in the 2 position by flux and in positions 4 and 6 by group-transfer enzyme exchanges involving the [1,3 ^{14}C]-DHAP product. The triosephosphate formed by the F-type pathway is unlabeled.

Exposing the Problem of Assigning a Reaction Scheme to the Nonoxidative PP

The reactions and enzymes shown in Figure 4 occur in liver cytoplasm and probably in the soluble enzyme compartments of the tissues of most animals (exceptions are adipocytes and possibly lactating mammary gland), plants, and some microorganisms. The failure to uncover "uncontentious" evidence for both F- and L-pathways that permitted the placement of C-3 to C-8 glycolyl phosphates in a reaction order and with stoichiometry that satisfied flux demands of a metabolic pathway or cycle, is the crux of this 50-year-old enigma. Finding an answer to the problem proved to be quick, obvious, and simple. Uncovering irrefutable evidence and proof for the explanation was a more pressing task that was solved by Flanigan *et al.* in 1993. It was the universal use of ^{14}C isotopes in prediction-labeling experiments to both inquire into mechanism and predicate theories for quantifying the F- and L-type

pathways, which was the first fundamental error. The second misjudgment was lack of attention to the consequences of the glycolyl-group exchange reactions that are actively catalyzed by TK_x, TA_x, and Ald_x. The subscript x is used to distinguish exchange catalysis from the mass transfer activity of these enzymes. Moreover, there was an inchoate recognition and warning that both functions were simultaneously active during the unique catalytic roles of these enzymes in PP and PS. The qualitative and partial definition of TK_x and TA_x by Katz and Wood proved to be an insufficient and largely unheeded alarm to the PC measurers.

Flanigan and co-workers used ^{13}C-NMR spectroscopy for their investigations, thus bypassing any controversy concerning results that depended on "wet" chemical methods for the determination of ^{14}C labeling patterns. The maximum catalytic capacities for exchange by the three enzymes were all quantified in reaction mixtures at mass-transfer equilibrium, by measuring, for TA, the rate of exchange of the ^{13}C-TA dihydroxyacetone group with unlabeled Seh 7-P. TK_x was measured by the rate of incorporation of a (2-^{13}C)-TK glycolaldehyde group to unlabeled Fru 6-P and Ald_x by the exchange of an unlabeled DHAP-Ald group from D-*g*-D-*a*-Oct 1,8-P_2 to [1-^{13}C]-Rib 5-P and measurement of the rate of formation of [4-^{13}C]-D-*g*-D-*a*-Oct 1,8-P_2. A comparison of the exchange capacities of these enzymes with the maximum nonoxidative PP flux rates in three liver preparations showed that TK_x and Ald_x exceeded flux by 9–19 times in liver cytosol and acetone-powder enzyme preparations *in vitro* and by 5 in hepatocytes. TA_x was less effective in exchange, only exceeding the flux rate by 1.6 and 5 in liver cytosol and acetone-powder preparations. Values for the ratios of the rates of group exchange and pathway flux are important because of the feature roles of liver and of these preparations in the establishment and status of the schemes of Figures 2 and 4 in biochemistry. The prevalence of exchange activity was also investigated using the dominant TK_x rates relative to the max PP flux rates of normal and regenerating liver, Morris hepatoma, mammary carcinoma, melanoma, colonic epithelium, spinach chloroplasts, and epididymal adipocytes. TK_x rates in these preparations exceeded PP flux by 5–600 times.

Conclusion

It is the conclusion of this brief history that sufficient evidence is on record to show that predictions and calculations based on ^{14}C-distributions in PP products and intermediates are misleading. The isotope patterns cannot reveal the order of the reaction sequences, which can only be measured by an uncompromised net flow of carbon. Instead, the ^{14}C-distributions mainly reflect a composition of disorder, induced by random combinations of group exchanges that scramble, if not obliterate, flux influences. Thus, the description and metabolic map of PP is "in error" in biochemical texts.

How Should We Now View the PP—With or Without Conceptual Structures?

The reactions of Figure 1 are not in contention. The enzymes and intermediates of Figures 2 and 4 are probably present in most tissues, particularly where Ald activity is greater than that of TA. There is, however, no secure evidence that the individual reactions of either Figure 1 or 2 are so linked that they constitute a linear metabolic pathway with ordered reactant and end-product stoichiometry or fixed direction of operational flux. Nor is there uncontentious proof that the PP generally operates as a metabolic cycle. The reaction array is best perceived now as it was in 1958, when the late Prof. Merton Utter (Western Reserve University School of Medicine) so suggested limiting these reactions to an unstructured pool or reservoir of glycolyl phosphates, with as many accessible inputs and exits as there are intermediates in Figures 2 and 4. This includes hexose and triose phosphates that may react reversibly to form or be formed from pentose phosphates by mass action effects and in the process mix with all of the other glycolyl phosphates, which are not constrained by stoichiometric obligation to "connecting" reaction sequences, and which may be freely removed by the needs of other metabolism.

Glossary

metabolic pathway A linear sequential order of consecutive enzymatic reactions that proceed from a flux-generating step. The pentose pathway (PP) consists of a set of freely diffusible soluble enzymes, coenzymes, and reactants.

non-oxidative PP (Figures 2 and 4) has the sum reaction of Eqn 1

$$3 \text{ Pentose 5-P} \longleftrightarrow 2 \text{ Fructose 6-P} + 1 \text{ Glyceraldehyde 3-P}. \quad [5]$$

oxidative segment of PP This segment is assigned the stoichiometry of eqn. [6] because of its link with the reactions of Figures 2 and 4.

$$3 \text{ Glc 6-P} + 6 \text{ NADP}^+ \longrightarrow 3 \text{ CO}_2 + 3 \text{ pentose 5-P} + 6 \text{ NADPH} + 6\text{H}^+. \quad [6]$$

pentose cycle (PC) This cycle is a theoretical construct, based on the reactions of Figure 2 for F-type PC and Figure 4 for L-type PC and

the reaction of eqn. [7]. The PC mechanisms permit mathematical treatment of theoretical ^{14}C distributions, generated by a conforming metabolism of labeled glucose, which leads to specific formulae for quantifying the two varieties of PC. The sum of eqns. [5], [6], and [7] is [8], which is the sum reaction of both F-type and L-type PC.

$$2\ \text{Fructose 6-P} \xleftrightarrow{\text{Glucosephosphate isomerase (EC 5.3.1.9)}} 2\ \text{Glucose 6-P}, \qquad [7]$$

$$\text{Glucose 6-P} + 6\ \text{NADP}^+ \longrightarrow 3\ \text{CO}_2 + \text{Gra 3-P} + 6\ \text{NADPH} + 6\ \text{H}^+. \qquad [8]$$

Biography

John F. Williams is Professor Emeritus and a former Professor and Head of Biochemistry in the faculties at the Australian National University, Canberra. He was a Research Fellow at Merton College, Oxford and is presently Visiting Fellow in The Research School of Chemistry at ANU. His principal research interests are in intermediary metabolism. He holds a Ph.D. from the University of New South Wales and D.Sc. from the ANU, and he received postdoctoral training at Western Reserve University School of Medicine.

Peptide Amidation

Mark J. Niciu, Richard E. Mains and Betty A. Eipper
The University of Connecticut Health Center, Farmington, Connecticut, USA

Generation of a C-terminal α-amide group on a peptide occurs by hydroxylation and cleavage of a C-terminal glycine residue and is a prevalent posttranslational modification essential for the production of many of the peptides that serve as hormones and neurotransmitters. Approximately half of all bioactive peptides are α-amidated, including gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), oxytocin, vasopressin, calcitonin, gastrin, cholecystokinin (CCK), neuropeptide Y (NPY), substance P and pituitary adenylate cyclase-activating polypeptide (PACAP). The α-amide group prevents ionization of the C terminus, which may increase receptor binding, hydrophobicity and/or half-life. In vertebrates, C-terminal α-amidation is accomplished via the activity of peptidylglycine α-amidating monooxygenase (PAM), a bifunctional enzyme localized to large dense core vesicles in neuroendocrine tissues.

Biochemistry and Enzymology of PAM

PAM is composed of two protease-resistant catalytic cores targeted to the lumenal compartment of secretory granules, peptidylglycine α-hydroxylating monooxygenase (PHM; EC 1.14.17.3) and peptidyl-α-hydroxyglycine α-amidating lyase (PAL; EC 4.3.2.5). PHM catalyzes the stereospecific α-hydroxylation of all C-terminally glycine-extended peptide substrates. PAL then catalyzes cleavage of the N–C bond of the α-hydroxylglycine, generating the α-amidated peptide product and glyoxylate (Figure 1).

PAM Structure

Bifunctional PAM is a type I integral membrane protein whose structure is highly conserved in vertebrate phylogeny. From N to C terminus, it contains a signal sequence, proregion, PHM catalytic core, noncatalytic spacer region (exon A), PAL catalytic core, transmembrane domain and cytosolic domain. The hydrophobic signal sequence is cleaved cotranslationally in the endoplasmic reticulum; the prosequence is removed in a post*trans*-Golgi network compartment. Tissue-specific endoproteolytic cleavage at pairs of basic amino acids can remove the pro-region, separate the two catalytic domains, and release the catalytic domains from the transmembrane domain. Poorly conserved linker regions follow both catalytic domains and are susceptible to cleavage by exogenous proteases. Additionally, alternative splicing can generate soluble, monofunctional PHM or soluble, bifunctional PAM. Soluble PAM proteins are secreted with their amidated product peptides while integral membrane PAM proteins undergo endocytosis, guided by routing determinants and phosphorylation at multiple sites in the cytosolic domain (Figure 2).

PAM Substrates

Virtually any peptide with a C-terminal glycine residue can serve as a PAM substrate. PAM generates α-amides of all 20 amino acids. In addition, PAM catalyzes the amidation of nonpeptidergic substrates such as fatty acyl glycines, glutathione, the aspirin metabolite salicylurate, bile acid glycine conjugates and leukotriene C_4. In addition to stereospecific α-hydroxylation of glycine-extended precursors, purified PHM can also catalyze N-dealkylation, O-dealkylation, and sulfoxidation of nonpeptidergic substrates.

Peptidylglycine α-hydroxylating Monooxygenase – PHM

Essential Cofactors

PHM requires the presence of molecular oxygen, a single electron donor (generally ascorbic acid or vitamin C), and copper.

Ascorbic Acid (Vitamin C) Ascorbate is transported across the plasma membrane via a Na^+-dependent transporter enriched in neuroendocrine tissue, SVCT2. How cytosolic ascorbate reaches the lumen of the secretory pathway is currently unclear. Nevertheless, concentrations of ascorbate are five to tenfold higher in the lumen of the secretory pathway than in the cytosol. The mM concentrations of ascorbate in the

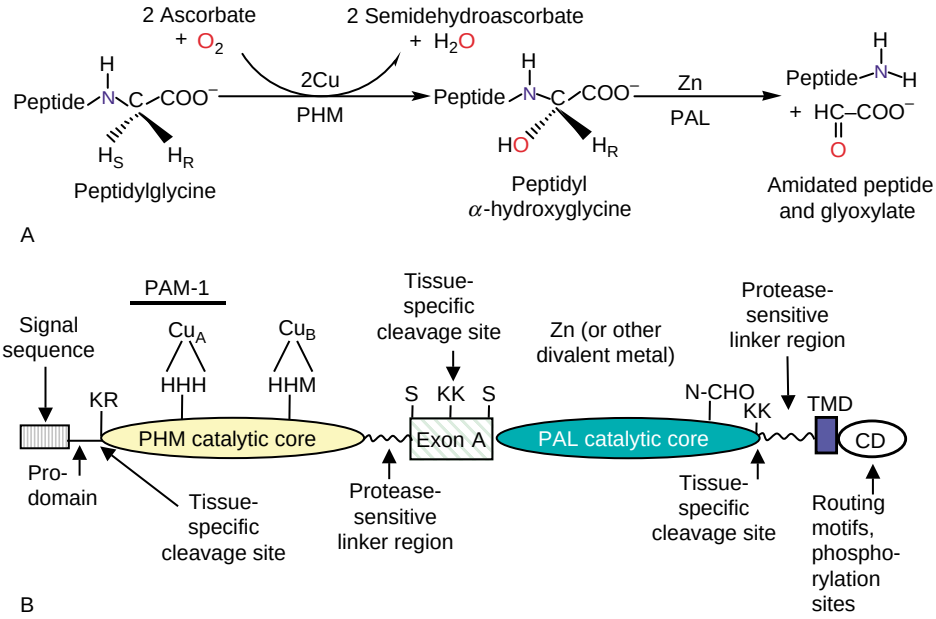

FIGURE 1 PAM reaction and structure. (A) Bifunctional PAM-catalyzed conversion of glycine-extended precursor into hydroxyglycine intermediate and amidated product plus glyoxylate. (B) Domains of integral membrane PAM-1 with salient features: KR and KK lysine-arginine and lysine-lysine dibasic cleavage sites; H, copper-binding histidine; M, copper-binding methionine; N-CHO, N-linked glycosylation site; TMD, transmembrane domain; CD, cytosolic domain; P, phosphorylation sites.

lumenal compartment ensure that lumenal copper is reduced, as required for the enzymatic cleavage of molecular oxygen by PHM. In this oxidation–reduction reaction, PHM converts 2 mol of ascorbate into 2 mol of semidehydroascorbate, which disproportionate to form dehydroascorbate and ascorbate. Other single-electron reductants can substitute for ascorbate to provide reducing equivalents for Cu^{2+}; consistent with this, no ascorbate-specific binding site has been identified on PHM.

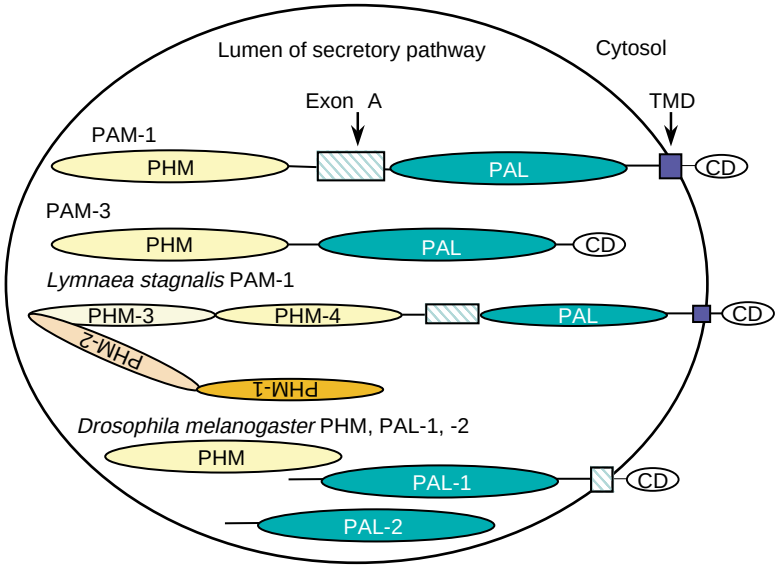

FIGURE 2 PAM in secretory granules. Soluble and membrane PAM isoforms from rat, pond snail and fruit fly in mature secretory granule. Alternative mRNA splicing at "hot spots" generates soluble PAM-3, which lacks exon A and the TMD; it is secreted with the amidated product. *Lymnaea stagnalis* membrane PAM contains four functional PHM domains and an exon A-like linker sequence. *Drosophila* PHM and PAL-1/-2 are encoded on separate genes. PAL-1 is a soluble protein and may be secreted with processed peptide. PAL-2 contains a transmembrane domain and may be recycled via endocytosis to post-Golgi complex compartments.

Copper Copper is required in trace amounts by a limited group of cuproenzymes. However, in excess, copper can support the Fenton reaction, generating reactive oxygen species, that attack cellular constituents with diffusion-limited kinetics. To avoid this problem, copper transporters and copper chaperones deliver this critical metal to these cuproenzymes while preventing toxic intracellular actions. The transport of Cu^{1+} across the plasma membrane requires Ctr1 in mammals. Atox1, a cytosolic copper chaperone, delivers Cu^{1+} to ATP7A and ATP7B, homologous P-type ATPases that pump Cu^{1+} into the lumen of the secretory pathway, where it can be loaded onto lumenal cuproproteins or excreted from the cell.

Structure and Reaction Mechanism

PHM binds two moles of copper, each of which plays a distinct role in the α-hydroxylation reaction. Composed almost entirely of β strands, the catalytic core of PHM consists of two structurally homologous domains (Figure 3). Mutagenesis and phylogenetic comparisons identify a limited number of conserved residues. The copper binding sites are conserved: 3 histidine residues in the N-terminal half of PHM bind Cu_A and two histidines plus one methionine residue in the C-terminal half bind Cu_B. Although reducing equivalents donated by both Cu_A and Cu_B are essential to the reaction, the two Cu ions are separated by a 10Å solvent filled cleft.

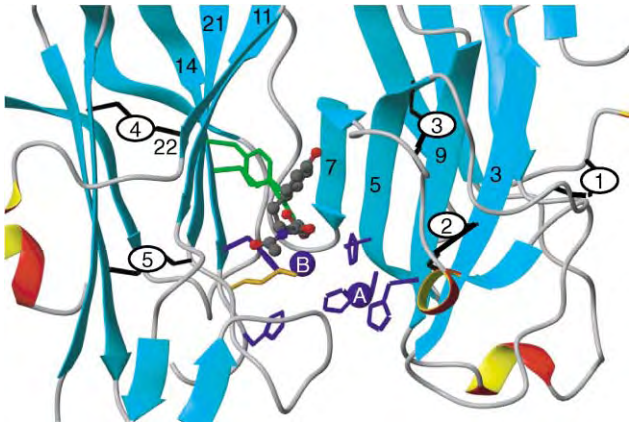

FIGURE 3 PHM active site. The structure determined by crystallization of oxidized PHMcc with its Ac-diiodo-Tyr-Gly substrate is shown to illustrate the structural role played by the disulfide bonds (Prigge, S. T., Mains, R. E., Eipper, B. A., and Amzel, L. M. (2000). New insights into copper monooxygenases and peptide amidation: Structure, mechanism and function. *Cell Mol. Life Sci.* 57, 1236–1259). Histidine ligands to Cu_A and Cu_B are blue; the methionine ligand to Cu_B is gold; substrate binding residues are green; the substrate is shown in ball and stick format. The disulfide bonds in PHM are numbered (except for bond 1, they are totally conserved): 1, Cys^{47}-Cys^{186}; 2, Cys^{81}-Cys^{126}, links β3 to the β5-β6 loop; 3, Cys^{114}-Cys^{131}, links β5 to the β6-β7 loop; 4, Cys^{227}-Cys^{334}, links β13 to β22; 5, Cys^{293}-Cys^{315}, links β19 to β21.

The glycine-extended peptide substrate binds in a conserved, hydrophobic substrate-binding pocket located near Cu_B, placing the α-carbon of the glycine adjacent to molecular oxygen bound to Cu_B with the C terminus of the glycine residue salt bridged to a conserved arginine residue. Several hydrophobic residues near the active site are conserved, along with proline and glycine residues that define the loop regions. The molecular oxygen consumed in the reaction binds only to the enzyme/peptidylglycine complex, and it is not yet clear how electron transfer is accomplished. The reaction is tightly coupled, with little generation of reactive oxygen species, and the two copper ions do not move much closer to each other during catalysis.

Pharmacological Inhibition

Disulfiram, used clinically in the treatment of chronic alcoholism, inhibits PHM activity *in vivo* via its ability to chelate copper. When assayed *in vitro*, after the addition of exogenous copper, the catalytic core of rat PHM displays paradoxically enhanced activity after *in vivo* disulfiram administration. A mechanism-based inhibitor of PHM, trans-styrylacetic acid (phenylbutenoic acid), has also been identified.

Peptidyl-α-Hydroxylglycine α-Amidating Lyase

Limited trypsin digestion and analysis of peptidyl-α-hydroxylglycine α-amidating lyase (PAL) truncation mutants revealed a stable catalytic core with no subdomains. The single N-linked glycosylation site near the COOH terminus of PAL is utilized, although glycosylation is without effect on the catalytic activity of PAL. When treated with divalent metal ion chelators, PAL activity was reduced and its thermal and protease resistance were decreased, suggesting both structural and catalytic roles for divalent metal ions. Approximately 0.7 mol of zinc is bound per mole of enzyme. The four cysteine residues in PAL form disulfide bonds, and conserved histidine, aspartate and glutamate residues are involved in binding zinc, playing both structural and catalytic roles. No reliable mechanism-based small molecule inhibitors of PAL have been characterized. The reaction catalyzed by PAL is most similar to the reaction catalyzed by ureidoglycolate lyase.

Evolutionary Relationships

The process of peptide amidation is highly conserved. In invertebrates like *Drosophila melanogaster* and *Caenorhabditis elegans*, PHM and PAL are encoded by separate genes; a single PHM gene may be accompanied by more than one PAL gene. PHM and PAL homologues

are not found in the genome of *Saccharomyces cerevisiae*. Intriguingly, *Lymnaea stagnalis*, a molluscan pond snail, expresses a huge membrane PAM with four independent, catalytically active PHM domains followed by a single PAL domain. *Schistosoma mansoni*, a nematode and potent human pathogen, expresses a heavily glycosylated, soluble PHM with atypical catalytic features. The copper binding ligands, substrate binding site, disulfide bonds, and selected glycine and proline residues of PHM are conserved across species.

The cofactor requirements of PHM suggest homology to another copper, ascorbate and dioxygen-requiring enzyme, dopamine-β-monooxygenase (DBM; EC 1.14.17.1). DBM converts dopamine to norephinephrine in selected neurons and adrenal chromaffin cells. The catalytic core of PHM is 32% identical to a 291 amino acid stretch in DBM. The Cu_A and Cu_B-binding motifs and disulfide-bonding patterns of PHM are conserved in DBM. *Cnidarians*, such as the sea anemone and *Hydra*, use amidated peptides, not catecholamines like norephinephrine for neural transmission, suggesting that PHM is the more ancestral enzyme. cDNA library screening of human senescent fibroblasts revealed the presence of a third sequence with significant homology to PHM, monooxygenase X (MOX; X13255). No substrates or hydroxylated products have yet been identified for this putative monooxygenase.

PAM Expression

PAM expression is most prevalent in heart atria, the pituitary gland, and peptide-producing neurons of the central and enteric nervous systems. Nevertheless, PAM expression is widespread, as transcripts can be detected in airway and olfactory epithelia, smooth muscle cells, endothelium, brain ependymal cells, astrocytes, and fibroblasts.

During development, PAM is first detected immunohistochemically at embryonic day 9 (E9) in the putative cardiogenic region and at E13 in peptide-producing neurons. PAM is also highly expressed in limb mesoderm and mesenchyme flanking the nasal, maxillary, palatal and dental epithelia during embryonic tissue fusion and remodeling. Most *Drosophila* PHM knockout flies die as young larvae, during the molting process, with malformation of the mouth hooks. A role for PAM in these areas during development is not yet clear.

PAM Molecular Genetics

The human *PAM* gene is located on chromosome 5q14-21 and the mouse *Pam* gene is on chromosome 1. The rat PAM gene contains at least twenty-eight exons encompassing >160 kB. At least two putative promoters upstream of the translational start site and proregion in exon two have been identified. PHM is encoded by exons three to fourteen (excluding exon thirteen). The alternately spliced non-catalytic region between PHM and PAL is encoded by exon sixteen, which is bordered by at least forty kB of intronic sequence. PAL is encoded by exons seventeen to twenty-four. Most of the intron/exon junctions in rat, which preferentially produce bifunctional PAM mRNA transcripts, and *D. melanogaster*, which contains separate PHM and PAL genes, are conserved. Interestingly, rat breeding stocks vary in their alternative splicing of PAM: Harlan Sprague-Dawley rats eliminate the exon A linker in their mRNA transcripts in pituitary, while Charles River Sprague-Dawley rats retain this domain.

Dysregulated Peptide Amidation

Due to the plethora of physiological functions regulated by amidated peptides, deficits in peptide amidation have very detrimental consequences for the organism.

Overexpression of Amidated Peptides

Many amidated peptides, e.g., PACAP, NPY, and gastrin-releasing peptide (GRP), serve as autocrine or paracrine growth factors. Numerous tumors of neuroendocrine origin secrete amidated peptides that serve this function, and PAM expression is concomitantly up-regulated. Amidated peptides secreted by neuroendocrine tumors disrupt normal physiological function. For example, small cell lung carcinomas often secrete GRP, while amidated isoforms of parathyroid hormone related protein (PTHrP) sustain bone growth and produce the hypercalcemia of malignancy. Gastrin-secreting tumors ("gastrinomas") are frequently encountered in Zollinger-Ellison syndrome, which presents clinically as peptic ulceration; vasoactive intestinal polypeptide-secreting tumors ("VIPomas") of pancreatic or duodenal origin present with voluminous watery diarrhea in Verner-Morrison syndrome. Hence, pharmacological inhibition of PAM activity may be a rational therapeutic strategy in the treatment of such amidated peptide-secreting tumors.

Impaired Peptide Amidation

Based on assays of amidated product peptides, peptide amidation is impaired in the context of dietary deficiencies of ascorbate or copper, genetic deficiencies of copper-translocating proteins or targeted gene disruption of the PAM gene.

Impaired Copper Delivery

A reduction in copper delivery to the secretory pathway results in a diminished ability to produce amidated peptides. This can be the result of nutritional deficiencies of copper or ascorbate or genetic malfunctioning of copper transporters. In mammals, ATP7A receives Cu^{+} from the cytosolic chaperone Atox1 and transports it into the lumen of the secretory pathway where the catalytic cores of cuproenzymes like PHM, DBM and tyrosinase reside. Mutations in ATP7A result in the X-linked copper-deficiency disorder, Menkes disease, which presents clinically with profound neurodegeneration. The mottled brindled (Mo^{Br}) mouse, which contains a six base pair in-frame deletion in ATP7A, serves as the mouse model of Menkes disease. Although PAM protein expression is unchanged, the concentrations of amidated neuropeptides, *e.g.*, joining peptide (JP), CCK, and PACAP, are reduced in the pituitary gland and central nervous system of afflicted males relative to age-matched wild type mice.

Targeted Gene Disruption

Insertion of a P-element containing transposon within the *D. melanogaster* PHM transcriptional unit eliminated PHM expression and resulted in early larval lethality with relatively few morphological defects. Recently, PAM null mice have been created. These mice do not survive past embryonic day 14.5, with the most noticeable defect being intractable edema. No PHM or PAL enzymatic activity is detectable in homogenates of null embryos, and heterozygotes display half the wild type level of PHM and PAL activity in age-matched wild type mice. Thus PAM is the only enzyme responsible for C-terminal peptide α-amidation *in vivo*.

Biography

Mark Niciu is an M.D.-Ph.D. student and Betty Eipper and Richard Mains are Professors in the Neuroscience Department at the University of Connecticut Health Center in Farmington, CT.

Drs. Eipper and Mains received their Ph.D. from Harvard University and were postdoctoral fellows with Dr. Ed Herbert at the University of Oregon. They developed an interest in peptide amidation when they observed that pituitary cells maintained in serum-free medium failed to amidate the products of proopiomelanocortin processing. Subsequent cloning and characterization of PAM identified ascorbate as the missing factor.

Periplasmic Electron Transport Systems in Bacteria

David J. Richardson
University of East Anglia, Norwich, UK

Gary Sawers
John Innes Centre, Norwich, UK

Rob J.M. Van Spanning
Free University of Amsterdam, The Netherlands

The periplasmic compartment lies between the inner (cytoplasmic) and outer membranes of Gram-negative bacteria. It is frequently termed the "periplasmic space," but this is a misnomer as the term "space" suggests a void and the periplasmic compartment is far from that. In fact, it is a highly metabolically active compartment where many important respiratory electron transfer proteins are located. In bacteria these periplasmic redox proteins result in a great respiratory diversity, as they can facilitate electron transfer between a range of electron donors (e.g., formate, hydrogen, reduced nitrogen species, and reduced sulfur species) and electron acceptors (e.g., nitrogen and sulfur oxyanions, dimethylsulfoxide, and trimethylamine N oxide). This underlies the success of bacteria in colonizing a wide range of the Earth's oxic and anoxic environments and the important contribution of bacteria to critical biogeochemical element cycles, such as the nitrogen, sulfur, and carbon cycles.

Respiratory Electron Transport Systems

In mammalian mitochondrial respiration, electrons flow from low-potential cytoplasmic electron donors (e.g., NADH or succinate) to the high-potential electron acceptor oxygen. The site of oxygen reduction is the aa_3-type cytochrome *c* oxidase that is located within the cytoplasmic membrane (Figure 1). The key postulate of P. Mitchell's chemiosmotic theory is that many energy-consuming reactions catalyzed by integral membrane proteins, such as the ATP synthase, are driven by the energy contained within a transmembrane-proton electrochemical gradient (proton-motive force (PMF)), which is generated by the electron transport system. Proton translocation is achieved via membrane-associated electron transfer proteins. Mitchell described a redox loop mechanism whereby two electrons are transferred from the positive (P, or bacterial periplasmic) side of the membrane to the negative (N, or bacterial cytoplasmic) side of the membrane. There they combine with two protons to reduce a quinone to quinol. The quinol then diffuses back across the membrane where it is reoxidized at the P face releasing protons (Figure 1B). This movement of negative charge from the P to the N side of the membrane, and counter movement of protons, produces a PMF. Structure–function studies of two key integral membrane enzymes of respiration (the structurally defined cytochrome bc_1 complex and the aa_3-type cytochrome *c* oxidase) illustrate yet another three different mechanisms that couple electron transfer to PMF generation. The cytochrome bc_1 complex utilizes a proton-motive Q-cycle mechanism that results in a q^+/e^- ratio of 1 (Figure 1A). The aa_3-type cytochrome *c* oxidase employs two different mechanisms to build up the PMF. Reduction of oxygen at the catalytic site involves proton transfer from the cytoplasm and electron transfer from a periplasmic donor. As a consequence, these charge movements from opposite sides of the membrane give rise to a net charge separation of 1 per electron transferred, $1q^+/e^-$. In addition, it utilizes a proton-pumping mechanism that results in one positive charge being moved across the membrane for each electron ($1\,q^+/e^-$). Therefore, the stoichiometry of charge movements in the oxidases adds up to $2\,q^+/e^-$ transferred from donor to oxygen. It is notable that neither the proton pump mechanism nor the Q-cycle mechanism of energy conservation was originally envisaged by Mitchell.

(B) The organization of redox loops using periplasmic electron donors found in some cytochrome bc_1 complex-independent bacterial respiratory systems.

Bacterial Periplasmic Respiratory Electron Transport Systems that are Dependent on the Cytochrome bc_1 Complex

The mammalian mitochondrial-type of electron transport system is present in many aerobic and facultative anaerobic bacteria, for example, the well-studied soil-denitrifying bacterium *Paracoccus denitrificans*. However, many bacteria additionally have alternative electron transport systems that utilize periplasmic electron donors and acceptors. In some cases the periplasmic oxido-reductases will integrate easily into a mitochondrial-type of electron transport chain. For example, in *P. denitrificans* the periplasmic oxido-reductases for the reduction of nitrite or nitrous oxide, which are important reactions of denitrification in the biogeochemical nitrogen cycle, can accept electrons via the cytochrome bc_1 complex (Figure 2). Due to the Q-cycle mechanism of the latter enzyme, the overall

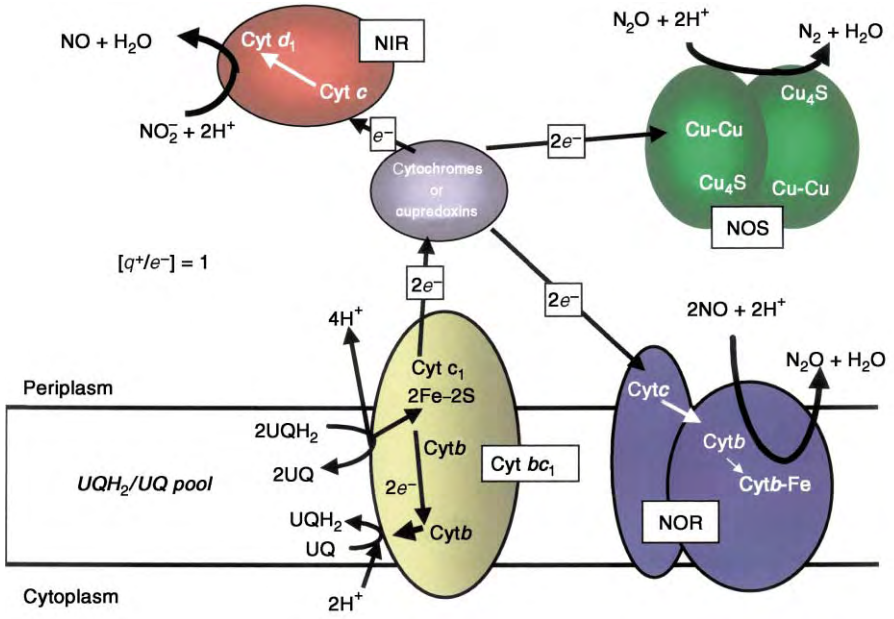

FIGURE 2 Cytochrome bc_1 complex-dependent periplasmic and membrane-bound oxido-reductases involved in denitrification in *Paracoccus* species. NIR, cytochrome cd_1 nitrite reductase dimer. NOR, nitric oxide reductase. NOS, nitrous oxide reductase.

electron transport pathway from quinol to nitrite and nitrous oxide is electrogenic, although the terminal nitrite and nitrous oxide reductases themselves are not. As a consequence, the electron transport from quinol to nitrite is less coupled ($q^+/e^- = 1$) (Figure 2) than electron transfer from quinol to oxygen ($q^+/e^- = 3$) (Figure 1A).

Periplasmic Electron Transport Systems that do not Depend on the Cytochrome bc_1 Complex

Many bacteria (e.g., *Escherichia coli*) do not have genes encoding a cytochrome bc_1 complex. Using periplasmic electron donors and acceptors independently of the cytochrome bc_1 complex can raise interesting questions about the bioenergetics of these systems, particularly with respect to the means by which the electron transfer process is coupled to the generation of a transmembrane electrochemical gradient. The molecular nature of some of these coupling mechanisms has been illuminated by recent structure–function studies on key anaerobic enzymes.

Some of these transmembrane enzymes possess two heme *b* groups at opposite sides of the membrane, which allows transmembrane electron transfer from a periplasmic to a cytoplasmic side. During oxidation of their substrate, two protons are released at the periplasmic side of the membrane while two electrons move inward via the hemes *b* to the cytoplasmic side of the membrane. There they are taken up by the acceptor along with two protons from the cytoplasm. This classical Mitchellian redox loop mechanism results in a net charge separation of one per electron transferred through the enzyme from donor to acceptor molecule ($1q^+/e^-$). Both dehydrogenases, which oxidize their substrate at the periplasmic side and reduce quinone at the cytoplasmic side, and terminal oxido-reductases, which oxidize quinol at the periplasmic site and reduce the acceptor at the cytoplasmic side, may have a redox-loop-type architecture. Examples of such electrogenic dehydrogenase are the HydABC-type hydrogenase and FdhN of *E. coli*, homologues of which are present in many bacteria and archae. An example of such an electrogenic terminal oxido-reductase is membrane-bound nitrate reductase (NarA). Periplasmic or membrane-bound enzymes that are not designed to contribute to the generation of a PMF will dissipate the redox free energy as heat. These enzymes receive their electrons and protons required for reduction of their allocated electron acceptor at the same side of the membrane, either the periplasm (trimethylamine N-oxide reductase (TOR), dimethylsulfoxide reductase (DMS), periplasmic nitrate reductase (Nap), the cytochrome *c* nitrite reductase (Nrf)), or the cytoplasm (succinate dehydrogenase, fumarate reductase). Electron transfer in pathways that are made up of a redox-loop-type dehydrogenase or oxido-reductase along with a non-electrogenic oxido-reductase or dehydrogenase, respectively, will yield a net proton movement of 1 from inside to outside during electron transfer from donor to terminal electron acceptor (q^+/e^- is 1) (Figure 3).

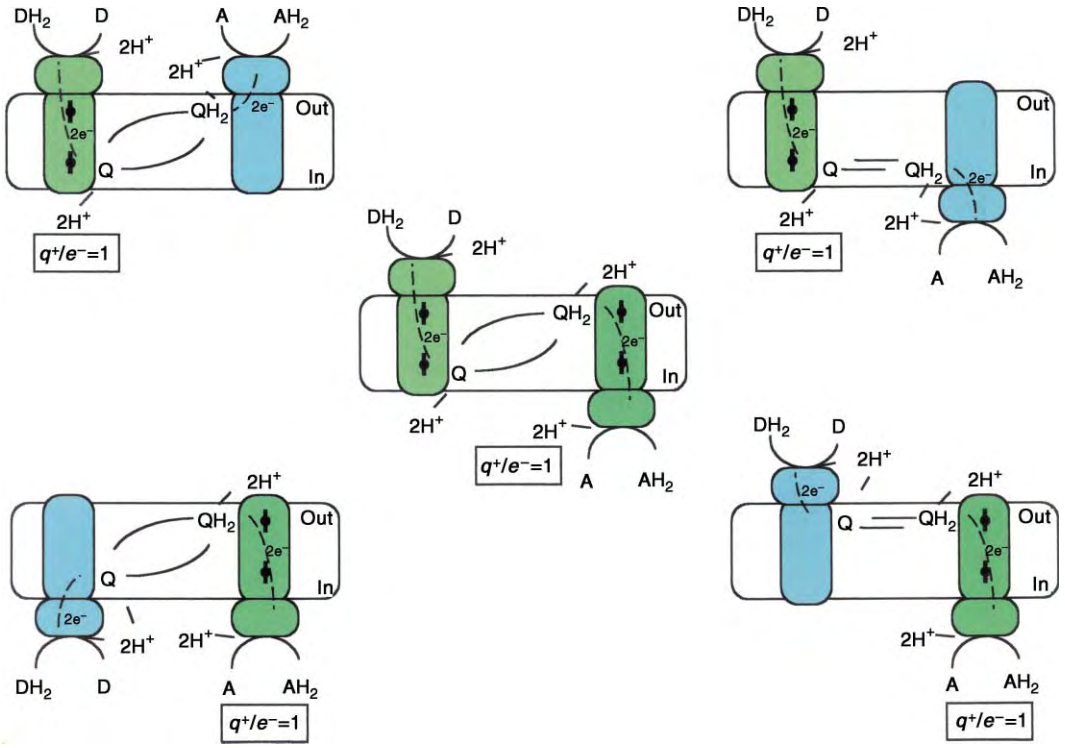

FIGURE 3 Examples of $q/e^- = 1$ and $q/e^- = 2$ redox loop mechanisms.

The most efficient free-energy transducing pathway of electron transfer from donor to acceptor requires the participation of a dehydrogenase and a terminal oxidoreductase, which both have a redox-loop-type architecture (Figure 3). The FdhN to NarA respiratory chain of *E. coli* and the Hyd to NarA (electron transfer from formate or hydrogen to nitrate, q/e^- is 2) are the classical systems used to illustrate such an efficient proton-motive redox loop.

Formate Dehydrogenase N

Formate is an important and widespread electron donor available to bacteria in anaerobic environments. During anaerobic growth with nitrate, *E. coli* can express a membrane-bound formate dehydrogenase (FdhN), which oxidizes formate in the periplasmic compartment and for which a high-resolution structure has been determined. The enzyme is a homo-trimer, with each monomeric unit being composed of an integral membrane di-heme cytochrome subunit (FdhI), a membrane-anchored periplasmic ferredoxin subunit (FdhH), binding four [4Fe–4S] clusters, and a periplasmic catalytic subunit (FdhG), which binds a [4Fe–4S] cluster and catalyzes formate oxidation at a Se-Mo-*bis*-guanine dinucleotide (Se-Mo-MGD) cofactor. Electrons extracted from formate at the periplasmic active site pass down a 90Å redox ladder to a menaquinone reductase site at the cytoplasmic face of the membrane. The redox ladder consists of eight redox centers, Se-Mo-*bis*-MGD, five iron–sulfur clusters, and two hemes. Each of these is within 12Å of its nearest neighbor, and this serves to ensure rapid electron transfer (Figure 4). In considering the whole electron transfer ladder from the Se-Mo-*bis*-MGD to the menaquinone, a notable feature is that the intermediary electron carriers usually function as one-electron transfer centers. However, formate oxidation and menaquinone reduction are two-electron reactions. Thus, the Se-Mo-*bis*-MGD plays a key role in gating electron transfer from formate into the redox ladder and the Q-reductase site is the key to gating the reduction of menaquinone.

Much of the FdhN redox ladder is periplasmic, being located in the extra-membranous periplasmic FdhGH subunits (Figure 4), but the two membrane-intrinsic hemes, bound within the four-helix bundle of FdhI, are critical to charge separation across the membrane. The midpoint redox potential at pH 7 of the formate/CO_2 couple is *c.* −420 mV and that of the MQH_2/MQ couple is *c.* −80 mV. This large, *c.* 340 mV, potential drop allows efficient electron transfer against a negative-inside membrane potential of *c.* 200 mV. The movement of one electron from the periplasmic (P) face to the cytoplasmic (C) face of the membrane and uptake of one proton at the C face gives a coupling stoichiometry of $q^+/e^- = 1$ (Figure 4).

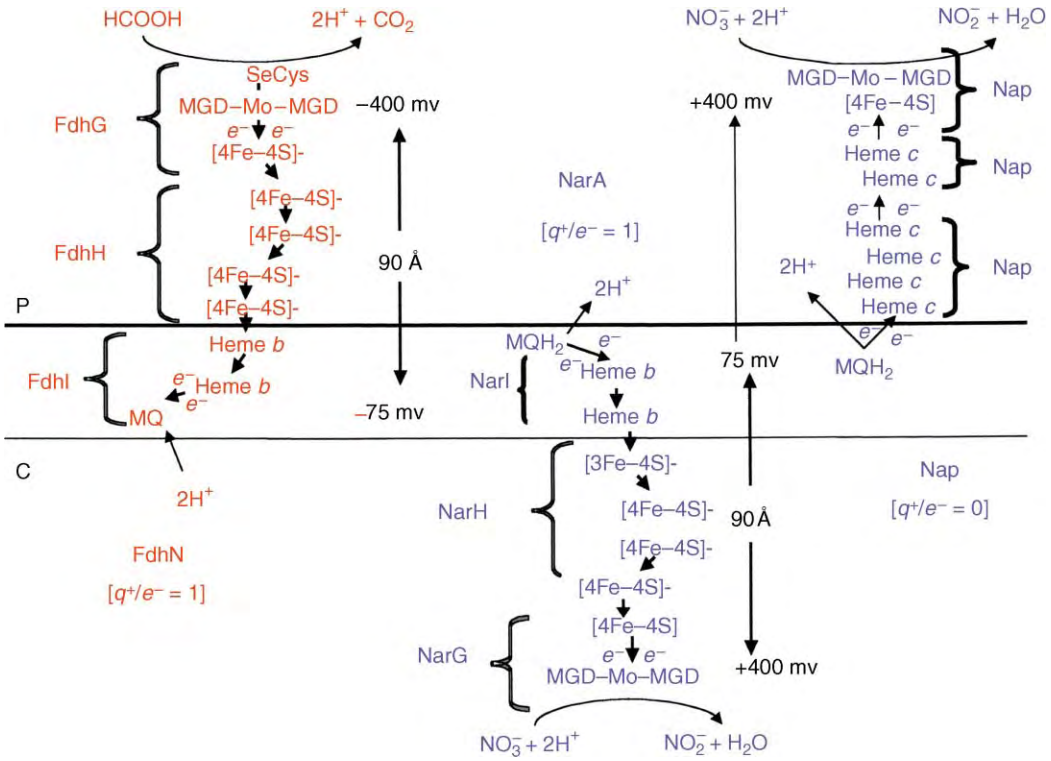

FIGURE 4 The organization of redox ladders involved in periplasmic formate-dependent nitrate reduction in *E. coli*. FdhN, formate dehydrogenase N. NarA, membrane-bound nitrate reductase A. Nap, periplasmic nitrate reductase.

Hydrogenase

Hydrogen is another important periplasmic electron donor for bacteria in anoxic environments. The Hya and Hyb enzymes of *E. coli* catalyze anaerobic hydrogen oxidation. There are no structures for these enzymes, but they are thought to be organized in a manner similar to FdhN. They are composed of three different subunits: an integral membrane di-heme subunit in which the hemes are stacked across the membrane; a periplasmic iron–sulfur protein (anchored by a single transmembrane helix); and a periplasmic catalytic subunit that binds a nickel–iron cofactor at the active side. The bioenergetics of periplasmic hydrogen oxidation are thus predicted to be very similar to that described for formate, with electrons extracted for hydrogen in the periplasm passing through a multi-cofactor redox ladder and combining with protons to reduce quinone at the cytoplasmic face, thus give $q^+/e^- = 1$.

Nitrate Reductase A

In *E. coli*, nitrate reductase A can serve as a second proton-motive arm in electron transfer from the periplasmic active site of FdhN or Hya (Figure 4). NarA is a three-subunit enzyme composed of NarGHI. NarG contains the *bis*-MGD molybdopterin cofactor at its catalytic site and a [4Fe–4S] cluster. NarH contains four additional iron–sulfur centers (one [3Fe–4S] and three [4Fe–4S]). NarGH are located in the cytoplasm and associate with NarI, an integral membrane protein of five transmembrane helices with the N-terminus and two inter-helix loops facing the periplasm. This subunit carries two hemes *b* stacked across the membrane. Oxidation of quinol occurs at the periplasmic side of NarI where the protons are released and the two electrons are moved from the outside low-potential heme *b* to the inside high-potential heme *b*. This charge separation makes the enzyme electrogenic, in that it contributes to the generation of a proton electrochemical gradient across the membrane (two charge separations during transfer of two electrons to nitrate; $q^+/e^- = 1$). Nar is organized in a manner very similar to FdhN, especially with respect to the equivalent FeS-containing NarH and FdhH subunits and Mo-*bis*-MGD NarG and FDHG catalytic subunits. However, the topology of the two systems is opposite (Figure 4), but the redox ladder arrangement of redox centers apparent in FdhN is also present in NarA. The midpoint redox potentials of individual cofactors in this ladder have been determined and suggest that both NarG and FdhN are part of a growing number of electron transfer complexes in bacteria that contain a mixture of endergonic and exergonic electron transfer steps. As in FdhN, the potential difference of *c*. 480 mV between the

MQH_2/MQ and nitrate/nitrite redox couples is sufficient to drive electron transfer across the membrane against the negative-inside PMF (Figure 4).

Non-Proton Motive Cytochrome bc_1 Complex-Independent Periplasmic Electron Transfer

In the FdhN–NarA electron transport system, both the quinone-reducing and quinol-oxidizing arms of the electron transport chain are proton-motive and, when operating together, they yield $q^+/e^- = 2$. However, in principle, only one arm needs to be proton-motive in order for a net PMF ($q^+/e^- = 1$) to be generated. Examples of this can be seen in a periplasmic formate–nitrate electron transport system in which nitrate is reduced by the periplasmic nitrate reductase (Nap) rather than NarA (Figure 3). Such a system operates under nitrate-limited growth conditions in *E. coli*.

The Periplasmic Nitrate Reductase (Nap)

Nap is widespread in many species of denitrifying and non-denitrifying proteobacteria, including both *P. denitrificans* and *E. coli*. Nap is normally found as part of a three-subunit electron transfer system composed of NapABC. NapA is a periplasmic catalytic subunit with a [4Fe–4S] cluster and a *bis*-MGD cofactor. The crystal structure of *Desulfovibrio desulfuricans* NapA reveals that the overall organization is similar to that of the catalytic subunits of the Mo-*bis*-MGD formate dehydrogenases. NapB is a periplasmic di-heme cytochrome *c*, with both hemes having bis-histidinyl ligation. NapC has a single N-terminal transmembrane helix that anchors a globular periplasmic domain with four *c*-type hemes to the periplasmic surface of the cytoplasmic membrane (Figure 4). All four hemes have relatively low midpoint redox potentials (in the region of 0 to −250 mV) and have *bis*-histidinyl axial ligation.

NapC may be made up of two subdomains, each containing a di-heme pair, and it belongs to a large family of bacterial tetra-heme and penta-heme cytochromes. These cytochromes have been proposed to participate in electron transfer between the quinol/quinone pool and periplasmic redox enzymes such as the trimethylamine N-oxide reductase, dimethylsulfoxide reductase, fumarate reductase, nitrite reductases, and hydroxylamine oxido-reductase. For an electron transport pathway from quinol to nitrate through Nap, the enzyme receives electrons from membrane-embedded quinols, which are donated to the tetra-heme periplasmic domain of NapC. From there they flow via the hemes in NapB and the [4Fe–4S] cluster in NapA to the bis-MGD-containing catalytic site of NapA where the two-electron reduction of nitrate to nitrite is catalyzed. As discussed above for NarA and FdhN, this electron transfer system also contains a mixture of endergonic and exergonic electron transfer steps but it is expected that none of the eight redox centers involved will be more than 14Å apart, thus ensuring rapid electron transfer. However, electron transfer from quinol to nitrate via Nap is non-electrogenic ($q^+/e^- = 0$) since both the electrons and the protons required for the reduction of nitrate to nitrite are taken up at the same side of the periplasmic face of the membrane.

Multi-Heme *c*-Type Cytochromes and Periplasmic Electron Transfer

Multi-Heme *c*-Type Cytochromes

In *E. coli* three other illustrative examples of non-electrogenic, quinol-oxidizing periplasmic electron transport systems that include extended redox ladders are illustrated in Figure 5. The cytochrome *c* nitrite reductase (Nrf) is a four-subunit electron transport system that involves 14 redox centers (10 *c*-type hemes and four [4Fe–4S] clusters). The trimethylamine N-oxide reductase (Tor) is a two-subunit system comprising of six redox centers (Mo-*bis*-MGD; and five *c*-type hemes). Finally, the dimethylsulfoxide reductase (Dms) is a three-subunit system containing an integral membrane subunit that is not involved in charge separation, and two periplasmic subunits that bind five redox centers (Mo-*bis*-MGD and four [4Fe–4S] clusters). Consideration of the Nap, Nrf, and Tor systems has revealed the participation of di-, tetra-, and penta-heme cytochromes in electron transfer. In mammalian mitochondria the P-facing cytochrome *c* involved in electron transfer is a small mono-heme protein. However, multi-heme cytochromes are a common feature of bacterial periplasmic electron transport. Other examples not mentioned so far include: (1) the octa-heme hydroxylamine oxido-reductase of nitrifying bacteria (e.g., *Nitrosomonas europeae*) and tetra-heme cytochrome *c554*, which, together with a tetra-heme NapC homologue CycB, mediate non-electrogenic electron transfer from hydroxylamine to quinone; (2) the tetra-heme fumarate reductase of *Shewanella* species that, together with the NapC homologue CymA, reduces fumarate to succinate using electrons drawn from the quinol pool. Structural analysis of these cytochromes and other multi-heme cytochromes such as the penta-heme NrfA reveals that the hemes are closely packed together to allow rapid electron transfer and are frequently arranged in pairs in which the porphyrin planes are nearly parallel or nearly perpendicular.

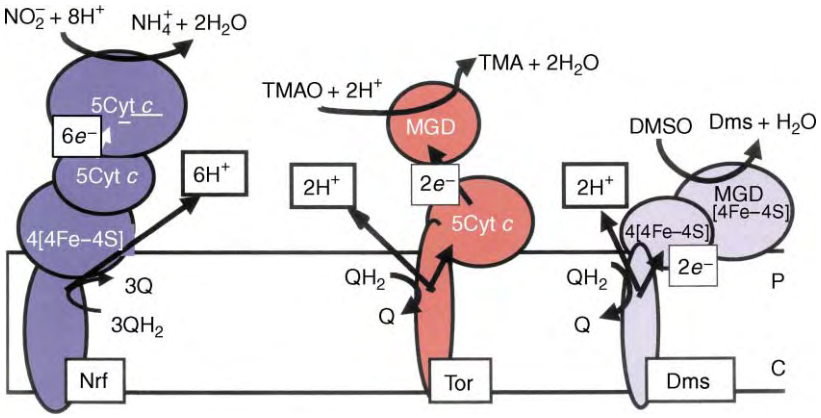

FIGURE 5 The organization of some non-electrogenic periplasmic electron transport systems in *E. coli*. Nrf, cytochrome *c* nitrite reductase, Tor, trimethylamine-N-oxide reductase; Dms, dimethylsulfoxide reductase.

Iron (III) Respiration and Inter-Membrane Periplasmic Electron Transport

Bacterial iron respiration is the process in which the Fe(III) acts as the terminal electron acceptor in an energy-conserving bacterial respiratory electron transport chain. It is an anaerobic process that provides a bacterium with a means of respiration when oxygen is absent and is distinct from the process of iron assimilation, in which iron is taken up into the cell by energy-consuming systems and incorporated into cell biomass. Although not a property of *E. coli*, the capacity for Fe(III) respiration is phylogenetically widespread and the ecological impact in microoxic and anoxic soils and sediments is considerable. A particular problem for gram-negative bacteria is that at neutral pH the speciation of Fe(III) is complex as the cation is present either as insoluble polynuclear oxo/hydroxo-bridged complexes or as soluble organic chelates. Thus, Fe(III) is frequently presented to bacteria in a range of insoluble forms. The best-characterized group of Fe(III)-respiring bacteria are species of the genus *Shewanella*, which are widespread facultative anaerobes of the gamma proteobacterium group. *Shewanella*, species can synthesize a number of periplasmic terminal respiratory reductases, including nitrate, nitrite, fumarate, and trimethylamine N-oxide reductases. During growth under iron-respiring conditions, *de novo* synthesis of a number of multi-heme *c*-type cytochromes that may a play a role in the Fe(III) respiration process occurs and a number of genetic loci that encode multi-heme cytochromes have been implicated as being important for Fe(III) respiration. Critically, these include an inner membrane tetra-heme cytochrome CymA (a NapC homologue), a small periplasmic 10 kDa tetra-heme cytochrome (STC); periplasmic deca-heme cytochromes (e.g., MtrA); and outer membrane cytochromes with deca-heme domains on the cell surface. The different cellular locations of these muti-heme cytochromes is critical to the transfer of electrons from the inner membrane across the periplasm to the outside of the outer-membrane where direct reduction of the insoluble extracellular substrate can occur. The multi-heme nature of the cytochromes may allow the proteins to form a multi-redox-centered electron wire that will be even longer than the redox ladders discussed for FdhN. Similar systems may also operate during the respiration of other insoluble respiratory substrates, such as manganese.

Synthesis of Periplasmic Electron Transport Systems

The periplasmic location of the cofactor-containing periplasmic electron transfer proteins raises the question as to how the organism assembles these proteins. This question is particularly relevant to a large protein complex with multiple redox centers, such as FdhN. In the case of periplasmic cytochromes *c* the protein is translocated in an unfolded state via the Sec pathway and heme is covalently attached using periplasmic or membrane-associated assembly proteins. However, many other classes of periplasmic redox protein possess a signal sequence, processed from the mature enzyme, that includes a twin arginine motif. This motif directs the protein to the twin arginine translocase (Tat), which transports pre-folded proteins with assembled redox cofactors. Some Tat substrates, including FdhGH are very large and consequently the pore of the Tat apparatus must be ~100Å in diameter to accommodate the largest substrates. The structure of the Tat complex is not yet known but there must be a gating mechanism, which maintains an ionic seal upon transport of these large substrates. The translocation process is also energy-driven, consuming PMF. This illustrates how

the overall consideration of the biochemistry and energetics of a periplasmic electron transfer system must take into account not only the operation of the system but also its biogenesis.

Glossary

electrogenic Property of a transmembrane electron transport enzyme that generates a PMF.

heme A tetrapyrrole with a coordinated iron that can mediate electron transfer when bound to proteins. In *c*-type cytochromes the heme is covalently bound to the protein.

iron–sulfur cluster A protein cofactor that comprises of inorganic iron and sulfur, which together form a cluster that is often involved in electron transfer.

periplasm A subcellular compartment that lies between the inner (cytoplasmic) and outer membrane of Gram-negative bacteria.

proton-motive force A transmembrane gradient of protons (Δp) that has an electrical component ($\Delta\psi$) and a chemical component (ΔpH). Its magnitude is normally given in units of mV and can be calculated from $\Delta p = \Delta\psi - 60\Delta\text{pH}$.

Biography

David Richardson is a Professor of Microbial Biochemistry and Director of the Centre for Metalloprotein Spectroscopy in the School of Biological Sciences at the University of East Anglia. He holds a Ph.D. in Biochemistry from the University of Birmingham. His principal research interests are in the field of bacterial respiration, where he studies the regulation, cellular organization, and biochemistry of a range of anaerobic electron transport systems. His contribution to this field was recognized by the Society for General Microbiology in 1999 when he was invited to give the Societies Fleming Lecture. He is on the editorial board of the *Journal of Biological Chemistry* and *Microbiology*.

Gary Sawers is a Project Leader in the Department of Molecular Microbiology at the John Innes Centre. He holds a Ph.D. in Biochemistry from the University of Dundee. His principal research interests include redox-dependent control of gene expression and metabolism in facultative anaerobes and *Streptomyces* and the biochemistry of metalloproteins. He is on the editorial board of *Microbiology*.

Rob van Spanning is an Assistant Professor in the Department of Molecular Cell Physiology at the Free University Amsterdam, The Netherlands. He holds a Ph.D. in Microbial Physiology and Molecular Microbiology from the Free University Amsterdam. His principal research interests are in understanding versatility and adaptive responses of bacterial respiration (from gene to function and back).

Peroxisome Proliferator-Activated Receptors

Mary C. Sugden, Edward A. Sugden and Mark J. Holness
Queen Mary, University of London, London, UK

PPARs (peroxisome proliferator-activated receptors) were originally identified by their ability to induce peroxisome proliferation, leading to the current nomenclaute. It has, however, emerged that PPARs do not induce peroxisome proliferation in man, but have an array of additional functions, most notably as master regulators of genes involved in metabolic control, particularly those involved in whole-body lipid homeostasis. PPARs are transcription factors, activated by binding key metabolic ligands, which exert their effects at the level of DNA to alter gene expression. Through this mechanism, PPARs, once activated, confer distinct properties of lipid handling to the tissues in which they are found, with an overall systemic lipid-lowering effect. There are three PPAR subtypes (α, γ, δ). PPAR subtypes are distributed non-uniformly in tissues. The individual PPARs act to reinforce each other's activities and also have complementary individual activities, all of wich are concerned with the removal of excess lipid from the blood. Acting as a team, the functions of the PPARs include regulation of fat breakdown by oxidation (PPARα and PPARδ), regulation of fat cell differentiation and lipid storage (PPARγ), together with others that include regulation of cholesterol fluxes into and out of cells (PPARγ and PPARδ). The physiological importance of the PPARs resides in lipid management, and the clinical importance of drugs acting via the PPARs lies in their ability to mimic nature's own messengers when harmful lipids accumulate. In this article, which of necessity cannot encompass all the actions of the PPARs, we will focus on how these receptors modulate lipid homeostasis in metabolically active tissues.

Lipids (triacylglycerol, cholesterol, phospholipids, fatty acids, and ketone bodies) are essential for many aspects of cellular processes, whilst also being linked to many pathological processes. Due to the varying demands of individual tissues for lipids, a highly regulated lipoprotein highway transports lipids to and from the periphery. The peroxisome proliferator-activated receptors (PPARs), α, γ, and δ, act as primary "metabolic" transcription factors, responding to fatty acids (FAs) and other metabolic signals to alter gene expression and thereby to confer distinct properties of lipid handling to the tissues in which they are found, with an overall systemic lipid-lowering effect. Thus, the PPARs act as a team with a common goal, but possess different attributes, including regulation of fat breakdown by oxidation (PPARα and PPARδ), regulation of adipocyte differentiation and fat storage (PPARγ), together with other functions that include regulation of cholesterol fluxes into and out of cells (PPARγ and PPARδ).

Lipids are essential for many aspects of cellular processes, including acting as substrates for energy production, steroid hormones and cellular structures. However, the availability and utilization of the various lipids must be carefully regulated since they are also linked to many pathological processes, including the development of obesity. The most familiar biological lipids are the triacylglycerols (TAG), which serve as principal energy stores, and cholesterol, both of which are present in the circulation at detectable levels. Because the hydrophobic lipids do not dissolve in water, moving them around the body requires transport mechanisms that are highly regulated. Due to the variable requirements for these compounds from a wide range of tissues, a lipoprotein highway exists that allows transport of the hydrophobic lipids with water soluble protein escorts enabling the movement of TAG and cholesterol to and from the periphery. TAG-enriched lipoproteins, chylomicrons (containing TAGs made from the re-esterification of newly absorbed FA and monoacylglycerol (MAG) in the gut) and very low density lipoproteins (VLDL) (containing TAG fabricated in the liver), deliver TAG to peripheral tissues for storage and energy production. The utilization by individual tissues of TAG in VLDL and chylomicron is carefully regulated through the expression of lipoprotein lipase (LPL), which is anchored to the outside of the cell in which it is expressed. LPL liberates FA and MAG in TAG for uptake by the tissue. Consequently, individual tissues can regulate their uptake of TAG-derived FA by altering the level of expression of LPL. At the same time, low-density lipoproteins (LDL) deliver cholesterol to tissues so that they can maintain membrane integrity and, in some instance, use it for the production of biologically important compounds, such as steroids.

Cholesterol uptake by cells is also regulated, in this case by the expression of the LDL receptor. In addition to the lipid highway from the liver/gut to peripheral tissues, a contraflow operates in the opposite direction, whereby high-density lipoproteins (HDL) transport surplus cholesterol from cells, such as those of the vessel wall, to the liver, where it can be redeployed to form bile. Gridlock in these lipid transfer and utilisation systems leading to the accumulation of VLDL and LDL in the circulation is integral to the development of metabolic diseases, including type 2 diabetes and cardiovascular disease.

PPARs: A Three-Pronged Attack

Peroxisome proliferator-activated receptors (PPARs) are transcription factors, activated by binding metabolic ligands, which exert their effects at the level of DNA to alter gene expression. There are three PPAR subtypes (α, γ, and δ). PPARs were originally identified by their ability to induce peroxisome proliferation, and this led to the current nomenclature. PPARα was first identified as the intracellular target for a particular class of rodent hepatocarcinogens, which include clofibrate. Clofibrate, a member of the fibrate amphipathic carboxylic acid family, was found to be a potent inducer of proliferation of peroxisomes, cell organelles found in high quantities in the liver, in addition to increasing FA oxidation and lowering lipid levels. Several other "peroxisome proliferating" agents were subsequently cloned. However, it has since emerged that the PPARs do not induce peroxisome proliferation in man, but have an array of additional functions, most notably as master regulators of genes involved in metabolic control, particularly those involved in whole-body lipid homeostasis. Inappropriately, the name PPAR has remained in common use! The PPAR subtypes are distributed non-uniformly in tissues. PPARα is expressed in a wide range of tissues and is highly expressed in liver, kidney, and heart. PPARγ has a more limited tissue distribution and is highly expressed in adipocytes and macrophages. PPARδ is widely expressed. After the PPARs are activated by binding specific ligands and/or by covalent modification (phosphorylation), they consort with another receptor, the 9-cis retinoic acid activated receptor (RXR), and, conjoined and active, recruit co-activators and together bind to peroxisome proliferator response elements (PPRE) to modify the expression of specific genes. This leads to an altered complement of enzymes in the cell, with a resultant alteration in cellular functional characteristics. Through this mechanism, each PPAR can, once activated, confer distinct properties of lipid handling to the tissues in which it is found, with an overall systemic lipid-lowering effect. The individual members of the PPAR gang act to reinforce each other's activities and also have complementary individual activities, all of which are concerned with the removal of excess lipid from the blood. Acting as a team with a common goal but differing attributes, the functions of the PPARs include regulation of fat breakdown by oxidation (PPARα and PPARδ), regulation of adipocyte differentiation and fat storage (PPARγ), together with others that include regulation of cholesterol fluxes in to and out of cells (PPARγ and PPARδ). The molecular messengers that bind to and activate the individual PPARs (the endogenous ligands) are not all identified. However, the close involvement of fat metabolism and lipid homeostasis with the PPAR family members arises, in part, because certain FAs and other lipid-derived molecules, including eicosanoids and arachidonic acid derivatives, can bind to and activate PPARs and are known to be primary natural ligands for these molecules. For example, PPARα is activated by polyunsaturated FAs, and PPARδ by long-chain FAs. Thereby, these lipid-signaling molecules can have power over their own fates by binding to PPARs and changing the expression of genes involved in modulating the patterns of tissue FA handling. The physiological importance of the PPARs thus resides in lipid management, and the clinical importance of drugs acting via the PPARs lies in their ability to mimic nature's own messengers when the task of lipid management becomes too onerous and harmful lipids accumulate. It is now established that the fibrates (e.g., clofibrate) and the anti-diabetic insulin-sensitizing thiazolidinediones (TZDs) both exert their systemic lipid-lowering effects via the PPARs. In this article, which of necessity cannot encompass all the actions of the PPARs, we will focus on how these receptors modulate lipid homeostasis in metabolically active tissues.

PPARα (NR1C1)

Too much FA, TAG or cholesterol circulating in the blood can be hazardous to health. High-fat diets, particularly those rich in very-long-chain FAs and polyunsaturated FAs induce FA oxidation via PPARα. Synthetic ligands for PPARα, in addition to the fibrate drugs, include phthalate ester plasticers, herbicides, and leukotriene D4 receptor antagonists. The fibrate PPARα agonists (clofibrate, gemfibrozil, fenofibrate, bezafibrate, and ciprofibrate) have been in clinical use for over 40 years for the treatment of dylipidemia.

The liver occupies a central position in whole-body lipid handling. In the case of FAs, the liver is capable of either oxidizing, or storing FAs depending on the prevailing requirements. FAs are stored after conversion to the TAG component of VLDL, and this function can be increased when FA delivery is higher than that

required to fuel hepatic ATP requirements via β oxidation. Incoming FAs, derived from the diet or endogenous stores, are re-esterified and stored in the fed state. During starvation, FAs, released from adipose tissue, are taken up by the liver and oxidized to create the water-soluble lipid-derived fuels, the ketone bodies (which are easily transported and oxidized by peripheral tissues), while TAG is incorporated into VLDL which is released into the circulation. These latter metabolic transformations of incoming FAs are enhanced by PPARα, the primary PPAR subtype expressed in liver. PPARα regulates specific genes that code for regulatory proteins involved in almost every stages of hepatic FA utilization, including FA uptake into the cell across the cell membrane, its retention within the cell, and its oxidation leading to ATP production and ketone body formation (Figure 1). PPARα therefore fulfills a critical role in the regulation of hepatic FA handling and, indeed, is essential for the up-regulation of the capacity of the liver for FA utilization in starvation or when lipid delivery is increased by a diet high in fat. This adaptive role is best illustrated by the inadequate response to high-fat feeding seen in PPARα-deficient mice, the Jack Sprats of lipid biochemistry. These animals exhibit an impaired ability to up-regulate hepatic FA oxidation in response to a high-fat diet, despite increases in FA supply, and the liver becomes engorged with lipid. Similarly, PPARα-deficient mice are unable to adapt to starvation, where delivery of FA from adipose tissue is increased. Secondary to impaired FA oxidation, compromised hepatic energy generation results in a low blood glucose concentration (hypoglycemia) when PPARα-deficient mice are fasted. Hypoglycemia arises by virtue of the necessity to continue to use glucose at high rates, rather than to be able to switch to FA or (in extrahepatic tissues) ketone bodies as alternative energy fuels, and because hepatic FA oxidation allows hepatic glucose synthesis (gluconeogenesis) through the generation of ATP and essential cofactors. The accumulation of large amounts of lipid in livers of PPARα-deficient mice, either on fasting or when they are maintained on a high-fat diet demonstrates the critical importance of PPARα-linked functions in matching hepatic FA delivery to FA clearance when the systemic delivery of lipid is increased. Hence, the TAG-lowering action of fibrates and related PPARα-targeted drugs in patients with hyperlipidemia is ascribed to increased FA clearance via oxidation, primarily but not exclusively in liver. Within the liver, PPARα also is heavily involved in the regulation of the synthesis and catabolism of lipoproteins, including some steps of the HDL synthetic pathway. Increased diversion of FA into oxidation decreases the availability of fatty acyl-CoA substrates for TAG synthesis, and thereby decreases VLDL

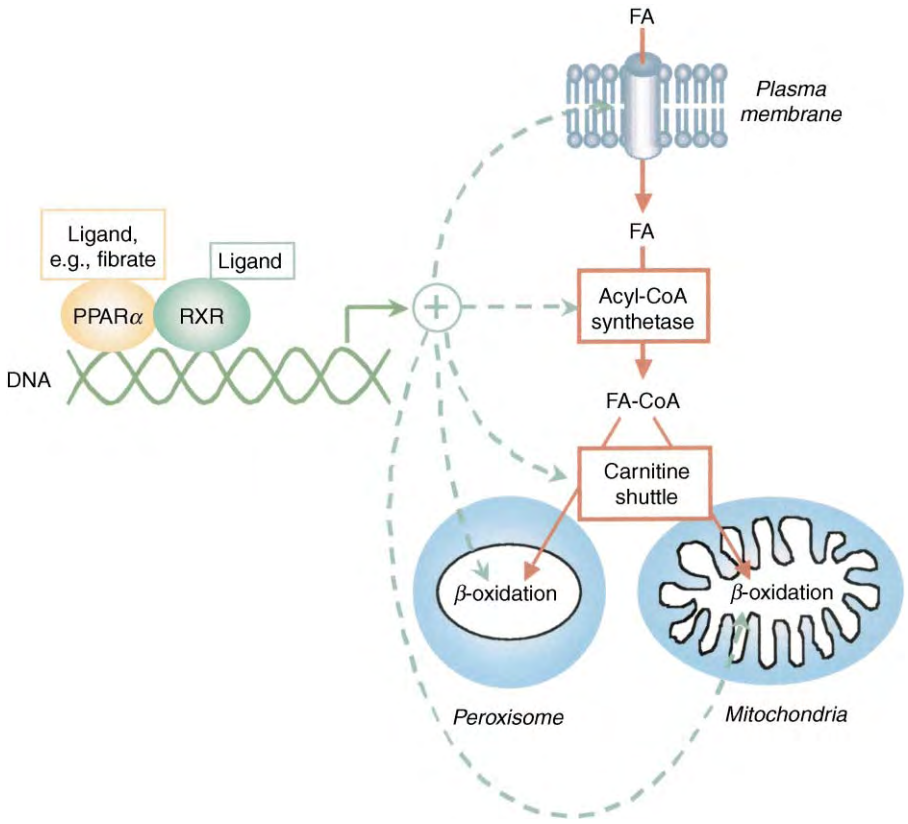

FIGURE 1 Mechanisms whereby activation of PPARα regulates fatty acid uptake, sequestration in the cell and oxidation.

secretion by the liver. In addition, PPARα inhibits expression of apolipoprotein (apo) C-III (a protein that may inhibit the TAG-hydrolysing action of LPL) and so enhances the hydrolysis of TAG contained in lipoproteins, and increases the hepatic uptake of TAG-enriched lipoprotein remnants. This decreases plasma TAG levels further and increases the transfer of other surface components of TAG-rich particles to HDL.

As well as in liver, PPARα is expressed abundantly in other tissues that are normally characterized by high rates of lipid oxidation. It is also present in the artery wall in monocytes/macrophages, vascular smooth muscle cells and endothelial cells. We focus here on the role of PPARα in kidney and heart, tissues which have a high energy demand related to their physiological functions. In these tissues, PPARα activation again enhances the expression of genes involved in FA uptake, activation, and oxidation. PPARα-deficient mice subjected to ischemia/reperfusion injury respond with greater renal cortical necrosis and worse kidney function compared with wild-type controls, indicating the vital role of PPARα in this tissue. PPARα is found predominantly in the renal cortex. Like liver, the renal cortex is a site of gluconeogenesis. Altered renal gluconeogenesis is increasingly recognized as contributing to fasting hyperglycemia in diabetes mellitus, and assumes increasing importance for maintenance of glycaemia after very prolonged food deprivation. Hence, as in liver, PPARα-facilitated gluconeogenesis driven by enhanced FA oxidation is likely.

Although functionally quite distinct from liver and kidney, there is ample evidence for an important role for PPARα in cardiac function in some circumstances. In adulthood, although the heart is a metabolic omnivore using most available fuels, lipids constitute the predominant energy substrate. However, during fetal and early life, in cardiac hypertrophy and in the failing heart, glucose utilization assumes greater importance, possibly as an adaptation to limited oxygen availability. Oxygen is essential for ATP production from FAs, but glucose oxidation needs less oxygen per mole than FA oxidation and glucose utilization can proceed, albeit less efficiently, in the absence of oxygen. The downside is that less ATP is generated per mole of glucose oxidized and when excess dietary lipid can be ingested, as in extrauterine life, the potential exists for myocardial lipid accumulation and lipotoxicity. Accordingly, the importance of PPARα in the adult heart appears relatively limited when the dietary lipid supply or endogenous lipid production is restricted, but PPARα assumes an important role in cardiac lipid management when lipid delivery to the heart is increased. PPARα-deficient mice provided with free access to a high-carbohydrate low-fat diet do not show any obvious cardiac abnormalities, but they accumulate myocardial lipid on starvation or if a high-fat diet is provided. This indicates a vital function for PPARα in allowing cardiac FA oxidation to occur at a rate sufficient to prevent the harmful accumulation of lipid within the heart itself.

Changes in the activity of the PPARα signaling pathway to gene expression characterize many common myocardial diseases. Whether changes in cardiac PPARα signaling are adaptive or causally related to myocardial pathology remains controversial, but there is no doubt that poor lipid management can cause a broken heart! Cardiac PPARα expression and activity are suppressed in the pathologically hypertrophied heart. The resultant decrease in the capacity for FA oxidation is associated with increased rates of glucose utilization and reversion to the fetal pattern of substrate use. Although causality between the reciprocal changes in lipid and glucose utilization has not been established, this metabolic switch may serve to preserve ventricular function within the context of pressure overload. The expression and activity of both PPARα and RXR are also suppressed in the hypoxic cardiac myocyte. To date, there are no reports of worsening of cardiac function in humans with cardiac hypertrophy through the use of the PPARα agonist fibrates. It is interesting that the heart is closely associated with adipose tissue in adult man, and epicardial and pericardial depots can represent a significant fraction of the total mass of the heart, suggesting a possible role as a local FA source. Both neutral lipid and FA adversely affect myofibrillar function. An intriguing possibility is that cardiac adipose tissue may act as a potential local sink for FA, mopping up FA when they are delivered in excess of the cardiac ATP requirement or when they cannot be cleared through oxidation, for example, during cardiac hypertrophy. The heart expresses LPL and, interestingly, LPL activity in cardiac myocytes is inhibited by PPARα activation. This effect may again help protect against a potentially toxic oversupply of FAs to the myocardium.

Epidemiological studies reveal that people with diabetes are at an extraordinary high risk for the development of cardiovascular disease. The heart in uncontrolled diabetes is constrained from switching to glucose oxidation and relies almost exclusively on lipid as an energy source. Cardiac-specific over-expression of PPARα, in the absence of alterations in lipid-fuel delivery, enhances the myocardial capacity for FA oxidation. This, however, is maladaptive, since many of the metabolic abnormalities of the diabetic heart, including decreased glucose utilization and ventricular dysfunction, are recapitulated. In this situation, the profile of myocardial TAG species is similar to the lipid species in the circulation, suggesting that the expanded lipid reservoir reflects increased uptake incompletely balanced by a corresponding increase in oxidation. When mice with cardiac-specific PPARα overexpression are made diabetic, they develop a more severe

cardiomyopathy than wild-type controls. In contrast, PPARα null mice are protected from cardiomyopathy.

PPARγ (NR1C3)

PPARγ, the predominant molecular target for the insulin-sensitizing TZDs and for specific prostanoids, such as 15-deoxy-$\Delta^{12,14}$ prostaglandin J2, is abundantly expressed in adipocytes, macrophages, the placenta and the fetal heart. The role of PPARγ as a critical regulator of adipose tissue development and metabolism is perhaps most well-established of the functions of the PPARs. Adipocytes expand as animals fatten, then shrink when the stored TAGs within them is mobilized because of food scarcity or, in the case of Mrs Sprat or the Atkins diet, lack of carbohydrate. A key feature of the fat cell is its ability to release the FA derived from TAG into the bloodstream: most other tissues are less altruistic and use FA derived from their endogenous TAG themselves. Detectable changes in gene expression in response to PPARγ activation in adipose tissue includes the induction of genes that allow adipose tissue to take up and accumulate lipid (Figure 2). Through this action, PPARγ contributes to lowering of circulating FA and TAG levels and, by sequestering lipid in the adipocyte, reduces the burden of excessive lipid delivery to tissues other than adipose tissue, including heart, skeletal muscle, kidney, and liver, where its accumulation could have deleterious effects. PPARγ can therefore enhance whole-body insulin action even though it is predominantly expressed in adipose tissue (which makes a relatively minor contribution to insulin-stimulated glucose disposal in lean individuals) by limiting the supply of lipid to other insulin-sensitive tissues and reducing the ability of FA to oppose insulin's actions in these tissues.

In addition to effects on genes involved in adipocyte lipid storage, TZDs increase adipocyte expression of the insulin-sensitive glucose transporter GLUT4, which allows increased use of circulating glucose for the synthesis of glycerol-phosphate which, in turn, allows FA esterification to form storage TAG (Figure 2). In addition, the TZDs may actually allow the fat cell to express enzymes that allow glycerol released from TAG breakdown (lipolysis) to be reclaimed or synthesized from circulating lactate, a process termed glyceroneogenesis (Figure 2). The presence of glycerol kinase allows glycerol released via the hydrolysis of stored triglyceride to be converted to glycerol phosphate which, in turn, allows reincorporation of released FA, or of FA derived from exogenous lipoproteins, into storage TAG, albeit at an energetic cost to the adipocyte. However, in obese people, as much as half of the body mass can be adipose tissue due to excessive enlargement of adipocytes and the presence of increased numbers of adipocytes.

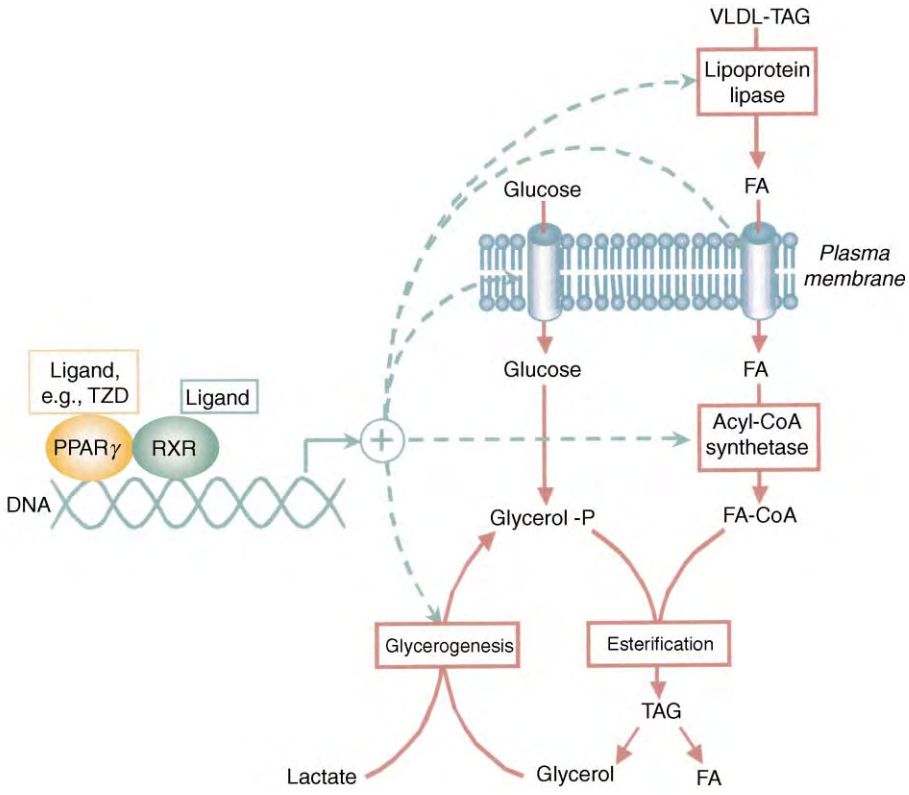

FIGURE 2 Mechanisms whereby activation of PPARγ regulates fatty acid uptake, sequestration and storage and glucose uptake and glycerogenesis in adipocytes.

Obese people invariably become glucose intolerant and insulin resistant, as well as developing other obesity-related complications which increase morbidity and mortality. "We fat all creatures else to fat us, and we fat ourselves for maggots" (Hamlet). It follows that the long-term use of TZDs could actually exacerbate obesity and insulin resistance, despite its more acute beneficial insulin-sensitizing action due to adipose-tissue lipid sequestration.

An additional action of PPARγ activation in adipose tissue is altered rates of secretion of biologically active adipokines (signaling molecules secreted by adipocytes), including leptin and TNFα, which can modulate insulin sensitivity in non-adipose tissue. Both leptin and TNFα have a role in obesity. Samples of adipocytes from obese people produce much more TNFα than those from lean people. Leptin is a molecule that informs the brain that adipose tissue is replete with lipid and signals a need to cease eating. PPARγ suppresses the production of both leptin and TNFα, thereby fooling the adipocyte that enough (lipid) is not enough, and allowing the adipocyte to continue to accumulate even more lipid.

Effects of the TZDs to ameliorate hyperglycemia and hyperlipidemia in fatless mice demonstrate that, although predominantly expressed in adipose tissue, PPARγ ligands may exert their effects via PPARγ in tissues in addition to adipose tissue. PPARγ agonists have been reported to be cardioprotective against ischaemic insult and to modify the cardiac hypertrophic growth response to pressure overload. However, most cardiac effects are likely to be indirect because of the low level of expression of PPARγ in cardiac myocytes themselves in adulthood, although the adipose tissue surrounding the heart itself may be targeted directly and act as a lipid buffer.

Most kinds of mammalian cells synthesize adequate cholesterol for their needs, but the human diet usually contains more than enough to supply our cells. Only the liver can degrade and eliminate cholesterol, so any excess has to be transported there from other tissues. LDL particles are rich in cholesterol. Some LDL leak through the thin lining of major vessels, where they become trapped under the endothelial cells, a process facilitated by hypertension (high blood pressure). Trapped LDL molecules attract macrophages, immune cells that can take up and degrade LDL. Some trapped LDL react with oxygen in the blood. Unfortunately, the oxidized LDL appear to be able to enter the macrophages in almost unlimited quantities, accumulating as pale, greasy particles that resemble the appearance of foam. Death of the lipid-bloated macrophages (foam cells) releases their lipid content forming fatty streaks in the arteries. The endothelial cells over the fatty streaks can become damaged and are replaced with fibrous plaques, narrowing the arteries. In the final stages of cardiovascular disease, the stiff narrow arteries ulcerate, increasing the risk of forming a blood clot, which will plug blood flow completely. The increased risk of cardiovascular disease in diabetic patients has prompted study of PPARγ function in lipid-laden macrophages. It has been reported that activation of PPARγ with the TZDs promotes cholesterol efflux from macrophages, improving the status of the atherosclerotic lesion, whereas macrophages lacking PPARγ are defective in cholesterol efflux and display accelerated lesion progression. Activation of PPARγ by components of oxidized LDL (9-hydroxyoctadecadienoic acid, 13-hydroxyoctadecadienoic acid) however, enhances macrophage lipid accumulation through induction of a scavenger receptor/transporter (FA translocase/CD36).

PPARδ (NR1C2)

Compared with PPARα and PPARγ, relatively little is known about PPARδ (also called PPARβ or FA-activated receptor, FAAR), except that it is relatively ubiquitously expressed. Nevertheless, its importance of PPARδ is established by the observation that most PPARδ-deficient mice die early in embryonic development due to a placental defect and those few that do survive have a reduced fat mass. PPARδ may also be involved in the cellular differentiation and inflammatory response of the epidermis. Importantly, PPARδ has been shown to mediate VLDL signaling to gene expression in the roving macrophages. Exposure of macrophages to VLDL results in enhanced expression of a lipid-droplet-coating protein that is implicated in lipid storage in these cells. Studies of PPARδ-deficient macrophages reveal that the TAG components of VLDL, released by LPL, serve as direct ligands for PPARδ to induce this protein, with accompanying lipid accumulation within the macrophage. These new data reveal a pathway whereby VLDL itself can directly regulate gene expression in atherosclerotic lesions.

Pharmacological activation of PPARδ lowers fasting TAG and LDL levels while increasing levels of HDL (the cardioprotective lipoprotein). It is unclear which tissue is targeted although skeletal muscle, in which PPARδ is highly expressed, is suspected. Slow-twitch oxidative skeletal muscle is a major site of FA catabolism, particularly during starvation and long-term exercise, when circulating lipid delivery increases. However, most evidence suggests that signaling via PPARα impacts predominantly on the regulation of lipid gene expression and fat burning in fast-twitch, not slow-twitch, skeletal muscle, even though fast-twitch muscle does not normally oxidize FA as avidly as slow oxidative muscle. Whereas PPARα ablation in the mouse results in abnormally high accumulation of neutral lipid in heart and liver in response to interventions increasing FA delivery, such as starvation, starvation of

PPARα-deficient mice leads to only minor abnormalities of skeletal-muscle FA metabolism. The lack of accumulation of neutral lipid has been attributed to the findings that PPARδ is the major type of PPAR found in mouse skeletal muscle. PPARδ may therefore assume greater importance in the modulation of lipid metabolism than PPARα in skeletal muscle, a conclusion supported by findings that PPARδ mRNA expression levels in muscle are dramatically increased on fasting, under conditions where FA oxidation by skeletal muscle is increased. Interestingly, PPARδ is also relatively abundant in the heart and exposure of cardiac myocytes to either PPARα- or PPARδ-specific agonists leads to significant induction of PPAR target genes involved in FA uptake and oxidation and both PPARs can be activated by FAs within this system.

Last Words

The question is raised as to why some non-adipose tissues express multiple PPARs, for example, PPARγ and PPARδ in macrophages, PPARα and PPARδ in muscle. Activation of all three PPARs appears to decrease systemic lipid availability and to decrease lipid (TAG and/or cholesterol) storage in non-adipose tissue. One possibility is that each individual PPAR activates overlapping but distinct downstream metabolic pathways. Perhaps more likely, it may be that the physiological ligands (presumably upstream lipid-based messengers) for activation of each of the PPARs are unique and that such ligand distinctness allows specificity of cellular downstream metabolic responses. PPARs are thus jacks of all trades, and masters of (at least) one! Although their individual specific physiological roles still require much further investigation, it is clear that, as ligand-activated transcription factors, the PPARs represent attractive targets for the development of selective therapeutic agents for pharmacological modulation of lipid metabolism.

Biography

Mary C. Sugden is Professor in the Centre for Diabetes and Metabolic Medicine, ICMS at Bart's and the London School of Medicine and Dentistry in London, UK. Her principal research interests lie in the broad fields of insulin secretiion and action and in metabolic regulation, particularly with respect to fuel preference and the regulatory interactions between glucose and fats as energy sources. She holds M.A. and D.Phil. degrees from the University of Oxford and a D.Sc. from the University of London. Edward A. Sugden is associated with the group and assisted with analysis of the accessibility of the text to a lay audience.

Mark J. Holness a Senior Lecturer in the Centre for Diabetes and Metabolic Medicine, ICMS at Bart's and the London School of Medicine and Dentistry in London, UK. He holds B.Sc. and Ph.D. degress from the University of London. His principal research interests include the etiology of insulin resistance elicited by modification of dietary and hormonal status in early life and/or adulthood, the impact of lipid quantity and quality on pancreatic beta cell function and the role of PPARα in mediating changes in insulin sensitivity and secretion.

Peroxisomes

Suresh Subramani
University of California, San Diego, California, USA

Peroxisomes are among the simplest of the subcellular organelles that are characteristic of all eukaryotic cells. With ~60 known enzymes in the matrix and ~45 documented integral or peripheral membrane proteins, it is a reasonable guess that this organelle has only ~125 proteins, which makes it much less complex than other organelles. The peroxisome derives its name from the fact that many metabolic enzymes that generate hydrogen peroxide as a by-product are sequestered here because peroxides are toxic to cells. Within peroxisomes, hydrogen peroxide is degraded by the enzyme, catalase, to water and oxygen. Peroxisomes are surrounded by a single membrane and they range in diameter from 0.1 to 1 μm. They exist either in the form of a network of interconnected tubules (peroxisome reticulum), as in liver cells, or as individual microperoxisomes in other cells such as tissue culture fibroblasts.

Peroxisome-Like Organelles

Peroxisomes are related to specialized peroxisomes called glycosomes in parasites such as Trypanosomes, and to plant glyoxysomes, but are unrelated to hydrogenosomes, mitochondria, and chloroplasts. Collectively, peroxisomes, glyoxysomes, and glycosomes are also referred to as microbodies.

Peroxisome Distribution and Origin

Peroxisomes exist in all eukaryotes from single- and multicellular microorganisms, to plants and animals. Unlike mitochondria, nuclei, and chloroplasts, peroxisomes have no DNA. Consequently all their proteins are encoded by nuclear genes. They are proposed to have originated from endosymbionts that subsequently lost their DNA, but the evidence for an endosymbiont origin is much weaker than it is for mitochondria and chloroplasts.

Regulation of Peroxisome Number, Volume, and Contents

Peroxisomes can be induced to proliferate in many organisms in response to metabolic needs. Examples include the induction of proliferation of hepatic peroxisomes by fibrate drugs, phthalate plasticizers and xenobiotics, or the induction of peroxisomes in the methylotrophic yeast, *Pichia pastoris*, by methanol or oleate. The contents of the organelle are also responsive to the environment, as illustrated by the fact that peroxisomes of yeasts grown on oleate have induced levels of the fatty acid β-oxidation enzymes, whereas methylotrophic yeasts grown on methanol have elevated levels of alcohol oxidase and dihydroxyacetone synthase. Peroxisome volume can also be regulated by proteins such as Pex11p and Pex25p. Some mechanism must also exist for monitoring the need for peroxisomes and their function, because excess peroxisomes can be turned over by autophagic mechanisms involving the lysosome in mammals, or its yeast equivalent, the vacuole.

Functions of Peroxisomes

The principal function of peroxisomes is to house many metabolic pathways that are involved in various aspects of lipid metabolism. These include the following:

1. enzymes involved in the degradative oxidation (e.g., β-oxidation of very long chain fatty acids, 2-methyl-branched fatty acids, dicarboxylic acids, leukotrienes, bile acid intermediates and cholesterol side chains, and both α- and β-oxidation of 3-methyl-branched chain fatty acids);
2. the early steps in the synthesis of ether glycerolipids or plasmalogens;
3. the formation of bile acids, dolichol, and cholesterol; and
4. the catabolism of purines, polyamines, and amino acids, and the detoxification of reactive oxygen species such as hydrogen peroxide, superoxide anions, and epoxides. In methylotrophic yeasts, peroxisomes are also involved in the metabolism of methanol and methyl amines.

Glycosomes contain the glycolytic enzymes, in addition to enzymes common to most peroxisomes, whereas plant gloxysomes have some or all of the

glyoxylate pathway enzymes. Peroxisomes in the leaves of plants also participate in photorespiration.

Despite the fragility of the organelle during biochemical purification, the peroxisome membrane is impermeable to small molecules such as NAD(H), NADP(H), acetyl-CoA, and even protons *in vivo*. Consequently, it is not surprising that the peroxisomal membrane has a number of transporters for fatty acids, fatty-acyl-CoA esters, metabolites, and ATP.

Involvement in Human Disease

There are ~20 peroxisomal disorders, many of which are fatal. These diseases affect either a single metabolic enzyme, or the assembly of the organelle itself (Table I). Almost all of the genes involved in the human peroxisome biogenesis disorders (PBDs) are now known – they fall within the 25 *PEX* genes required for peroxisome biogenesis. Mouse models for human PBDs offer the promise of better insights into the symptoms of these diseases, their diagnoses, and eventually for therapeutic intervention.

Biogenesis of Peroxisomes

Because peroxisomes have no DNA, all their proteins must be imported from genes encoded in the nucleus. Most of proteins that reside in the peroxisome matrix and membrane are synthesized in the cytosol and then imported posttranslationally to the organelle. About 25 *PEX* genes, encoding proteins named peroxins, are necessary for the biogenesis of the organelle. Most of these genes are found in multiple organisms and 13 are conserved in humans (Table II). The general principles of biogenesis appear to be common to organisms across the evolutionary spectrum, but there are indeed organism-specific variations. More recently, additional *PEX* genes (*PEX23–PEX32*) have been defined and many of these are involved in the control of peroxisome division and number, rather than in protein import.

Peroxisomal Matrix Protein Import

Proteins destined for the peroxisome matrix have a few peroxisome targeting signals (PTSs). Most matrix polypeptides have a conserved, C-terminal, tripeptide PTS1 (-SKL in the one letter amino-acid code, or its conserved variants). Others have an N-terminal or internal sequence termed PTS2 [(R/K) (L/V/I))X_5(H/Q) (L/A)]. A few proteins, such *Saccharomyces cerevisiae* acyl-CoA oxidase, either have no canonical PTS1 sequence or have one that is dispensable, suggesting that they may possess other, as yet undefined, features that allow them to be targeted to the peroxisome lumen.

Matrix proteins synthesized in the cytosol are bound by cytosolic receptors – Pex5p in the case of PTS1, and

TABLE I

Human Peroxisomal Disorders Involving Metabolism and Biogenesis

Disease	*Peroxisomal enzyme affected*
Peroxisomal metabolic disorders	
Pseudoneonatal adrenoleukodystrophy	Acyl-CoA oxidase (Acox1)
Multifunctional protein 2 (MFP2) deficiency	MFP2 involved in β-oxidation of very long chain and 2-methylbranched fatty acids
Peroxisomal thiolase deficiency	3-ketoacyl-CoA-thiolase
X-linked adrenoleukodystrophy	ALDp (transporter)
Rhizomelic chondrodysplasia punctata Type 2	Dihydroxyacetonephosphate acyltransferase
Rhizomelic chondrodysplasia punctata Type 3	Alkyl-dihydroxyacetonephosphate synthase
Refsum's disease (classical)	Phytanoyl-CoA hydroxylase
Glutaric aciduria Type 3	Glutaryl-CoA oxidase
Hyperoxaluria Type I	Alanine:glyoxylate aminotransferase
Acatalasaemia	Catalase
Mevalonic aciduria	Mevalonate kinase
Di/trihydroxycholestanoic acidaemia	Trihydroxycholestanoyl-CoA oxidase (Acox2)
Mulibrey nanism	TRIM37
Adult-onset sensory motor neuropathy	2-methylacyl-CoA racemase
Disease	**Peroxin affected**
Peroxisome biogenesis disorders	
Zellweger syndrome	Pex1, Pex2, Pex3, Pex5, Pex6, Pex10, Pex12, Pex13, Pex16, Pex19
Neonatal adrenoleukodystrophy	Several peroxins (Pex1, Pex5, Pex6, Pex10, Pex12, Pex13)
Infantile Refsum's disease	Several peroxins (Pex1, Pex2, Pex5, Pex12)
Rhizomelic chondrodysplasia punctata Type I	Pex7

TABLE II

Proteins Involved in Peroxisome Biogenesis

Pex1	A 100–50 kDa ATPase (AAA family) in yeasts and humans. Interacts with Pex6 and other peroxins. Defects in Pex1 are the most common cause of the PBDs (CGI).
Pex2	A ~40 kDa integral PMP with a carboxy-terminal, cytoplasmically exposed, zinc-binding RING domain. Has been identified in yeasts and humans, interacts with Pex3, Pex10 and Pex12 and is defective in CG10 of the PBDs.
Pex3	A ~40 kDa integral PMP in yeast and humans that binds Pex19 and is defective in CG12 of the PBDs. Needed for assembly/stability of the RING–domain subcomplex comprised of Pex2, Pex10, Pex12 in yeast.
Pex4	A 20–24 kDa peroxisome-associated ubiquitin-conjugating enzyme that interacts with Pex22. Has been identified in several yeast species, but not in any metazoan.
Pex5	A ~70 kDa, predominantly cytoplasmic/partly peroxisomal protein that is found in yeasts, plants and humans. Contains a PTS1-binding, tetratricopeptide-repeat (TPR) domain in its carboxy-terminal half, interacts with several peroxins (Pex7, Pex8, Pex10, Pex12, Pex13 and Pex14) and is defective in CG2 of the PBDs.
Pex6	A ~100 kDa (AAA family) ATPase found in yeasts, plants and humans. Interacts with Pex1 and is defective in CG4 of the PBDs.
Pex7	A ~40 kDa, WD40-repeat-containing protein that binds the PTS2. Defective in CG11 of the PBDs.
Pex8	A variably sized (60–80 kDa), peripheral, but intraperoxisomal, PMP that interacts with Pex5 and the docking subcomplex, found only in yeast. It is an intraperoxisomal organizer of the peroxisomal import machinery in *S. cerevisiae*.
Pex9	A 44 kDa integral PMP found only in the yeast *Yarrowia lipolytica*.
Pex10	A ~35 kDa integral PMP with a carboxy-terminal, cytoplasmically-exposed, zinc binding RING domain. Has been identified in yeasts and humans, interacts with Pex2, Pex3, Pex5 and Pex12, and is defective in CG7 of the PBDs.
Pex11	A ~25 kDa integral PMP required for normal peroxisome abundance. Many species contain several Pex11 genes.
Pex12	A ~40 kDa integral PMP with a carboxy-terminal, cytoplasmically-exposed, zinc-binding RING domain. Has been identified in yeasts and humans, interacts with Pex2, Pex3, Pex5 and Pex10, and is defective in CG3 of the PBDs.
Pex13	A ~44 kDa integral PMP with a carboxy-terminal, cytoplasmically-exposed SH3 domain. Identified in yeasts and humans, interacts with Pex5 and Pex14, and is defective in CG13 of the PBDs.
Pex14	A ~40 kDa PMP of yeasts, plants and humans that interacts with Pex5, Pex8, Pex13 and Pex17.
Pex15	A 44 kDa integral PMP identified only in *Saccharomyces cerevisiae*. Interacts with Pex6 in yeast.
Pex16	In humans, Pex16 is a 36 kDa integral PMP that binds Pex19 and is defective in CG9 of the PBDs.
Pex17	A ~25 kDa integral PMP that interacts with Pex14. Has been identified only in *S. cerevisiae* and *P. pastoris*.
Pex18	A 31 kDa soluble protein involved only in PTS2-protein import. It is highly similar to Pex21, and might act as a Pex7 chaperone. Identified only in *S. cerevisiae*.
Pex19	A 33 kDa farnesylated protein of yeasts and humans. Predominantly cytoplasmic/partly peroxisomal, binds all known integral PMPs and recognizes some, but not all, mPTSs. It is defective in CG14 of the PBDs.
Pex20	A 46 kDa soluble protein involved only in PTS2-protein import. Identified only in *Y. lipolytica*. Substitutes functionally for Pex18/Pex21 in *S. cerevisiae*.
Pex21	A 31 kDa soluble protein involved only in PTS2-protein import, is highly similar to Pex18 and might act as a Pex7 chaperone. Identified only in *S. cerevisiae*.
Pex22	A 20 kDa integral PMP of yeasts that interacts with Pex4 and anchors it on the peroxisomal membrane.
Pex23	A 46 kDa integral PMP. Identified only in *Y. lipolytica*.
Pex24	A 61 kDa integral PMP found in yeasts required for the proper localization of some, but not all, PMPs and matrix proteins.
Pex25	A 45 kDa PMP found in *S. cerevisiae* that regulates peroxisome size and maintenance.

CG, complementation group; SH3, Src-Homology 3.

Pex7p in the case of PTS2 (see Figure 1). These receptor–cargo complexes then move to the peroxisome membrane where they dock with protein subcomplexes that are in or on the membrane. Two such complexes are a docking subcomplex, comprised minimally of peroxins Pex8p, Pex13p, Pex14p, and Pex17p, and a really interesting new gene (RING)–protein subcomplex, consisting of three RING–proteins Pex2p, Pex10p, and Pex12p (and other yeast peroxins, such as Pex3p and Pex8p). The RING–proteins have a characteristic zinc-binding domain and are members of a protein family whose first member was called RING. There is evidence that the protein subcomplexes are dynamic, e.g., the docking and RING–protein subcomplexes can come together as a larger complex during import. The PTS receptors, Pex5p and Pex7p, are believed to shuttle from the cytosol to the peroxisome membrane or lumen of the organelle, where they release their cargo, before they return back to the cytosol for another round of import. This is referred to as the extended shuttle model for matrix protein import. It is unclear at present whether the RING–protein subcomplex (also called the translocation complex in the literature) is involved directly in the translocation of proteins into peroxisomes, or in the shuttling of receptors (e.g., Pex5p) back to the cytosol. Many other peroxins and chaperones such as Djp1p, hsp70, and hsp40 are implicated in matrix protein import, but their precise roles are still under investigation.

The PTS2 pathway, which is dependent on the receptor, Pex7p, requires different additional proteins depending on the organism of its origin. In *S. cerevisiae*, the redundant proteins, Pex18p and Pex21p, fulfill this function, whereas in *Yarrowia lipolytica*, Pex20p is

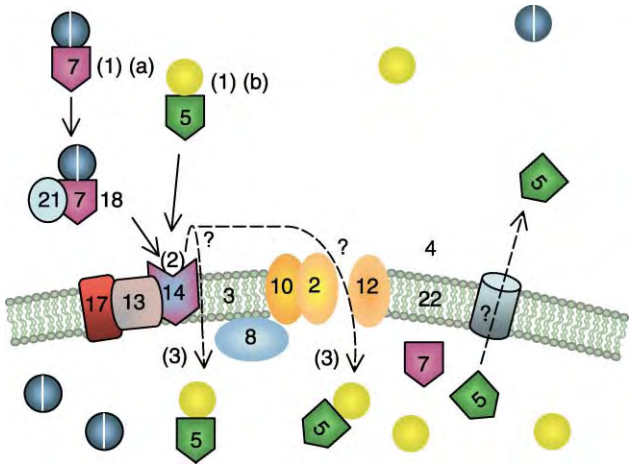

FIGURE 1 Model of peroxisomal matrix enzyme import. Numbers indicate the corresponding Pex protein. Three main steps are outlined: (1) Binding of PTS-containing proteins (yellow and blue circles depict PTS1- and multimeric PTS2-containing proteins, respectively) to the import receptors (Pex5p and Pex7p); (2) transport of receptor–cargo complexes to the peroxisome membrane and interactions with PMPs, such as Pex14p and, perhaps Pex13p, which are in a subcomplex with Pex17p and Pex8p; (3) receptor–cargo translocation through a proteinaceous pore formed either by the docking subcomplex (Pex14p, Pex13p, Pex17p, Pex8p) or the RING–peroxins subcomplex (Pex2p, Pex10p, Pex12p). PTS receptors may deliver cargo while inserted in the peroxisomal membrane or after entry into the lumen. Pex3p and Pex8p have been proposed to bridge proteins in the docking and RING–peroxins subcomplexes.

needed, and in mammals an alternatively spliced form of Pex5p (Pex5pL) is necessary for PTS2 import. However, the docking and RING–proteins are required in common for both PTS1 and PTS2 import pathways, leading to the current view that a common translocation machinery is involved for both these pathways.

Examples of organism-specific variations in the general scheme of biogenesis include the apparent lack of the entire PTS2 pathway (PTS2 proteins and Pex7p, the PTS2 receptor) in worms (*Caenorhabditis elegans*), and the dependence of the PTS2 import pathway on the PTS1 receptor, Pex5p, in mammals, but not in yeasts. However, even where such differences exist, the underlying molecular mechanism is similar. This is illustrated by the point that the proteins Pex18p and Pex21p from *S. cerevisiae*, Pex20p from *Y. lipolytica*, and Pex5pL in mammals all have a conserved motif that allows them to interact with Pex7p and/or PTS2 cargo to facilitate the PTS2 import pathway.

Unlike the transport of unfolded proteins into other organelles, such as the endoplasmic reticulum and mitochondria, folded and oligomeric proteins can be transported across the peroxisomal membrane. How such large multi-subunit complexes are transported across the membrane is unknown, because the translocon in the peroxisomal membrane has not been characterized.

Import of Peroxisomal Membrane Proteins

These proteins have one or more sequences (mPTSs) that direct them to the peroxisomal membrane with the correct topology. Although a dozen or so mPTSs have been defined in several yeast and mammalian peroxisomal membrane proteins (PMPs), they have no simple consensus sequence. The PMP receptor(s), the mechanism of insertion of PMPs into the peroxisomal membrane, and the rules that govern their topology are not completely known, although several peroxins that play a role in PMP biogenesis are defined. Most mutants affecting the import of either peroxisomal matrix or membrane proteins have organelle remnants, in some but perhaps not all, organisms.

Division and Proliferation of Peroxisomes

The division of peroxisomes is compatible with two models. One of these proposes that peroxisomes arise by budding and fission from pre-existing peroxisomes, and may be the one that is used in normal, mitotically dividing cells. The other model is that peroxisomes arise either *de novo* or from some other reservoir of membranes such as the endoplasmic reticulum. Mature peroxisomes are then generated from this membrane reservoir via a variety of biogenesis intermediates. This model may be more applicable to proliferating peroxisomes and to the regeneration of peroxisomes in *pex* mutants complemented by the affected gene.

He and his colleagues have made many important contributions to the field of peroxisome biogenesis and turnover.

Phage Display for Protein Binding

Henry B. Lowman
Genentech, Inc., San Francisco, California, USA

Phage display is a process in which large libraries of protein or peptide variants are prepared as fusion proteins with one of several coat proteins of bacteriophage. Because each phage-displayed variant is both displayed on the surface of the phage particle (virion) and encoded by the DNA packaged within that virion, phage display provides a useful means of purifying rare members of the library with specifically selected binding properties, amplifying the selected members over multiple rounds of selection, determining the sequence of the selected protein, and expressing the protein as a soluble product. Phage display has found many applications in the discovery, engineering, and analysis of peptides and proteins including 1) discovery of novel peptide mimotopes and human(ized) antibodies for binding to proteins and other targets, 2) affinity maturation and mutagenic scanning of antibodies and other proteins, and 3) identification of specific peptide substrates for proteases and other enzymes. Typically, filamentous phage such as Fd, M13 and related phages that infect *Escherichia coli* bacteria are used as vectors for phage display of peptide or protein diversity libraries.

Phage Display Vectors

Phage display is a rapid means for discovery of novel peptides and proteins from large libraries of genetically engineered variants. The process begins with construction of a phage or phagemid vector which encodes either an initial protein "scaffold" or a random peptide as a fusion protein with a phage coat protein. Typical constructs involve a promoter region driving expression of the fusion protein in which a secretion signal sequence (SS) is followed by the display gene and all or part of a phage coat protein, e.g., g3p or g8p (proteins encoded by gene-3 or gene-8 of bacteriophage M13). Alternatively, with appropriate modifications, the displayed protein may be fused at the C terminus of the coat protein. Filamentous phage(mids) are particularly useful vectors because their structure readily adapts to accommodate the size of DNA packaged into the virion.

Polyvalent and Monovalent Phage Display

When many copies of a fusion protein are displayed on each virion, each virion may simultaneously bind to several molecules of the target. In this format, called polyvalent display, even intrinsically weakly binding variants appear to bind tightly because of the avidity effect. As this effect can mask tighter binding (higher intrinsic affinity) interactions, constructs which limit the display of the fusion protein to yield virions that usually display no more than one copy were developed. This format, called monovalent display, facilitates stringent selections for very high-affinity interactions. Statistically, monovalent display vectors allow for display of multiple copies of the fusion protein by a small fraction of the virion population, but the difference between monovalent and polyvalent formats can be dramatic in terms of avidity effects. This difference has been exploited to: (1) identify novel, low-affinity binding peptides in a polyvalent system, followed by (2) "affinity maturation" of the low-affinity peptides through construction of secondary libraries and selection in a monovalent system.

Phage Vectors

Phage vectors consist of an essentially complete phage genome into which is inserted DNA encoding the protein or peptide of interest (Figure 1). Typically, the remainder of the phage genome is left unchanged and provides the other gene products needed for the phage life cycle. For facile growth and propagation of phage in *Escherichia coli*, the function of the fusion protein in the life cycle of the phage must be maintained and this places constraints on the types of fusions that are usually produced using phage vectors. For example, large proteins may be poorly displayed and/or may interfere with phage packaging or infection.

Phagemid Vectors

Phagemid vectors consist of a typical plasmid construct into which a phage origin of replication (ORI), including the phage-packaging region of DNA from the phage genome, and a gene for the displayed fusion protein have been inserted (Figure 1). In this case, the phagemid DNA can be replicated independently of phage production for mutagenesis and amplification. However, for phage

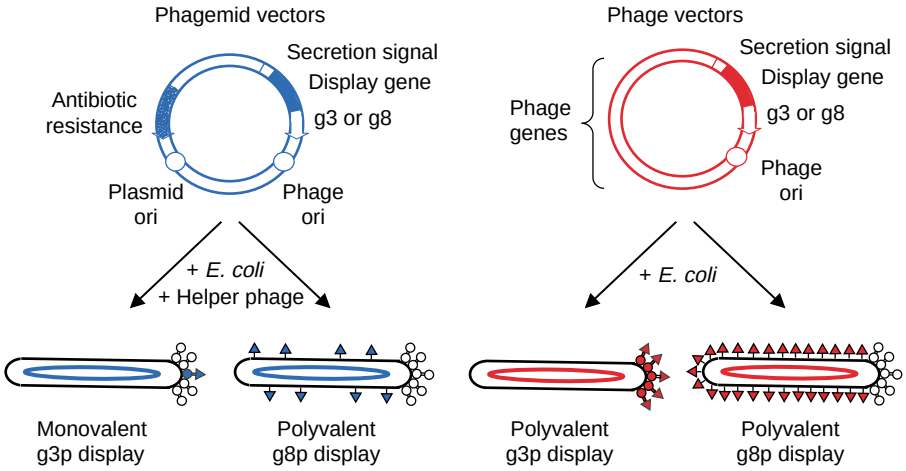

FIGURE 1 Construction of phagemid and phage vectors. Phagemid and phage DNA constructs are shown with appropriate origins of replication (ori), a gene for the protein of interest (shaded) fused the gene-3 or gene-8 encoded coat proteins of filamentous phage and preceded by a secretion-signal sequence, as well as a gene for antibiotic resistance. The remaining genes of the phage vector or helper phage encode other proteins. The DNA is packaged as a single strand in the virion (shown in cartoon form) with many copies of the g8 protein along the length of the particle, a few copies of the g3 protein (two-lobe structure) at one end, and other structural proteins (not shown). The g3p or g8p fusion proteins are shown as filled triangles attached to the corresponding coat protein. In monovalent phage display, expression of the fusion is statistically limited so that very few particles contain more than one copy of the fusion protein, while in polyvalent display, a range of fusion-protein densities is possible.

display, the remaining phage gene functions must be supplied by another construct, usually a "helper phage," which is packaged into virions with lower efficiency than the phagemid itself. When *E. coli* cells transfected with the phagemid, grown under selective pressure with an appropriate antibiotic, are infected with helper phage at an appropriate multiplicity of infection (MOI), both constructs undergo replication, but mature virions predominantly contain phagemid rather than helper-phage DNA. However, both types of particles can display the fusion protein; thus, antibiotic selection of cells containing the desired phagemid is needed. These examples indicate the most commonly used types of phage and phagemid vectors; however, other monovalent and polyvalent displaying phage and phagemid constructs have also been described.

Phage Libraries

A phage library may begin with a "wild-type" protein displayed on phage or with a phage(mid), into which DNA encoding completely novel peptides have been inserted.

Construction of Libraries

The generation of diversity in a phage-display library is usually accomplished by typical site-directed mutagenesis techniques, such as oligodirected single-stranded template mutagenesis, PCR mutagenesis, or cassette mutagenesis using restriction enzymes and DNA ligase to cut out a segment of DNA and replace it with a synthetic piece. Highly diverse DNA sequences can be generated using standard solid-phase deoxynucleotide synthesis techniques in which individual nucleotides are "randomized" by adding to the growing polynucleotide chain a mixture (which may be equimolar or of biased specified composition) of all four nucleotides, or a subset of A, G, C, or T, rather than a single nucleotide (Table I).

TABLE I
Nucleotide Abbreviations for Degenerate Codon Design

Abbreviation	Nucleotide
A	Adenosine
G	Guanosine
C	Cytidine
T	Thymidine
R	A, G
Y	C, T
B	C, G, T
D	A, G, T
H	A, C, T
K	G, T
M	A, C
V	A, C, G
W	A, T

TABLE II

Continued

The degeneracy of the genetic code makes possible the generation of chemically related subsets of codons depending on the amino acids encoded (Table II). Once oligonucleotides with appropriate diversity have been designed and synthesized, mutagenesis is carried out with the phage or phagemid vector on an appropriate scale to yield a sufficient number of DNA molecules (moles of product) to represent the desired diversity as described below. The mutagenesis products are transformed into *E. coli* and propagated in culture (along with helper phage in the case of phagemid vectors) to yield a library of peptide- or protein-displaying phage particles.

Design of Diversity Libraries

The key consideration in the design of diversity libraries is the combinatorial complexity of the DNA and protein resulting from incorporation of random nucleotides at a given number of sites. For example, using NNS codon degeneracy (Table II), all 20 commonly used L-amino acids are encoded by 32 codons. With one NNS codon randomized in this way, the library has a theoretical diversity of 32 at the DNA level and 20 at the protein level. However, this complexity grows quickly as a larger number multiple sites, n, are simultaneously randomized. The experimentally obtained complexity

or diversity of the library is limited to the number of DNA molecules that can be produced at the synthesis and mutagenesis stage, and subsequently transformed into *E. coli* and packaged into a solution of phage(mid) particles. Therefore, the number of randomized codons or the diversity of the degenerate codons may be restricted in order to obtain libraries that completely represent the designed diversity. At the virion level, phage particles are only soluble to a level of $\sim 10^{14}$ particles/ml (10^{17}/l; or 170 nM), presenting an ultimate practical limitation for phage libraries to be produced and used at the laboratory scale. Additional limitations are imposed by the process of transformation of the phage or phagemid construct into *E. coli*, so that libraries are more commonly on the order of 10^9 or 10^{10} as measured by the total number of transformants obtained after mutagenesis and transformation using electroporation or other techniques.

Phage-Binding Selections

Phage libraries yield useful and interesting variants through a process of selection and amplification analogous to affinity-based protein purification (Figure 2).

Preparation of Packaged Virions

Once the products of random mutagenesis have been transformed into *E. coli*, phage amplification occurs through propagation of the infected culture, which in the case of phagemid libraries also includes a helper phage. Since filamentous phage particles are not lytic, large numbers of phage particles are produced during a few hours of culture growth. As the displayed protein is secreted, it is incorporated into the coat of the virion. Once a large number of phage have been produced, they are separated from the *E. coli* host by centrifugation, and often further purified using a series of precipitation and resuspension steps. The final phage stock is a solution of phage particles that are ready for appropriate binding selections.

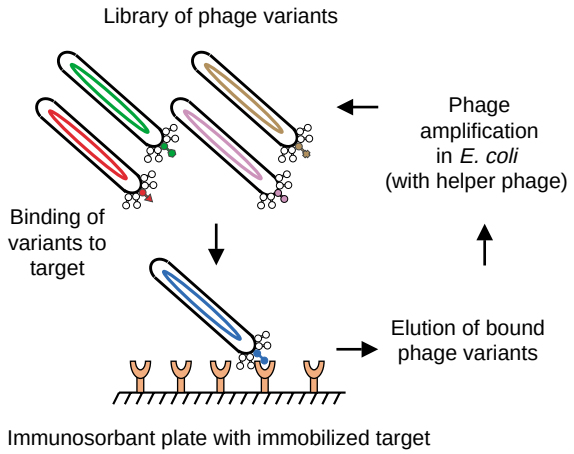

FIGURE 2 Affinity-selection process for binding to an immobilized target protein using a monovalent phagemid vector. One round of binding selection or "panning" is shown. A population of phage particles, each displaying a different peptide or protein variant, is allowed to bind to an immobilized target. After low-affinity variants are washed away, high-affinity variants are eluted and propagated to produce an enriched pool of high-affinity variants, which may be subjected to further rounds of selection.

Phage Binding and Elution

Early phage-binding selections used a simple process for separating variant protein phage that bind to a target molecule from those that do not bind. The target molecule was coated directly onto immunosorbent plastic plates or affixed to chemically activated resins. A variation on this technique involves binding of phage to a labeled target in solution, then capturing the bound phage through use of an affinity matrix that binds to the labeled target. Thereafter, the phage library is allowed to bind to the immobilized target, and then removed. Nonbinding and weakly binding phage variants are washed away, and the remaining tightly bound variants are eluted using affinity-selective reagents (e.g., a competing protein), mild to severe chaotropic agents, ranging from high/low pH buffers to urea, or site-specific proteases. Following elution, phage can be amplified by infecting fresh *E. coli* cells, and the resulting population again subjected to binding selection. This cycle is typically repeated for several rounds, followed by analysis of selectants through DNA sequencing, which may yield nonrandom occurrences of amino acids at p (particular) positions (i.e., a consensus sequence), or through direct binding analysis as described later. As in ELISA experiments, nonspecific binding leads to artifacts in phage display and can be reduced using proteins or detergents that block these typically low-affinity interactions. However, large diversity libraries sometimes contain peptides that can bind to the blocking agent itself. An enrichment ratio, representing the number of phage binding to the intended target versus the number binding to the matrix or blocking agent, is often used to monitor specificity during multiple rounds of binding selection.

Phage-Binding Analysis

The individual clones selected through phage display are often further analyzed in the form of the recombinant phage particles. Beyond the ability to select relatively rare protein variants with specific binding properties from diversity libraries of millions to tens-of-billions of combinatorial variants, phage display is also used to

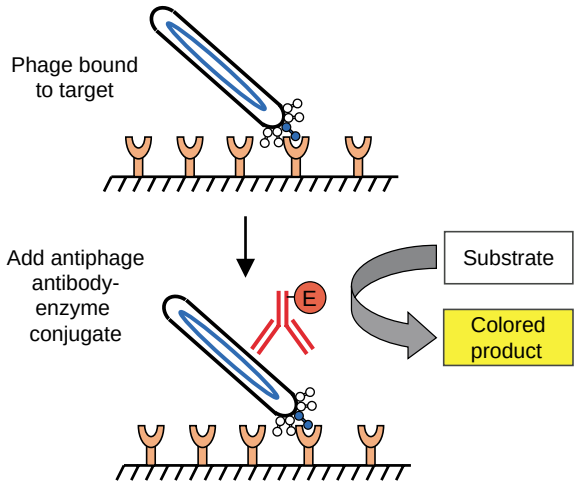

FIGURE 3 Binding assays using phage display. Binding of phage-displayed protein variants is analyzed as in a typical ELISA experiment, with binding of phage to an immobilized target followed by detection with an antiphage antibody conjugated to an appropriate enzyme such as horseradish peroxidase. Relative amounts of bound phage are measured by the amount of color produced when an appropriate substrate is added.

analyze protein–protein-binding interactions without the need to separately purify large numbers of protein variants. For example, to map the binding site on a phage displayed protein for a target protein, the target protein may be coated on an ELISA plate, and mutants or libraries of mutants constructed for phage display. In the case of point-mutation analysis, a phage stock of each mutant is prepared and titrated as in a typical protein-binding ELISA (Figure 3). Alternatively, using libraries of protein variants, the outcome of sequencing many selected variants may be analyzed to determine statistically which amino acids are preferred or disallowed at multiple positions. The utility of phage display has been demonstrated using many systems in which the results of phage selections and binding analysis have been translated into functional proteins whose properties correspond closely to their phage-displayed forms.

Glossary

degenerate codon A three-nucleotide (triplet) sequence encoding more than one amino acid, realized by synthesis of a pool of triplets having more than one nucleotide at one or more positions. Degenerate codons may be represented in shorthand according to standard abbreviations, e.g., RNS, for (A or G) followed by (A, G, C, or T), followed by (G or C).

elution Process of dissociation which causes the dissociation of bound phage from an immobilized target molecule, for example, using low pH or chaotropic agents.

enrichment Process by which peptide or protein variants with specific binding properties are amplified from a diverse library. An enrichment ratio of the number of phage eluted from an immobilized target divided by the number eluted from a control is often used to measure enrichment.

enzyme-linked immunosorbent assay (ELISA) An assay for binding affinity, typically in which a target molecule is coated onto a plastic plate, a second molecule (the analyte) is added, and a third molecule is used to detect binding of the analyte.

helper phage A bacteriophage which supplies the necessary gene products for packaging of a phagemid construct and is usually deficient in packaging itself into virions.

panning Process of selecting phage for binding to a target protein, especially when the target is coated onto an immunosorbent plastic plate.

phagemid A DNA vector constructed from the combination of replication and other genetic elements from a plasmid with replication, packaging, and other genetic elements from the genome of a bacteriophage.

Pheromone Receptors (Yeast)

James B. Konopka
State University of New York, Stony Brook, New York, USA

Jeremy W. Thorner
University of California, Berkeley, California, USA

Fungal cells secrete substances (pheromones) that stimulate the ability of haploid cells of different mating types to conjugate, thereby forming diploid cells. Compounds used by various fungal species include terpenes (e.g., *Allomyces* spp.), steroids (e.g., *Achlya* spp.), and peptides (many ascomycetes). The best-characterized fungal pheromone receptors are those for the peptide mating pheromones of the budding yeast, *Saccharomyces cerevisiae*. These receptors are integral membrane proteins that contain seven highly hydrophobic, and potentially α-helical, transmembrane segments. They bind their cognate pheromone at the cell surface, and then activate an intracellular heterotrimeric G protein that initiates a signaling pathway. This pathway induces physiological responses, including the expression of many genes needed to divert cells from the mitotic cell cycle required for vegetative proliferation into a developmental program that permits the fusion of the participating haploid cells. These yeast pheromone receptors are representatives of a very large superfamily that is conserved from yeast to humans.

Pheromone Receptors are Necessary for Conjugation

Pheromone signaling occurs only between cells of different mating type. In *Saccharomyces cerevisiae*, there are two mating types, which are defined by the combination of pheromone and receptor they produce (Figure 1). Haploid cells of the **a**-mating type secrete the **a**-factor pheromone, and express in their plasma membrane, the receptor (Ste2) for α-factor; conversely, haploids of the α-mating type produce α-factor pheromone and, express at their surface, the receptor (Ste3) for **a**-factor. The α-factor is an unmodified 13-residue peptide that is processed from a larger precursor and secreted from cells via the standard secretory pathway. By contrast, **a**-factor is a 12-residue lipopeptide that is modified by farnesylation of the side chain and methyl esterification of the carboxyl group of its C-terminal Cys residue and then exported from cells through the action of a dedicated ATP-driven transporter (Ste6). Cell-type identity is established by genes at the mating type locus (*MAT*) on chromosome III, which encode transcriptional regulators that control expression of the corresponding pheromones and receptors. The gene products required for signaling downstream of the receptors are identical and are expressed in both *MAT***a** and *MAT*α-cells. The genomes of other ascomycetes (i.e., those that pack their spores into an ascus), including the fission yeast, *Schizosaccharomyces pombe*, and the human pathogen, *Candida albicans*, encode homologues of both Ste2 and Ste3. However, in certain basidiomycetes, including the plant rust, *Ustilago maydis*, and the human pathogen, *Cryptococcus neoformans*, the pheromone receptors in the different mating types are all related to Ste3. Furthermore, other groups of fungi, such as many basidiomycetes (including mushrooms), have more than two and often many combinatorial possibilities for distinct mating types and, hence, correspondingly more complex regulation.

Binding of pheromone to a receptor triggers a signal-transduction pathway necessary for eliciting the physiological responses required to differentiate the cells and prepare them for mating. These responses include arrest of cell division in G1 to synchronize the cell cycles of the mating partners, and transcriptional induction of genes that specify proteins required for agglutination, specialized morphogenesis, cell fusion, and nuclear fusion. These proteins and the capacities they confer permit the cells to conjoin, fuse, and form a diploid zygote.

Pheromone Receptors Stimulate a Signal Transduction Pathway

The pheromone receptors induce mating by stimulating a G protein-initiated signaling pathway that has been extensively studied in *S. cerevisiae* and will be described briefly here. Upon binding of the cognate pheromone, an activated pheromone receptor stimulates exchange of GTP for GDP in the α-subunit (Gpa1) of the coupled heterotrimeric G protein. The ensuing conformational

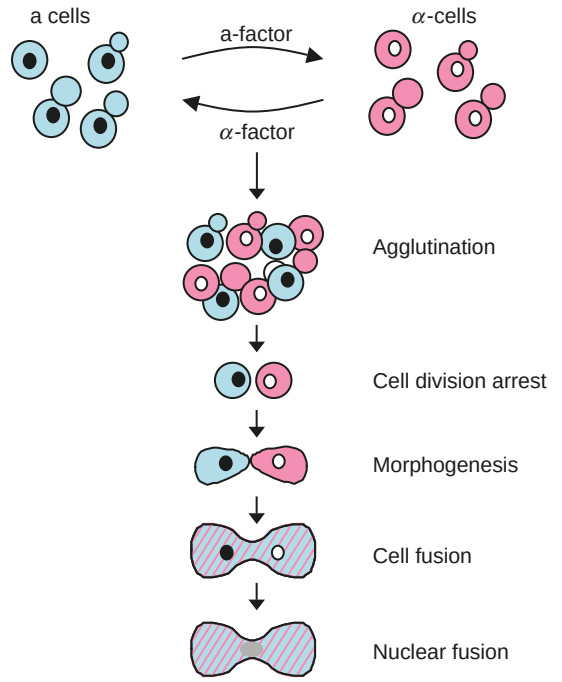

FIGURE 1 Landmark events during conjugation of *S. cerevisiae*. Intercellular communication between cells of mating type **a** and cells of mating type α induces the indicated stages of conjugation, as described in the text.

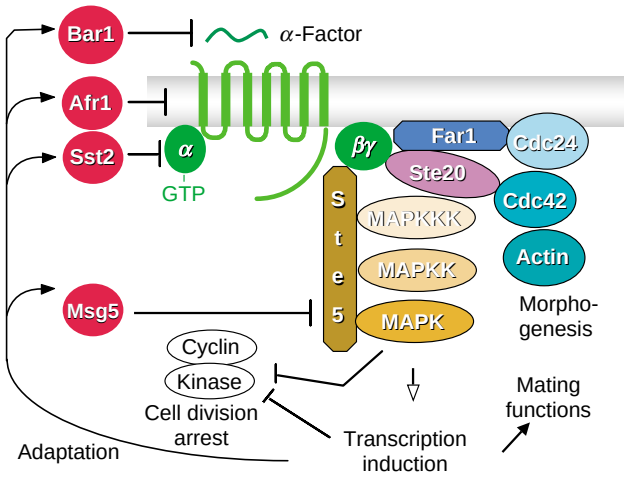

FIGURE 2 Schematic representation of the mating pheromone response pathway in *S. cerevisiae*. A diagram showing the main components involved in transmitting the pheromone signal in *MAT***a** cells. A similar pathway operates in *MAT*α-cells. Activated pheromone receptors stimulate the Gα-subunit to release the G$\beta\gamma$-subunits. The free G$\beta\gamma$-subunits then recruit a scaffold protein, Ste5, to the membrane. Ste5 carries the components of a MAP kinase cascade and places them in proximity to another protein kinase, Ste20. The free G$\beta\gamma$ complex also recruits another scaffold protein, Far1, which carries the activator (Cdc24) of the small GTPase, Cdc42, which is, in turn, the activator of Ste20. Ste20 is further concentrated at these sites because its C terminus also binds to free G$\beta\gamma$-subunits. Conjunction of these components achieved by the pheromone-dependent and receptor-initiated release of G$\beta\gamma$ results in activation of the protein kinase cascade, and ultimately stimulates the pheromone-responsive transcription factor, Ste12, in the nucleus. Activation of Cdc42 also promotes actin polymerization and other aspects of morphogenesis to promote highly polarized growth. Negative regulators of the pathway (shown in red on the left side) are also induced and constitute a negative feedback loop. Bar1 is a secreted protease that degrades α-factor in the medium. Afr1 negatively regulates receptor function. Sst2 is an RGS protein that promotes hydrolysis of the GTP bound to the Gα-subunit. Msg5 is a phosphatase that dephosphorylates and inactivates the terminal MAPK (Fus3).

change in GTP-bound Gpa1 dissociates its associated G$\beta\gamma$ complex (Ste4-Ste18). The free G$\beta\gamma$ complex, which is firmly anchored in the plasma membrane by both C-terminal farnesylation and carboxymethylation of the C-terminal Cys and palmitoylation of the penultimate Cys in Ste18, now exposes surfaces that are able to bind and recruit to the plasma membrane the proteins needed for subsequent events (Figure 2).

One protein that binds to G$\beta\gamma$ is Ste5, which acts as a scaffold by associating with the three protein kinases, Ste11 (MEKK or MAPKKK), Ste7 (MEK or MAPKK), and Fus3 (ERK or MAPK) of a mitogen-activated protein kinase (MAPK) cascade. The existence of such a cascade was first demonstrated unequivocally in *S. cerevisiae*. Phosphorylation and activation of Ste11 requires the action of yet another protein kinase, Ste20. Ste20 is recruited to the membrane in two ways. The activator of Ste20, the small GTPase, Cdc42 (a protein of about 21 kDa), is tethered to the membrane because it is geranylgeranylated and carboxymethylated on its C-terminal Cys, and, in its GTP-bound state, binds to the N-terminal regulatory domain of Ste20. Thus, Ste20 was the first member of the family of protein kinases known as PAKs (for p21-activated protein kinases) to be recognized. In addition, Ste20 is localized specifically near the rest of the pheromone response machinery at the plasma membrane because a motif near the C terminus of Ste20 binds to G$\beta\gamma$. The third component recruited to the plasma membrane by the released G$\beta\gamma$ complex is another scaffold protein (Far1) that carries the guanine nucleotide exchange factor (Cdc24) that stimulates conversion of Cdc42 from its GDP- to its GTP-bound state. Once activated via this phosphorylation cascade, Fus3 is released from Ste5, translocates to the nucleus, and relieves negative regulation of a transcription factor (Ste12) that is poised on the promoters of pheromone-responsive genes, thereby inducing the expression of those genes. Complete sequence analysis of the *S. cerevisiae* genome, accomplished in 1996, identified all of the genes that contain potential Ste12-binding sites in their promoter regions, subsequent chromatin immunoprecipitation demonstrated that many of these promoters are indeed occupied by Ste12 before induction, and now with the advent of DNA microarrays, all genes actually induced by pheromone have been identified. Not surprisingly,

this set of genes includes those needed for cell cycle arrest, agglutination, morphological changes, cell fusion, and nuclear fusion. Interestingly, many signaling components, including the pheromones and receptors, as well as additional gene products that function in adaptation (down-regulation) of the response are induced as part of the highly organized intercellular communication that occurs between mating cells. Collectively, these gene products control the spatial and temporal events of the mating process, as well as recovery from those changes if conjugation does not occur successfully (Figure 2).

Pheromone Receptors Sense Spatial Gradients

A key role played by pheromone receptors in conjugation is in sensing the position of the mating partner and providing proper spatial orientation for the subsequent morphogenesis that enables cells of opposite mating type to grow toward each other, thereby enhancing the probability of their encounter and subsequent fusion. The ability of a yeast cell to track a gradient of pheromone emanating from a cell of the opposite mating type requires dynamic interplay of signaling and adaptation, particularly at the level of the pheromones and receptors. For example, exposure of *MAT*α cells to **a**-factor increases transcription of the α-factor genes, whereas exposure of *MAT***a** cells to α-factor induces expression of an extracellular protease that degrades α-factor in the medium. Another aspect of this interplay involves removal of ligand-bound receptors by endocytosis and their replacement by newly synthesized receptors, which are deposited at the site on the surface immediately adjacent to the partner cell (because the oriented morphogenesis mentioned above directs secretory vesicles to their destination). This behavior sustains the highest degree of receptor activation in the region nearest to the site, on the surface that is exposed to the highest concentration of pheromone emanating from the closest potential partner. Such localized receptor signaling is thought to establish and then reinforce the spatial cues that stimulate properly oriented actin polymerization and other aspects of the directed morphogenesis necessary for conjugation.

Pheromone Receptors are Regulated at Several Levels

Control of pheromone receptor expression and function are key for proper intercellular communication and also for allowing cells to return to normal growth in the event that mating does not occur. These controls have been best studied for Ste2 (α-factor receptor). The C-terminal cytosolic domain of Ste2 is the target for several adaptation mechanisms (and similar mechanisms are known to regulate the **a**-factor receptor, Ste3). First, once ligand-bound, rapid phosphorylation of Ste2 within the C-terminal sequence appears to inhibit the ability of the receptor to continue to signal. It is most likely that the conformational change caused by pheromone binding makes the C-terminal segment of the receptor more accessible to certain protein kinases (casein kinase I family members) that are constitutive residents of the plasma membrane, once again due to the prenylation, carboxylmethylation, and palmitoylation of the C termini of these enzymes. Second, phosphorylation creates a determinant that leads to recognition by a ubiquitin ligase complex and the subsequent covalent addition of ubiquitin to Lys337 in the C terminus (Figure 3). This monoubiquitination triggers endocytosis and removal of the receptor from the cell surface. Third, receptors are also regulated by association with a protein (Afr1) that localizes to the neck of the growing projection in mating cells, prevents receptor-G protein coupling, and thereby restricts receptors that are competent to signal to the leading edge of the projection.

Other components of the pheromone signaling pathway also undergo pheromone-induced down-regulation. For example, induction of Sst2, the first regulator of G protein-signaling (RGS) protein to be recognized, promotes hydrolysis of the GTP bound to Gpa1, thereby deactivating Gα and promoting its reassociation with G$\beta\gamma$. Similarly, induction of Msg5, a dual-specificity MAPK-specific phosphatase, dephosphorylates and thereby inactivates Fus3 (Figure 2).

Pheromone Receptor Synthesis Requires the Secretory Pathway

In the description that follows, Ste2 will continue to be the model because it has been studied most extensively. Ste2 is inserted into the plasma membrane such that it spans the membrane seven times (Figure 3). Biogenesis of Ste2 commences with its import into the endoplasmic reticulum (ER) via a classical N-terminal signal peptide, with concomitant addition of two Asn-linked oligosaccharides, which are further modified and extended with mannose-rich outer chains during transport of Ste2 through the Golgi complex. Although this N-glycosylation does not seem to be critical for receptor function, it may direct or stabilize proper folding of Ste2. While still in the secretory pathway, Ste2 self-associates to form dimers. The interface is thought to include a region of the first transmembrane segment (TMD1) containing Gly56 and Gly60 (Figure 3), which form a GxxxG motif similar to one that mediates dimerization of the red

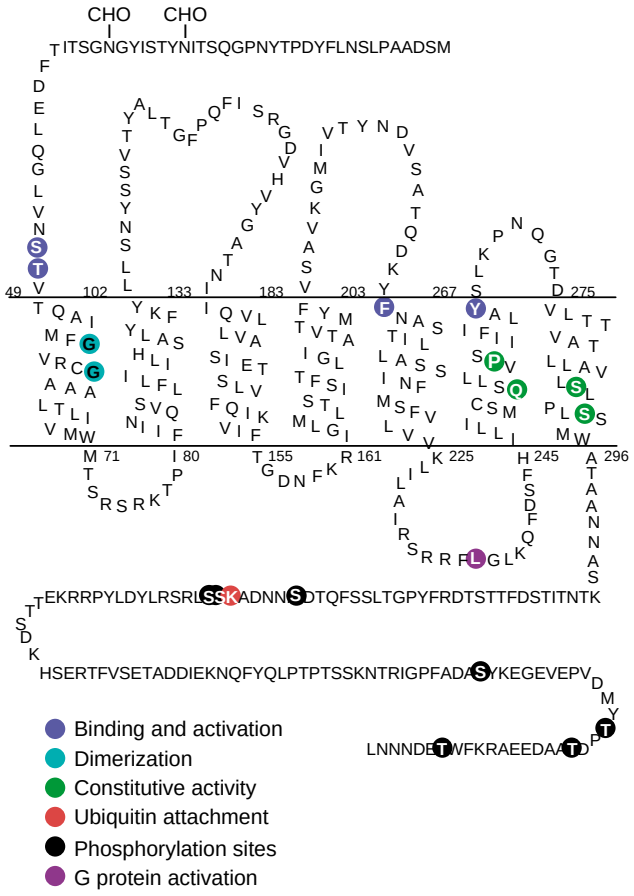

FIGURE 3 Primary structure of *S. cerevisiae* Ste2 (α-factor receptor). The amino acid sequence of Ste2, in the one-letter code, is arranged to represent the seven membrane-spanning elements in their presumed topology across the plasma membrane. Residues discussed in the text that have key functional properties in receptor signaling and adaptation are shaded according to their role in ligand recognition (blue), receptor dimerization (turquoise), conformational constraint (green), phosphorylation (black), and ubiquitination (red). Two sites in the extracellular amino terminus are modified by N-linked glycosylation (CHO). The consensus site for attachment of Asn-linked oligosaccharide (N-X-T or N-X-S) at residue 25 is used close to 100% of the time, whereas that at residue 32 is used only about 50% of the time, and that at residue 46 is not used at all, presumably because it is too close to the membrane for recognition by the eight-subunit oligosaccharyltransferase enzyme complex that transfers the mannose-rich core oligosaccharide from its membrane-bound dolichol carrier to N-X-T or N-X-S motifs in secreted and membrane-localized proteins. Certain naturally occurring neutral polymorphisms exist in the primary structure of Ste2, specifically: residue 269 is E in some *S. cerevisiae* strains, but K in others.

blood cell transmembrane protein, glycophorin A. Dimerization appears to be important for efficient trafficking of Ste2 to the plasma membrane and available evidence suggests that the native signaling-competent state of Ste2 is the dimer. Receptors that fold improperly in the ER are ultimately degraded by ER quality control-mechanisms; those misfolded receptors that make it to the Golgi are sorted to the vacuole (equivalent of the mammalian lysosome) for degradation. It is not clear where or when, properly folded and dimerized receptors first encounter and couple to the quiescent form of the G$\alpha\beta\gamma$ heterotrimer (Gpa1-Ste4-Ste18). However, receptors at the plasma membrane are associated with the heterotrimeric G protein in preactivation complexes primed for the arrival of their pheromone ligand.

Pheromone Receptors Bind Ligand via Contacts with the Extracellular Ends of the Transmembrane Segments

The ligand-binding site in the pheromone receptors (and in other seven-transmembrane segment, G protein-coupled receptors) are conceivably rather complex in that they have the potential to be composed of determinants that reside within the seven transmembrane segments, and/or the three extracellular loops, and/or the extracellular N-terminal extension (or combinations of these elements). The lipid modification of **a**-factor has prevented the application of standard methods for analyzing its binding to Ste3. Hence, the binding of α-factor to Ste2 has been examined in much greater detail. A combination of genetic and biochemical studies strongly implicates residues near the extracellular ends of the transmembrane segments (TMDs) as forming the α-factor-binding pocket. This conclusion suggests a model for receptor activation in which ligand binding to the ends of the TMDs could influence the overall packing or structure of part or all the seven-helix bundle. The resulting conformational change could then be relayed to the intracellular side, and thereby communicated to the associated G protein to promote its activation. Two residues in Ste2 that are necessary for pheromone-induced receptor activation are Phe204, situated near the end of TMD5, which is required for high-affinity α-factor binding, and Tyr266, located near the end of TMD6, which, although not important for binding affinity *per se*, is nonetheless needed for subsequent signaling. The extracellular ends of TMDs 5 and 6, are of course, directly connected to their intracellular ends, and the third intracellular loop of Ste2, which spans the intracellular ends of TMDs 5 and 6, has been implicated in G protein-activation. This situation provides a ready explanation for how conformational change upon pheromone binding could be directly coupled to the associated G protein. Residues (Ser47 and Thr48) near the end of TMD1 are also thought to contact α-factor and may constitute part of the ligand-binding pocket, but do not appear to play a significant role in activation.

Pheromone Receptor Activation may Involve Relief of Conformational Constraint

Current models for signaling by G protein-coupled receptors (GPCRs) suggest that, in the absence of ligand, the off-state is conformationally restricted and that conformational changes upon ligand binding are manifested as greater conformational flexibility. Insights about the conformational state of Ste2 that accompanies its activation have been provided by analysis of constitutively active mutants that signal in a ligand-independent manner. These mutations primarily alter residues within the TMDs, suggesting that constitutive activity can result from changes in the packing of the bundle of transmembrane α-helices. Genetic analysis of constitutive mutants suggests that one restraint may involve interaction between TMD6 and TMD7 mediated via H-bonding between Gln253 in TMD6 and both Ser288 and Ser292 in TMD7. Likewise, a high degree of constitutive receptor activity is caused by substitutions that alter Pro258 in TMD6. In an otherwise α-helical segment, Pro has the unique property of introducing a kink. Thus, substitution of Pro258 with other residues should affect the topology of TMD6. Moreover, TMD6 is the segment whose intracellular end is the most proximal to those residues in the third intracellular loop most strongly implicated in G protein-activation. Hence, the effect of substitution of Pro258 in TMD6 may reflect the conformational change induced within TMD6 that normally occurs only upon ligand binding. In this regard, it is noteworthy that the majority of mammalian receptors of this class also contain Pro at a similar position in TMD6. In those mammalian proteins where it has been examined, the Pro in TMD6 has been implicated in receptor activation, suggesting mechanistic similarities in the activation process from yeast to humans.

Pheromone Receptors Promote G-Protein Activation via the Third Intracellular Loop

The receptor residues on its cytoplasmic surface that contact the G protein and promote GDP–GTP exchange on the Gα-subunit have not been pinpointed precisely. Analysis of chimeras between Ste2 and Gpa1 indicate that merely bringing the receptor and G protein into close proximity is not sufficient to stimulate GDP–GTP exchange because ligand stimulation is still required for activation of downstream signaling by such receptor-Gα hybrids. As discussed above, current evidence suggests that pheromone binding promotes a conformational change at the extracellular ends of the transmembrane helical bundle in Ste2 that is propagated to the intracellular ends of the transmembrane segments, thereby probably exposing previously buried residues that promote G-protein activation. Mutagenesis indicates that, in Ste2, the third intracellular loop certainly plays a key role. Consistent with this view, biochemical studies have demonstrated conformational changes in the third intracellular loop that are induced upon ligand binding. Remarkably, functional ligand-dependent Ste2 can be reconstituted by co-expressing halves of the receptor that are split in the middle of the third intracellular loop. Thus, it is possible that the residues closest to where TMDs 5 and 6 exit, the plasma membrane boundaries are the most important for G protein activation, assuming that the residues closest to the cut ends of such split receptors are the least likely to remain in their native condition. However, substitution of Leu236 (with His) very near the "middle" (at least in terms of primary sequence) of the third loop, yields a Ste2 mutant that displays an essentially wild-type level of surface expression, an essentially wild-type ability to bind α-factor, and an essentially wild-type level of association with the G$\alpha\beta\gamma$ heterotrimer, yet is strongly defective in promoting signaling, suggesting it is specifically defective in activation of the associated G protein. Interestingly, Ste2(L236H) still undergoes ligand-stimulated endocytosis, indicating that the conformational changes and the determinants recognized by the endocytic machinery are distinct from those required for G-protein activation.

Further confounding understanding of the mechanism of G protein-activation is the fact that, although Ste2 and Ste3 both act through the same G protein (Gpa1-Ste4-Ste18), Ste2 and Ste3 do not share any recognizably significant tracts of sequence similarity, even at the intracellular ends of TMDs 5 and 6 or within the third intracellular loop. In this same regard, certain seven-transmembrane segment receptors from other organisms, including mammals, have been expressed in *S. cerevisiae* and in response to the appropriate agonist, are able to activate, albeit to different extents, the endogenous yeast G protein. Again, this cross-species functionality occurs even though the heterologous receptors do not share any obvious sequence identity with the yeast pheromone receptors. Although the ability of receptors from yeast to man to activate the same G protein suggests a common mechanism underlying receptor and G protein activation, the structural determinants of that common action are not readily apparent. Nevertheless, continued functional studies of the yeast pheromone receptors are likely to continue to shed light on how this important class of receptors operates.

Glossary

agonist A ligand that activates a receptor to transduce a signal.

ligand A substance, such as a mating pheromone, that binds to a receptor molecule.

mating projection A term used to describe the distinctive type of morphogenesis observed in yeast treated with mating pheromone. This structure is thought to form the conjugation bridge that connects mating cells. Commonly referred to as a shmoo.

transmembrane domain A region of a protein that spans a membrane bilayer. These domains are typically present in an ordered structure, such as an α-helix or β-sheet, which allows the polar carbonyl groups of polypeptide chains to be shielded from the hydrophobic membrane bilayer. In the case of the GPCRs the transmembrane domains are thought to form an α-helical structure.

PHO Regulon

Bengt L. Persson
University of Kalmar, Kalmar, Sweden

The *PHO* (*pho*sphatase-encoding) regulon of the yeast *Saccharomyces cerevisiae* is a genetic regulatory circuit, involving structural and regulatory units, essential for controlled expression of phosphatase genes. The network consists of components encoded by ~30 genes which upon expression allow for a coordinated cellular response and adaptation to changes in availability of extracellular phosphate. When phosphate becomes limiting, the cells respond by an increase in the synthesis of high-affinity transporters and phosphatases in order to scavenge phosphate from the environment. Several of the *PHO* regulon components of *S. cerevisiae* are homologous to proteins that take part in the regulation of the eukaryotic cell cycle, including a cyclin-dependent kinase (CDK, Pho85), a cyclin, (Pho80) and a CDK inhibitor (Pho81). The regulator complex formed by these determines the transcription of executive genes encoding the phosphate transporters and phosphatases.

Background

Regulation of cellular activities in response to external nutrient levels is fundamental to all living cells. To achieve this, the cells make use of numerous and varied mechanisms by which changes in the extracellular conditions can be sensed.

Phosphate, an essential nutrient for all organisms, is required for the synthesis of many cellular components (nucleic acids, proteins, lipids, and sugars) as well as for metabolic needs (cellular metabolic pathways such as glycolysis and ATP production). In every cell, whether of prokaryotic or eukaryotic origin, phosphate acquisition plays a key role in maintaining cellular phosphate homeostasis. Therefore, these organisms have evolved regulatory mechanisms for acquisition, storage, and release of this molecule allowing them to respond and adapt to fluctuations in phosphate availability. Phosphate metabolism in the yeast *S. cerevisiae* has been extensively studied for many years and this unicellular organism has provided an excellent model system for understanding how a cell makes a coordinated response to environmental phosphate changes. This organism responds to a diverse array of signals, and many of the responses involve the regulation of gene expression. The transcriptional regulation results in a corresponding adjustment in signaling systems that are activated by a changed phosphate status. The signal transduction pathway involved in the regulation of phosphate-responsive genes is complex and involves at least 22 different genes. The regulation of cellular phosphate uptake activity as well as phosphate starvation responses are maintained by a phosphate signal transduction pathway, the so-called *PHO* regulon. The preferred phosphate source is inorganic phosphate (Pi). Carrier-mediated Pi transport across the plasma membrane, an essential step in the utilization of Pi by *S. cerevisiae*, is mediated by several specific plasma membrane transport systems allowing the cell to switch between a low-affinity and a high-affinity mode of phosphate acquisition. However, when Pi becomes limiting in the growth media, there is an increased production of a high-affinity transport system and of secreted phosphatases that scavenge Pi from a variety of organic compounds through the action of periplasmically located acid phosphatases and of alkaline phosphatases presumably involved in releasing Pi from intracellular substrates. The ability of yeast to utilize various Pi sources is thus highly regulated, and the expression of the genes required for the utilization has been a major topic of study for many years.

The *PHO* Genes and their Regulation

The expression of the *PHO* genes is under tight regulation of the *PHO* regulon. The status of the regulon is commonly genetically and biochemically monitored by use of the activity of a secreted acid phosphatase (the gene product of *PHO5*), which is transcriptionally induced in response to Pi starvation. Although secreted acid phosphatases are encoded by several genes, *PHO3*, *PHO5*, *PHO11*, and *PHO12*, the Pho5 protein is responsible for more than 90% of the acid phosphatase activity of the cells. Most of the information on *PHO5* regulation has been obtained by the isolation and characterization of *PHO* regulon mutants that are defective in Pi regulation of acid phosphatase synthesis.

Besides *PHO5* and its homologues, *PHO11* and *PHO12*, additional genes of the *PHO* regulon which are activated by a Pi-starvation signal include the vacuolar alkaline phosphatase gene, *PHO8*, the genes encoding high-affinity Pi transporters of the plasma membrane, *PHO84* and *PHO89*, the *PHO86* gene encoding an endoplasmatic reticulum (ER) resident protein required for the ER exit of the synthesized Pho84 protein, and the *PHO81* gene encoding an inhibitor (CKI) of a cyclin-dependent kinase (CDK).

At least five regulatory proteins of the *PHO* pathway are believed to be involved in the transcriptional regulation of the *PHO* genes: A complex of the Pho85 CDK and its cyclin Pho80, and the CKI Pho81, together with the transcription factors Pho4 and Pho2 constitute the core components of the regulation (Figure 1). By a yet unknown mechanism, Pi limitation initiates a signal transduction cascade that activates Pho81, the inhibitor of the phosphorylation activity of the cyclin–CDK, Pho80–Pho85.

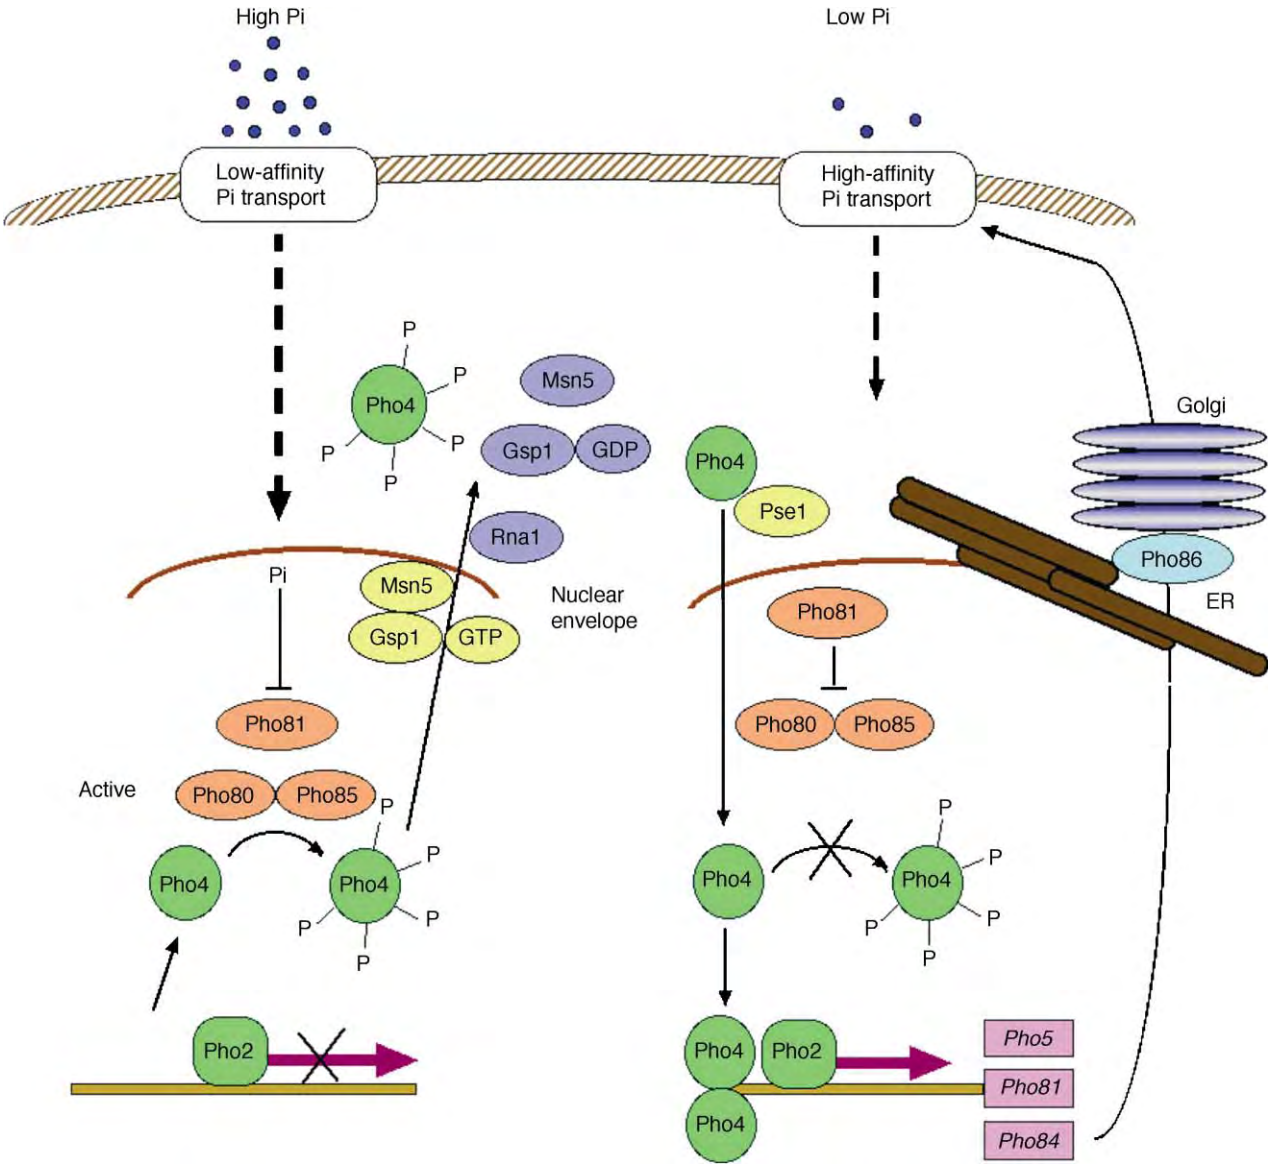

FIGURE 1 Transcriptional regulation of *PHO* genes through the *PHO* regulon at high (left) and low (right) external Pi concentrations. When Pi is abundant, the transcription factor Pho4 is phosphorylated by the Pho80–Pho85 cyclin–CDK complex, assembled with the Msn and Gsp1 proteins and exported to the cytoplasm resulting in a repressed transcription of the *PHO* genes. The CDK inhibitor, Pho81, is associated with the Pho80–Pho85 complex at both high and low Pi conditions, but exerts its inhibition on the complex under conditions of Pi limitations. Under these conditions, the Pho4 will be transported into the nucleus in unphosphorylated form via the Pse1 protein and together with Pho2 bind to the promoter regions and activate transcription of the *PHO* genes. Expression of *PHO*84, encoding a high-affinity Pi transporter results in synthesis and Pho86-mediated delivery of the Pho84 transporter via Golgi to the plasma membrane.

Pho2, Pho4, and Pho81 are positive regulators of *PHO5* and deletion of these genes confer an inability to induce *PHO5* expression upon Pi limitation. Deletion analysis of the *PHO5* promoter has revealed two distinct regulatory elements (upstream activator sequences, UAS), UAS1 and UAS2, to which the transcription factor Pho4 binds under Pi starvation, but not under high-Pi conditions. The binding sequences for Pho4, CACGTG or CACGTT, have been identified and the existence of at least one copy of these sequences has been shown in the immediate promoter region of all but one of the described *PHO* genes, suggesting that Pho4 is a transcriptional activator for all these genes. The structure of the DNA-binding domain of Pho4, resolved to 2.8Å, has revealed a folding of this domain into a C-terminal basic helix-loop-helix (bHLH) motif. A native cysteine residue in the bHLH motif is essential for Pho4 dimerization, binding of the homodimer to the UAS of *PHO5*, and for transcriptional activation of the *PHO* regulon. When localized to the nucleus, Pho4 binds to the two bHLH consensus sequences (CACGTG or CACGTT) in the *PHO* promoter sequences, and the transcriptional regulator Pho2, a homeobox DNA-binding protein, binds cooperatively with Pho4 to activate expression of target genes. As Pho2 binds to its consensus sequence (T/C)TAA(T/A)T(T/G)AAT with low affinity it interacts with several other proteins and participates in the regulation of a diverse array of genes. For its function in *PHO* regulation, Pho2 acts through multiple DNA-binding sites. At the *PHO5* promoter region, one of these sites significantly overlaps with the Pho4-binding site as UAS1, while another two sites flank the second Pho4-binding site, UAS2. As access of the transcriptional regulators Pho2 and Pho4 is aided or hindered by the chromatin structure, the nature of DNA packing is important for the regulation of gene expression. For a chromatin remodeling function in *PHO5* region, the participation of a nuclear-located inositol polyphosphate kinase, Arg82, has been proposed. Factors implicated in chromatin-packing arrangements are histone-DNA interactions in promoter regions of certain *PHO* genes, and acetylation, methylation, or phosphorylation of histones.

A central role in Pi regulation has been demonstrated for the Pho80 cyclin and the Pho85 cyclin-dependent kinase which upon complex formation allows for a differential hyperphosphorylation of the Pho4 transcription factor in the nucleus. Pho85 is one of five CDKs found in *S. cerevisiae*. Activation of CDKs requires binding of a cyclin. At least ten different cyclins involved in cell cycle and/or metabolic regulation are known to bind Pho85. In the Pi assimilation process, the kinase function of Pho85 is activated by interaction with Pho80 whereby the kinase activity of the Pho80–Pho85 cyclin–CDK complex phosphorylates Pho4. Protein phosphorylation has been found to play an important role in the control of diverse cellular processes, especially that of transcriptional factors in regulation of gene expression. The phosphorylated state of Pho4 is important for its localization in the cell and thus for its activity in transcriptional regulation of the *PHO* genes. The CKI Pho81 binds to the Pho80–Pho85 protein complex when cells are grown at both high and low Pi conditions but a pronounced inhibition of the kinase activity and hence an abolished hyperphosphorylation is seen only at Pi-limiting conditions. Under these conditions, the *PHO* genes, including *PHO81*, are activated. The unphosphorylated form of Pho4, which has a low affinity for the nuclear exportin receptor Msn5, is presumably transported into the nucleus through an import pathway that utilizes the importin Pse1. In contrast, the hyperphosphorylated form of Pho4, which is unable to bind to Pse1, is accessible for complex formation with Msn5 and Gsp1, a yeast Ran homologue, after which the complex is transported into the cytoplasm. Dissociation of the complex in the cytoplasm involves the participation of Rna1, a GTPase-activating protein responsible for the conversion of the GTP bound to Gsp1 in its complex active form to GDP. Thus, Pho4 is concentrated to the nucleus when yeast cells are starved for Pi and is predominantly cytoplasmic when yeast cells are grown at high, repressive Pi conditions. It has been proposed that also Pho2 can be phosphorylated by a kinase, possibly indicating a similar mechanism whereby the transcriptional activity of Pho2 may thus be regulated by a phosphate switch, not only enhancing the transcriptional activity but also facilitating the interaction between Pho2 and Pho4. Only when Pho2 is phosphorylated, the *PHO5* can be expressed under Pi limiting conditions. Transcription of *PHO* genes under Pi limitation would thus necessitate Pho4 dephosphorylation as well as Pho2 phosphorylation. Such a feedback Pi-controlled regulation of transcription ensures balanced levels of regulatory proteins and a swift response to changes in Pi concentrations.

The positive feedback-regulated inhibition of Pho85–Pho80 exerted by Pho81, makes Pho81 a key player in the *PHO* regulatory pathway. Pho81 harbors a tandem repeat of six ankyrin consensus regions, of which one is regarded to play an essential role in the CKI/CDK complex interaction. However, both the mechanisms by which the Pi limitation signal is transduced to Pho81 and where the signal originates are still unclear.

Due to a comprehensive identification and characterization of the *PHO*-regulated genes in the yeast genome, the late events in the *PHO* pathway are now well understood, an important step toward an understanding of the physiological regulation of Pi metabolism.

Glossary

ankyrin region Protein domains that contain 33-amino acid long sequences that often occur in tandem arrays and are involved in protein's molecular recognition.

CDK Cyclin-dependent kinases, a family of protein kinases that control cell cycle progression in all eukaryotes and require physical association with cyclins to achieve full enzymatic activity. CDK's are regulated by phosphoryation and dephosphorylation events.

CKI Cyclin-dependent kinase inhibitor, small protein that binds stoichiometrically to regulate the activity of CDKs.

cyclin Protein found in certain eukaryotic cells that helps regulate the cell cycle by causing cells to begin mitosis. Cyclins are regulatory subunits of the cyclin-dependent protein kinases.

homeobox genes Genes with a shared nucleotide segment that are involved in the formation of bodily segmentation during embryologic development.

***PHO* regulon** Genetic regulatory network of scattered genes involving structural and regulatory units active in phosphate signal transduction.

promoter A DNA sequence that enables a gene to be transcribed.

Biography

Bengt L. Persson is a Professor in the Department of Chemistry and Biomedical Sciences at the University of Kalmar. His principal research interests are in molecular membrane biochemistry and cellular regulation of phosphate acquisition systems. He holds a Ph.D. from the University of Stockholm and received his postdoctoral training at the University of California, Los Angeles. He is presently conducting research on phosphate transport regulation at the Universities of Stockholm and Kalmar and has authored several papers on phosphate transporters of yeast.

Phosphatidylinositol Bisphosphate and Trisphosphate

Alex Toker
Harvard Medical School, Boston, Massachusetts, USA

Phosphatidylinositol (PtdIns) is a minor membrane phospholipid which is found in all eukaryotic cells. It is the precursor of a family of phosphorylated lipids which are collectively known as phosphoinositides, and rather than serving a structural role in cellular membranes, they act as functional second messengers to transduce biochemical signals in the cell. The article in detail discusses the synthesis, hydrolysis, and cellular functions of phosphotidylinosital bisphosphate and trisphosphate.

Phosphoinositides are composed of a water-soluble inositol ring which can be phosphorylated at each of three positions (D-3, D-4, and D-5), and a greasy fatty acid tail which is attached to a glycerol and linked to the inostol ring by a phosphodiester bond (Figure 1). The concerted actions of phosphoinositide kinases, phosphoinositide phosphatases, and phospholipases on phosphatidylinositol leads to the production of seven additional phosphoinositides which are known to exist in cells (Figure 2). Of these, phosphatidylinositol-4,5-bisphosphate (PtdIns-4,5-P_2) and phosphatidylinositol-3,4,5-trisphosphate (PtdIns-3,4,5-P_3) are the best understood and characterized. Both the synthesis and the degradation of PtdIns-4,5-P_2 and PtdIns-3,4,5-P_3 are tightly regulated, and this ensures efficient and coordinated signaling through these second messengers. Biochemical and genetic studies have implicated both PtdIns-4,5-P_2 and PtdIns-3,4,5-P_3 in numerous cellular responses, such as cell growth, cell survival, cell motility and modulation of the actin cytoskeleton, gene transcription and vesicle trafficking (Figure 3). The importance of these phosphoinositides in cell biology is exemplified by the fact that deregulation in the metabolism or mechanism of action of these lipids often results in human diseases such as cancer and type 2 diabetes.

Phosphatidylinositol-4,5-Bisphosphate

Synthesis

PtdIns-4,5-P_2 is often considered to be one of the most important functional lipids in eukaryotic cells, because it not only has a functional second messenger role *per se*, but can also serve as an intermediate for the production of additional lipid mediators. It can serve as a substrate for phosphoinositide 3-kinase (PI 3-K) to produce PtdIns-3,4,5-P_3, it can be hydrolyzed by phospholipases to produce diacylglycerol (DAG) and soluble inositol phosphates, and it can also be dephosphorylated by D-4 and D-5 lipid phosphatases (Figure 2). Although the bulk of PtdIns-4,5-P_2 is found at the plasma membrane, other distinct pools of PtdIns-4,5-P_2 have been reported. For example, there exists a nuclear phosphoinositide cycle where PtdIns-4,5-P_2 production has been detected. However, there are relatively modest, if any, changes in the total levels of PtdIns-4,5-P_2 upon cellular stimulation with agonists such as growth factors or hormones. This is difficult to reconcile with the second messenger hypothesis which dictates that a lipid mediator must rapidly accumulate to amplify downstream signaling. Therefore, it is likely that the constitutive levels of PtdIns-4,5-P_2 change locally at discrete intracellular sites, such that the accumulation of this lipid is regulated both spatially and temporally. In addition, there are two other isomers of phosphatidylinositol bisphosphate: PtdIns-3,4-P_2 and the recently discovered PtdIns-3,5-P_2. The function of these two phosphoinositides is not entirely clear, but they are likely to mediate certain responses downstream of PI 3-K.

The synthesis of PtdIns-4,5-P_2 is controlled by the sequential action of phosphoinositide 4-kinases, which use phosphotidylinositol (PtdIns) as substrate and produce PtdIns-4-P, and phosphoinositide phosphate kinases (PIPKs), which can use either PtdIns-4-P or PtdIns-5-P as substrates. In both cases, the product is PtdIns-4,5-P_2 (Figure 2). Much is known about the enzymes which produce PtdIns-4,5-P_2. There are two families of PIPKs, type I and type II. Type I kinases preferentially phosphorylate PtdIns-4-P at the D-5 position, and this appears to be the major route of PtdIns-4,5-P_2 synthesis. However, it was recently discovered that type II PIPKs can phosphorylate PtdIns-5-P at the D-4 position, and so it is likely that in some instances this represents an important pathway for the

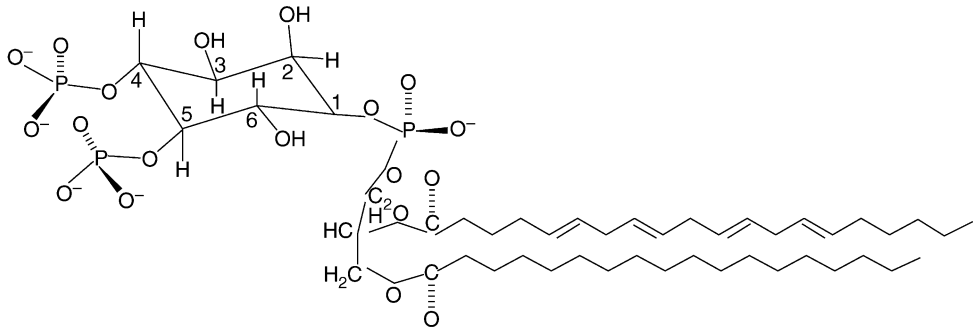

FIGURE 1 Structure of phosphatidylinositol-4,5-bisphosphate. The structure shows PtdIns-4,5-P_2\, which contains an inositol head group connected to a diacylglycerol via a phosphodiester linkage. The fatty acid moiety is typically stearoyl-arachidonyl. The inositol head group can be phosphorylated at one of three positions, D-3, D-4, and D-5. Shown are phosphate groups at the D-4 and D-5 position in PtdIns-4,5-P_2. Phosphoinositide 3-kinases phosphorylate the D-3 position of PtdIns-4,5-P_2 to produce PtdIns-3,4,5-P_3.

generation of PtdIns-4,5-P_2. Several forms of both type I and type II PIPKs exist in mammalian cells, and homologues are also found in lower eukaryotes such as yeasts, highlighting the importance of these enzymes in biology. The crystal structure of a type II enzyme has been solved, and has revealed an elongated, flat surface covered with highly basic, positively charged amino acids which are ideally positioned for interaction with the negatively charged phosphoinositides such as PtdIns-5-P. Finally, a separate route of synthesis for PtdIns-4,5-P_2 is the dephosphorylation of PtdIns-3,4,5-P_3 by D-3 phosphoinositide phosphatases, though it is not clear what fraction of the bulk PtdIns-4,5-P_2 pool is accounted for by this mechanism. Regardless, PIPKs represent the major pathway leading to the production of PtdIns-4,5-P_2, and as such their activities are tightly controlled.

Hydrolysis

PtdIns-4,5-P_2 is hydrolyzed by phosphoinositide-specific phospholipases. These enzymes, also known as type C phospholipases (PLC), hydrolyze PtdIns-4,5-P_2 into two important second messengers: the membrane-bound fatty acid moiety, also known as diacylglycerol (DAG), and the soluble portion which is an inositol trisphosphate (Ins-1,4,5-P_3, when PtdIns-4,5-P_2 is the PLC substrate). Each of these products has important roles

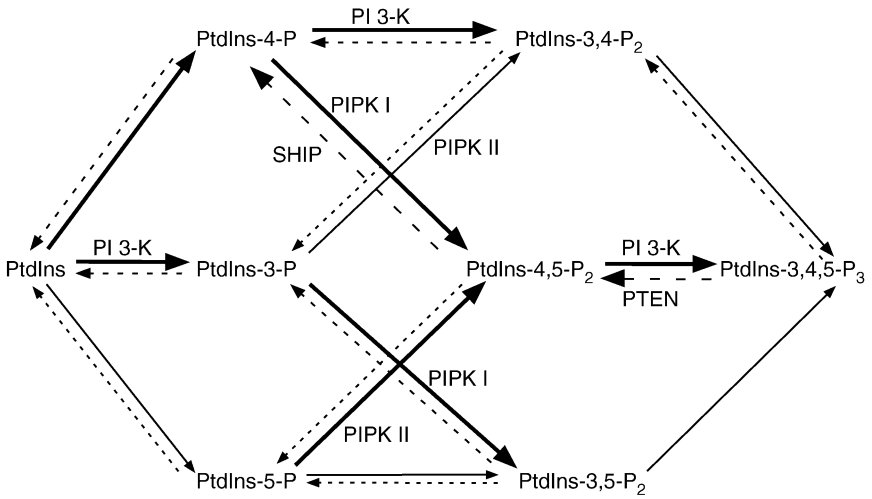

FIGURE 2 Phosphoinositide metabolism. The pathways responsible for the production of all known phosphoinositides are shown. The concerted actions of phosphoinositide kinases, such as PIPKs (type I and type II phosphoinositide 4-phophate and 5-phosphate kinases) and phosphoinositide 3-kinases (PI 3-K), as well as phosphatases (PTEN and SHIP) leads to the production of seven distinct phosphoinositides, from the precursor phosphatidylinositol (PtdIns). Although all of the forward (solid arrows, mediated by kinases) and reverse (broken arrows, mediated by phosphatases) reactions are possible, the pathways which are likely to predominate in cells are shown in bold arrows.

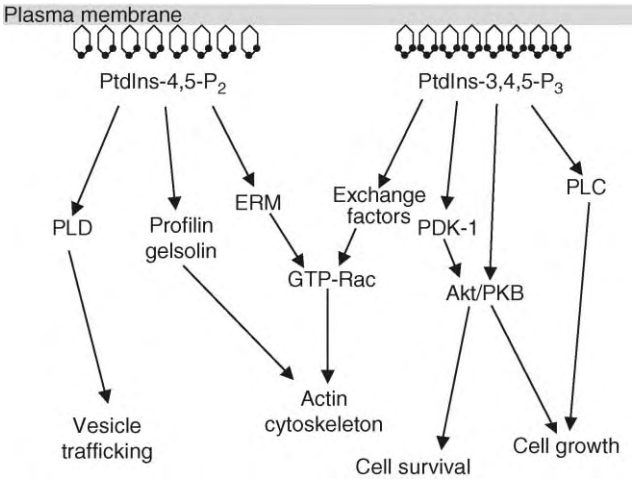

FIGURE 3 Targets of PtdIns-4,5-P_2 and PtdIns-3,4,5-P_3. A large number of proteins whose activities are directly regulated by either PtdIns-4,5-P_2 or PtdIns-3,4,5-P_3 exist. A few of these are depicted and serve to illustrate that the binding of the phosphoinositide to the protein can alter its cellular location as well as directly influencing catalytic activity when enzymes are the targets. These interactions are responsible for the activation of secondary signaling pathways, which ultimately lead to numerous physiological responses, as depicted. In many cases, PtdIns-4,5-P_2 and PtdIns-3,4,5-P_3 have overlapping functions, due to the activation of distinct effector molecules, such as the remodeling of the actin cytoskeleton which occurs as a consequence of both PtdIns-4,5-P_2- and PtdIns-3,4,5-P_3-dependent signaling.

in lipid signaling. DAG is the activator for members of the protein kinase C family of serine/threonine kinases, which are recruited to the membrane at the site of DAG production. Ins-1,4,5-P_3 plays an equally important role in lipid signaling as it is responsible for the release of Ca^{2+} from internal stores, such as the endoplasmic reticulum.

Although four distinct families of PLC exist in mammalian cells, they all share a similar catalytic mechanism employing calcium as a cofactor. All members of the PLC family use PtdIns-4-P and PtdIns-4,5-P_2 as substrates. PLCβ enzymes are regulated by binding to both $\beta\gamma$-as well as α-subunits of heterotrimeric GTP-binding proteins. PLCδ also appears to be regulated by G proteins, although the mechanism is unclear, and it is also reported that increases in Ca^{2+} alone are sufficient to activate PLCδ. Phospholipases belonging to the PLCγ family are activated by the binding of SH2 domains to phosphotyrosine-containing sequences in receptor tyrosine kinases, and as such participate in growth-factor-dependent responses such as cell growth. Tyrosine phosphorylation of PLCγ is also important in controlling catalytic activity. Very recently a new PLC subtype has been described, PLCε, and has shown to be a novel effector of the GTP bound form of the Ras GTPase. The diversity and complexity of the PLC family underscores the importance of PtdIns-4,5-P_2 hydrolysis and DAG/Ins-1,4,5-P_3 production in mediating cell proliferation, differentiation, and cell motility.

Cellular Function

In addition to serving as the substrate for additional lipid second messengers, PtdIns-4,5-P_2 is an important lipid mediator in its own right. Numerous studies have shown that PtdIns-4,5-P_2 can modulate the activity of proteins which regulate actin assembly, leading to rearrangements of the actin cytoskeleton (Figure 3). For example, PtdIns-4,5-P_2 has been shown to promote actin polymerization by directly interacting with actin-binding proteins such as profilin. Similarly, actin-capping proteins, such as CapZ, prevent spontaneous actin assembly by capping the free ends of actin filaments, and the binding to PtdIns-4,5-P_2 disrupts this capping event leading to filament assembly. The list of actin-binding proteins whose activities are also regulated by PtdIns-4,5-P_2 includes gelsolin, cofilin, filamin, and vinculin. The small GTPase Rac also plays an important role in the remodeling of the actin cytoskeleton, and in some instances this requires PtdIns-4,5-P_2. For example, the ERM family of proteins (*E*zrin, *R*adixin, and *M*oesin), a family of Rac effector molecules, are also PtdIns-4,5-P_2-binding proteins which regulate dynamic actin assembly, again linking PtdIns-4,5-P_2 function to the actin cytoskeleton. Rac, in the active GTP bound form, also interacts with PIP kinases, which are responsible for PtdIns-4,5-P_2 synthesis. Recent studies in cells have provided further evidence that PtdIns-4,5-P_2 is a critical regulator of the actin cytoskeleton. For example, expression of type I PIPK enzymes in cells leads to a dramatic reorganization of the actin cytoskeleton, and PIPK I appears to be targeted to focal adhesions, sites of cellular contact with the extracellular matrix. This targeting provides clear evidence for the localized accumulation of PtdIns-4,5-P_2 in the cell. Studies such as these, carried out in mammalian cells, have also been corroborated in yeasts, whereby genetic ablation of PIP kinases (such as Mss4p) leads to abnormalities in the actin cytoskeleton, which can be rescued by the introduction of human PIPK isoforms.

PtdIns-4,5-P_2 is also an important cofactor for the activity of a number of signaling enzymes. The best example is for *p*hospho*l*ipase *D* (PLD), an enzyme responsible for the production of *p*hosphotidic *a*cid (PA) in the cell. PLD requires PtdIns-4,5-P_2 for efficient catalytic function. Because certain PIP kinases also depend on PA for enzymatic activity, and PtdIns-4,5-P_2 stimulates PLD leading to PA production, the net result is a positive amplification loop which leads to amplification of PA and PtdIns-4,5-P_2 synthesis at specific intracellular compartment where these enzymes are located. Both PIPKs and PLD have been implicated in trafficking and secretion, and as such their products are

directly involved in controlling vesicle formation, as well as endocytosis (Figure 3).

Phosphatidylinositol-3,4,5-Trisphosphate

Synthesis

Unlike its substrate PtdIns-4,5-P_2, phosphotidylinositol-3,4-trisphosphate (PtdIns-3,4,5-P_3) is nominally absent in unstimulated cells and rapidly accumulates in response to virtually all known growth factors, hormones, cytokines, and other stimuli. In most cells, production of PtdIns-3,4,5-P_3 typically peaks within seconds to a few minutes after stimulation, and declines to near basal levels after 1–2 h. A second peak of PtdIns-3,4,5-P_3 has been observed in cells between 4 and 8 h after stimulation with mitogens such as platelet-derived growth factor (PDGF). This second peak of PtdIns-3,4,5-P_3 is responsible for efficient cell cycle progression in fibroblasts, specifically entry into the S phase where DNA synthesis occurs. Although the bulk of PtdIns-3,4,5-P_3 is produced at the plasma membrane, it is also known that there are discrete intracellular locations where this phosphoinositide is also found, particularly the nucleus. PI 3-Ks are responsible for the production of PtdIns-3,4,5-P_3 in higher eukaryotes. These enzymes phosphorylate the D-3 position of the inositol head ring, and depending on the substrate, four distinct products can result: PtdIns-3-P, PtdIns-3,5-P_2, PtdIns-3,4-P_2, and PtdIns-3,4,5-P_3 (Figure 1). Although different forms of PI 3-Ks exist, each with unique substrate selectivity, the class Ia enzymes are responsible for the production of PtdIns-3,4,5-P_3 in cells. These PI 3-Ks are composed of a p85 regulatory subunit and a p110 catalytic subunit. The regulatory subunit binds to specific phosphotyrosine-containing sequences in the cytosolic domains of activated receptor tyrosine kinases, via a tandem repeat of two Src-Homology 2 (SH2) domains. This interaction facilitates the activation of the catalytic subunit, whose activity is also increased by a direct interaction with the activated form of the small GTPase Ras. The newly activated PI 3-K converts PtdIns-4,5-P_2 to PtdIns-3,4,5-P_3. In addition, class Ib PI 3-Ks are also capable of producing PtdIns-3,4,5-P_3, and these kinases are typically activated downstream of heterotrimeric G protein-coupled receptors, such as the thrombin receptor in platelets. Class Ib enzymes are also composed of two subunits, a p120 catalytic subunit and a p101 regulatory subunit, which confers sensitivity to G$\beta\gamma$. Class Ib enzymes also require activated Ras for full catalytic function. Thus, the primary route of synthesis for PtdIns-3,4,5-P_3 in cells is through the activation of class I PI 3-Ks which use PtdIns-4,5-P_2 as substrate.

PtdIns-3,4,5-P_3 Phosphatases

Because the production of PtdIns-3,4,5-P_3 is critical for a number of physiological responses in cells, mechanisms exist which mediate the termination of PI 3-K and PtdIns-3,4,5-P_3 signaling. PI 3-K lipid products, including PtdIns-3,4,5-P_3, are not degraded by phospholipases, but instead are down-regulated by at least two different types of phosphoinositide phosphatases. SHIP1 and SHIP2 (*SH*2-containing *i*nositol 5′-*p*hosphatases) are lipid phosphatases which specifically remove the D-5 phosphate from both PtdIns-4,5-P_2 and PtdIns-3,4,5-P_3 (Figure 2). The action of SHIP1/2 on PtdIns-3,4,5-P_3 results in the production of PtdIns-3,4-P_2, and although this can impair signaling downstream of PI 3-K, PtdIns-3,4-P_2 is able to mediate certain responses which overlap with PtdIns-3,4,5-P_3. Despite this, loss of SHIP2 increases insulin sensitivity in responsive tissues such as muscle and fat. *P*hosphatase and *ten*sin (PTEN) homologue deleted on chromosome 1, is a D-3 phosphatase which dephosphorylates PtdIns-3,4,5-P_3 with PtdIns-4,5-P_2 as the product (Figure 2). PTEN is very effective at terminating PI 3-K and PtdIns-3,4,5-P_3 signaling, and this is evidenced by the fact that mutations in the PTEN gene have been detected in a large fraction of advanced human tumors. For this reason, PTEN is referred to as a tumor-suppressor gene. Thus, efficient termination of PtdIns-3,4,5-P_3 signaling is of critical importance for intracellular signaling, and deregulation of this signal can have adverse consequences for cellular responses, often leading to diseases such as diabetes and cancer.

PtdIns-3,4,5-P_3-Binding Proteins

The mechanism by which PI 3-K activates downstream secondary signaling pathway is by the recruitment of cytosolic proteins to the plasma membrane at the site of PtdIns-3,4,5-P_3 production. This recruitment can have a number of consequences; in addition to causing a change in the cellular location of the protein, it can induce a conformation change, and in the case of enzymes, it can increase (and sometimes decrease) enzymatic activity. Typically, a combination of these events results from the PtdIns-3,4,5-P_3-protein interaction. A number of protein domains have evolved which specifically recognize phosphoinositides, particularly PtdIns-3,4,5-P_3. The first described example is the *P*leckstrin *H*omology (PH) domain, a 100 amino acid sequence found in several signaling proteins which participate in PI 3-K responses. PH domains are found in both serine-threonine protein kinases (e.g., Akt/PKB and PDK-1), tyrosine kinases (e.g., Tec family kinases such as Btk), guanine nucleotide exchange factors of small GTP-binding proteins (e.g., SOS, Grp-1 and pREX), and GTPases themselves (e.g., dynamin). In some of these

cases, the PtdIns-3,4,5-P_3-protein interaction is well understood. For example, recruitment of Akt/PKB to the plasma membrane occurs in response to PtdIns-3,4,5-P_3 production. The PH domain of Akt/PKB directly binds to PtdIns-3,4,5-P_3 with high affinity and selectivity, and this leads to a conformational change in the protein kinase which leads to unfolding of the PH domain, revealing a sequence in the catalytic domain known as the activation loop. The PDK-1 kinase, which also has a PH domain and is recruited to the membrane simultaneously with Akt/PKB, can now phosphorylate Akt/PKB at a critical threonine residue in this loop. The phosphorylated Akt/PKB is now fully catalytically competent and can itself phosphorylate downstream protein substrates. This elegant mechanism is recapitulated in a large number of other protein kinases which are also regulated by PtdIns-3,4,5-P_3 or PDK-1, or both (e.g., protein kinase C and S6-kinases).

Recently, a distinct phosphoinositide-binding domain was described, and termed the *p*ho*x (PX)* domain. This 130 amino acid domain is also found in many important signaling proteins, and was originally described in the $p40^{phox}$ and $p47^{phox}$ subunit of the NADPH-oxidase superoxide-generating complex in phagocytic cells. Although PX domains do not appear to bind to PtdIns-3,4,5-P_3, they bind with high affinity to PtdIns-3-P and PtdIns-3,4-P_2, and thus are important in mediating signaling downstream of these PI 3-K lipids. Another domain which has been shown to bind PtdIns-3,4,5-P_3 is the SH2 domain. Although less well understood, binding of PtdIns-3,4,5-P_3 to the SH2 domain of the phospholipase PLCγ-1, for example, leads to an increase in its enzymatic activity. Thus, several domains have evolved in higher eukaryotic cells which have the ability to bind with distinct affinities and selectivity to PtdIns-3,4,5-P_3, and other phosphoinositides. This interaction has a profound effect on downstream signaling and cellular responses.

Cellular Function

Numerous biochemical, pharmacological, and genetic studies have demonstrated that PI 3-K, and its product PtdIns-3,4,5-P_3, regulates a multitude of cellular responses. These include cell growth, protection from cell death (apoptosis), remodeling of the actin cytoskeleton, cell migration and invasion, metabolism and insulin responses, cell cycle regulation, and gene transcription (Figure 3). It is beyond the scope of this article to discuss all of these in any detail, but some notable examples are given. Activation of the protein kinase Akt/PKB by the PI 3-K pathway regulates cellular survival mechanisms, as well as insulin-dependent metabolism. Most proteins which mediate Akt/PKB-dependent cellular survival are inhibited by the phosphorylation event. For example, phosphorylation of the Forkhead family of transcription factors (e.g., FKHR-L1) by Akt/PKB inhibits their translocation to the nucleus due to the creation of a binding site for 14-3-3, a family of molecular chaperones. This retention of FKHR-L1 in the cytoplasm inhibits the transactivation of genes intimately associated with cell death, and the net effect is an increase in survival. Similarly, Akt/PKB phosphorylation of the pro-apoptotic protein Bad also facilitates 14-3-3 binding, and this prevents Bad from binding to the anti-apoptotic proteins Bcl-2 and Bcl-X_L, effectively preventing apoptosis. Akt/PKB can also regulate both cell cycle progression and gluconeogenesis/glycolysis by phosphorylating *g*lycogen *s*ynthase *k*inase-*3* (GSK-3). This phosphorylation inhibits the elevated constitutive activity of GSK-3, which can no longer phosphorylate proteins such as Myc, the cell cycle regulator cyclin D, and glycogen synthase. Thus, Akt/PKB signaling results in the activation of several pathways which are normally inhibited by GSK-3.

Not all PI 3-K responses are mediated by Akt/PKB. In fact there are several other kinases which are activated by PtdIns-3,4,5-P_3 signaling, and which have important roles in cell physiology. For example, the S6-kinases, S6K-1 and S6K-2, regulate protein synthesis and insulin responses. The protein kinase C family of kinases can also be regulated by PtdIns-3,4,5-P_3-dependent mechanisms, and have been shown to mediate both cell growth and survival mechanisms, though these are not as well understood as the Akt/PKB pathway. The Tec family kinase *B*ruton's *t*yrosine *k*inase (Btk), which binds to PtdIns-3,4,5-P_3 via its PH domain, is important for B cell development, and importantly, genetic mutations within its PH domain have been shown to give rise to certain immunodeficiencies in humans.

Finally, regulation of the dynamics of the actin cytoskeleton is also achieved by PtdIns-3,4,5-P_3-dependent responses, and this leads to increased cell migration of many cell types (Figure 3). One important mechanism by which PtdIns-3,4,5-P_3 regulates such responses is by activating the small GTP-binding protein Rac, known to contribute to actin remodeling and directional migration in response to chemotactic stimuli. Small GTPases such as Rac are activated by binding to GTP, and this is stimulated by the activation of Rac-specific guanine nucleotide exchange factors, such as SOS, Vav and in particular, pREX. These exchange factors have PH domains which in some cases have been shown to bind to PtdIns-3,4,5-P_3, leading to an increase in exchange activity towards Rac. In summary, the diverse cellular responses attributed to PI 3-K signaling are explained by the fact that there exist numerous signaling proteins which interact with PtdIns-3,4,5-P_3. This binding has a profound

consequence on the function of the protein, leading to the activation of downstream pathways.

Glossary

phosphatidylinositol Membrane phospholipid which is a precursor to all known phosphoinositides and is composed of an inositol head ring and fatty acid tail.

phosphoinositide Phospholipid second messenger which is found in intracellular membranes and which can be phosphorylated on the inositol head ring at the D-3, D-4, and D-5 positions resulting in seven known phosphorylated species.

phosphoinositide kinase An enzyme which can use phosphoinositides as substrates, and can phosphorylate the inositol head ring at either the D-3, D-4, or D-5 positions.

phosphoinositide phosphatase An enzyme which can specifically remove the D-3, D-4, or D-5 phosphate from phosphorylated phosphoinositides.

phospholipase An enzyme which can hydrolyze the phosphodiester bond in phospholipids and produce soluble inositol lipids and membrane-bound diacylglycerol; type C phospholipases specifically use phosphoinositides as substrates.

PH domain A protein domain composed of approximately of 100 amino acids which can specifically bind to Ptdins-4,5-P_2 and Ptdins-3,4,5-P_3.

Biography

Alex Toker is an Associate Professor of Pathology at the Beth Israel Deaconess Medical Center, Harvard Medical School, Boston. His principal research interests are the role of lipid signaling pathways and protein kinases in regulating carcinoma cell growth, survival, and invasion. He holds a Ph.D. from the National Institute for Medical Research, London, and has done postdoctoral research first at Tufts University Medical School, then at Harvard Medical School, Boston. He joined the staff at the Boston Biomedical Research Institute, as a Staff Scientist in 1997, and in 2000 moved to the Department of Pathology, BIDMC.

Phosphatidylinositol-3-Phosphate

Joseph V. Virbasius and Michael P. Czech
University of Massachusetts Medical School, Worcester, Massachusetts, USA

Phosphatidylinositol is a polar phospholipid which comprises a small fraction of the total membrane lipids in cells. The hydroxyl moieties of the inositol head group may be reversibly modified by transfer of a phosphate group from ATP to one or more of three positions. This reaction is catalyzed by the class of enzymes referred to as phosphatidylinositol kinases (PI kinases). Specific PI kinases can produce three monophosphorylated phosphatidylinositols, PtdIns(3)P, PtdIns(4)P, and PtdIns(5)P in intact cells. These can be further phosphorylated by PI kinases to yield such polyphosphoinositides as PtdIns(4,5)P_2 and PtdIns(3,4,5)P_3, which function in regulating plasma membrane activities and cell signaling cascades, respectively. Although it is likely that PtdIns(4)P and PtdIns(5)P have important functions, molecular targets of these phosphoinositides have yet to be characterized. In contrast, through both genetic and biochemical studies our understanding of PtdIns(3)P functions and the PI 3-kinases which specifically produce PtdIns(3)P are well advanced. In recent years, a large number of proteins that interact with PtdIns(3)P have been discovered and their roles in various cellular processes including membrane trafficking and signaling have been elucidated.

Synthesis and Turnover of PtdIns(3)P

Although PtdIns(3)P synthesis is not known to be acutely activated by extracellular stimuli as is the case for certain other phosphoinositides, PtdIns(3)P content of membranes appears to be dynamically regulated and spatially restricted in intracellular compartments. Current data indicate that PtdIns(3)P is found primarily, and perhaps exclusively, in endosomal membranes (Figure 1). These membranes are vesicular structures which delimit compartments derived from endocytic internalization of patches of membrane from the cell surface. Mechanisms for generation of PtdIns(3)P must therefore be activated concurrently with or shortly after endocytosis, while turnover of PtdIns(3)P by hydrolysis or additional phosphorylation must occur during the progression of endosomes toward their cellular fates. These fates include recycling to the plasma membrane and fusion with lysosomes. Cellular proteins embedded in these membrane patches can likewise be targeted for recycling back to the plasma membrane where they may resume their functions, or for degradation in the lysosome. Recent discoveries indicate that PtdIns(3)P and its molecular targets play critical regulatory roles in such membrane trafficking pathways of endosomes, and thus help to determine the cellular distribution and fate of membrane proteins such as receptors for growth factors.

Synthesis of PtdIns(3)P by PI 3-Kinases

In the yeast genome, a single gene encoding a PtdIns 3-kinase has been identified. *VPS34* was originally identified in a screen for mutants that failed to properly direct a protein degradation enzyme to the vacuole, the organelle with functions similar to the lysosome of animal cells. The 100 kDa protein encoded by this gene, *Vps34p*, has a domain highly similar to mammalian PI 3-kinase and was subsequently shown to have PI 3-kinase activity. *Vps34p* exists in a complex with a 150 kDa serine/threonine kinase,Vps15p, which serves to target the Vps34p enzyme to membranes where its substrate phosphatidylinositol resides. Phosphorylation of Vps34p by the protein kinase activity of Vps15p is required for full activity of the Vps34p PI 3-kinase. A homologous PI 3-kinase complex exists in all eukaryotes studied. The mammalian Vps34 PI 3-kinase (also referred to as a class III PI 3-kinase) appears to be the predominant enzyme which produces PtdIns(3)P in cells. Although Class I and II PI 3-kinases are also capable of phosphorylating PI *in vitro*, their contribution to PtdIns(3)P production *in vivo* is not established. Additionally, other PtdIns(3)P-producing activities which differ from known enzymes in terms of inhibitor sensitivities have been reported to exist.

Dephosphorylation of PtdIns(3)P

PtdIns(3)P may be converted back to phosphatidylinositol by the action of a 3-phosphatase, an enzyme which catalyses the hydrolysis of the phosphate group on the 3′ position of the inositol ring. A number of

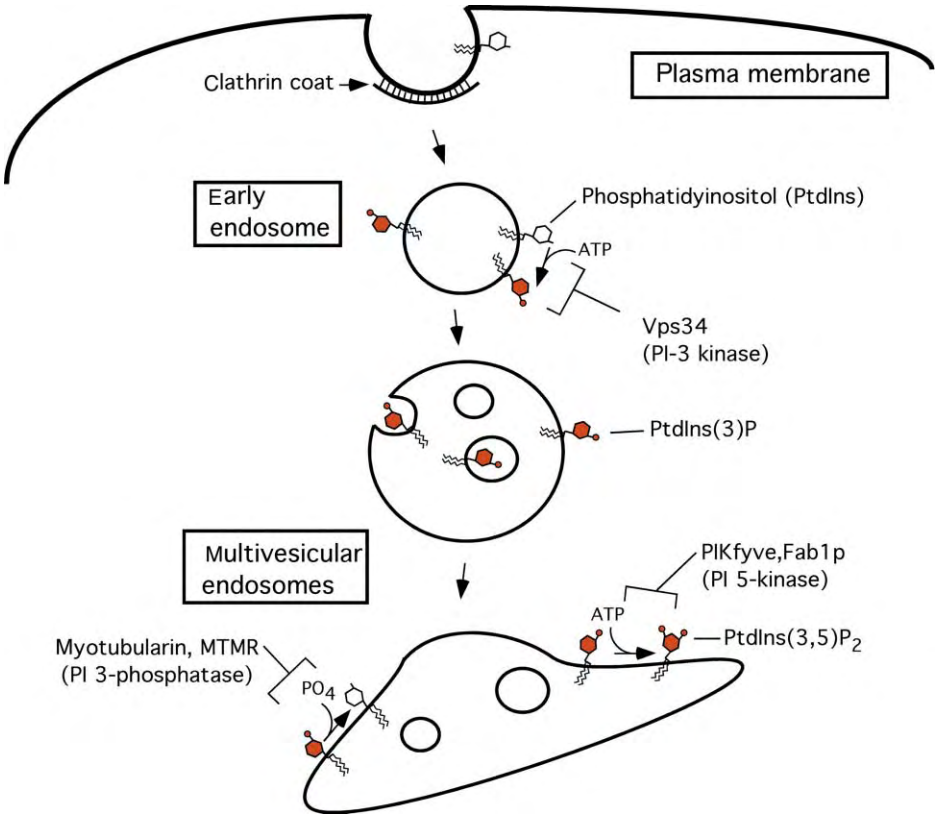

FIGURE 1 Production and turnover of PtdIns(3)P in endosomal membranes. In the process known as endocytosis patches of plasma membrane invaginate as the result of formation of clathrin coats. Subsequent scission from the plasma membrane and uncoating of these vesicles produce early endosomes where PtdIns(3)P is produced by the Vps34 PI 3-kinase. PtdIns(3)P also persists on the limiting membrane as well as intralumenal vesicles of the multivesicular endosome, a product of fusion of early endosomes. During subsequent maturation, the PtdIns(3)P may be hydrolyzed by the action of myotubularin family PI- phosphatases, or further phosphorylated by the PIKfyve/Fab1p PI 5-kinases to produce PtdIns(3,5)P2. These reactions may also take place in the intralumenal vesicles.

phosphoinositide phosphatases have been characterized in yeast and mammalian systems, but to date, activity against PtdIns(3)P has been attributed only to members of the myotubularin family. This family consists of at least 12 genes in humans with one putative homologue in yeast. Of the human proteins, eight have functional phosphatase domains, the others have similar protein sequences but apparently no catalytic activity. These proteins also have potential phosphoinositide-binding PH domains while two have FYVE domains likely to specifically target PtdIns(3)P. Details regarding the activity of myotubularin proteins in cells have yet to be reported. However, mutations in a number of human myotubularin genes have been linked to neuromuscular diseases pointing to significant roles in development or function of neural and muscle tissues.

Phosphorylation of PtdIns(3)P

In addition to hydrolysis of the 3-phosphate group by phosphatases, PtdIns(3)P levels may be modulated by additional phosphorylation. Recently, it was shown that significant levels of PtdIns(3,5)P_2 are present in yeast and mammalian cells. This phosphoinositide appears to be formed primarily by phosphorylation of PtdIns(3)P at the 5′ position of the inositol ring. The Fab1 protein of yeast and a mammalian homologue called PIKfyve possess this enzymatic activity. Both of these proteins are also able to bind specifically to PtdIns(3)P via a FYVE domain. Conversion of PtdIns(3)P to PtdIns(3,5)P_2 would serve to terminate PtdIns(3)P-dependent cellular functions, but may also contribute to cellular responses to osmotic stress or other signals as well as to maturation of endosomes. The relative contribution of phosphorylation versus hydrolysis to PtdIns(3)P turnover is as yet undetermined.

Molecular Targets and Cellular Functions of PtdIns(3)P

Protein Domains that Bind to PtdIns(3)P

Two structurally unrelated protein domains have been shown to bind to PtdIns(3)P. The first to be discovered

was the FYVE domain (named for the first four proteins in which it was recognized, Fab1p, YOTB, Vac1p, and EEA1). The domain is characterized by a RING finger structure which binds two Zn molecules. It is found in five yeast proteins and ~30 human proteins. Binding of FYVE domains to PtdIns(3)P-containing membranes relies on a combination of nonspecific membrane interactions and a groove which specifically accommodates the phosphate group of PtdIns(3)P while sterically excluding other phosphoinositide head groups. To date all FYVE domains studied bind exclusively to PtdIns(3)P.

The phox homology (PX) domain was first recognized in two components of the phagocyte NADPH oxidase (phox) complex (p40phox and p47phox). It is structurally unrelated to the FYVE domain except for a somewhat similar binding pocket which accommodates the inositol 3-phosphate head group. However, comparison of the crystal structures of the p40phox PX domain bound to dibutanoyl PtdIns(3)P and the FYVE domain of early endosome antigen-1(EEA1) bound to the head group inositol 1,3bisphosphate indicates that both proteins utilize basic residues to bind both phosphate and hydroxyl groups in the lipid head group. All 15 PX domains in yeast bind PtdIns(3)P with varying affinities. Of the mammalian proteins characterized, many bind PtdIns(3)P strongly, while several have lower affinity for other, and in some cases several, phosphoinositides.

PtdIns(3)P-Binding Proteins in Endosomal Membrane Trafficking

In accordance with the predominant localization of PtdIns(3)P to membranes of the endosomal system, several PtdIns(3)P binding proteins have been shown to function in various steps of endosome fusion, sorting, and maturation (Table I). In mammalian cells, a major function of these events is to direct membrane components to the lysosome whereas sorting of proteins to the vacuole is a major function in yeast.

Following internalization of plasma membrane patches to form small membrane vesicles denoted as early endosomes, a process of maturation is initiated which involves fusion of early endosomes into larger multivesicular bodies. These multivesicular bodies form specialized subdomains marked by the recruitment of different sets of proteins. Eventually these specialized domains and their cargo proteins form new compartments, which may then be returned to the plasma membrane or delivered to lysosomes or the trans-Golgi complex. This process is controlled in part by various members of the small GTPase Rab family. Rab5 in particular is required for fusion of early endosomes and it accomplishes this in part by stimulating the production of PtdIns(3)P via Vps34, with the resulting recruitment of PtdIns(3)P-binding proteins to the endosomes. Such proteins include EEA1 and rabenosyn-5, which both bind Rab5 itself as well as PtdIns(3)P via a FYVE domain. Once recruited to the endosome through these mechanisms, EEA1 and rabenosyn-5 appear to function in the tethering, docking, and ultimate fusion of early endosomes.

The sorting nexin (SNX) family containing up to 25 human proteins and the yeast homologues Mvp1p, Vps5p, Vps17p, and Grd19p all contain a PX domain. All of the yeast SNX proteins and some of the mammalian counterparts have been found to bind preferentially or specifically to PtdIns(3)P, and most characterized SNX proteins localize at least partially to endosomes. Consistent with the importance of PtdIns(3)P in vacuolar protein sorting in yeast, Vps5p and Vps17p have a role in the retrieval of the vacuolar protein sorting receptor Vps10p while Mvp1p and Grd19 participate in Golgi to vacuole trafficking. In mammalian cells, roles of the various SNX proteins are being assigned, and the emerging picture suggests that different sorting nexins may be required for regulating the distinct fates of endosomes, i.e., recycling to the cell surface, delivery to lysosomes, or delivery to the trans Golgi.

TABLE I

Cellular Functions of PtdIns(3)P and some Associated Proteins

Cellular function	Domain	PtdIns(3)P-binding proteins
Endosome fusion/maturation	FYVE	EEA1, rabenosyn-5, PIKfyve/Fab1p
Golgi-vacuole trafficking (yeast)	FYVE	Vps27p, Vac1p, Fab1p
	PX	Grd19p, Mvp1p, Vps5p, Vam7p
Receptor sorting/ targeting to lysosome	FYVE	Hrs
	PX	Sorting nexins
Signal transduction	FYVE	SARA
	PX	CISK
Phagosome function/maturation	FYVE	EEA1
	PX	$p40^{phox}$

PtdIns(3)P in Phagocytosis and Bacterial Invasion

Many of the PtdIns(3)P-binding proteins involved in the endocytic process are likely involved in the similar processes of phagocytosis and host cell invasion by bacteria and parasites. Phagosomes, like endosomes, form by invagination of patches of the plasma membrane followed by "pinching off" and sealing to form a

self-contained intracellular compartment. PtdIns(3)P appears transiently on phagosomes in a manner which parallels its appearance and disappearance in endosomes. Phagosomal PtdIns(3)P is apparently generated by the targeting and activation of the VPS34 PI 3-kinase. As in early endosomes, the PtdIns(3)P synthesized in phagosomes recruits FYVE- and PX-domain containing proteins including EEA1. Likewise, in the process of secretion-mediated invasion by *Salmonella*, the membrane vacuole which envelops the invading bacterial cells accumulates PtdIns(3)P. In certain cell types, recruitment of the NADPH oxidase to phagosomes may occur via PX domains in its p40 and p47 subunits. This mechanism may contribute to defense against pathogens since the NADPH oxidase produces reactive oxygen species toxic to invading bacterial cells. Disruption of this recruitment mechanism by pathogenic bacteria enhances their ability to escape host cell defenses.

PtdIns(3)P and Signaling from the Endosomal System

Recently it has become clear that the endosomal system is an essential component of signal transduction pathways regulating proliferation, survival, differentiation, and stress responses. Current evidence suggests that growth factor receptors, many of which are internalized into endosomes following binding of their ligands, can continue to generate signals to downstream effectors as they transit through the endosomal system. Furthermore, internalization and delivery of such receptors to lysosomes for degradation is an important mechanism for down-regulation of signaling in a variety of systems.

The FYVE-domain protein, SARA, localizes to early endosomes via its association with PtdIns(3)P. SARA also binds to Smad2, a downstream target of the transforming growth factor-β (TGFβ) receptor. Association of the SARA–Smad complex appears to be essential for efficient phosphorylation of Smad by the internalized receptor. Thus, PtdIns(3)P in endosomes can serve to assemble signaling complexes in which the local concentration of components is increased by association with specific intracellular membranes. The FYVE domain-containing protein homologue of the yeast protein Vps27p (Hrs) may function in a similar manner in the TGFβ signaling pathway. However, in other systems, Hrs may promote the internalization and ultimate degradation of growth factor receptors. Thus, there is precedent for the involvement of PtdIns(3)P-binding proteins in attenuation as well as enhancement of growth factor signals.

Endosomal localization via PtdIns(3)P binding may also serve to target or sequester components of signaling pathways several steps removed from the initial receptor signal. The PX domain-containing protein kinase CISK (also denoted SGK3) is localized to endosomes and may function in this way. Like its related family members Akt and SGK, CISK is activated by regulatory protein kinases in response to growth factor-mediated regulation of PI 3-kinases that produce PtdIns(3,4,5)P_3. Based on its endosomal disposition, it seems likely that the substrates of the CISK protein kinase are similarly localized. CISK may function to attenuate apoptosis or to promote other processes yet to be discovered based on this unique association with the endosomal compartment.

PtdIns(3)P may also serve as a component of the cellular stress response. In yeast and mammalian cells, PtdIns(3,5)P_2 is formed in response to osmotic stress by the FYVE-domain proteins Fab1p and PIKFYVE, respectively. Effectors of PtdIns(3,5)P specific for this function have not been identified.

Biography

Joseph Virbasius is an Assistant Professor and Dr. Michael Czech is a Professor and Chair of Molecular Medicine at the University of Massachusetts Medical School in Worcester. Their research interests include molecular mechanisms of insulin action and functions of PI 3-kinase and its downstream effectors in insulin-responsive cells. Dr. Virbasius holds a Ph.D. from Northwestern University and served as a postdoctoral fellow at the University of Massachusetts Medical School.

Michael Czech holds a Ph.D. from Brown University. He was a postdoctoral fellow in the Department of Biochemistry at Duke University Medical School from 1972 to 1974 and was a Professor of physiological chemistry at Brown University before coming to the University of Massachusetts Medical School as Chair of the Department of Biochemistry and Molecular Biology in 1981.

Phosphofructokinase-2/Fructose Bisphosphatase-2

Daniel M. Raben
The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

6-Phosphofructo-2-kinase/fructose-2,6-bisphosphatase (PFK-2/FBPase-2) is a bifunctional enzyme wherein a single polypeptide chain contains two enzymatic activities—PFK-2 and FBPase-2. PFK-2 catalyzes the transfer of phosphate from ATP to the second carbon (C-2) of fructose-6-phosphate (F6P), an intermediate in the glycolytic pathway, generating fructose-2, 6-bisphosphate (F2,6BP). Conversely, FBPase-2 catalyzes the dephosphorylation of F2,6BP resulting in the liberation of free inorganic phosphate and regeneration of F6P. In this manner, these two physically linked enzymes function to modulate the cellular concentration of F2,6BP. The importance of this regulation cannot be overstated as this sugar plays an essential signaling role in regulating glucose metabolism in a variety of tissues. Perhaps most importantly, it is largely responsible for regulating the balance between glycolysis and gluconeogenesis in the liver. This balance, critical for maintaining blood glucose levels within the normal range regardless of the nutritional state, principally results from the fact that F2,6BP activates a key regulatory glycolytic enzyme, PFK-1 (6-phosphofructo-1-kinase) and inhibits a regulatory enzyme in gluconeogenesis, FBPase-1 (fructose-1,6-bisphosphatase). Therefore, in the liver, when F2,6BP levels are high, glycolysis predominates and when F2,6BP levels are low, gluconeogenesis predominates. In other tissues, F2,6BP levels mainly serve to help regulate glycolytic flux. By regulating the level of this phosphorylated sugar, PFK-2/FBPase-2 activities play a central role in maintaining glucose homeostasis and utilization.

Discovery of PFK-2/FBPase-2

As with many discoveries, the identification of PFK-2/FBPase-2 was preceded by the discovery of its product F2,6BP. This sugar was first identified as the mediator responsible for stimulating hepatic gluconeogenesis. It had been known for some time that gluconeogenesis was induced in liver by elevated levels of glucagon. Emil van Shaftingen and Henri-Gery Hers demonstrated that rat liver lysates contained an acid-labile phosphoric acid ester that greatly stimulated PFK-1. The concentration of this compound in isolated hepatocytes was significantly increased by glucose and decreased by glucagon. They also showed that this molecule was F2,6BP. Following this discovery, Hers and Uyeda identified PFK-2/FBPase-2 in rat liver as the bifunctional enzyme responsible for the generation and degradation of F2,6BP.

General Structure of PFK-2/FBPase-2

In mammalian tissues, PFK-2/FBPase-2 is a single protein with the PFK-2 activity located at the N-terminal end and the FBPase-2 located at the C terminus. Structural analyses demonstrated that the catalytic domains are flanked by regulatory regions at both the N and C termini. The enzyme functions as a dimer with protein–protein contacts being made at the regulatory regions at the N terminus only. In contrast to this structure, the yeast PFK-2 and FBPase-2 enzymes are separate proteins, but most likely function as dimers.

Enzymology of PFK-2

While PFK-2 shares the same substrate as PFK-1, F6P, the reaction catalyzed by PFK-2 differs from that catalyzed by PFK-1 in four important aspects. First, PFK-1 catalyzes the transfer of the γ-phosphate of ATP to C-1 of F6P generating F1,6BP while PFK-2 catalyzes the transfer of this ATP phosphate to C-2 yielding F2,6BP. Second, PFK-1 is an α-anomer while PFK-2 prefers the β-anomer. Third, PFK-1 is strongly inhibited by ATP while PFK-2 is not sensitive to this nucleotide. Finally, PFK-2 is inhibited by both of its products, ADP and F2,6BP, which are activators of PFK-1.

The complete catalytic mechanism of PFK-2-mediated phosphorylation of F6P has not been elucidated. Important features of the reaction have, however, been identified. In general, PFK-2 activity is much

weaker than that of PFK-1. This may be due to the fact that specific residues involved in accelerating catalysis in PFK-1 are absent in PFK-2. The pH optimum of the enzyme-catalyzed reaction is between 8 and 9, requires magnesium, and prefers ATP as the phosphate donor, but will also use GTP. Inhibition studies indicate that the PFK-2-mediated transfer of phosphate from ATP to F6P occurs via a sequential-ordered mechanism with ATP binding prior to F6P binding. Binding sites for ATP and F6P have been identified as well as residues critical for catalysis.

Enzymology of FBPase-2

Much more is known about the reaction mechanism used for FBPase-2-mediated hydrolysis. The enzyme has a pH optimum between 5.5 and 6.5 and does not require divalent cations. FBPase-2 specifically hydrolyzes the phosphate on carbon 2 (C-2) of F2,6BP and will not hydrolyze C-6 of either F2,6BP, F1,6BP or glucose-1,6-bisphosphate. However, it is inhibited by both its substrate and product—F6P and F2,6BP. Interestingly, the FBPase-2 reaction mechanism involves an intermediate in which F6P is covalently bound to a histidine residue on the enzyme. This covalent intermediate has been useful in structural studies designed to elucidate the reaction mechanism, which appears to resemble, but is not identical to, the mechanism used by serine proteases. Both involve a "catalytic triad" in which three residues work together to form an intermediate in which the substrate is covalently bound to the enzyme followed by hydrolysis of this intermediate to release the product from the enzyme. In the case of serine proteases, a serine residue on the enzyme is covalently bound to the catalytic intermediate while in FBPase-2 a phosphohistidine is formed and F6P is released. The dissociation of the F6P product appears to be the rate-limiting step.

Isoforms of PFK-2/FBPase-2

Since the discovery of PFK-2/FBPase-2 mammalian tissues, a number of mammalian isoforms have been identified from four genes, which include alternatively spliced products. In all isoforms, the catalytic domains are highly conserved while the N and C termini are most divergent. Most tissues contain varying amounts of different isoforms, with one isoform predominating. For example, in liver ~10% of the total PFK-2/FBPase-2 is the skeletal muscle isoform. Even within the predominant liver isoform there are two different species, a 54–55 kDa species and a 58 kDa species with only the 58 kDa species being regulated by phosphorylation. In addition to these mammalian isoforms, yeast contain PFK-2 and FBPase-2 activities, but in this case the enzymes are monomeric although they likely work as dimers.

In addition to sequence differences, kinetic properties of the kinase and bisphosphatase activities also differ among the various isoforms. While the substrate affinities (measured as a K_m) and maximum velocities (V_{max}) vary between isoforms, there are some notable differences. Comparison of bovine brain, liver, and testes shows that these isoforms have similar kinetic properties for PFK-2 in terms of K_m for F6P, but the liver and muscle FBPase-2 enzymes have K_m values for F2,6BP that are approximately 100- to 1000-fold lower than the other isoforms. Based on V_{max}, the skeletal muscle also appears to have the lowest kinase activity and high-phosphatase activity, while the placental isoform has the highest kinase activity with very low-phosphatase activity.

Regulation and Physiological Roles of Specific Isoforms in Specific Tissues

PFK-2/FBPase-2 is exquisitely poised to regulate the levels of F2,6BP. F6P exerts a substrate level control over PFK-2 and is a product inhibitor of FBPase-2. The K_m of PFK-2 and K_i of FBPase-2 for F6P are within the physiological concentration ranges of this phosphorylated sugar in different tissues suggesting that small changes in the levels of F6P result in significant reciprocal alterations in these two enzymatic activities. Such alterations have different effects in different tissues, depending on the isoforms and relative level of the endogenous PFK-2/FBPase-2 activities.

Perhaps the best-studied form of PFK-2/FBPase-2 regulation involves the phosphorylation of the enzyme. Both the liver and heart isozymes are subject to regulation by phosphorylation. The brain isoform is phosphorylated, but this phosphorylation does not appear to affect enzymatic activities. Muscle and testis isoforms are not phosphorylated. A liver isoform (58 kDa) was the first one shown to be regulated by a PKA (protein kinase A)-mediated phosphorylation stimulated by the glucagon-induced second-messenger cyclic AMP (cAMP). Further studies showed that PFK-2/FBPase-2 is phosphorylated on a specific serine residue, serine-32, near the N terminus. This phosphorylation leads to inhibition of PKF-2 and activation of FBPase-2. For PFK-2 at physiological pH, this is primarily due to an increase in the K_m (i.e., lower affinity) for F6P, without affecting the K_m for ATP, and only slightly perturbing V_{max}. In contrast, this phosphorylation activates FBPase-2 by increasing the V_{max} of the enzyme without affecting the K_m for F2,6BP. It is believed that this effect is largely due to an increase in

the rate of F6P dissociation from FBPase-2, which enhances the rate at which the phosphohistidine intermediate is hydrolyzed. Consistent with the critical role of this enzyme in regulating liver carbohydrate metabolism, phosphorylation of the enzyme can be reversed by specific, regulated protein phosphatases (protein phosphatase 2A and 2C), which serves to activate PFK-2 while inhibiting FBPase-2. On the other hand, phosphorylation of the heart isoform modulates only the PFK-2 activity without affecting FBPase-2. Importantly, in stark contrast to the liver isoform, phosphorylation of the heart isoform activates PFK-2. In bovine and rat hearts, phosphorylation lowers the K_m (i.e., increases the affinity) for F6P. The bovine heart isoform may be phosphorylated by PKA, and the rat heart isoform can be phosphorylated and modulated by either PKA or the calcium/calmodulin-dependent protein kinase.

The fact that PKF-2 and FBPase-2 are located near the N and C termini respectively, on the same polypeptide begs the question as to how both activities of the liver enzyme are affected by a phosphorylation near the N terminus. While the exact mechanism underlying the reciprocal regulation of these two activities has not been resolved, a current view is that in the nonphosphorylated state, the N termini of two polypeptides interact and activate the kinase while the C-terminal regions are separated (Figure 1). This is consistent with the crystal structure of the rat testis PFK-2/FBPase-2. Phosphorylation is believed to induce a conformational change in the enzyme resulting in the separation of the N termini, which inactivates the kinase while activating the phosphatase.

The above regulation provides for short-term, acute regulation for rapid, transient responses. The enzyme is also subject to long-term regulation mediated by gene expression. Both insulin and dexamethazone stimulate an increase in the level of PFK-2/FBPase-2 gene expression. Consistent with this, levels of liver PFK-2/FBPase-2 are depressed during starvation or diabetes and increase upon re-feeding or administration of insulin, respectively. Additionally, levels of PFK-2/FBPase-2 decrease following partial hepatectomy and increase during liver regeneration.

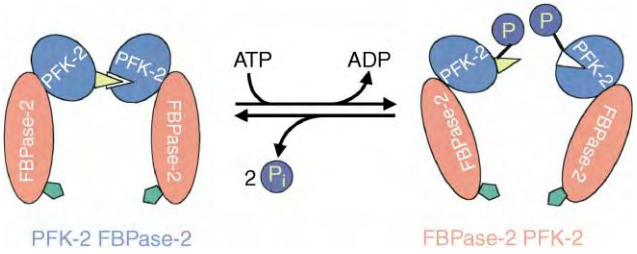

FIGURE 1 Reciprocal regulation of dimeric PFK-2/FBPase-2 in liver by phosphorylation. The blue indicates the N-terminal region containing PFK-2 activity and the red indicates the C terminus containing the FBPase-2 activity. The triangle at the N terminus and the pentagon at the C terminus represent regulatory regions.

The differences in isoforms and their regulation suggest different roles for each isoform. This is most dramatically seen when comparing the regulation of the liver isoform with that of the heart isoform. Liver not only consumes energy, it also stores energy mainly in the form of glycogen. It is also the only tissue, besides kidney to a small extent, which engages in gluconeogenesis to supply glucose to other glucose-dependent tissues in times of need. In that, as previously mentioned, the liver isoform is exquisitely poised to reciprocally regulate the level and activities of PFK-2/FBPase-2. This regulation is sensitive to glucose levels or hormones involved in regulating carbohydrate metabolism such as insulin, which stimulates glycolysis, and glucagons, which induces gluconeogenesis. On the other hand, heart muscle is a constant energy-consuming tissue, and, therefore, engages in glycolysis but not gluconeogenesis. Indeed, the heart does not respond to glucagon but does respond to another hormone that signals through PKA, epinephrine (adrenaline). Therefore, it is not surprising that the regulated heart isoform of PFK-2/FBPase-2 responds to phosphorylation by increasing PFK-2 activity, as this hormone would signal a need for increased glycolytic flux. The increased PFK-2 activity would lead to an increase in F2,6BP levels, thereby increasing glycolysis via activation of PFK-1. The regulation of liver and heart isoforms exemplifies how differential regulation of specific isoforms can serve different roles depending on the needs of various tissues in which they are expressed. This further illuminates the significant role PFK-2/FBPase-2 plays in appropriately regulating carbohydrate metabolism.

Glossary

anomer Stereoisomer (diastereoisomer) of sugars which differ with respect to their configuration about their anomeric carbon. The anomeric carbon is the carbon which forms a new stereocenter, when the sugar cyclizes on the former carbonyl carbon. The configuration may be α or β.

ATP Adenosine triphosphate, a molecule consisting of the nitrogenous base adenine linked to the sugar ribose, and containing three phosphate groups attached to the ribose. ATP, present in all living cells, serves as the principal energy source of energy for cells.

cAMP Cyclic adenosine monophosphate, a cyclic form of adenosine monophosphate where a single phosphate is attached to both

the third and fifth carbon of the ribose sugar linked to adenine. It is important in transmitting intracellular, as well as extracellular, signals induced by many agonists. cAMP binds to and activates the cAMP-dependent protein kinase, PKA.

gluconeogenesis The synthesis of glucose from noncarbohydrate sources occurring primarily in the liver and to a small extent in the kidney. It is stimulated during starvation or intense exercise.

glycolysis (glycolytic pathway) The anaerobic metabolism of glucose to pyruvate. This metabolism generates two molecules of ATP and one molecule of NADH per glucose molecule. The NADH may be used to generate energy in the form of ATP and the pyruvate may enter the tricarboxylic acid cycle to yield NADH for energy production under aerobic conditions.

GTP Guanosine triphosphate, a molecule consisting of the nitrogenous base, guanine, linked to the sugar ribose. The ribose contains three phosphate groups attached to the 5′ carbon. GTP is another source of metabolic energy and is involved in protein synthesis and a number of signal transduction cascades.

K_m A kinetic parameter that indicates the affinity of an enzyme for its substrate and often called the "Michaelis constant." It is defined as the concentration of substrate that results in half the maximal rate (V_{max}) of the enzyme-catalyzed reaction.

protein kinase A (PKA) An enzyme that catalyzes the phosphorylation of proteins on specific serine or theronine residues in response to cAMP.

V_{max} The maximal initial velocity of an enzyme-catalyzed reaction that occurs at saturating substrate concentrations.

Biography

Daniel M. Raben is an Associate Professor in the Department of Biological Chemistry at the Johns Hopkins University School of Medicine. His principal research interests are in the broad fields of lipid biochemistry and chemistry, and signal transduction. He holds a Ph.D. from Washington University in St. Louis, Missouri and received his postdoctoral training at the University of California at Irvine. He is a well-published investigator, including several review articles on lipid-mediated signal transduction, and is on the editorial board of a number of biochemical journals.

Phosphoinositide 3-Kinase

Khatereh Ahmadi
PIramed Ltd., UK

Michael Waterfield
Ludwig Institute for Cancer Research, London, UK

The phosphoinositide 3-kinases (PI 3-kinases) are enzymes with intrinsic lipid kinase activity whose substrates are membrane phosphatidylinositol lipids. When activated by cell surface receptors, such as those that recognize growth factors, PI 3-kinases generate a PIP3 (phosphatidylinositol 3,4,5-triphosphate) second messenger lipid that binds and activates at the membrane, enzymes that control signal networks which control the life, death, and differentiated functions of cells. The loss of control of PI 3-kinase activity has been shown to be instrumental in causation or maintenance of major human diseases such as cancer, diabetes, and inflammation.

Identification of PI 3-Kinases as Signaling Molecules: A Historical Perspective

Signal transduction enables cells to communicate with each other and respond to their external environment through receptors on cell surfaces, which are activated by external ligands such as growth factors. Receptors send signals to the internal control systems of the cell and to internal organelles such as the mitochondria and the nucleus via a series of molecular cascades known as signaling pathways.

In the early 1990s, it was shown that ligand activation of receptors that have intrinsic tyrosine kinases (TK) causes autophosphorylation at specific sites on their kinase domains, initiating the formation of a signaling complex. Phosphoinositide (PI) 3-kinase activity was first found associated with the transforming complex of middle-T (mT) antigen and pp60c-src from polyoma virus-transformed cells and subsequently with the PDGF (platelet-derived growth factor) receptor, mediated by amino acid recognition sites around specific tyrosine residues. Since then it has become clear that PI 3-kinases are recruited to almost every receptor complex, including activated oncogenes and growth factor receptors, as well as heterotrimeric G proteins, a key effector of activated receptors.

PI 3-Kinases Phosphorylate Lipids

The discovery that the main product of these transforming protein-associated kinases was a PI that had a phosphate group on the D3 position of the inositol ring added a new second messenger to the armory of specific signal molecules used by cells. Three distinct signal molecules that are phosphorylated on the 3 position of the inositol ring can be generated by three classes of PI 3-kinase from specific phosphoinositol substrates. The signal molecules formed are phosphatidylinositol 3-phosphate or PI3P, PI(3,4)P2, and PI(3,4,5)P3 (see Figure 1).

A wide variety of receptor-mediated stimuli can lead to the rapid production of PI(3,4)P2 and PI(3,4,5)P3 in cells, whereas the intracellular levels of PI3P seem mostly unaffected by external cell stimulation. PI3P is used for internal cellular protein trafficking. The hydrolysis of these lipids occurs through the action of lipid phosphatases that remove the three phosphate groups from the inositol ring, thus regulating PI 3-kinase activity. The lipid signaling pathway initiated by PI 3-kinase is distinct from the classical pathway in which activation of phospholipase C causes to production of Ins(1,4,5)P3 and diacylglycerol, ultimately leading to mobilization of calcium and activation of protein kinase C.

Activation and Regulation of PI 3-Kinases

PI 3-kinase was first purified from bovine brain tissue as a lipid kinase activity and was shown, through a classical series of systematic biochemical analyses, followed by molecular cloning and expression of the recombinant proteins, to be a heterodimeric enzyme containing a

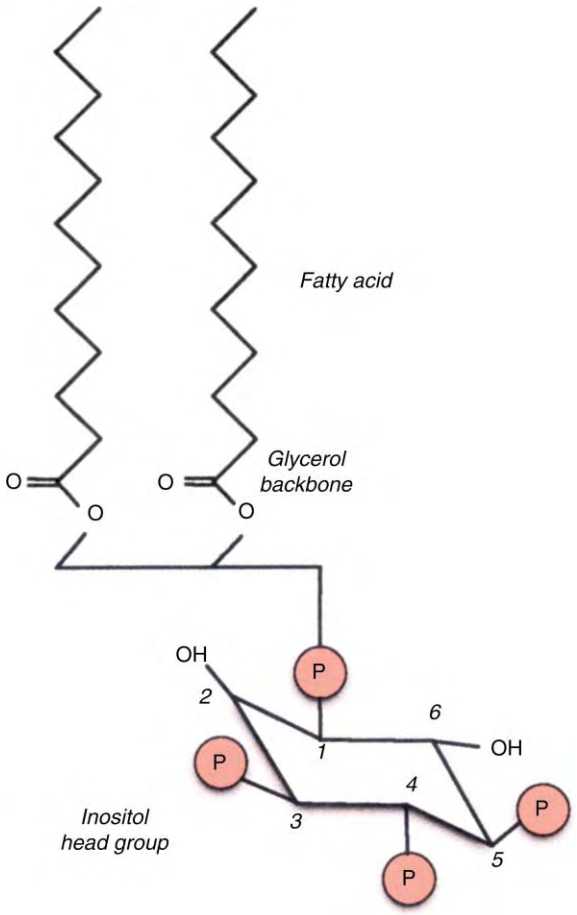

FIGURE 1 The signal molecule phosphatidylinositol 3-phosphate (PI 3-phosphate or PIP3).

110 kDa catalytic subunit (p110), and an 85 kDa adaptor subunit (p85). The primary structures of the p85 and p110 subunits were revealed through cDNA cloning using protein sequence data, thus shedding light on the mode of interaction between p85 and tyrosine phosphorylated proteins. The p85 subunit contains an N-terminal (src homology) SH3 domain, which binds to proline-rich sequences and two SH2 domains separated by an inter SH2 domain. SH2 domains have been found in many signaling proteins and bind phosphotyrosine residues within a specific polypeptide context, YXXM, where Y is a tyrosine, M is a methionine, and X can be any amino acid. The adaptor subunit also contains a breakpoint cluster region homology (BH) domain. These distinct functional domains make p85 an important interactive protein with a major regulatory role.

The p110 subunit was shown to contain an ATP-binding site, which is responsible for the catalytic activity of the enzyme. More recently the three-dimensional structure of a p110 (gamma) subunit revealed a modular structure comprising a Ras-binding domain (RBD), a C2 domain, a helical domain, and a catalytic domain. This structure has been invaluable in rationalizing the allosteric activation and regulation of PI 3-kinase, its ability to bind membranes, and its substrate specificity.

PI 3-kinases are recruited to activated receptors directly or to associated substrate scaffold molecules such as Grb3 or Shc through the binding of the SH2 domains of the p85 subunit to phosphorylated tyrosine residues. The current paradigm for the activation of PI 3-kinase is that interaction with the receptor brings the enzyme into close proximity to the membrane that contains the lipid substrates of PI 3-kinase. The p110 catalytic subunit is thus able to phosphorylate the lipids, which then act as second messengers, initiating a cellular signal that is carried to the cytoplasm, mitochondrion, or nucleus through a cascade of signaling molecules.

Down-Regulation of PI 3-Kinase Activity

The phosphatases SHIP (SH2 domain-containing inositol 5-phosphatase) and PTEN (phosphatase and tensin homologue deleted on chromosome 10) play a role in down-regulating PI 3-kinase activity by removing phosphate groups from the 3-phosphorylated lipid products of the enzyme. PTEN was identified as a tumor suppressor and tyrosine phosphatase. PTEN is now known to be the second most commonly mutated gene in all human cancers. SHIPs remove phosphate groups from the 5 position of the inositol ring and bind to diverse receptors and adaptor molecules.

PI 3-Kinases are a Family of Enzymes

Once the importance of PI 3-kinases in cell physiology was realized, several groups set out to purify and characterize PI-3 kinases from a variety of tissues. Eight PI 3-kinase isoforms are now known; they are divided into three classes based on their structure and *in vitro* substrate specificity.

Class I PI 3-Kinases

The class I molecules can use PI, PI(4)P, or PI(4,5)P2 as substrates *in vitro*. However, *in vivo*, they show a strong preference for PI(4,5)P2. The class I enzyme subtypes have been subdivided into class Ia and class Ib based on their mode of regulation (see Figure 2). The class Ia enzymes consist of three isoforms, p110α, p110β, and p110, which are encoded by three separate genes. The class Ia enzymes use p85 as their adaptor subunit, but this has at least seven adaptor variants, which are the alternative spliced products of three separate genes,

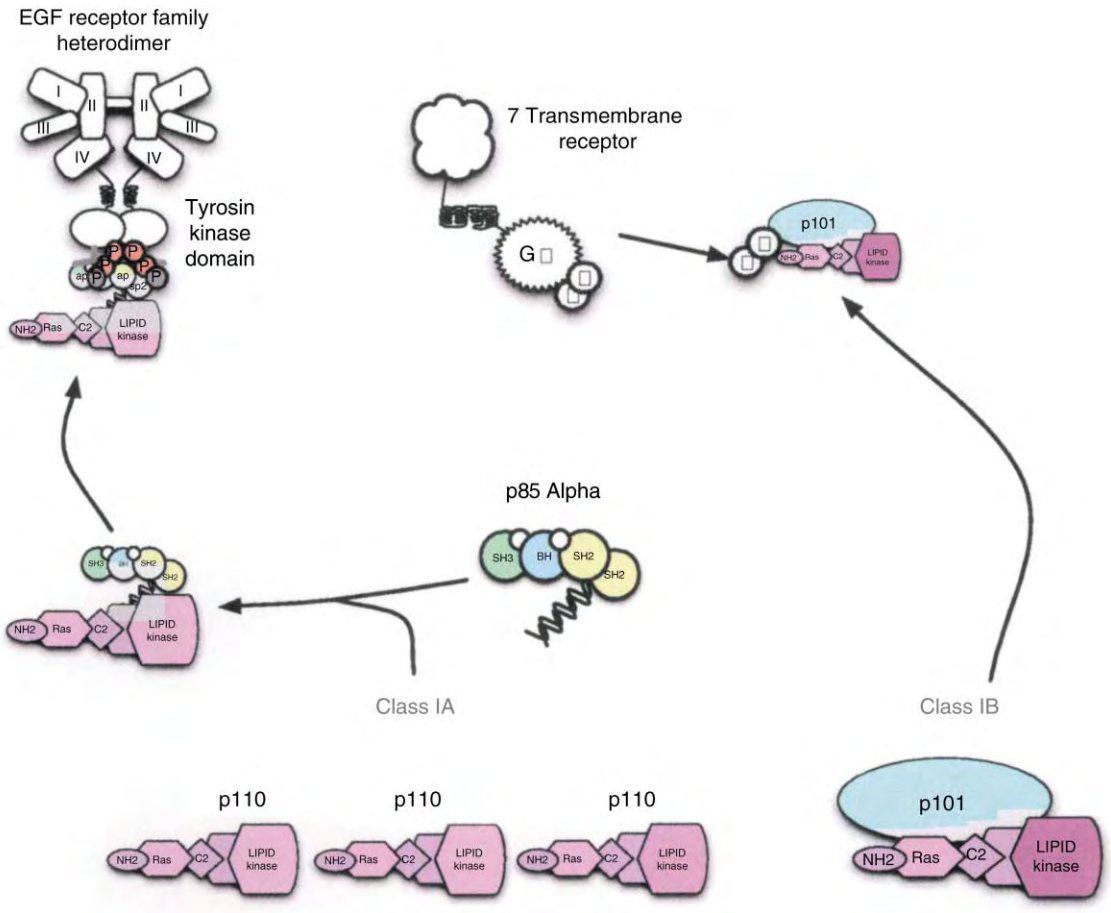

FIGURE 2 The class I PI 3-kinases are divided into groups Ia and Ib. Group 1a includes three catalytic subunits, p110α, β, and δ, which form heterodimers with their regulatory subunit p85. Class Ib includes the PI 3-kinase γ, which associates with the protein p101. The PI 3-kinases have amino-terminal (NH_2), Ras-binding, C2, and lipid kinase domains. The regulatory subunit p85 has an SH2 (src homology) region, which binds to phosphorylated sequences on growth factor receptors such as those of the EGF (epidermal growth factor) family, SH3, and BH domains. The PI 3-kinase γ is activated by G protein $\beta\gamma$ subunits that are released by signals from seven transmembrane receptors.

namely, p85α, p85β, and p55γ. The p110α and p110β subtypes are expressed ubiquitously, whereas p110δ has an expression pattern that is mainly restricted to hematopoietic cells. All mammalian cell types studied express at least one class Ia PI 3-kinase isoform class Ia PI 3-kinases are conserved in evolution and have been found and studied in *Drosophila melanogaster, Caenorhabditis elegans*, and *Dictyostelium discoideum*, as well as more recently in transgenic mice, with dramatic results.

Only one class Ib isoform exists, p110γ, which is activated by G protein-coupled receptors by binding to the G$\beta\gamma$ subunits of heterotrimeric G proteins. The p110γ catalytic subunit does not partner with the p85 adaptor subunits; instead, it forms a complex with a 101 kDa regulatory protein known as p101, which is not homologous to any known protein. The role of p101 is unresolved, although it may be involved in the interaction with G$\beta\gamma$. The p110γ/p101 complex has only been found in mammals and has a tissue distribution mainly restricted to hematopoietic cells. Some studies have shown that the class Ia isoform p110β can also bind to G$\beta\gamma$ and thus be activated by G protein-coupled receptors *in vitro*; however, the physiological significance of this interaction has not been established.

All class I subtypes bind to ras, a signaling molecule that is a key regulator of cell growth and transformation, which means that activated ras can turn on the PI 3-kinase pathway.

Transgenic mouse studies have helped to elucidate the functional specificity of the class I isoforms *in vivo*. For example, p110δ and p110γ clearly have a role in the regulation of the immune response, reflecting their restricted tissue distribution. P110γ knockout mice, in studies reported by three groups, had impaired neutrophil and macrophage chemotaxis and function and consequently were unable to mount an inflammatory response to bacterial infections. In another study, p110γ knockout mice were used to show that the enzyme acts as a negative regulator of heart muscle contractility.

The p110δ knockout mice have been described in studies by three groups, and the data have confirmed that p110δ functions primarily in B and T lymphocytes. The p110δ-deficient mice failed to raise an adequate immune response due to compromised B- and T-cell antigen receptor signaling. Deletion of the p110α gene gave an embryonic lethal phenotype, as did deletion of the p110β gene, which indicates that these isoforms play important roles in development.

Knockout studies of the adaptor subunits have shown that p85 is involved both in the cellular immune response and in the control of glucose metabolism Transgenic mice with deletions of all p85 isoforms resulted in perinatal lethality. Mice with were hypoglycemic, showed lower insulin levels, and had increased glucose tolerance. In addition, p85α knockout mice had diminished B-cell activity but functional T-cells, indicating that p85β but not p85α may be important in T-cell signaling.

Class II PI 3-Kinases

The class II enzymes have larger molecular weight catalytic subunits of 170 kDa, with a C-terminal C2 domain that can bind phospholipids *in vitro* in a Ca^{2+}-independent manner and possible amino-terminal protein interaction domains. The class II PI 3-kinases use mainly PI, and to a lesser extent PI(4)P and PI(4,5)P2, as substrates *in vitro*. However, the *in vivo* substrate specificity of class II PI 3-kinase is presently unknown. Three class II isoforms have been found in mammals, C2α, C2β, and C2γ. Only one isoform exists in *D. melanogaster*, and when it is mutated, developmental defects are induced. The function of PI 3-kinase class II in mammalian cells is far less characterized than that of the class I enzymes.

Class III PI 3-Kinases

The class III enzymes are homologues of the yeast enzyme vps34p; both enzymes use PI only as a substrate *in vitro*. Class III PI 3-kinases have a role in intracellular trafficking of proteins.

Signaling Downstream of PI 3-Kinases

The number of targets downstream of PI 3-kinase, which impinge on cellular functions as diverse as growth, apoptosis, glucose homeostasis, and heart muscle contractility, are ever expanding and comprise a vast area of research, a detailed account of which would be beyond the scope of this article.

The first direct target in downstream PI 3-kinase signaling is created by the interaction of their lipid products, the 3-phosphoinositides with proteins that have specific PI3P lipid-binding domains. Such proteins containing either a PH (pleckstrin homology) domain, such as AKT/PKB and PDK1, or a FYVE domain, named after the first four proteins shown to contain it, Fab1p, YOTB, Vac1p, and early endosome antigen 1 (EEA1). Both bind 3-phosphoinositides.

The protein AKT is a major player in PI 3-kinase signaling, lying directly downstream of PI 3-kinase in the pathway (see Figure 3). Both AKT and PDK contain PH domains and hence are brought to the membrane by binding to 3-phosphoinositides following PI 3-kinase activation. AKT activation is thought to occur via phosphorylation at two sites: Thr308 by PDK1 and S473 by a putative PDK2 molecule yet to be established. Once activated, AKT phosphorylates and regulates a diverse set of molecules. For example, AKT phosphorylates and inhibits the BCL-2 family member BAD and caspase 9, both of which promote apoptosis, and the forkhead transcription factors, which stimulate transcription of pro-apoptotic genes. These events have a combined antiapoptotic effect on the cell. AKT activation affects cell cycle activation by increasing cyclin D transcription and translation and by reducing levels of the cyclin-dependent kinase inhibitor p27kip1.

Studies of PI 3-kinase signaling in *D. melanogaster* have shown that overexpression of Dp110 in imaging disks increases cell growth and creates larger flies. The link between PI 3-kinase and cell growth is likely due to the fact the PI 3-kinase lies downstream of the insulin receptor and upstream of p70S6 kinase, which when activated phosphorylates the 40S ribosomal protein, S6. This process increases the translation of the 5′-TOP mRNAs, which encode ribosomal proteins and protein synthesis elongation factors. Another player in this pathway is mammalian target of rapamycin (mTOR), which lies downstream of PI 3-kinase and activates p70S6 kinase as well as the eukaryotic translation initiation factor (4E-BP1), promoting protein translation and ultimately cell growth.

The effects of PI 3-kinases on the regulation of the actin cytoskeleton occur not through AKT but via their interaction with guanosine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs) for small GTPases, such as Rac and members of the Arf family. These molecules are known to contain PH domains and thus are likely to be directly downstream of PI 3-kinases. The exact mechanism of the interaction of PI 3-kinase lipid products and GEFs has not been established, but it is clear that PI 3-kinase has at least a regulatory role in the organization of the cytoskeleton and thus cell motility.

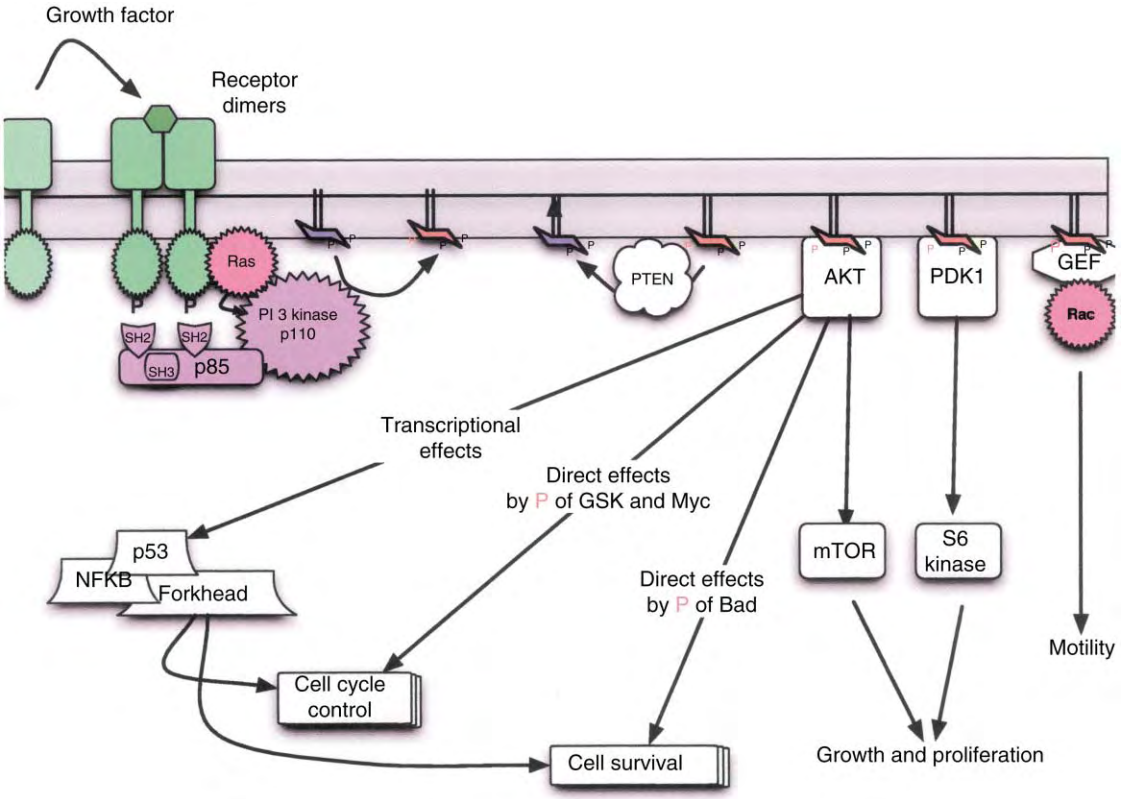

FIGURE 3 The PI 3-kinase signal pathways.

The Role of PI 3-Kinases in Human Disease

It is clear from the diverse role which PI 3-kinases plays in the cell that aberrations of the PI 3-kinase pathway are likely to perturb cellular homeostasis, leading to disease. Evidence has accumulated from transgenic manipulation studies of the PI 3-kinase genes in mice as well as from studies of disease models in nature. Interestingly, the transgenic studies in mice have revealed that the class I isoforms play important and distinct functions in cells of different tissue origin. Pharmaceutical companies have started to exploit the therapeutic potential of isoform selective PI 3-kinase inhibitors for various indications.

Cancer

The strongest link between PI 3-kinase and cancer is the tumor suppressor PTEN, which has been found to be the second most commonly mutated gene in cancer after p53 and a negative regulator of PI 3-kinase through its lipid phosphatase activity. Mutations that destroy function or the loss of PTEN are especially prevalent in prostate, brain (glioblastoma), and endometrial cancers. Increased PI 3-kinase activity associated either with lack of PTEN activity or mutation of the PI 3-kinase gene itself, as has been shown to occur in certain cancers, can promote the oncogenic action of this enzyme. Increased PI 3-kinase activity may lead to loss of the ability to regulate cell survival, loss of control of the cell cycle, and alterations in motility, which are some of the key events in cellular cancer progression. In addition, the enzyme PI 3-kinase lies downstream of the vascular endothelial growth factor (VEGF) receptor, a growth factor signal system that promotes angiogenesis in solid tumors, a key factor in supporting tumor growth. Therefore, inhibitors to PI 3-kinase would be suitable candidates for clinical evaluation in oncology.

Inflammatory Disease

Studies in transgenic mice either lacking or with mutated forms of the p110δ and p110γ isoforms have shown that these two enzymes have specific roles in regulating the immune response. Both isoforms have a tissue expression restricted mainly to hematopoietic cells. In addition, elegant studies in mice have allowed the differentiation of the role of these two isoforms. Thus p110γ has been shown to be involved in the innate immune response through regulation of macrophage and neutrophil function.

Knock-in mice with kinase-dead mutant versions of p110δ have been constructed, showing that this isoform regulated the development and function of B- and T-cell lymphocytes and thus the adaptive immune response. Several pharmaceutical companies have established programs to evaluate isoform-specific inhibitors to p110δ and p110γ in autoimmune and allergic disease.

Cardiovascular Disease

Tissue-specific knockout studies of PTEN have implicated the importance of PI 3-kinase enzymes in controlling both cardiac contractility and hypertrophy. Additional studies of these mice that involve the expression of dominant negative p110α and p110γ enzymes have given clues to the role of each isoform in the heart. The p110α isoform was found to be responsible for increases in the size of cardiomyocyte cells and p110γ to be associated with decreased heart contractility. Surprisingly, there were high levels of p110γ in total heart extracts of these mice, as this isoform was considered to be present primarily in leukocytes. Therefore, isoform selective inhibitors of PI 3-kinase may have therapeutic potential in treating heart failure.

Glossary

Akt A serine/threonine protein kinase that is activated by the lipid products of PI 3-kinase.

phosphatidylinositol 3,4,5-triphosphate (PIP3) A phosphatidylinositide that has three phosphate groups on the 3, 4, and 5 positions of the inositol ring that acts as a second messenger molecule in cells.

PI 3-kinase A family of enzymes that phosphorylate inositolphosphates on the 3 position of the inositol ring.

PTEN A lipid phosphatase that removes the phosphate from the 3 position of PIP3, thus down-regulating the growth and proliferation signal.

Biography

Khatereh Ahmadi is Project Manager of the PI 3-kinase drug discovery program in oncology at Piramed, a start-up biotechnology company in the United Kingdom. She obtained a Ph.D. in immunology at Kings College London and was a postdoctoral Research Fellow at the Ludwig Institute for Cancer Research, working on PI 3-kinase biochemistry and molecular biology with Michael Waterfield. She managed the drug development program that led to the discovery of specific new inhibitors for these enzymes.

Michael Waterfield is Director of Research at the Ludwig Institute for Cancer Research at University College London where he is also Courtauld Professor of Biochemistry. With Peter Parker he first purified and characterized the PI 3-kinase enzymes and then co-developed specific inhibitors of these enzymes. Previously, he co-discovered the functional role of the sis oncogenes, and in studies of signal transduction with other colleagues, he purified and cloned the EGF receptor and found that when truncated it functioned as an oncogene. In 2003 he co-founded the Piramed company to develop PI 3-kinase inhibitors.

Phosphoinositide 4- and 5-Kinases and Phosphatases

Shawn F. Bairstow, Matthew W. Bunce and Richard A. Anderson
University of Wisconsin, Madison, Wisconsin, USA

Phosphoinositides are one of the many phospholipid families found within membrane bilayers of eukaryotic cells. Site-specific phosphorylation of phosphoinositides by lipid kinases results in the generation of multiple phosphatidylinositol phosphate isomers. These mono- or poly-phosphorylated isomers can be further modified by additional enzymes or can directly modulate numerous cellular functions. Because of the potential for phosphoinositides to alter a variety of cellular processes, their synthesis must be strictly regulated. A number of phosphoinositide kinases and phosphatases have been identified and characterized. By adding or removing phosphate groups at specific positions along the inositol ring, these kinases and phosphatases dictate the signaling capacity of phosphoinositides.

Phosphoinositides

Structure

The basic structure of phosphoinositides consists of a six-carbon inositol ring linked by a phosphodiester bond to diacylglycerol (DAG) (Figure 1). The two fatty acid tails of the DAG moiety anchor phosphoinositides into the various membrane structures throughout eukaryotic cells, such as the endoplasmic reticulum, Golgi apparatus, and plasma membrane. *In vivo*, phosphoinositides can be phosphorylated at the 3-, 4-, and 5-hydroxyl positions along the inositol ring in all possible combinations.

Nomenclature

Phosphatidylinositol (PI) is the initial substrate for a number of phosphoinositide kinases that phosphorylate the hydroxyl groups along the inositol ring. Mono- and polyphosphorylated phosphoinositides are named with respect to the positions of the inositol ring that are phosphorylated. Phosphorylation of PI at the 4-hydroxyl position generates phosphatidylinositol 4-phosphate (PI4P); a subsequent phosphorylation at the 5-hydroxyl position generates phosphatidylinositol 4,5-bisphosphate ($PI(4,5)P_2$). Phosphatidylinositol can be singly or severally phosphorylated at the 3-, 4-, and 5-hydroxyl positions to yield phosphatidylinositol mono-, bis-, or trisphosphate molecules.

Phosphatidylinositol 4-Kinases

Subfamilies

Phosphatidylinositol 4-kinases (PI 4-kinases) use PI as a substrate to generate PI4P. PI 4-kinases are classified as either type II or type III kinases based on their structural and kinetic properties. Two mammalian isoforms termed α and β have been identified for each PI 4-kinase subfamily. Type III PI 4-kinases are structurally and kinetically similar to PI 3-kinases. PI 3-kinases and type III PI 4-kinases have homologous catalytic domains, and type III PI 4-kinases are even inhibited by known PI 3-kinase inhibitors, such as wortmannin. Type II PI 4-kinases do not share these structural or catalytic similarities with PI 3-kinases.

Cellular Functions

The higher-order species such as $PI(4,5)P_2$ and $PI(3,4,5)P_3$ have received significant attention, whereas PI4P has typically been thought of simply as a metabolic intermediate in the synthesis of other phosphoinositides. However, a number of functional studies have demonstrated important roles for PI 4-kinases *in vivo*. Type II PI4-kinases have been linked to roles in both secretion and endocytosis. Type III PI4-kinases have been most thoroughly characterized in the budding yeast *Saccharomyces cerevisiae*. Stt4 and Pik1, the yeast homologues of mammalian type III α- and β-isoforms, respectively, are targeted to distinct subcellular locations and perform nonredundant functions. Pik1 is targeted to the nucleus and Golgi. The nuclear function of Pik1 is unknown, but several studies have indicated that Pik1 is required

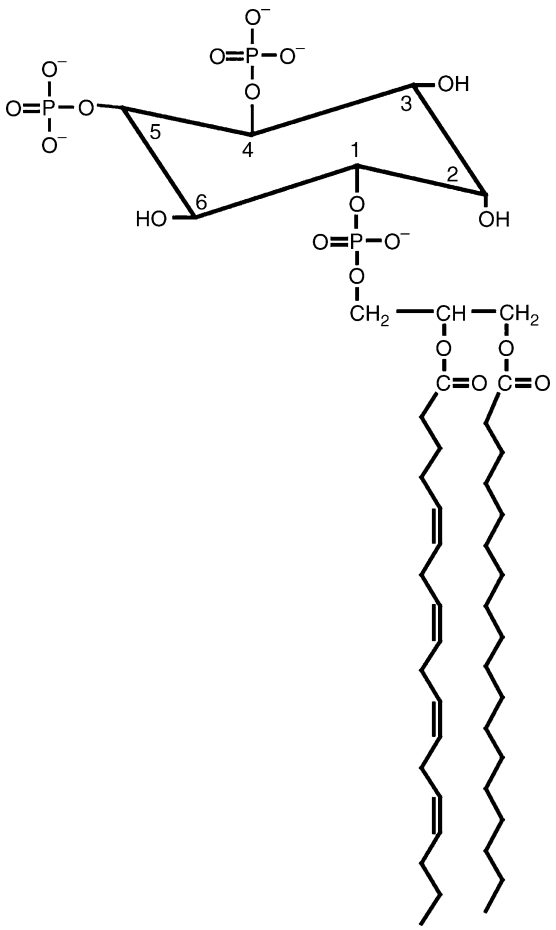

FIGURE 1 Phosphoinositide structure. Phosphoinositides are comprised of a six-carbon inositol ring linked by a phosphodiester bond to diacylglycerol. The inositol ring is numbered counterclockwise starting at the phosphodiester linkage. *In vivo*, phosphoinositides are phosphorylated at the 3, 4, and 5 positions of the inositol ring; phosphatidylinositol 4,5-bisphosphate ($PI(4,5)P_2$) is pictured.

for normal secretion from the Golgi. PI 4-kinase β, the mammalian homologue to Pik1, has also been implicated in Golgi function. Stt4 localizes primarily to the plasma membrane and ER and has been linked to actin cytoskeleton organization and cell wall stability. The PI4P generated specifically by Stt4 can be further phosphorylated by Mss4, the yeast homologue of type I phosphatidylinositol phosphate kinases, or dephosphorylated by the phosphoinositide phosphatase Sac1. The interplay between Stt4, Mss4, and Sac1 control actin dynamics in *S. cerevisiae*. As mentioned above, Pik1 and Stt4 are functionally nonredundant. A loss of activity in either PI 4-kinase causes a unique phenotype that cannot be rescued by increasing the activity of the other kinase. These observations suggest that Pik1 and Stt4 each generate discrete pools of PI4P at different subcellular locations, and that these pools of PI4P are utilized by unique sets of effectors.

Phosphatidylinositol Phosphate Kinases

Phosphatidylinositol phosphate kinases (PIP kinases) generate phosphatidylinositol bisphosphate (PIP_2) from phosphatidylinositol monophosphate isomers. PIP kinases are classified into type I, II or III subfamilies based on their structural and kinetic properties. Members of all three subfamilies have highly conserved kinase domains toward the C-terminus of the proteins, with more variable flanking sequences. Each PIP kinase subfamily has unique substrate specificity dictated by a region at the C-terminal end of the kinase domain named the activation loop. The activation loop is nearly identical for different isoforms within a subfamily but divergent between subfamilies (Figure 2).

Type I PIP Kinases

Type I PIP kinases are PI4P 5-kinases, i.e., they use PI4P as a substrate to generate $PI(4,5)P_2$. Three mammalian type I PIP kinase isoforms termed α, β, and γ have been identified. Type I PIP kinases modulate the organization of the actin cytoskeleton. $PI(4,5)P_2$ regulates the activity of many proteins that process actin at the plasma membrane. Mss4, the yeast homologue of mammalian type I PIP kinases, is required for proper actin cytoskeleton organization and cell wall integrity. Yeast lacking Mss4 activity can be rescued by expressing mammalian type I PIP kinase isoforms, illustrating that type I PIP kinases are functionally conserved in eukaryotes. Mammalian type I PIP kinases localize to sites of cortical actin dynamics, such as lamellipodia and focal adhesions, and modulate the assembly of these structures in a $PI(4,5)P_2$-dependent manner. The type Iγ isoform is targeted to focal adhesions by an association with the protein talin and is tyrosine phosphorylated in a focal-adhesion-kinase (FAK)-dependent manner. Kinase-dead PIP kinase Iγ mutants block focal adhesion assembly, reinforcing the requirement for $PI(4,5)P_2$ in focal adhesion signaling.

Type II PIP Kinases

Type II PIP kinases are PI5P 4-kinases, generating $PI(4,5)P_2$ from PI5P in a catalytically distinct reaction from type I PIP kinases. Like type I PIP kinases, the type II subfamily is comprised of α-, β-, and γ-isoforms. *In vivo* functions for type II PIP kinases have not been clearly defined. Although type I and type II PIP kinases both produce $PI(4,5)P_2$, the two subfamilies are functionally nonredundant. No homologues for mammalian type II PIP kinases have been identified in *S. cerevisiae*, so type II PIP kinases may have specialized functions in higher eukaryotes. One such function could be to modulate receptor-mediated signaling, as the type

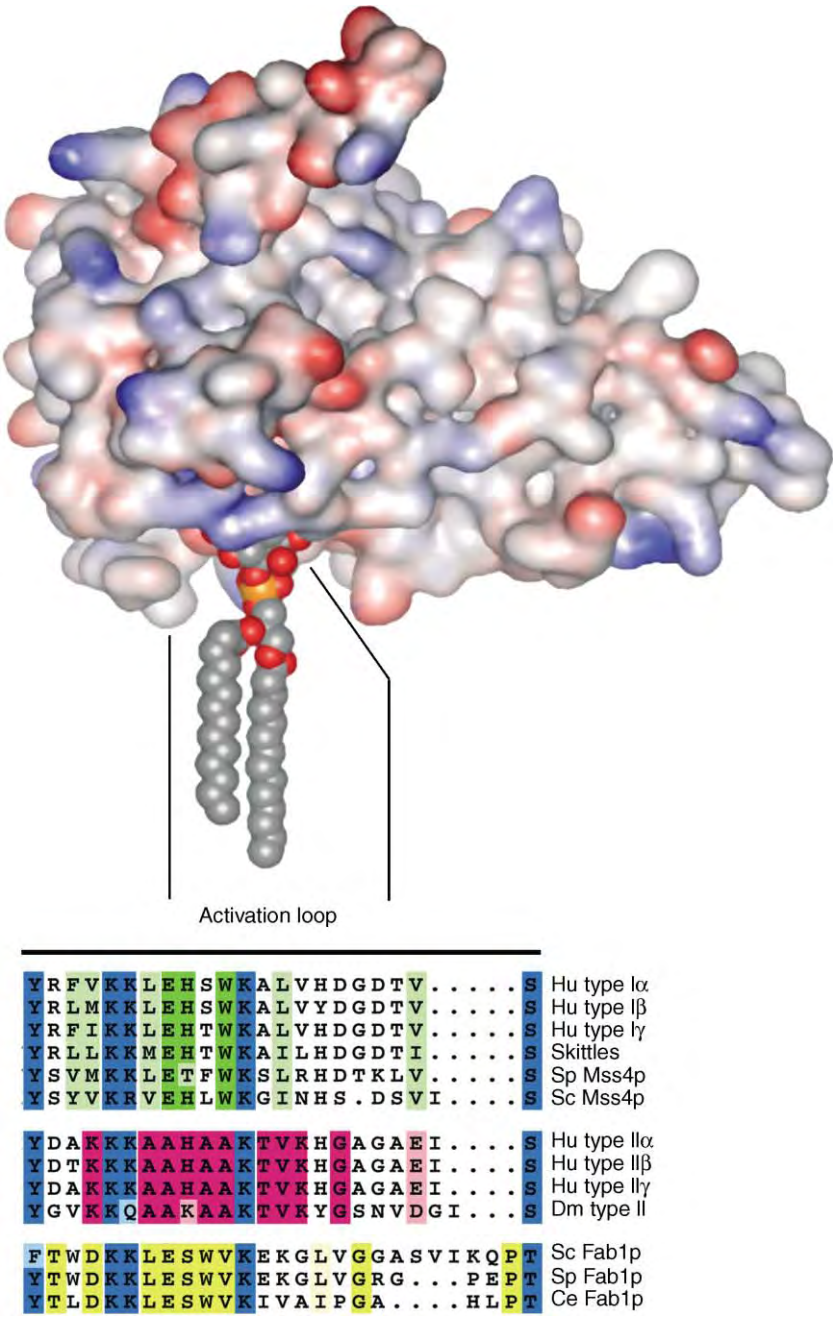

FIGURE 2 PIP kinase structure and the activation loop. The crystal structure for the human type IIβ PIP kinase isoform is shown above with PI5P modeled into the active site. Although the activation loop was not resolved in the crystal structure, its position relative to the active site is illustrated. A sequence alignment of type I, type II, and type III PIP kinase activation loops is shown below the crystal structure. The activation loop is highly conserved among members of each subfamily but divergent between subfamilies. Hu – human, Sp – *S. pombe*, Sc – *S. cerevisiae*, Dm – *D. melanogaster*, Ce – *C. elegans*.

IIβ-isoform has been identified in a complex with the p55 TNFα transmembrane receptor.

Type III PIP Kinases

Type III PIP kinases are PI3P 5-kinases, generating PI(3,5)P_2 from PI3P. The *S. cerevisiae* protein Fab1 was the first type III PIP kinase to be identified. In yeast, Fab1 and PI(3,5)P_2 are involved in vacuole morphology, membrane trafficking, and stress response. Type III PIP kinases were not initially identified in mammalian cells, and *in vitro* studies suggested that type I isoforms can generate PI(3,5)P_2 and thus may perform similar functions to those of Fab1 in yeast. More recently, however, proteins homologous to ScFab1 have been identified in mammalian cells. These mammalian enzymes have

similar *in vivo* substrate specificity to the *S. cerevisiae* Fab1 enzyme and appear to regulate membrane trafficking in a manner comparable to ScFab1.

Phosphatidylinositol Phosphatases

Phosphatidylinositol phosphatases are enzymes that can selectively dephosphorylate both lipid phosphoinositides and soluble inositol polyphosphates. As a family, they can be subdivided by their catalytic properties and substrate specificity.

Phosphoinositide 4-Phosphatases

The Phosphoinositide 4-Phosphatases (Inositol Polyphosphate 4-Phosphatases) are a family of enzymes that dephosphorylate the 4-position of the inositol ring in a magnesium-independent manner. The members of this family can utilize PI(3,4)P_2, Ins(3,4)P_2, and Ins(1,3,4)P_3 as substrates *in vitro*, generating PI3P, Ins3P, and Ins(1,3)P_2, respectively. Two genes have been identified in humans corresponding to type I and type II 4-phosphatases. These genes can be alternatively spliced, resulting in expression of several variant phosphatases. Both types share a 37% total sequence identity and a conserved CKSAKDRT consensus sequence. This C–X_5–R consensus sequence is consistent with other magnesium-independent phosphatases.

Cellular Functions of 4-Phosphatases

The PI-3 Kinase (PI3K) signaling pathway impacts cell growth, glucose metabolism, and apoptosis. Activation of the PI3K pathway results in the generation of PI(3,4,5)P_3 and PI(3,4)P_2, which stimulate downstream effectors such as protein kinase B/Akt and PI3K-dependent kinase 1. Phosphoinositide 4-phosphatases are thought to participate in regulation of the PI3K pathway by converting PI(3,4)P_2 to PI3P, thus attenuating the PI3K signal and subsequently deactivating PI3K effectors. An association identified between a PI 4-phosphatase and the PI3K p85 regulatory subunit supports this putative function for PI 4-phosphatases.

Phosphoinositide 5-Phosphatases

Phosphoinositide 5-phosphatases (inositol polyphosphate 5-phosphatases) dephosphorylate the 5-position of the inositol ring in a magnesium-dependent manner. This family collectively can utilize four substrates: PI(4,5)P_2, PI(3,4,5)P_3, Ins(1,4,5)P_3, and Ins(1,3,4,5)P_4. PI 5-Phosphatases contain a bipartite consensus sequence, (F/I)WXGDXN(F/Y)R, followed several amino acids downstream by (R/N)XP(S/A) (W/Y) (C/T)DR(I/V) (L/I). PI 5-phosphatases are classified into four groups based on their substrate specificity.

Group I 5-Phosphatases

Group I 5-phosphatases use Ins(1,4,5)P_3 and Ins(1,3,4,5)P_4 as substrates. Type I 5-phosphatase, one member of this group, is thought to play a role in the regulation of cellular calcium levels. Ins(1,4,5)P_3 (IP_3) is a pivotal regulator of cellular calcium levels and is generated by the cleavage of PIP_2 by phospholipase C. The resulting IP_3 binds to the IP_3 receptor, triggering a release of calcium ions from intercellular stores. Type I 5-phosphatase decreases this signal by dephosphorylating IP_3 into Ins(1,4)P_2.

Group II 5-Phosphatases

Members of group II 5-phosphatases can utilize all four of the substrates mentioned above. The synaptojanins, type II 5-phosphatase and the Oculocerebrorenal Syndrome of Lowe (OCRL) gene product, OCRL-1, are all members of this group. OCRL is an X-linked disorder resulting in mental retardation, renal dysfunction, and congenital cataracts. Although the pathogenesis for these symptoms is not currently known, OCRL-1 dysfunction results in an increase in PI(4,5)P_2 levels, as observed in cells cultured from individuals with this disorder. Interestingly, OCRL-1 shares 51% identity with type II 5-phosphatase. However, this enzyme cannot compensate for the lack of OCRL-1 activity, possibly due to a difference in substrate specificity or tissue localization. The synaptojanins have functions distinct from OCRL-1 and type II 5-phosphatase. Synaptojanin 1 has been shown to function in recycling of vesicles at neuronal synapses. Synaptojanin 2, on the other hand, is somewhat less characterized. This protein is alternatively spliced and some variants have been shown to have functions overlapping that of synaptojanin 1, while other variants have been localized to distinct cellular compartments, such as the outer mitochondrial membrane.

Group III 5-Phosphatases

Group III 5-phosphatases are active toward PI(3,4,5)P_3 and Ins(1,3,4,5)P_4, which have a 3-position phosphate group. Src homology domain containing inositol phosphatases (SHIPs), SHIP1 and SHIP2 are important members of this group. These proteins share 50% sequence identity and similar substrate specificity, but differ in their tissue expression levels. SHIP1 is primarily expressed in hematopoetic tissues while SHIP2 is expressed in nonhematopoetic tissues. Recent work has demonstrated an importance of SHIPs in signal

transduction. SHIP2 has been shown to associate with specific tyrosine kinase receptors, such as the EGF receptor. This places the phosphatase in an ideal location to attenuate the increased PI(3,4,5)P_3 and PI(3,4)P_2 levels generated by PI3K, which is also recruited to these receptors. SHIP2 mouse knockout experiments support SHIP2's role in PI3K signal termination and also suggest a link between SHIP2 activity and insulin resistance, a primary factor in type 2 diabetes.

Group IV 5-Phosphatases

Group IV phosphatases are the least-characterized of the four groups. One member, phosphoinositide 5-phosphatase type IV, has recently been identified. This phosphatase utilizes PI(3,4,5)P_3 as its primary substrate, but has also been shown to dephosphorylate PI(4,5)P_2 under certain conditions. Expression levels are highest in the brain for both humans and mice, with lower expression in other tissues. The cellular function of this phosphatase has yet to be determined.

Biography

Shawn F. Bairstow is a graduate student in the Department of Biomolecular Chemistry at the University of Wisconsin-Madison. His primary research focus is the spatial and temporal targeting of the type Iγ PIP kinase isoform and its involvement in focal adhesion assembly. He earned a B.S. in Biochemistry from the University of Illinois-Campaign/Urbana where he performed undergraduate research focusing on the catalytic mechanism of cytochrome P450.

Matthew W. Bunce earned a B.S. in Biochemistry at Virginia Tech and is currently a predoctoral graduate student in the lab of Dr. Richard Anderson at the University of Wisconsin-Madison. His research is focused on determining how PIP kinases interact with their substrates, and also on the identification and characterization of binding partners that direct PIP kinases to their unique subcellular compartments and modulate PIP kinase signaling.

Richard A. Anderson is Professor of Pharmacology and Director of Molecular and Cellular Pharmacology at the University of Wisconsin-Madison. His principal research interest is in cell signaling with an emphasis on phosphoinositide signal transduction mechanisms that modulate cancer development and metastasis. He holds a Ph.D. from the University of Minnesota and did his postdoctoral work at Yale University with Vincent T. Marchesi. He has authored numerous articles on the role of PIP kinases in signal transduction.

Phosphoinositide-Dependent Protein Kinases

Nick R. Leslie and C. Peter Downes
University of Dundee, Dundee, UK

The cells of multicellular organisms respond to external stimuli, such as growth factors, cytokines, neurotransmitters, and many hormones through regulated changes in the levels of cellular signaling molecules, termed second messengers. The inositol phospholipids (collectively known as phosphoinositides) are constituents of cell membranes that play important roles as second messengers in signal transduction and membrane trafficking. Many of the downstream effects of phosphoinositide signaling are mediated through reversible protein phosphorylation and in this article the principal focus will be upon protein kinases that function as downstream targets of the phosphoinositide 3-kinase (PI 3-kinase) lipid signaling pathway.

Phosphoinositide Signaling – An Overview

Phosphoinositides are a small family of differentially phosphorylated membrane-localized lipid second messengers. These lipids comprise the hydrophilic cyclic polyol, myo-inositol (Ins), linked via a diester phosphate in the 1-position to diacylglycerol, the hydrophobic membrane anchor. Several families of lipid kinases and phosphatases selectively insert and remove monoester phosphates in three of the remaining positions of the inositol ring, generating the eight currently known phosphoinositide species. This review focuses on some of the most intensively studied phosphoinositide signaling pathways initiated when growth factors, cytokines or insulin, and related hormones trigger the activation of one or more of the type I PI 3-kinases. These enzymes phosphorylate a small proportion of the cellular phosphatidylinositol 4,5 bisphosphate (PtdIns(4,5)P_2) to generate PtdIns(3,4,5)P_3 (often abbreviated to PIP_3). The latter is further metabolized by 5-phosphatases to PtdIns(3,4)P_2 or is returned to the PtdIns(4,5)P_2 pool by the tumor suppressor lipid phosphatase PTEN. PtdIns(3,4,5)P_3 activates downstream signaling through proteins which possess a phosphoinositide binding domain capable of distinguishing this target lipid within a membrane that contains at least 100-fold higher levels of the parent lipid PtdIns(4,5)P_2. Several modular protein domain families have now been identified that include members able to bind to specific phosphoinositides, such as pleckstrin homology (PH), Phox homology (PX), FYVE, and ENTH domains. Other domains, such as FERM, and PDZ domains may also function as phosphoinositide-binding motifs, although evidence for their selectivity between different phosphoinositides is currently lacking. In almost all cases presently identified, the PtdIns(3,4,5)P_3-specific-binding motifs mediating PI 3-kinase-dependent signaling are members of the PH domain family.

Protein Kinase B/Akt

Since the 1990s, it has become evident not only that PI 3-kinase signaling plays a pivotal role in regulating many diverse and significant cellular processes, including cellular proliferation, survival, size, and motility, but that many of the downstream effectors of PtdIns(3,4,5)P_3 are protein kinases. The best evidence for regulation by PtdIns(3,4,5)P_3 exists for three classes of kinase that carry PH domains able specifically to bind this lipid: the Ser/Thr kinases, PKB (or Akt), PDK1, and the Tec family Tyr kinases. Space limitations prevent us from addressing such enzymes as GSK3 or PAK, which can clearly be regulated by the PI 3-kinase pathway, though not by directly binding to PtdIns(3,4,5)P_3 and these enzymes can also be regulated by PI 3-kinase independent pathways. The PI 3-kinase signaling pathway has been dissected extensively using biochemical and genetic approaches. Significantly, the stimulated production of PtdIns(3,4,5)P_3 by PI 3-kinase enzymes is conserved in species from slime molds, through nematodes and flies to vertebrates. In species of all of these groups, genetic studies indicate that a principal (though not exclusive) cellular mediator of this signaling pathway is protein kinase B (PKB).

PKB, also known as Akt, has a C-terminal serine/threonine kinase domain and an N-terminal PH domain

that binds with high specificity to PtdIns(3,4,5)P_3 and PtdIns(3,4)P_2. The enzyme has been shown to be activated by phosphorylation of two key residues, threonine 308, in the activation loop (or T-loop) of the kinase domain, and serine 473 in the C-terminal tail. These phosphorylation events in turn are believed to alter the conformation of PKB greatly enhancing its activity, and although much of this work has focused on PKB, it now appears that a number of related kinases may be regulated by analogous mechanisms. Although PtdIns(3,4,5)P_3 and PI(3,4)P_2 do not directly enhance the activity of PKB *in vitro*, they play a critical role in the phosphorylation and activation of PKB, by recruiting PKB to the plasma membrane where it is activated, and by opening the conformation of the protein to allow phosphorylation. Thus it seems that in a normal cellular context the activity state of PKB is largely governed by cellular levels of PtdIns(3,4,5)P_3 and PI(3,4)P_2.

PDK1 and the Regulation of the AGC Kinases

3-Phosphoinositide dependent kinase 1 (PDK1) has been identified as the activating kinase that phosphorylates PKB in a PI 3-kinase dependent process at Thr 308 *in vitro* and *in vivo* (see Figure 1). This protein serine/threonine kinase also has a PH domain that specifically binds PtdIns(3,4,5)P_3 and PI(3,4)P_2 and is found both in the cytosol and on the plasma membrane. Significantly, after its initial identification as a PKB kinase, subsequent work has shown that it also phosphorylates and activates many other related kinases. A point of current controversy is whether the function of PDK1 itself is regulated through mechanisms such as phosphorylation or translocation to the plasma membrane. It has been proposed that PDK1 translocates to the plasma membrane in response to stimulated rises in cellular PtdIns(3,4,5)P_3 levels, as does PKB. However, this conclusion is not supported by other work, and as PDK1 has an affinity approximately tenfold greater for these lipids than does PKB, an alternative idea is that a pool of cellular PDK1 may be constitutively associated with the plasma membrane and that its activity is not normally regulated by changes in the levels of these lipids. It has also been proposed that PDK1 is activated in stimulated cells by tyrosine phosphorylation, possibly by a Src family kinase, although once more other work argues against this, and phosphorylation has not been observed in response to physiological stimuli, or in cells expressing physiological levels of the relevant kinases. Most of this work on the regulation of PDK1 function would suggest that if it is to be viewed as a phosphoinositide-regulated kinase, this regulation occurs through direct or indirect effects of PtdIns(3,4,5)P_3 on its substrates, rather than on PDK1 itself.

PKB exists as three isoforms in human cells (PKBα, β, and γ) but is itself a part of a diverse structurally-related

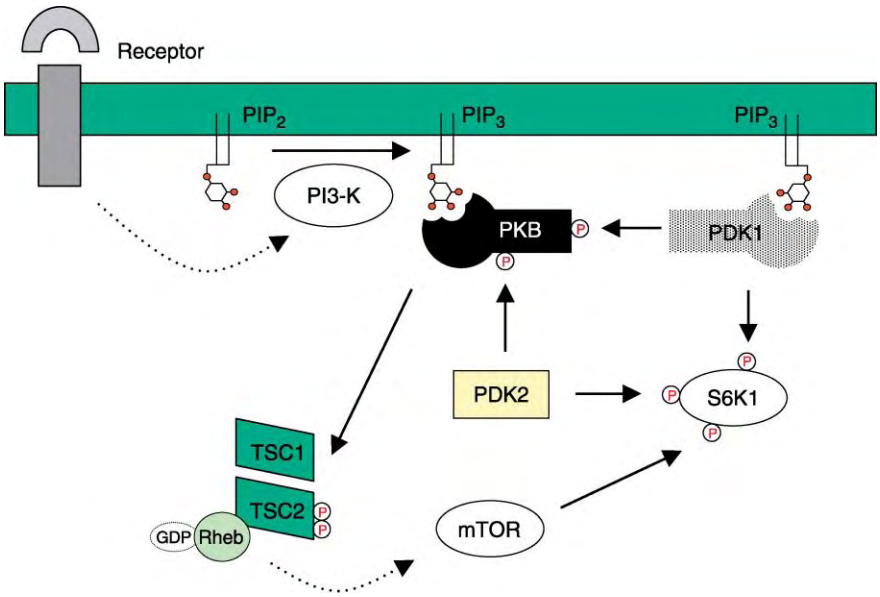

FIGURE 1 Mechanism of activation of PKB, mTOR, and S6K1 by PI 3-kinase. A model is shown for the activation of downstream kinases by a transmembrane receptor activating PI 3-kinase. Molecules are shown in the stimulated conformation. In unstimulated cells, PI3-kinase is less active, PIP_3 levels are low, PKB is cytosolic and along with TSC2 and S6K1, is unphosphorylated and inactive. Active TSC2 promotes the conversion of GTP to GDP by Rheb, although the mechanism by which this leads to the activation of mTOR signaling is unclear. Direct phosphorylation events are shown by bold arrows, indirect mechanisms of activation are represented by dotted arrows. Phosphates are represented by a circled letter P.

family of protein kinases, which are phosphorylated by PDK1 at a residue in the T-loop of each kinase. Although this PDK1-mediated phosphorylation plays a role in the activation of each of these kinases, in contrast to PKB, the phosphorylation of other family members is not directly responsive to cellular PtdIns(3,4,5)P_3 levels, and alternative signaling inputs seem to be required to activate these other kinases strongly. To allow efficient activation, most of these related kinases require the interaction of a hydrophobic motif, positioned C-terminal to their kinase domain, with a hydrophobic pocket on PDK1. In some cases, e.g., S6K1 and SGK, this hydrophobic motif contains a serine or threonine that must be phosphorylated to allow interaction with and activation by PDK1. In these cases, it appears that this phosphorylation is in turn mediated by an unknown PI 3-kinase-dependent kinase. In contrast, in place of this serine or threonine residue, PKCζ and PRK2 have an acidic residue which appears to mediate phosphorylation-independent interaction with, and activation by, PDK1. PKCζ, and probably the other atypical PKC kinases, PKCι and PKCλ, are also unusual in that there is some evidence for the direct activation of the kinase through interaction with PtdIns(3,4,5)P_3. However, these kinases lack a PH domain or other identified PtdIns(3,4,5)P_3-binding motif, and the mechanism and physiological relevance of this apparent activation is unclear.

PDK2 – The Unidentified Hydrophobic Motif Kinase

The term PDK2 was used originally to describe the unidentified kinase responsible for the phosphorylation of PKB at the hydrophobic motif serine 473. Since then, although several candidates have been proposed, such as ILK, MAPKAP-K2, NEK6, and both PKB and PDK1 themselves, the identity of PDK2 is still not clear. What is clear, however, is that most of the AGC family kinases become phosphorylated at a serine or threonine residue in a hydrophobic motif C-terminal to the kinase domain, and that this phosphorylation plays a critical role in the activation of each enzyme. It is quite possible that different PDK2s exist for different AGC family kinases, and it appears that a substantial component of the PI 3-kinase-dependent activation of kinases such as SGK and S6K1 may be mediated by an as yet unknown phosphoinositide-dependent hydrophobic motif kinase. As a consequence of the mechanisms of activation of this family of kinases, increases in cellular PtdIns(3,4,5)P_3 levels seem sufficient to activate PKB, since PtdIns(3,4,5)P_3 and PH domain-dependent colocalization of PKB and PDK1 appears to be the principal mechanism of regulation of this kinase. In contrast, most other PDK1-regulated kinases seem to require regulated docking with PDK1 through a protein–protein interaction to mediate activation in the cytosol, and it is this docking step that may be regulated by different upstream pathways, some of which may themselves involve phosphoinositide-dependent kinases.

Much of the interest in PKB stems from its role in mediating many of the effects of PI 3-kinase activation. Evidence now indicates that a substantial portion of the effects of elevated PtdIns(3,4,5)P_3 levels on cell-cycle progression, survival, growth, and insulin responses are mimicked by activation of PKB alone. In contrast, most PI 3-kinase-dependent cytoskeletal regulation appears to be PKB independent, but may rather result from the interaction of PtdIns(3,4,5)P_3 with the PH domains of guanine-nucleotide-exchange factors for Rho family GTPases. These findings go some way to explaining why isoforms of PKB have been found to be over-expressed in a range of human tumor types, and why activation of PKB activity appears to be an even more common feature of tumors.

Regulators of Cellular Growth – mTOR and S6K1

Work addressing the stimulation of cell growth by PtdIns(3,4,5)P_3 signaling implicates two protein kinases as key players in this process, the mammalian target of rapamycin (mTOR), and ribosomal protein S6 kinase 1 (S6K1, also known as p70S6K). While S6K1 seems to regulate translation through several mechanisms, mTOR has been proposed to play a central role in cellular growth control, as its activity is responsive to nutrients and ATP and is able to regulate a range of downstream processes related to cell growth, including transcription, tRNA and ribosome synthesis, autophagy, and nutrient transporter function. Although recent work has shed significant light on the regulation of both of these kinases, particularly the inputs from PtdIns(3,4,5)P_3 signaling, their regulation appears complex and many questions remain unanswered. mTOR activity now appears to be inhibited in nongrowing cells by the small GTPase Rheb, and a protein complex of two proteins, TSC1 and TSC2, the latter of which can function as a GTPase activating protein for Rheb. Upon activation of PI 3-kinase and PKB, TSC2 is phosphorylated by PKB, Rheb becomes inactive (in the GDP bound state) causing activation of mTOR. S6K1 is then believed to be stimulated through phosphorylation by activated mTOR (in addition to other activating

inputs such as PDK1). This model is represented in Figure 1.

The study of S6K1, and many other kinases that are affected by PtdIns(3,4,5)P_3 signaling, with the exception of PKB, highlights a possible role for the level of basal PtdIns(3,4,5)P_3 present in unstimulated growing cells in culture. For example, S6K1 can be potently activated by G protein-coupled receptors under conditions where PtdIns(3,4,5)P_3 levels do not increase. Thus, PtdIns(3,4,5)P_3 can play a permissive rather than stimulatory role in G protein-coupled receptor mediated S6K1 activation. Significantly, a similar role for basal PtdIns(3,4,5)P_3 has been proposed in the regulation of other molecules, such as Ras and PKCδ.

One important piece of evidence that cell growth responses stimulated by mTOR and S6K1 are downstream effectors specifically of PtdIns(3,4,5)P_3 is the sensitivity of PTEN null ES cells, MEFs, and tumors to the immunosuppressant rapamycin. Deletion of the PtdIns(3,4,5)P_3 specific phosphatase, PTEN, elevates PtdIns(3,4,5)P_3 levels and activates downstream PI 3-kinase dependent signaling without stimulating other pathways. Since these cells are unusually sensitive to growth inhibition by the mTOR (and thus S6K1) inhibitor rapamycin, this suggests that these pathways are significantly activated by increased PtdIns(3,4,5)P_3 levels, and that this is important for cell growth and tumor development.

Tec Family Kinases

The Tec family of tyrosine kinases has been implicated in signaling by lymphocyte antigen receptors. These kinases have an N-terminal PtdIns(3,4,5)P_3 binding PH domain and a C-terminal tyrosine kinase domain. They also contain a proline-rich region, and SH3 and SH2 domains in the central region of the proteins. It is believed that their activation requires recruitment to the plasma membrane by interaction of PtdIns(3,4,5)P_3 with the PH domain, and subsequent activation by members of the Src family of tyrosine kinases through phosphorylation of the kinase domain activation loop. These kinases are rather restricted in the range of tissues where they are expressed, most being hematopoietic specific, and appear to play a role most significantly in lymphocyte signaling. This picture has stemmed from the original identification of the first family member, Bruton's tyrosine kinase (Btk), as the gene mutated in a human immunodeficiency. The family is now known to include Btk, Tec, Itk, Bmx, and the slightly divergent Rlk. Interestingly, in Rlk, the PH domain has been replaced by an N-terminal palmitoylation and membrane targeting signal, leading to PI 3-kinase independent activation.

Perspectives

This article has focused largely upon well-studied kinases that are regulated through PtdIns(3,4,5)P_3 and PI(3,4)P_2 and the PI 3-kinase signaling pathway, and their roles in regulating cellular proliferation, survival, and growth. However, evidence for the regulation of kinases in these and other cellular signaling pathways by other phosphoinositides is emerging. For example, serum and glucocorticoid inducible protein kinase 3 (SGK3 or CISK) is localized to endosomes through a PX-domain-mediated interaction, probably via PtdIns(3)P. Although tethering to endosomes appears to be required for CISK to function, there is also evidence that its catalytic activity is controlled through stimulated type I PI 3-kinases and hence via a mechanism that also involves PtdIns(3,4,5)P_3. Since the human genome contains ~48 genes encoding proteins, many unstudied, with both a protein kinase domain, and a domain recognized as a potential phosphoinositide-binding domain (42 with PH domains and 6 with PX domains), it is quite possible that novel kinases exist that are regulated by any of the phosphoinositides and play a role in the regulation of quite distinct cellular processes.

Biography

Nick Leslie is a research fellow in the Division of Cell Signalling at the University of Dundee. He obtained his Ph.D. from Glasgow University (1995). Postdoctoral work at the Beatson Institute in Glasgow and the Division of Cell Signalling in Dundee University focused on mammalian signal transduction. His current projects involve phosphoinositide signaling and the tumor suppressor phosphatase PTEN.

Peter Downes is Director of the Inositol Lipid Signalling Laboratory in the Division of Cell Signalling, University of Dundee. He obtained his Ph.D. at the University of Birmingham, UK. After postdoctoral research in the MRC Neurochemical Pharmacology Unit in Cambridge, he worked for several years in the pharmaceutical industry before being appointed Professor of Biochemistry at the University of Dundee in 1989. He has been investigating the roles of inositol lipids in cell signalling for nearly 25 years.

Phospholipase A_2

Timothy R. Smith and Edward A. Dennis
University of California, San Diego, California, USA

Phospholipid membranes serve not only as structural components of the cell but are integral as a storage form for the precursors of numerous signaling molecules critically involved in a variety of inflammatory and immune responses including the production of the eicosanoids. Phospholipase A_2 (PLA_2) refers to a superfamily of enzymes that catalyze the hydrolysis of fatty acid esters from the *sn*-2 position of membrane phospholipids yielding a free fatty acid and a lysophospholipid. These enzymes have been shown to function both intra- and extracellularly and in some cases display molecular cross-talk between multiple family members. A classification system has been devised to subdivide the PLA_2 superfamily into 14 distinct groups based on sequence and structural homologies. Within these 14 groups, there are two distinct catalytic mechanisms employing either a catalytic serine or histidine, which the PLA_2 enzymes utilize to produce free fatty acids and lysophospholipids from membrane phospholipids. When the free fatty acid produced is an unsaturated one, such as arachidonic acid, it can be converted to the bioactive prostaglandins, leukotrienes and lipoxins by various downstream enzymes. Depending on the composition of the phospholipid precursor, the lysophospholipid can be converted to platelet activating factor (PAF), a potent inflammatory signaling molecule. While most PLA_2 enzymes function as signal initiators, the PAF acetyl hydrolases, which are actually PLA_2s, break down PAF and oxidized phospholipids to end the signaling process.

Phospholipase A_2 (PLA_2) Structures and Catalytic Mechanism

PLA_2 Enzymes Using a Catalytic Histidine ($sPLA_2$s)

The PLA_2 enzymes, initially described as small, secreted enzymes containing multiple disulfide bonds and a catalytic histidine, were first isolated and characterized from snake venoms and human pancreatic secretions. Based on their small size and the fact that they were secreted, these enzymes were referred to as $sPLA_2$s. The $sPLA_2$ enzymes are typically small, compact proteins held together by a network of integral disulfide bonds. These enzymes all contain an N-terminal signal peptide sequence that leads to them being secreted from cells and working extracellularly on membrane phospholipids. The only exception is that of the pancreatic group IB PLA_2 that is secreted with its propeptide intact and requires cleavage by trypsin in order to be catalytically active in the gut as a digestive enzyme. All of these enzymes share a requirement for millimolar levels of Ca^{2+}, which is necessary for catalysis. The catalytic core of the $sPLA_2$ enzymes is a His/Asp dyad made up of the catalytic histidine and a structurally adjacent aspartate residue. None of the $sPLA_2$ molecules show appreciable substrate specificity for saturated versus unsaturated fatty acids.

The structure and catalytic mechanism of *sn*-2 ester bond cleavage has been elucidated for the evolutionarily related Group I, II, V, and X PLA_2s. X-ray structures have been determined for the Group IA and IB, several of the Group II subfamily, the Group V and the Group X, and all of the members of these groups share a common protein fold and are 13–18 kDa in size. They all possess six common disulfide bond linkages. These disulfide bonds provide stabilization of the protein structure and allow the enzyme to remain functional in environmental extremes. There are up to two additional disulfide bonds that have been used to differentiate the groups from one another. Additionally they all share a common Ca^{2+} binding loop that includes the catalytically essential Asp. This residue acts to provide two coordinate interactions for the Ca^{2+} molecule that serves to stabilize the transition state of the PLA_2 reaction.

The first step in catalysis for any of the $sPLA_2$s is binding to the membrane interface. The Group I and II enzymes have been shown to preferentially bind to anionic vesicles that include phosphatidylserine or phosphatidylethanolamine while the group V and X PLA_2s are able to efficiently bind to zwitterionic vesicles, and are able to work on a phosphatidylcholine surface equally well. Once the enzyme is bound to the surface and Ca^{2+} is coordinated into the enzyme via the Asp, catalysis can occur. The catalysis is similar to

that observed with other lipase enzymes utilizing a histidine residue. The active site His recruits a water molecule and orients it for nucleophilic attack on the ester linkage of the *sn-2* fatty acid. The Ca^{2+} molecule is critical in positioning the catalytic water and the phosphate of the lipid. The result is the production of a free fatty acid and lysophospholipid coordinated to the Ca^{2+}. The catalytic mechanism for the other $sPLA_2$s (group III, IX, XI, XII, XIII, and XIV) is similar to that for the group I, II, V, and X, but with the exception of the group III enzyme, X-ray structures have not been reported to verify this.

PLA_2 Enzymes Utilizing a Catalytic Serine

In the mid-1980s, several laboratories discovered and characterized a cytosolic PLA_2 activity that utilized a catalytic serine as opposed to a histidine. Today, there are three classes of PLA_2 enzymes that utilize a catalytic serine, the $cPLA_2$s (group IV), the $iPLA_2$s (group VI), and the PAF-acetyl hydrolases (group VII and VIII).

$cPLA_2$

There are three PLA_2 enzymes classified as $cPLA_2$, group IVA, IVB, and IVC. The group IVA PLA_2 is the enzyme typically referred to as $cPLA_2$ and has been studied extensively. The group IVB and IVC enzymes have only recently been cloned and little is known about their structure, catalysis, or signaling roles.

The group IVA enzyme is an 85 kDa cytosolic enzyme initially cloned and purified from human neutrophils, platelets and monocytes. This enzyme contains two structurally distinct protein domains, a C2 domain and an α/β hydrolase PLA_2 catalytic domain. X-ray structure determination of the group IVA molecule by the Dessen and Somers group revealed that it possesses a novel fold unlike any other previously solved α/β hydrolase. The C2 domain controls the calcium-dependent enzyme translocation to the endoplasmic reticulum and nuclear envelope where the enzyme is catalytically active. The C2 domain and catalytic domain fold and can function independently, but the two domains together are required for biological activity. In addition to PLA_2 activity, the group IVA enzyme possesses both lysophospholipase and transacylase activity. There are several serine residues that are differentially phosphorylated on the group IVA enzyme; while none of these phosphorylation sites are critical for enzymatic activity, when modified they can increase the specific activity of the enzyme two to three fold. The group IVA enzyme utilizes micromolar levels of Ca^{2+} that binds to the C2 domain, but unlike the $sPLA_2$ enzymes the calcium functions in enzyme translocation and not for catalysis. Also unlike the $sPLA_2$s, the group IVA PLA2 shows a 10- to 20-fold specificity for arachidonic acid at the *sn-2* position over saturated or other unsaturated fatty acids.

The group IVA catalytic core is the Ser/Asp catalytic dyad with the serine in a Gly-Leu-Ser-Gly-Ser sequence similar to that of the classical lipase Gly-X-Ser-X-Gly motif found in other α/β hydrolases. The Ser/Asp dyad is unique among the α/β hydrolases and more closely resembles that of serine proteases, suggesting a novel catalytic mechanism. The proposed catalytic mechanism for the Group IVA PLA_2 enzyme is that once bound to the membrane bilayer, the side chain of an Arg stabilizes the phosphate head group of a membrane phospholipid in the active site. Once the enzyme-substrate complex is formed, the catalytic Asp activates the Ser side chain during nucleophilic attack of the *sn-2* acyl chain of the lipid. A serine acyl intermediate is formed, releasing a lysophospholipid, which then undergoes water mediated hydrolysis, releasing the free fatty acid chain. The oxyanion transition state is stabilized by the backbone amide protons of a Gly-Gly-Gly sequence.

$iPLA_2$

Like the group IV PLA_2 enzyme, the $iPLA_2$ enzyme has multiple group members, the group VIA PLA_2 and the group VIB PLA_2. These enzymes both localize in the cytosol and are unique from the group IV family of PLA_2s in that they are calcium-independent. The group VIA PLA_2 is most often referred to as $iPLA_2$ and was initially purified and characterized from the murine $P388D_1$ macrophage-like cell line. Of all of the $iPLA_2$ family members, the most is known about the enzymology and structural features of this enzyme. The group VIB enzyme has only recently been cloned and little is known about its enzymology or structure.

The group VIA enzyme is an 85–88 kDa cytosolic protein that is expressed as several distinct splice variants, only two of which are catalytically active (group VIA-1 and VIA-2). The enzyme contains a series of N-terminal ankyrin repeats, typically involved in the formation of protein–protein interactions, and the mouse group VIA-1 enzyme has been shown to function as a 340 kDa oligomeric complex. The group VIA-2 PLA2 has a 54 amino acid insertion in the eighth ankyrin repeat, likely a membrane-binding domain. The enzyme shows a consensus lipase motif, Gly-Thr-Ser-Thr-Gly. Other residues critical for catalysis have yet to be identified and the mechanism by which the $iPLA_2$ cleaves the *sn-2* linkage is still unclear, but it is likely to be an α/β hydrolase with a catalytic Ser/Asp dyad like the group IVA PLA_2. Like the group IVA enzyme, the group VIA PLA_2 exhibits both lysophospholipase and transacylase activities. Nucleotide di- and tri-phosphates have been shown to stabilize the purified enzyme and the nucleotides are not turned over during this process,

suggesting a structural role. Unfortunately at this time there is not a reported X-ray crystal structure of the group VIA PLA_2, so little is known about the overall fold or active site geometry.

PAF Acetyl-Hydrolase

The PAF acetyl-hydrolases are a family of enzymes first cloned in the mid-1990s that include members of both the group VII and group VIII PLA_2 enzymes. These enzymes are constitutively active, catalyzing the hydrolysis of short acyl chains at the *sn-2* position of 1-O-alkyl-2-acetyl phosphatidylcholine (PAF). They are unique among the PLA_2s in that they have little to no measurable activity on acyl chains longer than nine carbons.

The group VIIA PLA_2 is found in the blood plasma and is a 45 kDa monomeric enzyme of the α/β hydrolase family. This enzyme possesses a consensus lipase motif, Gly-His-Ser-Phe-Gly, with a catalytic serine residue. Unlike the group IV enzymes, the group VIIA proteins possess a classical hydrolase triad of Ser, Asp, and His, suggesting that its catalytic mechanism is similar to that of other α/β hydrolases. The group VIIA enzyme is the circulating form of the enzyme typically found associated with lipoproteins and binding to LDL causes an increase in PAF-AH activity through, as yet, an unknown mechanism. This enzyme has been reported to hydrolyze oxidized phospholipids in addition to PAF. The group VIIB enzyme is an intracellular monomeric 40 kDa protein closely related to the group VIIA enzyme with an identical active site lipase motif. Both of the group VII enzymes are able to hydrolyze PAF molecules with *sn-2* acyl chains as long as 5 carbons.

The group VIII enzyme is found most abundantly in brain tissues and is comprised of three subunits, α-1, α-2, and β, of which the α-1 and α-2 subunits both possess PAF-AH activity. The α-1 and α-2 subunits are 29 and 30 kDa respectively and share a 63% sequence identity between them. Both subunits contain a modified lipase motif of Gly-Asp-Ser-Met-Val and Gly-Asp-Ser-Leu-Val respectively. These enzymes both possess a classical Ser, Asp, His triad, again suggesting that their catalytic mechanisms is similar to that of other serine esterases. The β subunit does not possess any PLA_2 activity and is likely a structural or regulatory protein.

PLA_2 Cellular and Signaling Roles

The PLA_2 enzymes have been shown to be involved ubiquitously in almost all lipid signaling and metabolism functions within the cell. The group IVA and VIA enzymes have been shown to be linked to apoptosis. Additionally, the group VIA PLA_2 has been shown to be directly involved in cellular phospholipid remodeling. One of the most studied aspects of the mammalian PLA_2s, including the group II and V $sPLA_2$s and the group IVA $cPLA_2$, is their role in the production of arachidonic acid used in the production of the pro-inflammatory eicosanoids, including prostaglandins, leukotrienes, and lipoxins. These molecules play critical signaling roles in pathways as diverse as pain and inflammation, allergic responses, implantation and parturition, vasoconstriction and dilation, and renal function. Finally, the role of the group VII and VIII PLA_2 enzymes, the PAF acetyl hydrolases, is to break down the pro-inflammatory PAF molecule and terminate the signaling process. The group VIIA enzyme has also been shown to be associated with lipoproteins such as HDL and LDL and is thought to be critically involved in the breakdown of oxidized phospholipids.

Biography

Edward A. Dennis is a Professor of Chemistry and Biochemistry at the University of California, San Diego. Since the 1970s, Dr. Dennis' laboratory has studied the structure and function of the phospholipase A_2 superfamily of enzymes, publishing over 250 articles on these topics. The Dennis laboratory was the first to purify and characterize the calcium independent PLA_2, has worked extensively on developing models for the action of PLA_2 enzymes at lipid interfaces, and explored the roles of individual PLA_2s in the eicosanoid cascade of macrophages.

Timothy Smith has been a Postdoctoral Associate in the Dennis laboratory since December 2000, working on the structural and biochemical characteristics of the calcium independent PLA_2 enzyme.

Phospholipase C

Fujio Sekiya, Yeun Ju Kim and Sue Goo Rhee
National Heart, Lung, and Blood Institute, Bethesda, Maryland, USA

Phospholipase C (PLC) is an enzyme that cleaves a glycerophospholipid at the phosphodiester bond between the glycerol backbone and the phosphate group. All known eukaryotic PLCs, including those implicated in calcium signaling in animal cells, utilize only phosphoinositides (phosphatidylinositol and its phosphorylated derivatives) as substrates, hence called phosphoinositide-specific PLC and frequently just referred to as PLC. The minor constituent of plasma membranes, phosphatidylinositol 4,5-bisphosphate (PIP2), appears to be the only physiological substrate of PLCs, though in test tubes other phosphoinositides can be hydrolyzed. PLC cleavage of PIP2 simultaneously generates two second messengers, inositol 1,4,5-trisphosphate (IP3) and 1,2-diacylglycerol (DAG). PLC is not a single entity but consists of members with various structures, and mechanisms to regulate PLC isozymes are also diverse. To date, 12 different mammalian PLCs have been identified, and they are grouped into 5 subfamilies based on their primary structures.

Biological Consequences of PLC Action

Early studies by Hokin and Hokin in the1950s revealed that stimulation of cells could induce rapid metabolism of inositol phospholipids, and in 1975 Robert Michell suggested the connection between phosphoinositide hydrolysis and calcium mobilization. Functions of IP3 and DAG as important second messengers were established in the mid-1980s by Michael Berridge and Yasutomi Nishizuka, respectively. It was these landmark discoveries that brought special attention to PLC as the key enzyme to generate the two second messengers.

The soluble part of PIP2 cleavage product, IP3, binds to its intracellular receptor present on the calcium storage site endoplasmic reticulum (ER), and the receptor constitutes a channel to gate calcium ions. IP3 ligation opens the channel, causing a transient increase in the cytoplasmic calcium concentration. The other cleavage product DAG stays in the plasma membrane and recruits protein kinase C (PKC) isozymes. Activation of certain PKC isozymes requires both binding to DAG and calcium ions. Activated PKC elicits a wide range of cellular responses through phosphorylation of many kinds of substrate proteins (Figure 1).

Increasing evidence indicates that PIP2 by itself participates in many cellular processes through binding to a number of proteins. First, the phospholipid is a focal point to bridge plasma membranes and networks of cytoskeletal proteins. It thus plays key roles in maintenance of cell morphology as well as in control of motility. Second, it can modify activities of various enzymes and channels; phospholipase D and capsaicin receptor (ion channel) are a few examples among many such PIP2 effectors. Third, it provides a platform to form functional signaling complexes, because many of those proteins participating in the complexes have lipid-binding modules, such as PH, FERM, and ENTH domains. Consistent with their physiological significance, cellular levels of PIP2 are maintained through strictly regulated production/destruction mechanisms involving many lipid kinases and phosphatases. Activation of PLC leads to a rapid reduction in cellular PIP2 level. Thus, both generation of IP3/DAG and destruction of PIP2 by PLC can dramatically affect the cell's physiology in many ways.

Given such diverse and profound consequences, PLC activation is one of central mechanisms of cellular signaling, and its activity is tightly controlled in cells. Indeed, a large number of hormones, growth factors, and neurotransmitters rely on PLC in transmitting their signals across plasma membranes.

Biochemistry of PLC

Structure of PLC

PLC has been found in yeasts, slime molds, plants, and animals, and is probably present in all taxa of eukaryotes. All eukaryotic PLCs appear to be evolved from a single archetype, and it is in the animal kingdom that PLC diversified. Eleven different genes encoding PLC isozymes have been identified in mammals, and they are grouped into four subfamilies, named as β, γ, δ, and ε. In addition, an isozyme named ζ, which has the simplest structure, has been found recently (Figure 2). Animals, from the nematode *Caenorhabditis elegans*

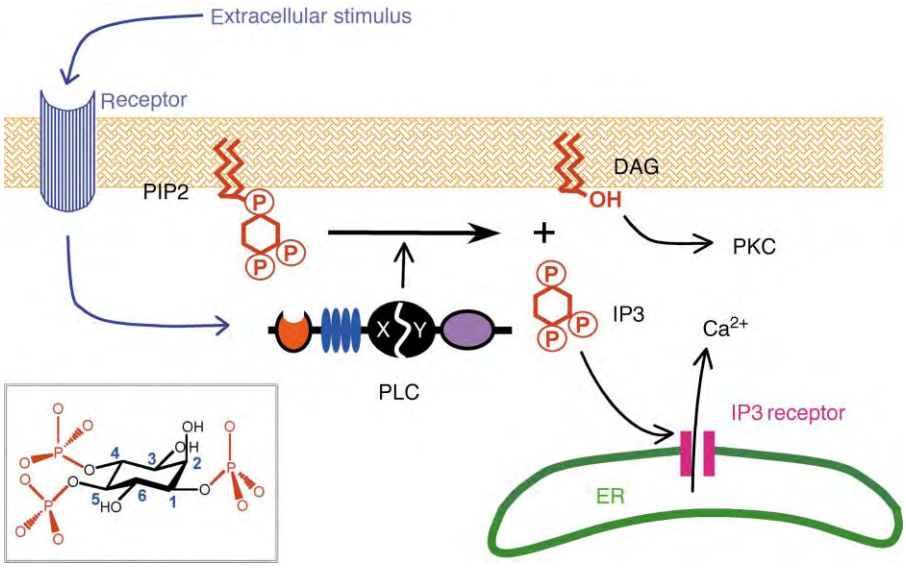

FIGURE 1 A scheme for the action of PLC in the cell. For abbreviations, see text. Inset shows chemical structure of IP3.

to the fly to the human, appear to have all subtypes, but only the primitive δ-like (or ζ-like) PLCs are found in other eukaryotes. The protein originally termed PLC-α was turned out to be a proteolytic fragment of PLC-δ1, and was thus eliminated from the nomenclature. Some isozymes have alternatively spliced variants at the mRNA level, and the total number of mammalian PLC polypeptides exceeds 20.

All PLC isozymes possess common structural features, indicating origination from a common ancestor. The δ-isozyme consists of an N-terminal PH (pleckstrin-homology) domain, four copies of EF-hands, regions called X and Y, followed by a C2 domain. Other three types of PLC isozymes are made up by additions (or replacements) of some regulatory domain structures to the δ-subtype (Figure 2). PH domains are ~120-residue units, which oftentimes function as membrane-binding sites through interaction with phosphoinositides. EF-hands are the calcium-binding motifs identified in calmodulin, but it is unclear whether PLC's EF-hands actually bind calcium ions. C2 domains (~120 residues) are the structures originally found in PKC that act as calcium-dependent lipid-binding modules. X and Y regions are unique to eukaryotic PLCs. Evidence shows that the two regions together form a discrete unit of catalyst, though they are separated by a linker in the primary structure.

Mechanism of Catalysis

Based on crystallographic structures of PLC-δ1 and biochemical data, the catalytic mechanism for PLC has been postulated. Calcium ion, which is required for all PLC isozymes, was seen in the catalytic center interacting with the IP3 moiety of PIP2; the cation activates the 2-hydroxy group of inositol ring that in turn attacks the 1-phosphate, cleaving off the head group to form a 1,2-cyclic phosphate intermediate and DAG. The cyclic derivatives are subsequently hydrolyzed to acyclic inositolphosphates. Several positive residues found in the active site pocket interact with the phosphate groups at the 4- and 5-positions of inositol ring, explaining the preference of enzyme for PIP2 over phosphatidylinositol or phosphatidylinositol 4-phosphate. The structure has also indicated that the pocket cannot accommodate phosphoinositides with phosphate at the 3-position (e.g., phosphatidylinositol 3,4,5-trisphosphate), explaining why 3-phosphorylated inositides are not substrates of PLC.

PLC Isozymes and their Regulation Mechanisms

PLC-β

Signals of many chemical and physical stimuli are received by cells via receptors that couple to heterotrimeric G proteins. A large portion of such stimulation induces PIP2 hydrolysis by activating PLC-β isozymes. Beta isozymes (β1 ~ β4; ~150 kDa) are unique in having long C-terminal extensions that are absent in other classes of isozymes (Figure 2).

Upon activation of receptor, the receptor-associated αβγ heterotrimer of G protein dissociates into α- and βγ-subunits. Both α-and βγ-subunits are able to transmit signals. The members of G_q family of α-subunits (αq, α11,

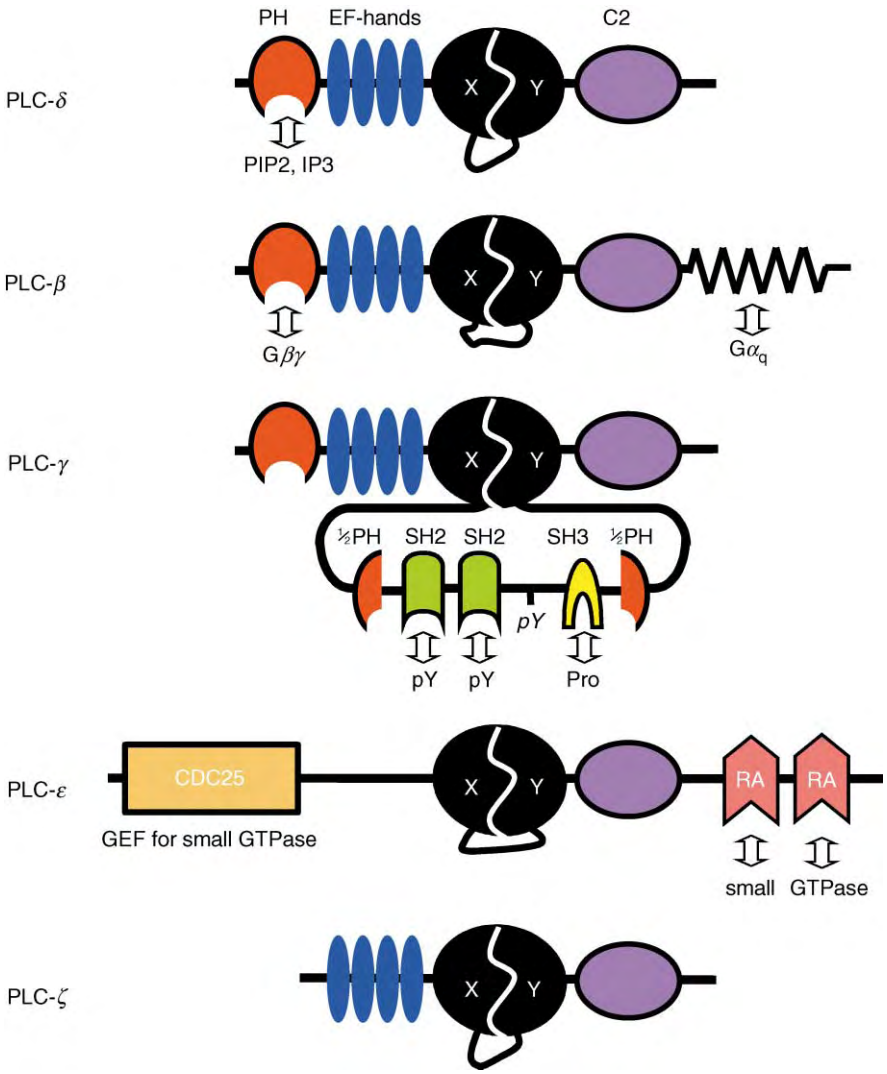

FIGURE 2 Structural organizations of PLC isozymes. Known ligands of domains of PLCs are shown. *p*Y, phosphotyrosine; Pro, proline-rich sequence.

α14, and α16) can activate PLC-β, but not PLC-δ and PLC-γ. In contrast, the α-subunits of other G protein subclasses (Gs, Gi, and G12/13) do not activate PLC-β. Also, $\beta\gamma$-complexes can specifically stimulate PLC-β. αq- and $\beta\gamma$-subunits appear to interact with different regions in the PLC-β molecule: αq is recognized by the C-terminal region unique to β-isozymes, whereas the $\beta\gamma$-subunit binds to the N-terminal PH domain. In most cells the Gi family of G protein is abundant compared to other classes. It is considered that only Gi-coupled receptors can provide significant amounts of $\beta\gamma$, and that agonists inducing activation of Gi are responsible for $\beta\gamma$-mediated activation of PLC-β.

Four isozymes of this subfamily appear to be expressed in different tissues and to have different sensitivities to the G protein subunits. PLC-β1 and β3 are widely expressed in various tissues and are more sensitive to the activation by αq compared to other isozymes. PLC-β2 expression is restricted to blood cells and is most sensitive to the activation by $\beta\gamma$ among the four PLC-βs. PLC-β4 expression is only seen in some parts of the brain and in the retina. Genes for all four β-isozymes have been disrupted in mice, and none of those single knockouts appeared to be fatal, probably because their functions overlap. Reported phenotypes of knockouts include: PLC-β1, epilepsy; PLC-β2, dysfunctions in neutrophils and platelets; PLC-β3, hyperresponse to opioid stimulation; and PLC-β4, ataxia and impairment in visual perception.

PLC-γ

Activation of PLC-γ is controlled by phosphorylation of its tyrosine residues, and the two isozymes of this subfamily (γ1 and γ2; $\sim$140 kDa) have a long linker sequence between the X and Y regions, which is indispensable for their regulation. The linker region consists of a half of a PH domain, two SH2

(Src-homology 2) domains, an SH3 (Src-homology 3) domain, and the remaining half of the split PH domain (Figure 2).

Binding of peptide growth factors (such as platelet-derived growth factor, epidermal growth factor, and nerve growth factor) to their cognate receptors results in activation of the intrinsic protein tyrosine kinase activity of the receptor and consequent autophosphrylation of their cytoplasmic tails, creating docking sites for phosphotyrosine-binding motifs. PLC-γ binds those phosphotyrosines using its SH2 domain and is then phosphorylated by the receptor protein tyrosine kinases. Tyrosine phosphorylation that occurs within the linker region leads to activation of PLC-γ by a mechanism not fully understood.

Immunoreceptors in blood cells, such as the T-cell receptor and the B-cell receptor for antigens, do not have intrinsic tyrosine kinase activity but are also able to activate PLC-γ. Ligand-induced clustering of immunoreceptors causes phosphorylation in the domain termed immunoreceptor tyrosine-based activation motif (ITAM) by receptor-associated Src-family tyrosine kinases (e.g., Lck, Lyn, and Fyn). Phosphorylated ITAMs recruit and activate Syk-family tyrosine kinases (Syk and ZAP-70), and the recruited Syk-kinases, in turn, phosphorylate many kinds of adaptor proteins, such as linker of activation of T cells (LATs) and B-cell linker protein (BLNK). PLC-γ then binds to and is phosphorylated by the resultant supermolecular complex consisting of aggregated immunoreceptors, Src kinases, Syk kinases, and adaptor proteins. Stimulation of blood cells, moreover, can activate another class of tyrosine kinase, Tec-family kinases (e.g., Btk), via a phosphoinositide 3-kinase-dependent mechanism. Tec-kinases are also implicated in PLC-γ activation.

PLC-γ1 is expressed ubiquitously and disruption of its gene is lethal at an early embryotic stage. PLC-γ2 is expressed in a set of hematopoietic lineages including B cells, platelets, neutrophils, and mast cells. Knockout of γ2 is not lethal but abolishes maturation of B cells, resulting in immunodeficiency, and causes dysfunctions of Fc-receptor-mediated signaling in platelets and mast cells.

PLC-δ

PLC-δ isozymes (δ1 ~ δ4; ~90 kDa) have simpler structures compared to other isozymes (Figure 2). They lack obvious regulatory domains that facilitate coupling to receptors. The exact nature of their activation mechanisms remains unclear, but probably they do not couple to hormone receptors directly. PLC-δ has greater calcium sensitivity compared to β- and γ-isozymes. It is proposed that PLC-δ can be secondarily activated when cytoplasmic calcium concentrations are elevated via PLC-β(or PLC-γ)/IP3-mediated mechanisms. The PH domain of PLC-δ binds to PIP2 and also recognizes IP3 with a higher affinity: this domain is thought to mediate tethering of PLC-δ to plasma membranes. When PIP2 hydrolysis occurs, generated IP3 causes dissociation of the enzyme from membranes, thus terminating the reaction. This mechanism constitutes a feedback negative regulation system for this isozyme.

Among four δ-isozymes known, gene targeting of δ1 and δ4 isozymes has been conducted. Both resulted non-fatal. PLC-δ1-deficient mice experienced progressive hair loss. The isozyme appears to be necessary for commitment of skin stem cells. Male homozygotes of PLC-δ4-deficient mice were infertile, and it was reasoned that the isozyme was required for the acrosome reaction of sperms.

PLC-ε

The ε-isozyme (>200 kDa) contains a CDC25-like domain in the N terminus, which has guanine nucleotide exchange factor (GEF) activity toward small GTPases, and two copies of Ras-binding motifs (RA domains) following the C2 domain, but neither a PH domain nor EF-hand is evident (Figure 2). It has been shown that (1) PLC-ε is capable of catalyzing PIP2 hydrolysis both *in vitro* and *in vivo*, (2) the CDC25-like domain can function as a GEF for Rap1A but not for Ras, and (3) the RA domains are able to bind to active forms of Ras and Rap1A. Because of the presence of domain structures that interact with small GTPase of Ras superfamily, it seems likely that PLCs-ε regulation utilizes these class of proteins. Whether they are regulators (upstream of PLC-ε) or effectors (downstream) or both is yet to be determined. Studies done so far are somewhat inconsistent with each other, and it is still premature to picture the exact mechanism by which this isozyme functions in the cell.

PLC-ζ

A novel type of PLC named PLC-ζ (~70 kDa) was recently identified as a sperm-specific isozyme. PLC-ζ has a very primitive structure. It even lacks the N-terminal PH domain (Figure 2) and rather resembles PLCs found in plants or yeasts. A phylogeny analysis revealed its least divergence from a hypothetical precursor among all mammalian PLCs. It has been shown that this sperm-specific isozyme is responsible to calcium oscillation in fertilizing eggs.

Glossary

diacylglycerol A product of PIP2 cleaved by PLC. It serves as a second messenger activating some members of PKCs, and is readily converted to phosphatidic acid in the cell by the action of diacylglycerol kinases.

IP3 The other product of PIP2 cleavage by PLC. IP3 is also a short-life second messenger due to inactivation either through dephosphorylation by specific phosphatases or through phosphorylation by the IP3 kinase.

pleckstrin homology (PH) domain A domain structure that occurs in a wide range of proteins involved in intracellular signaling or as constituents of the cytoskeleton. It was originally found in pleckstrin (platelet C-kinase substrate protein). It binds to phosphoinositides such as PIP2 and/or PIP3.

Src homology 2/3 (SH2/3) domain Domain structures that occur in various signaling proteins, initially identified in the protooncoprotein *src*. SH2 domain recognizes phosphorylated tyrosine residues in target peptides, whereas SH3 domain binds to peptide sequences rich in proline residues.

Phospholipase D

Mary M. LaLonde and Michael A. Frohman
Stony Brook University, Stony Brook, New York, USA

The phospholipase D gene superfamily encodes a diverse array of enzymes that carry out phosphodiesterase actions on phospholipid and DNA substrates. All members share a structural domain known as the HKD catalytic motif. While bacterial PLD is constitutively active, eukaryotic PLDs are tightly regulated by signaling pathways. Mammalian PLD is synergistically regulated by PI4,5P_2, ARF, and Rho GTPases, and protein kinase C. Upon activation, eukaryotic PLDs, which are phsophatidylcholine-specific, cleave the substrate phosphatidylcholine to yield the pleiotropic lipid phosphatidic acid, which can serve as either a signal transducer, lipid anchor, signaling intermediate, or fusogenic lipid. *In vivo* roles for PLD consist of regulated membrane trafficking events including prospore membrane formation in yeast and regulated secretion in neuroendocrine cells, and cell shape dynamics.

Introduction

Phospholipase D (PLD) was the founding member of a superfamily that is now recognized to include phosphatidylserine synthase, a cardiolipin synthase, an atypical endonuclease, an enzyme that rescues covalently bound topoisomerase from DNA, a toxin from the black-death causative agent Yersinia pestis, a viral envelope protein required for pox virus (e.g., smallpox) pathogenesis, and many other gene products of unknown function. Despite the biologically diverse functional roles that these proteins undertake, they share a common catalytic mechanism that invariably targets a phosphodiester bond found in a varied set of substrates (see Figures 1 and 2). The phosphodiester-bond-containing substrates include several phospholipid species in which the phosphodiester bond forms a bridge between the lipid phosphate portion of the molecule and its headgroup; DNA, where the phosphodiester bond forms the link between individual nucleotides and a DNA-topoisomerase complex linked by the bond that occasionally inadvertently persists during DNA unwinding. Additional homologues that encode the PLD catalytic motif, but for which no function has been assigned, still await characterization. No doubt there are yet other interesting substrates and stories that will emerge from continued study of this superfamily.

PLDs found in yeast and animals catalyze hydrolysis of the phosphodiester bond found in the phospholipid phosphatidylcholine (PC). This generates soluble choline and the lipid phosphatidic acid (PA). Bacterial PLDs are promiscuous and will also use as substrate phospholipids with other headgroups, such as phosphatidylethanolamine or phosphatidylinositol. Although the hydrolysis of these phospholipids has been reported in mammals and yeast, the hydrolyzing proteins have not been identified and the eukaryotic PLDs have never been shown to perform these activities. Hence, additional genes of related function, if not sequence, may await discovery.

PLD Gene Families

The PLD gene families are relatively small in yeast (one member) and animals (generally one or two members). By contrast, plants encode up to a dozen PLDs, some of which are highly similar to the mammalian genes in structure. Two mammalian PLDs exist, PLD1 and PLD2, which are structurally similar and 55% identical on the amino acid level but are thought to be regulated somewhat differently and to carry out different cell biological roles. PLD1 has more commonly been shown to regulate vesicular trafficking events whereas PLD2 has been associated more often with regulation of cell shape. However, some overlap in function has also been described. Although many (but not all) cell types express both isozymes, the relative amounts of PLD1 and PLD2 expressed in individual tissues vary dramatically, suggesting that the enzymes carry out cell-type specific rather than universal constitutive roles.

PLD Structure

PLD superfamily members are defined by the presence of one or two copies of the consensus sequence, $HXK(X)_4D(X)_6GSXN$, denoted as the "HKD" domain, which encodes the key residues involved in catalysis (Figure 3). *Bona fide* PLD proteins also

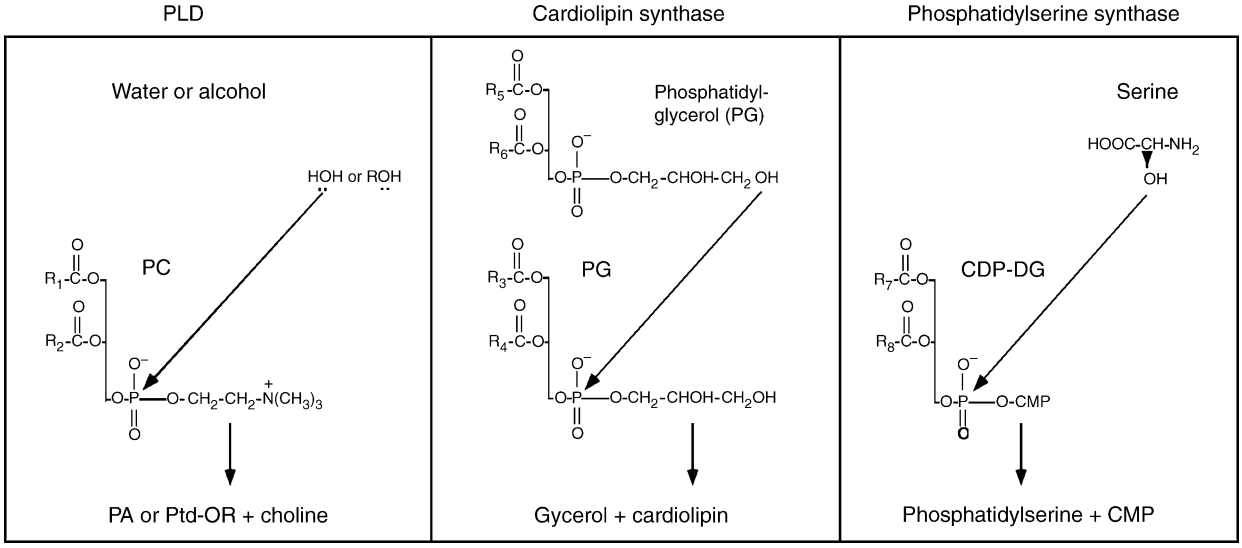

FIGURE 1 PLD, cardiolipin synthase, and phosphatidylserine synthase catalytic reactions. Each reaction involves nucleophile attack on a phosphate bond as shown. Two biochemical activities for PLD have been observed: phosphodiester bond hydrolysis and phospholipid transphosphatidylation. Using H_2O as an electron donor, PLD functions as a phospholipid hydrolysis enzyme, cleaving phosphatidylcholine (PC) to produce phosphatidic acid (PA) and choline. Through the same mechanism, but using alcohol instead of H_2O as the electron donor, PLD can generate phosphatidylalcohols. Nucleophiles that can be used by PLD include exogenously supplied butanol or endogenous diacylglycerol, yielding phosphatidylbutanol and bisphosphatidic acid, respectively. CLS and PSS only carry out synthetic reactions in which alcohols are used as the nucleophile, as shown. Reprinted from Sung, T. C., Roper, R., Zhang, Y., Rudge, S., Temel, R., Hammond, S., Morris, A., Moss, B., Engebrecht, J., and Frohman, M. (1997). Mutagenesis of phospholipase D defines a superfamily including a *trans*-Golgi viral protein required for poxvirus pathogenicity. *EMBO J.* **16**, 4519-4530, with permission of Oxford University Press.

invariably contain several additional conserved domains that assist in proper functioning of the catalytic site. The PLD catalytic core is comprised of two HKD motifs that juxtapose to create the active site, within which the histidine residues directly coordinate the transphosphatidylation reaction. This results in the formation of a covalent phosphatidyl-enzyme intermediate. Both HKD domains must be intact for PLD to be catalytically active. It has been suggested that protein modulators of mammalian PLD activity may influence activation by affecting the orientation of the HKD domains or their distance from the substrate. However, this remains hypothetical since only the mammalian isoforms are thusly regulated, and they have not yet been crystallized in a complex, with or even without their regulators.

Other domains universally found in animal and yeast PLD proteins include a PH domain, which is not essential for enzymatic activity but does regulate subcellular localization and translocation. A basic amino acid-rich phosphatidylinositol 4,5 bisphosphate ($PI4,5P_2$) binding site located near the center of the proteins is essential for catalysis, and plays an important but less conserved role in membrane association and subcellular localization. In addition to these domains, the proteins encode a Phox homology (PX) domain which also helps direct PLD subcellular localization. Finally, mammalian PLD1 is regulated not only by the phospholipid $PI4,5P_2$, but by at least three separate protein factors as well. These effectors (ARF GTPases, Rho GTPases, and PKC family members) act synergistically through binding at distinct sites in PLD1.

Regulation

Overview

Whereas bacterial PLD is constitutively active, eukaryotic PLD is generally activated during events associated with dynamic changes in cells. PLD in plants is activated by wounding and other external environmental cues. PLD in mammals has long been recognized to be activated in response to agonists that stimulate cells through G-protein-coupled or tyrosine kinase receptors. Examples of such agonists include neurotransmitters, serum-derived growth factors, hormones, and cytokines. Yeast PLD does not appear to be directly activated by receptor systems, but its transcription and its subcellular localization are tightly regulated by signaling pathways, which lead qualitatively to the same outcome.

Regulation of Mammalian Phospholipase D

Stimulation of mammalian PLD through G-protein-coupled or tyrosine kinase receptors is mediated principally by a phospholipid ($PI4,5P_2$) and three classes of proteins: ARF GTPases, Rho GTPases, and protein kinase C (PKC). The specific mechanism of

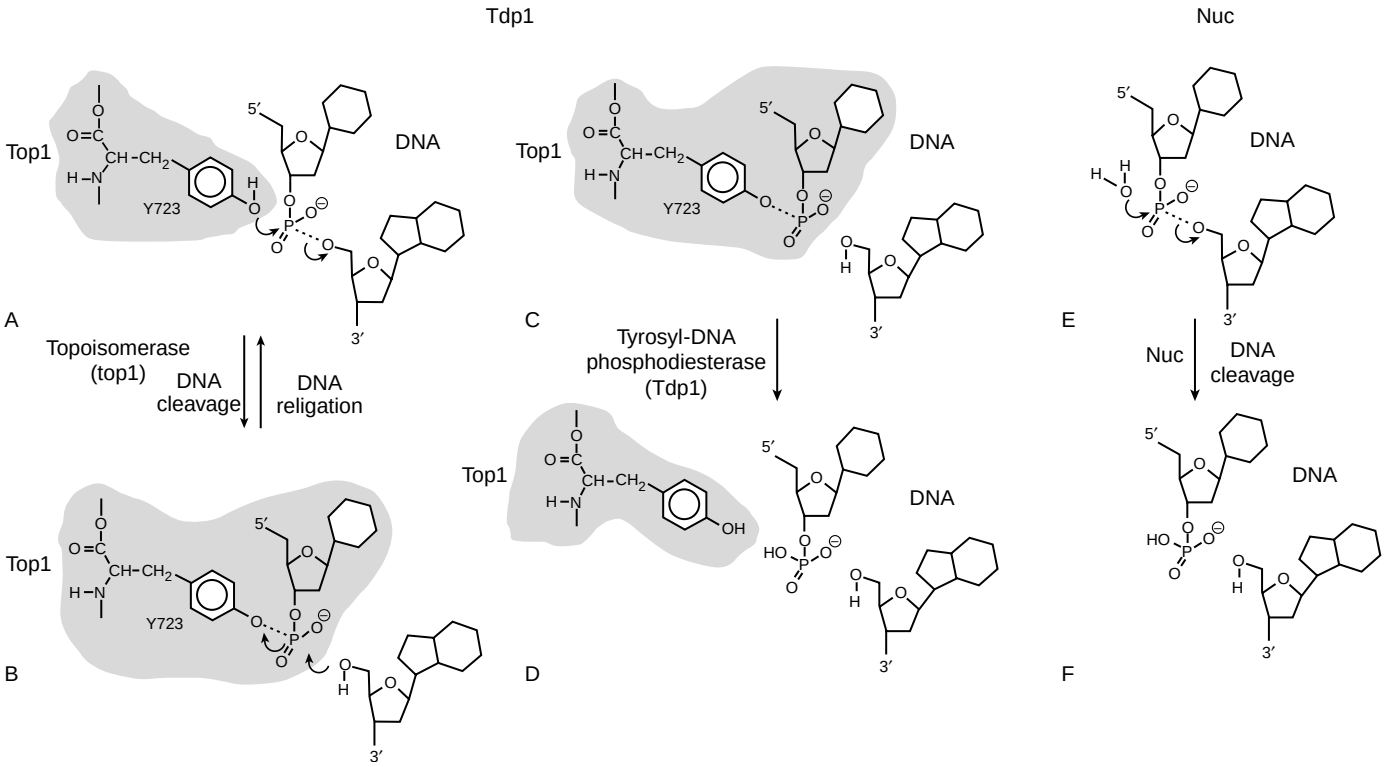

FIGURE 2 Schematic representation of mechanism of action of more divergent members of the PLD superfamily. (A) Topoisomerase I (top1) reversibly generates a cleavage complex by forming a covalent link between tyrosine 723 in top1 and the DNA backbone (B). (C, D) If top1 becomes stalled in the cleavage complex form, it is rescued by Tdp1 hydrolysis of the phosphotyrosyl (phosphodiester) bond (dotted line in (C)). (E,F) The bacterial endonuclease Nuc similarly uses water to attack the backbone phosphodiester bond in DNA to hydrolyze it. Cartoon adapted from Debethune *et al.* (2002).

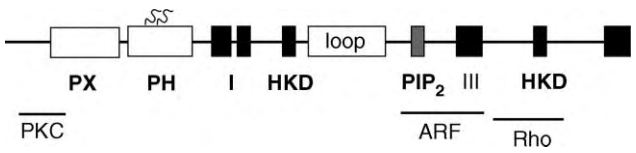

FIGURE 3 PLD structure. Mammalian PLD contains catalytic domains (HKD, I, III, and C-terminus), a $PI4,5P_2$ interacting motif (PIP_2), and PX and PH-membrane association domains. The PH domain is palmitoylated in PLD1. PLD1's activators Rho, ARF, and PKC interact with PLD1 within the regions depicted to activate it.

PLD activation varies with cell type and receptor system examined.

Phosphoinositides

A role for phosphoinositides in the regulation of PLD was first suggested by the finding that $PI4,5P_2$ was required for ARF stimulation of PLD in HL-60 cells and has since been confirmed using purified reagents in *in vitro* reconstitution systems. Activation of PLD1 by phosphoinositides is independent of the stimulatory effects of GTP-binding proteins and protein kinases. Phosphoinositides may function to anchor PLD to the phospholipid surface, thereby increasing the rate of catalysis by placing PLD in close proximity to its substrate.

Protein Kinase C

PKCα and PKCβ directly and indirectly mediate agonist-dependent activation of PLD. Overexpression of either PKC isoform potentiates PLD responses to agonists such as endothelin, thrombin, and PDGF. Down-regulation of PKC through long-term exposure to phorbol esters, antisense depletion of PKCα, or mutation of the site in PLD1 at which PKC interacts decreases agonist-stimulated PLD activity. PKC most commonly activates its targets through phosphorylation. Although PKC does phosphorylate PLD1, it has been shown convincingly that this is not the mechanism through which it activates the same. Activation by PKCα occurs in the absence of ATP (*in vitro*) and is not inhibited by staurosporine, a catalytic-site inhibitor. This non-kinase-dependent stimulatory activity resides within the regulatory domain of PKCα, and PKCα interacts directly with the amino terminus of PLD1. PKC also mediates activation of PLD through a kinase-dependent non-direct mechanism involving calcium influx into cells but which otherwise is not understood clearly. For both PLD isoforms, multiple kinase-dependent downstream consequences of PKC activation may also contribute to PLD activation. To give one such example, a major substrate for PKC subsequent to activation is the protein myristoylated alanine-rich C-Kinase substrate (MARCKS). Under basal conditions, MARCKS localizes to membrane surfaces through multiple low-affinity interactions with $PI4,5P_2$. Once phosphorylated by PKC, MARCKS relocates to the cytosol, making the previously sequestered $PI4,5P_2$ available for other interactions including PLD activation. Consistent with this idea, mutations to MARCKS that eliminate its phosphorylation decrease PKC-mediated PLD activation.

Rho Family of GTPases

The finding that a GTPγS-dependent factor required for PLD activity in neutrophils was removed by RhoGDI first suggested a role for Rho in PLD activation. Rho has since been shown to mediate agonist-dependent PLD activation downstream of numerous agonist-receptor combinations. Many studies on this topic have inhibited Rho using bacterial toxins such as C3 exotoxin from *C. botulinum* (inactivates Rho through ADP-ribosylation) or Toxin B from *C. difficile* (blocks Rho function through monoglucosylation). Dominant-negative Rho mutants have also been used and block phorbol ester-stimulated PLD activity in human adenocarcinoma A549 cells, suggesting that there is cross-talk between the Rho and PKC activation pathways. Direct activation of PLD1 by Rho through an interaction at the C-terminus has been demonstrated; this appears not to be the case, however, for PLD2. Indirect mechanisms of activation are also likely. Rho activates phosphatidylinositol 4-phosphate 5-kinase, which phosphorylates phosphatidylinositol-4-phosphate to generate $PI4,5P_2$, the cofactor required for PLD activity. Rho may also regulate PLD activity through activation of Rho kinase.

ADP-Ribosylation Factor Family of GTPases

ARF is the most potent activator of PLD activity *in vitro*. Activation of PLD by ARF is GTP-dependent, and appears to involve the N-terminus of ARF and the C-terminus of PLD. ARF proteins have been shown to mediate PLD activation by a number of agonists, including insulin, PDGF, angiotensin II, endothelin, N-FMLP, and glutamate. ARF-mediated activation of PLD is not believed to be specific to any particular ARF isoform. Overexpression of dominant-negative ARF1 and ARF6 mutants or BFA-mediated interference with ARF activation inhibits agonist-induced PLD activation in some settings.

Protein Phosphorylation

Both PLD isoforms appear to be phosphorylated by PKC. Recent studies indicate that PLD1 and PLD2 may be phosphorylated by serine/threonine kinases, including cyclic AMP-dependent protein kinase and calcium-calmodulin-dependent protein kinase, as well as by receptor and non-receptor tyrosine kinases. For example, mouse PLD2 associates with EGFR in a

ligand-independent manner and becomes tyrosine phosphorylated on Y11 in response to signaling by EGF. However, since mutation of Y11 to alanine does not affect PLD activation, and since this residue is not conserved in human PLD2, the physiological significance of the modification is not clear. Ultimately, the physiological relevance of phosphorylation on PLD activity and function has not yet been convincingly demonstrated.

Subcellular Localization of Mammalian Phospholipase D

Phospholipase D activity has been reported in almost every cellular compartment, including the plasma membrane, mitochondria, secretory granules, lysosomes, Golgi, endoplasmic reticulum membranes, and nuclear envelope. Immunolocalization of PLD protein presents a more restricted picture. PLD1 is found primarily on peri-nuclear vesicles in many cell types and on the plasma membrane in others; PLD2 is found primarily on the plasma membrane. However, the proteins may transit through multiple subcellular sites subsequent to cellular stimulation, leading to a record of PLD activity at a broader range of sites. The PLD1 PH domain is palmitoylated and this appears to play a role in targeting PLD1 to specific locations. Elimination of palmitoylation through mutation of key amino acids results in the redistribution of PLD1 from peri-nuclear vesicles to the plasma membrane. PLD2 contains one palmitoylation site. It is not known whether its subcellular localization is effected through lipid modification.

Function of PLD's Product

PA is a pleiotropic lipid. Four basic roles have been proposed for it.

Signal Transducer

PA has been shown to stimulate the activity of several different kinds of enzymes. One of these is phosphatidylinositol 4-phosphate 5-kinase, which phosphorylates the lipid phosphatidylinositol 4-phosphate (PI4P) to generate PI4,5P_2. PI4,5P_2 is well known for its roles in regulating trafficking of membrane vesicles in cells and for regulating cell shape and changes in morphology. PA also activates NADPH oxidase, which plays an important role as part of the neutrophil-mediated immunological response to infection. Another target has been identified recently as mTor, a key component in the regulation of protein translation and cell growth. Additional enzymes regulated by PA are likely to continue to emerge; current candidates include ARF GAPs, enzymes that deactivate ARF small G-proteins and thus are involved in regulating vesicular trafficking and cell shape.

Lipid Anchor

PA has also been reported to bind to and anchor a rapidly growing list of proteins involved in signaling, regulating vesicular trafficking and cell shape, or that have unknown functions. Although in some of these cases, PA may also be stimulating changes in the biochemical behaviors of the target proteins and thus act as a signal transducer, it seems likely that in many of the instances, it serves as a means to recruit effector molecules to a focused location in the cell. For example, at sites of budding from the Golgi or exocytosis at the plasma membrane. In another such example, Raf-1 kinase is activated by the oncogene Ras only at membrane surfaces, but Raf-1 is normally cytosolic and has been reported to become membrane associated only through interaction with PA, like the one which occurs subsequent to insulin receptor activation.

Signaling Intermediate

PA can also be dephosphorylated to yield diacylglycerol, a key lipid which activates protein kinase C (PKC), or monodeacylated to form lysoPA, a potent mitogen found in serum that mediates cell proliferation and shape change.

Biophysical Role

Space-filling models have suggested that with two acyl chains and a small headgroup, PA may act as a "hinge" lipid and promote membrane curvature towards the leaflet in which it is located. Conversely, lysoPA, which has the same headgroup but only one acyl chain, has been proposed to promote membrane curvature in the opposite direction. Since membrane vesicles undergoing budding from or fusion into planar membrane surfaces, pass through energetically unfavorable transition states as the membranes bend and fold at the neck of the vesicles, it is an attractive idea that conversion of PA into lysoPA, and vice versa, could make these events happen more efficiently (i.e., lower the activation energy). These models are supported by the observations that endophilin I, a protein that promotes endocytosis, is an enzyme that converts lysoPA into PA, and that adding PA to vesicles promotes accelerated rates of fusion in *in vitro* reconstitution assays.

Cell Biological Roles

Yeast

PLD function is best understood in yeast, where it was identified in a genetic screen for mutants unable to complete the late stages of meiosis. At the point in the meiotic process where PLD is required, duplication of the chromosomal DNA has been completed and individual sets of chromosomes are segregating to each pole of the four-lobed nucleus. The outer half of the spindle pole body found at each pole serves as a nucleating site for the formation of a new structure called the prospore membrane. The prospore membrane is built by aggregation and fusion of vesicles sent from the Golgi apparatus. These vesicles normally function in exocytosis and travel to the plasma membrane, but are redirected to the spindle pole body to build the prospore membrane during meiosis. As meiosis progresses, the prospore membranes grow in length and extend to cover each lobe of the nucleus (picture someone rolling socks onto their hands and feet), and eventually pinch off the nuclear lobes. This results in the "capture" of individual sets of chromosomes in their own nuclear envelopes. Each of these are immature spores, and the prospore membrane now surrounding them becomes the new plasma membrane. A cell wall eventually forms around each spore, making them ready for release from the original yeast cell.

When PLD is missing, the prospore membrane fails to form. PLD is distributed throughout the cell prior to meiosis but translocates to the spindle pole at the time when the prospore membrane needs to be built. PLD activity is not required for its translocation, indicating that it is not involved in the trafficking of membrane vesicles to the spindle pole body; however, the vesicles subsequently fail to aggregate and fuse when PLD is missing or catalytically inactive.

Although the precise mechanism mediated by PLD or its product PA in prospore membrane development remains unknown, this is the best-understood example of what is now recognized as a common theme for PLD function; regulation of vesicle production, trafficking, or fusion.

Mammals

Investigation of roles for PLD in mammals has been more challenging. Cells and animals lacking PLD have not yet been generated, and specific pharmacological PLD agonists and antagonists have not been identified. Nonetheless, an approach for probing PLD function exists that has been widely used, although interested readers need to keep in mind that it comes with significant caveats. This method involves exposing cells to moderately high levels of primary alcohols such as ethanol or 1-butanol. Short-chain primary alcohols can competitively substitute for water in the PLD hydrolysis reaction, leading to formation of phosphatidylalcohols at the expense of PA. Phosphatidylalcohols are believed to be relatively inert; that is, they do not activate the downstream pathways triggered by PA. Accordingly, diverting PA production to phosphatidylalcohol diminishes PLD-mediated activation of PA-dependent events. In addition, since phosphatidylalcohols are relatively metabolically inert, they serve as a history of PLD activation over the period during which the alcohols are present. Measuring accumulation of phosphatidylalcohols is very useful for quantitating PLD activity, since PA, in contrast, turns over rapidly once formed, and in fact can be generated through pathways other than PLD as well. Limitations of this approach include the facts that alcohols alter the fluidity of membranes, which affects many biological processes, and block activation of many tyrosine kinase receptors; for example, the insulin receptor. Moreover, at the concentrations of alcohol required to divert PA production effectively, levels of phosphatidylinositol lipids become significantly altered; for example, PIP levels decrease dramatically. Accordingly, although alcohol-mediated inhibition of PA production provides initial evidence for PA involvement in specific processes, it should not be considered definitive in the absence of other approaches. More recent approaches for manipulating PLD activity include overexpression or injection of wild-type PLD proteins to increase levels of activity or use of catalytically inactive PLD proteins to serve as dominant interfering mutants. Using such techniques, roles have been described for PLD in a number of settings.

Secretion

One of the better-characterized model systems involves regulated secretion from neuroendocrine cells, such as primary adrenal chromaffin cells. Exposure of these cells to the agonist nicotine stimulates receptors that activate PLD and triggers release of catecholamines through fusion of neurotransmitter-containing secretory granules with the plasma membrane. Analogous to the role of PLD in yeast meiosis, PLD in adrenal chromaffin cells is found on the acceptor membrane, in this case the plasma membrane. Increasing PLD activity through overexpression leads to increased regulated exocytosis and reducing PLD activity through any of the approaches described above leads to inhibition of catecholamine release. In this setting, PA appears to mediate the rate and efficacy of fusion of secretory granules into the plasma membrane as inhibition of PLD activity leads to individual granules fusing into the plasma membrane and disgorging their contents more slowly (Figure 4). Once again, the precise mechanism of PA function remains unknown, and could involve more than one of the possibilities described above. PLD activity has

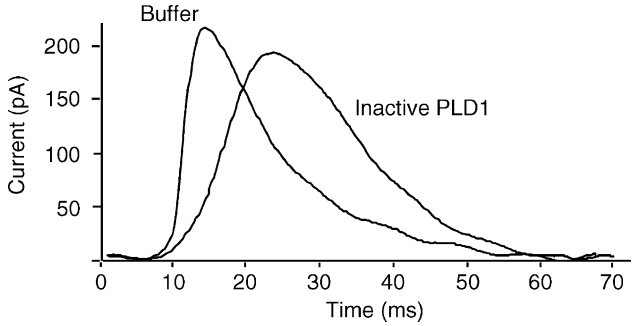

FIGURE 4 Catalytically inactive PLD1 inhibits nicotine-evoked catecholamine secretion from chromaffin cells, revealing a requirement for PA in the fusion of secretory granules into the plasma membrane. Chromaffin cells were microinjected with buffer or with catalytically inactive PLD1 protein which acts as a dominant negative mutant. Cells were stimulated 10–15 min later by a local application of nicotine for 5 s. Catecholamine secretion, which causes a change in local conductance due to its highly charged nature, was recorded using a carbon fiber electrode. Numerous spikes of current, representing fusion of individual granules of catecholamines with the plasma membrane are observed, but many fewer after injection of catalytically inactive PLD1 (not shown). Individual fusion events are shown above on the millisecond timescale. The fusion event observed for a normal (buffer-injected) cell occurs rapidly. The fusion event in the cell injected with catalytically inactive PLD1 protein occurs more slowly, indicated that the fusion pore formed between the secretory granule and the plasma membrane enlarges at a slower rate, causing the contents to be released more slowly as well. Reprinted from Vitale, N., Caumont, A. S., Chasserot-Golaz, S., Du, G., Wu, S., Sciorra, V. A., Morris, A. J., Frohman, M. A., and Bader, M. F. (2001). Phospholipase D1: a key factor for the exocytotic machinery in neuroendocrine cells. *EMBO J.* **20**, 2424–2434, with permission of Oxford University Press.

similarly been shown to promote or be required for fusion of histamine-containing secretory granules into the plasma membrane after IgE-triggered degranulation of mast cells, and for translocation of the Glut-4 glucose transporter from storage vesicles to the plasma membrane subsequent to insulin stimulation.

Finally, PLD activity has also been shown to promote the release of membrane vesicles from the trans-Golgi in endocrine cells. It may be that PLD promotes both budding and fusion of vesicles. Alternatively, the budding process could be facilitated by PLD-regulated fusion of vesicles into the trans-Golgi at an earlier step.

Morphology

The activators that stimulate mammalian PLD, i.e., ARF and Rho small G-protein family members and protein kinase C, are also well known for their roles in controlling changes in cell shape. Although, again, the precise role played by PA remains undefined, it is clear that inhibition of PLD activity blocks actin cytoskeleton-mediated cell shape changes in some settings (for example, formation of actin stress fibers in response to agonist stimulation) and that overexpression of PLD promotes them. At high levels of overexpression of the PLD2 isoform, cells undergo spontaneous changes in morphology, extending finger-like projections and undergoing continued ruffling. These sorts of responses indicate that PLD and PA play a role in regulating cell shape, although their role at normal levels of expression remains to be determined. Leading hypotheses include the possibilities that PLD activity increases levels of $PI4,5P_2$, a lipid known to be involved in reorganization of the actin cytoskeleton, or that it activates ARF GAPs, enzymes that deactivate ARF-stimulated pathways.

Other Roles

PLD-generated PA also promotes activation of Raf-1 kinase and mTor, key regulatory factors in cell growth, and NADPH-oxidase, a component of the respiratory burst response in inflammation and infection.

Summary

Phospholipase D, a lipid-modifying enzyme activated via complex regulation through G-protein and receptor tyrosine kinase signal transduction pathways, has roles in numerous cell biological settings including vesicular trafficking, cell shape modifications, and proliferation.

Glossary

phosphatidylalcohols Biologically inert, metabolically inactive compounds formed when primary alcohols are available to serve as the nucleophile instead of water in a PLD reaction.

phospholipases Enzymes that cleave phospholipids. Phospholipase A, C, and D each cleave distinct sites on phospholipids.

phospholipid A membrane lipid consisting of one or more fatty acid side chains linked to a glycerol phosphate backbone. The phosphate group frequently terminates in a "headgroup" such as choline or inositol via a phosphodiester bond that constitutes the target for PLD superfamily action.

Phospholipid Metabolism in Mammals

Claudia Kent
University of Michigan, Ann Arbor, Michigan, USA

Phospholipids form the bilayer matrix of all natural biological membranes. In mammals, phospholipids take on additional importance as components of lipoproteins and as intermediates in signal transduction pathways. While the term "phospholipid" includes any lipid containing a phosphate moiety, in everyday usage the term has come to refer to glycerophospholipids, which are lipids containing glycerol phosphate as the "backbone," plus the phosphosphingolipid, sphingomyelin. These molecules are synthesized *de novo* in all mammalian cells, and actively degraded in those cells by multiple phospholipases. This article focuses on the metabolism of glycerophospholipids.

Biosynthesis of Phospholipids

Diacylglycerophospholipids

Major Glycerophospholipid Classes

The structures of the major classes of mammalian phospholipids are shown in Figure 1. Phosphatidate, or *sn*-1,2-diacylglycerol-3-phosphate, is a central intermediate in the biosynthesis of all phospholipids. In addition, this lipid has various functions in signal transduction pathways. Phosphatidylcholine is the major eukaryotic phospholipid, usually accounting for 40–50% of cellular phospholipids. Phosphatidylcholine plays a major structural role in biological membranes because of its excellent bilayer-forming properties. It is also found as a structural component of serum lipoproteins and pulmonary surfactant. In addition, phosphatidylcholine is a component of signal transduction pathways as a substrate for phospholipases that produce lipid mediators.

Phosphatidylethanolamine is also a major mammalian phospholipid, accounting for ~20–30% of cellular phospholipids. This lipid also plays a structural role in the bilayer, contributing to curvature stress because of its nonlamellar propensities, which in turn influences membrane–protein interactions. Phosphatidylserine represents roughly 10–15% of cellular phospholipids. This lipid plays a critical role in apoptosis, during which its exposure on the external leaflet of the plasma membrane is a recognition feature for engulfment by phagocytic cells.

Phosphatidylglycerol is found only in trace amounts in most mammalian cells, primarily in mitochondria. In lung, however, appreciable amounts of phosphatidylglycerol are found in type II alveolar cells and in their principal secretory product, pulmonary surfactant. The metabolic derivative of phosphatidylglycerol is diphosphatidylglycerol, commonly called cardiolipin; this lipid is found exclusively in mitochondria, where its role is to interact with proteins of the electron transport chain. Phosphatidylinositol is an important constituent of mammalian membranes, but is more widely appreciated as a substrate for kinases that convert it to multiply phosphorylated forms that participate in many signal transduction pathways.

Biosynthesis of the Central Intermediates

All mammalian glycerophospholipids, as well as triacylglycerols, are ultimately derived from phosphatidate. The main source of phosphatidate is the fatty acylation of *sn*-glycerol-3-phosphate (Figure 2), which in turn is formed by the reduction of dihydroxyacetone phosphate, a central intermediate of the glycolytic/gluconeogenic pathway. The first fatty acyl group is added by glycerol-3-phosphate acyltransferase, forming the product 1-acylglycerol-3-phosphate or lysophosphatidate. Two isoforms of glycerol-3-phosphate acyltransferase are found in mammals, one in the endoplasmic reticulum and the other in the mitochondrial outer membrane. The *sn*-2 position of lysophosphatidate is acylated by 1-acylglycerol-3-phosphate acyltransferase, a component of the endoplasmic reticulum. Fatty acyl-CoA serves as the donor for both acyltransferase reactions. Phosphatidate may also be formed by the action of phospholipase D, as is discussed in this article later, or by the action of diacylglycerol kinase; however, these last two enzymes do not participate in *de novo* phospholipid biosynthesis.

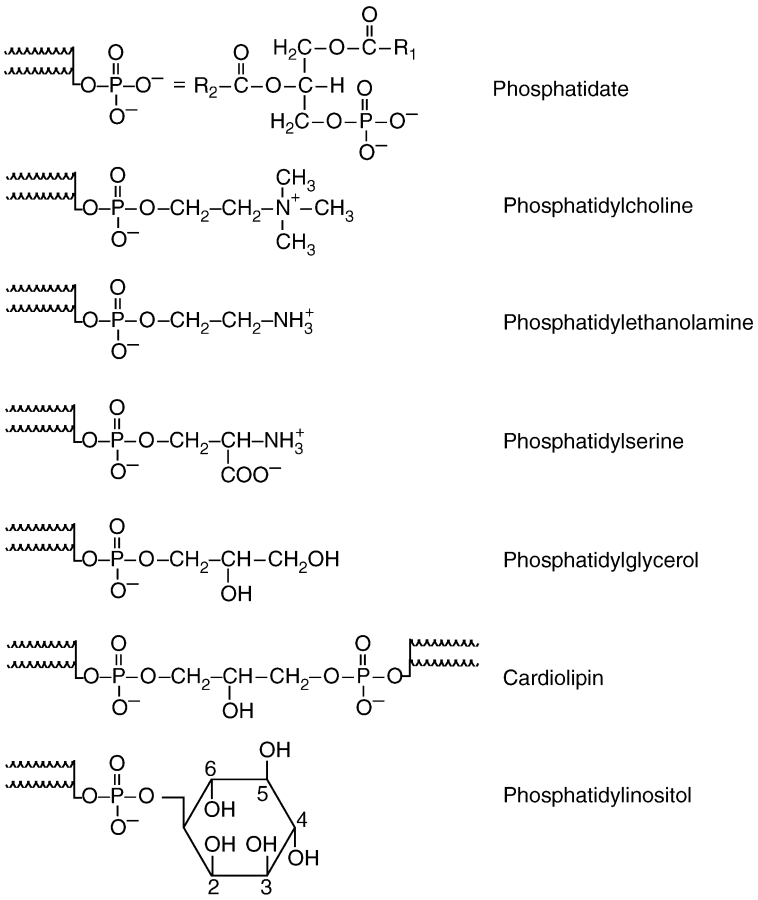

FIGURE 1 Structures of major glycerophospholipid classes. R_1 and R_2 refer to the different fatty acyl chains esterified to positions 1 and 2 of *sn*-glycerol-3-phosphate. The diacylglycerol moiety is represented by wavy horizontal lines connected to a vertical line.

Newly synthesized phosphatidate is channeled into two biosynthetic pathways, which are then used for the synthesis of different groups of phospholipids. In one pathway, phosphatidate phosphohydrolase converts its substrate to *sn*-1,2-diacylglycerol. Two isoforms of phosphatidate phosphohydrolase are found in mammalian cells; the one involved in glycerolipid biosynthesis appears to be both cytosolic and in the endoplasmic reticulum. The other isoform is plasma membrane-associated and functions primarily in signal transduction. The other pathway of phosphatidate utilization involves the formation of CDP-diacylglycerol, which takes place primarily in the endoplasmic reticulum.

The Diacylglycerol Pathway: Biosynthesis of Phosphatidylcholine, Phosphatidylethanolamine, and Phosphatidylserine

The biosynthetic pathways for all glycerophospholipids include at least one cytidylylated intermediate. The pathways for *de novo* biosynthesis of lipids that are derived from diacylglycerol involve the use of CDP-choline or CDP-ethanolamine (Figure 3). These nucleotide intermediates are made by the phosphorylation of choline and ethanolamine by choline/ethanolamine kinases, followed by transfer to the CMP moiety of CTP, catalyzed by phosphocholine and phosphoethanolamine cytidylyltransferases. The CDP-alcohols then react with diacylglycerol to form phosphatidylcholine and phosphatidylethanolamine.

The choline and ethanolamine kinases are soluble enzymes and are presumed to be cytosolic. Most of these enzymes can use either choline or ethanolamine as substrate but ethanolamine-specific kinases also exist. The cytidylyltransferases are specific for either phosphocholine or phosphoethanolamine and are regulatory for the CDP-choline and -ethanolamine pathways. There are nuclear and cytoplasmic isoforms of the phosphocholine cytidylyltransferase that are encoded by separate genes. These isoforms have an intriguing mode of regulation in which a membrane-binding segment of the enzyme "senses" the lipid composition and conveys a deficit of phosphatidylcholine to the active site of the enzyme, which is then activated in response to

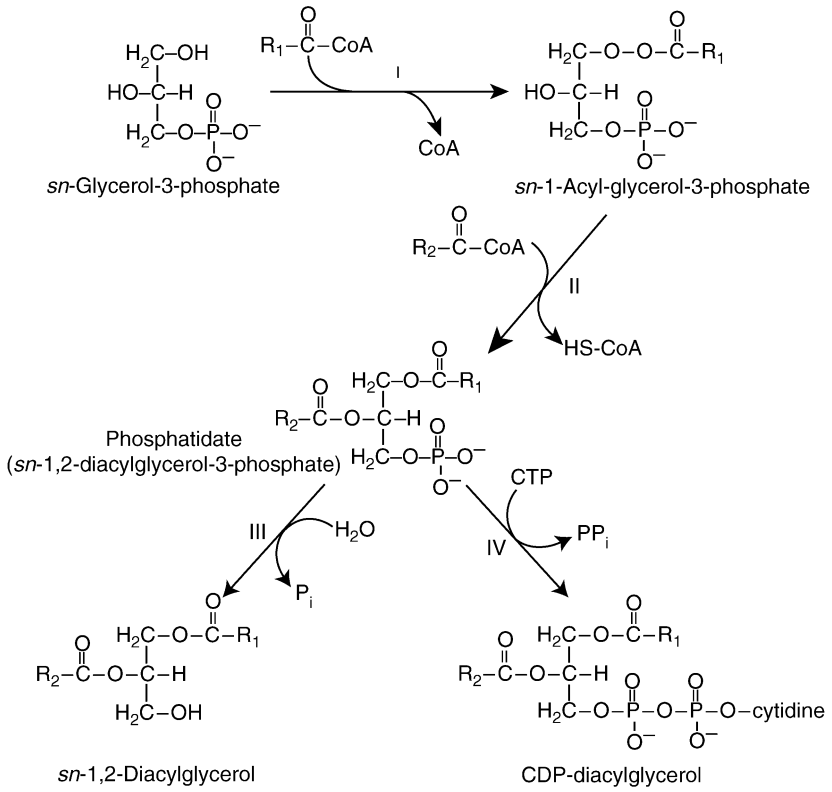

FIGURE 2 Biosynthesis of central intermediates of glycerophospholipid biosynthesis. Enzymes are I, glycerol-3-phosphate acyltransferase; II, 1-acylglycerol-3-phosphate acyltransferase; III, phosphatidate phosphohydrolase, and IV, CDP-diacylglycerol synthase.

the deficit. The phosphoethanolamine cytidylyltransferase is readily solubilized but appears to be associated with the endoplasmic reticulum. The alcohol phosphotransferases that catalyze the last steps, the formation of phosphatidylcholine and phosphatidylethanolamine, are embedded in the endoplasmic reticulum.

The CDP-choline pathway is the only mode for biosynthesis of phosphatidylcholine in most mammalian tissues. In liver, however, phosphatidylcholine is also made by the stepwise methylation of phosphatidylethanolamine, with S-adenosylmethionine as the methyl donor. In mammals, one phospholipid methyltransferase carries out all three steps; this methyltransferase activity is found in a specialized portion of the endoplasmic reticulum known as the mitochondria-associated membrane.

The CDP-ethanolamine pathway is important for the biosynthesis of ether lipids, but is a minor pathway for biosynthesis of diacyl ethanolamine phosphoglyceride. The predominant pathway for biosynthesis of the diacyl lipid is, rather, the decarboxylation of phosphatidylserine. The latter lipid in mammals is produced by exchange enzymes, in which serine exchanges with either the choline moiety of phosphatidylcholine, or ethanolamine of phosphatidylethanolamine, to form phosphatidylserine. The enzymes catalyzing these two exchanges are distinct; the choline exchange enzyme is responsible for bulk production of phosphatidylserine, which is then decarboxylated to form phosphatidylethanolamine. It is intriguing that the exchange enzymes are components of the endoplasmic reticulum, while the decarboxylase is mitochondrial. This dual location necessitates phospholipid transport systems that facilitate the transfer of phosphatidylserine and ethanolamine between these locations.

The CDP-Diacylglycerol Pathway: Synthesis of Phosphatidylglycerol, Cardiolipin, and Phosphatidylinositol

The nucleotide intermediate, CDP-diacylglycerol, is used for the biosynthesis of non-nitrogenous glycerophospholipids in mammals (Figure 4). In the pathway for the synthesis of the mitochondrial lipid, cardiolipin, CDP-diacylglycerol reacts with glycerol-3-phosphate to form phosphatidylglycerol-3-phosphate, which is then hydrolyzed to form phosphatidylglycerol. The usual fate of phosphatidylglycerol is to be converted to cardiolipin. In mammals that conversion involves reaction of phosphatidylglycerol with another molecule of CDP-diacylglycerol.

CDP-diacylglycerol is also used for the biosynthesis of phosphatidylinositol by reaction of the nucleotide lipid with free inositol. This reaction takes place predominantly in the endoplasmic reticulum. A number of phosphoinositide kinases have been identified that convert phosphatidylinositol to polyphosphoinositides.

Biosynthesis of Ether Glycerophospholipids

Ether phospholipids, in which the *sn*-1 acyl linkage is replaced by an ether bond, are major constituents of certain tissues, especially brain. They appear to play an

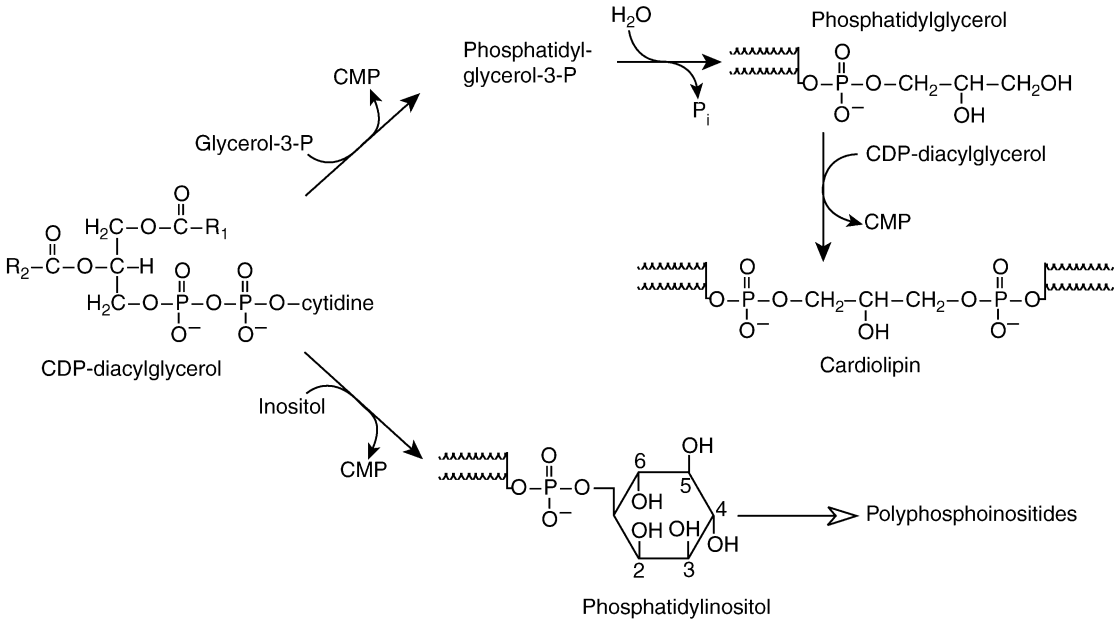

FIGURE 4 Synthesis of phospholipids derived from CDP-diacylglycerol. The open arrow in the lower right represents many phosphorylation steps leading to the polyphosphoinositides.

important role in mammalian physiology as judged by the severity of diseases resulting from abnormalities in their metabolism. These lipids are derived from dihydroxyacetone phosphate, which becomes fatty acylated at position 1 (Figure 5). The fatty acyl group is then replaced by a fatty alcohol to create the ether linkage. Reduction at C-2 followed by a second acylation produces 1-alkyl-2-acyl-glycerol-3-phosphate. This compound is then dephosphorylated, and the resultant free hydroxyl reacts with CDP-ethanolamine to produce 1-alkyl-2-acylglycerol-3-phosphoethanolamine, also known as plasmanylethanolamine. Introduction of a double bond at this stage into the fatty alcohol moiety results in the formation of the plasmalogen, plasmenylethanolamine. The mechanism of formation of plasmanyl/plasmenyl choline is not well established but may occur after hydrolysis of the ethanolamine ether lipids to 1-alkyl/alkenyl-2-acylglycerol, followed by reaction with CDP-choline. Ether lipid biosynthesis is unusual in that the first two enzymes are located in peroxisomes, the third step occurs in both peroxisomes and the endoplasmic reticulum, and the remaining steps occur in the endoplasmic reticulum.

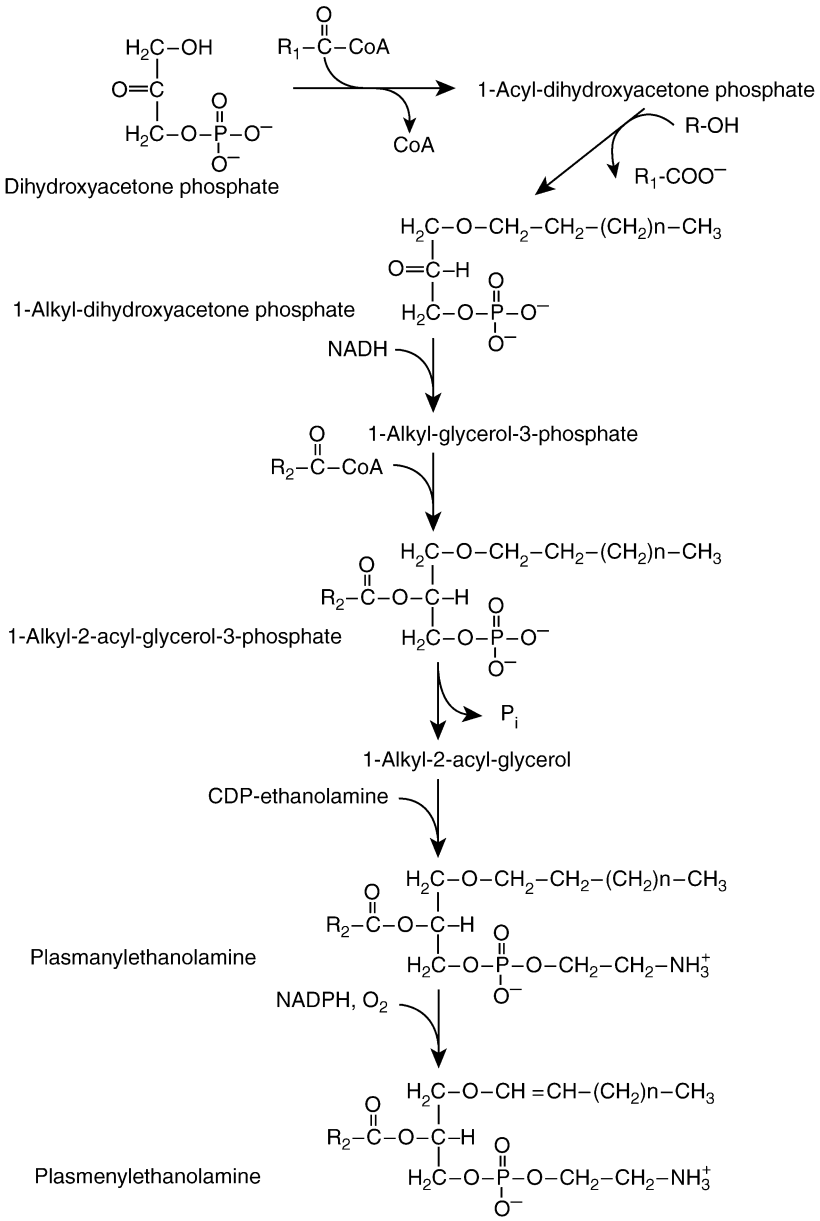

FIGURE 5 Biosynthesis of the ether lipids, plasmanylethanolamine, and plasmenylethanolamine. The ethanolamine ether lipids are precursors of choline ether lipids, but the conversion steps have not been firmly established.

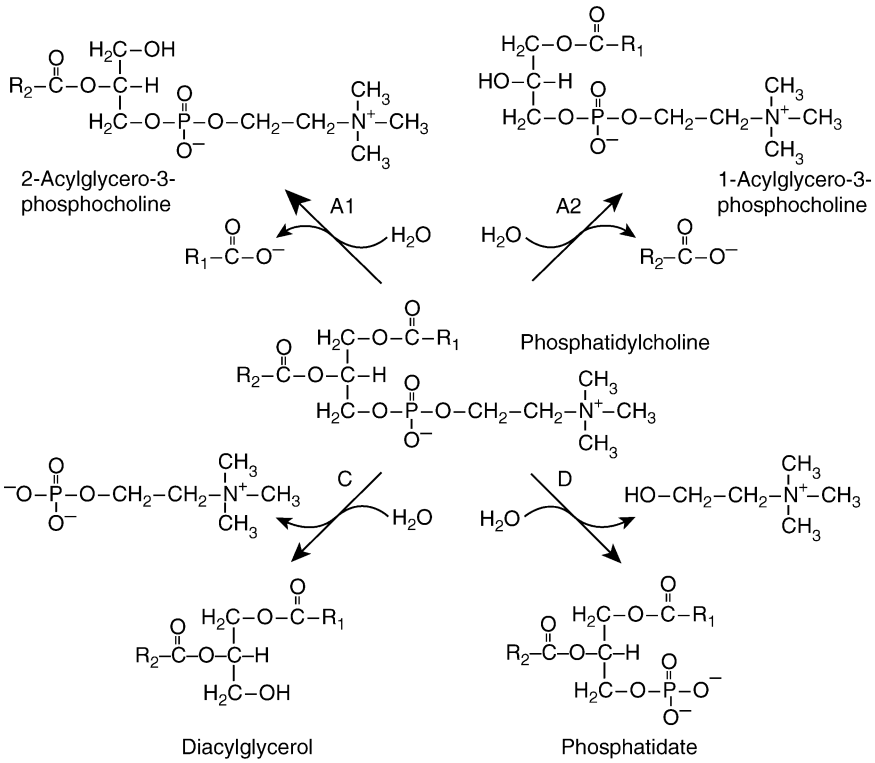

FIGURE 6 Specificity of phospholipases. A1, A2, C, and D refer to phospholipases of that specificity, as described in the text.

Catabolism of Phospholipids: Phospholipases

The degradation of phospholipids takes place during normal membrane turnover, as well as in response to the need for production of lipid mediators. The phospholipases that perform this degradation are divided into four general classes according to the reactions they catalyze (Figure 6). Hydrolysis of the fatty ester bond at C-1 is catalyzed by phospholipase A1. Multiple phospholipases A1 are found in mammals. Lysosomal phospholipase A1 functions in general phospholipid catabolism while phosphatidylserine-specific phospholipase A1 appears to generate the lipid-signaling molecule, 2-lysophosphatidylserine.

The best-studied phospholipases are phospholipases A2, which hydrolyze the ester bond at C-2. Mammalian phospholipases A2 function predominantly in the generation of free arachidonate, which is then converted by cyclooxygenases and lipoxygenases to a variety of eicosanoid-signaling molecules. Platelet-activating factor acetylhydrolase is a very specific phospholipase A2 that utilizes 1-alkyl-2-acetylphosphatidylcholine, also known as platelet activating factor, an important inflammatory lipid. Phospholipases A2 are also found in lysosomes where they play a more general catabolic role.

The phosphate ester bonds of phospholipids are hydrolyzed by phospholipases C, with the production of diacylglycerol, and D, with the production of phosphatidate. The best-studied phospholipases C are those involved in the hydrolysis of polyphosphoinositides, with the generation of diacylglycerol, which activates certain protein kinases, as well as inositol polyphosphates, which have many signaling functions. Phospholipases D mainly hydrolyze phosphatidylcholine and function both in signal transduction as well as in vesicular trafficking. Catabolism of sphingomyelin in mammals is carried out by neutral and acid sphingomyelinases that have a C-type specificity in that they generate ceramide and phosphocholine.

Glossary

ceramide The "backbone" of sphingolipids, consisting of sphingosine with an amide linkage to a fatty acid.

ether lipids Lipids containing a hydrocarbon chain in ether linkage to C-1 of the glycerol phosphate backbone.

glycerophospholipids Lipids composed of a backbone of *sn*-glycerol-3-phosphate, the first and second positions of which are fatty acylated.

phosphatidate *sn*-1,2-diacylglycerol-3-phosphate, also called phosphatidic acid.

phospholipase An enzyme catalyzing the hydrolysis of a phospholipid.

plasmalogen An ether lipid containing a *cis* double bond in the hydrocarbon chain, adjacent to the ether linkage.

polyphosphoinositide A phospholipid derived by phosphorylation of the inositol ring of phosphatidylinositol.

sphingomyelin A phospholipid consisting of ceramide linked to phosphocholine.

Biography

Claudia Kent is a Professor of Biological Chemistry at the University of Michigan. Her research interests have centered on phospholipid metabolism in eukaryotes and prokaryotes, with the principal focus being the enzymes that regulate phosphatidylcholine metabolism. She obtained a Ph.D. from Johns Hopkins University, and was a postdoctoral trainee at Washington University and a faculty member in biochemistry at Purdue University before moving to Michigan.

Phospholipid Synthesis in Yeast

Gil-Soo Han and George M. Carman
Rutgers University, New Brunswick, New Jersey, USA

Phospholipids are essential molecules that contribute to the structural definition of the cell. They also play a role as signaling molecules that participate in the regulation of cellular processes. The yeast *Saccharomyces cerevisiae* has been used as a model system to study phospholipid synthesis and its regulation in eukaryotes. Molecular, genetic, and biochemical studies have shown that phospholipid synthesis is regulated in a coordinated fashion. The mechanisms that govern this regulation mediate the mRNA and protein levels of the biosynthetic enzymes, as well as their activity and localization.

Phospholipid Composition

The major phospholipids found in the membranes of *S. cerevisiae* include phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), and phosphatidylserine (PS) (Figure 1). Mitochondrial membranes also contain phosphatidylglycerol (PG) and cardiolipin (CL). The composition of phospholipids in the cell can vary dramatically when culture conditions are altered. However, the average charge of the membrane phospholipids remains relatively constant. Genetic and biochemical regulation of the enzymes in the phospholipid biosynthetic pathways can compensate for changes in the levels of phospholipids of one charge by orchestrating parallel changes in the levels of phospholipids of the opposite charge.

Phospholipid Synthesis

Phospholipid synthesis is a complex process containing many branch points. A key molecule in this process is phosphatidate (PA). It plays a central role in phospholipid synthesis as the precursor of all phospholipids synthesized via the CDP–diacylglycerol (DAG), CDP–choline, and CDP–ethanolamine pathways (Figure 2). In the CDP–DAG pathway, PA is converted to CDP–DAG, which is then utilized for the synthesis of PS, PE, and PC. CDP–DAG is also utilized for the synthesis of PI and CL. In the CDP–choline and CDP–ethanolamine pathways, DAG is generated from the dephosphorylation of PA, and is utilized for the synthesis of PC or PE when cells are supplemented with choline or ethanolamine, respectively. The DAG derived from PA is also used for the synthesis of triacylglycerols. The nucleotide CTP is another important precursor in the synthesis of phospholipids. CTP, which is synthesized from UTP, is the direct precursor of the activated, energy-rich phospholipid pathway intermediates CDP–DAG, CDP–choline, and CDP–ethanolamine (Figure 2).

Synthesis of PA

PA is synthesized from glycerol 3-phosphate via two acylation reactions. The first acylation step, which results in the formation of lysoPA, is catalyzed by the *GAT1*- and *GAT2*-encoded glycerol 3-phosphate acyltransferases. Deletion of either gene does not affect cell viability, but deletion of both genes results in a lethal phenotype. Acylation of lysoPA, which is catalyzed by the *SLC1*-encoded lysoPA acyltransferase, generates PA. In addition to the *de novo* synthesis, PA can be produced from phospholipid turnover: (1) hydrolysis of PC by the *SPO14/PLD1*-encoded phospholipase D; (2) phosphorylation of DAG by CTP-dependent DAG kinase (whose structural gene is not yet known); and (3) dephosphorylation of diacylglycerol pyrophosphate (DGPP) by the *DPP1*- and *LPP1*-encoded lipid phosphate phosphatase enzymes.

CDP–DAG Pathway

PS, PE, and PC are synthesized via reactions in the CDP–DAG pathway. The committed step in this pathway is the synthesis of CDP–DAG from PA and CTP. This reaction is catalyzed by the essential enzyme CDP–DAG synthase, which is encoded by the *CDS1* gene. CDP–DAG is then converted to PS by the *PSS1/CHO1*-encoded PS synthase. This enzyme displaces the CMP moiety of CDP–DAG with serine. PS is then decarboxylated to PE by the *PSD1*- and *PSD2*-encoded PS decarboxylases. The *PSD1*-encoded PS decarboxylase is responsible for $>90\%$ of the cellular PS decarboxylase activity, while the *PSD2*-encoded enzyme is responsible for $\sim 10\%$ of the enzyme activity. Finally, PE is

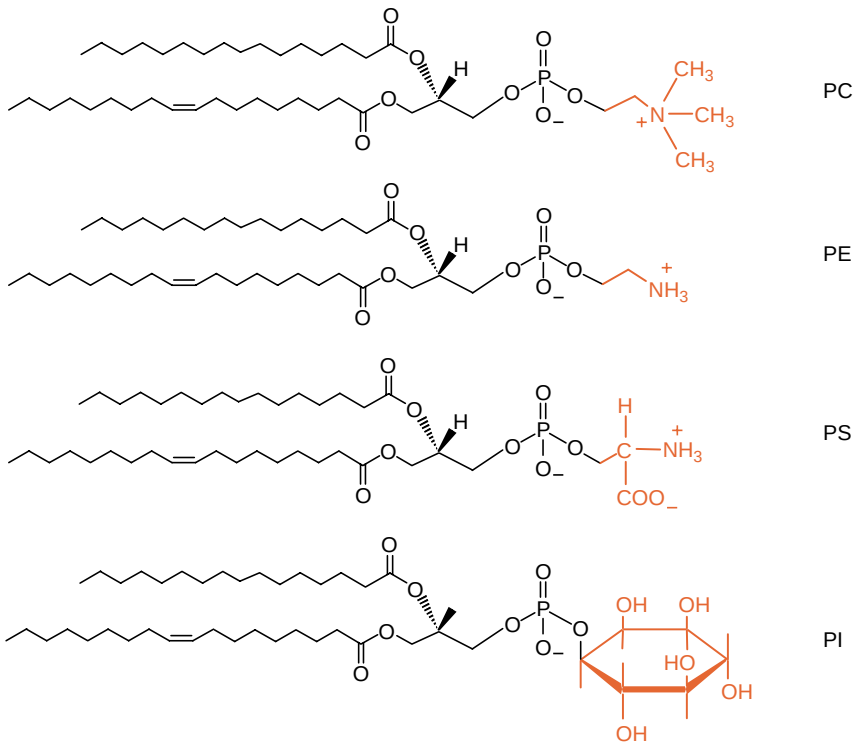

FIGURE 1 Major phospholipids in *S. cerevisiae*. The phospholipid headgroups (i.e., choline, ethanolamine, serine, and inositol) are shown in red.

converted to PC via three sequential methylation reactions. The first methylation reaction is catalyzed by the *PEM1/CHO2*-encoded PE methyltransferase, whereas the last two methylation reactions are catalyzed by the *PEM2/OPI3*-encoded phospholipid methyltransferase.

CDP–Choline and CDP–Ethanolamine (Kennedy) Pathways

When cells are supplemented with choline and ethanolamine, PC and PE are also synthesized via the CDP–choline and CDP–ethanolamine pathways, respectively. In the CDP–choline pathway, choline is phosphorylated with ATP to form phosphocholine by the *CKI1*-encoded choline kinase. Phosphocholine is then converted to CDP–choline by the reaction catalyzed by the *CCT1/PCT1*-encoded phosphocholine cytidylyltransferase. In the last step, PC is synthesized from CDP–choline and DAG by the *CPT1*-encoded choline phosphotransferase. The enzyme reactions in the CDP–ethanolamine pathway are similar to those in the CDP–choline pathway. The *EKI1*-encoded ethanolamine kinase catalyzes the phosphorylation of ethanolamine to phosphoethanolamine. Phosphoethanolamine is then converted to CDP–ethanolamine by the *ECT1*-encoded phosphoethanolamine cytidylyltransferase. In the last step, PE is synthesized from CDP–ethanolamine and DAG by the *EPT1*-encoded ethanolamine phosphotransferase. The Kennedy pathways become essential when the enzymes in the CDP–DAG pathway are defective or repressed. Mutants defective in the synthesis of PS, PE, or PC require choline for growth in order to synthesize PC via the CDP–choline pathway. Mutants defective in the synthesis of PS and PE can also synthesize PC if they are supplemented with ethanolamine. Ethanolamine is converted to PE via the CDP–ethanolamine pathway, and the PE is subsequently methylated to form PC via the CDP–DAG pathway. The CDP–choline pathway was once viewed as an auxiliary or salvage pathway used by cells when the CDP–DAG pathway was compromised. However, it is now known that the CDP–choline pathway contributes to PC synthesis even when wild-type cells are grown in the absence of exogenous choline. The PC synthesized via the CDP–DAG pathway is constantly hydrolyzed to form free choline and PA through the reaction catalyzed by the *SPO14/PLD1*-encoded phospholipase D. The free choline is incorporated back into PC via the CDP–choline pathway, and the PA is recycled into PC and other phospholipids via CDP–DAG and DAG.

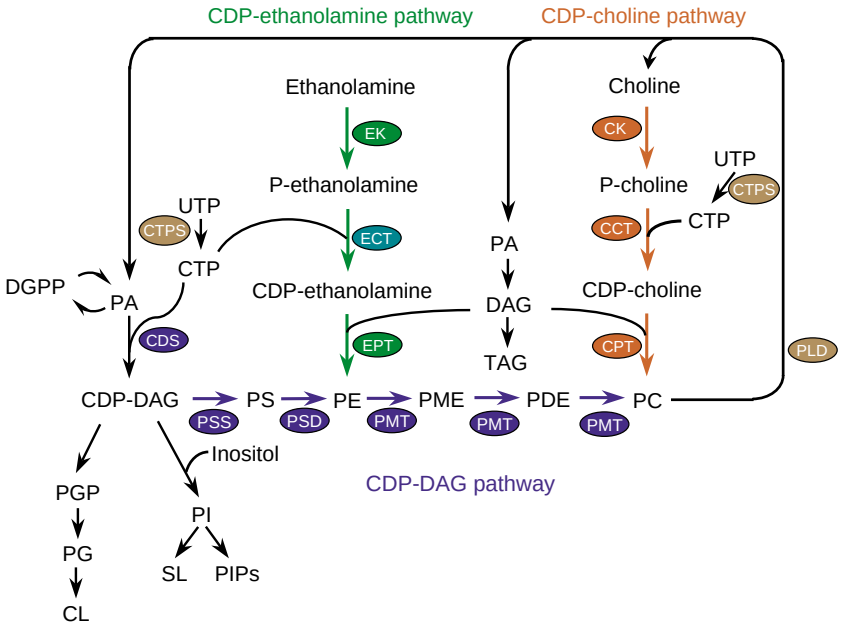

FIGURE 2 Pathways for the synthesis of the major phospholipids in *S. cerevisiae*. The pathways shown for synthesis of phospholipids include the relevant steps discussed in the text. The CDP–DAG, CDP–choline, and CDP–ethanolamine pathways are indicated. The enzymes CDP–DAG synthase (CDS), PS synthase (PSS), PS decarboxylase (PSD), and the PE methyltransferases (PMT) catalyze reactions that lead to the formation of PC by the CDP–DAG pathway (shown in blue). Choline kinase (CK), choline–P cytidylyltransferase (CCT), and choline phosphotransferase (CPT) catalyze reactions that lead to the formation of PC by the CDP–choline pathway (shown in red). Ethanolamine kinase (ET), ethanolamine-P cytidylyltransferase (ECT), and ethanolamine phosphotransferase (EPT) catalyze reactions that lead to the formation of PE by the CDP–ethanolamine pathway (shown in green). The reactions catalyzed by CTP synthetase (CTPS) and phospholipase D (PLD) are shown in brown. A more comprehensive description that includes the synthesis of PA and additional steps in these pathways may be found elsewhere. PA, phosphatidate; CDP–DAG, CDP–diacylglycerol; PS, phosphatidylserine; PE, phosphatidylethanolamine; PME, phosphatidylmonomethylethanolamine; PDE, phosphatidyldimethylethanolamine; PC, phosphatidylcholine; DAG, diacylglycerol; TAG, triacylglycerol; PGP, phosphatidylglycerophosphate; PG, phosphatidylglycerol; CL, cardiolipin; SL, sphingolipids; PIPs, polyphosphoinositides, DGPP, diacylglycerol pyrophosphate.

Other Pathways from CDP–DAG

The essential *PIS1*-encoded PI synthase enzyme catalyzes the displacement of the CMP moiety of CDP–DAG with inositol, resulting in the formation of PI. In this reaction, the water-soluble inositol is provided either by receptor-mediated transport from the growth medium or by *de novo* synthesis from glucose 6-phosphate. When cells are grown in the absence of inositol, glucose 6-phosphate is converted to inositol 1-phosphate, which is catalyzed by the *INO1*-encoded inositol 1-phosphate synthase. Inositol 1-phosphate is then dephosphorylated to form inositol by the *INM1*-encoded inositol monophosphatase. PI is itself a branch point in phospholipid biosynthesis: it is further converted to multiple phosphorylated forms (polyphosphoinositides) by PI kinases, or its phosphoinositol moiety is transferred to ceramide to form sphingolipids. In the CL pathway, CDP–DAG is converted to phosphatidylglycerolphosphate (PGP) by displacement of CMP from CDP–DAG with glycerol 3-phosphate. This reaction is catalyzed by the *PGS1/PEL1*-encoded PGP synthase. PGP is then converted to PG by PGP phosphatase whose structural gene has not yet been identified. In the last step, CL is synthesized from PG and CDP–DAG by *CLS1/CRD1*-encoded CL synthase.

Regulation of Phospholipid Synthesis

Phospholipid synthesis is regulated by a number of factors. These include water-soluble phospholipid precursors (e.g., inositol and choline), nucleotides (e.g., ATP and CTP), lipids (e.g., PA, CDP–DAG, and sphingolipids), growth phase, and phosphorylation. The regulation of phospholipid synthesis by these factors is complex and mediated not only by genetic mechanisms that control the synthesis of mRNA and protein, but also by biochemical mechanisms that modulate enzyme activity.

Genetic Regulation

The effect of inositol supplementation on phospholipid synthesis is a representative example of genetic regulation. When wild-type cells are grown in the presence of inositol, the levels of PS, PE, and PC decrease, while the level of PI increases. These changes in phospholipid composition result from the coordinated regulation of enzyme activities in phospholipid synthesis. Genetic regulation by inositol supplementation affects the enzyme activities by controlling protein content at the transcriptional level. Thus, inositol supplementation represses the transcription of *INO1* and other genes in the CDP–DAG and CDP–choline pathways, whereas inositol starvation stimulates the transcription of the coregulated genes. In many instances, the repressive effect of inositol is enhanced by the addition of choline or ethanolamine to the growth medium. All of the coordinately regulated genes contain a *cis*-acting element, UAS_{INO} (inositol-sensitive upstream activation sequence), in the promoter region. The UAS_{INO} element has the core consensus-binding site (CANNTG) for basic helix-loop-helix (bHLH) proteins. Ino2p and Ino4p are members of the bHLH family of DNA-binding proteins. They bind the UAS_{INO} element as a heterodimer and activate transcription. In addition, Ino2p (but not Ino4p) contains a transcriptional activation domain and is subject to autoregulatory control. Thus, levels of Ino2p appear to be limiting for the formation of the Ino2p/Ino4p heterodimer. In contrast, Opi1p represses the transcription of UAS_{INO}-containing genes. Opi1p contains a leucine zipper and two glutamine-rich domains that are required for Opi1p repressor activity. Opi1p mediates its negative regulatory activity through the UAS_{INO} element, but not by direct interaction. Instead, *in vitro* data indicate that Opi1p interacts with DNA-bound Ino2p within the leucine zipper domain of Opi1p. In addition, the global repressor Sin3p interacts with the N-terminal region of Opi1p. Studies using mutant alleles of *INO2*, *INO4*, *OPI1*, and *SIN3* support a model whereby these interactions play a role in the expression of UAS_{INO}-containing genes *in vivo*.

In addition to inositol, the transcription of the UAS_{INO}-containing genes is also regulated by growth phase. Cells entering stationary phase reveal the repression of the *INO1* gene expression even in the absence of inositol from the growth media. The stationary phase repression of *INO1* transcription is also controlled by Opi1p. Deletion of the *OPI1* gene results in the derepression of *INO1* transcription in stationary phase.

Some enzymes in phospholipid synthesis are regulated in an opposite fashion: they are up-regulated by inositol and derepressed in stationary phase. For example, inositol supplementation results in an increase in the level of DGPP phosphatase (encoded by *DPP1*) activity in both exponential and stationary phase cells. The activity is greater in stationary phase cells when compared with exponential phase cells, and the inositol- and growth phase-dependent regulation of DGPP phosphatase are additive. Analyses of DGPP phosphatase mRNA and protein levels indicate that transcriptional regulation is responsible for the control of the enzyme activity. This regulation is not mediated through a UAS_{INO} element, as the element does not exist in the *DPP1* promoter.

Biochemical Regulation

Alterations in phospholipid synthesis in response to environmental changes are also regulated by biochemical mechanisms. In addition to its role in regulating enzyme expression, inositol regulates the activity of phospholipid biosynthetic enzymes. Inositol inhibits PS synthase activity as a noncompetitive inhibitor, and regulates PI synthase activity through substrate availability. Since both enzymes share the common substrate CDP–DAG, inositol-mediated regulation of PS synthase activity contributes to the synthesis of PI at the expense of PS.

Phosphorylation is a mechanism by which an enzyme activity may be regulated, and indeed several phospholipid biosynthetic enzymes are phosphorylated. For example, the CTP synthetase, choline kinase, and PA phosphatase enzymes are phosphorylated and activated by protein kinase A, whereas the phosphorylation of PS synthase by protein kinase A results in the inhibition of activity. These phosphorylation reactions favor the synthesis of PC via the CDP–choline pathway.

Lipids regulate some phospholipid biosynthetic enzymes. For example, PS synthase activity is stimulated by PA and inhibited by CL and DAG. The PA phosphatase enzyme is stimulated by CL, CDP–DAG, PI, and DGPP. PS synthase and PA phosphatase are also inhibited by the sphingoid bases phytosphingosine and sphinganine.

Nucleotides regulate the activity of some phospholipid biosynthetic enzymes. For example, choline kinase is subject to allosteric regulation by its substrate ATP and its product ADP. ATP promotes the oligomerization of choline kinase, whereas ADP inhibits its activity by affecting the catalytic properties of the enzyme and the apparent affinity of the enzyme for substrates ATP and choline. CTP inhibits PS synthase activity by chelating its cofactor manganese ions. CTP synthetase is regulated by CTP product inhibition. The CTP-mediated inhibition of CTP synthetase activity increases the positive cooperativity of the enzyme for UTP. CTP synthetase with a mutation at Glu^{161} is less sensitive to CTP product inhibition, and cells carrying the mutant CTP synthetase accumulate elevated levels of CTP.

Because CTP inhibits PS synthase activity, the higher levels of CTP result in an increase in the utilization of the CDP–choline pathway at the expense of the CDP–DAG pathway.

In this article, we have only scratched the surface in discussing the complex mechanisms that govern the synthesis of membrane phospholipids. Moreover, once phospholipids are synthesized, they must be transported to the various organelles in the cell. These processes are complex, and in some cases, they regulate phospholipid synthesis. The availability of sequence information of the yeast genome continues to facilitate studies on the molecular genetic and biochemical mechanisms that regulate phospholipid synthesis.

biochemical regulation Process of controlling the activity of enzymes.

genetic regulation Process of controlling the expression of genes.

phospholipid A lipid molecule that contains two fatty acyl chains that are esterified to the *sn*-1 and *sn*-2 positions of a glycerol phosphate backbone. Different phospholipid molecules (e.g., PC, PE, etc.) are distinguished by the water-soluble head group (e.g., choline, ethanolamine, etc.) that is attached to the phosphate moiety of the molecule.

Saccharomyces cerevisiae A species of yeast that is commonly used in genetic and biochemical research. It serves as an excellent model eukaryotic organism because it is easily cultured and genetically manipulated.

He received a B.A. degree from William Paterson College, an M.S. degree from Seton Hall University, and a Ph.D. from the University of Massachusetts. His postdoctoral training was at the University of Texas Medical School in Houston. Dr. Carman's laboratory is recognized internationally for its work on the biochemical and molecular characterization of phospholipid metabolism in yeast. Dr. Carman is a Fellow of the American Academy of Microbiology.

Photoreceptors

King-Wai Yau
Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Photoreceptors are cells that can detect light by virtue of a light-absorbing pigment they contain. In most cases, photoreceptors are neurons in the nervous system, and they signal light to the organism for behavioral changes. In some cases, however, photoreceptors are simply modified epithelial cells, such as melanophores in lower animals that can change color by virtue of aggregation or dispersion of intracellular pigmented granules in response to illumination. In humans, all photoreceptors known to date are present in the retina of the eyes. In lower vertebrates such as birds and fish, photoreceptors are also present in the pineal gland and elsewhere in the brain (deep-brain photoreceptors). In some lizards and frogs, photoreceptors are present in the parietal eye (also called the third eye or the frontal organ). In invertebrates, photoreceptors are present in diverse locations either singly or in small or large clusters to form well- or ill-defined eyes. In this article, the discussion is confined to vertebrate photoreceptors in the nervous system.

Retinal Photoreceptors

The well-known retinal photoreceptors in all vertebrates are the rods and cones. Rods are extremely sensitive to light, being able to detect and signal the absorption of a single photon; they are responsible for dim-light vision. Cones are much less sensitive to light, and they also adapt to steady light much more effectively than rods; they are responsible for bright-light vision. In most animals, including humans, rods are predominant in the retina. In occasional diurnal species (such as ground squirrel), however, cones are very abundant.

Rods

In mammals, all rods in a retina are identical. Morphologically, they can be distinguished into the outer segment, the inner segment, the cell body, and the synaptic terminal (Figure 1).

Outer Segment

The outer segment is a modified cilium that has become a highly expanded structure, with hundreds of internalized membrane disks stacked on top of each other and oriented transverse to the longitudinal axis of the cell. The membrane disks are chock-full of the rod visual pigment, rhodopsin, a transmembrane protein. Rhodopsin consists of rod opsin, the apoprotein, covalently linked to the chromophore, 11-*cis*-retinaldehyde (a derivative of vitamin A). In the mammalian retina, there is a single class of rods, all with the same opsin. The wavelength of maximum absorption (λ_{max}) of rhodopsin is near 500 nm (blue-green monochromatic light).

Inner Segment

The inner segment contains much of the metabolic machinery of the cell, and gives rise to the outer segment. The part of the inner segment adjacent to the outer segment is packed with mitochondria, reflecting the heavy metabolic load on the cell.

Cell Body

The cell body contains primarily the nucleus of the cell.

Synaptic Terminal

The synaptic terminal contacts second-order retinal neurons, including the bipolar and horizontal cells. It releases glutamate as the neurotransmitter. The synapse has a ribbon structure that is typical of most sensory neurons.

Cones

In humans, there are three types of cones, each with a different cone opsin covalently linked to 11-*cis*-retinaldehyde. The three cone pigments have λ_{max} at ~430 nm (blue), 530 nm (green), and 560 nm (yellow), respectively. The functional interactions between the three cone types allow us to perceive colors. The morphology of cones is very similar to that of rods, except that the membrane disks in the outer segment are continuous with the plasma membrane.

Phototransduction

The process by which light triggers an electrical response (the signal that neurons use to communicate with each

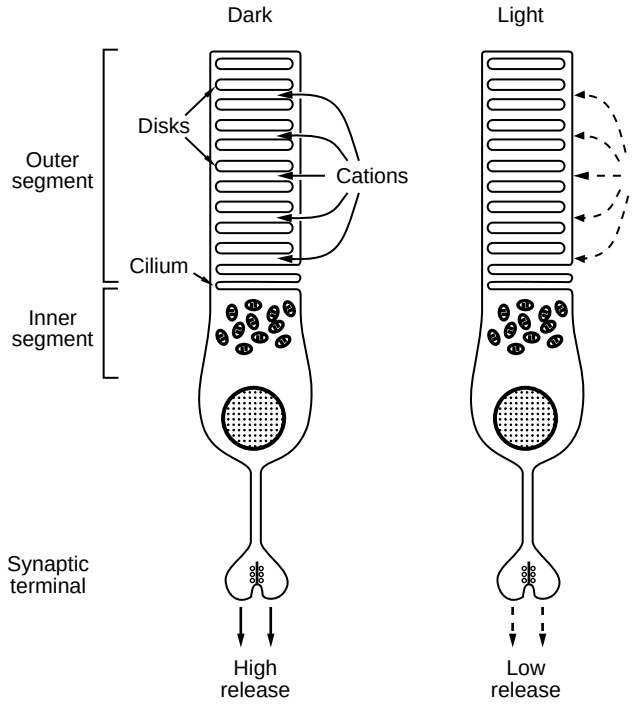

FIGURE 1 Diagram to show the overall morphology of a retinal rod photoreceptor and its response to light. See Figure 2 for the phototransduction mechanism underlying the response. Reproduced from Yau K.-W. (1994). Phototransduction mechanism in retinal rods and cones. The Friendenwald Lecture. *Invest. Ophthalmol. Vis. Sci.* **35**, 10–32, with permission through Copyright Clearance Center, Inc.

other) in rods and cones is called phototransduction. It is similar in both photoreceptor classes, and is now very well understood (Figure 2). There are nonselective cation channels on the plasma membrane of the outer segment that open (i.e., conduct ions) upon binding intracellular cGMP (cGMP-gated channels). In darkness, the free cGMP concentration in the outer segment is relatively high, thus keeping some of these cGMP-gated channels open. These open channels depolarize the cell and sustain a continuous release of glutamate from the synaptic terminal. Upon absorbing a photon, the 11-*cis*-retinaldehyde in a visual pigment molecule isomerizes to all-*trans*-retinaldehyde, as a result of which the opsin moiety undergoes several extremely rapid conformational changes, one of which (meta-II state) is catalytically active. It activates a G protein called transducin, which in turn stimulates a cGMP-phosphodiesterase to hydrolyze cGMP. As a result, the free cGMP concentration decreases, and the cGMP-gated channels close, producing a membrane hyperpolarization that reduces or completely stops neurotransmitter release from the synapse. This signal is picked up by the second-order retinal neurons. The inward, depolarizing membrane current through the open cGMP-gated channels in darkness in part involves Ca^{2+} (the rest is mostly Na^{+}), which is steadily pumped out of the cell by an antiporter involving exchange of external Na^{+} for internal Ca^{2+} and K^{+}. The dark Ca^{2+} influx decreases or stops in the light because the cGMP-gated channels close, but the Ca^{2+} efflux through the Na/Ca,K exchange continues, as a

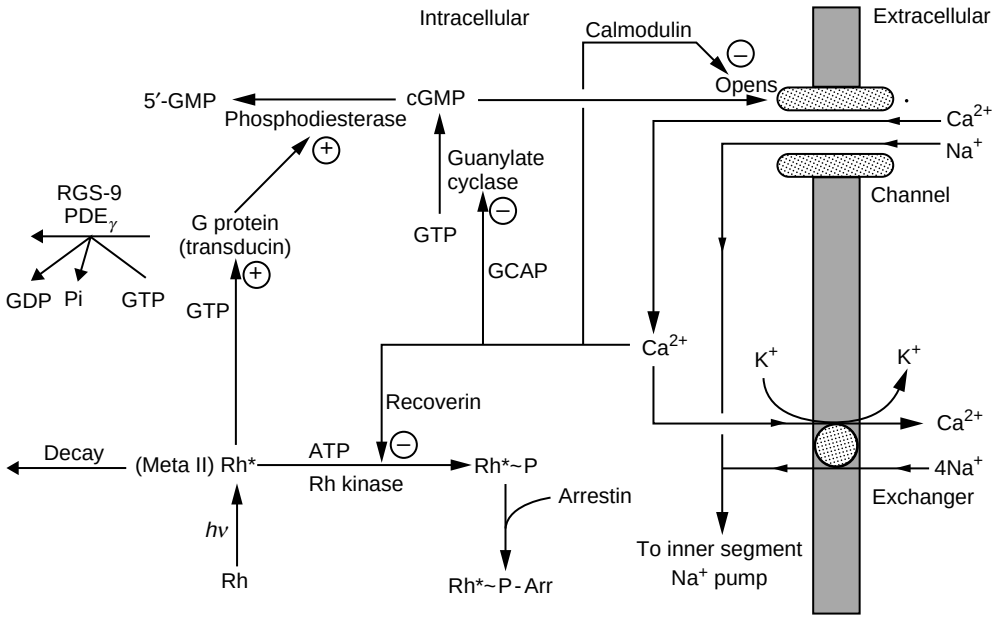

FIGURE 2 Phototransduction mechanism underlying the light response in rods. GCAP, guanylate-cyclase-activating protein; *hν*, photon; Rh, rhodopsin; Rh*, photoactivated rhodopsin; Rh* ~ P, phosphorylated form of rhodopsin; RGS-9, regulator of G protein-signaling isoform 9; PDE_{γ}, inhibitory (γ) subunit of the phosphodiesterase; +, stimulation or positive modulation; −, inhibition or negative modulation. Modified from Koutalos, Y., and Yau, K.-W. (1996). Regulation of light sensitivity in retinal rods. *Trends Neurosci.* **19**, 73–81, with permission from Elsevier.

result of which the free Ca^{2+} in the outer segment decreases. This Ca^{2+} decrease triggers negative feedback on multiple targets in the phototransduction machinery, leading to an attenuation of the initial cGMP decrease induced by light, and hence reopening of some of the cGMP-gated channels. This negative feedback constitutes the key mechanism for light adaptation by the photoreceptor, and is particularly important for cones because they function in bright light. The active, meta-II state of the pigment is deactivated by phosphorylation followed by binding of a protein called arrestin, which caps the pigment activity. After a delay, the meta-II decays into the inactive meta-III state and eventually splits into apo-opsin and all-*trans*-retinaldehyde (i.e, the pigment is bleached). The latter is reduced to all-*trans*-retinol (i.e., the corresponding alcohol), then leaves the photoreceptor to the neighboring retinal pigment epithelial cells, where all-*trans*-retinol is reisomerized/reoxidized to 11-*cis*-retinaldehyde. The 11-*cis*-retinaldehyde returns to the rod and cone outer segments, where it recombines with opsin to form a functional pigment molecule again.

Retinal Nonrod / Noncone Photoreceptors

Very recently, a different class of retinal photoreceptors has been discovered. These are a small subset of retinal ganglion cells, third-order retinal neurons that send light signals to the brain via their axons (optic-nerve fibers). The activity of the great majority of retinal ganglion cells is synaptically driven by the second-order retinal neurons, which in turn receive inputs from rods and cones. About 1% of the ganglion cells, however, are also intrinsically photosensitive. They express an opsin-like protein, melanopsin, which may or may not be the photopigment that makes these cells photosensitive (Figure 3). Light depolarizes these cells, leading to the firing of action potentials. The phototransduction mechanism underlying this depolarizing response is still unknown. While most retinal ganglion cells convey light information for image-forming vision, such as used in the detection and recognition of objects, the intrinsically photosensitive ganglion cells convey light information for nonimage-forming (accessory) visual functions, such as circadian photoentrainment and the pupillary light reflex. Accordingly, their axons project primarily to brain nuclei involved in these functions.

Parietal-Eye Photoreceptor

The parietal-eye photoreceptor bears remarkable morphological similarity to rods and cones (especially cones).

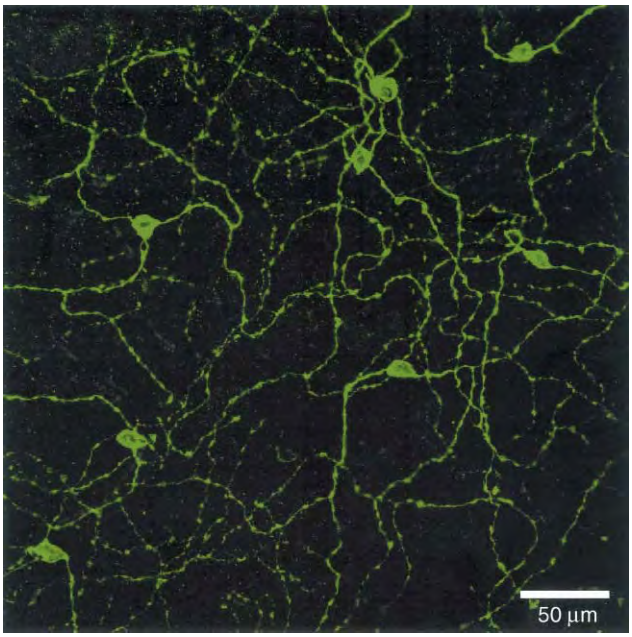

FIGURE 3 Immunofluorescent labeling of a flat-mounted rat retina with an antimelanopsin antibody. Green color shows the labeling. Stacked confocal images. (Reproduced from Hattar, S., Liao, H.-W., Takao, M., Berson, D. M., and Yau, K.-W. (2002). Melanopsin-containing retinal ganglion cells: Architecture, projections and intrinsic photosensitivity. *Science* **295**, 1065–1070, with permission.)

However, there are several interesting differences between them and rods and cones. First, even in isolation, the parietal-eye photoreceptor continues to respond to light after intense illumination, suggesting that there is a chromophore-recycling system within the cell that allows autonomous pigment regeneration. Second, there appear to be two pigments in the same cell, optimally responding to blue and green light, respectively. The green pigment when active depolarizes the cell, whereas the blue pigment when active hyperpolarizes the cell. The phototransduction mechanism is very similar to that in rods and cones, except that, although the blue pigment activates a cGMP-phosphodiesterase, the green pigment inhibits it. Thus, there is a chromatic antagonism in a given cell. Depending on the relative intensities of green and blue light, the cGMP level rises or falls, causing the cGMP-gated channels to open or close, hence a depolarization or hyperpolarization. The exact function of the parietal eye is unclear, but may also have to do with circadian photoentrainment.

Pineal Photoreceptors

In birds and fish, the pineal gland is photosensitive. Morphologically, the pineal photoreceptors roughly resemble rods and cones. Light elicits a hyperpolarizing response from these cells, with an underlying

transduction mechanism also similar to that in rods and cones.

Deep-Brain Photoreceptors

At least in birds, there is evidence that certain cells in the brain are intrinsically photosensitive. Also, immunocytochemistry and *in situ* hybridization studies suggest that opsin proteins are present in small populations/ clusters of neurons in the diencephalon. No other details are known at present.

Photosynthesis

Richard C. Leegood
University of Sheffield, Sheffield, UK

Photosynthesis involves the capture of the Sun's energy into biochemical energy that sustains all life on Earth. It is a massive process that has radically changed the composition of the atmosphere. Its scale can be judged from the fact that man's entire fossil fuel use from 1860 to 1988 was equivalent to only two years' global photosynthesis. Although photosynthesis occurs in a wide range of organisms (bacteria, cyanobacteria, algae, and plants), and about a third of it occurs in the oceans, the present discussion will concentrate on plants.

Photosynthetic Structures

Leaves contain many different types of cell, including stomata, which regulate gas exchange through the epidermis, and the photosynthetic palisade and mesophyll cells, which are thin-walled and have abundant air spaces for the diffusion of gases. Chloroplasts are the organelles which carry out photosynthesis within these cells. The chloroplast has a double-membrane envelope, which regulates transport of metabolites and proteins with the cytosol. It contains thylakoids, a system of membranes, which contain the components of photosynthetic light harvesting (including chlorophyll), electron transport, and ATP synthesis. The thylakoids form sacs with an internal lumen. Thylakoid sacs can occur singly or in stacks, called grana, which resemble a pile of coins. The soluble phase of the chloroplast is the stroma, which contains enzymes of a wide range of biosynthetic processes (Figure 1).

Harvesting Light

Light Harvesting

The first step in photosynthesis is light absorption by pigments. Besides various types of chlorophyll, these pigments include carotenoids, and open-chain tetrapyrrole bilin pigments found in, for example, cyanobacteria. Chlorophyll is a pigment based on a tetrapyrrole ring, rather like hemoglobin, except that it contains magnesium rather than iron. The ring is linked to a long side chain. Chlorophyll absorbs blue and red light, while it transmits the green, and hence appears green. In plants, two types of chlorophyll, *a* and *b*, increase the range of wavelengths absorbed. The light energy absorbed by chlorophyll molecules can either be lost as heat or fluorescence, or it can be transferred between adjacent chlorophyll molecules by resonance transfer. Chlorophyll and carotenoids associate with proteins in light-harvesting complexes. The light-harvesting complexes are doughnut shaped in bacteria, probably surrounding the reaction center. A light-harvesting complex acts like an antenna, similar to a satellite dish, feeding photons into the reaction centers, which contain a dimeric form of chlorophyll, where charge separation occurs. The concept of an antenna arose from the discovery in 1932, by Emerson and Arnold, that only one CO_2 molecule was produced from ~2500 chlorophyll molecules after a short flash of light.

At a higher level of organization, the leaf and its cells are also adapted to harvest light efficiently. In shade, the photosynthetic apparatus is spread out in large thin leaves, to increase the area of light capture and to allow light to penetrate adequately, and there is more light-harvesting chlorophyll per antenna. Within the leaf, epidermal cells can act to focus light, elongated palisade cells act as light guides, while mesophyll cells reflect light, acting like a "hall of mirrors" and increasing the distance that photons travel, thereby increasing the chance that they will hit an antenna complex.

Energy Capture

Reaction centers are multisubunit protein complexes situated in the photosynthetic membrane. These complexes contain the reaction center chlorophylls as well as other components involved in electron transfer. The reaction center is the core of the photosynthetic process, converting the energy of sunlight into a usable chemical form. Reaction centers carry out light-driven electron transfer reactions that result in charge separation across the photosynthetic membrane. Rapid electron transfer to secondary acceptors is necessary to prevent recombination of these separated charges. There are two classes of reaction center with different terminal electron acceptors: those with Fe_4S_4 clusters (type 1) and those

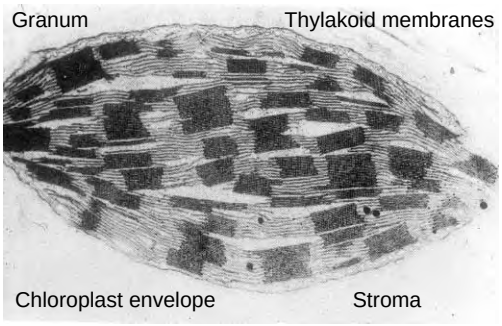

FIGURE 1 Electron micrograph of a chloroplast from maize.

with pheophytin/quinones (type 2). In plants, green algae and cyanobacteria, both reaction centers are present (in photosystems 1 and 2 respectively), while photosynthetic bacteria have only one type of reaction center (e.g., type 1 in green sulfur bacteria, type 2 in purple bacteria). In plants, photosystem 2 contains a chlorophyll dimer which, when in the excited state ($P680^*$), is an extremely strong reducing agent. An acceptor molecule, a quinone, Q, becomes reduced, leaving the positively charged chlorophyll dimer ($P680^+$). This is an extremely strong oxidant, so strong that it can extract electrons from water.

Water Oxidation

Water oxidation is a unique feature of photosystem 2. Water is the electron donor for photosynthetic electron transport. Each photon absorbed by P680 enables it to extract one electron from a manganese-containing enzyme, in an oxygen-evolving complex. Once four electrons have been extracted, this complex can, in turn, oxidize water, releasing O_2 to the atmosphere, as well as releasing $4H^+$ to the thylakoid lumen. Photosynthetic bacteria utilize other sources, such as H_2S or organic compounds, as electron donors.

Energy Dissipation and Repair

In addition to acting as accessory pigments in the antenna, carotenoids also have a photoprotective function. When there is an excess of light energy (e.g., when CO_2 uptake is limited by stomatal closure brought about by water stress), carotenoids can quench the excited triplet state of chlorophyll before it reacts with oxygen, forming destructive singlet state oxygen. Carotenoids can also regulate energy flow in the antenna by dissipating excitation of the chlorophylls as heat (nonphotochemical chlorophyll fluorescence quenching). Energy dissipation is associated with the accumulation of the carotenoid, zeaxanthin, which is interconverted with another carotenoid, violaxanthin, in the xanthophyll cycle. Physical changes, such as chloroplast movements within cells and heliotropic leaf movements, can also reduce or enhance light absorption, and photorespiration can dissipate excess photosynthetic energy. Photosystem 2 itself is very prone to photodamage, with one of its components, the D1 protein, undergoing constant turnover. The photosystem 2 complex is continuously disassembled and reassembled to insert repaired D1.

Electron Transport and ATP Synthesis

There are two photosystems, 1 and 2, involved in photosynthesis in plants, algae, and cyanobacteria. The structures of both have been determined. In 1960, Hill and Bendall published the "Z" scheme, which describes how the two photosystems and the electron carriers are organized with respect to their redox potentials (Figure 2). Electrons from photosystem 2 reduce a number of intermediate electron carriers, such as plastoquinone (PQ), the cytochrome *b/f* complex (including the Rieske iron-sulfur center) and plastocyanin (PC). The reaction center of photosystem 1 (P700) receives its electrons from photosystem II via these carriers and thus oxidizes Q. Photosystem 1 reduces an initial acceptor, A_o, then a series of Fe–S acceptors and ferredoxin (Fd, another iron–sulfur protein) and, finally, NADP is reduced to NADPH. Electrons may also cycle around photosystem 1, leading to ATP generation, as also occurs in some photosynthetic bacteria.

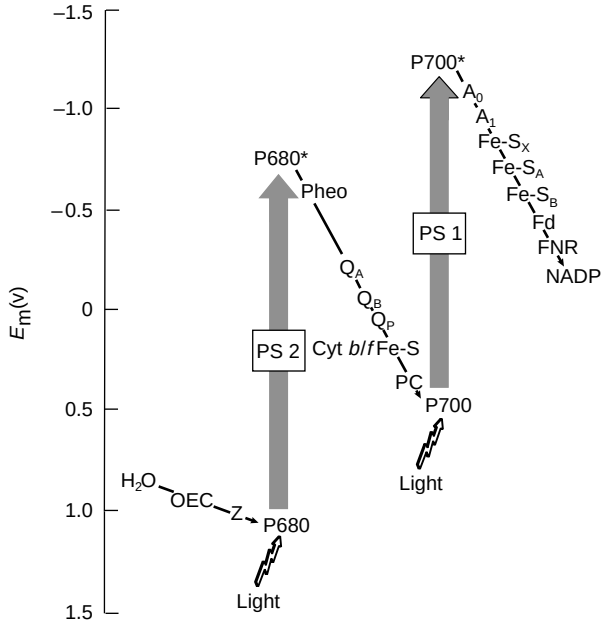

FIGURE 2 The Z-scheme of photosynthetic electron transport, showing the mid-point redox potentials of electron donors, acceptors, and carriers.

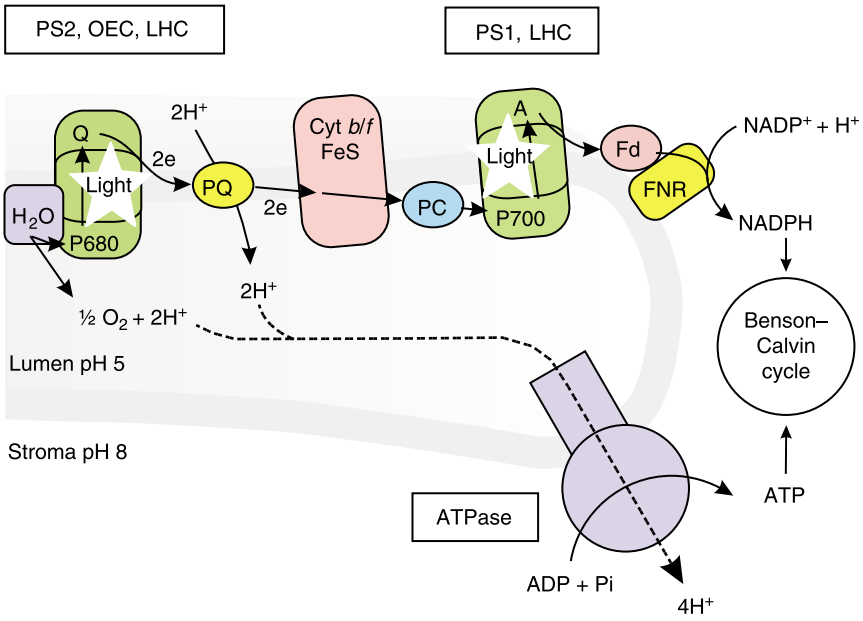

FIGURE 3 Organization of photosynthetic electron transport within the thylakoid membrane, showing how proton production and translocation generates a proton gradient between the thylakoid lumen and the stroma.

Electron transport components are organized within the thylakoid membrane so that, as electrons flow from water to NADP, protons are transferred from the stroma to the thylakoid lumen (Figure 3). This is possible because the key component linking the two photosystems is PQ which is a hydrogen carrier, carrying both an electron (e) and a proton (H^+). Electrons from photosystem II reducePQ, together with protons from the stroma, while oxidation of PQ releases electrons to the cytochome *b/f* complex and protons to the thylakoid lumen. This proton shuttle is driven by photosynthetic electron transport. Protons are also released to the thylakoid lumen when water is oxidized. These processes decrease the pH in the stroma (from pH 7 in the dark to pH 8 in the light) and acidifies the lumen (to ~pH 5). A pH gradient is therefore created which is used to drive ATP synthesis (chemiosmosis). For each molecule of ATP synthesized, $4H^+$ move from the lumen to the stroma. Movement of protons through the ATPase causes its central crankshaft-like core to rotate. This rotational movement causes conformational changes in the active sites of other subunits which result in the synthesis of ATP from ADP and Pi.

Carbon Fixation and Photorespiration

The chloroplast is one of the plant cell's most important factories. ATP and NADPH are utilized to drive biosynthetic processes in the chloroplasts, including the reduction of sulfate and nitrite and the synthesis of lipids and amino acids, in addition to CO_2 fixation.

Benson–Calvin Cycle

Although often termed the "dark reaction" of photosynthesis, CO_2 fixation can only proceed in the light, both because it requires photosynthetically-generated ATP and NADPH and because many of the enzymes which catalyze the process are themselves activated by light. The Benson–Calvin cycle (or Reductive Pentose Phosphate Pathway) is the only mechanism in plants and algae which can catalyze the net fixation of CO_2, although some bacteria have an alternative mechanism. The Benson–Calvin cycle (Figure 4) was discovered in the early 1950s by Melvin Calvin and co-workers, who supplied algae, such as *Chlorella*, with $^{14}CO_2$. The first product of photosynthesis, containing 100% of the radioactivity at zero time, was a three-carbon compound, glycerate 3-phosphate (hence the term C_3 plants). The primary acceptor was identified as ribulose 1,5-bisphosphate (RuBP). RuBP is a five-carbon sugar phosphate which is carboxylated to form two molecules of glycerate-3-P. The Benson–Calvin cycle comprises three phases: (1) carboxylation by ribulose 1,5-bisphosphate carboxylase-oxygenase (Rubisco); (2) reduction of glycerate-3-P to triose-P (which requires ATP and NADPH); and (3) regeneration of the acceptor, RuBP, from triose-P in a "sugar-phosphate shuffle," which requires ATP. Triose-P is a simple sugar phosphate produced by the Calvin cycle. Triose-P that is not

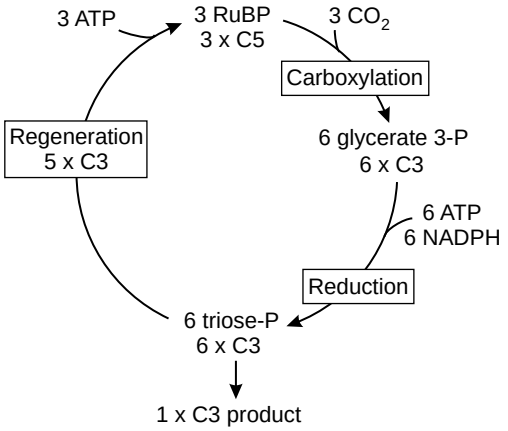

FIGURE 4 A simplified scheme for the Benson–Calvin cycle, showing the carboxylation of RuBP by Rubisco, reduction of glycerate 3-P to triose-P, and regeneration of the initial acceptor from triose-P.

needed for regeneration of RuBP can either be converted to starch in the chloroplast or it can be exported to the cytosol, via the phosphate translocator, to make sucrose.

Photorespiration

Rubisco is an inefficient enzyme. It has a slow catalytic turnover rate, and about half the soluble protein in leaves is Rubisco, making it the most abundant protein in nature.

$$\text{RuBP} + \text{O}_2 \xrightarrow{\text{RuBP oxygenase}} \text{glycerate-3-P} + \text{glycollate-2-P}$$

Rubisco also catalyzes a side-reaction with oxygen, an inevitable consequence of its reaction mechanism. Rubisco evolved in the photosynthetic bacteria in an atmosphere which was richer in CO_2 and depleted in O_2 by comparison with the present atmosphere. The ratio of oxygenation to carboxylation by Rubisco depends upon the relative concentrations of CO_2 and O_2 and oxygenation increases as the temperature increases. Photorespiration is the process by which two molecules of glycollate-2-P, which is not a metabolite of the Benson–Calvin cycle, are retrieved and converted into two molecules of an amino acid, glycine (C2), and then into one molecule of glycerate-3-P (C3). This involves shuttling of metabolites between the chloroplasts, cytosol, peroxisomes, and mitochondria. During this process, one quarter of the carbon in glycollate-2-P is lost as CO_2 and ammonia is liberated. Photorespiration is therefore a wasteful process because it both reduces carbon gain and dissipates photosynthetic energy (because CO_2 is fixed and released again). There is, therefore, a selection pressure on plants to reduce the rate of photorespiration by means of CO_2-concentrating mechanisms, so as to improve their carbon economy. This will be particularly strong when high rates of photorespiration are favored, as at high temperatures. However, a future doubling of ambient CO_2 will reduce photorespiration by ~50% and it would be completely eliminated by a 5-fold rise in atmospheric CO_2.

CO_2-Concentrating Mechanisms

C_4 Photosynthesis

C_4 plants include many tropical grasses and are among the world's most important crop species (maize, sugar cane). Although small in terms of total number of flowering plant species (3%), they constitute ~50% of the 10,000 grass species. Their productivity is high and C_4 grasses in savanna regions (15% of the Earth's vegetated surface) are responsible for ~20% of global photosynthesis. C_4 plants have a distinctive leaf anatomy (Kranz anatomy), with chlorophyll-containing mesophyll and bundle-sheath cells, which form a gas-tight cylinder surrounding the vascular bundle. A CO_2 pump (the C_4 cycle) takes CO_2 from the mesophyll and transfers it into the bundle-sheath, which contains Rubisco and the enzymes of the Benson–Calvin cycle (Figure 5). The process raises the concentration of CO_2 in the bundle-sheath, sufficient to saturate Rubisco with CO_2 and to eliminate photorespiration. Like all pumps, the C_4 cycle requires an input of energy in the form of ATP. Recently, two terrestrial plants have been shown to have single-celled C_4 photosynthesis.

The mechanism of photosynthesis in C_4 plants was elucidated in the 1960 s by Hatch and Slack in Australia. C_4 plants are so-called because the first product of CO_2

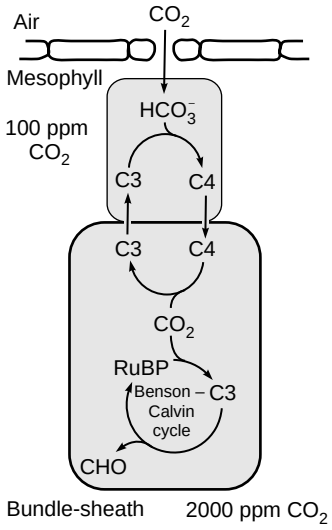

FIGURE 5 A simplified scheme for the mechanism of C_4 photosynthesis, showing how the C_4 cycle shuttles C_4 acids into to bundle-sheath, where they are decarboxylated to raise the CO_2 concentration in the vicinity of Rubisco and thereby suppress photorespiration.

fixation is a C4 organic acid, oxaloacetate, formed by the carboxylation of phosphoenolpyruvate (PEP) by PEP carboxylase. The oxaloacetate is converted to other C4 acids (malate or aspartate) and transferred to the bundle-sheath. Transport of metabolites between the mesophyll and bundle-sheath occurs by diffusion via plasmodesmata. In the bundle-sheath, the C4 acids are decarboxylated to generate CO_2, and a C3 compound returns to the mesophyll. The mechanism of decarboxylation differs, with NADP-malic enzyme in the chloroplast (maize), NAD-malic enzyme in the mitochondria (millet), or PEP carboxykinase in the cytosol (e.g., guinea grass).

C_4 plants are commonly found in warm-to-high temperature environments, such as tropical grasslands, where photorespiratory rates would be high in C_3 plants. C_4 plants have double the water-use efficiency of C_3 plants because photosynthesis can operate at low intercellular concentrations of CO_2, and hence lower stomatal conductances. Nitrogen-use efficiency is also improved because Rubisco is used more efficiently, due to the suppression of photorespiration.

Aquatic Photosynthesis

The aquatic environment poses serious problems for the acquisition of CO_2. First, the diffusion of CO_2 in water is 10 000 times slower than in air. Second, inorganic carbon is present in water as CO_2, HCO_3^- and CO_3^{2-}, the relative amounts of which depend upon the pH of the water. Most inorganic carbon in alkaline waters is therefore present as carbonate and bicarbonate. Photosynthesis by aquatic plants, algae, and phytoplankton may raise the local O_2 concentration and enhance photorespiration. Aquatic organisms (cyanobacteria, micro- and macro-algae, aquatic angiosperms) have developed means of taking up dissolved inorganic carbon (CO_2 and HCO_3^-) actively from their environment. They can concentrate it internally in Rubisco-containing structures, such as carboxysomes and pyrenoids, and thus suppress photorespiration.

Crassulacean Acid Metabolism

Leaves are faced with a difficult task. Leaf cells have thin walls and the intercellular spaces are saturated with water vapor. As leaves assimilate CO_2 (5 000 litres of air are needed to manufacture 1 g of sucrose), they need to restrict the amount of water lost from the leaf via the stomata. There is therefore a conflict between the requirements for CO_2 fixation and water conservation. Crassulacean acid metabolism (CAM) is a photosynthetic adaptation to periodic water supply, occurring in plants in arid regions (e.g., cacti) or in tropical epiphytes (e.g., orchids and bromeliads). CAM plants close their stomata during the day and take up CO_2 at night, when the air temperature is lower. Water loss can be lowered by an order of magnitude. CAM occurs in between 5% and 10% of plants and is always associated with succulence, at least at a cellular level.

Although the biochemistry is similar to that of C_4 plants, two carboxylations are now separated in time rather than in space. Malic acid is synthesized from carbohydrates, via PEP carboxylase, at night and is stored in the vacuole. During the day malate is decarboxylated, via PEP carboxykinase or NAD(P)-malic enzymes in the cytosol, CO_2 is refixed via the Benson–Clavin cycle, and carbohydrates are reformed. This process occurs behind closed stomata. The internal concentration of CO_2 is raised as high as 10 000 ppm, which also suppresses photorespiration. CAM plants show a high degree of metabolic flexibility. Seedlings and well-watered plants may show little or no CAM and perform C_3 photosynthesis, opening their stomata during the day. This allows increased carbon gain during periods of water availability or during seedling establishment. Water or salt stress can then induce CAM, switching on gene expression for synthesis of the component enzymes.

Biography

Richard C. Leegood is a Professor of Plant Sciences in the Department of Animal and Plant Sciences and a member of the Robert Hill Institute for Photosynthesis Research at the University of Sheffield, U.K. His principal research interests are carbon and nitrogen metabolism and their regulation in plants. He holds a Ph.D. from the University of Cambridge. He has authored and edited several texts and many review articles in the field of photosynthesis and metabolism.

Photosynthetic Carbon Dioxide Fixation

Matthew J. Paul
Rothamsted Research, Harpenden, UK

Photosynthetic carbon dioxide fixation is the point of entry of carbon into organic molecules. Light provides the energy (ATP) and reducing power (NADPH) from electron flow in chloroplasts for CO_2 to be reduced to triose phosphate in reactions of the Calvin cycle. The cycle is the starting point for the synthesis of sugars, amino acids, and other plant products. Accompanying the provision of ATP and NADPH in light reactions of photosynthesis is the production of O_2. Thus, photosynthesis generates organic molecules that underpin all biology and agriculture and provides the necessary oxygen that also enables aerobic respiration to proceed for them to be metabolized in the growth and maintenance of all living things. In Earth's early history, photosynthesis enabled the evolution of complex multicellular life forms and continues till today to regulate the gas composition of the atmosphere and hence climate.

Light Provides Energy (ATP) and Reducing Power (NADPH) for CO_2 Fixation

Photons in the range 400–700 nm – except green light, which is reflected – drive photosynthesis through provision of ATP and NADPH. Light also regulates the Calvin cycle in other ways. Photons interact with electrons in chlorophylls of light-harvesting antenna in thylakoid membranes of chloroplasts. There are two light-absorbing photosystems that cooperate in the reduction of NADP by electrons derived from water. Energy is passed from these to reaction centers of photosystem II, where electrons are excited and passed to an acceptor and down an electron transport chain to photosystem I. Electrons and protons pass to NADP, yielding NADPH. The open reaction of photosystem II is filled with electrons from water, from which O_2 is evolved. A pH gradient across the thylakoid membrane from H^+ accumulation in the thylakoid lumen provides the impetus for ATP synthesis by ATP synthase (Figure 1).

The Path of Carbon in Photosynthesis

The sequence of reactions that fix CO_2 into triose phosphate using ATP and NADPH from these light reactions was determined using C14 radioisotopes by Melvin Calvin and colleagues, for which the Nobel prize for chemistry was awarded. This sequence of reactions is now known as the Calvin cycle, reductive pentose phosphate pathway, or photosynthetic carbon reduction cycle. It consists of three distinct phases. First, the fixation of CO_2 into 3-phosphoglyceric acid (3-PGA) (carboxylation). Second, the reduction of 3-PGA into the triose phosphate, glyceraldehyde-3-phosphate (GAP), which can be exported to the cytosol for sucrose synthesis or remain in the chloroplast for starch synthesis or the other biosynthetic reactions that occur there. Triose phosphate also has to remain in the cycle to allow regeneration of the CO_2 acceptor, ribulose 1,5-bisphosphate (RuBP), in the third, regenerative phase of the cycle (Figure 2).

Carboxylation Phase

Carboxylation is catalyzed by the Earth's most abundant protein, ribulose bisphosphate carboxylase/oxygenase (Rubisco), which can constitute up to 50% of the soluble protein in a leaf. The combination of CO_2 with RuBP, a five-carbon compound, yields two molecules of the three carbon compound 3-PGA. Many enzymes will bind molecules in addition to the ones they have primary affinity for, if they are present at high enough concentrations. Present-day atmospheric O_2 concentration is a thousand times higher than that of CO_2 and in ambient conditions oxygenation of RuBP also occurs. This produces phosphoglycolate which is metabolized in the glycolate pathway outside the chloroplast and returned to the Calvin cycle as 3-PGA in a process termed photorespiration because CO_2 is evolved in the process (Figure 1). Some plants have evolved a supplementary

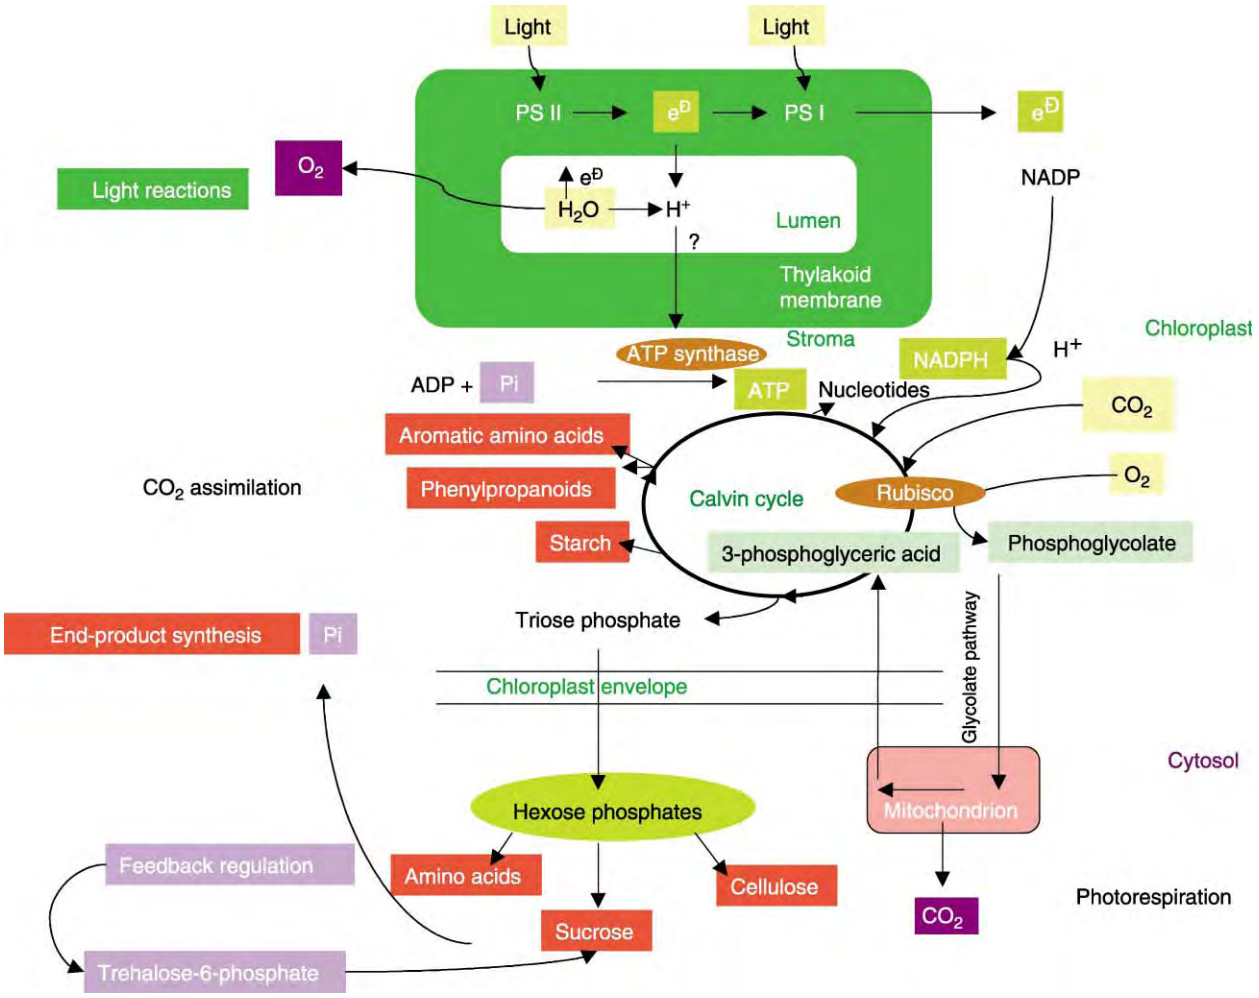

FIGURE 1 Schematic of photosynthetic metabolism summarizing the principal components of light reactions, CO_2 fixation into the Calvin cycle and the synthesis of end products.

carboxylation reaction catalyzed by phosphoenol pyruvate carboxylase where minimal oxygenation occurs. Such plants are known as C4 plants because the first products of CO_2 fixation are carboxylic acids containing four carbon atoms. A high concentration of CO_2 generated from the decarboxylation of these acids at the site of the Calvin cycle minimizes the oxygenation reaction of Rubisco and hence suppresses photorespiration. Other specialized plants known as Crassulacean acid metabolism (CAM) plants fix CO_2 into C4 acids at night. These metabolic adaptations of C4 and CAM ensure a high intercellular CO_2 concentration which maintains a small stomatal aperture, conserving water, an overriding selection force in some environments. In CAM plants stomata can be shut for much of the day and is observed in more extreme xerophytes such as cacti and succulents. C4 grasses are very common in Australia. More recent evolution has resulted in these adaptations rather than large modification of the properties of Rubisco to further favor carboxylation rather than oxygenation. Instead Rubisco has been the target of biotechnologists to improve photosynthesis. However, altering Rubisco properties more in favor of carboxylation has proved technically demanding and is being superseded by other strategies of enhancing photosynthesis.

Reduction Phase

The 3-PGA produced in the carboxylation phase (and returned from photorespiration) is reduced to triose phosphate, GAP, in two steps. The first, a phosphorylation step, requires ATP. The 1,3-bisphosphoglycerate formed is then reduced with NADPH to GAP. The high ATP and NADPH concentrations associated with photosynthesis shift these reactions in favor of triose phosphate.

Regeneration Phase

Triose phosphate is essentially the end product of photosynthesis as it is exported from the chloroplast.

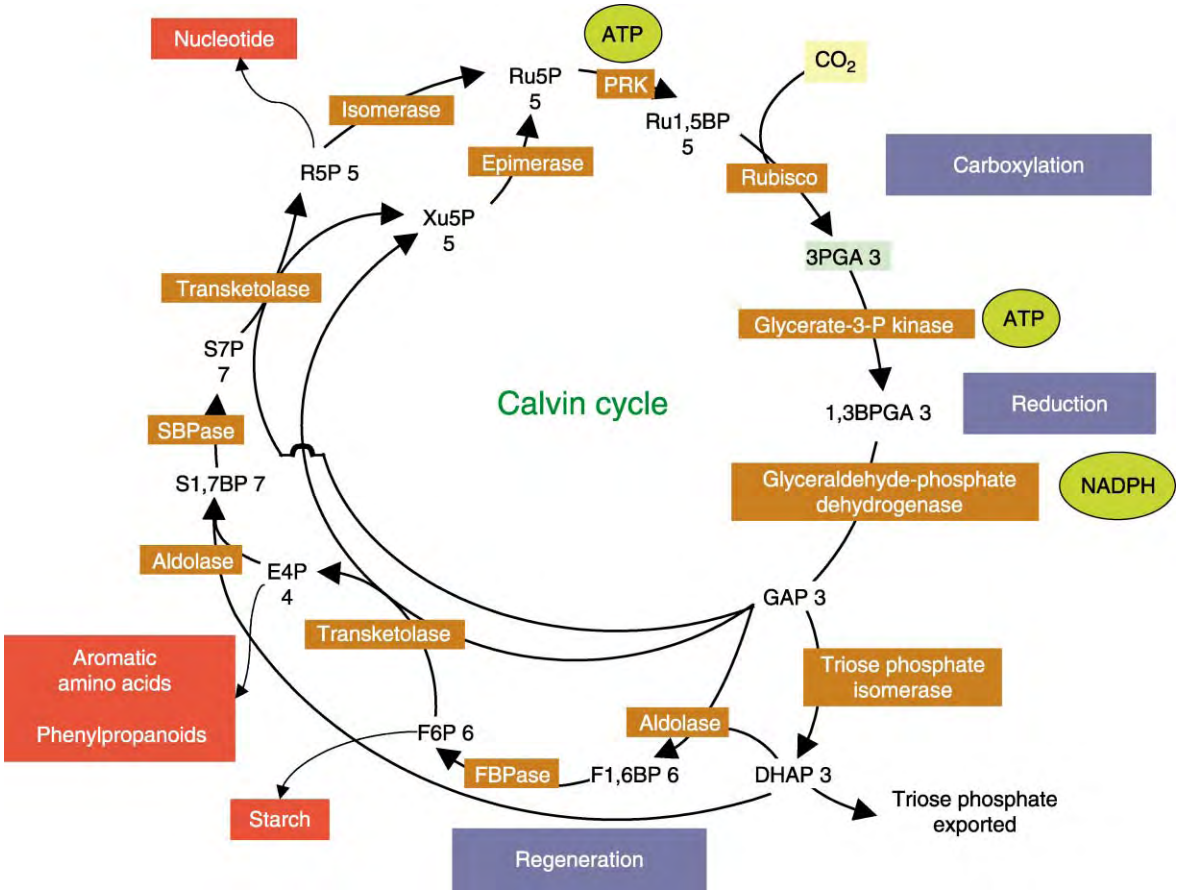

FIGURE 2 Calvin cycle of reactions that incorporate CO_2 into triose phosphate and which regenerate ribulose-1,5-bisphosphate (Ru1,5BP) for continued CO_2 fixation. Numbers after compounds indicate number of carbon atoms. 3-PGA, 3-phosphoglyceric acid; 1,3 BPGA, 1,3 bisphosphoglyceric acid; GAP, glyceraldehydes-3-phosphate; DHAP, dihydroacetone phosphate; F1,6BP, fructose-1,6-bisphosphate; F6P, fructose 6-phosphate; E4P, erythrose-4-phosphate; S1,7BP, sedoheptulose-1,7-bisphosphate; S7P, sedoheptulose-7-phosphate; R5P, ribose-5-phosphate; Ru5P, ribulose-5-phosphate; Xu5P, xylulose-5-phosphate. Enzymes are Rubisco, ribulose-1,5-bisphosphatase; FBPase, fructose-1,6-bisphosphatase; SBPase, sedoheptulose-1,7-bisphosphatase; PRK, phosphoribulokinase.

However, some must be retained in the cycle to resynthesize the acceptor molecule for CO_2 fixation, RuBP to keep the cycle going. In this series of reactions, five trioses are converted into three pentoses. The first part involves the conversion of GAP to fructose-6-phosphate (F6P). Then the carbon atoms in F6P, GAP, and dihydroxyacetone phosphate are rearranged into the pentose, ribulose-5-phosphate (Ru5P). In the final step Ru5P is converted to RuBP in an ATP-requiring step. Like the rest of the cycle this phase is highly regulated and can strongly affect the ultimate rate of CO_2 fixation. An important branch point in this segment of the cycle, catalyzed by transketolase links primary and secondary metabolism. The substrates and products of transketolase can supply carbon (erythrose-4-phosphate) for the synthesis of aromatic amino acids and phenylpropanoids (compounds important for flavor, texture, color), nucleotide synthesis (R5P), and starch (F6P) in addition to the regeneration of RuBP.

Regulation of the Calvin Cycle

Metabolic regulation enables the balance between substrate and product of enzyme-catalyzed reactions to be maintained so that ordered metabolic flow to sustain life can occur in response to developmental requirements and environmental constraints. The Calvin cycle is regulated by light which ensures its temporal separation and prevents competition with other reactions, such as the oxidative pentose phosphate pathway, also present in the chloroplast stroma. Light regulates the cycle through provision of ATP and NADPH, which regulate those steps dependent on them. Light also causes an increase in the pH of the chloroplast stroma to ~8, the pH optimum for Calvin cycle enzymes. Pumping of protons into the thylakoids is also coupled with flow of magnesium necessary for enzyme activity into the stroma. A further way that light regulates the cycle is through photosynthetic electron transport. Reducing equivalents from photosystem I via ferredoxin-thioredoxin reductase

reduce the thiol groups of GAP dehydrogenase (GAPDH), fructose-1,6-bisphosphatase (FBPase), sedoheptulose-1,7-bisphosphatase (SBPase) and phosphoribulokinase (PRK) increasing their activity. Rubisco is activated by CO_2 and magnesium in a process called carbamylation, a process promoted by an activating protein, Rubisco activase. Enzymes of the Calvin cycle are associated as enzyme complexes. For example GAPDH and PRK are linked by the protein CP12. The precise role of this association of such complexes is not yet known, but is likely to facilitate further regulation of metabolic flow.

Are Some Calvin Cycle Enzymes More Important in Regulating Carbon Flux than Others?

The equilibrium position of reactions catalyzed by Rubisco, SBPase, FBPase, and PRK as a consequence of their regulation lies very much in favor of the end-product. These enzymes are termed irreversible enzymes because of the large amount of energy that would be required to reverse the reaction. Such enzymes have traditionally been seen as key enzymes because of their importance in directing carbon flow. Since the early 1990s genetic modification has enabled individual enzymes to be targeted through use of antisense RNA to decrease the synthesis of target proteins. Lines of transgenic plants exhibiting progressive decreases in activity of an enzyme has enabled metabolic control analysis to be undertaken and flux control coefficients for individual enzymes assigned. For the Calvin cycle a change in enzyme activity can then be related to flux through the pathway by measuring CO_2 uptake by leaves using infra-red gas analysis. The flux control coefficient is given as $C = \delta J/J$, where J is original flux, and δJ is changed flux. This coefficient can also be written as $C = \delta E/E$, where E is original enzyme activity, and δE is changed enzyme activity.

So, if a 50% decrease in enzyme activity achieves a 25% decrease in CO_2 uptake then the flux control coefficient is 0.5 (25/50); essentially half the control of the pathway resides with that enzyme. If a 50% decrease achieves no change in flux then the flux control coefficient is zero and the enzyme is in excess under those conditions. Over the course of a day, and during the life cycle of a plant, an enzyme may exhibit a range of flux control coefficients. Variation during the course of a day will be caused largely by changes in illumination, whereas over the life cycle by nitrogen availability and changes in light environment. Both light and nitrogen affect the amount of enzyme synthesized and light affects enzyme activity to different extents for different enzymes, so relative contributions to flux control change. Other aspects of environment, for example temperature and phosphorus nutrition are also influential.

Calvin Cycle Enzymes that Most Limit Flux

The first enzyme for which detailed flux control analysis was conducted using transgenics was Rubisco. Quite surprisingly at the time, in view of the perceived importance of the enzyme, the first data showed that removing half of it with antisense resulted in little change in CO_2 fixation. However, when plants were grown at high light the flux control coefficient rose, and combined with low nitrogen, could reach 0.8. Rubisco is the enzyme that imposes the greatest potential limitation of Calvin cycle carbon fixation. SBPase is another enzyme with a potentially high flux control coefficient at high light. A major surprise was that nonregulated equilibrium enzymes, aldolase, and transketolase could have flux control coefficients around 0.3 under high light conditions. Other enzymes in the cycle when decreased up to 50% have showed no large impact on flux. The most extreme example of this is phosphoribulokinase, where a decrease up to 85% has no impact on CO_2 fixation.

The important message to come from this work is that both highly regulated and unregulated equilibrium enzymes could control flux. The work supported the von Caemmerer and Farquhar 1981 model, which proposed that photosynthesis was colimited between carboxylation (Rubisco activity) and the capacity to regenerate ribulose-1,5-bisphosphate. Control was seen as poised between carboxylation and regeneration, but under saturating light the balance would shift toward Rubisco and under low light toward regeneration. The research using antisense confirmed this assumption and gave useful indications as to which enzymes in the regeneration phase would be most likely to increase rates of CO_2 fixation if their activities could be increased. Thus, there would most likely be benefit if one or more of activities of SBPase, aldolase, or transketolase could be increased.

Genetic Modification of Photosynthesis to Improve Growth and Yield

Direct Targeting of Calvin Cycle

In support of the findings of flux control analysis, expression of a bifunctional SBPase/FBPase from a cyanobacterium resulted in increased photosynthesis and biomass production. This was the first report of an increase in activity of one or more Calvin cycle enzymes

benefiting photosynthesis and biomass production. There is also evidence that overexpressing the plant SBPase improves photosynthetic rates. Improved photosynthesis has also been achieved through expressing a cyanobacterial gene in plants involved in HCO_3^- accumulation which releases CO_2 within the leaf for CO_2 fixation and hence improves carboxylation. These former targets constitute direct targeting of the Calvin cycle. Another approach has been to target feedback mechanisms that regulate CO_2 fixation.

Feedback Regulation of the Calvin Cycle and its Targeting to Improve Photosynthesis

In addition to the sophisticated control mechanisms that relate CO_2 fixation to light availability (feedforward regulation), feedback mechanisms relate Calvin cycle activity to the demand for the end products of photosynthesis. Inorganic phosphate (Pi) is a component of phosphorylated intermediates in pathways and is liberated when end product, e.g., sucrose, is synthesized (sucrose contains no Pi). This recycling of Pi is necessary to ensure that metabolic flow can continue. Photophosphorylation and ATP synthesis are particularly sensitive to Pi supply. Slow recycling of Pi caused by low temperature, for example, can restrict the recycling of Pi and so limit photosynthesis.

Demand for end product is also determined by the genetic potential of the plant for growth and by other environmental factors, particularly nitrogen, which facilitates high growth rates. The assimilation of nitrogen into amino acids requires carbon skeletons derived from triose phosphates supplied by the Calvin cycle. An impairment of nitrogen supply slows growth, which can lead to a build of sugar in leaves, because photosynthates are no longer being used in growth and nitrogen assimilation. It was shown in 1990 that seven maize photosynthetic genes were repressed by glucose or sucrose in a maize protoplast system. Further evidence of control of photosynthetic gene expression by sugars has been obtained where sugars were made to accumulate in leaves due to genetic modification, environmental treatments (high CO_2 and low N, in particular), and through direct feeding of sugars to leaves. The exact mechanism through which this may operate is not clear, but it is likely to be part of a fundamental metabolic signaling process that links photosynthesis with requirement for sugar. Recently it has been shown that modification of such feedback mechanisms may be a way forward to improving photosynthesis. The trehalose pathway, once thought to have become largely extinct in plants, is now known to be ubiquitous with an indispensable role in regulating carbohydrate use. Modification of a key component of this regulation, trehalose 6-phosphate (T6P), has been shown to alter sugar metabolism in growth processes and alter photosynthesis. There is a close correlation between T6P, Rubisco content, and photosynthetic rate. Increasing amounts of T6P by genetic modification increased amounts of Rubisco and photosynthetic rate of leaves. It is thought that T6P links carbohydrate utilization to photosynthesis as part of a feedback loop that regulates photosynthesis in response to sugar use. Modification of this process provides a route toward increasing Rubisco activity and photosynthesis.

Photosynthetic CO_2 Fixation of Whole Plants

A central strategy of photosynthetic regulation of whole plants is to balance photosynthetic rate of leaves with the overall leaf area of the plant. Surveys of variations in photosynthesis per unit leaf area of many crops demonstrate a strong negative relationship with leaf area. Many environmental factors, particularly light, and the genetic make up of the plant determine this trade off. Growth rate and productivity are more closely related to leaf area than the photosynthetic rate of individual leaves. This is reflected in crop breeding for yield which has increased leaf area often at the expense of photosynthetic rate. Large leaf area combined with use of fertilizers and control of pests and diseases has maximized photosynthesis per unit of land for high crop yields. Improvements in yields in this way may be reaching a limit, so advances in improvement of photosynthetic rate combined with large leaf area may be the way forward to increasing photosynthesis and for future productivity gains. The complexity of photosynthetic regulation at the pathway and whole plant level show there are many things to consider in trying to genetically engineer photosynthesis and productivity. However, the nature of recent progress gives much room for optimism.

Biography

Matthew Paul is a Research Leader at Rothamsted Research, grant aided by the Biological and Biotechnological Sciences Research Council of the United Kingdom. His principal research interests are the regulation of sugar metabolism and photosynthesis by metabolic signaling processes and in particular the role of the trehalose pathway in this regard. He holds a Ph.D. from the University of Leicester and worked as a Royal Society postdoctoral fellow at the University of Bayreuth, Germany.

Photosystem I, Structure and Function

Petra Fromme
Arizona State University, Tempe, Arizona, USA

Photosystem I (PS I) is a bio-solar energy converter that plays the key role in the first steps of oxygenic photosynthesis: the conversion of the light energy from the sun into chemical energy. It is a large membrane protein complex, consisting of 12 proteins, to which 127 cofactors (as chlorophylls, carotenoids, FeS clusters, and vitamin K1) are noncovalently bound. The function of PS I can be described as a bio-solar cell. It captures the light from the sun by a large antenna system (consisting of 90 chlorophylls and 22 carotenoids) and transfers the energy to the center of the complex, where the electron transfer chain is located. When the excitation energy reaches the center of the complex, charge separation takes place. An electron is ejected and transferred across the membrane to the terminal FeS cluster by a chain of six different electron carriers. In the next step of the reaction cycle, the electron is transferred from PS I to the soluble electron carrier protein ferredoxin leading finally to the reduction of $NADP^+$ to NADPH by the ferredoxin:NADP:reductase (FNR). The cycle is completed by the re-reduction of the donor site of PS I by either plastocyanin or cytochrome c_6.

Photosynthesis

Oxygenic photosynthesis is the main process on earth that converts the light energy from the sun into chemical energy. The process supplies all higher life on earth with food and produces all the oxygen in the atmosphere. Three different kinds of organisms are able to perform oxygen-evolving photosynthesis: plants, algae, and cyanobacteria. Whereas plants and algae are eukaryotic cells containing chloroplasts, cyanobacteria are prokaryotes. It was suggested that chloroplasts had been formed in early times of evolution by endosymbiosis. During this process an ancestor of the plant cell may have incorporated an early ancestor of cyanobacteria which subsequently lost its independent status and became a cell organelle in later stages of evolution. Whereas this process may have occurred billions of years ago, the primary steps of photosynthesis have been conserved and are still essentially the same in plants and cyanobacteria.

The initial steps of photosynthesis, the light reactions, occur on a membrane system, known as the thylakoids. Two large membrane protein complexes – the photosystems I and II (abbreviated as PS I and PS II, respectively) that are embedded in this membrane – catalyze the initial steps of photosynthesis, the light-induced charge separation. A pool of plastoquinones, the cytochrome b_6f complex, and plastocyanine or cytochrome c_6 functionally couple both photosystems. The thylakoid membrane is charged by this process (comparable to the charging of a battery) and a proton gradient develops across the membrane. Both the electrical gradient and the proton gradient (i.e., the electrochemical gradient) drive the synthesis of ATP. Reduced hydrogen for sugar formation is provided by reduction of $NADP^+$ and H^+ to NADPH. The reaction is driven by the electrons provided by PS I.

Function of PS I

PS I is a large membrane protein complex; in cyanobacteria it consists of 12 protein subunits to which 127 cofactors are noncovalently bound. It catalyzes the light-driven electron transfer from the soluble Cu-containing protein plastocyanine on the lumenal side (i.e., the inside of the thylakoids) to ferredoxin at the stromal side (outside) of the thylakoid membrane. Cyanobacteria can also use the hem containing soluble protein cytochrome c_6 as an alternate or unique electron donor to PS I. There is also some flexibility concerning the electron acceptor. In the case of iron deficiency, flavodoxin can act as the electron acceptor instead of ferredoxin.

In plants, the system contains at least four additional subunits whose functions are still under investigation. It is known that the main proteins, including all cofactor-binding sites, are well conserved between plants and cyanobacteria. However, detailed structural information is available only for the latter one from the X-ray structure of PS I from the thermophilic cyanobacterium *Synechococcus elongatus* at 2.5Å resolution. In cyanobacteria, PS I is a trimer with a molecular weight of more than 1000 kDa. Figure 1 shows the picture of the trimeric complex, pointing out the complex organization of this nano-bio-solar system. PS I is the largest and most complex membrane protein for which the structure has been determined.

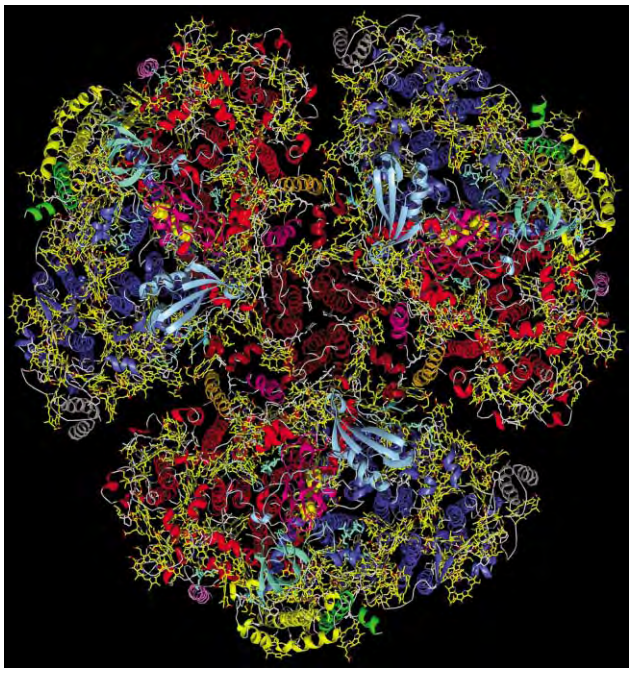

FIGURE 1 The trimeric structure of PS I from cyanobacteria; the view direction is from the stromal side onto the membrane plane. The 12 proteins are shown in a backbone representation (PsaA, blue; PsaB, red; PsaC, pink; PsaD, turquoise; PsaE, light blue; PsaF, yellow; PsaI, dark pink; PsaJ, green; PsaK, gray; PsaL, brown; PsaM, orange, and PsaX, light pink). The head groups of the chlorophylls are shown in yellow, their phytyl-tails have been omitted for clarity. The carotenoids are depicted in gray; the lipids, in dark turquoise.

Each monomeric unit contains 12 proteins, 96 chlorophylls (the pigments that give the plants the green color), 22 carotenoids (orange pigments, which become visible in autumn), 3 [4Fe–4S] clusters, 2 phylloquinone molecules, and 4 lipids.

The first step of the whole process is the light capturing, performed by the large antenna system, which consists of 90 antenna chlorophylls and 22 carotenoids. The energy is transferred to the center of the complex, where the electron transport chain is located. When the energy excites a special pair of two chlorophylls, located in the center of the complex, the "action" takes place and charge separation occurs. Due to its absorption maximum at 700 nm, this pair of chlorophylls was named P700. The electron is transferred from P700 across the membrane by a chain of electron carriers. These electron carriers were previously identified by spectroscopic investigations, and their historical names have been maintained. The electron transport chain consists of five steps. The electron is stepwise transferred from P700 to A (a chlorophyll *a* molecule), A0 (also a chlorophyll *a* molecule), A1 (a phylloquinone molecule) and from there to the three [4Fe–4S] clusters – FX, FA, and FB. After the docking of the soluble electron carrier ferredoxin, the electron is transferred from PS I to ferredoxin, which subsequently leaves the docking site responsible for bringing the electron to the ferredoxin-$NADP^+$-reductase, which then finally reduces $NADP^+$ to NADPH. After this process has occurred once, $P700^+$ has to be re-reduced to complete the reaction cycle. There is a docking site for soluble electron carrier proteins located at the lumenal site of the complex, just underneath P700. In plants reduced plastocyanine docks to this site and reduces $P700^+$, whereas cytochrome c_6 can substitute plastocyanine in cyanobacteria.

The Proteins

The structure and location of the proteins in PS I is shown in Figures 2A and 2B. Cyanobacterial PS I consists of 12 different protein subunits, which are named PsaA to PsaX, according to their genes. The two most important proteins are the large subunits PsaA and PsaB. They harbor most of the antenna system as well as most of the cofactors of the electron transport chain from P700 to the first FeS cluster, FX. The latter is a rare example of an inter-protein FeS cluster coordinated by four cysteines, two of them provided by PsaA and the other two cysteine ligands provided by PsaB. Each of the two large subunits consists of 11 transmembrane helices, connected by partially extended loops that also contain many secondary structural elements as α-helices and β-sheets. The docking site of plastocyanine/cytochrome c_6 is formed by two of these surface helices. The five C-terminal helices are located in the center of the PS I and surround the electron transfer chain, whereas the six N-terminal helices flank the inner core on both sites. They are arranged as a trimer of dimers and they coordinate a large part of the antenna pigments in PS I. The six smaller membrane-embedded proteins (PsaF, PsaI, PsaJ, PsaK, PsaL, and PsaX) surround the core formed by PsaA and PsaB. Their main function is the stabilization of the antenna complex. PsaL also has an important structural role, because it is involved in the formation of the trimer. A further function of the smaller subunits may be the interaction of PS I with external antenna complexes. Cyanobacteria contain large membrane-associated antenna complexes, called phycobillisomes, which are either connected to PS I or to PS II, depending on the light conditions. There is some indication from deletion mutants that PsaF may play an important role in the connection of PS I with the phycobillisomes. Under an environmental stress, such as iron deficiency, the phycobillisomes are degraded and PS I is supplied with additional energy by a ring of 18 subunits of a membrane integral antenna complex, which is named IsiA (for iron stress induced protein A). With a molecular weight of 43 kDa, this protein has homologies to the internal antenna protein of PS II (CP43) and is therefore also

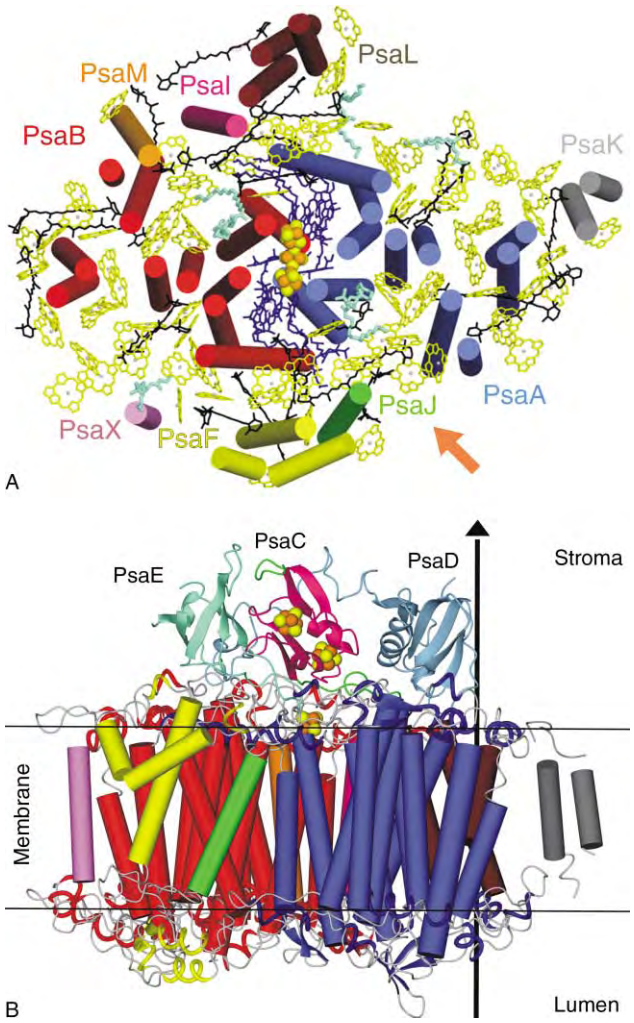

FIGURE 2 Arrangement of protein subunits and cofactors in one monomeric unit of PS I (A) view from the stromal side onto the membrane plane. The three stromal subunits have been omitted for clarity. Color coding of the membrane intrinsic subunits is as shown in Figure 1: PsaA, blue; PsaB, red; PsaF, yellow; PsaI, dark pink; PsaJ, green, PsaK, gray; PsaL, brown; PsaM, orange, and PsaX, light pink. Transmembrane α-helices of the membrane intrinsic subunits are represented as colored cylinders, the loops as well as the three stromal subunits PsaC, PsaD, and PsaE are omitted for clarity. (B) Side view of the monomer of the PS I complex. The view is parallel to the membrane plane. The orange arrow in (A) indicates the view direction in (B). All cofactors have been omitted except the three FeS clusters. For an explanation of the colors see legend to Figure 1. The three stromal subunits PsaE (light green), PsaC (violet), and PsaD (light blue) are located on top of the transmembrane α-helices.

called CP43′. The interaction with the IsiA ring may be performed by PsaF, PsaJ, PsaK, and PsaX.

Plant PS I is very homologous to its cyanobacterial sister, however the external antenna systems are quite different in plants and cyanobacteria. Plants do not have phycobillisomes, instead, the membrane intrinsic antenna proteins LHCI (light harvesting complex I) and LHCII (light harvesting complex II) can be connected to the monomeric core of PS I.

In addition, the plant system does not contain PsaM and PsaX but instead contains at least four additional proteins not found in cyanobacteria: PsaG, PsaH, PsaN, and PsaO. There is not any detailed structural information available on the plant PS I, but biochemical studies have shown that PsaH and PsaO may be located close to PsaL, and may interact with the LHC II complex, whereas the interaction with the LHC I complex is mediated by PsaF, PsaJ, and PsaK. PsaF is also involved in the docking of plastocyanine in plants by its lumenal N-terminal extension.

Both in plants and cyanobacteria, three extrinsic subunits, which do not contain any transmembrane helices, are located at the stromal site of the PS I complex. These three subunits (PsaC, PsaD, and PsaE) form a "stromal hump" that extends the membrane by 35Å and provides the docking site for the soluble electron carriers ferredoxin and flavodoxin. The central subunit PsaC thereby carries the terminal electron acceptors, the two [4Fe–4S] clusters named FA and FB.

The Electron Transport Chain

The electron transport chain is the heart of PS I. Figure 3 shows the structural organization of the cofactors of the electron transport chain. The organic cofactors of the electron transfer chain are arranged in two branches. They are named the A- and B-branches, because most – but not all – cofactors of the A-branch and B-branch are coordinated by PsaA and PsaB, respectively.

The pair of chlorophylls assigned to P700 is located close to the lumenal surface of PS I. It consists of two chemically different chlorophyll molecules. The chlorophyll on the B-branch is the common chlorophyll *a* molecule, chemically identical to all of the other 95 chlorophylls in PS I, whereas the chlorophyll at the A-branch is chlorophyll *a*′, the epimer at the C13 position of the chlorine ring system. The protein environment further enhances the asymmetry of the two chlorophylls: three hydrogen bonds are formed between the protein and the P700-chlorophyll *a*′ at the A-branch, whereas the P700 chlorophyll at the B-branch does not form any hydrogen bonds to the protein environment. The asymmetry could lead to significant differences in the redox potential of both chlorophylls, which may explain why more than 85% of the unpaired electron of $P700^+$ is located, on the B-branch chlorophyll. A possible function of the asymmetry may be a gating of electrons along the two branches but to date this suggestion has not been proven experimentally. From P700 the electron is transferred via one of the chlorophylls from the second pair chlorophylls, "A", to the first stable electron acceptor "A0," which may be located on one of the chlorophylls located in the middle of the membrane.

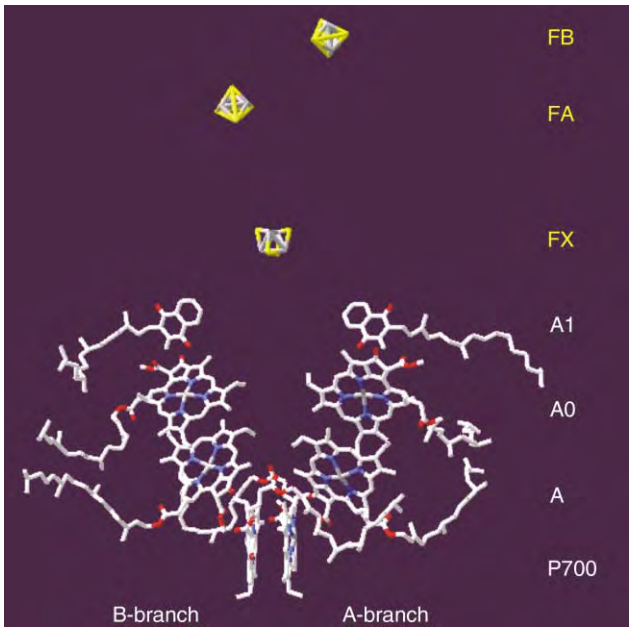

FIGURE 3 The electron transfer system of PS I. The view is parallel to the membrane plane. The organic cofactors of the electron transfer chain are arranged in two branches. The left branch is called the B-branch, whereas the right branch is the A-branch. The three [4Fe–4S] clusters FX, FA, and FB are located at the stromal side of the membrane (on top of the figure). At right margin the names of the cofactors are given as derived from spectroscopic investigations.

These first steps of electron transport occur in less than 3 ps (3/1000 000 000 parts of a second) so that the second pair of chlorophylls has not been detected by spectroscopy so far. The coordination of the chlorophylls of "A" and "A0" is very remarkable, because none of them is coordinated by histidine, the favorite side chain for providing the fifth ligand to the Mg^{2+} in a chlorophyll molecule. Instead, both chlorophylls of "A" are coordinated by a water molecule, which forms the second H-bond to two asparagine side chains of the opposite branch. That means that the first electron acceptor at the A-branch is coordinated by PsaB and *vice versa*. The coordination of the two chlorophylls of "A0" is even more remarkable. The sulfur atom of methionine in both cases provides the fifth ligand of the Mg^{2+}. This is very unusual, because there should be only a very weak interaction between sulfur as a weak acid and Mg^{2+} as a strong base. In can be suggested that the weak interaction hinders a strong base (like water) from entering the site, thereby leading to a chlorophyll which may behave as if it lacks a fifth ligand. There is not an example of a sulphur–Mg^{2+} ligandation in the whole realm of inorganic or organic chemistry. It may be responsible for the extreme negative redox potential of A0 of -1000 mV. The unusual ligandation is absolutely essential for the electron transport, because replacement of the Methionine by histidine, which provides a strong ligand to the chlorophyll, blocks electron transport at the level of A0. In the next step of the electron transfer chain; the electron is further transferred from A0 to one of the phylloquinones, which represent the electron acceptor "A1". The two phylloquinones, which may represent A1, are located at the stromal side of the membrane. The binding pockets are identical on both sites but differ significantly from all other quinone-binding pockets found in proteins so far. Both quinones are π-stacked with a tryptophane residue and both show asymmetric hydrogen bonding: only one of the two oxygen atoms forms an H-bond to an NH backbone group, whereas the other oxygen atom is not hydrogen bonded at all. This could lead to a protein-induced asymmetry in the distribution of the unpaired electron in the radical state $A1^{-\cdot}$, formed when one of the phylloquinones gets reduced. This may answer the question of why A1 has the most negative redox potential (-770 mV) of all quinones found in nature. The electron proceeds from A1 to the FeS cluster FX. This is the rate-limiting step of the electron transfer in PS I. Still, a lively scientific discussion is going on regarding the question of whether one or both branches are active.

There is now experimental evidence that this step can proceed on both branches, but with different rates. In the green algae *Chlamydomonas reinhardtii*, the electron transfer is about a factor of 50 slower on the A- than on the B-branch. This could be the result of a higher activation energy barrier on the A- compared to the B-branch. This finding raises the question of the reason for this difference. There is not a significant difference concerning the protein environment in both branches, but there are two lipid molecules located close to the pathway from A1 to FX that could be responsible for the asymmetry. A negatively charged phospholipid is located on the slower A-branch and the electron has to be transferred against this negative charge, whereas on the faster B-branch a neutral galactolipid has replaced the phospholipid. This is the most reasonable explanation for the higher activation energy barrier.

The Antenna System

The antenna system of PS I consists of 90 chlorophyll *a* molecules and 22 carotenes. The arrangement of the pigments is shown in Figure 4. The function of the antenna chlorophylls (shown in green) is to capture light and transfer the excitation energy to the center of the complex, where the electron transfer chain is located (pigments of the electron transfer chain are shown in blue). The efficiency of the energy transfer is very high. After excitation of any of the antenna chlorophylls the chance that the energy is successfully transferred to P700

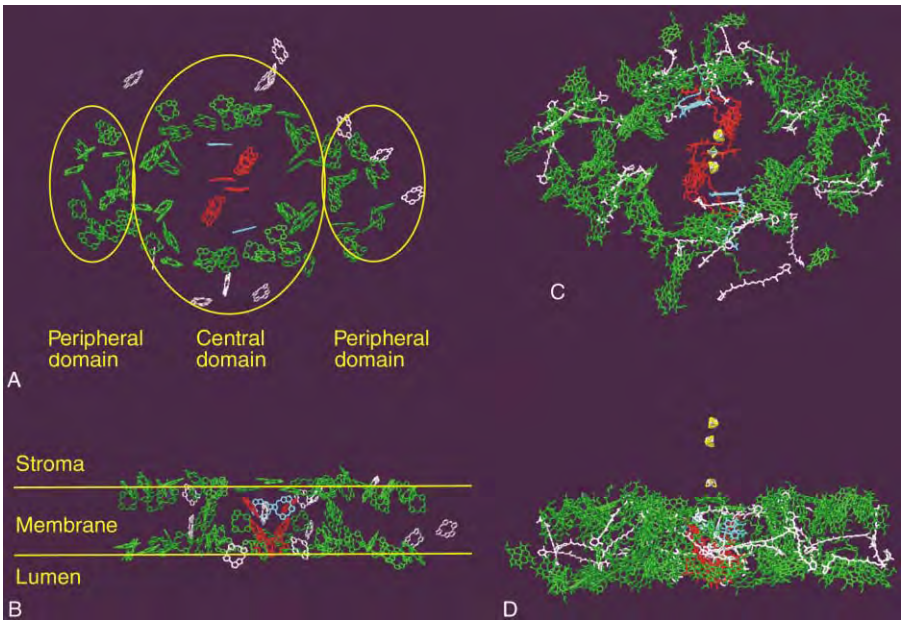

FIGURE 4 The antenna system of PS I (A) Organization of the chlorophylls. The view is from the stromal side onto the membrane plane. For clarity only the ring system of the chlorophylls is shown. The antenna chlorophylls that are coordinated by PsaA and PsaB are shown in green, the chlorophylls coordinated by the smaller membrane integral subunits are depicted in gray. The chlorophylls of the electron transport chain are highlighted in red and the two chlorophylls that may link the electron transport chain and the antenna system are depicted in turquoise. (B) Organization of the chlorophylls. Side view of the cofactors of PS I; the view direction is parallel to the membrane plane. The colors depicted are the same as shown in (A). (C) Complete depiction of the cofactors of the antenna system and the electron transfer chain. The view direction is as in (A). All antenna chlorophylls are shown in green, the carotenoids in white, the chlorophylls of the electron transfer chain in red and the FeS clusters in yellow/gray. (D) Complete depiction of the cofactors of the antenna system and the electron transfer chain. The view direction is as in (B) and the colors are identical to (C).

and subsequent charge separation occurs is 99.98% at room temperature.

The arrangement of the antenna system in PS I is unique. Instead of forming a symmetric ring surrounding the reaction center core, as it is in the light harvesting systems of purple bacteria, the chlorophylls form a clustered network. Each of the chlorophylls have several neighbors at a distance of less than 15Å, so energy can be efficiently transferred in multiple pathways to the center of the complex. The system can be, to some extent, compared to the nerve-network system in the brain where multiple connections are responsible for the high efficiency of information transfer. The antenna system in PS I is highly optimized for efficiency and robustness. The side view along the membrane plane shows that it can be divided into a central domain, which surrounds the electron transfer chain, and two peripheral domains, flanking the core on both sides. In the peripheral domains, the antenna chlorophylls are arranged in two layers, one close to the stromal surface of the membrane and the other close to the lumenal surface of the membrane. When a peripheral antenna chlorophyll is excited the energy will be first transferred from this "two-dimensional" layer to the central domain. In the central domain, chlorophylls are distributed over the full depths of the membrane, i.e., the excitation energy can be exchanged between the two layers. From the chlorophylls of the central domain the excitation energy is then transferred to the electron transfer chain. There are two chlorophylls that seem to structurally link the antenna system to the electron transfer chain (yellow in Figure 4), but the question as to whether they play a crucial role in energy transfer is still not solved.

The carotenoids fulfill three functions in PS I. They play a structural role, function as additional antenna pigments and prevent the system from damage by over-excitation caused by excess light (photoinhibition). The latter function is very critical for the whole system. Chlorophylls are in principle dangerous and reactive molecules. Over-excitation can lead to the formation of chlorophyll triplets (Chl^3), which can react with oxygen to form the highly toxic singlet oxygen, a very dangerous cell poison. Multiple interactions can be observed between the carotenoids and the chlorophylls of the antenna system. The carotenoids are distributed over the whole antenna system and prevent photo damage by the quenching of chlorophyll triplet states. The energy from the triplet chlorophylls is transferred to

the carotenoids that form the carotenoids' triplet state Car^3. The energy of the Car^3 is too low to react with O_2, this results in the carotenoids returning to the ground state by the dissipation of the energy just as heat, thereby preventing photodamage. The system works very efficiently, even under high-light conditions, as the Chl^3 triplet state cannot be detected in the intact PS I.

Biography

Petra Fromme is a Professor in the Department of Chemistry and Biochemistry at Arizona State University. Her principal research interest is in the broad field of the structure and function of membrane proteins, with a special focus on the proteins involved in the primary steps of photosynthesis. Her group and co-workers have determined the structures of both PS I and PS II. She holds a Ph.D. in chemistry from the Technical University Berlin and has authored several reviews and book chapters on the structure and function of PS I and PS II. She has received several awards, including the Hill Award from the Photosynthetic Society, the Lemberg Fellowship of the Australian National Academy of Science, and the Biology 2001 award of the Academy of Science of Goettingen. She is a fellow of the Biophysical Society and the Gesellschaft fuer Biologische Chemie.

Photosystem I: F_X, F_A, and F_B Iron–Sulfur Clusters

Mikhail L. Antonkine
Max-Planck Institut für Bioanorganische Chemie, Mülheim, Germany

John H. Golbeck
Pennsylvania State University, University Park, Pennsylvania, USA

Photosystem I is a membrane-bound pigment–protein complex found in photosynthetic organisms that converts the energy of light into chemical bond energy. It is classified as a type I reaction center because it uses iron–sulfur clusters as the terminal electron acceptors. Two variants of low-potential iron–sulfur clusters are employed in photosystem I. The membrane-spanning subunits PsaA and PsaB provide the binding site for F_X, which is a rare instance of an interpolypeptide [4Fe–4S] cluster ligated between the protein heterodimer. The stromal subunit PsaC provides the binding sites for F_A and F_B, which are [4Fe–4S] clusters located on a tightly bound, bacterial ferredoxin-like protein. F_X, F_A, and F_B serve as electron wires to vector the electron from the initial site of charge separation located deep in the membrane to soluble ferredoxin located on the stromal surface of the membrane. They provide good examples of how the physical and biochemical properties of iron–sulfur clusters can be adjusted to suit a specific function in electron transfer.

Photosynthesis

Photosynthesis is the process by which solar energy is converted into chemical bond energy by living organisms. This process can be conveniently divided into two parts, the light reactions and the dark reactions. The light reactions employ four major membrane-bound multisubunit complexes in the energy-conversion process: photosystem I, photosystem II, the cytochrome b_6f- Reiske iron–sulfur complex, and ATP synthase. NADPH is produced directly as a result of photosystem I, and molecular oxygen is produced directly as a result of photosystem II. A proton gradient is generated, in part, by the cytochrome b_6f- Reiske iron–sulfur complex and utilized by ATP synthase for the generation of ATP. During the dark reactions, carbon dioxide is enzymatically converted into carbohydrates at the expense of ATP and NADPH. The chemical bond energy of ATP and NADPH is also used by the organism for cellular processes such as metabolism, growth, and reproduction.

Types of Photosynthetic Reaction Centers

Two types of photosynthetic reaction centers have evolved that are capable of performing light-induced charge separation. Type I reaction centers utilize iron–sulfur clusters as terminal electron acceptors. This type is represented by the green-sulfur bacterial reaction center, the heliobacterial reaction center, and photosystem I in cyanobacteria, algae, and higher plants. Type II reaction centers utilize quinones as terminal electron acceptors. This type is represented by the purple bacterial reaction center, the green nonsulfur bacterial reaction center, and photosystem II in cyanobacteria, algae, and higher plants. Photosystem I is the best studied of the type I reaction centers and is considered the prototype for the entire class.

Photosystem I: The Best-Studied Type I Reaction Center

Photosystem I is a component of the photosynthetic electron transfer chain in all oxygen-evolving organisms. The X-ray crystal structure of cyanobacterial photosystem I has been solved at a resolution of 2.5Å. This large membrane-bound pigment–protein complex exists as a trimer in cyanobacteria; each monomer consists of 12 subunits, labeled PsaA through PsaF, PsaI through PsaM, and PsaX. Among the 127 cofactors are 96 chlorophylls, 2 phylloquinones, and 3 [4Fe–4S] clusters, referred to as F_X, F_A, and F_B. The majority of the electron transfer cofactors are bound to the two large, membrane-embedded subunits PsaA and PsaB. They form the heterodimeric core of photosystem I, and are related by a pseudo-C_2 symmetry axis that also includes the electron transfer cofactors (Figure 1A). The terminal

electron acceptors, iron–sulfur clusters F_A and F_B, are bound to the PsaC subunit on the stromal (cytoplasmic) side of the thylakoid membrane (Figure 1B). Light-induced charge separation occurs between the primary electron donor P700 ($E_m' \sim -1300$ mV), which is a chlorophyll a/a′ heterodimer located on the luminal (inner) side of the membrane, and the primary electron acceptor A_0 ($E_m' \sim -1000$ mV), which is a chlorophyll a monomer. The electron is quickly passed to A_1 ($E_m' \sim -800$ mV), which is a phylloquinone molecule, to F_X ($E_m' = -705$ mV), the interpolypeptide [4Fe–4S] cluster, and finally to F_A ($E_m' = -540$ mV) and F_B ($E_m' = -590$ mV), the [4Fe–4S] clusters bound to PsaC. The soluble protein ferredoxin accepts the electron from F_B on the stromal side of the membrane and interacts with NADP:ferredoxin oxidoreductase to generate NADPH. The initial charge-separated state between $P700^+$ and A_0^- is thus stabilized by the displacement of the electron through a series of acceptors arranged from the lumenal to the stromal side of the thylakoid membrane. The F_X, F_A, and F_B iron–sulfur clusters participate in this process by functioning as a molecular wire. This allows the charge-separated state to be separated in space and lengthened in time, thus permitting a high quantum yield. This strategy represents an excellent example of how Gibbs free energy, in the form of diminishing reductive power of every successive cofactor, is traded to gain time in the form of longer-lived charge-separated states.

Iron–Sulfur Clusters in Biology

Geometry and Oxidation States

Iron–sulfur clusters are one of the most common biological cofactors. They are employed in biological systems in many different roles. For example, iron–sulfur clusters can play a structural role (endonuclease III) as well as a functional role such as in catalysis (aconitase) and in the regulation of gene expression (SoxR). However, by far the most common function is in electron transfer. A few examples include relatively simple proteins such as plant and bacterial ferredoxins, and complex multisubunit proteins such as hydrogenase, complex I, and photosystem I. There are four basic prototypes of iron–sulfur clusters; each differs in the number of iron and sulfur atoms. These differences lead to a widespread variation in geometry, in reduction potential, and ultimately in biological function. (1) In a rubredoxin, a single iron is tetrahedrally coordinated by four cysteine ligands. (2) In a [2Fe–2S] cluster, the iron atoms are bridged by the sulfur atoms in a rhombic structure. Each of the iron atoms is ligated by two cysteines (although in the case of Rieske iron–sulfur proteins, one of the iron atoms is ligated by two histidines) that are positioned in a plane perpendicular to the bridging sulfur atoms. (3) In a [4Fe–4S] cluster, the iron and sulfur atoms alternate in corner positions of a cube (Figure 2). Each of the iron atoms is ligated by a cysteine (in rare instances by water or aspartate); the sulfur atoms form a tetrahedron around the cluster. (4) In a [3Fe–4S] cluster, one of the iron atoms is missing from the corner of the cube; hence, the overall geometry is nearly the same as that of a [4Fe–4S] cluster. Among these prototypes, the [4Fe–4S] clusters are unique because they can potentially exist in three different oxidation states 3+, 2+, and 1+. However, in any given protein, only one of the two different oxidation–reduction pairs is found: 3+/2+ or 2+/1+; the choice is determined by the surrounding protein matrix. In high potential iron–sulfur proteins (HiPIP), the 3+/2+ pair is used, and in low-potential iron–sulfur proteins, the 2+/1+ pair is used. Thus, the protein plays a crucial role in determining the oxidation–reduction pair employed by the cofactor, thereby determining the approximate range of its midpoint potential. The midpoint potential of a [4Fe–4S] cluster is further modulated by coulombic interaction with the protein, polarizability of the protein, and accessibility to solvent; these factors specify the biological function of the [4Fe–4S] cluster. In photosystem I, low-potential [4Fe–4S] clusters are found. In the reduced (+1) state there exist three Fe^{2+} ions and one Fe^{3+} ion, however, due to valence delocalization, only two pairs of iron atoms are observed. One is an equal-valence pair in which both iron atoms exist in a 2+ oxidation state, and the other is mixed-valance pair in which both iron atoms exist in a 2.5+ oxidation state. The position of both pairs, with respect to protein ligands, can change at room temperature, i.e., any iron atom can assume the 2+ or 2.5+ oxidation state at any time, and as a result, the mixed- and equal-valence pairs migrate around the cube. Since in proteins the [4Fe–4S] clusters are slightly distorted due to the interactions with a nonhomogeneous matrix, preferential positions for both pairs exist. The positions can be determined by studying temperature dependence of the NMR chemical shift of the αH and βCH_2 protons of the cysteines ligands of the [4Fe–4S] cluster in a biologically relevant temperature range. In the reduced (+1) state, low-potential [4Fe–4S] clusters are paramagnetic, i.e., the cluster as a whole has an unpaired electron. This property allows detection by electron paramagnetic resonance (EPR) spectroscopy, which is sensitive only to paramagnetic species. Thus, EPR spectroscopy focuses on the properties of the cofactor and not on the properties of the surrounding protein matrix, which is diamagnetic. However, the EPR spectrum is sensitive to changes in the environment of the cofactor caused by changes in surrounding protein. A combination of these properties makes EPR an indispensable tool in the investigation of protein

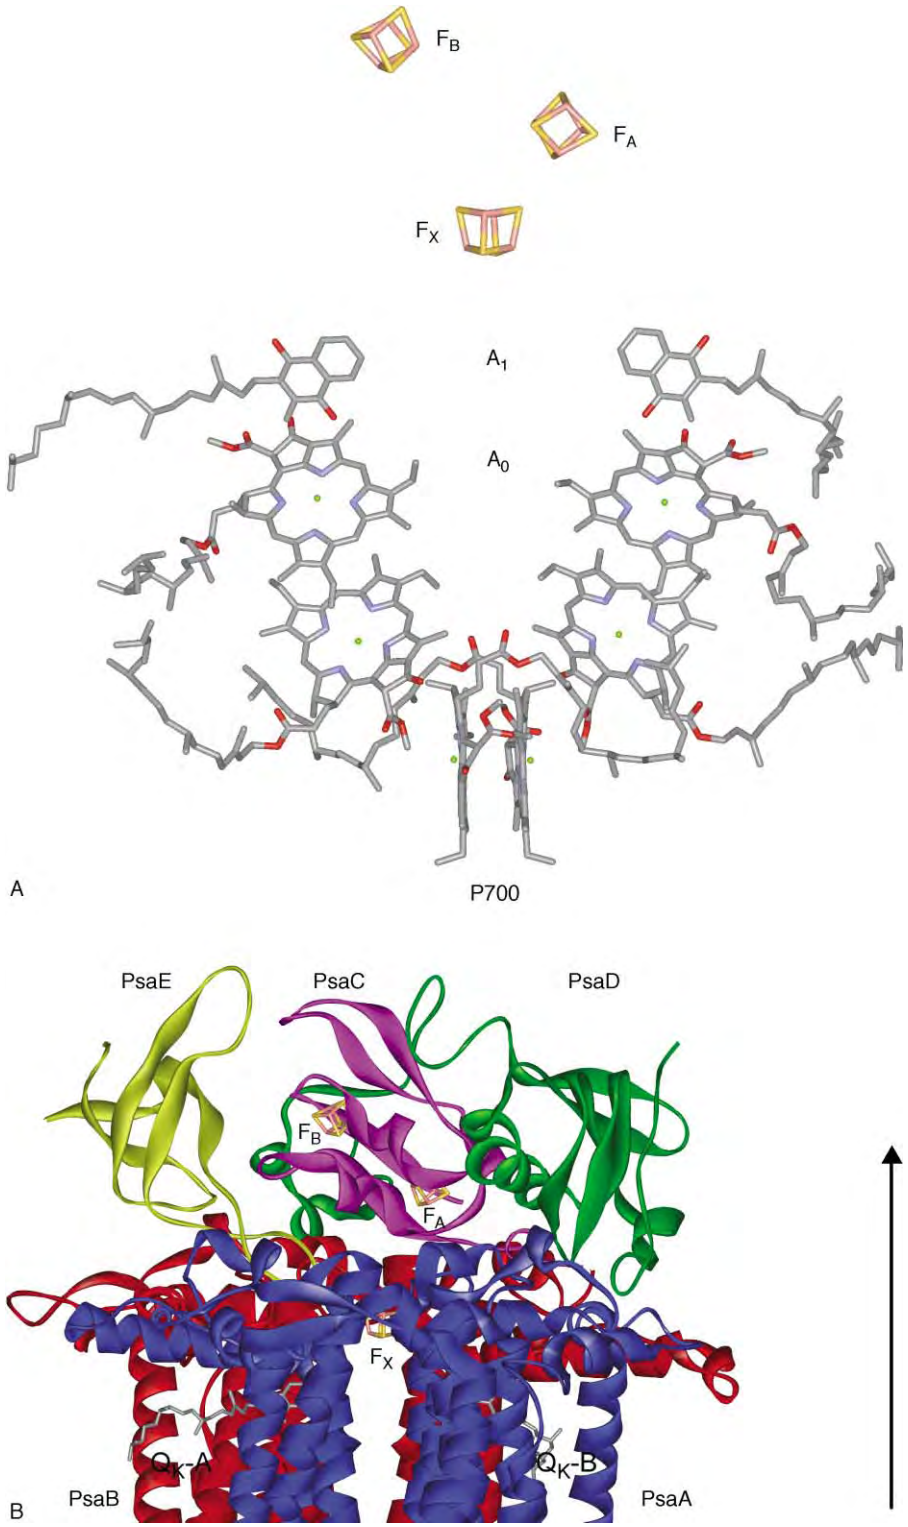

FIGURE 1 The X-ray structure of photosystem I at 2.5Å resolution (PDB entry 1JB0). Detail of the structural model of the photosystem I monomer. View parallel to the membrane plane. (A) Photosystem I cofactors involved in electron transfer. All cofactors are shown as "stick" models; the positions of the carbon, nitrogen, and oxygen atoms are indicated by light gray, blue, and red colors respectively. The positions of Mg^{2+} ions are indicted by green spheres. The [4Fe–4S] clusters F_X, F_A, and F_B are shown as cubes in which the yellow corners indicate the positions of sulfur atoms and the pink corners the position of iron atoms. Note the C_2-symmetric arrangement of cofactors P700, A_0, A_1, and F_X, all of which are bound by two core, membrane-spanning subunits PsaA and PsaB; as well as the symmetry-breaking arrangement of cofactors F_A and F_B, bound by stromal subunit PsaC. (B) The complete backbones of the stromal subunits PsaC, PsaD, and PsaE proteins, as well as their respective arrangement on the stromal surface of the PsaA/PsaB heterodimer. PsaA is shown in blue, PsaB in red, PsaC in magenta, PsaD in green, PsaE in olive; peripheral proteins are omitted for clarity; [4Fe–4S] iron–sulfur clusters F_X, F_A, and F_B are shown as cubes, in which the yellow corners indicate positions of

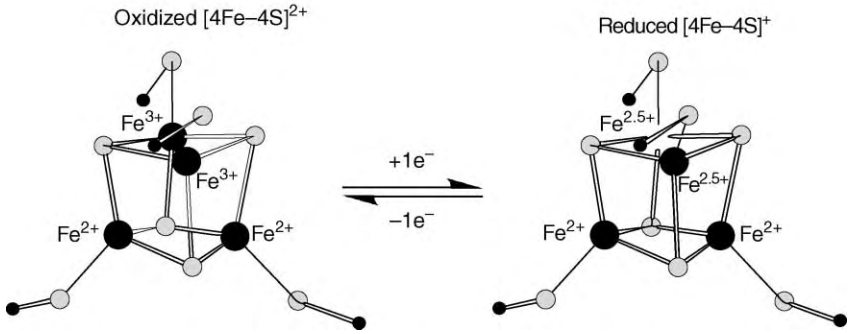

FIGURE 2 The structure of a [4Fe–4S] cluster. The presence of equal valence (Fe^{2+}) and mixed valence ($Fe^{2.5+}$) iron pairs in the reduced state is shown. The iron and sulfide atoms of the [4Fe–4S] clusters as well as sulfur and Cβ atoms of the cysteines ligating the [4Fe–4S] cluster are shown with iron atoms as large black spheres, sulfur atoms as light-gray spheres and Cβ as small black spheres. Reprinted from Vassiliev, I. R., Antonkine, M. L., and Golbeck, J. H. (2001). Iron–sulfur clusters in Type I reaction centers. *Biochim. Biophys. Acta* (special issue on Photosystem I), **1507**, 139–160, with permission from Elsevier.

cofactors in general, and iron–sulfur clusters in particular. This technique is especially advantageous for studying of cofactors in large protein complexes, in which it is difficult to apply other techniques due to the presence of interfering chromophores or to the size of the biomolecule.

Self-Assembly in Solution

Iron–sulfur clusters self-assemble in aqueous solutions under anaerobic (oxygen-free) conditions in presence of iron and sulfide ions along with a thiol-containing reductant. If an apoprotein with an iron–sulfur cluster-binding site is added to the solution, the clusters self-insert into the site via a thiol exchange mechanism. In the living cell the assembly of iron–sulfur clusters is tightly regulated and is performed by a set of special enzymes that act sequentially. However, iron–sulfur proteins with *in vitro* or *in vivo* inserted clusters have identical spectroscopic and biochemical properties. Thus, *in vitro* insertion of clusters is a useful preparative tool for investigation of iron–sulfur proteins.

The F_X, F_A, and F_B Clusters of Photosystem I

F_X, the Interpolypeptide [4Fe–4S] Cluster Bound by PsaA and PsaB

F_X in the interpolypeptide iron–sulfur cluster bound between the PsaA and PsaB subunits (Figure 1). EXAFS and Mössbauer spectroscopic studies unambiguously identified F_X as a [4Fe–4S] cluster. The midpoint potential of F_X was measured directly and was found to be -705 mV, making it one of the most reducing [4Fe–4S] clusters known in biology. The binding site of F_X was identified from amino acid sequences of the PsaA and PsaB polypeptides that comprise the membrane-bound core of photosystem I. The site consists of two identical amino acids sequences, FPCDGPGRGGTC, located in loops connecting helices *j* and *k* on PsaA and *j*′ and *k*′ on PsaB. Each of these sequences provides two conserved cysteine ligands to the cluster; thus, F_X represents a highly unusual instance of a [4Fe–4S] cluster bound between a protein heterodimer. The high-resolution crystal structure of cyanobacterial photosystem I shows that charged amino acids within the conserved F_X-binding sequences on PsaA and PsaB provide a set of ionic contacts for the binding of PsaC. The F_X-binding sequences on both PsaA and PsaB are parts of large, extramembrane loops that have a completely symmetric three-dimensional structure. In addition to providing ligands for F_X they serve several additional functions such as forming the ionic contacts with PsaC and shielding the F_X cluster from molecular oxygen. F_X is additionally shielded by α-helices that comprise the core of the PsaA/PsaB heterodimer. The iron protein of nitrogenase (e.g., protein data bank (PDB) entry 1CP2) and 2-hydroxyglutaryl-CoA dehydratase component A (PDB entry 1HUX) are the only other proteins that have both an interpolypeptide [4Fe–4S] cluster and a solved three-dimensional

sulfur atoms and light-brown corners the position of iron atoms; quinones Q_K-A and Q_K-B are shown as "stick" models, both represent the acceptor A_1 bound to PsaA and PsaB respectively. The position of the trimer C_3-symmetry axis is indicated by an arrow. Reprinted from Antonkine, M. L., Jordan, P., Fromme, P., Krauβ, N., Golbeck, J. H., and Stehlik, D. (2003). Assembly of protein subunits within the stromal ridge of Photosystem I. Structural changes between unbound and sequentially PS I-bound polypeptides and correlated changes of the magnetic properties of the terminal iron–sulfur clusters. *J. Mol. Biol.*, **327**, 671–697, with permission from Elsevier.

structure. However, the environments of these [4Fe–4S] clusters are significantly different in that each subunit of these homodimeric proteins has two fully conserved cysteines that are located far apart from each other in the amino acid sequence. Hence, in these proteins, there is no short consensus binding sequence for the [4Fe–4S] cluster as exists for F_X. It follows that properties of these interpolypeptide [4Fe–4S] clusters are also very different from F_X. They have midpoint potentials of -420 to -430 mV (i.e., 250–300 mV more oxidizing than F_X), which is more typical for low-potential [4Fe–4S] clusters in monocluster and dicluster bacterial ferredoxins. Moreover, the [4Fe–4S] clusters in nitrogenase and 2-hydroxyglutaryl-CoA dehydratase component A are highly oxygen sensitive, probably because the binding site of the interpolypeptide cluster is open and accessible. In contrast, F_X needs to be oxygen insensitive because it is probably assembled as an intermediate in the biogenesis of the photosystem I reaction center.

F_A AND F_B, THE [4Fe–4S] CLUSTERS BOUND BY PSAC

The Amino Acid Sequence of PsaC

F_A and F_B are iron–sulfur clusters bound to the PsaC subunit. A 9 kDa iron–sulfur protein, with an unusual EPR spectrum, was originally isolated by methanol/acetone extraction of spinach chloroplast membranes. Although at the time no function could be assigned, it was later shown to be identical to PsaC. When this protein was rebound to photosystem I cores, the characteristic EPR signals of F_A and F_B could be restored to that found in the wild type. The amino acid sequence of PsaC in a variety of organisms was deduced by direct amino acid sequencing of the protein and from the sequences of the *psaC* genes. The 80 amino acids are extremely well conserved both in cyanobacteria and in higher plants. PsaC has sequence similarity to bacterial ferredoxins, from which it is presumed to have evolved, in the regions surrounding the two [4Fe–4S] clusters (Figure 3). Similar to bacterial ferredoxins, PsaC contains two consensus [4Fe–4S] cluster-binding sites consisting of C(I)xxC(II)xxC(III)xxxC(IV)P, where C is cysteine, P is proline, and x is any other amino acid. Cysteines I, II, and III of the first binding site ligate the first [4Fe–4S] cluster, while cysteine IV ligates the second [4Fe–4S] cluster; cysteines I′, II′, and III′ of the second binding site ligate the second [4Fe–4S] cluster, while cysteine IV′ ligates the first [4Fe–4S] cluster. The distance between the two [4Fe–4S] clusters in the protein is predetermined by the distance between Cys(III) and Cys(IV) in the binding site because they always ligate different clusters. Through site-directed mutagenesis studies, it was shown that in PsaC cysteines 10, 13, 16, and 57 ligate F_B and cysteines 47, 50, 53, and 20 ligate F_A. F_B and F_A in PsaC are equivalent to cluster I and cluster II in bacterial ferredoxins, respectively. The similarity of PsaC to bacterial ferredoxins fostered the use of the three-dimensional structures of these proteins as models for PsaC. This is a valid approach, particularly if one is interested in the structure of the iron–sulfur core of the protein. However, there are several significant regions where their amino acid sequences differ. PsaC has a sequence insertion between the two consensus iron–sulfur binding sites and a sequence extension at the C-terminal end of the protein. Not surprisingly both of these sequences are involved in photosystem I-specific functions of PsaC. The sequence insertion, known as the Z-loop, participates in ferredoxin/flavodoxin binding and the C-terminal

sequence extension is one of the key elements involved in binding to the photosystem I core. One of the interesting features of the amino acid sequence of PsaC that was not recognized immediately is the increased number of charged amino acids in the vicinity of the binding site of the F_A cluster, as compared both to the binding site of F_B and to the binding sites of clusters I and II in bacterial ferredoxins. The basic amino acids of the F_A site are now known to be responsible for binding PsaC; they form the majority of the contacts that anchor PsaC to the PsaA/PsaB heterodimer. This is achieved by formation of ionic bonds with acidic amino acids in the [4Fe–4S] cluster F_X-binding site.

The Three-Dimensional Structure PsaC

PsaC is tightly bound to the PsaA/PsaB stromal surface and is packed between the PsaD and PsaE subunits (Figure 1B). However, PsaC is also a highly soluble protein, a property that has allowed study of its structure in the unbound state. The biochemical and magnetic properties of the F_A and F_B iron–sulfur clusters are similar in unbound PsaC, while they are distinctly different in photosystem I-bound PsaC. Rebinding studies of PsaC, PsaD, and PsaE to the PsaA/PsaB core proteins have been aided by the availability of large amounts of recombinant PsaC, PsaD, and PsaE proteins from overexpression systems in *Escherichia coli*. The EPR properties of F_A and F_B change in three distinct steps during the assembly of photosystem I. The first is unbound PsaC in solution; the second is PsaC bound to photosystem I in the absence of PsaD; and the third is PsaC bound to photosystem I in the presence of PsaD. The presence or absence of PsaE has no effect on the EPR properties of F_A and F_B. Since EPR is highly sensitive to changing environment of the [4Fe–4S] clusters, these results were interpreted as a change in the conformation of PsaC in three distinct steps. PsaD does not bind any cofactors; rather, the binding of PsaD induces conformational changes in PsaC and locks it into its final state. The solution structure for unbound PsaC (PDB entry 1K0T) was solved by NMR. In the iron–sulfur core of PsaC, the [4Fe–4S] clusters F_A and F_B are connected by two short α-helices and assume a very similar geometry in both unbound and bound PsaC (Figure 4). As predicted from the amino acid sequence, this region shows structural features similar to those of bacterial ferredoxins. In particular, the position, distance and relative orientation of the two [4Fe–4S] clusters as well as the conformation of two-cluster consensus binding sites are similar in PsaC and bacterial ferredoxins. A comparison of the unbound PsaC structure with that in the X-ray structure of bound PsaC reveals significant differences that mainly concern the structure of the N, pre-C, and C termini. In unbound PsaC the C terminus assumes a disordered helical conformation, and is clearly different from the extended coil conformation in bound PsaC. Indeed, this is one of the structural elements required to anchor PsaC to the photosystem I core heterodimer. In solution, the N terminus of PsaC is in contact with the pre-C-terminal region (equivalent to the C terminus in bacterial ferredoxins). As compared to bound PsaC, the N terminus in unbound PsaC is bent and is located in between the pre-C-terminal region and the iron–sulfur core region of the protein. The same N- and pre-C-terminal regions are arranged as an antiparallel β-sheet and are much closer to F_A-binding site in bound PsaC. The antiparallel β-sheet arrangement of the N terminus and C terminus (equivalent to the pre-C terminus in PsaC) is typical for bacterial ferredoxins. Thus, PsaC assumes a ferredoxin-like conformation only in the photosystem I-bound form.

Assembly of the Stromal Subunits of Photosystem I

The changes in the structure of PsaC are caused by the sequential formation of multiple networks of ionic and hydrogen bond contacts with the PsaA/PsaB core proteins and with the other two proteins of the stromal side, PsaD, and PsaE. A comparison of the structure of unbound and bound PsaC, PsaD, and PsaE suggests a probable assembly scenario for the sequential binding of the stromal proteins. The assembly of F_X and the proper folding of the large loops that provide a binding site for F_X are preconditions for the binding of the stromal proteins. PsaC has a defined three-dimensional structure only after insertion of both [4Fe–4S] clusters. Therefore, the presence of the iron–sulfur clusters F_A and F_B is precondition for binding of the PsaC and the other stromal proteins. PsaC binds first. Its conformation changes after it binds to photosystem I; the binding of PsaD causes further conformational changes in PsaC, whereupon both assume their final structures. The biochemical and magnetic properties of [4Fe–4S] clusters F_A and F_B, typical for the photosystem I bound state of PsaC, are now established. PsaE probably binds last of the three stromal proteins, thereby completing the assembly process.

Resolution of the Sequence of Electron Transfer: $F_X > F_A > F_B$

Since the reduction potential of F_A (E_m' −540 mV) is higher than F_B (E_m' −590 mV), it was long assumed that F_A was the terminal electron acceptor in photosystem I. In this view, electron transfer in photosystem I is always thermodynamically favorable from $P700^*$ ($E_m' = -1300$ mV) to soluble ferredoxin ($E_m' = -420$ mV). However, EPR studies of PsaC

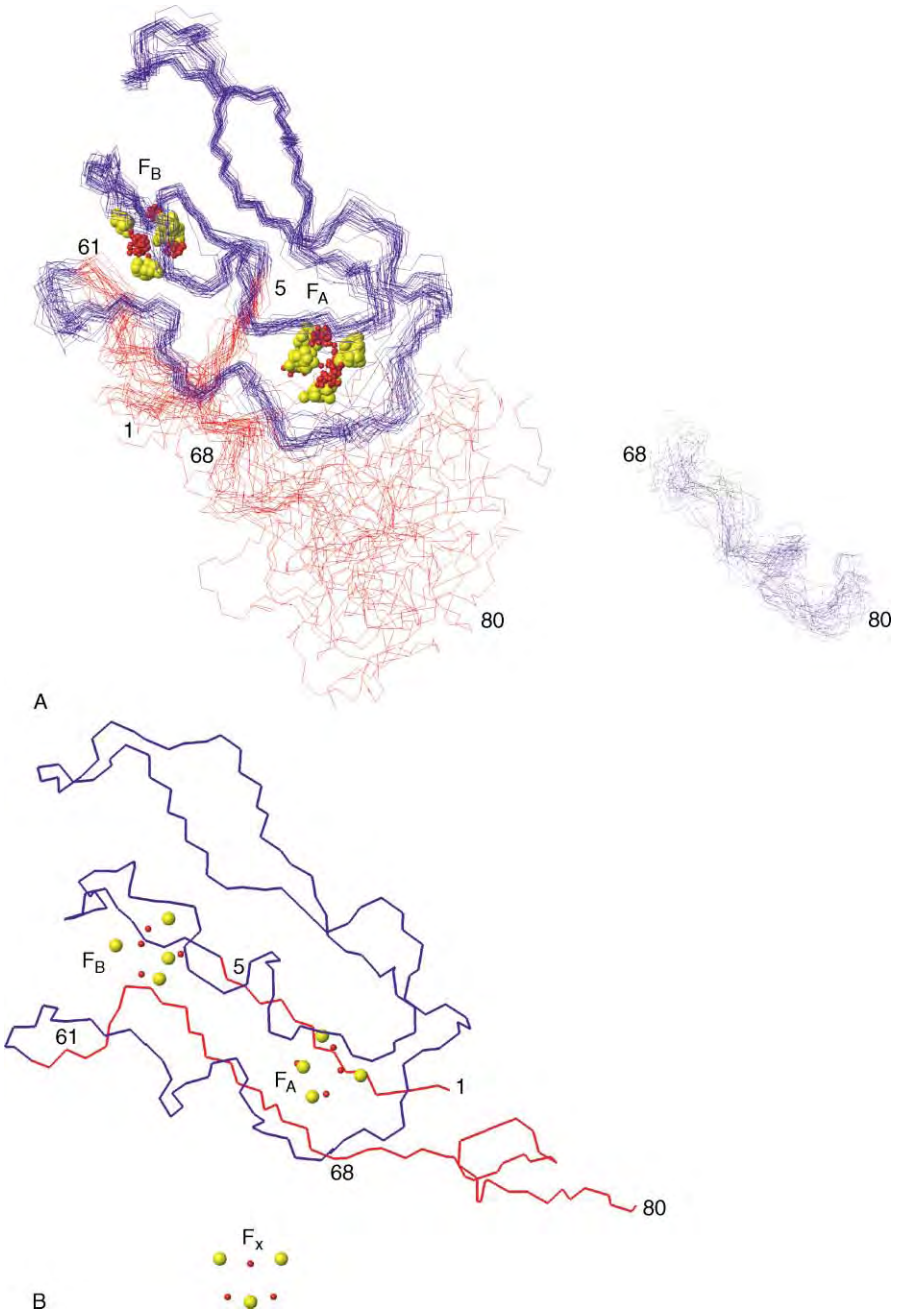

FIGURE 4 Comparison of the NMR solution structure of unbound PsaC (PDB entry 1K0T) with bound PsaC as part of the 2.5Å X-ray structure of Photosystem I (PDB entry 1JB0). The regions where the two structures show significant differences are identified by the red color. Iron atoms are represented by red circles, and sulfur atoms are represented by yellow circles. (A) Backbone drawing of the final family of 30 superimposed structures of unbound, oxidized PsaC from *Synechococcus* sp. PCC 7002 determined by solution NMR. Backbone of the family of 30 structures is shown in a superposition of residues 5–67. The iron and sulfur atoms of the [4Fe–4S] clusters of each of the 30 structures are shown. The view direction is equivalent to the membrane plane of the assembled photosystem I complex (see Figure 1). The inset shows the backbone of residues 68–80 in the same family of 30 PsaC structures. Superposition of solely the residues 68–80 reveals the helical secondary structure of the C-terminus. (B) Structure of photosystem I-bound PsaC taken from the PS I X-ray structure at 2.5Å X-ray resolution (PDB entry 1JB0). The polypeptide backbone and iron–sulfur clusters F_A and F_B are shown. F_X is included to indicate the position and the correct orientation of PsaC on PS I. This figure was prepared using MOLMOL. Reprinted from Antonkine, M. L., Jordan, P., Fromme, P., Krau*β*, N., Golbeck, J. H., and Stehlik, D. (2003). Assembly of protein subunits within the stromal ridge of Photosystem I. Biol.*, **327**, 671–697, with permission from Elsevier.

mutants, in which cysteine II in the F_A or F_B consensus binding sequence was changed to glycine, alanine, serine, or aspartate, led to the assessment that F_B is the terminal electron acceptor in photosystem I. This was in agreement with EPR relaxation and optical spectroscopy data obtained, around the same time, on photosystem I samples with selectively destroyed F_B. The presence of this small, thermodynamically unfavorable electron transfer step has little consequence because overall, electron transfer remains highly thermodynamically favorable from the excited state of $P700^*$ to ferredoxin. Furthermore, each forward electron transfer step in photosystem I is sufficiently rapid such that charge recombination events are negligible, and this results in the extraordinary quantum yield of ~1.0.

Glossary

cofactor Organic or inorganic molecule bound (covalently or through non-covalent interactions) to the protein that is necessary for/or aiding its function. For example, chlorophylls, quinones, and iron–sulfur clusters are cofactors in photosystem I.

F_A A low potential [4Fe–4S] cluster bound by cysteines 20, 47, 50, and 53 of the PsaC subunit of photosystem I; it is equivalent to Cluster II in bacterial ferredoxins that contain two [4Fe–4S] clusters.

F_B A low potential [4Fe–4S] cluster bound by cysteines 10, 13, 16, and 57 of the PsaC subunit of photosystem I; it is equivalent to Cluster I in bacterial ferredoxins that contain two [4Fe–4S] clusters.

F_X A low potential interpolypeptide, [4Fe–4S] cluster bound by two consensus FPCDGPGRGGTC sequences on the PsaA and PsaB subunits of photosystem I.

high-potential iron–sulfur proteins (HiPIP) These contain [4Fe–4S] clusters that shuttle between oxidation states of 3+/2+ .

low-potential iron–sulfur proteins These contain [4Fe–4S] clusters that shuttle between oxidations states of 2+/1+ .

quantum yield The number of electrons transferred per photon absorbed.

type I Photosynthetic reaction centers that use a [4Fe–4S] cluster as the terminal electron acceptor.

type II Photosynthetic reaction centers that use a mobile quinone as the terminal electron acceptor.

Biography

Mikhail L. Antonkine is Postdoctoral Fellow at Max-Planck Institut for Bioinoganic Chemistry. His principal research interests are the structure and function of iron–sulfur proteins including photosystem I. He holds a Ph.D. from the Pennsylvania State University and received postdoctoral training at The Free University of Berlin. He participated in determination of the solution structure of PsaC and in the

development of an assembly scenario for the stromal proteins of photosystem I.

John H. Golbeck is a Professor of Biochemistry and Biophysics at the Pennsylvania State University. His research interests are the structure, function, and organization of photosystem I and the biogenesis of iron–sulfur clusters. He holds a Ph.D. from Indiana University and received his postdoctoral training at Martin Marietta Laboratories. He developed methods to remove and reconstitute PsaC, PsaD, and PsaE in photosystem I, and he assigned the F_A and F_B clusters to the cysteine ligands on PsaC.

Photosystem II Light Harvesting System: Dynamic Behavior

Peter Horton and Alexander Ruban
University of Sheffield, Sheffield, UK

The light harvesting proteins of higher plants play a vital role in the regulation of photosynthesis. These proteins show striking structural and functional flexibility. This dynamic behavior provides a key physiological function to plants, which adapts them to continuously changing environmental conditions. In particular, dynamic properties of the light harvesting proteins of photosystem II promote the efficient collection of sunlight when the intensity is limiting photosynthesis and effective photoprotection when the intensity is excess.

Photosynthetic Light Harvesting

Photosystem II (PSII) is the multisubunit chloroplast membrane-associated pigment–protein complex that uses the energy of sunlight to drive the oxidation of water, evolving oxygen, donating electrons into the photosynthetic electron transfer chain, and depositing protons into the thylakoid lumen. Along with the photosystem I (PSI) it forms the electron–proton transfer chain, which drives the synthesis of ATP and NADPH (Figure 1). Vitally important components of both photosystems are the light-harvesting antennas, light-collecting units (mainly LHCI and LHCII for PSI and PSII, respectively) which ensure high rates of energy input into the photosynthetic reaction centers (RCI and RCII, respectively) by intercepting large numbers of light quanta of various energies/colors. The analogy of LHCs as funnels feeding the RCs with light energy is most appropriate.

Structure and Function of LHCII

The light-harvesting antenna of PSII consists of several proteins which together bind ~300 chlorophyll molecules. Associated tightly with the D1/D2 reaction center are the core antenna complexes CP47 and CP43. The remainder of the antenna consists of the Lhcb proteins, Lhcb1–6. These bind chlorophyll *a*, chlorophyll *b*, and xanthophylls to form several different complexes – LHCII, CP24, CP26, and CP29. LHCII is the main complex and contains ~40% of the PSII chlorophyll – it is the most abundant chlorophyll protein in nature.

Figure 2 depicts the current knowledge of LHCII structure on different levels of organization. The single monomeric unit is a relatively small protein, ~25–28 kDa, containing three transmembrane α-helical structures and binding 12 molecules of chlorophyll (seven chlorophyll *a* and five chlorophyll *b*). Three LHCII monomers are associated together into heterotrimers containing Lhcb1, Lhcb2, and Lhcb3. Additional pigments, carotenoids, are also present in LHCII. Two xanthophylls, luteins, are associated with the helices A and B. A third carotenoid, neoxanthin, is associated with the helix C and the trimer also binds peripherally the carotenoids violaxanthin or zeaxanthin. The xanthophylls play several important roles: (1) ensuring correct assembly of LHCII during biosynthesis; (2) protection of chlorophylls against photooxidation by quenching chlorophyll triplet states and scavenging oxygen radicals; (3) being structurally flexible molecules they allow dynamic behavior of LHCII leading to alteration in chlorophyll interaction and subsequent change in light collection efficiency; and (4) they modulate the interactions between LHCII trimers. Indeed, it was shown that extent of interaction between trimers depends on the type of peripherally bound carotenoid, violaxanthin, or zeaxanthin. *In vivo*, PSII unit is built on the stereo principle: two reaction center complexes build the dimeric PSII core complex, which binds four trimeric LHCII and six monomeric CP24, CP26, and CP29 (Figure 2C). In the photosynthetic membrane these PSII units are often seen as ordered arrays (Figure 2D). Here the LHCII antenna forms an entire network, or macrodomain, of monomeric and trimeric subunits, associated with each other and the reaction center complex. Associated with this macrostructure is the stacking of the complexes together in the characteristic grana membranes.

Three major parameters determine the efficiency of light harvesting: (1) cross-section or number of pigments and their ability to intercept light quanta with the broad

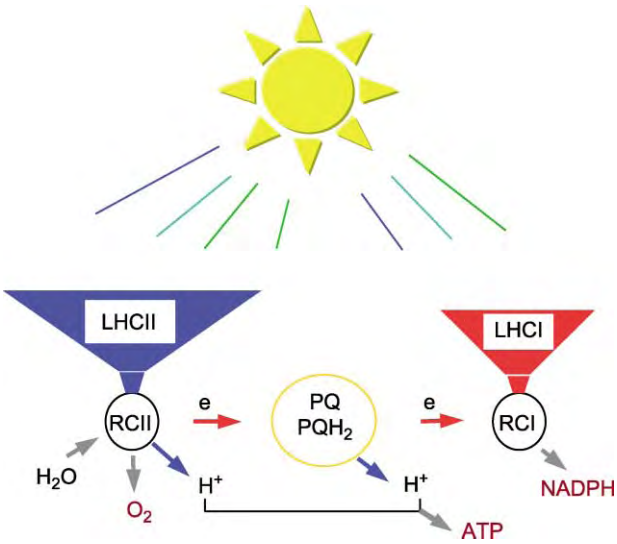

FIGURE 1 Photosynthetic electron transfer. LHCI and LHCII – light harvesting antenna of photosystem I and II, respectively; RCI and II – reaction centers; e – electrons; PQ and PQH_2 – intermediate electron carrier plastoquinone in oxidized and reduced form; H^+ – protons.

range of energy (color); (2) the time during which energy of light can be kept in antenna so it can be funneled into the reaction center; and (3) rate of the funneling. Thus, a large cross-section, long excitation energy lifetime, and high rate of energy transfer to the reaction center are the attributes of an efficient antenna and productive photosynthetic unit. Hence, the efficiency of light harvesting in PSII is determined by the number of LHCII subunits, the pigment order within them, the interaction between subunits and their closeness to the reaction center complex.

The Need for Control of the Light Reactions of Photosynthesis

The light and dark reactions of photosynthesis are tightly coupled, the ATP and NADPH provided by the electron-proton transfer system driving the fixation of CO_2 into carbohydrate. During a day, the light spectrum changes dramatically due to filtering by atmosphere, clouds and sometimes by other plants. Since LHCI and

LHCII have different capacities to absorb light of different colors – the former preferring more red light than the latter – there will be a frequent imbalance in light energy input into reaction centers. This imbalance will decrease the electron transfer efficiency, hence the quantum yield of photosynthesis. The light intensity is also a very changeable parameter, sometimes varying 1000-fold. Whenever light input exceeds the capacity of electron transport and CO_2 assimilation, there is an excess of light, which may cause photoinhibition – the destabilization (by over-reduction and over-energization) and even damage (by photo-oxidation and generation of reactive oxygen species) to photosynthetic components, mainly in PSII. The effects of changes in light delivery can be amplified by alterations in photosynthetic capacity brought about by changes in other environmental factors, or by changes in metabolic demand, which result in variation in the rate of turnover and the stoichiometry of ATP and NADPH.

In order to achieve balance and stability of the photosynthetic process, regulatory mechanisms are necessary. The plant cell first has to assemble a chloroplast with the "correct" composition, and then various parts of the photosynthetic process need to be able to adjust their activities in response to internal and external information. Thus, the electron transport and carbon metabolism can be considered to be linked by a feedback and feed-forward control network. There is a compromise between maximizing the collection and utilization of light, and the avoidance of instability when light is in excess. The most appropriate way of looking at the regulatory mechanisms is, given a fixed composition and a fluctuating environment, that they extend the range of conditions over which photosynthesis can remain in balance – they provide homeostasis of excitation energy level, redox state, and ΔpH.

To optimize light harvesting function, two distinct regulatory strategies are required. The first aims to balance the input of light energy to PSI and PSII reaction centers in order to optimize electron transfer rate – this is called the state transitions. The second should regulate the amount of light energy directed to PSII – this is called nonphotochemical energy dissipation, or quenching (NPQ). As a result of evolution, both regulatory mechanisms have developed in the LHCII system and rely on its abilities to sense the "state" of the light energy balance and structurally respond, being capable of dynamic behavior.

State Transitions

The Lhcb1 and Lhcb2 polypeptides of LHCII are reversibly phosphorylated by a redox-regulated thylakoid-associated protein kinase. Phosphorylation at threonine residues near the N terminus of LHCII

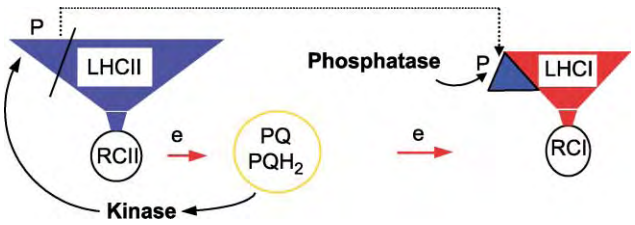

FIGURE 3 State transitions: the mechanism of compensation against imbalance of energy input into photosystems I and II. The redox controlled protein kinase phosphorylated LHCII when PQH_2 accumulates. A constitutive phosphatase activity dephosphorylates LHCII. This self-regulating system depends upon the different affinities of LHCII and phospho-LHCII for RCI and RCII.

weakens the association between PSII and LHCII, as a result of electrostatic and conformational changes. Phospho-LHCII partitions in favor of PSI, the association depending on the presence of the PSI-H subunit – in mutants without PSI-H phospho-LHCII remains associated with PSII. The kinase is activated when the plastoquinone pool is reduced, this being sensed by the quinone oxidation site on the cytochrome b_6f complex. The kinase therefore monitors the relative rates of delivery of excitation energy to PSII and PSI (Figure 3); overexcitation of PSII (state 1) activates the kinase, decreases delivery of excitation energy to PSII, and increases transfer to PSI (state 2). Levels of LHCII phosphorylation are lower at high light compared to low light, showing that the state transitions optimize photosynthesis in limiting light. This includes not only optimizing linear electron transport, but also the provision of optimal ΔpH and ATP/NADPH ratios by controlling the proportion of cyclic electron transfer around PSI.

Nonphotochemical Energy Dissipation

Energy-Dependent Quenching, qE

Dissipation, or quenching, of excess excitation energy absorbed by LHCII occurs by two processes, distinguished by the speeds with which they are induced upon exposure to illumination, their relaxation times in darkness and the light intensity threshholds. The major process under "normal" conditions is called qE, since it depends upon the energization of the thylakoid membrane as a result of ΔpH formation. Thus, the progressive increase in ΔpH that occurs as light saturation of photosynthesis is reached and is the trigger for energy dissipation. It can therefore be referred to as feedback de-excitation. The formation of qE occurs within seconds – minutes of exposure to excess light, and relaxes with a similar rate in darkness. In contrast, the sustained qI-type of quenching may take several

minutes or even hours to appear and relax, and under some conditions (such as low temperature) may be stable for days.

The Site of Quenching

Application of mathematical models for PSII energy transfer showed that quenching associated with qE occurred in the light harvesting antenna. Refinements of the analysis showed that qE is best explained by the transition between two states of the antenna, with different rate constants for energy dissipation. Subsequently, analysis of the chlorophyll fluorescence lifetimes provided direct support for this suggestion. Spectroscopic data and biochemical analysis confirmed that the PSII antenna was the site of quenching. A powerful way to determine which proteins are involved in qE is to investigate plants deficient in specific components. Experiments using plants deficient in all of the Lhcb proteins suggested that qE was not a property of the core antenna. However, plants in which Lhcb1 and 2, Lhcb4 and 5 have been separately reduced to less than 5% wild-type levels of protein by antisense technology show little or no change in qE, and in plants it has not proved possible to invoke a particular antenna complex as having an obligatory role. A major landmark in qE research was the identification of the *npq4* mutant, a mutant lacking qE and which is deficient in the Lhc-related protein PsbS. This four-helix protein is located in PSII, and contains protonatable amino acid residues which are thought to sense the thylakoid lumen pH.

The Xanthophyll Cycle

Under conditions of excess light, violaxanthin is de-epoxidized to zeaxanthin via the mono-epoxide antheraxanthin due to the activation of violaxanthin de-epoxidase, a thylakoid lumen enzyme. Another enzyme, zeaxanthin epoxidase, reverses the reaction in low light. A vast amount of data, from a wide variety of plant species under many different environments, showed correlations between the extent of qE and the de-epoxidation state of the xanthophyll cycle pool. Zeaxanthin is an activator of qE in that the apparent pK_a of the protonation reaction inducing qE shifts from near 4.5 to well over 5.0 in the presence of zeaxanthin. Since the ΔpH *in vivo* does not fall below 5.5, qE will depend completely on de-epoxidation of violaxanthin. Therefore, qE is an allosteric process, under the control of the interacting effects of protonation and zeaxanthin binding, similar to a regulated enzyme (Figure 4). This mode of regulation explained how the chloroplast could have a ΔpH high enough in limiting light to allow ATP synthesis without qE, yet in saturating light, how to have maximum electron transport rates and high qE simultaneously.

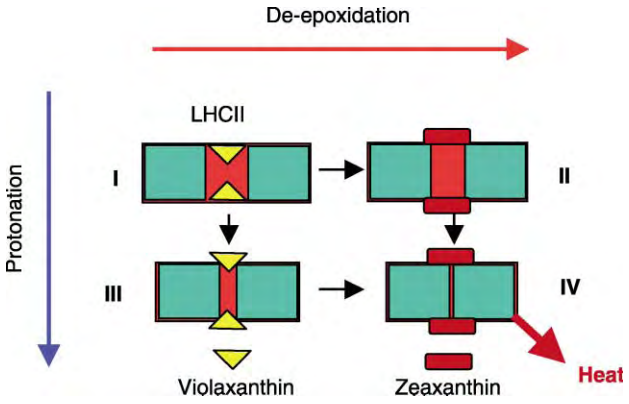

FIGURE 4 Model for the excess energy dissipation in the LHCII antenna. I – light-harvesting mode, a dark-adapted state; II – partially energy-dissipative, intermediate state; III – light "memory" mode, a dark-adapted mode after zeaxanthin was formed; IV – energy dissipative mode. The closeness of the boxes represents the extent of pigment interaction in LHCII and controls the level of quenching.

It has proved difficult to distinguish between the proposal that zeaxanthin was directly involved in quenching chlorophyll excited states by chlorophyll/zeaxanthin energy transfer, and the notion that zeaxanthin was working indirectly, modifying or inducing a quenching process intrinsic to the PSII antenna.

The Nature of the Quenched State of LHCII

Changes in the absorption spectra of chlorophyll and carotenoid occur upon formation of qE. A band with a maximum at 535 nm (ΔA_{535}) has attracted most attention, since its appearance is perfectly correlated to the amount of "quencher." Resonance Raman spectroscopy of leaves and chloroplasts has shown that ΔA_{535} is electronic in origin, and arises from a pool of one or two zeaxanthin molecules per PSII, which undergo a strong red shift in the presence of ΔpH. A similar red shift occurs when zeaxanthin binds to PsbS *in vitro*, and it is concluded that ΔA_{535} arises from this interaction.

Analysis of fluorescence lifetimes shows that the qE state of the PSII antenna has a lifetime of 0.4 ns, and the unquenched state 1.6 ns. Experiments with isolated light harvesting complexes have shown how such a change can arise. Detergent-solubilized LHCII has a lifetime of 4 ns, but reduction of the detergent concentration causes formation of oligomers with an average lifetime of 0.3 ns. This quenching has many features that are similar or identical to qE. The spectral changes in chlorophyll accompanying this *in vitro* quenching indicate that a particular LHCII domain is involved. The *in vitro* quenched state can also be investigated by reconstitution of light harvesting complexes with altered carotenoid content.

Substitution of lutein with zeaxanthin in LHCII causes partial chlorophyll fluorescence quenching.

In general, the ease with which LHCII *in vitro* can adopt a quenched state reflects the high density of pigment within it. Its design as a light harvesting complex means it maximizes the amount of chlorophyll per unit volume. Specific features of protein structure are needed to control the interactions between pigments, to promote energy transfer and to prevent formation of quenchers – dimers or excimers of chlorophylls and/or chlorophyll-xanthophyll associates. Therefore, only rather small changes in structure are needed to allow a quencher to form. Indeed, the activation energy for the formation of a quencher in LHCII is only 6 kcal mol^{-1}, indicative of the breakage of just a couple of H bonds. Thus, LHCII is uniquely poised to allow a switch between an unquenched state functioning in photosynthetic energy capture and a quenched state, dissipating excess energy as heat.

Biological Diversity of qE

The amount of qE in different plants is highly variable. High light grown plants may have 2–3 times more qE capacity and plant species adapted to growing in stressful environments have a much higher qE capacity than those inhabiting milder conditions. Genetic manipulation to increase the level of the PsbS protein results in an increase in qE, suggesting that the level of this protein is an important determinant of qE capacity.

Algae exhibit different qE properties as compared to higher plants. In *Chlamydomonas*, qE is smaller and forms more slowly, and mutation of an LHCII subunit decreases the capacity of qE, suggesting that here a less efficient process is controlled directly by the antenna and not by PsbS. In diatoms, which have light harvesting proteins of a different type, qE can be much larger than in higher plants, and its formation and relaxation totally depend upon the de-epoxidation of the violaxanthin analogue, diadinoxanthin. It seems that some features of the molecular mechanism for the regulation of light harvesting have diverged during evolution of classes of organisms.

Other Responses of LHCII to Excess Light

The sustained qI-type of quenching appears to also result, in part at least, from alteration in the antenna of PSII. At low temperature strong quenching is induced by light which has some features diagnostic of an increase in aggregation state of LHCII – formation of a red-shifted fluorescence emission band at 77 K. This state of LHCII seems to be semipermanent in some evergreen plants during winter. The mechanism by which such quenching is formed is currently unknown, although one possibility is that it arises from a direct effect of light on LHCII. Such an effect is well known for LHCII *in vitro*, and it appears to be triggered by a light-induced dissociation of trimers into monomers. At elevated temperature increased light-induced quenching arises from a different process – LHCII dissociates from PSII to be quenched by PSI, in a process that resembles the state transition, and in fact phosphorylation of LHCII and elevated temperature act synergistically.

When plants grown under low light are exposed to a sustained increase in light intensity, LHCII degradation is induced. Only monomers can be the substrates for proteolysis, and so this process must be preceded by a light-induced breakdown of trimers. Little is known about the biochemistry or regulation of this proteolytic process. Under extreme conditions, not only LHCII but complete photosystems are degraded as the plants seek to minimize oxidative damage.

The content of LHCII varies significantly depending on the light intensity under which the plants are grown. Typically, a low light grown plant may have 4–5 trimers per PSII core complex, whereas in high light this reduces to 1–2. The extra LHCII in low light plants appears to be present in membrane domains deficient in PSII core complexes. These LHCII domains can still be involved in efficient energy transfer, even transferring energy to pigments on opposite membranes in the grana.

The adjustment of the composition of photosystem II upon growth in high light compared to low light maintains the redox potential and ΔpH at the correct level, optimizing photosynthesis and avoiding oxidative stress. At higher growth irradiance, when LHCII cannot decrease any more, there are increases in the capacity for photoprotection (e.g., through an increase in xanthophyll cycle activity or PsbS content) and, eventually, decrease in the chlorophyll content of the leaf in order to lower light absorption. Even macroscopic events such as chloroplast movements or changes in leaf orientation can be similarly viewed as contributing to the optimization of light harvesting and counter-acting photodamage. Thus, plants do whatever they can, by a multitude of mechanisms, to limit the level of excitation energy in the PSII antenna, giving balance with the demands of photosynthesis, and optimising the redox state and ΔpH.

Glossary

grana membrane The characteristic organization of the chloroplast thylakoids in which regions of membrane become tightly appressed together to form stacks of membranes, associated with the lateral segregation of the photosystems.

nonphotochemical quenching The quenching of chlorophyll fluorescence that arises because of an increase in thermal dissipation of excitation energy, contrasted to the photochemical quenching that arises because energy is used to drive photosynthetic electron transfer.

ΔpH The pH gradient, ~pH 7–8 outside and pH 5–6 inside, across the thylakoid membrane that results from light-induced proton uptake.

photoinhibition The inhibition of photosynthesis that arises during excess illumination, either from sustained quenching of antenna or reaction center complexes, or from accumulation of damaged photosystem II D1 proteins.

state transitions The reversible adaptation of the light harvesting system to differential excitation of PSI and PSII; in state 1, induced by overexcitation of PSI, energy transfer from LHCII to PSII is maximum, and in state 2, induced by overexcitation of PSII, energy transfer from LHCII to PSI is maximum.

xanthophyll cycle The reversible de-epoxidation of thylakoid bound violaxanthin to zeaxanthin, via the intermediate antheraxanthin.

Biography

Peter Horton is a Professor of Plant Biochemistry in the department of Molecular Biology and Biotechnology at the University of Sheffield in the United Kingdom. His principal research interest is in photosynthesis and related aspects of plant biology. He holds a D.Phil. and D.Sc. from the University of York and received postdoctoral training at Purdue University. He has developed the concepts involved in the regulation of the light reactions of photosynthesis, establishing the role of LHCII phosphorylation in the state transitions, developing the methodology and framework of chlorophyll fluorescence analysis, and determining the basic mechanisms underlying nonphotochemical quenching.

Alexander Ruban is a Research Associate at the University of Sheffield where his principal research interest is in the biophysical aspects of photosynthesis. He holds a Ph.D. from the University of Kiev. Dr. Ruban has developed a number of spectroscopic approaches to investigate the dynamics of LHCII *in vitro* and *in vivo*.

Photosystem II: Assembly and Turnover of the D1 Protein

Eira Kanervo and Eva-Mari Aro
University of Turku, Turku, Finland

Photosystem II (PSII) is an integral membrane protein complex of ~25 subunits. It resides in the thylakoid membrane of organisms performing oxygenic photosynthesis, i.e., in chloroplasts of higher plants, mosses, ferns and algae, as well as in prokaryotic cyanobacteria. The synthesis and assembly of a new PSII complex in eukaryotic organisms require cooperation of both chloroplast and nuclear genomes. Besides structural protein subunits, PSII contains pigments and cofactors involved in the photochemistry of PSII. Most of the cofactors are ligated to the reaction center proteins D1 and D2. Such an arrangement together with the toxic nature of PSII photochemistry renders the reaction center prone to a photo-induced damage and accelerates the turnover rate of PSII subunits. The primary target of photodamage and the most rapidly turning-over subunit is the D1 protein. This protein has to be constantly replaced in order to maintain the PSII complex in an active state. This dynamic process, known as the PSII photoinhibition repair cycle, occurs in the thylakoid membrane at the rate depending on light intensity. The repair cycle is an absolute requirement for the maintenance of PSII complexes active in photosynthesis.

Biogenesis and Assembly of a New PSII Complex

Cooperation between Chloroplast and Nucleus

The PSII complex of eukaryotic organisms contains both nuclear and chloroplast-encoded gene products, as is the case with other photosynthetic protein complexes in the thylakoid membrane. This indicates that a tight cooperation exists between the organelle and nucleus in building up the PSII complex. From at least 25 genes encoding the PSII proteins, 15 genes reside in the chloroplast genome, rest of them locating in the nucleus.

Targeting the Chloroplast-Encoded PSII Proteins

The majority of the PSII core proteins are chloroplast encoded. These comprise the D1, D2, CP43, CP47, cyt $b559\alpha$, and cyt $b559\beta$ proteins encoded by the *psbA*, *psbD*, *psbC*, *psbB*, *psbE*, and *psbF* genes, respectively. In addition, the PSII core proteins include the *psbH*, *psbI*, *psbJ*, *psbK*, *psbL*, *psbM*, *psbN*, *psbTc*, and *psbZ* gene products of low molecular weight. Translation of the chloroplast-encoded PSII core proteins takes place on the surface of the thylakoid membrane. Initiation of translation of many chloroplast-encoded proteins is regulated by nuclear-encoded mRNA-binding proteins. To what extent these proteins are involved in targeting the ribosome–mRNA complexes to the thylakoid membrane is, however, unclear. Insertion of the chloroplast-encoded PSII proteins to the thylakoid membrane occurs both co- and posttranslationally, and several soluble and membrane proteins are involved in assisting these processes. Cotranslational membrane insertion is typical for the PSII core proteins with several transmembrane helices, such as the D1, D2, CP43, and CP47 proteins.

Targeting the Nuclear-Encoded PSII Proteins

The nuclear-encoded PSII core monomer proteins are three low-molecular-weight (LMW) subunits, namely the *psbW*, *psbX*, and *psbTn* gene products. In addition, proteins of the light-harvesting chlorophyll *a/b*-binding protein complex II (LHCII) and the oxygen-evolving complex (OEC) are nuclear encoded. All the nuclear-encoded proteins are synthesized as precursors on cytosolic ribosomes. These precursors are subsequently targeted to the chloroplast via an N-terminal transit peptide, which is proteolytically cleaved after import into the chloroplast. The nuclear-encoded precursor proteins targeted to the thylakoid lumen contain a bipartite N-terminal transit peptide, the last part of which is removed after the arrival of the transported protein into the lumen. The lumenal proteins, including those for the OEC, use both the Sec machinery and the ΔpH pathway in their insertion and translocation to the lumenal side of the thylakoid membrane. Integration of the LHCII proteins to the membrane is dependent on the presence of the thylakoid-located Alb3 protein.

Assembly of a New PSII Complex

General Features

Understanding of the assembly of the PSII complex is, so far, in its infancy. Besides purely biochemical approaches, the assembly of PSII has been studied using plant and cyanobacterial mutants. Such mutants have been deficient in a specific PSII subunit or they have carried a mutation in a nuclear gene that affects the expression or assembly of a structural PSII subunit. Also studies on plastid development from etioplast to chloroplast have contributed to the understanding of PSII assembly. Furthermore, research on the light-induced turnover of the PSII complex has produced information that can be applied also for the research on the assembly process of a new PSII center.

Sequence of the Assembly of PSII Core, OEC and LHCII Proteins

Light is required for maturation of etioplasts to chloroplasts and for synthesis and assembly of most of the PSII subunits. However, some of the PSII subunits do not need light for synthesis, since they exist already in etioplasts. This is the case particularly with cyt *b559* and the OEC proteins. In the assembly of the PSII core proteins, the two-subunit cyt *b559* functions as the first assembly partner for the D2 protein. All these together form an initial complex that functions as a receptor for the cotranslational assembly of the precursor-D1 protein. The assembly process then continues by association of the *psbI* gene product and the CP47 protein to the PSII subcomplex. Subsequently, the *psbH* gene product, the CP43 protein, and several LMW subunits attach to the growing PSII subcomplex. Assembly of the additional LMW subunits, namely the *psbJ* and *psbL* gene products, is essential for subsequent proper association of the OEC proteins to the lumenal side of the PSII core monomer. Finally, the rest of the LMW subunits, such as the *psbK*, *psbW*, and *psbZ* gene products, are required for the last events of the assembly process. These events include dimerization of the PSII core monomer and the attachment of LHCII to the PSII complex resulting in formation of a PSII supercomplex. An array of such PSII supercomplexes exists in the grana membranes of chloroplasts.

Regulation of the PSII Assembly

Light is required for an efficient translation elongation and accumulation of the D1 protein as well as for synthesis of the CP43 and CP47 core proteins. In addition to light, regulation of synthesis and assembly of the PSII complex involves the availability of a variety of factors, including the ligation of pigments and cofactors (chlorophyll *a*, pheophytin, β-carotene, Fe, Mn, plastoquinone) and the availability of the assembly partners.

The chloroplast-encoded core proteins D1, D2, CP43, and CP47 are cotranslationally inserted into the thylakoid membrane. Pigments are thought to bind to these proteins during their cotranslational membrane translocation and during the concomitant association of the protein with its assembly partner(s). Light is needed for the chlorophyll biosynthesis at the level of conversion of protochlorophyllide to chlorophyll *a*. Currently, we lack information on details of the pigment binding, even though the importance of this event as a regulative step in the PSII assembly has been known for a long time. It is clear, however, that the chlorophyll-binding proteins of PSII are stabilized by ligation of pigments. Most chlorophyll-binding proteins do not accumulate at all in a nonpigmented form.

Successful synthesis of the PSII core proteins requires the availability of assembly partners. Synthesis of the D2 protein is dependent on the presence of cyt *b559*. Furthermore, cyt *b559*/D2 subcomplex is indispensable for the synthesis of D1, and the cyt *b559*/D2/D1 subcomplex, in turn, functions as an assembly partner for CP47. From the PSII core proteins, CP43 seems to be synthesized quite independently.

Turnover of the D1 Protein of PSII

PSII Photoinactivation and the D1 Protein Damage

The PSII complex performs a remarkable task in splitting water molecules to oxygen and hydrogen (protons). Such oxidizing electron transfer reactions of PSII in an atmosphere containing oxygen readily lead to the formation of highly reactive radicals that are potentially harmful to the protein moiety. Conditions that lead to imbalance between the various steps during the linear electron transfer process can lead to photoinactivation of PSII. Thus PSII, when performing its normal function, is hazardous for itself.

Photoinactivation of PSII increases almost linearily with increasing light intensity. Under low light the rate of photoinactivation is also low. The rate of inactivation correlates with the amount of photons absorbed and mediated to the reaction center. Upon inactivation, the PSII complex becomes unable to transfer electrons and split water molecules. A constant repair of inactivated complexes is required to guarantee the maintenance of a sufficient level of active PSII complexes for photosynthesis. The efficiency of repair is affected negatively by environmental stress factors, such as high light and the extremes of temperature. If the repair process cannot keep up with the rate of photodamage, nonfunctional PSII complexes start to accumulate. This situation leads to the measurable decrease in the rate of total photosynthesis.

The primary target of the photo-induced PSII damage is the reaction center protein D1. This fact reflects the "grand design" of PSII: only one protein of the multi-subunit complex is primarily destroyed, the rest of the proteins being rescued for further use, i.e., reparation of the PSII complex. The primary photodamage is thought to include a conformational change and an oxidative damage to the D1 protein. These events, in turn, trigger the reaction center protein D1 to a substrate for proteolytic degradation. However, the actual nature of the primary photodamage is not yet properly understood.

PSII Photoinhibition Repair Cycle

Start of the Repair Process

Active PSII centers exist as dimers in the thylakoid membranes of grana stacks (Figure 1). After a light-induced damage to PSII, the LHCII antenna dissociates and monomerization of PSII occurs. PSII monomers then migrate from the grana to the stroma-exposed thylakoid membranes where a contact with the components acting in degradation and synthesis of the D1 protein is feasible. OEC dissociates from PSII and a partial disassembly of the PSII core proteins takes place. The stages from photodamage to degradation of the D1 protein are regulated by phosphorylation-dephosphorylation events of the PSII core proteins.

Degradation of the D1 Protein

Degradation of the light-damaged D1 protein is a proteolytic process that occurs in a well-coordinated manner on the stroma-exposed thylakoid membranes, leaving the closest partner, the D2 protein, most often

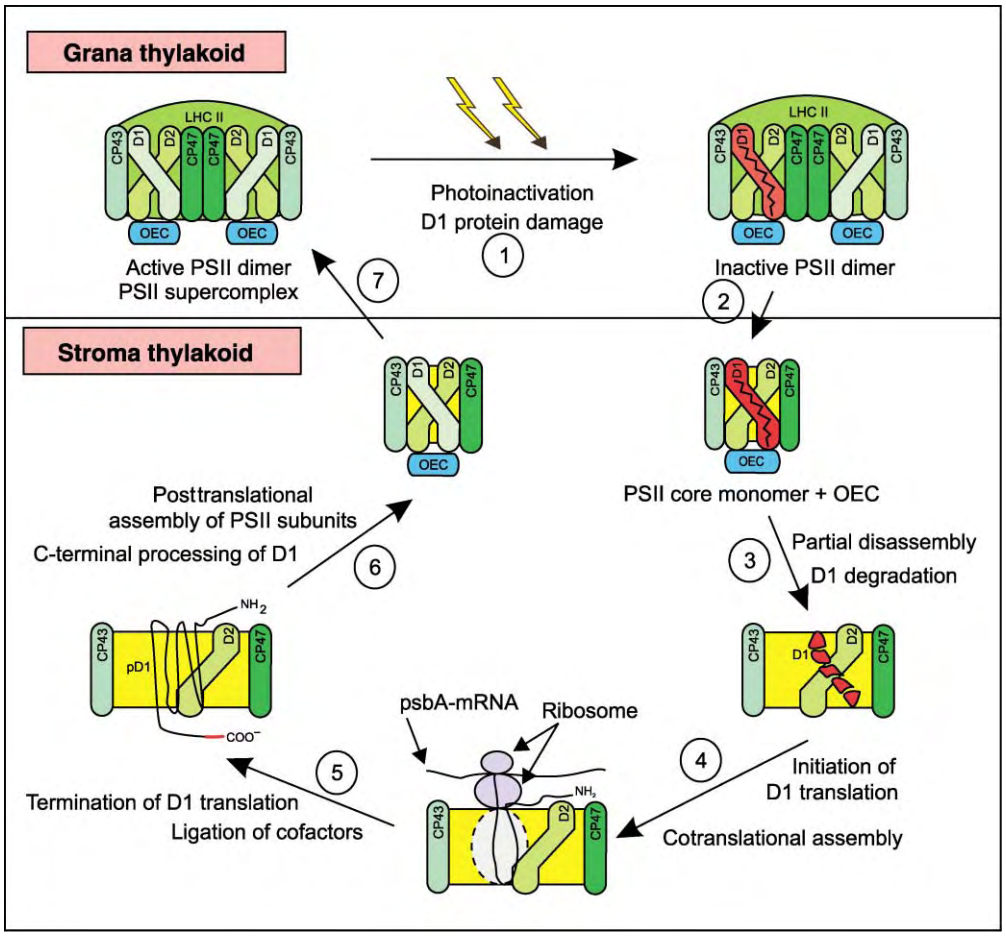

FIGURE 1 Model for the PSII photoinhibition repair cycle. 1) Photoinactivation of PSII and damage to the D1 protein. 2) Monomerization of the inactive PSII complex and its translocation from the grana thylakoids to the stroma-exposed thylakoids. 3) Partial disassembly of the PSII core proteins and proteolytic degradation of the D1 protein. 4) Initiation of D1 translation and cotranslational assembly of the nascent D1 chain into the D1-depleted PSII core monomer. 5) Ligation of cofactors during translation elongation and termination of D1 translation. 6) C-terminal processing of the pD1 protein; posttranslational assembly of the PSII core subunits and OEC. 7) Translocation of the repaired PSII monomer from the stroma-exposed thylakoids to the grana thylakoids; dimerization of PSII and the attachment of the LHCII antenna. D1, D2, CP43, CP47 = chlorophyll *a*-binding proteins of the PSII core; LHCII = light-harvesting chlorophyll *a*/*b* binding protein complex II; OEC = oxygen-evolving complex; pD1 = precursor-D1 protein.

intact. The D1 protein is an integral membrane protein with five transmembrane helices. Between helices there are loops both on the stromal and lumenal sides of the thylakoid membrane. The loops are the preferential sites of the primary cleavage of an integral membrane protein, in general, the stromal DE-loop being the most important one in the case of the D1 protein. The primary proteolysis of D1 produces fragments that are further degraded by the secondary proteolysis. Proteases from the DegP and FtsH families are known to act on the proteolysis of the D1 protein.

Synthesis of the D1 Protein

Synthesis of the D1 protein during the PSII repair cycle shares features with synthesis of the D1 protein in the assembly of a new PSII complex (see above). The D1 protein is encoded by the *psbA* gene residing in the chloroplast genome. The *psbA* mRNA-ribosome complex is targeted to the stroma-exposed thylakoid membrane, where elongation of the nascent D1 chain takes place. The nascent D1 chain is cotranslationally inserted into the thylakoid membrane, where the D2 protein and cyt *b559* act as the first association partners. Elongation is controlled by a variety of factors. Such factors include association of the nascent chain with a translocon, availability of the assembly partners, redox control of translation elongation and ligation of pigments. Resynthesis of the assembly partners is not needed, since they originate mainly from the existing PSII centers under repair.

When all the five transmembrane helices have been synthesized, the precursor D1 protein releases from the ribosome. The fifth transmembrane helix traverses the membrane, finally having its carboxy terminus in the thylakoid lumen.

Posttranslational Events of the D1 Synthesis and Reactivation of the PSII Complex

Posttranslational events of the D1 protein synthesis include several steps. First, during maturation of the D1 protein, the lumenal processing protease CtpA removes the extension of 9–16 amino acids from the carboxy terminus of the precursor D1 protein. This cleavage is necessary for ligation of the manganese cluster and reassociation of the OEC to the PSII complex. Before the OEC proteins can reassociate, the core proteins CP47, CP43 and most of the LMW subunits have to be reassembled to the PSII subcomplex. Finally, the properly assembled PSII monomer migrates back to the grana thylakoids, where PSII core dimerization and full reactivation of the PSII complex take place. The final reactivation stage also includes an association of the LHCII antenna proteins to the PSII dimer. These final stages in the grana thus accomplish the PSII photoinhibition repair cycle providing an active PSII dimer for photosynthesis.

Biography

Eva-Mari Aro is a Professor and Academy Professor in the Department of Biology at the University of Turku in Finland. Her principal interests are in the field of photosynthesis, including the photosystem II photoinhibition repair cycle, the assembly of PSII, and the redox regulation of thylakoid protein phosphorylation. Her scientific training abroad includes research visits to the University of California in Berkeley, USA, CEN Cadarache in France, the University of Stockholm in Sweden, and CSIRO in Canberra, Australia.

Eira Kanervo is a lecturer in the Department of Biology at the University of Turku in Finland. Her principal research interests include regulation of the D1 protein degradation and stress physiology of plants. She has been as a post-doc researcher at the National Institute for Basic Biology in Okazaki, Japan, and at the University of Linkoping, Sweden.

Photosystem II: Protein Components

James Barber
Imperial College, London, UK

Photosystem II (PSII) is a multisubunit protein complex embedded in the thylakoid membranes of oxygenic photosynthetic organisms: plants, algae, diatoms, and cyanobacteria. By using chlorophyll and several redox active cofactors, it captures and uses solar energy to split water into molecular oxygen and reducing equivalents.

$$2H_2O \xrightarrow[PSII]{4h\nu} O_2 + 4H^+ + 4e^-$$

To produce a dioxygen molecule, four photons ($h\nu$) are needed to provide the energy to split two water molecules The dioxygen released maintains our oxygenic atmosphere and provides an ozone layer which protects us from the damaging effects of UV radiation. The reducing equivalents which exit PSII as plastoquinol, are ultimately used, with the aid of additional light energy absorbed by photosystem I, to convert atmospheric carbon dioxide to the organic molecules that make up virtually all the biomass on our planet.

Morphology

Thylakoid Membrane

In chloroplasts of plants and green algae, the thylakoids are highly folded membranes having stacked (grana) and unstacked (stromal) lamellae regions. PSII is located mainly in the stacked regions. In cyanobacteria, diatoms, and other types of algae the thylakoids do not have a clear differentiation into stacked and unstacked regions and PSII is more evenly distributed along the plane of the membrane. In all cases the thylakoid membrane encloses an inner aqueous compartment known as the lumen while the outer compartment is either the stroma of the chloroplast or cytoplasm of cyanobacteria.

Reaction Center (RC)

RC is that part of a photosystem, like PSII, where light energy is converted to electrochemical potential energy. It is composed of protein-bound redox active cofactors that facilitate charge separation across the membrane.

Light-Harvesting Complexes

These pigment–protein complexes capture light energy and transfer it to the reaction center. They are often composed of several hundred pigment molecules, the exact number being dependent on growth conditions. Various pigments are used so as to fully utilize the solar spectrum and for PSII these are different types of chlorophyll, phycobilins, and carotenoids. Some light-harvesting complexes (LHCs) are contained within the thylakoid membrane (intrinsic) and some attach to the surface (extrinsic) of the membrane.

Redox Active Cofactors

P680

P680 is composed of a chlorophyll *a* molecule which, after excitation by the absorption of light to form $P680^*$, gives up an electron to an acceptor, converting it to $P680^{\cdot+}$. The redox potential of this radical cation is estimated to be 1.1 V or more, which is required to oxidize water. Its oxidation causes a bleach in its absorption spectrum centered at 680 nm. P680 is located on the lumenal side of the PSII RC. Recent work suggests that the excited state $P680^*$ is delocalized over four chlorophyll molecules and that upon oxidation the "hole" becomes localized on a single chlorophyll.

Pheophytin *A*

Pheophytin *a* (Pheo) is the primary electron acceptor of PSII located toward the stromal side of the RC. It receives an electron from $P680^*$ in a few picoseconds to form a radical pair $P680^{\cdot+}Pheo^{\cdot-}$. The reduction of Pheo can be detected as an optical absorption decrease at 422 nm and its reduction potential is ~ -600 mV.

Q_A

Q_A is a bound plastoquinone (PQ) molecule which undergoes a single reduction by $Pheo^{\cdot-}$ in $\sim$200 ps, forming the charge transport state $P680^{\cdot+}$ Pheo $Q_A^{\cdot-}$ where the redox potential of the semi-plastoquinone (Q_A^-) is ~ -150 mV.

Q_B

Q_B is also a plastoquinone (PQ) which can accept two electrons successively from $Q_A^{\cdot -}$ and together with two protons (H^+) from the stroma or cytoplasm to form plastoquinol (PQH_2). In this fully reduced form PQH_2 is released from the Q_B-binding site of the PSII RC and diffuses into the lipid matrix of the thylakoid membrane until it is oxidized by the cytochrome b_6f complex. The reducing equivalents are further "energized" by a second light reaction which occurs in photosystem I (PSI) so as to reach a redox potential sufficient to reduce carbon dioxide.

Y_Z

Y_Z is redox active tyrosine which reduces $P680^{\cdot +}$. In so doing, it loses an H^+ from its phenolic group and the resulting species is a neutral tyrosine radical $Y_Z^{\cdot}$.

$(Mn)_4$-Cluster

A cluster of four manganese atoms together with a Ca^{2+} atom, make the catalytic center (Mn_4Ca^{2+}-cluster), where the splitting of two substrate molecules occurs. The removal of 4e and $4H^+$ requires four successive oxidations of P680, and there is evidence that $Y_z^{\cdot}$ may act as an H^+ as well as an electron acceptor and therefore is directly involved in the water oxidation reaction.

Proteins

The RC core complex of PSII is composed of a large number of proteins encoded by Pcb genes (see Table I). The RC core is serviced by LHC proteins, the number and type of which varies between different types of organisms. Plants and green algae have their LHC proteins encoded by *cab* genes while red algae and cyanobacteria contain phycobiliproteins encoded by *apc* and *cpc* genes. Here we confine ourselves to PSII RC core proteins encoded by the *psb* genes (Figure 1).

PsbA-D1 Protein

After C-terminal posttranslational modification this protein has a molecular mass ~38 kDa and contains ~350 amino acids depending on species. It has five transmembrane α-helices (A–E), DE stromal surface α-helix, and CD lumenal surface α-helix. It binds the majority of the cofactors involved in PSII-mediated electron transport: Y_Z is Tyr161, $P680^{\cdot +}$ is chlorophyll *a* ligated by His198, Pheo is probably H-bounded by Tyr126 and Glu130, Q_B via interactions with His 215 and Ser 264. The Mn_4Ca^{2+}-cluster, is probably ligated by Asp170, Glu189, Ala344, His332, Glu 333, and His337. The D1 protein also binds a non-heme iron, which is normally redox inactive and positioned between Q_A and Q_B, and is ligated by His215 and His272.

Another important property of the D1 protein is that it turns over more rapidly than any other protein in the thylakoid membrane. This remarkable feature is linked to the fact that PSII is susceptible to photoinduced damage leading to photoinhibition and a lowering of photosynthetic efficiency. The degradation, synthesis, and reinsertion of this protein into the RC core complex represents a very important aspect of the dynamics of PSII.

PsbB-CP47

This highly conserved PSII RC protein consists of ~500 amino acids and has a molecular mass of ~56 kDa depending on species. It is often known as CP47 and has 6 transmembrane α-helices (I–VI) arranged in a ring consisting of 3 pairs with N and C termini exposed at the stromal surface. The lumenal loop joining transmembrane helices V and VI is large, consisting of 200 amino acids. It binds 16 chlorophyll *a* molecules and probably 3 β-carotenes. Most of the Chls are ligated to His residues located in the transmembrane helices and form an LHC system for the RC. The large lumenal loop functions indirectly in the water oxidation reaction by interacting with the D2 protein. Depletion of the *psb*B gene and a wide range of site-directed mutational studies have emphasized the absolute requirement of the PsbB protein in PSII assembly and function.

PsbC-CP43

After posttranslational processing the PsbC-CP43 protein, depending on species, contains ~470 amino acids and has a molecular mass of ~50 kDa. It is homologous with PsbB (CP47) in that it has 6 transmembrane α-helices arranged in the same way. It also contains a considerable number of histidine residues which are involved in ligating some of the 14 Chl*a* bound to this protein. Like CP47, CP43 probably binds 3 β-carotene molecules and has a large lumenal loop joining helices V and VI. However, this loop is slightly smaller, having ~150 amino acids. It also differs from CP47 in that in plants (but not in algae and cyanobacteria) the N-terminal threonine of CP43 can be reversibly phosphorylated. Moreover CP43 seems to be more weakly associated with PSII than with CP47, a feature which may be important when the D1 protein is degraded and replaced. Despite these differences, CP43, like CP47 acts as a LHC for PSII and its presence is also necessary for water splitting activity since it provides a ligand for the Mn_4Ca^{2+}-cluster.

TABLE I

Protein Subunits of PSII Core Reaction Center Complex

Gene	Subunit	Mass (kDa)	No. of transmembrane α-helices
*psb*A (c)	D1	38.021 (S)	5
*psb*B (c)	CP47	56.278 (S)	6
*psb*C (c)	CP43	50.066 (S)	6
*psb*D (c)	D2	39.418 (S)	5
*psb*E (c)	α-cyt b559	9.255 (S)	1
*psb*F (c)	β-cyt b559	4.409 (S)	1
*psb*H (c)	H protein	7.697 (S)	1
*psb*I (c)	I protein	4.195 (S)	1
*psb*J (c)	J protein	4.116 (P)	1
*psb*K (c)	K protein	4.283 (S)	1
*psb*L (c)	L protein	4.366 (S)	1
*psb*M (c)	M protein	3.755 (P)	1
*psb*N (c)	N protein	4.722 (T)	1
*psb*O (c)	33 kDa O protein	26.539 (S)	0
*psb*P (n)	23 kDa P protein	20.210 (S)	0
*psb*Q (n)	16 kDa Q protein	16.523 (S)	0
*psb*R (n)	R protein	10.236 (S)	0
*psb*S (n)	S protein	29.197 (S)	4
*psb*T (c)	T_C protein	3.849 (S)	1
*psb*T (n)	T_n protein	5.000 (A)	0
*psb*U	U protein	10.491 (Sy)	
*psb*V	V protein	15.121 (Sy)	0
*psb*W (n)	W protein	5.928 (S)	1
*psb*X (n)	X protein	4.225 (S)	1
*psb*Y (c)	Y protein	4202 (Sy)	1
*psb*Z (c)	Z protein	6.541 (S)	2

These proteins are products of the *psb*A to *psb*Z genes that occur in oxygenic organisms. In eukaryotic organisms the *psb* genes are located in either the chloroplast (c) or nuclear (n) genes. The molecular masses of the mature PsbA–PsbZ proteins are calculated from the protein sequences reported in the SwissProt database using the MacBioSpec program (Sciex Corp., Thornhill, ON, Canada) for spinach (S), pea (P), tobacco (T), *Arabidopsis* (A), and *Synechocystis* PCC6803 (Sy).

PsbD-D2 Protein

The PsbD-D2 protein is homologous to the D1 protein. Although it is slightly larger than the D1 protein, having in the region of 353 amino acids and a molecular mass of ~39.5 kDa, depending on species it has 5 transmembrane helical segments organized in the same way as the D1 protein. Compared with the D1 protein it is involved to a lesser extent in binding active cofactors. Another chlorophyll that forms a cluster constituting $P680^*$ is ligated to His197, while the binding of Q_A may involve at least His214, Phe261 and possibly Trp253 and Leu267. The D2 protein also provides ligands for the non-heme iron being His214 and His268. Normally the D2 protein does not turn over rapidly like the D1 protein but, under extreme conditions (e.g., irradiation with damaging UV light), it will be replaced by a repair process.

PsbE and PsbF

These are the α- and β-subunits respectively of cytochrome b559. After processing, the PsbE and PsbF contain 82 and 38 amino acids in most higher plants, and have molecular masses of ~9.3–4.4 kDa. Both subunits have a single transmembrane helix with their N termini exposed to the stromal surface.

The α-subunit is characterized by having a long C terminus of ~44 amino acid residues extending from the lumenal surface of the membrane while the β-subunit has essentially no lumenal domain. Of considerable importance is that each subunit contains a conserved

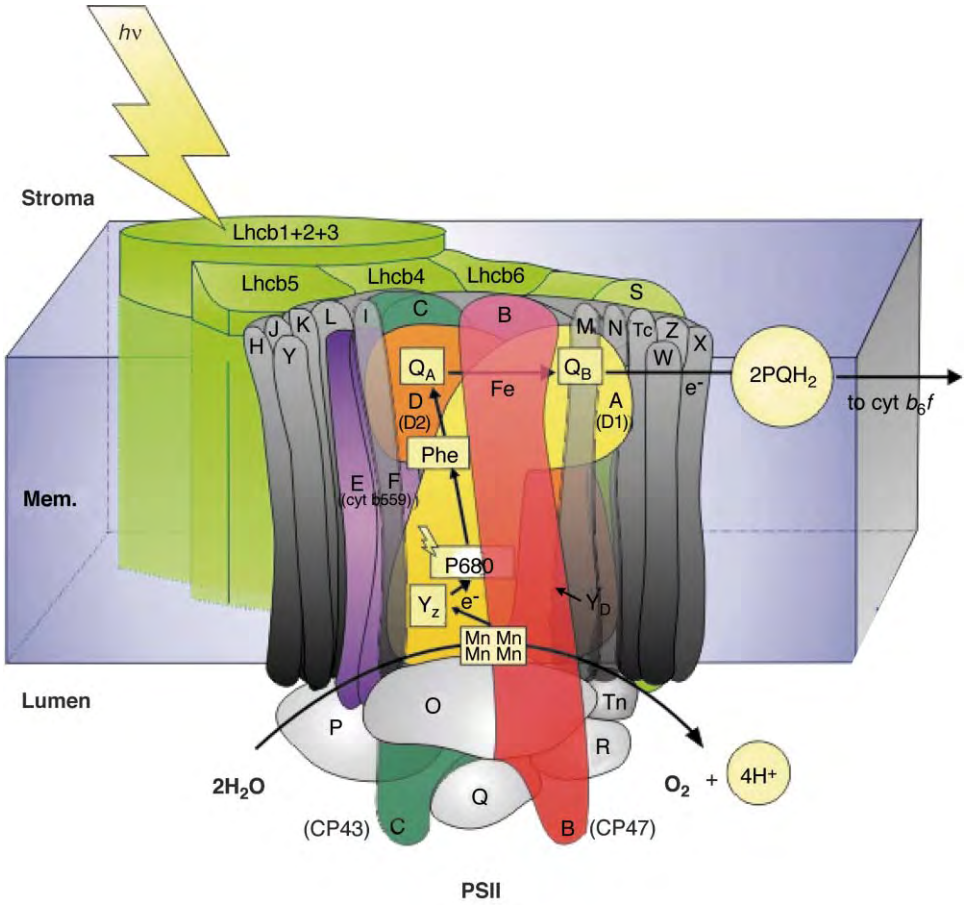

FIGURE 1 Cartoon showing the protein components of PSII of plants and algae, and the primary and secondary electron steps that occur in the reaction center D1 and D2 proteins. The RC core proteins are labeled according to their gene letter (e.g., *psb*A = A). Also shown are the Lhcb Chl*a*/Chl*b*-binding proteins encoded by *cab* genes that form the outer light-harvesting antenna system of higher plants and green algae.

histidine residue which is located within the membrane-spanning region towards the stromal surface. These two residues form axial ligands to the heme of the cytochrome. Although it had been argued by some that there are two cyt b559 per RC, there is strong evidence favoring a single copy of the cytochrome per RC. The deletion of the *psb*E gene results in a lack of assembly of PSII. On the other hand replacement of the His residue in the α-subunit can lead to an assembled and functionally active PSII complex even when no heme is ligated to the PsbE and PsbF proteins. Normally the heme has a high redox potential of $\sim$0.4 V but under some circumstances this potential is lowered to 0.15 V or less. The chemical basis of this redox shift and its significance, if any, is unclear. Under some circumstances, usually when the water splitting reactions are inhibited such as at low temperature, the heme of cyt b559 is oxidized by $P680^{+}$. According to recent structural models the heme is at least 40Å from P680, which is too far to account for the millisecond time constant for its oxidation. Accordingly it has been suggested that a β-carotene molecule bound within the D1/D2 heterodimer acts as a redox intermediate between the cyt b559 and $P680^{+}$. The reduction of the oxidized heme may involve Q_A^-, Q_B^-, or $Pheo^-$ but again there is a distance problem, with the required electron donation occurring over distances of 28Å or more, according to the recent X-ray structure. It seems likely that cyt b559 plays a protective role in minimizing photodamage of the RC.

PsbG

A chloroplast gene was initially called *psb*G but it was shown later that the product of this gene was not a PSII protein but rather a component of a chloroplast located NADPH/quinone oxidoreductase. This gene is now known as *ndh*K.

PsbH

In higher plants, the PsbH protein contains 72 amino acids and has a calculated mass of $\sim$7.7 kDa.

In cyanobacteria the protein is slightly smaller (~6.5 kDa) with a truncated N terminus and as such does not have the N-terminal threonine residue which is conserved in all higher plant and green algal sequences which is the site for reversible phosphorylation. The functional significance of the phosphorylation process is unclear. The higher plant protein is characterized by having a single transmembrane helix with a long N-terminal region consisting of ~41 amino acids at the stromal surface, which reduces to ~30 residues in the case of cyanobacteria. The *psb*H gene can be deleted from the cyanobacterium *Synechocystis* without impairing the assembly of PSII and photoautotrophic growth. The knockout mutant was, however, more sensitive to photoinhibition than the wild type. This sensitivity seemed to be due to the partial inhibition of the D1 protein repair process rather than to an increase in photochemical damage. In contrast, when the *psb*H gene was deleted in *Chlamydomonas reinhardtii*, PSII did not assemble.

PsbI

The PsbI protein has a molecular mass of ~4.2 kDa. In most eukaryotes this protein contains 35 amino acids and is predicted to have a single transmembrane helix with a short N-terminal region at its stromal end. It is located close to the D1/D2 heterodimer being adjacent to the B-helix of the D1 protein. Interestingly, the mature protein retains the initiating N-formyl group at its N-terminal methionine residue. The *psb*I gene has been deleted in the green alga *Chlamydomonas* and the cyanobacterium *Synechocystis*, without inhibiting PSII assembly and photoautotrophic growth. Thus, the function of the PsbI protein remains unknown.

PsbJ

In most organisms the *psb*J gene is located in a gene cluster also containing the *psb*E, *psb*F, and *psb*L genes. The PsbJ protein is highly conserved, consists of 39 amino acids and has a calculated molecular mass of 4.1 kDa. It is predicted to have one transmembrane helix. The *psb*J gene has been deleted in cyanobacteria to generate a knockout mutant which assembles PSII at a lower level than the wild type and consequently has a slower photoautotrophic growth rate.

PsbK

This ~43 kDa protein is highly conserved and has 37 amino acid residues. It is predicted to have a single transmembrane helix. Of particular note is that in higher plants, 24 amino acids are posttranslationally cleaved from the initial gene product. In cyanobacteria eight amino acids are removed after translation. These presequences probably bring about the insertion of the protein into the thylakoid membrane such that its N terminus is on the lumenal side. Deletion of the *psb*K gene in cyanobacteria has very little effect on photoautotrophic growth and PSII activity. In the case of green algae, however, the deletion of the gene destabilized the PSII complex and the transformant was unable to grow photoautotrophically.

PsbL

This highly conserved PSII protein contains 37 amino acids and has a calculated molecular mass of ~4.4 kDa. In most organisms its gene is located in the cluster together with *psb*E, *psb*F, and *psb*J. Hydropathy analysis suggests that it contains a single transmembrane helix. Inactivation of the *psb*L gene in cyanobacteria resulted in a loss of PSII-mediated oxygen evolution and the transformant was unable to grow photoautotrophically. It has also been reported that PsbL is required for normal functioning of the Q_A site based on studies with isolated PSII complexes. This conclusion was reinforced by the finding that PsbL is required for the oxidation of Y_Z by $P680^{+}$. As a consequence, the primary quinone acceptor is destabilized by the increased probability of rapid recombination between Q_A^- and $P680^{+}$.

PsbM

The PsbM protein is predicted to have one transmembrane helix with a very short N-terminal extension on the stromal side. It contains 33 amino acids and has a molecular mass of ~3.7 kDa. PsbM has been identified in PSII isolated from cyanobacteria and green algae. Together with PsbL and PsbTc this protein may function to stabilize PSII as a dimer.

PsbN

As in the case of PsbM, this protein is predicted to be in both cyanobacterial and plant PSII. However, it has not been detected directly in plant PSII although it has been identified in cyanobacteria. PsbN has a predicted single transmembrane helix. Deletion of both *psb*N and *psb*H genes from *Synechocystis* caused no effect other than those observed in the absence of *psb*H alone. Thus, the function and location of *psb*N are unknown.

PsbO

PsbO is a 33 kDa manganese stabilizing protein. Between higher plants and cyanobacteria this protein is

highly conserved containing, after processing, 241–247 residues. Although the mature PsbO protein is often referred to as the 33 kDa protein, its calculated molecular mass is ~26.5 kDa. It is an extrinsic protein with high β-sheet content and plays an important role in maintaining an optimal environment for water oxidation to occur. Various studies indicate that it does so by controlling Ca^{2+} and Cl^- levels at the catalytic site and by stabilizing the Mn_4-cluster, but it does not bind Mn directly. For this reason it is often called the "manganese stabilizing protein." Its deletion in cyanobacteria does not prevent water oxidation although the equivalent mutant in green alga does not assemble a functional PSII RC complex.

PsbP

PsbP is a 23 kDa extrinsic protein. After processing, this protein consists of ~186 amino acids with a calculated molecular mass of ~20 kDa. Although found in higher plants and green algae, it is not conserved in cyanobacteria. Like PsbO, its function seems to be to optimize the Ca^{2+} and Cl^- levels needed for the water oxidizing reaction and is located in the vicinity of the 33 kDa protein to which it binds.

PsbQ

The PsbQ mature protein contains ~49 amino acids and, like PsbP, is located close to the 33 kDa protein and the Mn_4-cluster. It is predicted to be an all α-protein and also seems to be involved in optimizing the ionic environment necessary for oxygen evolution. PsbQ, however, is not found in cyanobacterial PSII although a *psb*Q-like gene is present. Its binding to PSII requires the presence of PsbO and PsbP.

PsbR

The role of PsbR is unknown. It has a molecular mass of 10.2 kDa and consists of ~99 amino acids. It seems to be an extrinsic protein of plants, and is bound relatively tightly to the lumenal surface in the vicinity of the water splitting site. Whether it has a transmembrane helix is a matter for debate. It does not exist in cyanobacteria.

PsbS

The PsbS protein consists of ~205 amino acids and has an apparent molecular mass of 22 kDa although its calculated mass is ~29 kDa. It is predicted to have four transmembrane helices. Helices I and III, and II and IV, are homologous indicating that the protein is derived from internal gene duplication. Sequence homology studies suggest that PsbS is related to Chl*a*/Chl*b*-binding antenna Lhcb1–6 proteins (*cab* gene products) and is likely to be a chlorophyll-binding protein. A functional role for PsbS, therefore, could be to act as a pigment chaperonin which aids the incorporation of chlorophyll molecules into the various pigment-binding proteins of PSII. This protein has also been implicated in the protection of PSII against photoinduced damage (photoinhibition). It does not exist in cyanobacteria.

$PsbT_C$

The chloroplast-encoded $PsbT_C$ protein is also found in cyanobacteria. It contains 30–34 amino acids, has a molecular weight of ~3.9 kDa and retains the initiating N-formyl group on its N-terminal methionine residue. It is predicted to have a single transmembrane helix which is located in the N terminus of the protein. The *psb*T_C gene was formerly known as ycf8 and is located close to the *psb*B gene in the chloroplast genome. The first identification of this subunit was made by comparing wild type and a mutant of *Chlamydomonas* and lacked the *psb*T_C gene. This work also showed that the $PsbT_C$ is a PSII protein and is required for optimal activity under high-light conditions so as to prevent photoinhibition. It is located with PsbM and PsbL in the dimerization domain.

$PsbT_N$

A nuclear-encoded hydrophilic 5 kDa protein which copurifies with PsbO. Although its function is unknown, it seems to be an extrinsic protein located on the surface of PSII. The mature $PsbT_n$ protein consists of ~28 amino acids in higher plants and the presence of two cysteine residues suggests that it contains a disulfide bridge. It is not present in cyanobacteria.

PsbU

This is a cyanobacterial all α-protein reported to be extrinsically located on the lumenal surface of PSII close to the 33 kDa protein. It has an apparent molecular mass of ~11 kDa. It is also found in red algae but not in plants and green algae.

PsbV

PsbV is also known as cytochrome c550 and is found only in cyanobacteria and red algae. It has a molecular mass of 15 kDa and is an extrinsic protein found on the lumenal surface of PSII. It plays no direct role in water

oxidation although it does help to provide a Ca^{2+}/Cl^{-} environment at the catalytic site. It does not, however, bind directly to PsbO but indirectly via PsbU, which forms a bridge.

PsbW

The PsbW protein is found in higher plants and green algae. A cyanobacterial "PsbW-like" gene has also been documented which has a low homology with the eukaryotic equivalent, and therefore there is some uncertainty whether or not cyanobacteria contain the PsbW protein. In higher plants and green algae, it is nuclear-encoded and is processed to a mature protein having an apparent molecular mass of 6.1 kDa and consists of 54–56 amino acids. It is predicted to have one membrane-spanning region with its N terminus located on the lumenal side of the membrane. This orientation is consistent with the pre-sequence of the PsbW protein having characteristics of a target sequence typical for lumenal proteins. The function of PsbW is unknown.

PsbX

The PsbX protein is nuclear-encoded in higher plants and green algae, and consists of ~42 amino acids. In higher plants its synthesis is tightly regulated by light. The mature PsbX protein is reported to have a molecular mass of 4.1 kDa and predicted to have a single transmembrane helix. It has been detected in the oxygen-evolving PSII core complex of higher plants and cyanobacteria. The deletion of the *psb*X gene in cyanobacteria did not inhibit PSII assembly and photoautotrophic growth. However these studies suggest that PsbX may play a role in the function of Q_A and Q_B. It is located close to the B-helix of the D2 protein.

PsbY

This protein is located in PSII of plants, algae, and cyanobacteria. It has a molecular mass of ~4.2 kDa, consists of 36–39 amino acid residues, and has one transmembrane segment. The deletion of the *psb*Y gene in cyanobacteria did not impair the water oxidation process and is therefore likely to be located in a peripheral region of the PSII complex.

PsbZ

This 6.8 kDa protein contains 62 amino acids and forms two transmembrane helices. It is located at the peripheral edge of the PSII complex adjacent to PsbC (CP43) where, in plants and algae, it could be involved in binding the outer Chl*a*/Chl*b* light-harvesting systems.

Conclusion

Here 26 different Psb subunits have been described that are found in the PSII RC core. In a few cases, the subunits are either specific to plants and green algae or to red algae and cyanobacteria. In addition, there may be some other candidates which have yet to be characterized in detail. Recently X-ray structures of the cyanobacterial PSII RC core have been obtained and the resolution is now sufficient to unambiguously assign proteins to most electron densities. This has proved relatively easy for the D1, D2, CP43, CP47, PsbE, PsbF, and the extrinsic proteins. The most recent X-ray structure has identified the positions of 12 low-molecular-weight subunits in the cyanobacterial PSII complex.

Biography

James Barber is the Ernst Chain Professor of Biochemistry and Former Dean of the Royal College of Science and Head of the Department of Biochemistry at Imperial College, London. His principal research interest is light absorption and utilization in photosynthesis, with special focus on photosystem II and the water oxidation process. He has published over 500 papers, edited many specialized books, and was elected to Academia Europaeae in 1989 and a Foreign Member of the Swedish Royal Academy of Sciences in 2003.

Photosystem II: Water Oxidation, Overview

Fabrice Rappaport and Pierre Joliot
Centre National de la Recherche Scientifique, Paris, France

The appearance of oxygen-producing organisms about three billions years ago is widely believed to be at the origin of the conversion of our atmosphere from anaerobic to its present oxygen rich composition. The switch from reduced carbon or sulfur compound oxidation to water oxidation and carbon dioxide reduction did not only result in a major change in the gas composition of the earth atmosphere, but also boosted the apparition of aerobic metabolism, which produces 18 times more energy per unit of substrate than anaerobic metabolism. Photosynthetic oxygen evolution, which accompanies the conversion of solar energy to biomass is thus rightly considered as the source of most of the energy available to life on Earth as well as a mandatory process to fuel the respiratory metabolism. Since the discovery by Priestley of the gas exchange (oxygen production and carbon dioxide assimilation), resulting from the photosynthetic process, till today, much insight into the mechanism of water splitting into dioxygen has been gained with an impressive acceleration in the last 30 years. The enzymatic machinery which drives water oxidation is identified, its three-dimensional structure has first been determined, by the groups of W. Saenger and H.T. Witt, with a resolution of 3.5Å, which has improved since then. Yet, the precise chemistry and energetics of water splitting remains to be clarified, if not understood.

Photosystem II and the Water Splitting Enzyme

The Photosystem II Complex

Water oxidation into dioxygen (O_2) follows the equation: $2H_2O \rightarrow O_2 + 4H^+ + 4e^-$, where H^+ and e^- stand for protons and electrons, respectively. Water is obviously a very stable compound and its oxidation requires the availability of strongly oxidizing species (at pH 7.0 the midpoint potential of the H_2O/O_2 couple is 810 mV). This oxidizing power is formed at the expense of light absorption and the conversion of light energy into electrochemical energy. The action spectrum of oxygen emission showed that it is sensitized by pigments associated with Photosystem II (PS II). Photosystem II is a large pigment protein complex located in the thylakoid membrane of the chloroplast, in green algae or higher plants or in the cytoplasmic membrane in cyanobacteria. As illustrated in Figure 1, the core of PS II is composed of two homologous polypeptides (D_1 and D_2, D for diffuse electrophoretic profile) each of which consists of five transmembrane helices. It bears various redox cofactors among which a chlorophyll dimer (P_AP_B), two chlorophyll monomers (B_A and B_B), two pheophytins (Ph_A and P_B), and two quinones Q_A and Q_B. Among the various photosynthetic reaction centers, PS II is unique since it bears a tetra manganese cluster which, coupled to a redox active tyrosine Y_Z, is responsible for water splitting into oxygen. The core of the reaction center is surrounded by pigment (chlorophyll and carotenoid)-binding proteins, which increase by a factor of ~200 its absorption cross-section. Thus, under normal solar radiance, one photon is absorbed by PSII every 10 ms or so. The absorption of a photon by one of the chlorophyll borne by the pigment-binding proteins results in the formation of an excited state of a chlorophyll, i.e., an electron jumps from the highest occupied molecular orbital to the lowest unoccupied orbital of higher energy. Provided other pigments are close enough, this excitation energy may hop from one pigment to another and then be funneled to the core of the reaction center and more precisely to the primary donor P (denoted P^* in the excited state). The singularity of P resides in the fact that in its close vicinity one finds an electron acceptor (Ph_A). The excitation energy, by weakening the binding energy of the electron by the energy of the transition between the two molecular orbital, allows the electron transfer reaction between P^* and this nearby acceptor to occur, yielding the "charge separated state" ($P^+Ph_A^-$). This state is then further stabilized by successive electron transfer step between the different redox compounds. At room temperature the first oxidized cofactor is essentially P_A. It is reduced in a few tens of nanoseconds by the redox active Y_Z (Y161 of the D_1 polypeptide), which is in turn reduced at the expense of the water

splitting enzyme. As shown in Figure 1, despite the arrangement of the various redox cofactors in two symmetrical branches with respect to a pseudo C_2 symmetry axis perpendicular to the membrane plane, electron transfer only proceeds down one of these two branches indicating that function does not strictly follow structure.

The Water Splitting Enzyme

As just described, conversion of light energy into electrochemical energy is a one-electron process. However, water oxidation into dioxygen is a four-electron process. Taking advantage of the possibility to trigger the light-induced electron-transfer reaction by short light flashes P. Joliot showed that the oxygen emission yield is maximum after the third, seventh, eleventh… flash of a series (Figure 2). This oscillating pattern with a periodicity of four was modeled by B. Kok who postulated, on this basis, the existence of a charge storing device allowing, in a single catalytic unit associated with PSII, the accumulation of the four oxidizing equivalent needed to split water into oxygen. In this model, illustrated in Figure 2, the catalytic center has five different oxidation states (S_0, S_1, S_2, S_3, and S_4). Four successive light-induced oxidation triggers the four successive transitions between the S_i and S_{i+1} states. Upon S_4 formation, oxygen is produced and released while S_0 is regenerated. The beauty of the Kok model resides in its ability to fully describe the function of the enzyme without any assumption neither on the chemical nature of the transient states it involves, nor on the precise mechanism underlaid by the successive transition between the S states. This accounts for its success as a working model ever since it was enounced. Simultaneously to the discovery of this charge-storing device,

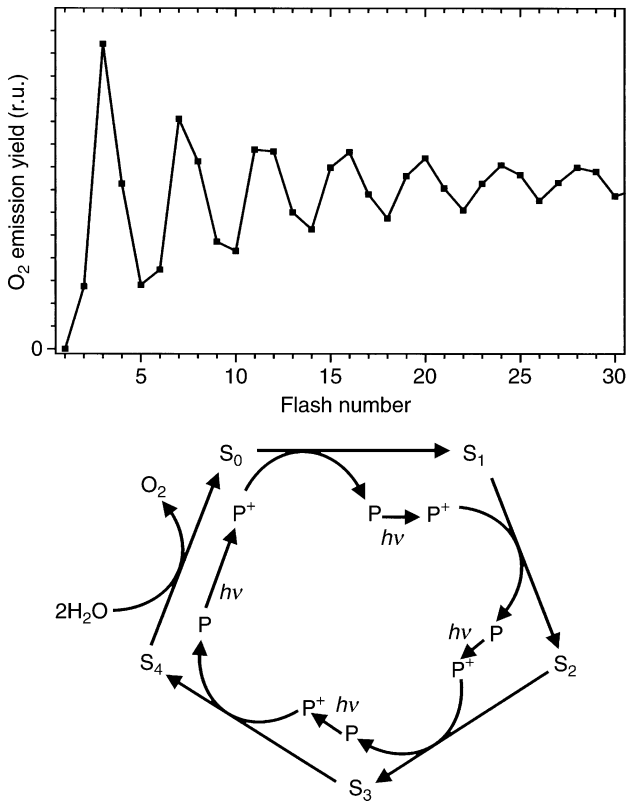

FIGURE 2 Top: The O_2 emission yield as a function of the flash number in a series. Note that this yield depends on the flash number with a periodicity of four. Bottom: The charge storing device allowing accumulation of the oxidizing power needed to split water as modeled by Kok.

Cheniae and co-workers evidenced the requirement for manganese atoms in water splitting. The determination of a stoichiometry of four Mn atoms per PSII complexes provided the chemical basis for the catalytic center where the accumulation of the oxidizing equivalent produced by light-induced charge separation occurs. Together with this manganese cluster, the catalytic center bears two ions, Ca^{2+} and Cl^-, which may be removed by various chemical treatments. In the absence of either one of these two ions, the lower S states (S_0 and S_1) may undergo oxidation but the advancement of the Kok cycle cannot be completed and water splitting is inhibited. The water splitting enzyme further comprises extrinsic polypeptides, which stabilizes the assembled tetranuclear cluster.

The Assembly of the Manganese Cluster

The ligands involved in the Mn cluster binding to the protein backbone are provided by the polypeptide D_1. They have not been all identified but amongst the good candidates are: three histidines, three carboxylic acids, and the C terminus alanine. The assembly of the Mn cluster requires Mn^{II}, in the $Mn(OH)^+$ or $Mn(OH)_2$ form, Ca^{2+}, Cl^- and light. The absorption of light by PSII produces the oxidant Y_Z^{ox},which oxidizes the Mn^{II} ions. The first oxidation of a Mn^{II} has a high quantum yield unlike the following steps which are needed for the oxidation-induced association of the stable tetra nuclear cluster.

The Thermodynamic and Kinetic Features of the Water Splitting Enzyme

Before attempting to address the mechanism of water oxidation one should question the thermodynamic and kinetic issues of this reaction. Obviously water is a very stable molecule under physiological condition, while its oxidation into molecular oxygen is likely to involve the transient formation of highly reactive species such as oxo-radicals, hydrogen peroxides, etc. The enzyme must meet the following requirements: accumulate enough oxidizing power to perform a very demanding reaction with respect to common biological redox potential but also prevent side reactions, which are thermodynamically made possible by the accumulation, in a single catalytic site, of such an oxidative power.

The Redox Potential of the Different S States

Until now, the redox potentials of the different S states have not been determined by direct redox titration. They could only be inferred from the redox potentials of other cofactors found in the PS II reaction centers combined with the free energy change associated with the electron transfer reaction between the S states and these cofactors. There are thus large error bars on the value, which can be found in the literature. The redox potential of the P^+/P couple, which drives the catalytic cycle, has been estimated to 1.1–1.3 V, making the P^+ species the strongest oxidant found in biology. With an estimated midpoint potential of $\sim$0.75 V, the S_1/S_0 couple lies $\sim$0.5 V below the P^+/P couple whereas the S_2/S_1, S_3/S_2, and S_4/S_3 midpoint potentials are estimated to $\sim$1 V. The overall free energy available to oxidize water is thus $\sim$3.75 V. This is sufficient to drive the reaction at neutral pH (the minimal driving force required to reversibly oxidize water at pH 7 is 0.81 V per electron) but becomes low when the reaction has to occur at a pH close to 5, a value often quoted when the photosynthetic chain is at work.

The Rates of Oxidation of the Various S States

The rates of the various electron transfer reactions between the oxidized tyrosine Y_Z^{ox} and the S-states S_i are in the tens or hundreds of microseconds for the three lower S states. The S_4 to S_0 transition is significantly slower, in the millisecond time range, and concomitant with O_2 production and release. Based on the distance between the electron acceptor Y_Z^{ox} and the Mn cluster (7Å) combined with the free energy changes associated with these reactions, these rates appear much too slow for the reaction to be kinetically limited by the electron transfer proper. This has been taken as an indication of either redox-induced structural changes or/and of a coupling with other processes than electron transfer such as proton transfer. Interestingly, a lag phase of a few tens of microseconds preceding the decay of S_4 into S_0, which is accompanied by O_2 release might evidence such events.

The Structure of the Catalytic Center and the Redox Events during the Reaction Cycle

Despite the tremendous amount of effort put into its elucidation, the structure as well as the valence of the Mn cluster are still matters of strong debate. Numerous sophisticated spectroscopic methods have been used to address this issue without completely succeeding to define a clear picture. Electron paramagnetic resonance (EPR) and X-ray absorption spectroscopy were by far the most productive methods and provided a set of possible structures. Recently, a low resolution crystallographic structure put additional constraints on the structures, which can be considered.

The Structure of the Manganese Cluster

The light-induced formation of the S_2 state results in a remarkable EPR signal which was first reported by Dismukes and Siderer. This signal shows very rich hyperfine structures (it is commonly referred to as the "multiline" signal), which have been taken as the spectroscopic signature of a mixed valence dinuclear Mn cluster. The multiline signal has provided experimental basis for modeling the structure and the valence state of the Mn cluster in the S_2 state. X-ray absorption spectroscopy (EXAFS), pioneered by M. Klein, has provided valuable data on the distances separating the heavy atoms such as Mn or Ca, which are found in the catalytic center. These data put severe constraints on the possible structures. From both the EPR and EXAFS data, a dimer of di-μ-oxo Mn dimers has long been favored. However, several other structures with oxo-bridged Mn atoms are compatible with the data. Although not settled yet, the debate seems to be converging to structures with three strongly coupled Mn and one weakly coupled Mn. Indeed the electron density map obtained by Zouni *et al*. can accommodate these structures but not the earlier favored dimers.

The Redox Events during the Catalytic Centers
