ABC Transporters

André Goffeau, Benoît De Hertogh and Philippe V. Baret
Université Catholique de Louvain, Louvain-la-Neuve, Belgium

The ABC proteins constitute the largest family of proteins. They are present in all living species from *Archaea* to *Homo sapiens*. They make up to 4% of the full genome complement of bacteria such as *Escherichia coli* or *Bacillus subtilis*. Each eukaryote genome contains several dozens of members (over 100 in the plant *Arabidopsis thaliana*). They are recognized by a consensus ATP-binding region of approximately 100 amino acids which include the two Walker A and B motifs encompassing a linker or C region (Figure 1). The ABC proteins catalyze a wide variety of physiological functions, most (but not all) of which being related to transport. This article describes the major physiological and biochemical functions as well as the structural properties of some of the best-known ABC transporters using examples from the yeast *Saccharomyces cerevisiae* and *Homo sapiens*.

Topology

Most, but not all, ABC proteins are ABC transporters. Each of those molecules contains, or is associated to, one or two cytoplasmic ATP-binding domains named nucleotide binding domains (NBDs) (Figure 1) and one or two transmembrane domains (TMDs) (Figure 2). Each TMD comprises usually six α-helix spans. Association of one TMD to one NBD results in a half-size ABC transporter; however, they are believed to function as homo- or heterodimers so that the minimal functional organization of an ABC transporter is considered to be TMD–NBD–TMD–NBD or NBD–TMD–NBD–TMD. In eukaryotes, two TMDs and two NBDs are often associated in one single molecule called full-sized ABC transporter. The topological relation between NBD(s) and TMDs is variable (Figure 2). In bacteria two NBDs often associate with two TMDs either as four single subunits encoded by the same operon or in various combinations of fused subunits. Association of other proteins may occur. The most prominent associated bacterial protein is the periplasmic solute-binding receptor, which in gram-negative bacteria is found in the periplasm, and in gram-positive bacteria is present often as a lipoprotein, bound to the external membrane surface via electrostatic interactions (Figure 3). The three domains of the bacterial ABC uptake transporters: namely the periplasmic binding receptor, the cytoplasmic NDB, and the membrane TMD are believed to have arisen from a common ancestral ABC transporter in which these three proteins were already present. However, during evolution, the sequence of the periplasmic solute-binding receptors diverges more rapidly than that of the TMDs, while that of NBDs is the least divergent. Thus, all NBDs are homologous, but this is not true for the TMDs or the receptors. Nevertheless, the phylogenetic clustering patterns in bacterial ABC from different species are generally the same for all three types of proteins, despite their variable rate of evolution.

The topology of some eukaryotic ABC effluxers can be complex as additional TM spans occur in some systems (Figure 3) as well as extra cytoplasmic domains of presumed regulatory function.

Phylogeny

The different families of ABC proteins transport a wide variety of substrates against their concentration gradient using the energy of ATP hydrolysis carried out by NBD. In bacteria, the transported substrates are either imported in or exported out of the cell. In eukaryotes, only extracytoplasmic exporters (transporting substrates either out of the cell or into organelles) are known up to now. Within the ABC superfamily, 61 phylogenetic families have been identified so far. These families generally correlate with substrate specificity. Their classification based both on functional and phylogenetic criteria has been carried out within the transporter classification (TC) system developed by Milton Saier in San Diego. The TC system has recently been endorsed by The International Union of the Biochemical and Molecular Biology Societies. In the TC system, prokaryotic ABC influx porters comprise 22 phylogenetic families including histidine permease, the first ABC transporter to be cloned and sequenced in the laboratory of Giovanna Ames in 1982. Another famous example is the MalEFGK operon classified in TC as a maltooligosaccharide porter within "the carbohydrate uptake transporter-1 (CUT1) family," and given the TC digit 3.A.1.1. In this operon, MalE is the receptor, MalF

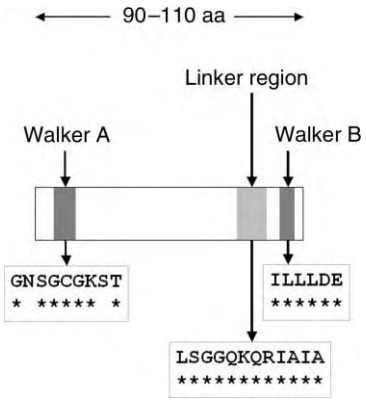

FIGURE 1 The consensus ATP-binding region of a typical ABC protein is made of approximately 100 amino acids (aa), including both Walker A and B motifs and the linker C region.

and MalG are distinct TMD subunits, and MalK is a double NBD.

The prokaryotic effluxers comprise 27 families including the multidrug exporter LmrA from the gram-positive *Lactococcus lactis* well studied by Will Koning and belonging to "the drug exporter-2 family" (3.A.1.117).

The eukaryotic ABCs can be grouped in only 12 efflux families including the famous MDR1 also named Pgp (permease-glycoprotein), discovered in 1986 by Ira Pastan, Michael Gottesman and colleagues, and shown to be involved in MDR of chemiotreated tumor cells. In the TC system, this ABC exporter is classified in "the multidrug resistance exporter family" (3.A.1.201).

The TC system is redundant with the Human Genome Organization (HUGO) classification adopted by the scientific community working on mammalian objects (mouse or man). The 45 human or mouse ABC proteins, comprising efflux transporters and

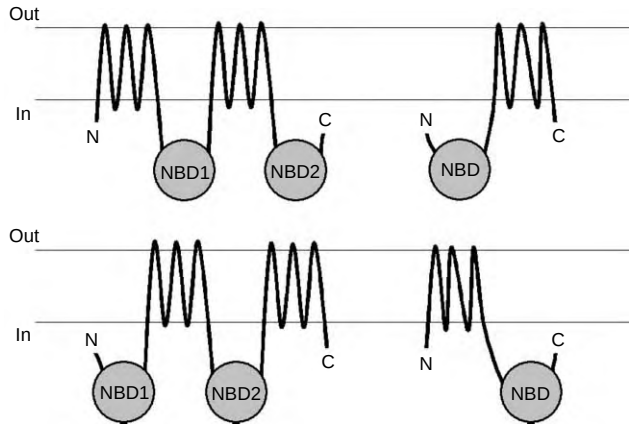

FIGURE 2 Example of topological relations between NBDs and transmembrane spans in full-sized and half-sized ABC transporters.

nontransporter proteins, have been classified in seven families named ABCA to ABCG according to topological and phylogenetical criteria that are less stringent than those used by TC. In its present form, the HUGO nomenclature and classification are difficult to use for identification of novel ABC from non-mammalian species. For instance, the *Saccharomyces cerevisiae* genome contains 32 ABC genes among which 22 (16 full-size and six small-size) are associated to transmembrane domains in four different topologies. Its largest family is the full-sized Pdr5p-like family identified in 1996 by Anabelle Decottignies and André Goffeau and shown later to be present in all fungi and plants. This family is not detected in the animal kingdom. Conversely, the large human and mouse ABCA subfamily is not represented in yeast genomes. There is a necessity to adopt a consistent classification system, which combines the TC and HUGO nomenclatures.

Function and Diseases

The immense variety of substrates transported in bacteria is reflected by the identification of 49 phylogenetic ABC families including 22 influx protein complexes and 27 efflux transporter systems. As they belong to Archaea, gram-negative and gram-positive plasma membranes that are widely different in organization and composition, the number and nature of proteins associated to given ABC transporters are variable and their transport mechanisms may be partly different. In bacterial and Archaea ABC, the variety of substrates: sugars, amino acids, lipids, ions, polysaccharides, peptides, proteins, toxins, drugs, antibiotics, xenobiotics and other metabolites is reflected by the divergence of the periplasmic sensor and that of the TMD, which must control both specificity of substrate and part of the coupling mechanism.

Even if all eukaryotic ABC transporters are effluxers that comprise subunits in which each TMD is fused to a NBD, some of them are not directly involved in moving substrates. For instance, in the cystic fibrosis transmembrane regulator CFTR, and in the sulfonylurea receptor SUR, the hydrolysis of ATP appears to be linked to the regulation of opening and closing of ion channels carried by the ABC protein itself or other proteins (Figure 3B). The conservation of NBD in all ABC transporters, however, suggests that a basic coupling mechanism exists for efflux and influx whatever the transported substrate. Moreover, distantly related proteins exist which utilize an NBD to drive diverse nontransport processes such as DNA repair or protein-elongation or regulation of RNAse activities.

The 32 yeast ABC proteins are in principle easy to study, as sensitive genetic tools are available. However, only a few successful cases of overexpressions and

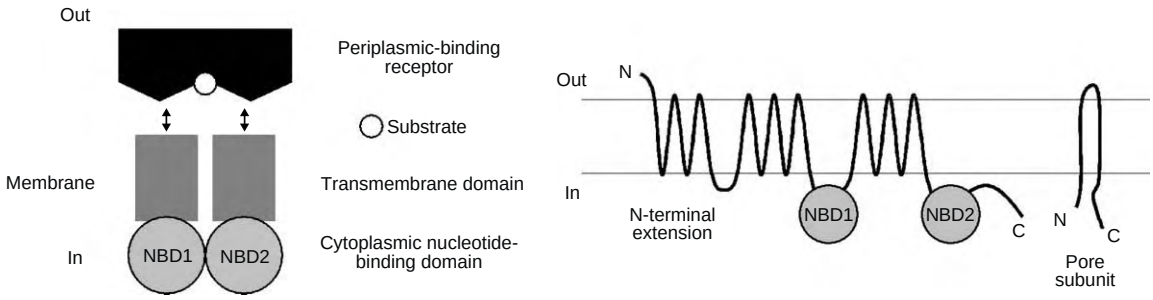

FIGURE 3 Example of proteins associated to bacterial and mammalian ABC transporters.

in vitro UTPase or ATPase measurements of purified ABCs have been reported. Only one purified yeast ABC transporter, the pleiotropic drug resistance effluxer Pdr5p, has been submitted to structural studies.

The biochemical study of human ABC transporters is often more advanced than that of the yeasts. The Pgp protein responsible for multiple drug resistance (MDR) in human cells is especially well studied. One strong impetus for the study of mammalian ABC transporters is their involvement in diseases. Many mendelian diseases and complex genetic disorders are caused by ABC transporters including cystic fibrosis, adrenoleukodystrophy, Stargardt disease, Tangier disease, immune deficiencies, progressive familial intrahepatic cholestasis, Dublin–Johnson syndrome, Pseudoxanthoma elasticum, persistent hyperinsulinemic hypoglycemia of infancy due to focal adenomatous hyperplasia, X-linked sideroblastosis and anemia, age-related macular degeneration, familial hypoapoproteinemia, Fundus flavimaculatis, Retinitis pigmentosum, cone rod dystrophy etc. Cell lines isolated from diseased tissues allow molecular study of the involved ABC transporter. Moreover, a variety of drug-resistant cell lines is available from MDR or MDR-related protein (MRP) tissues. Basic studies of human ABC transporters would greatly benefit from heterologous expression of human ABC transporter genes in yeast or other cells, but this technology is far from being satisfactory yet. Meanwhile, knockout technology in the mouse may be needed to begin to understand the molecular and physiological functions of the mammalian transporters.

Structure and Biochemical Mechanism

In 1998, the first high-resolution structure of a NBD, that from the histidine ABC importer HisP, was reported. Five years later, about six related structures were available and a consensus view emerged. NBDs are organized as dimers and two molecules of ATP are bound at their interface. Each nucleotide-binding site comprises a Walker A motif from monomer 1 and the C motif from monomer 2. This results from a "head-to-tail" arrangement of the two interacting monomers. This is supported by biochemical arguments and is coherent with the cooperative hydrolysis for ATP hydrolysis observed with MalK.

More recently, three structures of complete dimeric ABC transporters comprising both NDB and TMD were obtained: that of the presumed phospholipid flippase MsbA from *E. coli* and *Vibrio cholera* and that of the vitamin B12 importer BtuCD from *E. coli*. The structures obtained were dissimilar, which may not be too surprising taking into account the different conditions used, the different numbers of TM spans and the different functions (import or export) of the proteins analyzed. No generalization can be made, for instance, on the angle between the TM spans and the membrane plane or on the identification of the interaction domains between the TM spans. The nature of communication between the NBD and TMD is variable and carried out either through the long and complex so-called intracellular domain named ICD in MsbA, or through a short L-shaped linker between the transmembrane spans 6 and 7 in BtuCD. The nature, the size, the orientation, and the location of the so-called chamber (or water channel, or pore, or cone) presumed to be involved in substrate binding are also variable. No consensus interaction points between the NBDs (open or closed conformation) were observed. Obviously, more structures are needed on several transporters carrying out similar functions, such as drug efflux, for instance, to clarify these issues and to reach a consensus interpretation of the basic structural elements involved in the transport and in the coupling mechanism.

In contrast, recent analyses at the electron microscopy level of a bacteria (BmrA or YccV from *Bacillus subtilis*) and a yeast (Pdr5p) drug efflux ABC transporter came to a remarkably coherent set of conclusions. In both cases, the basic structural unit seems to comprise four joining NBDs (that corresponds to two full-size Pdr5p or four half-size BmrA), which are

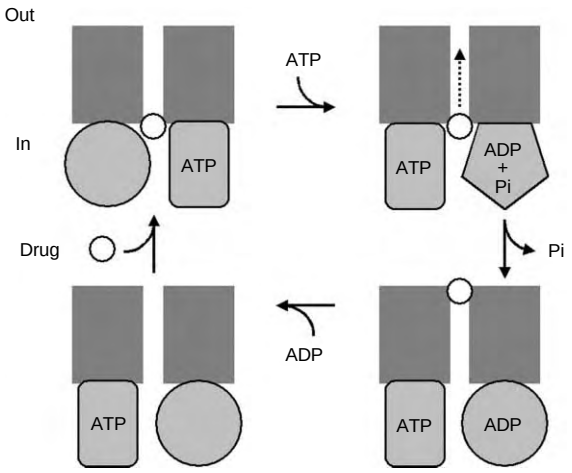

FIGURE 4 The alternating catalytic sites hypothesis for P-glycoprotein, according to Alan Senior. The NBDs have three ligands and four states: free, ATP bound, ADP + Pi bound, and ADP bound. They alternate in such a way that two ATPs never bind simultaneously. The binding of one ATP to one NBD induces hydrolysis at the other ATP. The drug is transported out during Pi release.

related to the TMDs through four distinct stalks. Each NBD is oriented at a fixed 90° angle relative to its neighbor NBDs. This raises the possibility of concerted rotation movements of the NBDs implying a certain flexibility of the stalks. No intramolecular or no intramembrane pores were observed even though there is room (or chamber) between the four stalks that join together at their NBDs tips.

These latter observations are difficult to reconcile with the mechanism of alternating sites established for the drug exporters, the human Pgp and the bacterial LmrA (Figure 4). In these cases the monomeric NBDs are similar and both are able to hydrolyze ATP. Hydrolysis of ATP at one NBD is believed to be responsible for drug release outside. Upon release of ADP and Pi, the other NBDs bind and then hydrolyze ATP while the drug is taken up inside. However, the simplest version of this "two-cylinder" mechanism cannot function when the two NBDs partners are not equivalent in a dimeric arrangement as it is the cases of yeast Pdr5p and human CFTR, where one of the two NBDs from a full-sized ABC molecule might be unable to hydrolyze ATP.

The Substrate Specificity of the ABC Multidrug Exporters

One of the most intriguing contemporary biochemical problems is the characterization of the interactions of the TMDs with their transported substrate. The most extraordinary feature in this context is the apparent lack of specificity of the yeast Pdr5p and human Pgp that transports hundreds of different chemicals, apparently contradicting the famous key/slot concept described in all enzymology textbooks. It must be recognized that the identification of presumed ABC substrates are often based on indirect data such as resistance or sensitivity of mutants or drug-induced transcription profiles. These measurements should in principle be corroborated by direct transport measurements, which are often difficult to obtain.

Regarding specificity of transport, one of the best-studied yeast transporters is Pdr5p through the capacity of its deleted mutants to gain growth sensitivity to an amazing variety of xenobiotics. From a large screen of several hundreds of toxic compounds, no chemical determinants for transported substrate specificity could be identified among a wide range of compounds including the fungicides anilinopyrimidines, benzimidazoles, benzenedicarbonitriles, dithiocarbamates, guanidines, imidothiazoles, polyenes, pyrimidynyl carbinols, and strobilurine analogues, the urea derivative and anilide herbicides, a wide collection of flavonoids and steroids, several membrane lipids resembling detergents, and newly synthesized lysosomotropic aminoesters. However, it could be concluded that Pdr5p shows considerable substrate overlap with members of the same ABC phylogenetic family or even with yeast drug effluxers from other families such as Snq2p or Yor1p. This was demonstrated by the numerous cases showing full sensitivity only in double or triple mutants. The most promiscuous substrates were: itraconazole, miconazole, nystatin, antimycin, nigericidin, and tetradodecylammonium bromide, which are transported by at least three distinct yeast ABC transporters. In contrast many substrates show relative specificity for a given pleiotropic drug resistance exporter. Prominent examples include cycloheximide, benomyl, fluxilazole, nuarimal, and soraphen for Pdr5p. From a first large scale screen it was concluded that Pdr5p's most efficient substrates were valinomycin, the antifungal azoles and rhodamine 6G. These compounds are inhibiting the growth of a sensitive PDR5 deletant at concentrations below the micromolar range. Up to now, the most potent competitive inhibitor of binding of rhodamine 6G to the yeast Pdr5p is the oestradiol derivative RU 49953, which exhibits a K_i of 23 nM.

Other recent systematic screens have provided more precise chemical information on the determinants of Pdr5p specificity. From such studies it was concluded that Pdr5p is capable of transporting substrates that neither ionize nor have electron pair donors and that are much simpler in structure than those handled by the human Pgp. The substrate optimum surface volume is about 200Å^3. Analysis of the interactions between imidazole derivatives, organotin and other compounds argues, that, as also established for Pgp, the Pdr5p comprises at least two substrate-binding sites. One site

might use only hydrophobic binding interactions. Some substrates may bind to two sites, others associate more specifically to only one site. However, the Pdr5p substrates-binding sites, behave differently from those of Pgp. This concept of overlapping substrate-binding sites may reconcile many previous observations concerning the substrate broad specificity of Pdr5p and Pgp, which up to now appeared contradictory.

Conclusion

The present frontiers in the study of ABC transporters are challenging. The evolutionary history of this large ubiquitous family has to be unraveled. Additional atomic structures have to be produced. Better heterologous overexpression systems have to be developed to allow further biochemical studies. Specific inhibitors of drug (and other) ABC exporters have to be screened for. The physiological mechanisms of ABC-linked diseases have to be further studied in mouse knockouts. Systems prone to specific inhibition of ABC transporters expression by interfering RNA have to be explored. Genetic therapy has to be developed.

MDR Membrane Proteins

Glossary

human genome organization (HUGO) An international association that comprises scientists involved in all aspects of the sequence of the human genome and its analysis.

linker C Small amino acids sequence signature involved in ATP binding of ABC proteins.

Pdr5p The major yeast ABC transporter, involved in pleiotropic drug resistance.

Pgp The first ABC transporter (glycoprotein) shown to be involved in mammalian multidrug resistance.

transmembrane span and transmembrane domain (TMS and TMD) The existence of the transmembrane span is predicted by frequency of hydrophobic residues in a reading window of about 17 amino acids. In ABC transporters, the transmembrane domains usually comprises six continuous transmembrane spans.

transporter classification (TC) Classification of over 800 transporters families, developed by Milton Saier (UCSD), based on a combination of mechanistic and phylogenetic criteria.

Walker A and B Small consensus of amino acid sequences involved in ATP binding.

Biography

André Goffeau is Emeritus Professor at the Université Catholique de Louvain (Belgium), Department of Physiological Chemistry. He investigates the P-type ATPases and the ABC transporters in *S. cerevisiae*. He has initiated and organized the sequencing of the yeast genome. He is interested in the phylogenetic classification of yeast membrane proteins.

Benoît De Hertogh is Ingénieur Agronome at the Université Catholique de Louvain (Belgium), Department of Quantitative Genetics. He is completing a Ph.D. thesis on population genetics on the genetical basis of fertility in livestock. He is interested in comparative genomics of membrane proteins.

Philippe V. Baret is Associate Professor at the Université Catholique de Louvain (Belgium), Department of Quantitative Genetics. He is modeling the relationship between genes and phenotypes, with a peculiar interest in quantitative trait loci mapping and cladistic approaches.

Abscisic Acid (ABA)

Ramanjulu Sunkar and Jian-Kang Zhu
University of Arizona, Tucson, Arizona, USA

Plants perceive a variety of environmental and endogenous signals, which elicit appropriate responses with altered metabolism, growth, and development. Phytohormones are signaling molecules, present in trace quantities and are tightly controlled by various biosynthetic, catabolic, and conjugation pathways. Changes in hormone concentration determine a wide range of plant responses, some of which involve interactions with environmental factors. One such important phytohormone is abscisic acid (ABA), a sesquiterpenoid (15-carbon) which is partly produced in chloroplasts and other plastids. A low basal level of ABA is required for normal growth and development of plants. However, a dramatic and rapid increase in ABA levels occurs due to *de novo* synthesis in vegetative parts of the plants exposed to osmotic stress, as well as in developing seeds during maturation. Elevated levels of ABA play a central role in promoting stomatal closure, dehydration tolerance, leaf senescence, seed dormancy and maturation, and coordinated growth of roots and shoots. ABA apparently acts as a signal of reduced water availability. This is manifested at the physiological level, by controlling germination, stomatal movements, and growth. At the molecular level, ABA-dependent changes in gene expression and posttranslational modifications underpin these physiological processes.

Mutants As Tools for Studying ABA Biosynthesis and Signaling

Mutant plants with altered biosynthesis, perception, or responses have been crucial in identification of various components involved in ABA biosynthesis and signaling. The genetic screens and selections that have been used include production of nondormant seeds, loss or gain of sensitivity to ABA during germination, seedling or root growth, and altered expression of reporter genes. These approaches have yielded three classes of ABA mutants: ABA-deficient, -hypersensitive, and -insensitive mutants. The characteristic feature of ABA-deficient mutants is a wilty phenotype largely due to impaired stomatal closure (impaired ABA biosynthesis in *aba1/los6*, *vp14*, *aba2*, and *aba3/los5* mutants; *ABA1*, *VP14*, *ABA2*, and ABA3 encode enzymes of ABA biosynthetic pathway, zeaxanthin epoxidase (ZEP), *9-cis* epoxycarotenoid dioxygenase (NCED), short-chain alcohol dehydrogenase/reductase (SDR), and molybdenum cofactor sulfurase (MoCoSu) respectively). Hypersensitive mutants display enhanced sensitivity to ABA, resulting in diminished germination rates at low ABA concentrations and reduced water loss due to enhanced ABA-induced stomatal closure (*Arabidopsis era1, sad1, abh1, hyl1, rop10, and fiery1*). The *ERA1* gene encodes a protein farnesyltransferase; *HYL1*, *SAD1*, and *ABH1* genes encode different types of RNA-binding proteins; *ROP10* encodes a small G protein; and *FIERY1* encodes an inositol polyphosphate 1-phosphatase. In addition to these mutants, silencing of the calcium sensor SCaBP5 and protein kinase PKS3 resulted in ABA hypersensitivity. ABA-insensitive mutants including *abi1*, *abi2*, *abi3*, *abi4*, *abi5*, and *rcn1* from *Arabidopsis*, and *vp1* (orthologue of *abi3*) from maize have been identified. This class of mutants display loss of ABA sensitivity, leading to nondormancy or vivipary. The genes *ABI1* and *ABI2* encode homologous-type 2C protein phosphatases; *RCN1* encodes a 2A-type protein phosphatase; *ABI3/VP1* encodes a B3 type of transcriptional activator; *ABI4* encodes an AP2-type transcription factor; and *ABI5* encodes a b-ZIP transcription factor.

ABA Biosynthesis

Osmotic stress induction of ABA accumulation is a complex signaling process from the initial water-stress perception, intracellular signal transduction, to gene expression or activation of the enzymes involved in the ABA biosynthesis. The chain of events from the perception of osmotic stress to the gene activation leading to ABA biosynthesis is unknown. Presumably, it involves reactive oxygen species (ROS)/calcium signaling and protein phosphorylation cascades. Significant progress has been made in recent years in cloning the genes encoding enzymes involved in ABA biosynthesis (Figure 1). Some of these genes in *Arabidopsis* are encoded by members of multi-gene families (NCED, abscisic aldehyde oxidase) while others are represented by single gene (ZEP, SDR, MoCoSu). Several of these genes appear to be transcriptionally activated by osmotic stress and ABA.

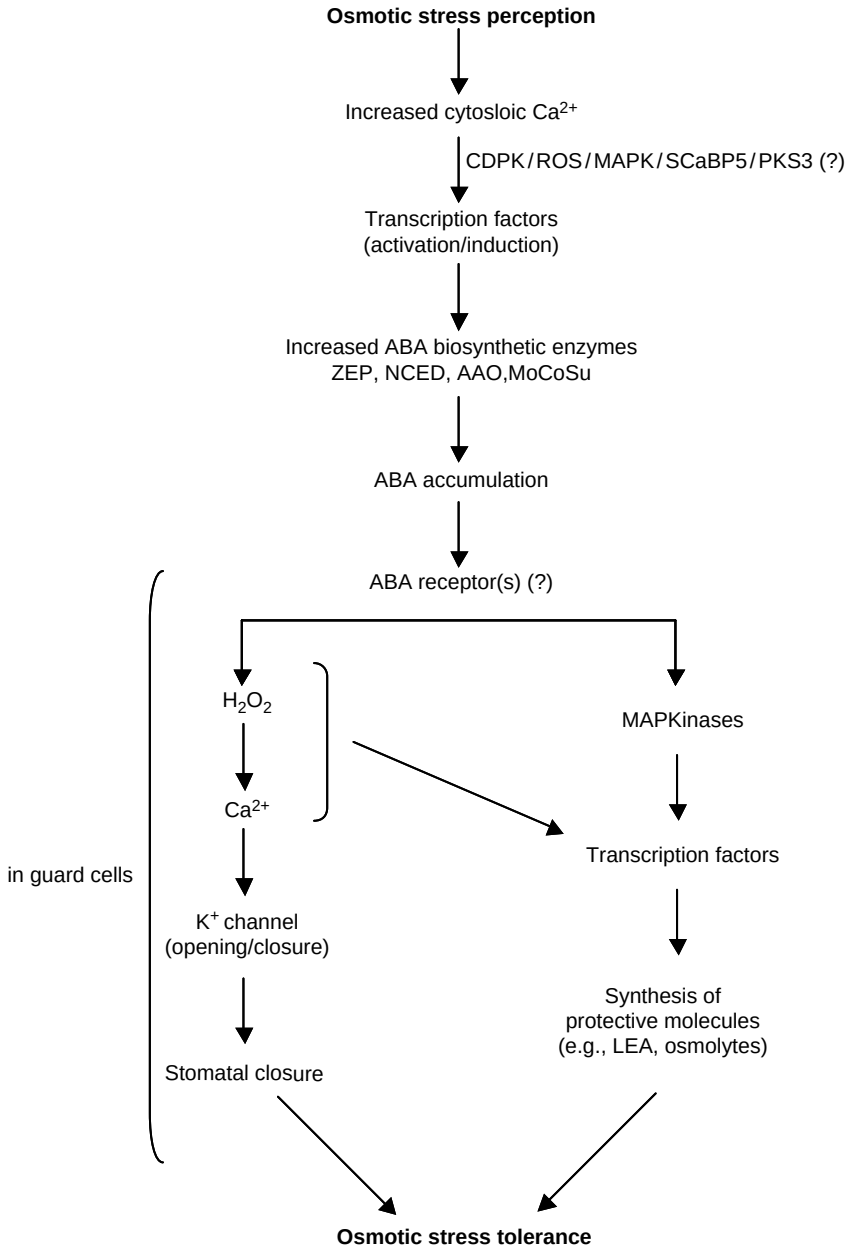

FIGURE 1 An overview of osmotic stress-induced biosynthesis of ABA and ABA mediated signaling leading to stomatal closure in guard cells and the regulation of gene expression in plants.

ABA biosynthesis in seeds is similar to that in the vegetative tissues. However, the regulation of ABA biosynthesis in developing seeds is not clear since these aspects were mainly investigated in vegetative tissues.

Role of ABA in Seed Development and Maturation

Seed development represents an important part of the plant's life cycle as the success of seedling establishment to a large extent is determined by the physiological and biochemical properties of the seed. Plant hormones, particularly ABA and gibberellic acid (GA), play antagonistic roles and are important regulators of seed maturation, germination, and postgerminative growth. ABA mediates several important functions in developing seeds such as seed maturation, synthesis of storage proteins, synthesis of late embryogenesis abundant (LEA) proteins, and initiation of seed dormancy, whereas GA is required to break dormancy and to trigger germination. It seems that two peaks of ABA accumulation coordinate these processes in developing seeds. The first peak of ABA is relatively large and occurs

about halfway during seed development (~10 days after pollination) and plays a role in the synthesis of storage proteins. The second peak is relatively weaker compared to the first peak and seems to be important for the synthesis of LEA proteins and for initiation of seed dormancy. During maturation, seeds lose up to 90% of their water content and are still viable. This ability to tolerate extreme dehydration is achieved by ABA-dependent accumulation of LEA proteins and compatible solutes such as sugars. LEA proteins appear to be important for desiccation tolerance by maintaining the structural integrity of membranes and proteins and controlling water exchange. Transcripts encoding either storage proteins or LEA proteins can be precociously induced by ABA in cultured embryos suggesting that endogenous ABA is indeed responsible for these processes. The analysis of promoter sequences for storage proteins and LEA genes corroborated with the ABA responsiveness of *cis*-elements and tissue specificity. Embryo enters a quiescent state (dormancy) at this stage which is also maintained by ABA.

ABA Signaling in Developing Seeds

ABA signaling components mediating seed dormancy and germination have been inferred from genetic analysis. The best known components involved in ABA signaling in seeds are PP2C-like phosphatases (ABI1 and ABI2) and transcription factors (ABI3, ABI4, and ABI5) and a farnesyltransferase (ERA1). *ABI1* and *ABI2* encode homologous type 2C serine/threonine protein phosphatases. The ABA signaling pathway appears to be negatively regulated by these phosphatases. *ABI3*, *ABI4,* and *ABI5* encode transcription factors of the B3, AP2, and b-ZIP domain families respectively and regulate the expression of ABA-inducible genes in seeds as well as in vegetative tissues. The *ABI3* gene encodes a transcriptional activator with homology to the seed-specific VP1 protein from maize. ABI3 plays a central role in the establishment of desiccation tolerance and dormancy during embryogenesis. ABI3 activates down stream genes and thus is a major player in ABA signaling. VP1 activates expression of ABA-inducible genes through the G-box promoter element. Interestingly, VP1 does not appear to bind to the element directly. Rather, VP1 regulation is likely mediated by protein–protein interactions with G-box-binding factors. In support of this model, the rice TRAB1 b-ZIP protein was shown to interact with rice VP1 in the yeast two-hybrid system. The *Arabidopsis* ABI5 is homologous to TRAB1 and similarly interacts with ABI3. Coexpression of ABI5 and ABI3 transcription factors, which interact physically, synergistically activate several promoters in the presence of ABA. ABI5 plays a role in protecting germinating embryos from drought. ABI5 accumulation, stability, and activity are regulated by ABA during germination. These findings suggest complex interactions of ABI3 and ABI5 in ABA signaling.

ABA as Mediator of Osmotic Stress Tolerance

ABA has dual roles during osmotic stress: (1) a rapid response in guard cells leading to stomatal closure and (2) a slower response of reprogramming gene expression patterns (Figure 1). Both roles are critical for water-stress tolerance.

Stomatal Closure Meditated by ABA

Guard cells, which flank stomatal pores, integrate and respond appropriately to changes in water levels mediated by ABA. ABA-deficient and ABA-insensitive mutants are prone to wilting and cannot withstand water-deficit conditions due to their inability to close stomata, while hypersensitive mutants exhibit opposite responses. ABA-induced stomatal closure is vital for plants to limit transpirational water loss during periods of drought. Investigations on ABA-induced stomatal movements have led to the identification of several components acting downstream of ABA. These include protein kinases and phosphatases, phospholipase C and D, slow anion channels, K^+ channels, G proteins, sphingosine-1-phosphate, syntaxin, cyclic ADP ribose (cADPR), ROS, and free calcium ions in the guard cell cytosol. However, a complete picture is yet to emerge and there are several missing links.

Stomatal opening and closure are coordinated by regulation of the relative activities of the inward- and outward-rectifying channels and anion channels. ABA-induced stomatal closure is mediated by a reduction in the turgor pressure of guard cells, which requires an efflux of K^+ and Cl^-, sucrose removal, and the conversion of malate to osmotically inactive starch. Therefore, opening or closing of guard cell ion channels determine the status of stomatal aperture.

Second Messengers (ROS and Ca^{2+})

Recent studies have established a role for H_2O_2 in ABA signaling through its influence on Ca^{2+} channels in guard cells. ABA stimulates H_2O_2 production in guard cells. The plasma membrane NADPH oxidase complex, which consists of many components, seems to be responsible for H_2O_2 generation. H_2O_2 triggered by ABA plays a vital role as signal mediator for the activation of downstream events including the opening

of Ca^{2+} channels, leading to increases in the cytosolic Ca^{2+} level. It appears that Ca^{2+} plays a very important role in ABA-mediated stomatal closure. ABA-induced changes in cytosolic Ca^{2+} concentration have been attributed to both Ca^{2+} release from internal stores and Ca^{2+} influx from external stores. Downstream to ABA, inositol triphosphate (IP3), cADPR, and possibly inositol hexakisphosphate (IP6) are also implicated in increasing cytosolic Ca^{2+} levels. The highly localized calcium oscillations in the cytoplasm then control various processes leading to ion efflux and stomatal closure. These include inhibition of inward rectifying K^+ channels and activation of outward rectifying K^+ channels in guard cells, reducing influx and increasing efflux of K^+ in guard cells, cation and anion channels in the plasma membrane, changes in the cytoskeleton, and movement of water through water channels in the tonoplast and plasma membrane. The activities of all these cellular structures need to be coordinated during ABA-induced stomatal closure.

ABA responses in guard cells require a specific cytosolic calcium signature. Guard cell cytosolic calcium oscillations with defined frequency and amplitude result in stomatal closure. In contrast, steady and sustained cytosolic calcium increases without oscillations fail to confer stomatal closure, suggesting that excessive, nonoscillating cytosolic calcium may interfere with or inhibit ABA responses. Hence in addition to calcium sensors as positive regulators of downstream ABA signaling, there may be calcium-sensing systems that regulate ABA responses negatively. Consistent with this hypothesis, a calcium sensor protein, SCaBP5, and a protein kinase, PKS3, involved in ABA signaling have been identified recently. *Arabidopsis* loss-of-function mutations in either of these genes resulted in ABA hypersensitivity during seed germination, vegetative growth, and stomatal closure.

Protein Phosphatases

Phosphorylation events are central to ABA signaling. The *abi1-1* and *abi2-1* mutations confer ABA insensitivity in seed germination, vegetative growth, and the expression of certain ABA-regulated genes. The fact that ABI1 and ABI2 are protein phosphatases suggests involvement of protein phosphorylation/dephosphorylation in regulating ABA signaling. Protein phosphatase genes *ABI1* and *ABI2* encoding type-2C protein phosphatases are up-regulated by ABA. These phosphatases, in general, are implicated in negative regulation of ABA signaling.

Kinases

Protein kinases that are specifically activated by ABA offer better understanding of the ABA signaling in plant cells. PKABA1 (abscisic acid-responsive protein kinase) from wheat, open stomata 1 (OST1) from *Arabidopsis*, and abscisic acid-activated protein kinase (AAPK) from fava bean are ABA-activated serine-threonine protein kinases. Both AAPK and OST1 display ABA-dependent autophosphorylation. Mutations in the *OST1* gene suppressed ABA-induced ROS production, which is important for stomatal closure, suggesting that OST1 is an important component acting upstream of ROS generation in ABA signaling. Dissection of guard cell signaling events identified a target for AAPK. AAPK activates AKIP1, which is highly similar to a single-stranded RNA-binding protein that binds heterogenous nuclear RNA (HnRNA). HnRNA-binding proteins are a class of proteins involved in transcriptional, posttranscriptional, and translational control of gene expression. AKIP1 is phosphorylated by AAPK and the phosphorylation activates AKIP1 and increases its affinity for a dehydrin (LEA-type) mRNA.

Kinases that act as negative regulators of ABA signaling have been identified. Silencing of PKS3 caused ABA hypersensitivity in seed germination, stomatal closing, and gene expression, suggesting that this protein acts as negative regulator that specifically modulates ABA signal transduction. These findings highlight the existence of ABA-dependent kinases that function both in guard cell signaling and in gene expression.

Farnesyltransferase

Farnesyltransferases influence protein structure or localization through mechanisms other than phosphorylation. Protein farnesylation, a posttranslational modification process, mediates the COOH-terminal lipidation of specific cellular proteins such as Ras and other G proteins. Deletion of the *Arabidopsis* farnesyltransferase gene *ERA1* or application of farnesyltransferase inhibitors resulted in ABA hypersensitivity of guard cell anion channel activation and of stomatal closing.

Cytoskeleton

ABA-induced stomatal closure requires a reorganization of the actin cytoskeleton of guard cells. A link for such an action has been demonstrated between ABA and actin through AtRac1. AtRac1 (*Arabidopsis* Rho-related small guanosine triphosphatase, GTPase) has been identified as a central component in ABA-mediated stomatal closure. In animals and yeast, Rho GTPases are key regulators of the actin cytoskeleton. GTPases are inactivated by ABA treatment leading to the disruption of guard cell actin organization. ABA-induced increase in cytosolic Ca^{2+} and the cytoskeleton reorganization seems to be another link in this pathway, suggesting that the ABA-induced increases in cytosolic

Ca^{2+} regulate cytoskeletal reorganization, in addition to ion channels.

RNA-Associated Proteins and ABA Signaling

Accumulation of some of the ABA-inducible proteins is also dependent on posttranscriptional regulation. RNA processing proteins may contribute to this level of regulation. Isolation of three ABA hypersensitive mutants *abh1*, *hyl1*, and *sad1* all encode RNA-associated proteins implicating that RNA processing modulates ABA signal transduction. The *hyl1* mutant shows ABA hypersensitivity during seed germination. The *HYL1* gene is ABA-regulated and encodes a nuclear dsRNA-binding protein. Mutation in this gene alters the plant responses to several exogenous hormones. The *abh1* mutation confers ABA hypersensitivity in seed germination, stomatal closure, and ABA-induced guard cell calcium increases. ABH1, an mRNA cap-binding protein, is a negative regulator of ABA responses including stomatal closure. The *sad1* mutant is not only hypersensitive to ABA but also to drought, unlike *abh1* and *hyl1* which are drought tolerant. *SAD1* encodes an Sm-like SnRNP protein required for mRNA splicing, export, and degradation. Similarly, AKIP1 is another RNA-binding protein that belongs to this group of proteins involved in ABA signaling. How these proteins execute their role in the ABA pathway is unknown but the findings provide a strong link between RNA processing and ABA signaling.

ABA-Induced Modulation of Gene Expression

The synthesis of endogenous ABA increases in response to osmotic stress, which in turn induces numerous stress-associated genes involved in the accumulation of osmoprotectants and LEA proteins, protein turnover, stress signaling pathways, and transcriptional regulation. ABA accumulated in response to osmotic stress is likely to be sensed by a receptor protein (sensor), albeit the identity and the location of such a component is yet unknown. The components of ABA signaling involved in transcriptional and posttranscriptional regulation have been less understood as compared to the guard cell signaling. MAPK cascade is an extensively used pathway in eukaryotic signaling. ABA signaling in plants may also use an MAPK pathway. MAPKs (AtMPK3 and AtMPK6) that are activated by ABA are known in plants. These MAPKs receive signals from the ANP1 family of MAPKKKs through MAPKKs (AtMKK4 and AtMKK5). However, a functional link between ABA and MAPK pathway is unknown, although ABA-dependent phosphatidic acid generated by phospholipase D may be responsible for the activation of the MAPK pathway. In addition to the MAPK pathway, CDPKs may also be involved in transmitting the ABA signal to the transcriptional machinery.

Transcription Factors

Several classes of transcription factors emerged as targets of ABA signaling events and comprise members of the basic leucine zipper proteins (b-ZIP), AP2, Myb, Myc (basic helix-loop-helix, b-HLH), and homeodomain-containing leucine zipper proteins (HD-ZIP). Several of the genes that encode transcription factors or DNA-binding proteins are regulated by ABA, suggesting that a cascade of transcription factors may mediate stimulus-dependent gene expression in ABA responses.

b-ZIP ABFs/AREBs and ABI5 belong to a family of basic leucine zipper class of transcription factors that bind to ABA responsive *cis*-acting elements (ABREs) and confer ABA responsive gene expression. ABF/AREB proteins respond at the transcriptional and posttranscriptional levels to drought and salt stress and appear to be specifically phosphorylated in response to ABA, mediated through ABA-activated protein kinase. ABF3 and ABF4/AREB2 overexpression in transgenic *Arabidopsis* plants resulted in ABA hypersensitivity, enhanced drought tolerance accompanied with decreased transpiration, suggesting that ABF3 and ABF4 are involved in stomatal closure mediated by ABA. Promoters of both *ABF3* and *ABF4* were found to be most active in roots and guard cells, consistent with their roles in stomatal regulation and water-stress response. Some of the target genes for b-ZIPs are LEA, and other ABA-dependent genes.

MYB and MYC Regulation of expression of many ABA-inducible genes has been postulated to involve the ABRE *cis*-elements in their promoter regions. However, the RD22 promoter does not contain any typical ABRE consensus sequence but still is activated by ABA, suggesting the possible involvement of other regulatory elements responding to ABA other than the ABRE-b-ZIP regulatory module. The *Rd22* promoter contains MYC- and MYB-binding elements responsible for drought and ABA activation. The transcription factors that bind these elements, AtMYB2 and AtMYC2 are able to induce *RD22* gene expression in response to drought and ABA. Consistent with their roles, transgenic plants overexpressing AtMYC2 and/or AtMYB2 are hypersensitive to ABA. Hypersensitivity to ABA was enhanced in transgenics when both genes are overexpressed together. On the other hand, knockout mutant in *AtMYC2* showed insensitivity to ABA.

HD-ZIP A number of HD-ZIP proteins have been suggested to be dependent on ABA signaling for their transcriptional regulation. *Arabidopsis* HD-ZIPs, *ATHB5*, *ATHB6*, *ATHB7*, and *ATHB12* are induced

by the exogenous application of ABA or abiotic stresses that cause ABA accumulation, indicating that these transcription factors form part of the ABA signaling. The target genes induced by HD-ZIPs are unknown.

ABRE (Abscisic Acid Responsive Elements)

Exploration on more downstream elements of ABA signaling in stress responses, especially drought and cold tolerance, identified ABREs in promoters of ABA-induced genes. In most cases, the ABREs contain a core ACGT motif, the most common of those is designated the G-box (CACGTG) that is recognized by b-ZIP transcription factors. The ABRE functions efficiently when two copies are located tandemly or when it is associated with a coupling element. *Cis*-elements called coupling elements which are active in combination with an ABRE but not alone have also been identified. In the promoters of barley genes *HVA22* and *HVA1*, the coupling elements CE1 and CE3 (ACGCGTGTCCTG) are necessary for activation by ABA. Dissection of these promoters defined ABA responsive complexes (ABRCs) consisting of a coupling element and an ABRE capable of conferring ABA inducible transcription.

Actin Assembly/Disassembly

Henry N. Higgs
Dartmouth Medical School, Hanover, New Hampshire, USA

Actin is a monomeric protein that polymerizes into helical filaments. Apart from its role in muscle cells as a scaffold for myosin-based contraction, actin's function often depends on its ability to assemble into filaments from monomers rapidly, and to disassemble equally rapidly. Actin alone can polymerize *in vitro*, but both the kinetics and equilibria of polymerization are controlled in cells by specific actin-binding proteins that serve to modify the assembly/disassembly cycle inherent to actin itself. Some actin-binding proteins of particular importance are sequestering proteins, profilin, capping protein, and ADF/cofilin.

Actin Structure

Actin Monomer Structures

Actin is a 43 kDa (375 amino acid) globular monomer, which binds a nucleotide (ATP or ADP in cells) in a deep cleft between two halves of the protein (Figure 1A). The affinity of actin for nucleotide is greatly increased by divalent cation. Due to its relative cytosolic abundance (100s of μM), Mg^{2+} is the main actin-bound divalent cation in cells, but other cations, especially Ca^{2+}, are used for special purposes *in vitro*.

Actin Isoforms and Model Systems

Mammals contain six highly conserved actin isoforms, with at least 93% amino acid identity (Table I). Actin from non-mammals is similarly conserved, with budding yeast 88% and *Acanthamoeba castellani* 95% identical to human non-muscle β-actin. Bacteria contain several proteins with some properties similar to actin, Mbl, and Mreb.

Much of the biochemical data on actin assembly/disassembly is derived from studies of vertebrate muscle actin. Seminal studies on actin biochemistry were begun by Straub and Feuer during World War II using rabbit muscle actin. The sole actin isoform of budding yeast has also been a model, due to the combination of biochemistry and genetics in this system.

The highly similar sequences of actins from diverse species suggest that results in these model systems will be close approximations for most actins. However, specific biochemical properties can vary between actins, such as affinities for some actin-binding proteins.

Individual cells can possess multiple actin isoforms simultaneously. Mammalian non-muscle cells often contain both β- and γ-actin. The reasons behind this diversity are not well understood, but differential subcellular localization has been observed. Some unicellular organisms possess multiple actin isoforms. For instance, Dictyostelium has ~20 actin genes.

Actin Filaments

Actin filaments are right-handed double helices, with ~13 monomers per turn (Figure 1B). Each monomer adds ~2.7Å to the filament, so there are ~370 monomers per μm. All monomers are oriented in the same direction along the helix, making the filament polar. Due to the filament's arrow-like appearance when coated with myosin, the two ends are often called "barbed" and "pointed", respectively. The nucleotide-binding cleft faces the pointed end. Some refer to the barbed and pointed ends as "+" and "−," respectively.

Actin Dynamics

General Concepts in Actin Assembly/Disassembly

Under polymerizing conditions, actin monomers spontaneously polymerize into filaments, without need of other proteins. Polymerization from monomers can be broken down to two processes: nucleation, whereby actin monomers assemble to form a trimeric nucleus; and elongation, whereby additional monomers add to this nucleus (Figure 2). Nucleation is highly unfavorable, with equilibrium dissociation constants in the mM range. Consequently, a major control point for cellular actin assembly is enhancement of nucleation rate. Elongation occurs rapidly at the barbed end, (diffusion-limited on-rate) and tenfold more slowly at the pointed end. For reasons explained later, at pointed end elongation rarely occurs in cells, and we will only consider barbed end elongation in this chapter.

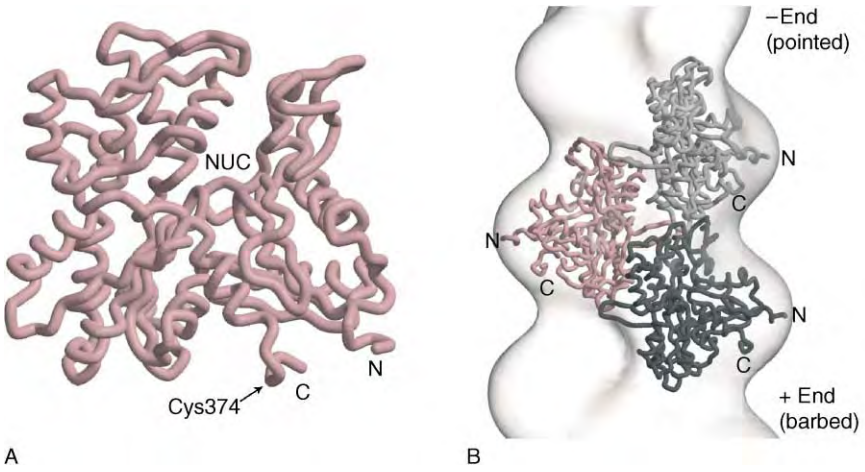

FIGURE 1 Structure of actin monomers and filaments. (A) Ribbon diagram of actin monomer backbone, oriented with the surface at the pointed end facing upwards. NUC = nucleotide/divalent cation-binding pocket. N and C termini are indicated, as well as cysteine374, which is labeled by pyrene-iodoacetimide. (B) Atomic model of three actin monomers fit into a three-dimensional reconstruction of an actin filament obtained by electron microscopy and image analysis. Both A and B are modified from images provided by Dorit Hanein and Niels Volkmann.

While both Mg-ATP and Mg-ADP monomers can nucleate and elongate, Mg-ATP monomers do both faster. Upon adding to filaments, monomers are referred to as "subunits."

Monomers hydrolyze ATP extremely slowly. Upon adding to a filament, the hydrolysis rate increases to $\sim 0.3\ \text{sec}^{-1}$. With a reasonable concentration of ATP-actin monomers, ATP hydrolysis occurs more slowly than elongation, which occurs at $10\ \mu\text{M}^{-1}\ \text{sec}^{-1}$. Thus, a "cap" of ATP-subunits builds up at the barbed end. Furthermore, the inorganic phosphate (Pi) hydrolysis product remains bound to the subunit for a considerable time before dissociating, while the ADP product remains tightly bound while the subunit remains on the filament.

TABLE I

Actin Isoforms

Species	Isoform	% identity[a]	GI #
Human	Non-muscle β	100	113270
Human	Non-muscle γ	98	113278
Human	Skeletal muscle	93	113287
Human	Cardiac	94	113272
Human	Smooth muscle α	94	113266
Human	Smooth muscle γ	93	113279
Rabbit	Skeletal muscle	93	71611
Chicken	Skeletal muscle	93	71613
Drosophila	Muscle 88F	95	2113792
Budding yeast	Sole Isoform	88	2262056
Acanthamoeba	[b]	95	71630

[a] To human non-muscle β.
[b] Number of actin isoforms unknown.

At steady state, three regions exist on an actin filament: ATP-subunits at the barbed end; ADP-Pi-subunits in the middle; and ADP-subunits toward the pointed end. As discussed later, Pi release is crucial to actin disassembly.

Subunits disassociate from both ends of a filament, and do so more rapidly from the barbed end than from the pointed end. ADP-subunits release from the barbed end faster than ATP-subunits. Once released from the filament, the monomer slowly exchanges its ADP with ATP, assuming an excess of ATP in solution.

Thus, actin assembly/disassembly occurs in a cycle (Figure 2). Nucleation occurs slowly, but filaments elongate rapidly once formed. Since barbed end elongation is tenfold faster than pointed end elongation, and since ATP hydrolysis occurs slowly, ADP-subunits are at higher concentration toward the pointed end. Subunits dissociate from both ends, and do so faster from the barbed end in both the ATP-and ADP-bound states. However, since monomer association is much more rapid at the barbed end, more net growth occurs at this end. Released ADP-monomers exchange ATP for ADP slowly (half-time ~ 50 s).

Through this cycle, equilibrium between assembly and disassembly is reached, in which the concentrations of actin in filaments and as monomers become constant. When ATP is in constant supply (and assuming an excess of Mg^{2+} over Ca^{2+}), the equilibrium monomer concentration is $\sim 0.1\ \mu\text{M}$ under polymerizing conditions. This monomer concentration, the "critical concentration," is always found in solution at equilibrium under these conditions. The concentration of actin in filaments is the excess above $0.1\ \mu\text{M}$. In other words, given $4\ \mu\text{M}$ actin under polymerizing conditions, $3.9\ \mu\text{M}$ will be in

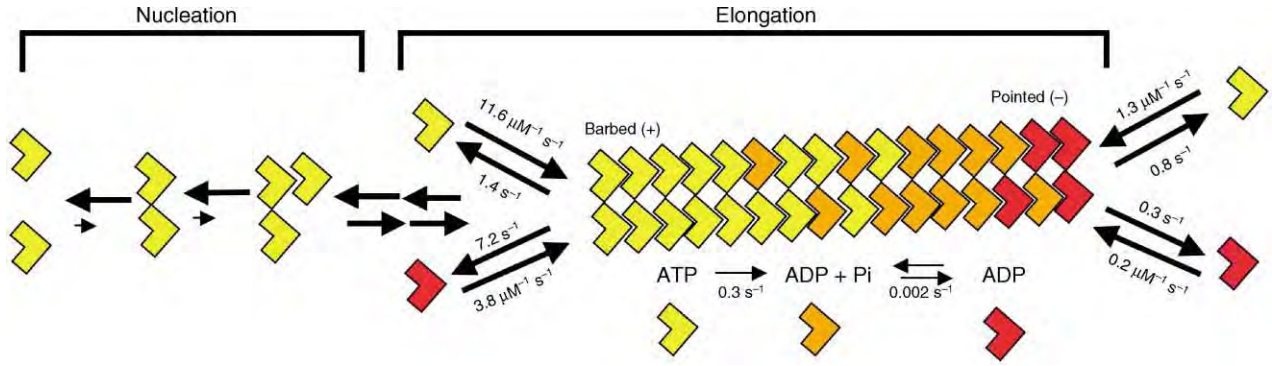

FIGURE 2 Assembly/disassembly of actin alone. Nucleation is highly unfavorable, signified by the large back arrows in the dimerization and trimerization steps. Once a tetramer is formed, the filament is more stable and monomers add to and disassemble from each end with the indicated kinetic constants (Pollard (1986) *J. Cell Biol*, **103**, 2747–2754). Subunits hydrolyze bound ATP slowly upon addition to filaments, and release the Pi product even more slowly, creating sectors of the filament enriched in ATP-actin (yellow), ADP-Pi-actin (orange), and ADP-actin (red). Upon release from the filament, the ADP on the monomer exchanges slowly with ATP.

filaments and 0.1 μM as monomers. With 100 μM actin, 99.9 μM is in filaments, 0.1 μM as monomers. At or below 0.1 μM, there are no filaments. Even at equilibrium, monomers constantly add to and release from both ends.

Polymerization Conditions

Three buffer conditions strongly affect actin's propensity to polymerize: ionic strength, the divalent cation present, and pH. Increased ionic strength increases elongation rate. The reason for this effect is not well understood, but thought to be due to masking of charge repulsion between the highly anionic actin monomers. The ionic effect reaches a maximum at around the equivalent of 50 mM KCl, and higher concentrations slow polymerization, probably due to inhibition of specific inter-monomer charge interactions in the filament. As for divalent cation, Mg-actin is better than Ca-actin at polymerizing, due to differences in monomer conformation. For pH, higher pH inhibits polymerization, likely due to increasing the net negative charge of actin, hence increasing charge repulsion between monomers.

Effects of Actin-Binding Proteins

Actin-binding proteins are widely expressed in eukaryotes, generally at concentrations that exert a significant effect on cellular actin assembly/disassembly. Each protein alters one or more aspects of actin's assembly/disassembly cycle. The basic biochemical functions of these proteins are discussed in this section and illustrated in Figure 3, while their coordinated cellular effects are described in the next section.

Sequestering Proteins

Sequestering proteins, present in most eukaryotic cells, bind actin monomers and prevent their addition to either end of filaments (Figure 3). Metazoan cells often contain the small protein, thymosin (5 kDa), the most well-characterized isoform being thymosin β4. Yeast do not have thymosins, but do express twinfilin, which can sequester. Twinifilin is present in mammals and other organisms as well.

Profilin

Profilin is a 13 kDa protein that binds actin monomers, preferring ATP-actin over ADP-actin about fivefold. Profilin binding has three consequences for actin (Figure 3). First, profilin strongly inhibits spontaneous nucleation. Second, profilin prevents monomer addition to pointed ends. Third, profilin serves as a nucleotide exchange factor for actin, increasing exchange of ATP or ADP at least fivefold, though by some accounts its effect is much greater. A common misconception is that profilin is a sequestering protein. Profilin-bound actin can add to barbed ends at a rate comparable to that of free monomer. An additional feature of profilin is that it binds stretches of polyproline found in many cytoskeletal proteins (e.g., VASP, formins, WASp/Scar/WAVE family proteins, vinculin), binding such proteins and an actin monomer simultaneously.

Capping Proteins

Capping protein is a heterodimer of 30 kDa subunits that binds filament barbed ends, preventing monomer addition (Figure 3). With barbed ends capped,

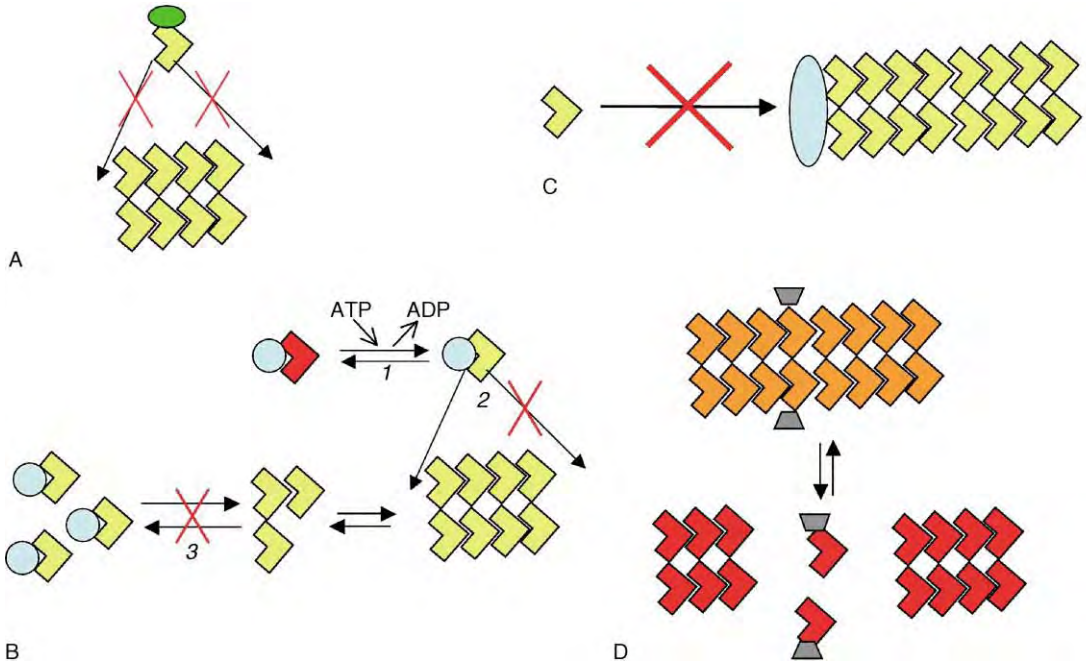

FIGURE 3 Effects of actin-binding proteins on actin dynamics. (A) Sequestering proteins (green oval) bind actin monomers and prevent addition to either end of the filament. (B) Profilin (light blue circle) binds monomers and has three effects: (1) acceleration of nucleotide exchange on monomers; (2) prevention of monomer addition to pointed ends; and (3) inhibition of spontaneous nucleation. (C) capping proteins (light blue oval) bind filament barbed ends and prevent monomer addition. (D) ADF/cofilin (gray trapezoid) binds ADP-subunits on filaments and promotes Pi release from other subunits. ADF/cofilin also severs filaments. These two activities result in accelerated filament depolymerization.

the critical concentration of actin shifts to 0.7 μM, the critical concentration of the pointed end. Capping protein's high affinity ($K_d < 1$ nM) and slow off-rate (half-life of capped barbed end is 30 min) cause a stable block to barbed end elongation. Members of the gelsolin family also cap barbed ends, in addition to severing filaments.

ADF/Cofilin

ADF/cofilin is a 15 kDa protein that binds both filaments and monomers, with a 40-fold preference for the ADP-bound state over ATP- or ADP-Pi states in both cases. Mammals contain two isoforms, ADF and cofilin. ADF/cofilin binding to filaments is cooperative, and accelerates Pi release from other subunits on the filament at least 20-fold. ADF/cofilin also severs filaments. ADF/cofilin is often referred to as a depolymerization factor, because its binding to filaments accelerates depolymerization. The mechanism of depolymerization acceleration probably involves both acceleration of Pi release (increasing subunit off-rate from filaments) and severing (creating more ends for depolymerization). However, ADF/cofilin does not prevent polymerization, as ADF/cofilin-bound monomers can still add to filaments.

Cellular Aspects of Actin Assembly/Disassembly

In mammalian cells, actin concentration is in the 50–200 μM range. Since the critical concentration is 0.1 μM, one would expect the vast majority of actin to be in filaments. However, the ratio of polymerized:unpolymerized actin is often around 1:1 in unactivated cells, while activated cells can reach close to 100% polymerized actin. The 1:1 ratio is maintained largely by the proteins discussed. Many mammalian cells contain more thymosin than actin, as well as a high concentration of profilin (e.g., Neutrophils have ~200 μM actin, 400 μM thymosin, and 100 μM profilin). Despite its lower concentration, profilin binds ATP-actin more tightly than thymosin (K_d of 0.2 μM vs >10 μM), so that monomers distribute between the two proteins. The rapid off-rates of monomers from these proteins (at or above five per second) allow rapid equilibration. Almost all monomers are bound to one protein or the other, leaving ~0.5 μM free actin monomer in cells. This low free monomer concentration virtually eliminates spontaneous nucleation in cytoplasm. Another consequence of these two proteins is that pointed end elongation is effectively suppressed, since thymosin prevents elongation from both ends and profilin prevents pointed

end elongation. For this reason, cellular filaments only elongate from barbed ends (except under specific conditions in muscle cells).

Cellular actin filaments are created by specific nucleation factors. Examples of such factors are Arp2/3 complex and formins. Both nucleation factors are tightly regulated. Thus, cells control the when and where of filament formation.

Mammalian cells contain ~1 μM capping protein, and its high affinity for barbed ends means that new filaments are capped rapidly (~1 s after formation). Capping protein is inhibited by bound polyphosphoinositides, which can promote cellular filament elongation. Some proteins can also inhibit capping protein by competing for barbed end binding, specifically VASP and formins. By controlling capping, cells control filament elongation.

The mechanisms by which cellular filaments disassemble are not understood fully, since off-rates from pointed ends can not explain the rapidity of disassembly in many circumstances. Filament networks 100s of nm thick can disassemble in seconds. ADF/cofilin clearly has a central role in this process, probably both by catalyzing Pi release from filaments and by severing filaments to create new ends for depolymerization. There is, however, evidence that ADF/cofilin may contribute to filament assembly upon initiation of cell motility, perhaps by severing to create new ends capable of elongating and supporting Arp2/3 complex-based nucleation.

The coordinated action of these proteins results in a cycle of assembly/disassembly in cells (Figure 4). Monomers shift from thymosin to profilin, then add to the barbed end. The filament-bound monomer hydrolyzes its ATP and retains ADP and Pi. ADF/cofilin binding to the filament accelerates Pi release and causes filament severing. Monomers dissociate from the pointed end and remain bound to ADF/cofilin. Monomeric ADP-actin exchanges between ADF/cofilin, thymosin, and profilin. Even though ADF/cofilin binds more tightly than profilin to ADP-actin, profilin is at higher concentration (100 versus ~20 μM), and the rapid off-rate from ADF/cofilin enables equilibration. Profilin catalyzes recharging of ATP onto its bound monomer, enabling re-addition of that monomer to the barbed end. Capping protein terminates barbed end elongation except under specific circumstances.

Profilin's ability to bind proline-rich sequences in VASP and formins may have interesting consequences. Both proteins are postulated to reside close to barbed ends of particular filaments and to compete for barbed end binding with capping protein. Binding of profilin-actin at these areas may enable preferential elongation of these filaments even in the presence of capping protein.

The above description is probably accurate for most eukaryotes, including mammals, other vertebrates and multicellular animals, and protozoa. Fungi such as *Saccharomyces cerevisiae* (budding yeast) are somewhat different, containing lower actin and profilin concentrations (5–10 μM for each) and no thymosin. A yeast sequestering protein, twinfilin, is present at unknown concentration. Unlike in vertebrates, most yeast actin (>90%) is polymerized. Yeast contain ADF/cofilin, capping protein, Arp2/3 complex and formins.

Actin assembly/disassembly in plants is poorly understood. Plants contain all the discussed proteins except thymosin. Plant profilin does not catalyze nucleotide exchange.

Other proteins, less well characterized at present, may play significant roles in actin assembly/disassembly.

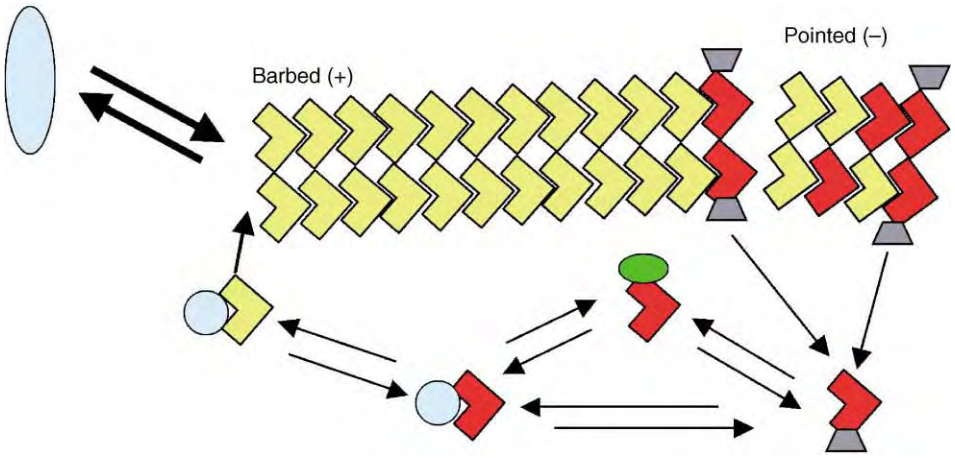

FIGURE 4 Concerted effects of actin-binding proteins in the assembly/disassembly cycle. Profilin-bound ATP-actin adds to the filament barbed end, then hydrolyzes its ATP slowly. ADF/cofilin binding accelerates Pi release along the filament, and severs the filament. ADF/cofilin-bound ADP-subunits release from filament ends. Profilin, thymosin, and ADF/cofilin compete for binding ADP-monomers. Profilin-bound ADP-monomers exchange ADP for ATP, enhancing their ability to assemble onto barbed ends.

TABLE II

Small Molecule Reagents Used in Actin Research

Reagent	Biochemical effect	Cellular effect	Cell-permeant?
Latrunculin A	Sequesters monomer	Depolymerization	Yes
Cytochalasins	Cap barbed ends	Depolymerization	Yes
Swinholide A	Sequesters dimers, severs filaments	Depolymerization	Yes
Phalloidin	Binds filaments	Prevent depolymerization	No
Jasplakinolide	Binds filaments	Prevent depolymerization	Yes

Srv2/CAP complex may accelerate ADF/cofilin-mediated filament depolymerization and monomer recycling. Aip1 may associate with ADF/cofilin and cap barbed ends.

Reagents Used in Actin Research

Small Molecules Affecting Actin Dynamics

Table II presents a catalogue of the reagents commonly used in actin research. While this table is simplistic, the effects of some reagents are not, and care must be taken to avoid artifacts. An example is the cytochalasins, a group of compounds commonly used to depolymerize cellular actin. This effect is attributed to the barbed end capping activity of cytochalasins. With barbed ends capped, filaments depolymerize from pointed ends since profilin and thymosin prohibit pointed end elongation. However, at higher concentrations, cytochalasins can have other effects, such as causing ATP hydrolysis on actin monomers through non-productive dimer formation. Use of concentrations below 1 μM largely suppress this secondary effect. In addition, cytochalasin B binds and inhibits a plasma membrane glucose transporter. Despite this property, cytochalasin B is sometimes used in preference to cytochalasin D, because the tenfold lower affinity of cytochalasin B for barbed ends enables more rapid wash-out during cellular recovery experiments.

Latrunculins (isomers A and B) can cause a similar cellular effect to cytochalasins (depolymerizing filaments), but by a different mechanism (sequestering monomers). In neither case do these compounds actively depolymerize filaments. What they do is block polymerization, leaving only depolymerization to occur by the normal cellular mechanisms.

Swinholide A binds/severs filaments, and binds/sequesters dimers, again causing cellular actin depolymerization. This compound has not been widely used in actin cell biology.

Two compounds stabilize filaments: phalloidin and jasplakinolide. Phalloidin is much better characterized. In the presence of phalloidin, the off-rate from barbed and pointed ends drops to near zero, and the critical concentration essentially becomes zero. Phalloidin also slows Pi release significantly. Phalloidin can be labeled with many compounds, including fluorophores, enabling localization of actin filaments in permeabilized cells. TRITC-phalloidin is especially useful, since its fluorescence increases 20-fold upon binding filaments. Since phalloidin is not cell-permeable, jasplakinolide is used for live cell studies. For either compound, concentrations equal to those of actin are necessary to block depolymerization fully, because they bind stoichiometrically along the filament.

Glossary

capping protein In theory, any protein that binds either barbed or pointed end of actin filament and prevents monomer addition to that end. In practice, used to mean barbed end capping protein, and often heterodimeric capping protein in particular.

critical concentration The concentration of monomers in a solution of actin at equilibrium between monomers and filaments. Under polymerizing conditions, the critical concentration with both the barbed and pointed ends free is ~0.1 μM. When the barbed end is capped, the critical concentration rises to 0.5–0.7 μM.

sequestering protein Protein that binds actin monomer and prevents addition to either end of the filament. Neither profilin nor cofilin are sequestering proteins.

Actin-Capping and -Severing Proteins

Sankar Maiti and James R. Bamburg
Colorado State University, Fort Collins, Colorado, USA

Actin is one of the major components of the cytoskeleton, a network of protein filaments that organizes the cytoplasm of eukaryotic cells. Actin filaments (F-actin), in the form of a right-handed double-stranded helix, are formed by assembly of globular (G-actin) monomer subunits in a head to tail orientation that gives the filaments a molecular polarity. Based on the orientation of an arrowhead pattern on F-actin decorated with a fragment of the muscle motor protein myosin, one end of the filament is called the barbed end and the other the pointed end. Spatial and temporal regulation of actin-filament assembly, disassembly, and stability in cells drives most aspects of cell motility, cell shape, and the interaction of a cell with its neighbors or surrounding matrix. Actin-capping and -severing proteins are special classes of actin-binding proteins (ABP) that regulate the assembly dynamics of actin filaments. Actin-capping proteins are classified into two groups, the barbed-end-capping proteins and the pointed-end-capping proteins. Depending on their binding affinity and off-rate constants, capping proteins slow down or stop the growth and/or depolymerization of filaments at the end to which they bind. Their interaction with actin may promote nucleation of new filaments, increase branching of filaments, and/or enhance filament depolymerization. Actin-severing proteins bind to the side of actin filaments and enhance fragmentation. Some severing proteins also become barbed-end-capping proteins (e.g., gelsolin) whereas others (e.g., ADF/cofilin) can provide both free barbed and pointed ends that can influence actin dynamics.

Actin

Actin is a major cytoskeletal protein in virtually all eukaryotic cells, usually comprising $>1\%$ of cellular protein. In muscle cells where it was first identified, F-actin is the major component of the thin filaments of the contractile apparatus where the myosin motor head groups of the thick filament walk along the actin thin filaments in an energy-dependent process, causing contraction. Mammals have six actin genes, each expressing a different isoform, but the structure of the 42.5 kDa actin monomer is highly conserved across phyla. G-actin has four quasi-subdomains at the center of which is bound an essential adenine nucleotide, either adenosine triphosphate (ATP) or adenosine diphosphate (ADP). As is the case with most molecular self-assembly systems, actin assembly is driven by a positive entropy change that arises from the displacement of water as the subunits come together. Following assembly, bound ATP is hydrolyzed to ADP through an ADP + Pi intermediate. Nucleotide hydrolysis provides the energy input required for actin filaments to maintain equilibrium binding constants for monomers that differ at the barbed and pointed ends. The concentration of monomer required to maintain the filament end is called the critical concentration, and is lower for the barbed end than for the pointed end. Thus, as monomer assembles into filaments and the monomer concentration decreases, the critical concentration of the pointed end is reached first. Monomers still add to the barbed end, leading to monomer loss from the pointed end. This phenomenon is called treadmilling. At steady state there is consumption of energy through ATP hydrolysis that drives the treadmilling of the actin subunits (Figure 1). In some cells this may account for up to 50% of the total ATP consumption. Tropomyosin, a short helical filamentous ABP, binds along the side of actin filaments and covers 5–7 actin subunits. Binding of tropomyosin usually aids in the formation of stable actin filaments, in part because they can inhibit the severing and depolymerizing activity of other ABPs. Dimers of actin are not stable and tend to dissociate but with addition of another monomer, the trimeric actin acts as a nucleus for filament formation. In the cell, spontaneous nucleation of filaments is kept at a minimum by the presence of actin monomer sequestering proteins. Thus, nucleation is a highly regulated event and may be initiated in the cell by three mechanisms: (1) the activation of certain actin binding proteins that help form trimeric nuclei; (2) the removal of capping proteins from the filament barbed ends; and (3) the severing of existing filaments to provide new barbed ends for filament elongation. The sites of nucleation and directionality of actin-filament growth is important for the development of cell polarity and cell migration and is regulated, in part, by the localized activity of capping and severing proteins.

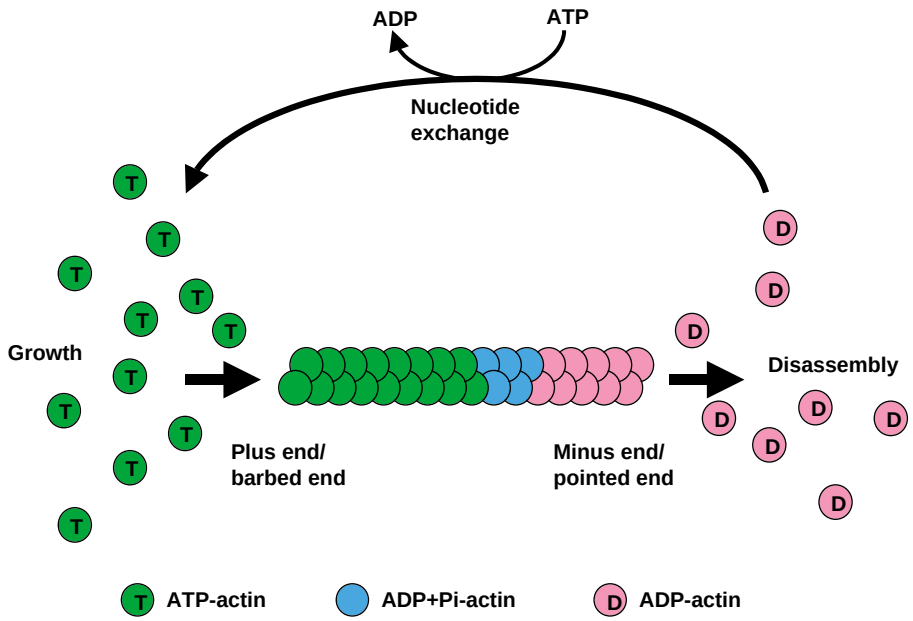

FIGURE 1 Dynamics of actin filaments at steady-state demonstrating treadmilling. ATP-actin adds onto the barbed end, nucleotide hydrolysis occurs and the inorganic phosphate dissociates leaving ADP-actin subunits to dissociate from the pointed end. Nucleotide exchange of ATP for ADP occurs on the monomer, giving rise to more ATP-actin for filament growth.

Actin Dynamics at the Leading Edge

Various cell membrane protrusions and inversions, especially lamellipodia, filopodia (microspikes), phagocytic cups, and upward ruffles are distinct morphologies of cells and are important for cell function, motility, and organismal development. These leading edge phenomena are based on actin-filament reorganization. In extending lamellipodia and filopodia, polarized arrays of actin filaments turn over very rapidly, with filament barbed ends facing toward the plasma membrane. The pointed ends of the filaments rapidly depolymerize at the rear of these arrays. In extending lamellipodia, the actin-filament growth is regulated mainly by Ena/VASP, capping protein, and Arp2/3 complex. The Arp2/3 complex causes branching of growing actin filaments and the barbed-end-capping protein limits the growth of newly assembled filaments to maintain short rigid filaments that can serve to push the membrane forward in the broad lamellipodium. Ena/VASP proteins bind to the barbed ends of growing actin filaments and inhibit the binding of Arp2/3 complex and capping protein, leading to the formation of longer and unbranched actin filaments, such as those found in the finger-like filopodial extensions (microspikes). This antagonism in barbed-end binding between Ena/VASP and Arp2/3 complex and capping protein, can help explain the often rapid conversion between lamellipodial and filopodial type of membrane protrusions seen at the leading edge of many migrating cells, especially within the growing tip of neurons, called the growth cone (Figure 2).

Pointed-End Binding and Branching

Arp2 and Arp3 are two actin-related proteins that form part of a seven-subunit complex known as the Arp2/3 complex, ubiquitous in eukaryotes. The Arp2/3 complex is required for generating the 70° branched actin filaments observed at the leading edge of expanding cell membranes in lamellipodia. There are several possible mechanisms for generating this type of filament array. The Arp2/3 complex may capture the pointed ends of actin filaments created by severing pre-existing

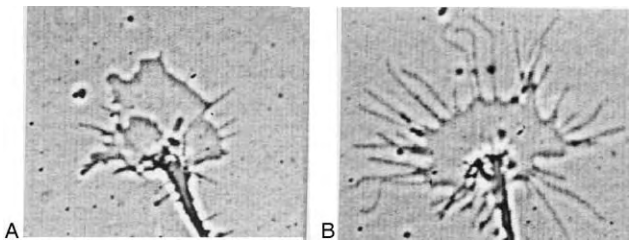

FIGURE 2 A typical dorsal root ganglion neuronal growth cone. Phase contrast picture in A shows growth cone exhibiting lamellipodial growth. Within a few minutes after reducing the osmolarity of the growth medium, the growth cone exhibits many long and active filopodia (B). Panel width = 44 μm.

filaments and then associate with the side of another pre-existing filament to create a branch point. Alternatively, Arp2/3 complex may bind at the barbed end of a growing filament to create a branch point. The Arp2/3 complex requires activation to become a potent nucleator of actin-filament growth. Activation can occur through the binding of members of the Wiskott–Aldrich syndrome protein (WASP) family, some of which are activated by signaling through G protein-coupled receptors. Arp2/3 complex can also be activated by other mechanisms. The active Arp2/3 complex can bind an actin monomer and initiate the nucleation of a new filament at an angle of ~70° to the mother filament. This branched actin-filament network, called the dendritic brush, generates the force needed for cell protrusion at the leading edge (Figure 3). To maintain proper stiffness and maintain the best angle for membrane expansion, the filaments are not allowed to grow very long before their barbed ends are capped by capping protein. The branching of filaments is inhibited by the binding of at least some forms of tropomyosin, which prevent Arp2/3 binding, and branching is also inhibited by proteins in the Ena/VASP family. The binding of tropomyosin and Ena/VASP proteins also inhibits binding of some barbed-end capping proteins, allowing filaments to grow into long parallel bundles, such as those that form filopodia.

Evolutionary and Structural Relationships between Some Severing and Severing/ Barbed-End-Capping Proteins

The present sequence, structural, and biochemical data suggest that many of the actin-binding proteins have evolved through gene duplication or mutation of DNA sequences encoding a small number of protein motifs. Variants of a single 15 kDa molecular module have evolved, which interact with both G-actin and F-actin with severing and capping functions that may be regulated by calcium and/or by specific phospholipids. Proteins in the ADF/cofilin family are single domain, bind both G-actin and F-actin, have pH-dependent actin-filament severing activity, and are found in all eukaryotes. Twinfilin is a 40 kDa protein with two ADF-homology

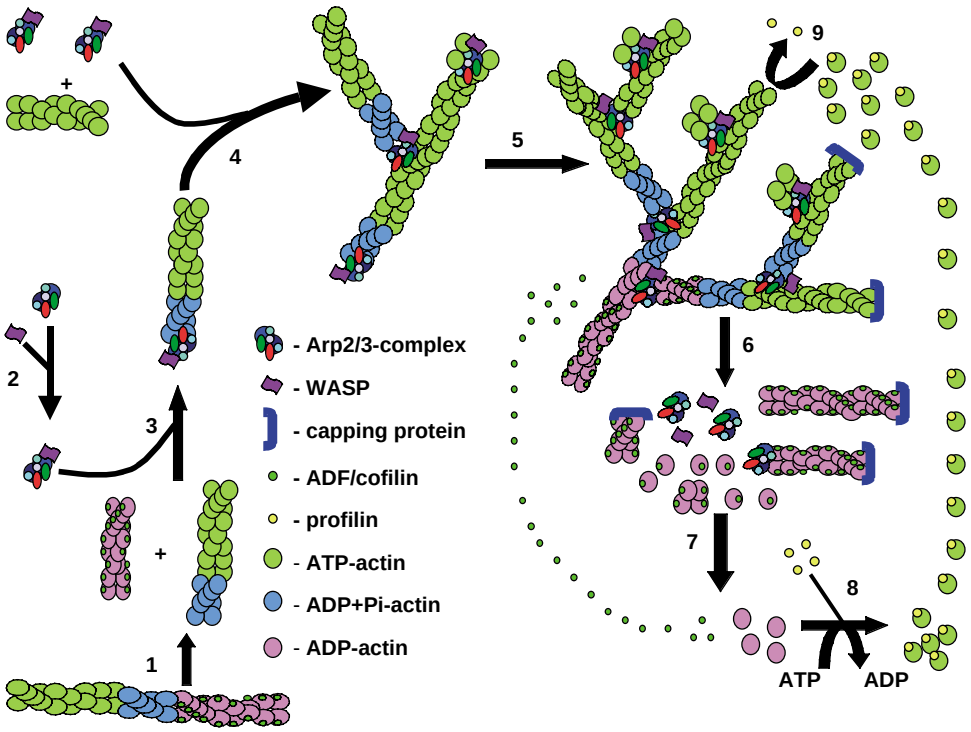

FIGURE 3 Schematic of actin-filament dynamics at the leading edge of a cell. (1) Severing of actin filament is one mechanism to create new barbed ends. (2) Activation of Arp2/3 complex by WASP can cause *de novo* nucleation of filaments, but active Arp2/3 complex may also be captured by pointed ends of severed filaments (3). (4) Arp2/3 complex either nucleates from the side or ends of actin filaments or when bound to actin, is captured along the side of a filament to create the 70° branches. Further growth of barbed ends with rapid capping and nucleation of new branches leads to complex networks of actin filaments (5). (6) ADF/cofilin-mediated severing and depolymerization of the filament arrays occurs when subunits become ADP-actin. Release of ADF/cofilin (7) and enhanced nucleotide exchange by profilin (8) provide profilin–actin complex that serves as a monomer pool for filament growth (9).

(ADF-H) domains connected by a small linker region. Twinfilin is found across the phyla. Unlike ADF/cofilin, twinfilin does not interact with F-actin and does not promote filament disassembly, but acts as an actin monomer sequestering protein thereby preventing spontaneous actin-filament assembly. CapG, severin, and fragmin contain three structural repeats of the 15 kDa ADF-H domain, and have barbed-end-capping and -severing activity. Presumed duplication of the three repeat-containing proteins gives rise to proteins with six ADF-H repeats, such as gelsolin, villin, and adseverin/scinderin, which are more complicated regulators of actin dynamics. Functions of all of the members of the three repeat and six repeat families are regulated by calcium and specific membrane phospholipids, and are commonly known as the gelsolin family of actin-filament-capping and -severing proteins. Although ADF/cofilins and some gelsolin family members show little or no sequence homology, structurally they display similar overall folding and secondary/tertiary structural elements suggesting both divergent and convergent evolutionary mechanisms may have given rise to these structurally related molecules.

The Three Segment Proteins: CapG, Severin, and Fragmin

CapG, severin, and fragmin are gelsolin family proteins containing three ADF-H segments. The first segment (S1) binds to G-actin and has the capping function whereas segments 2 and 3 (S2, S3) bind to F-actin. CapG is a 39 kDa barbed-end-capping protein, the name reflecting its capping function and structural similarity to gelsolin, though only half its size. CapG is highly expressed in macrophages and was initially known as macrophage-capping protein, gCap39 or Mbh1. CapG has a structure similar to severin and fragmin, but does not sever actin filaments as does severin and fragmin. CapG caps barbed ends of actin filaments at micromolar concentrations of Ca^{2+}, but it dissociates from barbed ends when Ca^{2+} levels return to their normal nanomolar levels, whereas gelsolin remains bound to the barbed ends under the same conditions. CapG is important for the actin-based motility of macrophages. Phosphatidylinositol-4,5-bisphosphate (PIP_2) binds to CapG thereby inhibiting its binding to F-actin. The actin monomer sequestering protein profilin is also able to dissociate CapG from actin-filament barbed ends when profilin is present at high concentration ($>10\ \mu M$).

CapG is also found within the nucleus as well as the cytoplasm, but its function there is unknown. Although CapG lacks a nuclear export signal, which is present in severin and fragmin, CapG does not contain any known nuclear localization signal. Thus, the method by which it is translocated into the nucleus is also unknown. Severin and fragmin, found in the slime moulds *Dictyostelium* and *Physarum* respectively, are structurally similar to CapG, but they also bind to the side of and sever F-actin as well as cap the barbed ends of the severed filaments. They have two Ca^{2+}-binding sites and can be thought of as small versions of gelsolin.

The Six Segment Proteins: Gelsolin, Villin, and Adseverin/Scinderin

Gelsolin, villin, and adseverin/scinderin contain six ADF-H repeats and are F-actin barbed-end-capping and -severing proteins. The N-terminal half of these proteins, with three repeats similar to CapG, severin, and fragmin, is able to bind two actin monomers and sever actin filaments. The C-terminal half is able to bind to a single actin monomer at elevated Ca^{2+} concentration.

Gelsolin, with a mass of 80 kDa, is expressed in all eukaryotes. The name arose from its ability to rapidly dissolve an actin gel and convert it into a soluble form. The N-terminal half of gelsolin contains two Ca^{2+}-binding sites, one of which is high affinity, in the submicromolar range. Gelsolin severs actin filaments at Ca^{2+} concentrations $>10^{-5}$ M. The severing mechanism probably involves the binding of gelsolin along the side of the filament and intercalation between actin subunits during the normal bending of the actin. After severing filaments, gelsolin remains bound to the barbed end of one new filament (Figure 4) and produces a new pointed end. At Ca^{2+} concentrations in the submicromolar range, gelsolin acts to cap barbed ends of actin filaments. An extracellular (secreted) isoform of gelsolin with molecular mass 83 kDa, called serum gelsolin, circulates in blood where it severs and caps actin filaments released from lysed cells. The resulting monomers of actin are then sequestered by vitamin D-binding protein, a potent monomer-binding protein and ultimately removed from circulation by liver. This mechanism prevents accumulation of actin filaments in the blood, which could potentially block circulation in capillaries.

Gelsolin binding to F-actin is inhibited by tropomyosin in two ways. Tropomyosin binding to F-actin induces a cooperative conformational change in actin filaments resulting in dissociation of gelsolin. Secondly, tropomyosin can directly bind gelsolin and thereby dissociate gelsolin from actin–gelsolin complex. Dissociation of gelsolin by tropomyosin from a gelsolin capped actin filament leads to formation of long filaments from smaller gelsolin-actin complexes, even from gelsolin–actin heterodimers, heterotrimers, and heterotetramers. PIP_2 can bind directly to gelsolin and dissociate gelsolin

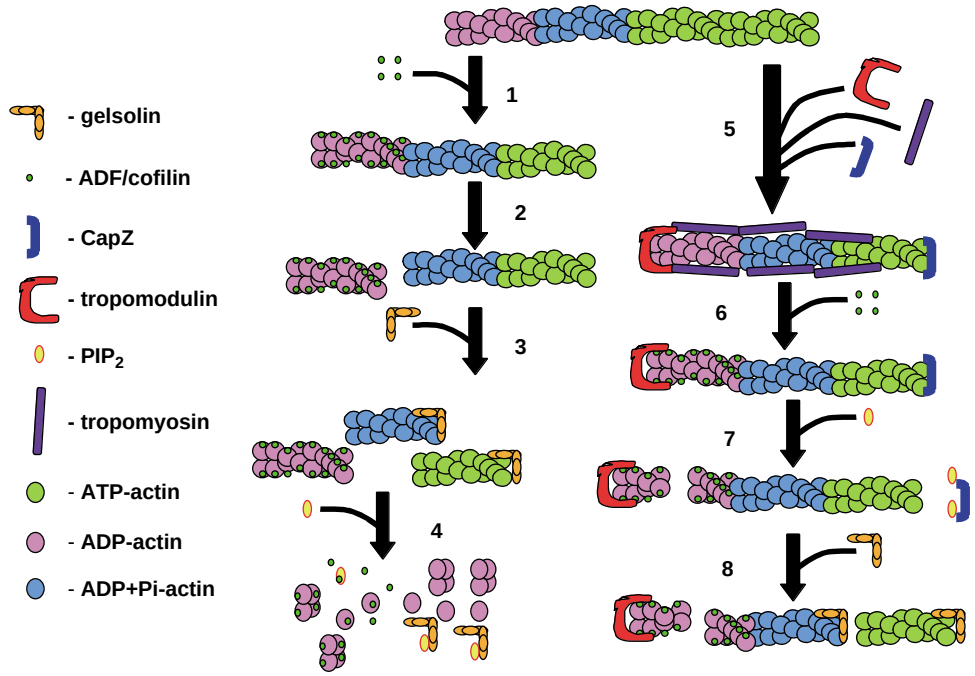

FIGURE 4 Diagrams showing actin-filament capping and severing by different types of molecules. (1) ADF/cofilin bind with highest affinity and cooperatively to ADP-actin and (2) sever actin filaments as well as enhancing monomer off-rates from the pointed ends (not shown). (5) Stable filaments generated by tropomodulin binding to pointed ends, CapZ binding to barbed ends and tropomyosin binding along filament length. ADF/cofilin competes for F-actin binding with some tropomyosins (6) and can lead to severing and exposure of new pointed ends (7). (4 and 7) PIP_2 regulates the binding of capping proteins, dissociating both gelsolin and CapZ from barbed ends of actin filaments. (3 and 8) Actin-filament capping and severing by gelsolin.

that is already bound to the barbed end of an actin filament to yield a free barbed end for growth. Gelsolin can be proteolytically cleaved by caspase-3 during apoptosis. The short amino-terminal cleavage (residues 1–352) fragment does not need Ca^{2+} for severing existing actin filaments and contributing to the progression of apoptosis.

Villin, a gelsolin family member with molecular mass of 92.5 kDa, controls actin assembly in the microvilli of epithelial cells. Villin has the unique property of being able to bundle actin filaments through an 8 kDa F-actin-binding module known as the villin headpiece. The activity of villin is highly regulated by Ca^{2+}. At submicromolar Ca^{2+} concentrations, villin bundles actin filaments whereas at micromolar Ca^{2+} concentrations it caps barbed ends of actin filaments and at >100 μM Ca^{2+} it severs F-actin. As with gelsolin, the activity of villin is regulated by both PIP_2 and Ca^{2+}. In addition, villin is regulated by phosphorylation on tyrosine in intestinal epithelial cells, a requirement for regulating the interaction of actin filaments with apical ion channels in the epithelial cells. Deletion of the villin gene in mice leads to accumulation of actin filaments within the epithelial cells making them prone to injury.

Adseverin, also known as Scinderin, is only expressed in secretory cells. It has slightly different temperature and Ca^{2+} sensitivity from gelsolin, but its functions appear to be very similar. During cell stimulation by Ca^{2+}, adseverin is activated and disassembles cortical F-actin to allow secretory vesicle exocitosis. As with gelsolin, adseverin binds to and is regulated by PIP_2.

The Single Domain ADF/Cofilin Family

Cell motility and morphogenesis require high rates of turnover of actin filaments, ~100–150-fold faster than occurs for purified actin *in vitro*. The ADF/cofilins are 13–19 kDa proteins containing a single ADF-H domain and are required for this high rate of actin-filament dynamics. They have been isolated or identified by genomic or cDNA analysis from more than 20 different animals, higher plants, fungi, yeasts, and protists. The lethality of the loss of the ADF/cofilin gene in organisms that express only a single gene for this family (e.g., yeast), demonstrates the essential nature of these proteins. Mammals have three separate genes for these proteins: ADF, the ubiquitous cofilin 1 and the muscle-specific cofilin 2. Within any given species, the three proteins are ~70% identical. In an ADF null mouse, cofilin 1 expression is up-regulated to compensate for the loss of ADF and the animals are viable. The only major defect observed is that the mice become blind due to corneal

thickening, even though cofilin 1 is up-regulated in the cornea. This finding, along with differences in the quantitative behavior of the three proteins *in vitro*, suggests that each isoform has some unique tissue specific function. Many ADF/cofilins have nuclear localization sequences, but the protein is usually cytosolic. However, it can be targeted to the nucleus, along with cytoplasmic actin, under certain conditions, although its function there is not known. ADF/cofilins enhance filament turnover (dynamize filaments) in two ways. They can bind cooperatively along the filament, stabilizing a "twisted" form of the actin that is more readily fragmented (severed), creating more filament ends that can either enhance depolymerization, if the environment is an actin monomer sequestering one, or nucleate filament elongation, if the pool of assembly competent monomer is sufficient to sustain growth. If F-actin is severed by ADF/cofilin at the leading edge of cells where active Arp2/3 complex is present, the Arp2/3 complex can capture the pointed ends of the newly severed filaments and bind them along the side of existing filaments to create the highly branched network.

The ADF/cofilin proteins also enhance the rate of subunit loss from the pointed end of filaments. ADF/cofilins bind ADP-actin subunits or monomer with higher affinity than they bind to ATP-actin. Thus, within an actin filament, ADF/cofilin binding is preferentially toward the pointed end, the desired region for filament turnover in cells (Figures 3 and 4). ADF/cofilin activity is regulated by pH: pH $>$ 7.3 favors severing and depolymerization whereas pH $<$ 7.1 favors F-actin binding. ADF/cofilin-mediated F-actin severing is inhibited by tropomyosin, several isoforms of which compete with ADF/cofilin for binding to F-actin. Actin binding, and thus ADF/cofilin activity, is inhibited by phosphorylation at a highly conserved serine residue (ser 3 in mammalian ADF and cofilin). Two related kinases, the LIM kinases and TES kinases, each with two members, phosphorylate ADF/cofilins. The removal of the phosphate from Ser3 may be through the general phosphatases, but a more specific phosphatase called slingshot appears to be the major ADF/cofilin phosphatase for regulated dephosphorylation (activation). Both the kinase and phosphatase pathways are regulated by upstream signaling events through which extracellular signals affect actin dynamics.

Actin-interacting protein 1 (Aip1) is an actin filament-capping protein with a molecular mass of ~65 kDa. *In vitro*, Aip-1 binds to F-actin weakly or not at all in the absence of ADF/cofilin, but caps the barbed end of filaments severed by ADF/cofilin in the presence of ADF/cofilin. Aip1 activity inhibits annealing of the ADF/cofilin severed filaments, maintaining a higher filament number, and blocks the growth at the filament barbed ends. In the nematode *Caenorhabditis elegans*, which expresses two forms of ADF/cofilin, the ubiquitous unc60A and the muscle specific unc60B, only the weaker F-actin-binding/severing species unc60B is able to form a high affinity complex with Aip-1 (unc78). Thus, Aip1 enhances the apparent severing activity of the weaker ADF/cofilin and gives this family of proteins the ability to function much like the severing and capping proteins discussed earlier.

Other Capping Proteins

There are several capping proteins that appear to be structurally unrelated to those with ADF-H domains. In general these proteins bind weakly to actin monomer but often bind strongly to dimer and thus they can stabilize the dimer and enhance nucleation of filament growth. They have high affinity for the filament ends to which they bind and they usually bind in a 1:1 stoichiometry with the filament (Figures 3 and 4). The main function of capping is to restrict the polymerization/depolymerization, thereby controlling the filament length *in vivo*. As mentioned before, limiting the growth of actin filaments at the leading edge of migrating cells is important for actin-assembly driven membrane protrusion (lamellipodial growth). Pointed-end-capping proteins are important for filament branching, regulating filament turnover, and cross-linking of actin filaments to other components of the cytoskeleton.

Barbed-End-Capping Proteins

CapZ

The most abundant barbed-end-capping protein is CapZ. In striated muscle cells, CapZ binds to actin filaments at the Z-disk, where CapZ also interacts with α-actinin, an actin cross-linking protein, to anchor the thin filaments from the neighboring sarcomere, the contractile unit of skeletal muscle. Nonsarcomeric isoforms of CapZ are localized at the site of membrane actin contact. Cap Z also interacts with two other regulators of actin dynamics, the actin-monomer-binding protein, twinfilin, and with CARMIL, a protein named for its service as a CapZ, Arp2/3 and myosin-I-linker. CapZ is a heterodimer composed of α- and β-subunits, which are 32 and 31 kDa, respectively. Each subunit has two isoforms. Both subunits are structurally similar, and assemble tightly to form a dimer with pseudo twofold rotational symmetry. The C-terminal ends of each subunit are flexible, hydrophobic, mobile in nature, and necessary for actin binding. This flexibility explains how CapZ can tightly bind two actin subunits or the barbed end of the double-stranded F-actin. Cells have capping protein in 1:1 molar ratio with actin filaments and 1:100 to 1:150 with respect to total actin subunits. *In vivo*, the capping activity is regulated by

PIP_2, which binds directly to CapZ inhibiting its capping activity. The generation of PIP_2 in platelets in response to thrombin, uncaps actin-filament barbed ends allowing localized filament growth needed for the shape changes of platelets associated with blood clot retraction.

Tensin

Tensin, a large focal adhesion molecule with a mass of ~ 200 kDa, caps the barbed ends of actin filaments within the focal adhesions of fibroblasts and muscle. Tensin interacts with other molecules within the focal adhesion. Tensin is very susceptible to proteolysis, especially by the calcium-activated calpain-II. Full-length recombinant tensin shows complete capping activity whereas "insertin," most likely a proteolytic fragment of tensin, only partially caps F-actin.

Pointed-End-Capping Proteins

Tropomodulin

Tropomodulin is a unique pointed-end-capping protein first discovered as an actin-tropomyosin-binding protein (Figure 4). The name tropomodulin was given, because it binds actin filaments tightly in the presence of tropomyosin. Human skeletal muscle tropomodulin is 40.5 kDa, but a related protein named leiomodin is 64 kDa and is found in smooth and cardiac muscle. Tropomodulin caps the pointed end of actin filaments in striated muscle, playing an important role in the assembly of the sarcomere. In striated muscle, tropomodulin is present in a 1:1 molar ratio with respect to actin filaments. The N-terminal half of tropomodulin is rod shaped and binds to the N-terminal part of tropomyosin. The C-terminal half of tropomodulin is responsible for capping the pointed end of F-actin. Although tropomodulin binds to actin filaments tightly, it does not bind to actin monomer. Binding affinity to the pointed end of F-actin is threefold higher in the presence of muscle tropomyosin. Tropomodulin is found in nonmuscle cells and it binds with differing affinities to F-actin containing different isoforms of tropomyosin, suggesting it might play a role in modulating filament turnover through regulating the dynamics at filament pointed ends, where ADF/cofilins function to enhance turnover. However, its cellular role is not well defined.

Spectrin/Band 4.1

Spectrin/band 4.1 acts as an F-actin pointed-end-capping complex *in vitro*. The proteins are expressed in a wide variety of tissues in multiple isoforms. Spectrin/band 4.1-actin complex was first isolated from red blood cell (erythrocyte) membranes, where actin filaments are short and of uniform length. Both ends of these filaments are capped, the pointed end with spectrin/band 4.1, but the nature of the barbed-end-capping protein is not known. Spectrin binds to some transmembrane proteins as well as to actin, forming a cortical cytoskeleton in erythrocytes.

Glossary

actin depolymerizing factor (ADF)/cofilin Related actin-binding proteins that increase the turnover of actin filaments *in vivo* through severing and enhancing the off-rate of subunits from the pointed ends of F-actin. The ADF-H domain is used to build larger versions of related proteins that can sever and cap filaments.

Arp2/3 complex A complex of two actin related proteins, Arp2 and Arp3, with five other proteins that can nucleate the growth of new actin filaments and cause branching of filaments at the leading edge of a migrating cell.

Ena/VASP Enabled/Vasodilator-stimulated phosphoprotein, a family of actin-binding proteins that bind to but do not cap the growing barbed end of actin filaments, reducing branching and aiding in growth of long filaments.

F-actin The dynamic filamentous cytoskeletal structures, composed of subunits of actin monomer (G-actin), that organize the cytoplasm to maintain the shape of eukaryotic cells.

filament capping The binding of a protein at the end of an actin filament to stop filament growth or depolymerization.

filament severing The process whereby a protein binds along the side of an actin filament and severs the filament into smaller pieces.

filament treadmilling The dynamic process in which actin filaments elongate at their barbed (plus) end by addition of subunits and at the same time disassemble at their pointed (minus) end with loss of subunits.

filopodia Finger-like protrusions with sensory capability that extend from the cell membrane and contain a bundle of parallel cross-linked actin filaments with uniform polarity.

lamellipodia Flat web-shaped membrane protrusions containing highly branched actin filaments, seen at the leading edge of many migrating cells.

WASP Wiscott–Aldrich syndrome protein, a family of actin-binding protein involved in actin-filament nucleation.

Biography

Dr. James R. Bamburg is a Professor of Biochemistry and Molecular Biology and Director of the Molecular, Cellular and Integrative Neuroscience Program at Colorado State University, Fort Collins, Colorado. His principal research interest is the neuronal cytoskeleton and its regulation by assembly modulatory proteins. He holds a Ph.D. degree from the University of Wisconsin, Madison and did postdoctoral research at Stanford University. He has had visiting scientific appointments at the Laboratory of Molecular Biology, Cambridge, UK; Woods Hole Marine Biology Laboratory, Massachusetts; Cell Biophysics Unit, Kings College, London; University of Otago, Dunedin, New Zealand; University of Sydney, Australia; Ludwig Institute, University of California, San Diego, California. He has authored over 100 papers, most dealing with aspects of actin-filament dynamics in neuronal systems.

Dr. Sankar Maiti received his Ph.D. in 2003 from Punjab University where he performed molecular studies on mechanism of protein folding and protein thermostability. He worked as a research fellow in the Institute of Microbial Technology in Chandigarh, India and is currently a postdoctoral fellow in the laboratory of Dr. Bamburg.

Actin-Related Proteins

R. Dyche Mullins
University of California, San Francisco, California, USA

Actin-related proteins (Arps) are a class of proteins found in all eukaryotes and many species of bacteria and archaea. Arps are defined by their degree of similarity to actin (conventional actin), a ubiquitous, eukaryotic cytoskeletal protein. All Arps are built around a common structural fold. This "actin fold" binds and hydrolyzes ATP. In most Arps, ATP hydrolysis is converted into a conformational change that regulates assembly and/or function of multiprotein complexes. Conventional actin assembles into two-stranded helical filaments that form structural scaffolds used to organize the intracellular space and to drive cell division, shape change, and cell locomotion. Eukaryotic Arps fall into ten groups (Figure 1 and Table I) that can be loosely grouped into two categories: (1) cytoskeleton-associated Arps (Arp1, Arp2, Arp3, and Arp10) that regulate the assembly and function of the actin and microtubule cytoskeletons; and (2) chromatin-associated Arps (Arp4–Arp9) that regulate the structure and function of eukaryotic chromatin. Prokaryotic Arps were discovered only recently and their functions are not well understood. The best-characterized prokaryotic Arps (MreB, Mbl, and the plasmid-encoded protein, ParM) polymerize into filaments required for proper cell shape and DNA segregation. The primary sequences of prokaryotic Arps are highly divergent from those of the eukaryotic Arps but we include them in this discussion based on the similarity of their biochemical activities and cellular functions to conventional actin and the eukaryotic Arps. The presence of Arps in chromatin-remodeling complexes and the importance of prokaryotic Arps in DNA segregation suggest that their role in the handling of DNA is as ancient and well conserved as their more well-known cytoskeletal functions.

The Actin Fold

There is little or no conservation of surface-exposed residues among Arps. This reflects the fact that the proteins in this family have different binding partners and cellular functions (Figure 1 and Table 1). All Arps, however, share a common structural fold. The core of the protein is formed from two globular domains (domain I and domain II) connected by a flexible hinge (Figure 2B). The interface between the two domains forms an ATP-binding pocket. Five highly conserved sequences – three ATP-binding loops and two connecting helices – line this pocket and define the "actin fold." These sequences are an adenosine-binding loop (adenosine), two phosphate binding loops (phosphate 1 and phosphate 2), and two connecting domains (connect 1 and connect 2). These sequences are conserved in actin, the Arps, and all other members of the actin superfamily (which includes proteins like hexokinase and HSP70) and they are always arranged in the following order: phosphate 1, connect 1, phosphate 2, adenosine, and connect 2 (Figure 2A). The ATP-binding loops are distributed between the two domains of the protein. Phosphate 1 is located in domain I and both phosphate 2 and adenosine are in domain II (Figure 2B). When all three loops interact with ATP the two domains are tightly associated. Hydrolysis of the gamma phosphate of ATP weakens binding to the phosphate 1 domain and causes the two domains of the protein to swing apart around the hinge formed by connect 1 and connect 2. Complete loss of nucleotide results in further opening of the protein around the hinge. In some members of the actin superfamily the binding of ATP to a nucleotide-free protein causes the domains to rotate by 30° around the hinge region (Figure 2C). The shift from closed to open conformation is used by Arps to regulate their interactions with other proteins.

Prokaryotic Arps

An actin cytoskeleton is thought to be a prerequisite for the establishment and maintenance of intracellular compartments and organelles and until recently actin was thought to be a strictly eukaryotic protein. Recent work, however, has identified actin-like proteins in prokaryotes. The first two prokaryotic actin-like proteins, MreB and Mbl, were discovered in *B. subtilis*. These proteins have very limited primary sequence similarity to conventional actin but, remarkably, they fold into three-dimensional structures very similar to actin and, like conventional actin, they polymerize into two-stranded filaments in a manner that depends on

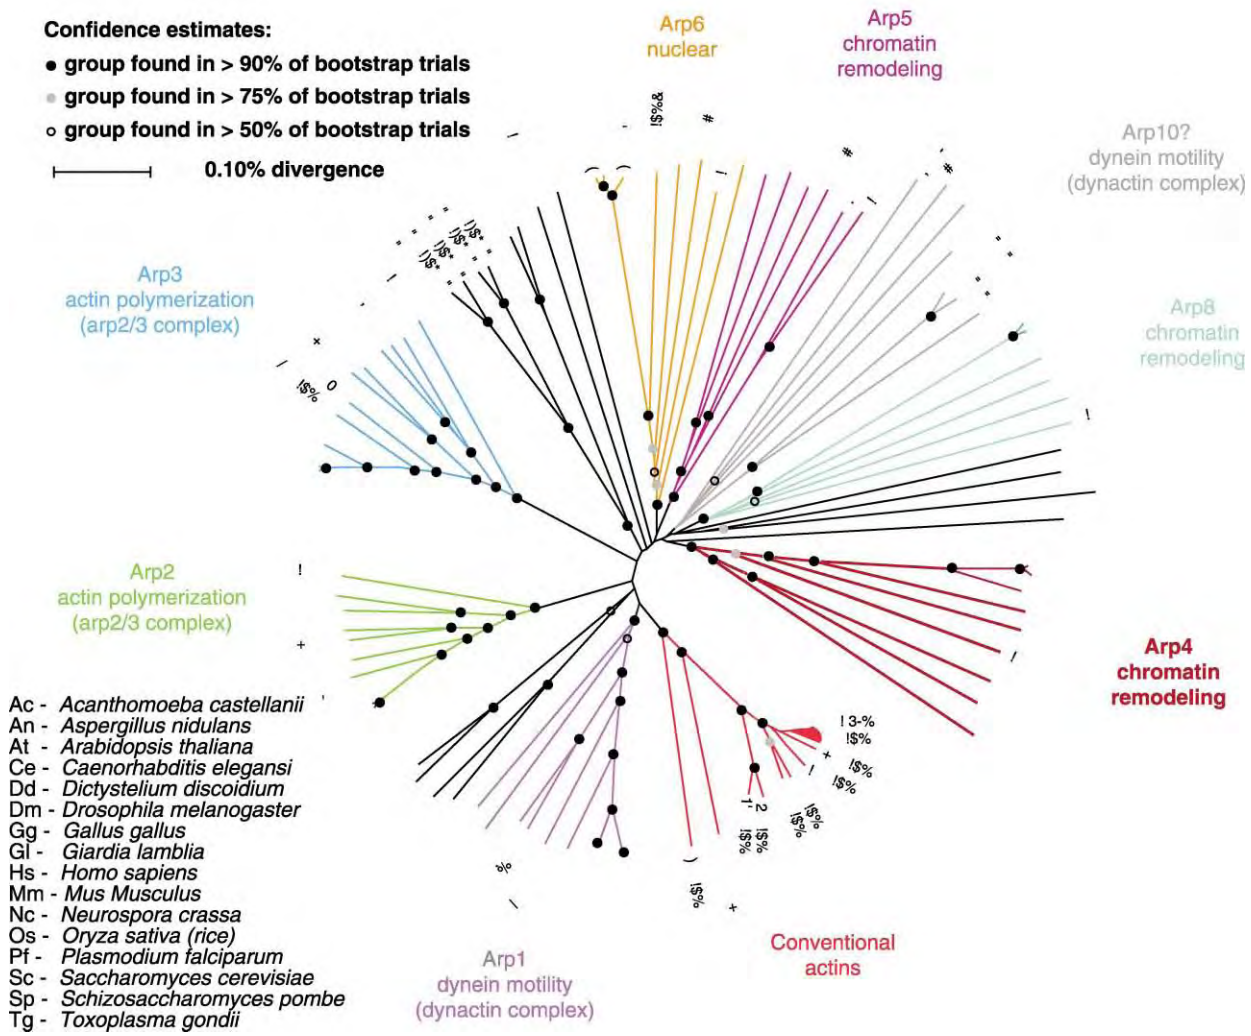

FIGURE 1 The eukaryotic Arp family is composed of ten, highly conserved members. Members fall broadly into two categories: cytoskeletal Arps (conventional actin, Arp1, Arp2, Arp3, and Arp10) and nuclear Arps (Arp4, Arp5, Arp6, Arp7, Arp8, and Arp9). The diagram is an unrooted phylogenetic tree of the actin superfamily. (Reprinted from *J. Cell Sci.* **202**(115), 2619–2622.) (Calculated by Clustal X Thompson J. D., Gibson, T. J., Plewniak, F., Jeanmougin, F., and Higgins, D. G. (1997) *Nucl. Acids Res.* **25**, 4876–4882.

ATP and salt. At present not much is known about the cellular roles of MreB and Mbl, but they do appear to form filaments *in vivo* that are required for proper positioning of the cell-wall synthesis machinery and proper shape determination of rod-shaped bacteria. In addition, MreB and Mbl are required for proper segregation of bacterial DNA during cell division. These are the types of functions performed by polymeric cytoskeletal elements in eukaryotes so it is fair to say that MreB and Mbl form a bona fide bacterial cytoskeleton.

Another remarkable prokaryotic actin-like protein is encoded by the *parM* locus of the low-copy drug resistance plasmid, R100. The R100 plasmid is stably maintained at one copy per cell in bacterial populations because it accurately segregates one copy each into daughter cells during each cell division. Three plasmid loci are required for this accurate segregation: ParR, *parM*, and ParC. ParR encodes a DNA-binding protein that binds tightly to the ParC locus. *parM* encodes an actin-like protein that assembles into two-stranded filaments in an ATP-dependent manner. The ParR protein bound to the ParC locus appears to nucleate formation of *parM* filaments, which drive plasmid segregation. This simple three-piece system may form a structure functionally equivalent to a mitotic spindle and may represent the minimal system for segregating DNA. Unlike conventional actin filaments in which ATP hydrolysis regulates interaction with depolymerizing factors (Figure 3B), ATP binding and hydrolysis directly control assembly and disassembly of ParM filaments. ATP-bound monomers polymerize into filaments.

TABLE I

Cellular Localization, Function and Multi-Protein Complexes of Eukaryotic Arps

Arp	Sequence similarity to actin	Cellular localization	Function	Multi-protein complexes
Actin	100% ident. 100% simil.	Cell cortex, leading edge, stress fibers, endosomes, vesicles, nucleus	Cell shape and motility, intracellular trafficking, chromatin remodeling (?), histone acetylation (?)	Actin filaments, INO80, BAF, and NuA4 complexes
Arp1	45% ident. 68% simil.	Golgi apparatus, transport vesicles, centrosomes, cell cortex	Dynein-driven intracellular movements	Dynactin complex
Arp2	45% ident. 69% simil.	Cell cortex, leading edge, some motile endosomes	Actin filament nucleation and crosslinking	Arp2/3 complex
Arp3	39% ident. 60% simil.	Cell cortex, leading edge, some motile endosomes	Actin filament nucleation and crosslinking	Arp2/3 complex
Arp4	30% ident. 53% simil.	Nucleus	Histone acetylation, chromatin remodeling, control of transcription	NuA4 and INO80 complexes
Arp5	26% ident. 51% simil.	Nucleus	Chromatin remodeling, control of transcription	INO80 complex
Arp6	24% ident. 46% simil.	Nucleus	Unknown	Unknown
Arp7	22% ident. 44% simil.	Nucleus	Chromatin remodeling, control of transcription	Swi/Snf and RSC complexes
Arp8	21% ident. 44% simil.	Nucleus	Chromatin remodeling, control of transcription	INO8 complex
Arp9	17% ident. 40% simil.	Nucleus	Chromatin remodeling, control of transcription	Swi/Snf and RSC complexes
Arp10	17% ident. 38% simil.	Golgi apparatus, transport vesicles, centrosomes, cell cortex	Dynein-driven intracellular movements	Dynactin complex

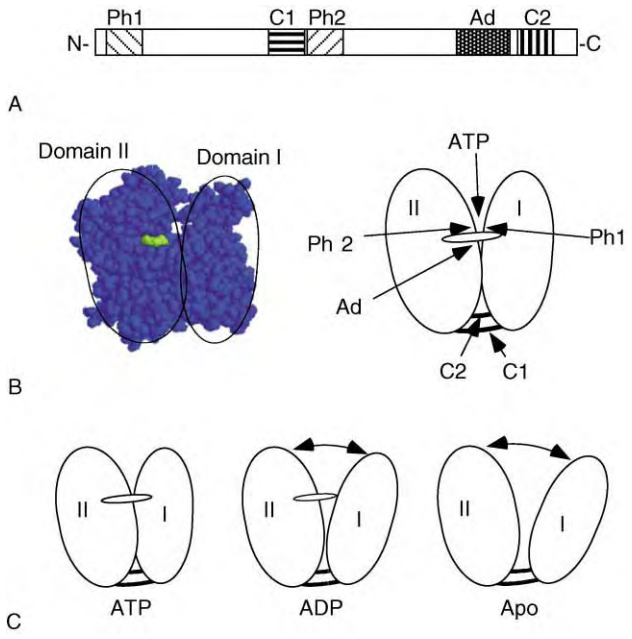

FIGURE 2 Organization and structure of Arps and the conformational changes driven by ATP binding and hydrolysis. (A) Organization of conserved sequences that define the ATP-binding pocket of the actin fold. Ph1 and Ph2: phosphate-binding loops. C1 and C2: connecting domains. Ad: adenosine-binding domain. The order of these sequences is the same in the primary amino acid sequence of all actin related proteins. (B) Atomic structure and domain organization of an actin monomer. The atomic structure of actin (left) is shown with a bound ATP molecule (green) and with ellipses identifying the two large domains – domain I and domain II – that define the ATP-binding pocket. The phosphate- and adenosine-binding sequences line the interface between domain I and domain II and interact with the ATP molecule (right). The connecting sequences (C1 and C2) link the two protein domains and act as a hinge. (C) Nucleotide-dependent conformational changes in the actin fold. ATP binding holds the domain I and domain II tightly together (ATP, left). Hydrolysis of the γ-phosphate of ATP to form ADP weakens the interaction with one of the phosphate-binding loops (Ph1) and causes the cleft between the domains to open (ADP, center). Loss of nucleotide from the binding pocket causes the cleft to open even further (Apo, right). Actin-related proteins use this conformational change to regulate their interactions with other proteins.

Within the filament, monomers hydrolyze ATP to ADP. ADP-bound filaments then rapidly disassemble (Figure 3A).

Eukrayotic Arps

Cytoskeletal Arps

We will briefly discuss conventional actin, which is well described in a separate article on actin dynamics in this encyclopedia. Arp1 and Arp10 are part of a dynein-activating (dynactin) complex that regulates activity of the microtubule motor protein dynein. Arp2 and Arp3 are subunits of the Arp2/3 complex – a protein complex that nucleates formation of new actin filaments in response to upstream signaling events (see Table I).

Conventional Actin

Actin is one of the most abundant and highly conserved proteins in eukaryotes. In motile cells actin is typically the most abundant cellular protein and is present at concentrations of 100–200 μM (or 5–10% of total cellular protein). Protozoans, such as budding and fission yeast and slime molds, generally express one isoform of actin. Metazoans typically express multiple, tissue-specific isoforms. Humans express at least six isoforms of actin: two striated muscle isoforms (α-skeletal and α-cardiac), two smooth muscle isoforms (α-smooth muscle and α-enteric), and two widely expressed cytoplasmic isoforms (β-cytoplasmic and γ-cytoplasmic). The α-skeletal and α-cardiac striated muscle isoforms are expressed specifically in muscle tissues where they form arrays of "thin" filaments that interdigitate with "thick" filaments composed of the motor protein myosin. Sliding of the thick and thin filaments past each other drives contraction of the muscle tissue. The thin filaments in muscle tissues are very stable structures whose architecture does not change much over time. The smooth muscle actins form less organized filament arrays involved in contraction of vascular and enteric smooth muscle. The cytoplasmic β- and γ-isoforms are the most widely expressed and form much more dynamic cytoskeletal structures. The β-isoform is ubiquitously expressed and is responsible for building the contractile ring that divides cells at the end of mitosis and for most actin-based intracellular traffic. The assembly of β-cytoplasmic actin also drives cell spreading and the amoeboid, or crawling, motility of many cell types, including those of the nervous and immune systems. The β-isoform is most closely related to protozoan actins. The γ-cytoplasmic isoform is expressed in many different cell types but it is much less abundant than β-cytoplasmic actin. The specific function of γ-actin is unknown.

The defining property of conventional actin is its self-assembly into helical polymeric filaments. Monomeric actin binds ATP with high (nanomolar) affinity but does not hydrolyze it. The transition from monomer to polymer stimulates the hydrolysis of ATP. Hydrolysis is not required for polymerization but rather for depolymerization. Cleavage of the γ-phosphate and its subsequent dissociation trigger a conformational change that enables binding of actin depolymerizing factors such as ADF or cofilin (Figure 3B).

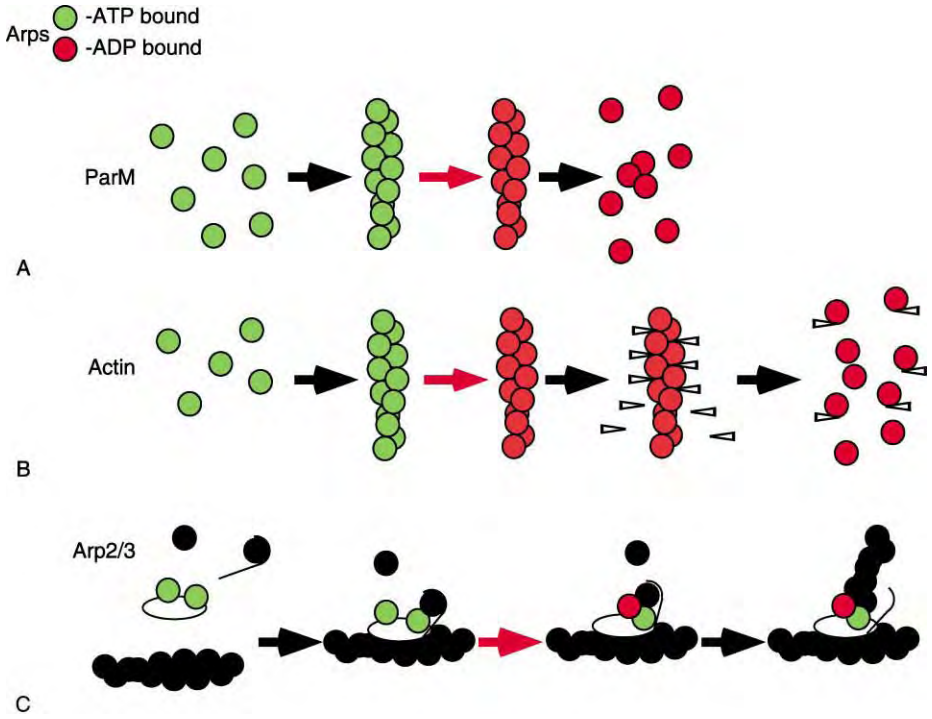

FIGURE 3 Regulation of actin and Arp function by ATP hydrolysis. The relationship between ATP hydrolysis and protein–protein interactions is best understood in the cytoskeletal Arps. (A) When bound to ATP the plasmid-encoded Arp, ParM (green circles), polymerizes into actin like filaments. Polymerization induces hydrolysis of bound ATP (red arrow); and the ADP ParM filaments (red circles) undergo a conformational change that causes them to rapidly fall apart. (B) Conventional actin and Arp1 (green circles) polymerize into similar two-stranded helical filaments. Polymerization induces ATP hydrolysis on both proteins (red arrow) but the filaments do not spontaneously disassemble. In the case of conventional actin, a conformational change in the ADP filament structure (red circles) promotes binding of actin depolymerization factors (white wedges), which drive filament disassembly. (C) As part of the Arp2/3 complex, Arp2 and Arp3 bind ATP (green circles are ATP-bound Arp2 and Arp3) and nucleate formation of new actin filaments. The nucleation reaction requires monomeric actin and a pre-formed actin filament (black circles) and an Arp2/3 activator (black hook). Assembly of these cofactors induces ATP hydrolysis on Arp2 and promotes a conformational change in the Arp2/3 complex that converts it into a filament nucleus.

Arp1

Arp1 is most closely related to conventional actin and, like actin, it assembles into a filamentous polymer. Arp1 forms part of a large (1.2 MDa) protein complex that modulates the activity of the microtubule motor protein dynein. Within the dynactin complex, ~10 Arp1 molecules assemble to form a short (37 nm), actin-like filament. This short filament functions as a scaffold that connects dynein motors to cargo vesicles. The Arp1 filaments bind an isoform of the actin-binding protein spectrin that is specific for the Golgi apparatus and for Golgi-derived vesicles. Arp1 and Golgi spectrin are thought to assemble into a membrane-associated meshwork that surrounds vesicles like a cargo net and allows dynein motors to move them around inside the cell.

In vitro, purified Arp1 polymerizes into short filaments indistinguishable from conventional actin filaments. Arp1 hydrolyzes ATP upon polymerization but this does not have a dramatic effect on filament stability *in vitro*. Like actin, Arp1 may hydrolyze ATP to modulate its affinity for an accessory factor required for filament disassembly (Figure 3B).

Arp2 and Arp3

Arp2 and Arp3 are both subunits of a seven-member protein complex, called the Arp2/3 complex that is an essential regulator of the actin cytoskeleton. The Arp2/3 complex nucleates formation of new actin filaments in response to activation of intracellular signaling systems. It also cross-links actin filaments into mechanically rigid networks so that, in general, it functions to convert intracellular signals into cytoskeletal structures. Within the complex the Arp2 and Arp3 subunits are thought to form a heterodimer with a surface that mimics the fast-growing, barbed end of an actin filament. This surface forms a template to initiate

actin filament formation. In the crystal structure of the complex Arp2 and Arp3 are separated by a large (40Å) cleft and formation of an actin-like Arp2–Arp3 dimer would require a significant conformational change. This conformational change may require ATP hydrolysis on one of the Arps (Figure 3C). Binding of ATP to Arp2/3 is required for actin nucleation and neither ADP nor nonhydrolyzable ATP analogues support Arp2/3-dependent actin filament nucleation. Further study is required to understand the connection between ATP hydrolysis and conformational changes on the Arp2/3 complex.

Chromatin-Associated Arps

Several Arps are associated with eukaryotic chromatin and with chromatin-remodeling complexes. In budding yeast, Arp4, Arp5, Arp7, Arp8, and Arp9 are subunits of ATP-dependent chromatin remodeling complexes. Very little is known about the molecular mechanisms of their activity, but presumably ATPase-driven conformational changes in the Arp subunits regulate the overall structure and activity of these complexes. All of these complexes contain two or four Arp subunits so it is possible that they function as heterodimers and that their interaction is regulated in a manner similar to that of the Arp2/3 complex described earlier.

Arp4

Arp4 is involved in chromatin remodeling and transcriptional activation. In budding yeast, Arp4 is a subunit of both the NuA4 histone acetyl-transferase complex and the INO80 chromatin-remodeling complex. The NuA4 complex acetylates histones H4 and H2A. Acetylation increases accessibility of the DNA within the nucleosome and recruits other chromatin remodeling enzymes to the region. Human cells contain a similar histone acetyl-transferase complex, called Tip60. This complex also contains an Arp4-type subunit in addition to at least one monomer of conventional actin. The INO80 complex contains Arp4 as well as Arp5, Arp8, and conventional actin. The precise role of Arp4 in these complexes is unknown but yeast Arp4 mutants exhibit phenotypes similar to mutants missing the catalytic acetylase subunit of NuA4, suggesting that it plays an integral role in the function of the NuA4 complex. Arp4 has also been shown to bind directly to histones. Its ATPase activity has not been well studied but Arp4 may use ATP binding and hydrolysis to regulate the interaction between chromatin remodeling complexes and DNA-bound histones.

Arp5 and Arp8

Arp5 and Arp8 (along with Arp4 and conventional actin) are members of the INO80 chromatin-remodeling complex. INO80 is a large (2 MDa) protein complex that plays a role in transcription of several important yeast genes including pho5, an essential regulator of phosphate metabolism. The total number of yeast genes that require INO80 activity for transcription is not known. Arp8 has been shown to bind directly to histones H3 and H4 so it may be directly involved in moving histones around on the DNA. Arp8 is also required for the incorporation of both Arp4 and conventional actin into the complex so it may play an important structural or scaffolding role.

Arp7 and Arp9

Arp7 and Arp9 associate tightly to form a heterodimer and dimerization appears to be important to their cellular function. In budding yeast, the Arp7/Arp9 dimer is an essential part of both the Swi/Snf and RSC chromatin remodeling complexes. Like the INO80 complex, these large complexes drive DNA and histone rearrangements necessary for transcription. Swi/Snf activity is required for transcription of ~5% of yeast genes while RSC activity is more globally important. As with the other chromatin-associated Arps, the precise functions of Arp7 and Arp9 are unknown. Loss of the RSC complex is lethal. The loss of either Arp7 or Arp9 causes severe growth defects *in vivo* but does not significantly impair RSC activity *in vitro*. So *in vivo* the Arp7/Arp9 dimer may act to correctly target or regulate the RSC complex.

Chromatin-Associated Conventional Actin

The large majority of cellular actin is cytoplasmic and generally actin is considered as a cytoskeletal protein whose function is limited to the cytoplasm. In many species, however, chromatin-remodeling complexes contain one or more tightly associated monomers of conventional actin. In addition to Arp4, the NuA4 complex contains a subunit of conventional actin. Also, the yeast INO80 complex and the mammalian BAF complex (a chromatin-remodeling complex similar to the budding yeast swi/snf) contain tightly associated actin monomers. The role of conventional actin in chromatin structure and remodeling is mysterious. It has been speculated that actin assembly in the nucleus could drive large-scale changes in chromatin architecture in the way that actin assembly in the cytoplasm drives

large-scale plasma membrane movements. It is also possible that short actin filaments form an essential scaffold for the assembly and function of chromatin organizing factors.

Arps of Unknown Function

We know almost nothing about the function of Arp6. In budding yeast Arp6 is localized to the nucleus so it may be part of a chromatin-remodeling complex or it may play a role in determining nuclear architecture.

Glossary

actin Ubiquitous, eukaryotic cytoskeletal protein. Actin monomers assemble into filaments that are used to organize the intracellular space and to define the shape and mechanical properties of eukaryotic cells.

ATP Adenosine triphosphate. It is the major energy currency of living cells. The removal or hydrolysis of phosphates from ATP releases energy that individual proteins can use to do work.

chromatin DNA that has been packaged and compacted by specialized proteins, called histones. The packaged DNA must be partially unpackaged (by chromatin remodeling complexes) to allow transcription of genes.

cytoskeleton A network of protein polymers that organize the intracellular space; transport intracellular cargos; determine cell shape; and drive cell locomotion. The three most important eukaryotic cytoskeletal polymers are actin filaments, microtubules, and intermediate filaments.

eukaryote A cell with a nucleus and other membrane-bound organelles.

histones DNA packaging proteins. In compacted chromatin DNA is wound around histones like thread around a spool.

primary sequence The sequence of amino acids that comprise a protein. Usually given from amino to carboxy terminus.

prokaryote A simple cell, such as a bacterium, that lacks a nucleus and other intracellular compartments.

Biography

R. Dyche Mullins is an Assistant Professor of Cellular and Molecular Pharmacology at the University of California Medical School, San Francisco. As an undergraduate, graduate student, and Postdoctoral Fellow he studied Electrical Engineering, Mathematics, and Biochemistry. His research goal is to understand how interactions between signaling molecules and structural molecules determine the architecture of living cells.

Adenosine Receptors

Lauren J. Murphree and Joel Linden
University of Virginia, Charlottesville, Virginia, USA

Adenosine is a purine nucleoside that serves as a link between energy metabolism and cell signaling. Adenosine is a physiologic regulator of all cell types that binds to G protein coupled receptors (GPCRs) that exist as four subtypes (A_1, A_{2A}, A_{2B}, and A_3). The receptor-mediated actions of adenosine have been extensively studied in the central nervous system, cardiac muscle, blood vessels, gastrointestinal tract, kidneys, lung, liver, immune system, and other tissues. In light of the clear therapeutic potential of selective adenosine receptor subtype-selective agonists or antagonists, new therapeutic candidates are being intensely pursued by the pharmaceutical industry. Naturally occurring xanthines are nonselective antagonists of adenosine receptors. One such compound, caffeine, is the most widely used psychotropic drug in the world.

Adenosine

Formation

Adenosine is a purine nucleoside that is formed within cells from the breakdown of adenosine monophosphate (AMP), which, in turn, is formed from adenosine triphosphate (ATP) and adenosine diphosphate (ADP) in the course of utilizing energy for cellular functions. Adenine nucleotides released from nerves, mast cells, platelets, endothelial cells, and dying cells also can be dephosphorylated in the extracellular space by ecto-nucleotidases. Increased energy utilization or hypoxia enhances the cellular formation of AMP, which is dephosphorylated by a 5′-nucleotidase in the rate-limiting step for adenosine production. The signaling molecule cyclic AMP (cAMP) can also be a source of AMP for adenosine production. Under resting conditions, a sizable fraction of adenosine is formed by the hydrolysis of *S*-adenosyl-homocysteine.

Location

Adenosine is produced in either the intracellular or extracellular spaces and can be transported across cell membranes in either direction by a family of nucleoside transporters that allow for equilibration of adenosine concentrations by facilitated diffusion or sodium-dependent active transport.

Regulation of Production

Production of adenosine is increased during periods of high metabolic activity or ischemia, when there is increased cellular demand for ATP or decreased delivery of oxygen. Adenosine also is derived from adenine nucleotides released from nerves, platelets, mast cells, or other cells. In the brain, adenosine release has been observed experimentally following various manipulations (e.g., hypoxia, ischemia, hypoglycemia, seizures, electrical stimulation, prolonged wakefulness, and application of free radicals). Changes in extracellular levels of adenosine of up to 100-fold have been observed following oxidative or ischemic stress.

Breakdown of Adenosine

Adenosine is eliminated by metabolic transformation to inosine by adenosine deaminase. It can also be phosphorylated to form AMP by adenosine kinase with a phosphate group donated by ATP, but this enzyme is inhibited in metabolically stressed cells.

Receptor Structure

Adenosine receptors (ARs) belong to a class of integral membrane proteins known as GPCRs. Members of this class of proteins have seven membrane-spanning α-helices with an extracellular amino terminus and an intracellular carboxy-terminal tail. All four subtypes are asparagine-linked glycoproteins and all but the A_{2A} receptor have palmitoylation sites near the C terminus.

Sequence Similarity

In the mammalian species thus far investigated, differences in protein sequence between species for each receptor subtype are generally much smaller than the differences between subtypes within a given species. For example, cloned mammalian A_1 receptors are 90–95% identical, but rat adenosine receptors have

similarities of ~60–80% across subtypes. The A_3 receptors are an exception to this rule, as they vary by as much as 30% across mammalian species.

Gene Structure

All four subtypes of adenosine receptors appear to have a similar genomic structure involving two coding exons separated by a single intron located in the region corresponding to the second intracellular loop (between transmembrane regions 3 and 4). The A_1 receptor, which is the most well studied, can be transcribed from two different and mutually exclusive promoters. Transcription from these promoters, located approximately 600 bp apart, appears to be differentially regulated. Table I lists some properties of the four AR subtypes.

Protein Structure

The most precise structural information for proteins has been obtained from X-ray diffraction of protein crystals. GPCRs, like most integral membrane proteins, have proven to be difficult to crystallize due in part to their large size and association with membrane lipids. Thus, most structural information about adenosine receptors has been derived through comparison with the known structures of the related proteins bacteriorhodopsin and mammalian rhodopsin. By comparing the amino acid sequence of an adenosine receptor with the structure of mammalian rhodopsin, researchers have developed models that aid in understanding receptor–ligand interactions. When combined with studies with mutated receptors and pharmacological data, the sites of interactions between the receptors and ligands appear to occur in helices 3, 5, 6, and 7.

Receptor Physiology and Localization

Adenosine receptor subtypes are differentially distributed throughout the body, allowing for adenosine to initiate a wide variety of physiologic responses. The A_1 and A_{2A} ARs have proven to be the easiest to study because of the available pharmacological tools (e.g., radioligands) and their high affinity for adenosine. Consequently, much more is known about the location and physiology of these receptors than about those of the A_{2B} and A_3 receptors, which were more recently discovered and have a lower affinity for the natural ligand.

A_1 Receptors

Adenosine acting through A_1 ARs has a diverse array of physiological actions. The A_1 AR is widely distributed (it is found in, e.g., liver, kidney, adipose tissue, lung, pancreas, and testis) but has been most extensively studied as a regulator of the central nervous system (CNS) and the cardiovascular system.

A_1 ARs in the CNS

In the CNS, A_1 ARs are located in many brain regions (especially the cortex, cerebellum, and hippocampus) and in the dorsal horn of the spinal cord. These receptors are important for regulating sleep and the excitability of neurons. The concept of adenosine as a regulator of sleep follows in part from the fact that caffeine, a naturally occurring AR antagonist, promotes wakefulness. Experimental evidence shows that adenosine concentrations in the brain rise during waking hours but decrease during subsequent recovery sleep. In addition, administration of A_1 agonists to brain *in vivo* promotes sleep and reduces arousal. A_1 ARs are also important for modulating the excitability of neurons. Adenosine acting at A_1 ARs causes an inhibition of synaptic activity by decreasing the neuron's ability to respond to excitatory molecules (i.e., neuropeptides and glutamate).

A_1 ARs in the Cardiovascular System

A_1 ARs are particularly important in the cardiovascular system and are expressed in the heart. Their effects are generally anti-adrenergic, leading to a decrease in heart

TABLE I

Properties of Human Adenosine Receptor Subtypes

Adenosine receptor subtype	Length (aa)	Protein Accession No.	GenBank Accession No.	GenBank Accession No. (mouse)	Chromosomal location
A_1	326	P30542	S45235	U05671	1q32.1
A_{2A}	410	P29274	S46950	U05672	22q11.2
A_{2B}	328	P29275	X68487	U05673	17p11.2–p12
A_3	318	P33765	L22607	L20331	1p13.3

rate and blood pressure. One of the most interesting physiological roles of A_1 ARs is in the phenomenon of ischemic preconditioning in the heart. During periods of low oxygen supply (ischemia), adenosine is released and activates A_1 ARs. This activation begins a cascade of events that protects the heart against a subsequent ischemic event (e.g., infarction and arrhythmia). A_1 receptors are also found on sympathetic nerve terminals, where they act to inhibit the release of norepinephrine.

A_{2A} ARs

A_{2A} ARs are highly expressed by cells in the striatum and olfactory tubercles of the brain, by cells in the spleen and thymus, and by cells in certain blood vessels and immune cells. Lower levels of expression occur in the heart and lung. Like the A_1 AR, the most widely studied effects of the A_{2A} AR are in the CNS and the cardiovascular system.

A_{2A} ARs in the CNS

A_{2A} ARs are highly expressed on small spiny neurons of the striatum, which also express D_2 dopamine receptors. The activities of A_{2A} ARs and D_2 dopamine receptors are antagonistic. Although A_{2A} receptors are coupled to G_s proteins in many tissues, in the striatum there is evidence to suggest that they signal through the related G protein, G_{olf}. Work using mice lacking the A_{2A} AR showed that these receptors also stimulate sensory nerve activity, are involved in mediating pain, and mediate the motor stimulant effects of caffeine.

A_{2A} ARs in the Cardiovascular System

In the cardiovascular system, the A_{2A} receptor plays two important roles: regulation of blood flow and inhibition of inflammatory cells. Activation of A_{2A} ARs is an important physiological mechanism for coupling energy demand to blood flow. When cells are using large amounts of energy (ATP), they produce adenosine. The adenosine binds to A_{2A} receptors on vascular smooth muscle and causes vasodilation, allowing more blood (and the nutrients it contains) to reach the tissue. A_{2A} ARs also play an autoregulatory role during the process of inflammation. Activation of this receptor causes an array of responses that are generally anti-inflammatory, including inhibition of neutrophil, monocyte, platelet, and T cell activation. A_{2A} ARs also protect against ischemic damage through a mechanism involving its anti-inflammatory properties, which is different from the ischemic preconditioning effects of the A_1 AR.

A_{2B} ARs

The A_{2B} AR is closely related to the A_{2A} AR, though with a much lower affinity for adenosine. This receptor is widely distributed. The epithelium of the cecum, colon, and bladder have high levels of expression of A_{2B}. Intermediate levels of expression exist in the lung, blood vessels, and eye, and low levels of expression occur in many tissues (e.g., adipose tissue, adrenal gland, brain, and kidney). The physiological role of the A_{2B} AR is not well characterized, but most researchers agree that it is involved in the relaxation of vascular smooth muscle and in the inhibition of monocyte and macrophage function, effects that are similar to those of the A_{2A} AR. The A_{2B} receptor stimulates fluid and chloride secretion from epithelial cells in the infected gut in response to AMP release from neutrophils, leading to diarrhea. The A_{2B} AR also seems to be involved in the stimulation of mast cell degranulation (a pro-inflammatory event) in some species, including humans.

A_3 ARs

Investigation of the physiology and localization of the A_3 AR has been ongoing since the receptor was cloned in 1991 by Meyerhof and co-workers, but characterization has proven to be difficult since there is great variability in its expression and function among species. It is expressed at low levels in the thyroid, brain, liver, kidney, heart, and intestine across species. Rats express high levels in testis and mast cells. In some species (including rats), activation of the A_3 AR enhances the release of mast cell mediators. A preconditioning effect similar to that caused by the A_1 AR can also result from A_3 activation in some species.

Signaling Downstream of Adenosine Receptors

Adenosine receptors, like all GPCRs, transmit signals to the cell interior by activating intracellular heterotrimeric GTP-binding proteins (G proteins) that consist of α-, β-, and γ-subunits. Activation of these receptors causes the α-subunit to exchange its bound GDP molecule for GTP and become active. The α-subunit then dissociates from the $\beta\gamma$ dimer and both can then activate downstream effectors.

The four adenosine receptor subtypes exert their varying effects by coupling to different G proteins, which are summarized in Table II. G protein α-subunits control the intracellular levels of many second messengers (e.g., cAMP and inositol triphosphate), which, in turn, activate downstream signaling pathways typical of G proteins. For example, A_1 and A_3 receptors generally

TABLE II

G Protein Coupling of Adenosine Receptors

AR Subtype	G protein	Second messengers
A_1	$G_{i/o}$	Decrease in cAMP
		Increase in IP_3/DAG via PLC
		Activation of PLA2 and PLD
A_{2A}	G_s	Increase in cAMP
	G_{olf}	Increase in cAMP
	$G_{15/16}$	Increase in IP_3
A_{2B}	G_s	Increase in cAMP
	$G_{q/11}$	Increase in IP_3/DAG via PLC
A_3	G_i	Decrease in cAMP
	$G_{q/11}$	Increase in IP_3/DAG via PLC

Note. DAG, diacylglycerol; IP_3, inositol triphosphate, PLC, phospholipase C; PLD, phospholipase D.

couple to G_i, which inhibits adenylyl cyclase, causing a decrease in intracellular cAMP, whereas A_{2A} and A_{2B} couple to G_s, which stimulates cAMP production. In some cells, A_{2B} receptors also are coupled to the calcium-mobilizing G protein, G_q.

Other Ligands

Because of their interesting properties, adenosine receptors are important pharmacological targets. There are several naturally occurring ligands in addition to adenosine, including caffeine, theophylline, and inosine. Inosine is a product of adenosine metabolism, occurs naturally in the body, and can activate A_3 receptors at high concentrations that occur in ischemic or inflamed tissues. Caffeine and theophylline are AR antagonists commonly found in coffee and tea.

Many investigators have developed synthetic ligands for adenosine receptors (see Figure 1). It has been particularly challenging to produce ligands that are selective for a given AR subtype, given the high degree of homology between the receptors. Selective compounds are desirable both as tools for understanding receptor functions and as potential drugs. All of the agonist ligands thus far developed are based on the structure of adenosine (an adenine base attached to a ribose moiety). Adenosine is rapidly metabolized. In human, it has a half-life in blood of only 2 s. Modification of this molecule at three different sites has led to agonists with increased longevity, improved selectivity, and nanomolar potency. Some of the most subtype-selective compounds that have been developed are shown in Figure 1.

Caffeine provided a lead compound for the development of xanthine AR antagonists. It belongs to a class of compounds called methylxanthines. Modification of the basic molecule produced high-affinity compounds, some of which show high potency and receptor-subtype selectivity (e.g., MRS1754 in Figure 1). Nonxanthine antagonists (e.g., ZM241385 in Figure 1) were developed later and many appear promising for use in therapeutic applications.

An additional class of ligands for adenosine receptors is known as allosteric enhancers, which were first identified by Bruns and Fergus in 1990. The prototype of the class is PD81723, which binds to the A_1 receptor at an allosteric site that is distinct from the adenosine-binding site, known as the orthosteric site. The binding of PD81723 and related allosteric enhancers increases agonist-binding affinity for the A_1 AR and amplifies the functional effect of the agonist. Allosteric enhancers seem to stabilize the conformation state of receptors that activate G proteins.

Therapeutic Possibilities

Adenosine is used clinically to treat certain tachycardias and to dilate coronary arteries to help in the diagnosis of coronary artery disease. There is great interest in developing more selective drugs that selectively activate or block specific adenosine receptor subtypes and that have a longer duration of action than adenosine.

A_1 Receptors

A_1 ARs are an attractive pharmacological target because of their ability to simulate ischemic preconditioning. Theoretically, an A_1 agonist could protect the heart (and other tissues) from a future ischemic episode, such as myocardial infarction. A_1 ARs are also attractive targets for anti-nociceptive agents because of their effects in the CNS. A_1 antagonists are undergoing clinical trials as diuretics for use in patients with congestive heart failure. A_1 agonists are being developed to reduce heart rate in certain arrhythmias.

A_{2A} Receptors

Both agonists and antagonists of the A_{2A} AR are being investigated for clinical use. Short-acting A_{2A} agonists may be useful for imaging coronary artery disease since they simulate the effect of exercise and dilate the coronary vasculature. Longer acting A_{2A} agonists may be useful for their anti-inflammatory properties in the treatment of asthma, sepsis, or ischemia–reperfusion injury. A_{2A} antagonists may be helpful in the treatment of CNS diseases, such as Parkinson's disease and schizophrenia.

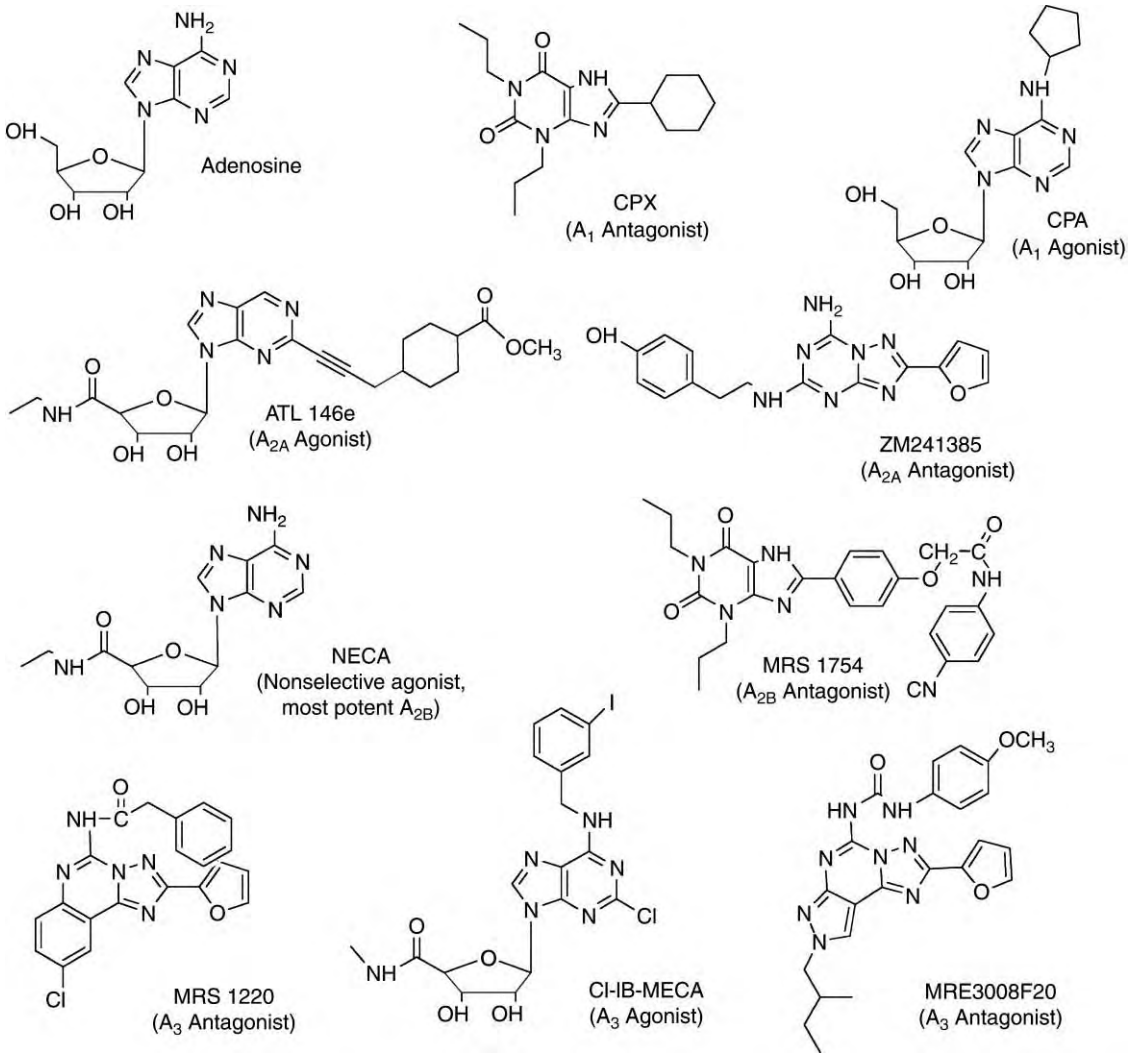

FIGURE 1 Adenosine receptor ligands.

A_{2B} Receptors

Antagonists of the A_{2B} AR are being developed as potential treatments for asthma since enprofylline and theophylline are used to prevent bronchoconstriction in asthmatics and are effective at concentrations that would indicate that the A_{2B} AR is its target. There is also some evidence to suggest that A_{2B} blockade may enhance the effects of insulin in liver and skeletal muscle and hence these compounds may be useful for the treatment of diabetes. Blockade of A_{2B} receptors may be useful for inhibiting angiogenesis.

A_3 Receptors

Some researchers have proposed the use of A_3 agonists as an adjuvant to chemotherapy since some compounds in this category have an anti-proliferative effect on tumor cells. However, some of these effects appear not to be receptor-mediated.

Glossary

agonist A ligand that binds to a receptor and causes activation, mimicking the effect of the endogenous ligand.

antagonist A ligand that binds to its receptor and inhibits its activity.

ligand A chemical or biological substance that binds to a receptor.

receptor A recognition site (usually a macromolecule, such as a protein) for a ligand that mediates the ligand's physiological effects.

Adenylyl Cyclases

Ronald Taussig
University of Texas Southwestern Medical Center, Dallas, Texas, USA

Adenylyl cyclases are enzymes that synthesize the intracellular second messenger, cyclic AMP (cAMP), which in turn triggers a cascade of biochemical changes that regulate a number of important cellular processes. These cAMP-regulated cellular processes play an important role in the control of a number of metabolic processes including the regulation of blood glucose homeostasis, learning and memory, and cell growth.

The Hormone-Regulated Adenylyl Cyclase System

In order to function and survive, cells must respond to a multitude of signals present in their environment. These include chemical messengers released from local or distant parts of the body (such as circulating hormones and neurotransmitters) and external stimuli (such as light and odorants). Typically, these chemical messengers do not cross the cell membrane, but rather transduce their signal to the interior of the cell utilizing a "hand-off' mechanism occurring at the plasma membrane. In this process, the stimulus or "first messenger" acts at the membrane to regulate the activity of an enzyme that synthesizes (or degrades) an intracellular "second messenger" that can in turn regulate downstream intracellular metabolic enzymes (Figure 1). Cyclic AMP (cAMP), which is synthesized by adenylyl cyclases, was the first of these second messengers identified, and this mechanism has subsequently shown to be utilized as a common biological strategy to regulate cellular behaviors.

Regulation of intracellular cAMP concentrations is principally controlled at the level of its synthesis, through the hormonal regulation of adenylyl cyclase, the enzyme responsible for the conversion of ATP into cAMP. The adenylyl cyclase system is comprised of three components: heptahelical G protein-coupled receptors for a variety of hormones, neurotransmitters, and odorants; heterotrimeric G proteins; and the catalytic entity itself. Nine isoforms of membrane-bound adenylyl cyclases and a single soluble form have been identified in man. The nine membrane-bound isoforms are subjected to hormonal regulation that is mediated by G proteins of the G_s, G_i subclasses. Most importantly, adenylyl cyclase isoforms have the ability to integrate the multitude of hormonal inputs relayed by these pathways to ultimately control intracellular cAMP levels.

Discovery

The identification of cAMP resulted from studies aimed at elucidating the biochemical mechanism underlying the breakdown of glycogen in liver cells that is triggered by the hormone glucagon. In his Nobel prize winning discoveries, Earl Sutherland demonstrated that the process involved two distinct stages, a binding of the hormone at the membrane that activated adenylyl cyclase and subsequently generated the second messenger cAMP, and the activation within the cell of the downstream enzymatic process. The later discoveries that the receptor and the adenylyl cyclase were two distinct entities, and the subsequent identification of a third component (the intervening heterotrimeric G protein) have provided our modern day model of the hormone-regulated adenylyl cyclase system. Almost three decades following the discovery of cAMP, the genetic material encoding the first adenylyl cyclase was isolated, which further exposed the complexity of this signaling system.

Members of the Family

Our current knowledge of the structure and function of the mammalian adenylyl cyclase family has reached a new understanding following the application of molecular approaches. Ten distinct genes encoding the soluble and membrane-bound adenylyl cyclases have been identified (Table I). These genes are broadly distributed on different chromosomes throughout the human genome. Further diversity of adenylyl cyclases is provided by alternatively spliced mRNAs derived from transcripts of some of the family members.

These ten genes are differentially expressed in various tissues in mammalian species. All isoforms of adenylyl

Arrows indicate the direction of the flow of information.

cyclase appear to be expressed in the brain; however, expression of each isoform is limited to specific regions of the central nervous system. Additionally, some adenylyl cyclase appears to be rather widely distributed in most tissues of the body (e.g., types 4, 6, and 7). All adenylyl cyclases have roughly the same size and contain between 1064 and 1610 amino acid residues. The deduced amino acid sequence of all identified adenylyl cyclase isoforms predicts a complex topology within the membrane (Figure 2). The noted exception is the soluble adenylyl cyclase (SAC), which is localized to the intracellular compartment and exhibits regulation quite distinct from the membrane-bound forms. This isoform is more related to an ancestral form found in bacteria than to the other types.

Based on the similarities of their amino acid sequences, and patterns of regulation by G protein pathways, the membrane-bound adenylyl cyclases can be grouped into subfamilies. The first group, comprised of the types 1 and 8, are characterized by their stimulation by calmodulin. The types 2, 4, and 7 adenylyl cyclases form the second group; characteristic of these isoforms is their stimulation by G protein $\beta\gamma$-subunits. Types 5 and 6, which are the two most related isoforms constitute the last group and are characterized by their inhibition by calcium. The type 9 is the largest and most diverse of the adenylyl cyclase isoforms, and like the type 3 enzyme, does not belong to any of the three groups outlined above.

Regulation of Adenylyl Cyclase Activity by G Proteins and Calcium

There are multiple classes of heterotrimeric G proteins that regulate adenylyl cyclases, either in a stimulatory (G_s family), or inhibitory (G_i family) manner. The two G protein families are normally coupled to distinct receptor subtypes. The $\beta\gamma$-subunits also regulate adenylyl cyclase activity, but in a manner specific to an adenylyl cyclase isoform. Additionally, calcium ions are very strong modulators of some isoforms of adenylyl cyclase; thus, G proteins that regulate calcium entry through voltage-dependent Ca^{2+} channels may also regulate adenylyl cyclase activity.

Hormonal activation of AC occurs primarily through receptors coupled to the stimulatory G protein G_s. G_s is the most widely distributed activator of all mammalian membrane-bound AC isoforms. All membrane-bound forms of adenylyl cyclases are regulated by G_s through the interaction of adenylyl cyclase with the Gα-subunit that is released from the $\beta\gamma$-subunits upon activation by a hormone-bound stimulating receptor (Figure 3A).

Members of the G_i family inhibit adenylyl cyclase activity through the binding of the alpha subunit to the cyclase, but this regulation exhibits selectivity for a

TABLE I

Localization and Expression of the Adenylyl Cyclase Gene Family

AC isoform	Length (amino acids)	Location (chromosome)	Sites of expression (tissue)
AC1	1135	7	Brain, adrenal medulla

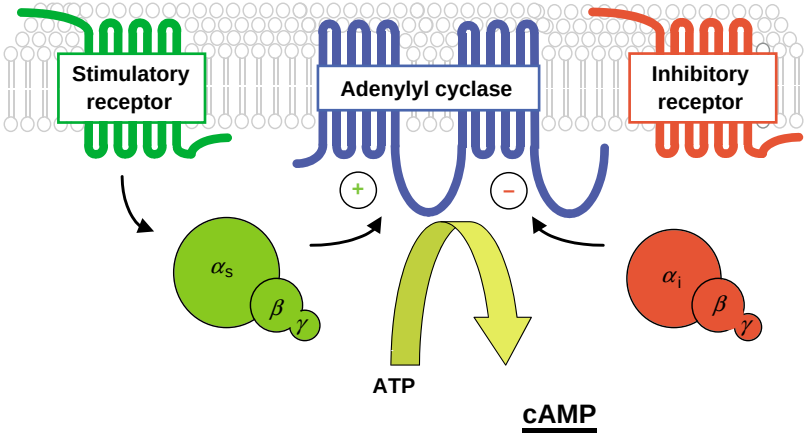

FIGURE 2 Schematic view of plasma membrane components that participate in the hormone-regulated adenylyl cyclase system. A prototypic adenylyl cyclase is shown. G protein-coupled receptors that enhance or inhibit adenylyl cyclase activity are shown in green and red respectively. All receptors of this family have a similar predicted structure and span the plasma membrane seven times. These receptors couple to their corresponding heterotrimeric G proteins (composed of an α-, β-, and γ-subunits); G_s (green) and G_i (red) couple to stimulatory and inhibitory receptors respectively. Adenylyl cyclase (shown in blue) is predicted to span the plasma membrane twelve times, and projects its active site towards the cytoplasmic side of the membrane. The result of extracellular messengers binding to the receptors results in the regulation of the conversion of ATP into cAMP by the enzyme adenylyl cyclase.

subset of adenylyl cyclase isoforms (Figure 3B). All three G_i family members (G_{i1}, G_{i2}, G_{i3}) inhibit types 1, 5, 6, and 8; the remaining cyclase isoforms are insensitive to this inhibitory input. Interestingly, this mode of inhibition is not through direct competition with G_s binding to the cyclase, and a number of experimental approaches demonstrate that $G_i\alpha$ exerts its effects at a site, symmetrical to the G_s binding site, and located on the side opposite the cyclase molecule.

As illustrated in Figure 3C, activation of inhibitory receptors leads to the release of G protein $\beta\gamma$-subunits which can exert profound regulation of adenylyl cyclase activity. Like regulation by the G_i α-subunit, this regulation is isoform specific. However, an added complication is that the $\beta\gamma$-subunits can either activate or inhibit the activity – types 2, 4, and 7 are activated whereas types 1 and 8 are inhibited.

Regulation of adenylyl cyclase activity by calcium is still more complex (Figure 4). At physiological intracellular calcium concentrations the types 3, 5, and 6 adenylyl cyclases are inhibited by calcium. For the types 5 and 6, this appears to be due to a direct effect of calcium on the adenylyl cyclase. Stimulation of adenylyl cyclase activity by calcium has been demonstrated for the types 1 and 8 isoforms, but this form of regulation requires calmodulin, a calcium-binding protein that regulates the activity of many cellular enzymes. Indeed, one of these calmodulin-regulated enzymes is a protein kinase, that mediates the inhibitory effects that were observed for the type 3 adenylyl cyclase.

Physiological Roles of Adenylyl Cyclases

The hormonal activation of adenylyl cyclases and the subsequent regulation of intracellular cAMP impacts on a wide array of cellular processes (Table II). These roles include diverse processes underlying regulation of blood sugar levels, regulation of heart function, water retention as well as higher brain functions of learning and memory. However, while much is known at the biochemical level regarding the regulation of the many adenylyl cyclase isoforms, the precise physiological roles of each isoform are less well known. A further complication is that each cell of our body expresses more than one isoform of adenylyl cyclase. Nevertheless, investigators have begun

FIGURE 3 Schematic representation of the isoform-specific regulation of adenylyl cyclases by G protein subunits. (A) Regulation of adenylyl cyclases by $G_s\alpha$. Upon activation of stimulatory receptors, the heterotrimeric G protein, G_s undergoes subunit dissociation whereby the $\beta\gamma$-subunits are released from the α-subunit. The α-subunit subsequently binds to the adenylyl cyclase and increases its catalytic activity, resulting in an increase in intracellular cAMP levels (+). (B) Regulation of adenylyl cyclases by $G_i\alpha$. Upon activation of inhibitory receptors, the heterotrimeric G protein, G_i undergoes subunit dissociation whereby the $\beta\gamma$-subunits are released from the α-subunit. The α-subunit subsequently binds to the adenylyl cyclase and decreases its catalytic activity, resulting in a decrease in intracellular cAMP levels (−). Specific isoforms of adenylyl cyclase that are responsive to G_i inhibition are noted. (C) Dual regulation of adenylyl cyclases by G-protein $\beta\gamma$-subunits. $\beta\gamma$-subunits released from G_i heterotrimers can either positively (+) or negatively (−) regulate adenylyl cyclases. Specific isoforms of adenylyl cyclase that are responsive to these 2 types of regulation are noted.

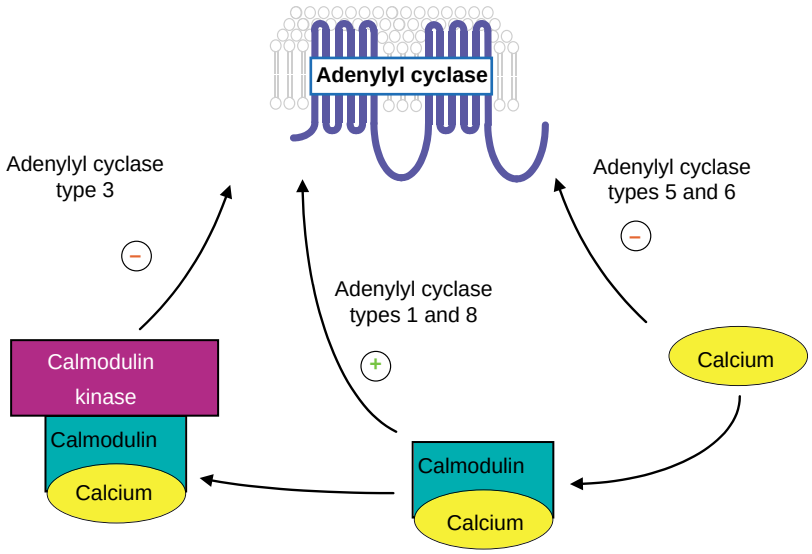

FIGURE 4 Schematic representation of the isoform-specific regulation of adenylyl cyclases by calcium. Increases in intracellular calcium can regulate the activities of adenylyl cyclases by at least three mechanisms. Calcium can directly bind to and inhibit AC 5 and 6. Calcium bound to calmodulin can bind directly to and activate AC 1 and 8, or can bind and activate a calmodulin-regulated kinase that can subsequently inhibit AC3.

to examine the specific roles of each adenylyl cyclase isoform through the use of mouse strains that are genetically altered by the removal of a particular adenylyl cyclase gene from the mouse genome. Such studies emphasize the involvement of cAMP signaling pathways in pattern formation of the brain and provide definitive evidence for roles of the types 1 and 8 adenylyl cyclases in higher brain function. Similar approaches have revealed a role for the type 3 cyclase in regulation of smooth muscle proliferation in the aorta and recently, a role of the type 5 cyclase in heart function.

A number of studies have uncovered both sporadic and inherited mutations in components of the adenylyl cyclase system associated, or in some cases, shown to be causal to certain human diseases. Mutations causing constitutively active receptors (resulting in elevated intracellular cAMP levels due to constant stimulation of adenylyl cyclase via $G_{s\alpha}$) have been found in patients with familial male precocious puberty/testotoxicosis (LH receptor), hyperfunctioning thyroid adenomas and nonautoimmune autosomal dominant hyperthyroidism (thyroid-stimulating hormone receptor), and Jansen-type metaphyseal chondrodysplasia (parathyroid hormone receptor). Similarly, diseases associated with constitutively activated G proteins ($G_{s\alpha}$) were also identified in patients with endocrine tumors, McCune–Albright syndrome, and testitoxicosis. However, to date no mutations associated with these diseases have been found in the adenylyl cyclase component of this system, but these investigations are ongoing. Here again, a major complication of these studies is the presence of multiple adenylyl cyclase isoforms that are present in each of the cell types.

Glossary

G protein A heterotrimeric protein composed of an α-, β-, and γ-subunit that binds and hydrolyzes GTP and transduces signals from outside to the inside of the cell.

receptor A protein that resides in the plasma membrane and specifically recognizes an extracellular signal and upon binding of this signal, transmits information to the cell interior.

second messenger A small molecule that is synthesized by a cellular protein and conveys the information within the cell that an extracellular signal has been received.

signal transduction The process of transmitting information from the outside to the inside of a cell, resulting in a change in cellular behavior.

Adrenergic Receptors

David B. Bylund
University of Nebraska Medical Center, Omaha, Nebraska, USA

Adrenergic receptors (adrenoceptors) mediate the central and peripheral actions of the neurotransmitter norepinephrine (noradrenaline) and the hormone epinephrine (adrenaline); they are widely distributed throughout the body. There are three major adrenergic receptor types: alpha-1, alpha-2, and beta. Each of these three receptor types is further divided into three subtypes. Adrenergic receptors are seven-transmembrane receptors, which consist of a single polypeptide chain with seven hydrophobic regions that are thought to form alpha helical structures that span or transverse the membrane. Because the mechanism of action of adrenergic receptors includes the activation of guanine nucleotide regulatory binding proteins (G proteins), they are also called G protein-coupled receptors.

Epinephrine and Norepinephrine

Norepinephrine (noradrenaline) is a neurotransmitter in both the peripheral and central nervous systems. Epinephrine (adrenaline) is a hormone released from the adrenal gland. Norepinephrine and epinephrine are catecholamines, because they have both the catechol moiety (two hydroxyl groups on a benzene ring) and an amine (NH_2). Both of these catecholamine messengers play important roles in the regulation of diverse physiological systems by acting through adrenergic receptors. Stimulation of adrenergic receptors by catecholamines released in response to activation of the sympathetic autonomic nervous system results in a variety of effects such as increased heart rate, regulation of vascular tone, and bronchodilatation. In the central nervous system, adrenergic receptors are involved in many functions including memory, learning, alertness, and the response to stress.

Norepinephrine is synthesized starting with the amino acid tyrosine, which is obtained from the diet and can also be synthesized from phenylalanine. Tyrosine is converted to dihydroxyphenylalanine (DOPA) by the enzyme tyrosine hydroxylase, and DOPA in turn is converted to dopamine. Dopamine is then converted to norepinephrine by the enzyme dopamine beta-hydroxylase. In the adrenal medulla and in a few brain regions, norepinephrine is converted to epinephrine by the enzyme phenylethanolamine N-methyltransferase. The major mechanism by which the effects of norepinephrine are terminated is re-uptake back into the nerve terminal by a high affinity norepinephrine transporter. Epinephrine, as well as norepinephrine are metabolized to inactive products. Norepinephrine is metabolized by the enzymes monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT) to 3-methoxy-4-hydroxyphenylglycol (MHPG) and 3-methoxy-4-hydroxymandelic acid (VMA). The major metabolite found in the blood and urine is MHPG. Epinephrine is similarly metabolized by MAO and COMT to VMA.

Classification and Mechanism of Action of Adrenergic Receptors

Adrenergic receptors were originally divided into two major types, alpha and beta, based on their pharmacological characteristics (i.e., rank order potency of agonists). Subsequently, the beta adrenergic receptors were subdivided into beta-1 and beta-2 subtypes; more recently, a beta-3 has been defined. The alpha adrenergic receptors were first subdivided into postsynaptic (alpha-1) and presynaptic (alpha-2) subtypes. After it was realized that not all alpha receptors with alpha-2 pharmacological characteristics were presynaptic, the pharmacological definition was used. The current classification scheme is based on three major types: alpha-1, alpha-2, and beta. Each of these three receptor types is further divided into three subtypes as shown in Figure 1: alpha-1A, alpha-1B, alpha-1D; alpha-2A, alpha-2B, alpha-2C; beta-1, beta-2, beta-3.

The binding of an agonist to an adrenergic receptor induces (or stabilizes) a conformational change that allows the receptor to interact with and activate a G protein. The activated receptor facilitates the exchange of GDP for GTP, leading to the dissociation of the α and $\beta\gamma$_ subunits of the G protein, which in turn stimulate or inhibit the activity various effectors. It is important to note that each of the three types of adrenergic receptors couples to a distinct class

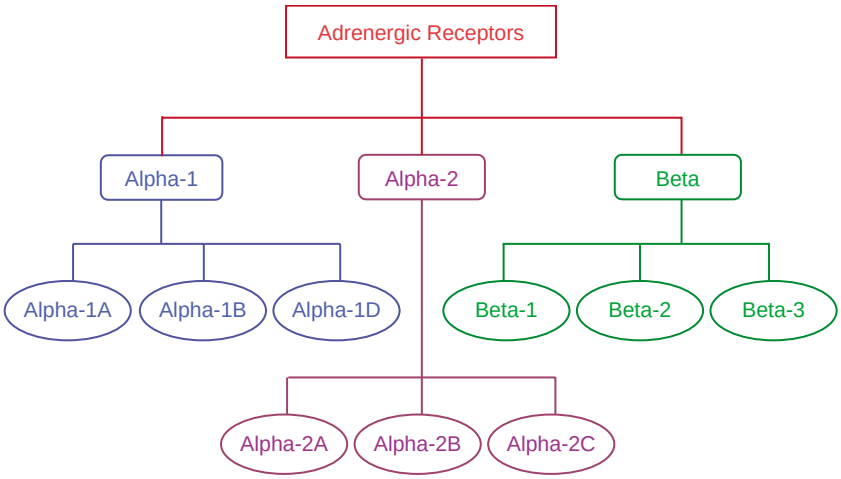

FIGURE 1 The classification scheme for adrenergic receptors.

of G proteins: alpha-1 to G_q; alpha-2 to $G_{i/o}$ and beta to G_s. In addition to G proteins, adrenergic receptors interact with other signaling proteins and pathways such as those involving tyrosine kinases.

Alpha-1 Adrenergic Receptors

Three genetic and four pharmacological alpha-1 adrenergic receptor subtypes have been defined. The alpha-1A and alpha-1B subtypes were initially defined based on their differential affinity for adrenergic agents, such as WB4101 and phentolamine, and on their differential sensitivities to the site-directed alkylating agent chloroethylclonidine. The alpha-1B subtype was subsequently cloned from the hamster and the alpha-1A was cloned from bovine brain, although it was originally called the alpha-1c adrenergic receptor. A third subtype, alpha-1D adrenergic receptor, was subsequently cloned from the rat cerebral cortex, although this clone was originally called the alpha-1a subtype by some investigators. A fourth pharmacological subtype, the alpha-1L, has been identified in vascular tissues from several species, but it may represent a conformational state of the alpha-1A receptor. The current classification scheme includes the alpha-1A, the alpha-1B and the alpha-1D, but there is no alpha-1C (Figure 1).

Pharmacological and Molecular Characteristics of Alpha-1 Adrenergic Receptors

In addition to norepinephrine and epinephrine, alpha-1 receptors are activated by various agonists such as phenylephrine (Neosynephrine) and methoxamine (Vasoxyl). These agonists are relative selective for alpha-1 receptors and have low affinity for alpha-2 and beta receptors. In contrast, they have similar affinities for the three alpha-1 subtypes and are thus nonsubtype selectively agonists. Similarly, antagonists including prazosin (Minipress) and tamsulosin (Flomax) are relatively selective for alpha-1 receptors and block alpha-2 and beta receptors only at high concentrations. Several other antagonists such as phentolamine (Regitine) and phenoxybenzamine (Dibenzyline) block both alpha-1 and alpha-2 adrenergic receptors with similar affinities. Alpha-1A selective antagonists include 5-methylurapidil and niguldipine, whereas cirazoline appears to be a selective alpha-1A agonist.

The alpha-1 adrenergic receptors are single polypeptide chains of 446 to 572 amino acid residues that span the membrane seven times, with the amino terminal being extracellular and the carboxy terminal intracellular. Thus, there are three intracellular loops and three extracellular loops. In contrast to the alpha-2 receptors, but similar to the beta receptors, the alpha-1 receptors have a long carboxy terminal tail (137–179) amino acid residues) and a short third intracellular loop (68–73 amino acid residues). The amino terminal of the alpha-1A and alpha-1B subtypes have three (alpha-1A) or four (alpha-1B) consensus sites for N-linked glycosylation. The carboxy terminal tails of all three subtypes are potentially palmitolyated, thus anchoring the tail to the membrane and forming a small fourth intracellular loop. The carboxy terminal tails also have multiple sites of phosphorylation that are thought to be important in the desensitization, recycling, and down-regulation of the receptor.

The human alpha-1 adrenergic receptor genes consist of two exons and a single large intron of at least 20 kilobases in the region corresponding to the sixth transmembrane domain. No splice variants are known

for the alpha-1B and alpha-1D subtypes. In contrast, at least 10 splice variants of human alpha-1A subtype have been reported, but only 4 produce full-length receptors.

Alpha-2 Adrenergic Receptors

Three genetic and four pharmacological alpha-2 adrenergic receptor subtypes have also been defined (Figure 1). The alpha-2A and alpha-2B subtypes were initially defined based on their differential affinity for adrenergic agents such as prazosin and oxymetazoline. These subtypes were subsequently cloned from human, rat, and mouse. A third subtype, alpha-2C, was originally identified in an opossum kidney cell line and has also been cloned from several species. A fourth pharmacological subtype, the alpha-2D, has been identified in the rat, mouse, and cow. This pharmacological subtype is a species orthologue of the human alpha-2A subtype, and thus it is not considered to be a separate genetic subtype.

Pharmacological and Molecular Characteristics of Alpha-2 Adrenergic Receptors

In addition to norepinephrine and epinephrine, alpha-2 receptors are activated by clonidine (Catapres) and brimonidine (Alphagan). These agonists are relatively selective for alpha-2 receptors and have lower affinity at alpha-1 and beta receptors. Similarly, the antagonist yohimibine is relatively selective for alpha-2 receptors and blocks alpha-1 and beta receptors only at higher concentrations. Antagonists that are at least somewhat selective for one of the alpha-2 subtypes include BRL44408 for the alpha-2A, prazosin and ARC-239 for the alpha-2B (note, however, that these two agents have much higher affinities for alpha-1 receptors), and rauwolscine for the alpha-2C subtype. Ozymetazoline is a partial agonist that has a higher affinity for the alpha-2A subtype when compared to the alpha-2B and alpha-2C subtypes.

The alpha-2 adrenergic receptors are single polypeptide chains of 450 to 462 amino acid residues. In contrast to the alpha-1 and beta receptors, the alpha-2 receptors tend to have long third intracellular loops (148–179 amino acid residues) and a short carboxy terminal tail (20–21 amino acid residues). The amino terminal of the alpha-2A and alpha-2C subtypes have two consensus sites for N-linked glycosylation, and the carboxy terminal tails of all three subtypes are potentially palmitolyated. The third intracellular loops have multiple sites of phosphorylation, which are thought to be important in the desensitization, recycling, and down-regulation of the receptor. The alpha-2 adrenergic receptor genes do not contain introns, and thus there are no splice variants.

Beta Adrenergic Receptors

Three beta adrenergic receptor subtypes have been identified. The beta-1 adrenergic receptor, the dominant receptor in heart and adipose tissue, is equally sensitive to epinephrine and norepinephrine, whereas the beta-2 adrenergic receptor, responsible for relaxation of vascular, uterine, and airway smooth muscle, is less sensitive to norepinephrine as compared to epinephrine. The beta-3 receptor is insensitive to the commonly used beta-adrenergic receptor antagonists and was previously referred to as the "atypical" beta adrenergic receptor. A beta-4 receptor has been postulated; however, definitive evidence of its existence is lacking, and it is now thought to be a "state" of the beta-1 adrenergic receptor.

Pharmacological and Molecular Characteristics of Beta Adrenergic Receptors

Isoproterenol (Isuprel) is the prototypic nonsubtype selective beta agonist that has no activity at alpha-1 and alpha-2 receptors except at high concentrations. Epinephrine is 10- to 100-fold more potent at the beta-2 receptor as compared to the beta-1 subtype, whereas norepinephrine is more potent than epinephrine at the beta-3 subtype. Many beta-2 selective agonists, such as terbutaline (Brethine) and salmeterol (Serevent), have been developed for the treatment of asthma. Due to their subtype selectivity, they have a lower incidence of side effects mediated by the beta-1 receptor. Propranolol (Inderal) is the prototypic nonsubtype selective beta antagonist that has equal affinities at the beta-1 and beta-2 subtypes. Other nonselective beta adrenergic antagonists include timolol (Blocadren), pindolol (Visken, which is actually a weak partial agonist), and carvedilol (Coreg), which is also an alpha-1 antagonist. Several beta-1 selective antagonists have been developed, such as metoprolol (Lopressor) and esmolol (Brevibloc).

The beta adrenergic receptors are single polypeptide chains of 408 to 477. In contrast to the alpha-2 receptors, but similar to the alpha-1 receptors, the beta receptors tend to have longer carboxy terminal tails (61–97 amino acid residues) and shorter third intracellular loops (54–80 aa). The amino terminal of the beta receptors have one or two consensus sites for N-linked glycosylation, and the carboxy terminal tails of all three subtypes are potentially palmitoylated. The carboxy terminal tails also have multiple sites of phosphorylation which are thought to be important in

the desensitization, recycling, and down-regulation of the receptor.

The beta-1 and beta-2 adrenergic receptor genes do not contain introns, thus they have no splice variants. In contrast, the beta-3 receptor has one intron, resulting in two splice variants. However, no functional differences have been found between the two splice variants.

Regulation of Adrenergic Receptors

The processes involved in desensitization and down-regulation have been extensively investigated for the beta-2 adrenergic receptor. The other adrenergic receptors, as well as many other G protein-coupled receptors, appear to behave in a similar manner. Initial uncoupling of the beta-2 receptor from the G protein after agonist binding is mediated by phosphorylation of specific residues in the carboxyl tail of the receptor. The phosphorylated beta-2 receptor serves as a substrate for the binding of β-arrestin, which not only uncouples the receptor from the signal transduction process but also serves as an adapter protein that mediates the binding of additional signaling proteins and entry into the internalization pathway. The mechanisms of beta-2 adrenergic receptor down-regulation appear to involve both an increase in the rate of degradation of the receptor as well as a decrease in the levels of beta receptor mRNA (8).

Adrenergic Receptor Signal Transduction Pathways

The alpha-1 adrenergic receptors activate the $G_{q/11}$ family of G proteins leading to the dissociation of the α and $\beta\gamma$ subunits and the subsequent stimulation of the enzyme phospholipase C. This enzyme hydrolyzes phosphatidylinositol 1,2-biphosphate in the membrane producing inositol trisphosphate (IP_3) and diacylglycerol. These molecules act as second messengers mediating intracellular Ca^{++} release via the IP_3 receptor and activating protein kinase C. Other signaling pathways that have also been shown to be activated by alpha-1 receptors include Ca^{++} influx via voltage-dependent and independent calcium channels, arachidonic acid release, and activation of phospholipase A_2, phospholipase D activation, and mitogen-activated protein kinase.

The alpha-2 adrenergic receptors activate the $G_{i/o}$ family of G proteins and alter (classically inhibit) the activity of the enzyme adenylyl cyclase, which in turn, decreases the concentration of the second messenger cyclic AMP. In addition, the stimulation of alpha-2 receptors can regulate several other effector systems including the activation of K^+ channels, inhibition or activation of Ca^{++} channels, and activation of phospholipase A_2, phospholipase C, and Na^+/H^+ exchange.

The beta adrenergic receptors activate the G_s family of G proteins and activate adenylyl cyclase, thus increasing in cyclic AMP concentrations. Beta adrenergic receptors interact with many other signaling proteins, including the phosphoprotein EBP50 (ezrinradixin-moesin-binding phosphoprotein-50), the Na^+/H^+ exchanger regulatory factor, and with CNrasGEF.

Adrenergic Receptor Polymorphisms

Polymorphisms have been identified in some of the alpha-2 and beta adrenergic receptor subtypes, which may have important clinical implications. A common polymorphism has been identified in the third intracellular loop of the alpha-2B receptor, which consists of a deletion of three glutamate residues (301–303); the deletion is a risk factor for acute coronary events, but not hypertension. This deletion results in a loss of short-term agonist-induced desensitization. A common polymorphism has been identified in the third intracellular loop of alpha-2C subtype, which consists of a deletion of four amino acid residues (322–325); the deletion results in an impaired coupling to several effectors.

The gene encoding the human beta-1 adrenergic receptor is quite polymorphic with 18 single nucleotide polymorphisms (SNPs), 7 of which cause amino acid substitutions. A total of 13 polymorphisms in the beta-2 adrenergic receptor gene and its transcriptional regulator upstream peptide have been identified. Three closely linked polymorphisms, two coding region at amino acid positions 16 and 27 and one in the upstream peptide, are common in the general Caucasian population. The glycine-16 receptor exhibits enhanced down-regulation *in vitro* after agonist exposure. In contrast, arginine-16 receptors are more resistant to down-regulation. Some studies have suggested a relationship among these polymorphisms, airway responsiveness (e.g., asthma) and the responsiveness to beta adrenergic agonists.

A tryptophan-64 to arginine polymorphism has been identified in the beta-3 adrenergic receptor. The allele frequency is approximately 30% in the Japanese population, higher in Pima Indians, and lower in Caucasians. Type 2 diabetic patients with this mutation showed a significantly younger onset-age of diabetes and an increased tendency to obesity, hyperinsulinemia, and hypertension.

Glossary

agonist Compound that binds to a receptor and activates it, thus causing a biological response.

antagonist Compound that binds to a receptor but does not activate it. It can block or inhibit the activation caused by an agonist.

desensitization Decrease in response of a tissue to a neurotransmitter or agonist drug following repeated administration.

down-regulation Decrease in the number or density of receptor binding sites following chronic agonist treatment.

partial agonist Agonist that has less than full efficacy in activating its receptor.

polymorphism Variability in DNA sequence that occurs with an allele frequency of greater than 1% in the population.

Biography

David B. Bylund is a professor and former chair of the Department of Pharmacology at the University of Nebraska Medical Center in Omaha, Nebraska. His main research interests are related to the regulation of adrenergic receptors and their role in mental disorders. He received his Ph.D. from the University of California at Davis and was a postdoctoral fellow at Johns Hopkins University. He was President of the American Society for Pharmacology and Experimental Therapeutics for 2003–2004.

Affinity Chromatography

Pedro Cuatrecasas
University of California, San Diego, California, USA

Meir Wilchek
Weizmann Institute of Science, Rehovot, Israel

Affinity chromatography (AC) is a variant of liquid chromatography in which biospecific and reversible interactions between biologically active or structurally unique and complementary molecules are used for the selective extraction, separation, purification, analysis, or tagging of specific macromolecules or cell components from crude biological samples. AC was first introduced as a procedure for purifying enzymes and proteins more than 30 years ago. AC is based on the principles of molecular recognition, and today it is one of the most powerful techniques available for purifying physiologically or structurally interacting proteins. In addition to the multitude of proteins purified by AC, the method has also been an indispensable tool for studying many biological processes, such as the mechanism of action of enzymes and hormones, protein–protein or cell–cell interactions, and others encountered in genetic engineering. The emergence of many related methodologies, which are based on molecular recognition (or biorecognition), has impacted virtually all fields of research in the biological sciences.

The Key Steps in AC

The first step involves the preparation of a matrix support (resin) material to which a unique "ligand" (typically a small molecule such as an enzyme inhibitor or substrate) is attached (coupled) irreversibly. This is accomplished by chemical activation of the inert resin followed by the irreversible attachment of the ligand (Figure 1). Such a derivatized resin is then used for purification of a biologically active compound by AC following a three-step process as illustrated in Figure 2. These steps are (1) adsorption or reversible attachment of the protein (or macromolecule) to be purified from the mixture to the resin, (2) thorough washing of this resin, and (3) then elution or removal of the protein from the resin. Generally, the used resin can be thoroughly washed and cleaned (regenerated) and used again for the same purpose.

Why and Where AC Works

Biological macromolecules such as enzymes, polynucleotides (like DNA and RNA), antibodies, receptors, and structural proteins normally interact with chemically different but highly specific molecules by virtue of conformationally unique active sites (such as in enzymes, for substrate binding and catalysis) or binding recognition sites (as for antigens, hormones, and oligonucleotides). If one of these partners of the interacting pair (e.g., enzyme inhibitor) is immobilized on a polymeric carrier, it can be used to attract and isolate the complementary partner (e.g., the enzyme) by simply passing a cell extract containing the latter through a chromatography column packed with the immobilized molecule. Molecules without appreciable affinity for the immobilized ligand will pass unretarded through the column, whereas those capable of binding to the ligand will be retained (adsorbed). Since this binding on the column is based on reversible interactions, the adsorbed component, which is chemically and physically free in solution, will upon continued passage of buffer through the column eventually also come off the column, depending on the strength of the interaction (i.e., affinity). The affinity will depend on factors such as the intrinsic affinity, the effective concentration of covalently bound ligand, temperature, and the composition of the buffer (e.g., pH and salt concentrations). Since the adsorption process is based on the principles of classical bimolecular interactions, a very important factor is also the concentration of the interacting molecule in the solute. The concentration of this component increases progressively as more sample is run through the column, thus effectively increasing its retention on the matrix support during the process of applying the sample through the column. After washing the column, the desired biomolecule adsorbed to the column can be removed (eluted) by varying the buffer conditions.

The distinguishing feature of AC over all other techniques used in purifying macromolecules is the

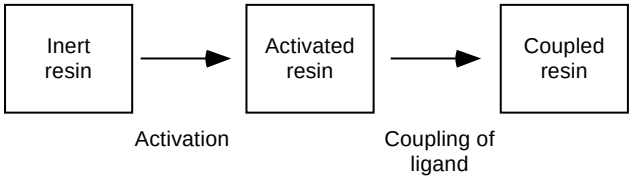

FIGURE 1 Schematic representation of the process of activation and immobilization of a specific ligand to a surface (resin) for the preparation of specific AC resins (solid supports). For the use of this resin in a purification procedure, see Figure 2.

fundamental dependence on the biological, or functional, rather than on the physicochemical (e.g., size, charge, shape, and hydrophobicity) properties of the molecule to be purified. Virtually all interacting systems consisting of two or more (e.g., when cofactors, metal ions, are essential for complex formation) components are suitable targets for affinity purification. Some of the classes of compounds which have been isolated by AC are described in Table I.

The Procedures Used in AC

Solid Carriers or Matrix Materials Used

Historically, nearly all of the applications of AC were performed under conditions of low pressure, using beaded particles of a size between 50 and 400 μm. A large number of macro-particle support materials for AC are commercially available. By far, the most popular support has been and continues to be agarose. Its success can be attributed not just to its inherently good qualities for AC, but also to its introduction in the initial discovery and its rapid acceptance and widespread use by the research community. Indeed, a literature survey has shown that agarose is used 90% of the time as a solid phase matrix for AC. A number of other supports have also been used successfully in applications of AC. Among these are cross-linked cellulose, trisacryl, Fractogel TSK, and silica (glass beads).

Activation of and Coupling to Carriers

There are many methods that can be used for the immobilization of ligands to polymeric support materials (carriers). A few of the more representative of these will be described briefly here. The most frequently used method (Figure 3) is the cyanogen bromide activation of agarose that leads to a highly reactive

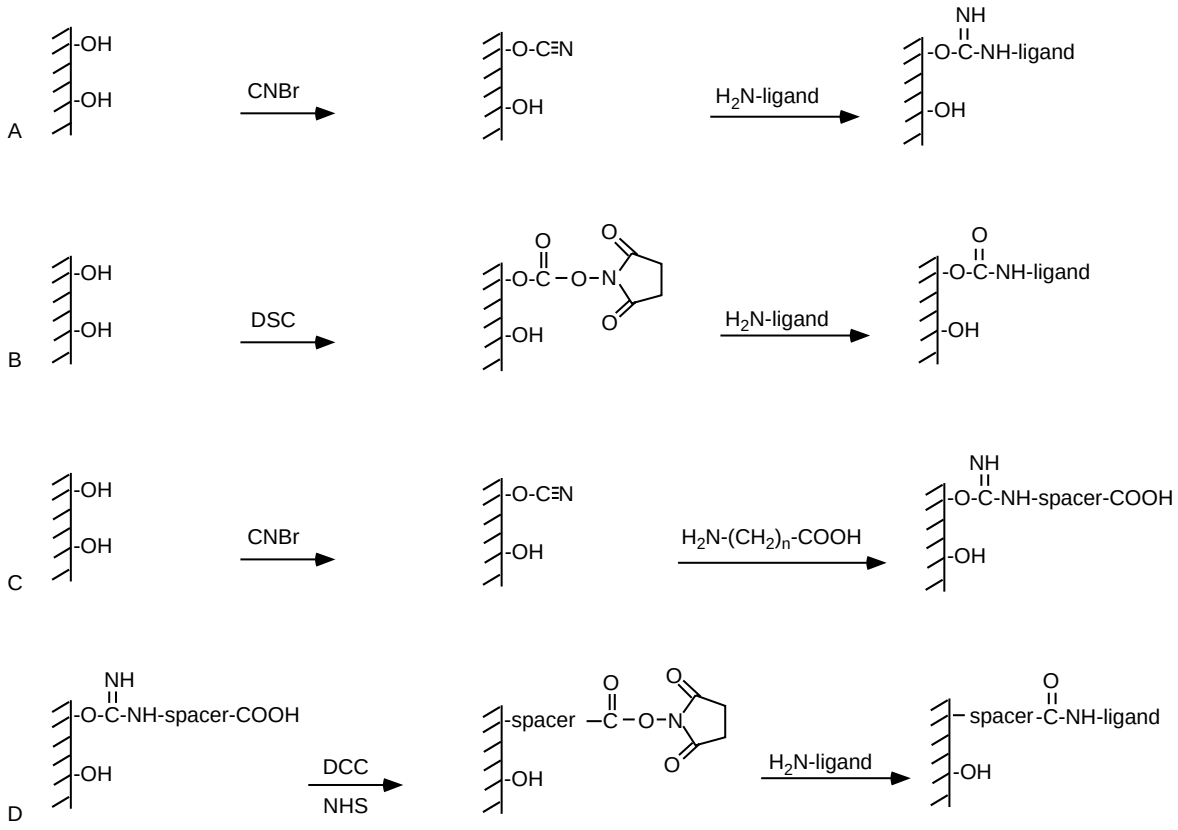

FIGURE 3 Immobilization of ligands to different activated resins. (A) Cyanate ester, obtained by activation with cyanogen bromide (CNBr), leading to isourea derivative; (B) *N*-hydroxysuccinimide carbonate obtained by activation with *N′N*-disuccinimidyl carbonate (DSC) giving a carbonate derivative; (C) Introduction of a spacer arm using *ω*-amino acids as the spacer resulting in a terminal carboxyl group; (D) Activation of carboxyl groups with dicyclohexylcarbodiimide (DCC) and *N*-hydroxysuccinimide (NHS) yielding a stable amide derivative.

cyanate ester (the activated resin is commercially available). Subsequent coupling of ligands to the activated matrix results in isourea linkages.

Since the earliest days of AC, active esters, in particular *N*-hydroxy-succinimide (NHS) esters, have also been used for immobilizing ligands (Figure 3). The preparation of active esters for subsequent coupling with primary amino group containing ligands requires a matrix that contains carboxylic acid groups. Such matrices can be prepared by activating the hydroxyl groups of agarose with various reagents, including cyanogen bromide and activated carbonates (Figure 3). Successive reaction occurs readily with ligands containing ω-amino acids of various size, depending on the length of the "spacer arm" required. The NHS ester is prepared by mixing the carboxylic matrix with dicyclohexylcarbodiimide and NHS. The covalent attachment via the amino groups of ligands proceeds spontaneously in aqueous solution, resulting in stable amide bonds.

Another method for activating polysaccharide-based polymeric supports like agarose, which contain hydroxyl groups, is the use of *N′N′*-disuccinimidyl carbonate (DSC), which forms highly reactive carbonate derivatives (Figure 3). These derivatives react with nucleophiles under mild, physiological conditions (pH 7.4), and the procedure results in a stable carbamate linkage of the coupled ligand.

Adsorption

An important step in AC is the selective extraction (adsorption) of the desired macromolecule by its unique binding to the immobilized ligand, thus removing it from the crude mixture in which it was present. The macromolecule, whether an enzyme, antibody, receptor, hormone, or growth factor, is selectively bound to the immobilized specific ligand, which can be a small synthetic or natural molecule, protein, peptide, polynucleotide, nucleotide, polysaccharide, carbohydrate, lipid, or vitamin. Functionally, such ligands may be substrate analogs or inhibitors, antibodies, antigens, coenzymes, or cofactors. The adsorption should be performed under the most favorable conditions for the interaction, including buffer pH, ionic strength, and special ions, as well as temperature. Molecules not possessing appreciable affinity for the immobilized counterpart will pass unretarded through the column.

Elution

After thoroughly washing the column (usually with adsorption buffer) the desired biomolecule can be eluted by using a buffer containing high concentrations of the same ligand (or a related one, such as a substrate instead of an inhibitor) that was used in the immobilized state. It may be necessary to stop the flow of the column for a period of time, and/or to adjust the temperature, to facilitate the ligand exchange and thus dissociation. Alternatively, the buffer composition can be changed such that the complex will no longer be stable. The buffer conditions usually changed are pH, ionic strength, metal chelators, and organic solvents. The conditions used must not result in irreversible denaturation and inactivation of the eluted macromolecule. If the macromolecule can totally recover its structure and function after total unfolding, effective and complete elution can be achieved with 6 M urea or guanidine (followed by dialysis of the eluate).

Techniques that Stem from AC

The broad scope of the basic concepts of AC has led to a wide variety of related applications. This has generated various subspecialty adaptations, many of which are now recognized by their own nomenclature, and some of which are covered by their own chapters in this volume. Here, we list some of these (Table II), and briefly discuss a few of the more exciting and recent examples.

TABLE II

Various Techniques Derived from Affinity Chromatography

Affinity capillary electrophoresis
Affinity electrophoresis
Affinity partitioning
Affinity precipitation
Affinity repulsion chromatography
Affinity tag chromatography

Library-derived affinity ligands
Membrane-based affinity chromatography
Metal–chelate affinity chromatography
Molecular imprinting affinity
Perfusion affinity
Receptor affinity chromatography
Tandem affinity purification (TAP)
Thiophilic chromatography
Weak affinity chromatography

Immunoaffinity Chromatography (IAC)

Among the most popular of these affinity-derived technologies is IAC on antibody columns to purify antigens. The growth of IAC has been ignited by the advancements over the past decade or two in the fields of molecular biology and biotechnology. Great need has existed for purifying pharmacologically active proteins for which ligands of small molecular weight are not available. Also, antibodies can now be produced against virtually any compound. Immobilized antibodies have also been used to remove toxic components from blood by hemoperfusion through affinity resins, and for a variety of applications of solid phase radio- or fluoroimmunoassay. In the biotechnology industry, IAC is providing methods for the large scale preparation of monoclonal antibodies.

AC and DNA Recombinant Techniques

Recent advances in molecular biology permit determination of the amino acid sequences of proteins by genetic approaches. Thus, large scale isolation of the protein from its native source is often unnecessary, except of course to determine posttranscriptional modifications. Since today most proteins are produced by recombinant technology and genetic engineering, the means for their purification is usually pre-engineered by introducing a biologically active tagging element into the gene itself. Such elements include various temporary "affinity tags" or "affinity tails" such as the His-Tag, which can be purified by metal-chelate AC. FLA–TM-peptide, which consists of eight amino acids, includes both an antigenic site and an enterokinase cleavage site. This affinity tag is used to purify a fusion protein on an immunoaffinity column, and the native protein is recovered by enterokinase cleavage. Fusion proteins can also be produced containing other large proteins such as glutathione transferase, protein A, maltose-binding proteins, cellulose-binding domains, and biotinylated sequences, all of which can serve as targets for purifying the fused proteins on specific ligand affinity columns.

IAC represents a valuable complement, especially when specific ligands that are suitable for immobilization and AC are not available. Today, because of the routine use of recombinant technologies and IAC, pure proteins are so readily obtained that often their function or ligand specificity are the major unknown factors.

We have seen a shift in the challenge toward the "discovery of the ligand," whether the ligand is the naturally occurring species (e.g., what is the substrate, the hormone, or vitamin for this protein), or synthetic. This search can sometimes be achieved using either a phage display library or a combinatorial library to

screen for molecules that may display specific binding. Such a molecule, if found, can then also be used as an affinity ligand for AC. Discovery of ligands can provide insight into the unknown function of genetically coded proteins and serve as useful tools for the purification of proteins or for the discovery of novel medicinal drugs.

AC and Proteomics: Tandem Affinity Purification (TAP)

In proteomics, the study of protein–protein interactions, especially those occurring in multiprotein cellular complexes, is one of the major challenges. When mass spectrometry (MS) is used, fast and reliable methods of protein purification are necessary. The method perhaps most suitable is affinity purification based on the fusion with tags to the target protein (Tandem Affinity Purification, TAP). The TAP procedures use two different tags for more effective purification on two different affinity columns. These procedures have advantages over other approaches since all of the directly and indirectly interacting components of a protein complex of the expressed protein can be identified and purified in a single experiment. It is claimed that the TAP biphase method will be useful to characterize large, multiprotein complexes, as shown recently in studies of the functional organization of the yeast proteome. In fact, the TAP approach may represent the first real *in vivo* use of affinity purification. This system, however, is not totally without potential problems and it is important to also monitor expression levels to avoid artifacts. Other precautions include the use of immunochemistry to ensure proper cellular localization of the proteins. Another major application of TAP proteins is that they may be used in searching for interacting proteins in discrete cellular domains.

AC and Biochips

Molecular biosensors based on the affinity concepts described here have evolved over the years in remarkable ways. Recently, a number of technologies have appeared that marry AC between solid phase technologies and sensitive analytic procedures. These include protein and antibody microarrays, mass spectrometric immunoassays, surface-enhanced laser desorption–ionization spectrometry, and surface plasma resonance (SPR). In SPR, a protein, antibody, DNA, or other large macromolecule is attached to a derivatized surface (i.e., glass or metal), creating a biochip. A complex mixture of macromolecules can then be passed over the chip surface and the retained molecules can be detected using various techniques. In some cases, detection is simply a matter of positional location on an ordered array using fluorescent markers; in other cases, the retentates on the chip are desorbed and ionized by lasers. Ionized components, then, are analyzed using time-of-flight or other mass spectrometry techniques. Still in others, mass changes consequent to macromolecular interactions are detected directly using changes in the surface refractive index (by SPR).

The SPR biosensor approach also provides some other unique characteristics. These include (1) access to on- and off-rate analyses of molecular interactions and (2) analyses, in real time, of the interaction dynamics. In addition, SPR has been combined with matrix assisted time-of-flight mass spectrometry to yield a two-dimensional quantitative and qualitative analysis technique. Together, these methods provide a means to detect subtle variations in hundreds of thousands of macromolecules, including single nucleotide polymorphisms in DNA and amino acid changes, or posttranslational modifications of peptides and proteins.

Glossary

affinity tags Molecules, like vitamins, peptides, amino acids, proteins, fluorophores or inhibitors, which are incorporated structurally into a protein (often by genetic approaches) to subsequently use with affinity resins to purify (as in AC), or otherwise detect the presence of, or to quantitate, the macromolecule that is thus tagged.

chromatography A technique used to separate mixtures of substances on the basis of differences in the ability to adsorb or attach to two different media, one being mobile, which is a moving fluid, and the other being stationary, which is a porous solid or gel, or a liquid coated on a solid support. Substances are carried along by the mobile phase at different rates, depending on their solubility (in a liquid mobile phase) or vapor pressure (in a gas mobile phase) and their avidity for the solid support. Examples are adsorption, column, gas, gas–liquid, gas–solid, gel filtration, high performance liquid, ion exchange, molecular exclusion, partition, thin layer, and affinity (AC).

ligands Molecules that bind with specificity and affinity to active sites or special binding sites of macromolecules, as substrates to an enzyme or a hormones to a receptor.

resin The solid (stationary) or adsorbent in the chromatographic procedure to which molecules are attached covalently for use in AC. Referred to synonymously as solid support, matrix, polymeric support (insoluble), or carrier.

spacer arms or extension arms Linear molecules, like amino acids, diamines or polyethylene glycol (PEG), that are attached irreversibly to the resin and to which specific ligands are then attached covalently for the purpose of allowing macromolecules to interact with the ligand with less potential steric hindrance by the resin.

Biography

Pedro Cuatrecasas is adjunct professor of Pharmacology and of Medicine at the University of California, San Diego. He received an M.D. from the Washington University School of Medicine, St. Louis. During more than twenty years, he was in charge of research and development at Burroughs Wellcome Co., Glaxo Inc., and Parke Davis/Warner Lambert Co. His research interests have included drug discovery, protein chemistry, hormone action, receptor chemistry and signal transduction.

Meir Wilchek is a professor at the Weizmann Institute of Science in Rehovot, Israel. He received his Ph.D. from the same institute and has been a frequent Visiting Scholar at the National Institute of Health, Bethesda, Maryland. His entire career has been devoted to the study of the biorecognition or "affinity" phenomenon, particularly the application of biorecognition for various purposes.

Cuatrecasas and Wilchek were the first to describe AC, over 30 years ago; they elucidated the basic principles, described the chemical procedures, and explored and suggested applications of these and related technologies.

Affinity Tags for Protein Purification

Joseph J. Falke and John A. Corbin
University of Colorado, Boulder, Colorado, USA

Selective immobilization of proteins greatly facilitates their purification, as well as their biochemical and biophysical characterization. When genetically fused to a target protein, a protein affinity tag provides a powerful tool to selectively capture and immobilize that target, in some cases providing single-step purification. Affinity tags consist of proteins or peptides with distinct amino acid sequences that are capable of a reversible, high affinity binding interaction with a specific partner molecule. The binding partner is linked to a large macroscopic particle or surface that renders it immobile, and thus it is readily amenable to manipulation. The highly specific interaction between the affinity tag and its cognate partner serves as the basis for selective capture of the target protein.

Applications of Affinity Tags

Affinity tags have proven to be tremendously effective tools for a wide variety of applications, and they are now incorporated as a standard feature to reduce the number of steps in purification protocols developed for recombinant proteins. In addition, affinity tags have become indispensable in the immobilization of proteins for display on a surface, where the tag ensures that the fusion protein of interest is oriented with its functional regions exposed to docking with other macromolecules. Affinity tags are also used to detect and quantitate target proteins and to analyze protein–protein or protein–ligand interactions. Related technologies are developing rapidly, including bioreactors for multistep enzymatic reactions and bioadsorbants for extraction or degradation of toxic contaminants.

Construction of a Fusion Protein

An affinity-tagged fusion protein typically consists of a single polypeptide chain with one or more affinity tags coupled to the C- or N-terminus of the target protein or inserted into a loop region. The coupling is via a peptide linker, usually up to 15 amino acids in length. If desired, the linker can contain a specific protease site for affinity tag removal. The use of multiple tags is increasingly common and endows the target protein with two or more unique molecular handles.

Selection Criteria for an Affinity Tag

Construction of a fusion protein begins with the selection of an affinity tag that is appropriate for the protein of interest (see below). The selection criteria include the size of the affinity tag, the organism that will be used to express the fusion protein, conditions for the immobilization or purification of the fusion protein, and the influence of the affinity tag on the structural and functional characterization of the target protein.

Affinity-Fusion Gene Constructs

To incorporate the selected affinity tag, a suitable expression plasmid vector is chosen and recombinant DNA techniques are used to insert the target gene next to the affinity tag gene. Numerous vectors are commercially available that code for a selected affinity tag and a linker peptide, the latter often containing an imbedded protease recognition sequence. Additionally, an inducible promoter is present to enhance and regulate fusion protein expression, and a multiple cloning site region is included to facilitate insertion of the target gene with the fusion site at the C- or N-terminus as desired. In some cases, the coding region for a signal peptide is included to promote the secretion of the fusion protein into a specific cellular compartment or into the extracellular medium. Newly developed vectors fuse two different tags to each terminus of a target protein, thereby allowing two-step isolation schemes with enhanced purity and ensuring that only fully intact forms of the fusion protein are isolated.

Linker Peptide Composition

The composition of the linker peptide can have a substantial impact on the function and utility of the fusion protein; therefore, a number of factors are considered during linker design. Typically, the linker is at least 5–10 residues long to allow free tumbling of

the fusion and target proteins relative to one another, thereby preventing unwanted steric hindrance to binding events. For linkers containing a proteolytic cleavage site (typically for enterokinase, factor Xa, thrombin, or tobacco etch virus (TEV)), inclusion of 5–10 flanking amino acids at both ends of the site ensures adequate accessibility to protease. Finally, the linker amino acid composition must be selected to minimize susceptibility to host organism proteases.

Overview of Fusion Protein Production and Immobilization

Purification of a recombinant fusion protein begins with the introduction of the expression plasmid into the host cell, followed by cell growth and induction of the fusion promoter. The host cells are lysed and the resulting lysate, containing the affinity-tagged protein, is incubated with a solid phase support to which the binding partner is coupled. Following binding of the tag to its immobilized partner, the support is washed to remove unbound components, yielding specific isolation of the tagged protein. If desired, the tagged protein can be released by either disrupting its interaction with the binding partner or by proteolysis of the linker region. Isolation and immobilization procedures often need to be optimized for each new affinity-tagged protein and expression host.

Features and Types of Affinity Tag Systems

The large number of affinity tags currently available offers a diverse spectrum of biochemical properties that can be exploited for protein immobilization in a variety of contexts. Affinity tags range in size from short peptides less than 1 kDa to proteins as large as 120 kDa, and they can be classified into general categories based on their binding partner interaction such as protein–ligand, polyamino acid–matrix, antigen–antibody, and protein–protein. New types of tags based on novel binding partner interactions continue to emerge at a rapid pace.

When choosing an affinity tag for a specific application, several features are considered. A subset of affinity tags possess the useful property of binding to their partner even under denaturing conditions. The ability to immobilize a tagged protein under denaturing conditions is a great advantage when the fusion protein is expressed in an insoluble or non-native form. Other tags utilize a binding partner interaction that is easily disrupted under mild conditions, thereby facilitating the recovery of target protein with full biological activity. Affinity tag size can also impact target protein function and structural integrity. Small tags generally have less impact on protein structure and function and often need not be removed, while large tags can be perturbing and thus are typically removed prior to structural and functional studies. On the other hand, certain large tags can significantly enhance the solubility of a fusion protein expressed at high levels; therefore, they are appropriate choices for the isolation of poorly soluble target proteins. Finally, when a target protein is toxic to the expression host, affinity tags that promote the aggregation of fusion protein into insoluble aggregates known as inclusion bodies are used. Key features of representative affinity tags are discussed below, and Table I presents a more comprehensive list.

Protein–Ligand Interaction Affinity Tags

Enzymes and small molecule-binding proteins are designed to bind their ligands with high specificity, thus many highly effective affinity tag systems are based on ligand-binding interactions. One of these is the widely utilized glutathione S-transferase (GST) tag (26 kDa) that binds with high specificity and low affinity ($K_D \sim 180\ \mu M$) to its substrate glutathione. Although the affinity of the GST tag for its ligand is low, commercially available immobilized glutathione matrices provide high local ligand concentrations that ensure adequate retention of the fusion protein. GST-tagged proteins are typically isolated from crude cell lysates by their interaction with immobilized glutathione on beads then eluted by competitive displacement with free, reduced glutathione. The low ligand affinity enables elution under mild, nondenaturing conditions. The GST tag often increases fusion protein solubility and stability, and it is ideally suited for overexpression of recombinant proteins in their native state. Often, the GST tag is proteolytically removed at the end of the purification due to its large size and tendency to form dimers. In other applications, the GST tag is retained and used to couple the target protein to a bead or surface for biochemical or biophysical studies.

Another family of affinity tags that relies on protein–ligand interactions are the cellulose-binding domains (CelBD). CelBDs are small, highly stable protein modules consisting of between 33 and 180 amino acids (3–20 kDa) that bind to different forms of cellulose or chitin with a broad range of affinities ($K_D \sim 0.01$ to $400\ \mu M$). CelBD fusions can be constructed with affinity tags inserted internally or linked to either the C- or N-terminus of the protein of interest. Over 180 different CelBDs have been identified, providing a spectrum of polysaccharide specificities, binding affinities, and targeting properties. Certain CelBDs bind

cellulose essentially irreversibly, making them ideal for protein immobilization, while other CelBDs exhibit easily reversible binding. Denaturing conditions or proteolysis are often needed to elute irreversible CelBDs, while reversible CelBDs can be eluted under mild conditions such as the use of a competitive ligand (cellbiose or ethylene glycol) or desorption with water. Finally, CelBDs can be selected that target the fusion protein for secretion or inclusion body formation.

The 51 amino acid chitin-binding domain (ChiBD) is derived from *Bacillus circulans* chitinase and exhibits high affinity, essentially irreversible binding to its ligand chitin, a natural carbohydrate polymer. ChiBD fusion proteins are immobilized under physiological conditions by adsorption to chitin coupled to a solid phase material. ChiBD fusion proteins often have an intein element incorporated into the linker region in place of a proteolytic recognition sequence. When remobilization of the fusion protein is desired, the intein element is activated and undergoes self-cleavage, resulting in the release of the target protein, while the intein-ChiBD region is retained on the solid phase. Similar inteins will probably soon be incorporated into the linkers of other affinity tags. Several other protein–ligand affinity tag systems are currently in use, each having unique advantages. For example, the 40 kDa maltose binding protein (MalBP) is a large tag that often increases fusion protein solubility. MalBP binds to cross-linked amylose with moderate affinity ($K_D \sim$ micromolar range), permitting MalBP tagged fusion proteins to be immobilized in a reversible fashion. The full length MalBP tag directs a fusion protein to the oxidizing *E. coli* periplasm, where MalBP is a native protein and where the fusion protein may benefit from disulfide bond formation. Alternatively, removal of the MalBP leader peptide yields retention of the fusion protein in the cytosol, where the greater volume can allow higher expression levels.

Polyamino Acid–Matrix Interaction Affinity Tags

Immobilized-metal affinity chromatography (IMAC) is a common technique used to purify recombinant proteins fused to a short peptide affinity tag. IMAC, which can be carried out under denaturing or nondenaturing conditions, relies on the interaction between multiple electron donors on the affinity tag with a transition metal ion (Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}) chelated to a solid phase support. The affinity tag is typically polyhistidine, ranging 6 to 12 residues in length fused to the N- or C-terminus of the target, where "6-His" is most common and the electron donor is the histidine imidazole ring. Recently, an affinity tag based on a natural peptide derived from the N-terminus of chicken lactate dehydrogenase has also been utilized. This HAT-tag contains 6 histidine residues interspersed within a 19-residue polypeptide (KDHLI HNVHK EEHAH AHNK) that binds to specifically Co^{2+}-carboxymethylaspartate and has a lower net charge than polyhistidine tags. The most widely employed metal chelator is iminodiacetic (IDA), while nitrilotriacetic acid (NTA) and carboxymethylated aspartic acid (trade name TALON) are also popular. The chelator is generally covalently coupled to polymer beads, or ferromagnetic beads for magnetic isolation. Adsorption of IMAC tagged proteins is normally performed at neutral to slightly basic pH to ensure that the histidine imidazole groups are not protonated. Mild elution conditions include ligand exchange with imidazole, extraction of the metal ion by a strong chelator like EDTA, or proteolytic elution. Low pH will also elute, but it can sometimes denature the target protein. IMAC is not recommended for target proteins possessing a metal center, since the metal can be stripped by the binding partner chelators.

The Arg-tag is another example of a small polyamino acid affinity tag, in this case designed to raise the isoelectric point of the fusion protein to enhance its binding to a cation exchange matrix. Mild elution conditions are generally a NaCl gradient at alkaline pH. This tag also binds to flat mica sheets, which may enable a variety of new applications.

Antibody–Epitope Interaction Affinity Tags

Recombinant DNA technology has been employed to create peptide epitopes that bind well-characterized antibodies. This process is known as epitope tagging and is complementary to a more traditional approach where a novel antibody is generated for an existing epitope. Both approaches have been exploited to develop affinity tag systems based on the binding interaction between a peptide epitope and its specific antibody partner. In some cases, several antibodies with different properties are available for a given epitope. Proteins fused to peptide epitope affinity tags can be captured by immunoaffinity interactions via immobilized monoclonal antibodies. Typical epitope tags range from 6 to 30 residues in length, are highly charged, and have little effect on protein structure–function. They can be fused at either the C- or N-terminus, or even inserted within the protein of interest. Epitope tag expression vectors are commercially available for mammalian, insect, yeast, and bacterial host cells and provide a variety of tags including c-myc, FLAG, HA, T7, V5, VSV-G, recA, Protein C, Protein A, and Protein Z. Some of these are optimized for immobilization while others are primarily used for protein detection. The importance of epitope tags is illustrated by their many applications including analysis of *in vivo* protein expression,

TABLE I

Commonly Used Affinity Tags and Their Features

						Nondenaturing		
Category of tag	**Name of tag**	**Number of residues in tag**	**Size of tag (kDa)**	**Location of tag**	**Immobile phase binding partner**	**Immobilization conditions**	**Affinity tag elution conditions (eluent)**	**Expression host[a]**
Protein–ligand interactions	Glutathione S-transferase	211	26	N-Term, C-Term	Glutathione	Yes	Yes (10 mM Reduced Glutathione)	B, Y, I, M
	Cellulose-binding domains	27–189	3–20	N-Term, C-Term, Internal	Cellulose and other cellulosics	Yes	Yes (water) or No (Guanidinium HCL)	B, Y, I, M
	Maltose-binding protein	396	40	N-Term, C-Term	Cross-linked amylose	Yes	Yes (10 mM Maltose)	B
	Chitin-binding domain	51	5.6	N-Term, C-Term	Chitin	Yes	No	B
Polyamino acid–matrix interactions	Polyhistidine	6–12	0.8–1.7	N-Term, C-Term, Internal	Metal chelate	Yes or No (Denaturants)	Yes (Imidazole) or No (Low pH)	B, Y, I, M, P
	Polyarginine	5–15	0.8–2.4	C-Term	Cation-exchange resin	Yes	Yes (NaCl gradient at alkaline pH)	B, P
Antibody–epitope interactions	Hemagglutinin (HA)	9	1.1	N-Term, C-Term	IgG	Yes	No (Low pH)	Y, M
	T7	11	1.1	N-Term	IgG	Yes	No (Low pH)	B, Y, M, P, I
	Synthetic protein A (Z domain)	58	7	N-Term	IgG	Yes	No (Low pH)	B, Y, I, M, P

	FLAG	8	1.0	N-Term, C-Term	mAb M1 and mAb M2	Yes	Yes (EDTA)	B, Y, I, M, P
	c-myc	11	1.2	N-Term, C-Term	IgG	Yes	Yes (free c-myc epitope)	B, Y, I, M, P
Protein–protein interactions	Biotin	~20–100	~2–11	N-Term, C-Term	Modified avidin or streptavidin	Yes	Yes (20 mM Biotin)	B, I, M
	Calmodulin-binding peptide	26	3	N-Term, C-Term	Calmodulin	Yes (+Ca^{2+})	Yes (+EGTA)	B
	Strep-tag II	8	1.1	N-Term, C-Term, Internal	Strep-tactin	Yes	Yes (desthiobiotin)	B, Y, I, M, P
	Streptavidin-binding peptide	38	4	C-Term	Streptavidin	Yes	Yes (biotin)	B
	Thioredoxin	109	11.7	N-Term, C-Term	Phenylarsine oxide-agarose	Yes	Yes (β-mercaptoethanol)	B
	His-patch thioredoxin	109	11.7	N-Term, C-Term	Metal chelate	Yes or no	Yes (Imidazole) or No (Low pH)	B
	S-tag	15	1.8	N-Term, C-Term	S-protein	Yes	Yes (2 M Sodium Thiocyanate)	B, I, M

[a] B = bacteria; Y = yeast; I = insect; M = mammalian; P = plant.

subcellular localization of gene products, determination of protein topology, cellular trafficking studies, and the investigation of protein–protein interactions. They are also important in protein purification and immobilization.

Antibody-binding partners are covalently coupled to agarose chromatography resins or magnetic glass beads. Immobilized antibodies tend to be less stable than many other affinity-binding partners due to their need for native structure. Elution under mild native conditions can be achieved by competitive displacement with free epitope, by proteolysis, or by exposure of the Ca^{2+} dependent FLAG-tag to EDTA.

Protein–Protein Interaction Affinity Tags

Several high-affinity and high-specificity protein–protein interactions identified in biological systems have been adapted for use as affinity tags. *In vivo* biotinylation enzymatically couples biotin, a small molecule vitamin, to a protein acceptor domain. The resulting modified protein provides an interesting example of a natural affinity tag. A number of well-characterized protein sequences are enzymatically biotinylated *in vivo*. These natural peptides of approximately 100 residues have been used as fusion tags that direct *in vivo* biotinylation of a fusion protein in a site-specific manner. Additionally, shorter synthetic peptides (approximately 20 residues) known as biotin acceptor peptides (BAPs) have been developed for use as biotin affinity tags.

The high-affinity, specific interaction between biotin and either avidin or streptavidin ($K_D \sim 10^{-15}$ M) serves as the basis for immobilization. Biotin-tagged fusion proteins are typically captured by binding to monomeric avidin or streptavidin coupled to a chromatography matrix or other surface. Elution with free biotin requires harsh conditions that can be detrimental to the target protein, but proteolytic elution can be carried out under mild conditions. Alternatively, the biotin-tag fusion can be immobilized to modified forms of avidin or streptavidin that exhibit lower biotin affinity. Elution can then be conducted under nondenaturing conditions by competitive displacement with free biotin or alkaline pH.

Other examples of protein–protein affinity tags include the Strep-tag, the calmodulin-binding peptide (CalBP), and the S-tag. The Strep-tag is a nine amino acid peptide that was developed as an artificial ligand for streptavidin. Further refinements to these molecules yielded the eight amino acid peptide Strep-tag II and a mutant form of streptavidin called Strep-Tactin capable of moderate-affinity binding ($K_D \sim 1$ μM). Strep-tag fusion proteins are bound to streptavidin under physiological conditions and are efficiently displaced by free biotin or a biotin derivative. The mild conditions used for binding and elution enable Strep-fusions to be utilized in their native state. This small, stable, and nonperturbing tag is ideal for many applications in which a small tag is required, and for applications where detection of the fusion protein on a Western blot or by ELISA is desired. Moreover, since the Strep-tag is not itself a metalloprotein and its elution does not require metal chelators, it is well suited for metalloprotein applications.

The 26 amino acid calmodulin-binding peptide (CalBP) was derived from the C-terminus of skeletal muscle light-chain kinase. The CalBP binds to calmodulin with high affinity ($K_D \sim 1$ nM) in the presence of low $CaCl_2$ concentrations (≥ 0.2 mM). The binding partner, calmodulin, is commercially available linked to chromatography resins that are used to immobilize CalBP fusions. CalBP fusion proteins are eluted under mild conditions by a Ca^{2+} chelating agent such as EGTA. CalBP fusions are primarily expressed in *E. coli* that lacks calmodulin family members and thus possesses no sequences evolved to bind to calmodulin. Eukaryotic cells are not recommended for expression of CalBP-tagged proteins due to their large number of endogenous proteins (approximately 30) that bind to calmodulin.

The S-tag protein fusion system consists of the S-peptide and its binding partner the S-protein, both derived from RNAase A. The S-tag binds to the S-protein with moderate affinity ($K_D \sim 100$ nM), resulting in a strong interaction that is influenced by pH, temperature, and ionic strength. A unique feature of the S-tag system is that ribonucleolytic activity is restored when the S-peptide is bound to the 103 amino acid S-protein. This enzymatic activity is exploited to measure the molar concentration of the S-tag fusion protein down to 20 fM in a highly sensitive and rapid assay. S-protein-based reagents have been developed to probe SDS-PAGE blots for S-tag fusions employing colorimetric or chemiluminescent detection of the target protein down to nanogram quantities.

Glossary

epitope tag Short polypeptide fused to a protein of interest so that it will be recognized as a high-affinity binding target by a specific, well-characterized antibody.

fusion protein Polypeptide made from a recombinant gene consisting of two or more gene fragments fused together.

immobilized metal-affinity chromatography (IMAC) A type of affinity chromatography based on the specific interaction between a metal chelate stationary phase and a metal-binding peptide fused to a protein of interest.

Biography

Joseph J. Falke is Professor of Chemistry and Biochemistry, and Chair of the Molecular Biophysics Program, at the University of Colorado, Boulder. His research interests are in the area of signal transduction, in particular the mechanisms of cellular chemotaxis pathways in bacterial and eukaryotic systems. He holds a Ph.D. in chemistry from the California Institute of Technology and carried out his postdoctoral research at the University of California, Berkeley. His laboratory has made fundamental discoveries regarding the molecular mechanisms of receptors and signaling proteins involved in chemical sensing.

John A. Corbin is a Postdoctoral Fellow in the Falke Laboratory at the University of Colorado, Boulder. He holds a Ph.D. in biology from the University of California, Santa Cruz. His research interests are in the general areas of protein structure, function, and mechanism.

A-Kinase Anchoring Proteins

Lorene K. Langeberg and John D. Scott
Howard Hughes Medical Institute, Vollum Institute, Oregon Health and Sciences University, Portland, Oregon, USA

The precise transmission of information from a plasma membrane receptor to the downstream target inside the cell is essential for the control of dynamic cellular functions. It has been proposed that the coordination of signaling pathways inside cells is achieved, in part, by the localization of signaling enzymes such as kinases and phosphatases near their intended protein substrates. The organization of these enzymes into signaling scaffolds facilitates the phosphorylation state of specific proteins at appropriate time and place.

Protein Phosphorylation

Protein phosphorylation is a predominant form of covalent modification of proteins inside cells. This bidirectional process, catalysed by protein kinases and reversed by phosphoprotein phosphatases, provides a flexible means of influencing the proteins that control cellular metabolism, transcription, division, and movement. The utility of this regulatory mechanism is underscored by evidence that ~30% of intracellular proteins are phosphoproteins.

Protein Kinase A

One well-studied "protein phosphorylation pathway" is regulated by the second messenger cAMP. When extracellular messengers bind to heptahelical receptors on the surface of the cell and recruit heterotrimeric G proteins to activate adenylyl cyclases on the inner face of the plasma membrane cAMP synthesis is triggered. This newly synthesized "second messenger" then diffuses to its sites of action. Although cAMP can modulate a few classes of signaling molecules, the predominant intracellular receptors are cAMP dependent protein kinases (PKA). The PKA holoenzyme is composed of two catalytic (C) subunits that are held in an inactive state by association with a regulatory (R) subunit dimer. The C subunits are expressed from three genes; Cα, Cβ, and Cγ, whereas the R subunits are transcribed from four genes; RIα, RIβ, RIIα, and RIIβ. The type I PKA (composed of RI dimers) is predominantly cytoplasmic and is most highly expressed in the immune system, whereas type II PKA (composed of RII dimers) associates with cellular structures and organelles and is abundant in the heart and brain.

Phosphorylation Specificity

One unresolved issue in cAMP signaling is the question of how this commonly used pathway is able to selectively regulate so many different cellular processes. For that reason, the mechanism by which PKA discriminates among its substrates is a topic of considerable interest. One hypothesis proposes that specific pools of the kinase are compartmentalized within the cell and are activated in close proximity to particular substrates. This can only occur if there is a means to both (1) selectively control the level of subcellular pools of cAMP and (2) maintain PKA in these environments. It has been proposed that a balance between adenylyl cyclase and phosphodiesterase activities leads to the establishment of intracellular gradients of cAMP. An equally important component of this model requires "scaffolding" proteins called "A-kinase anchoring proteins" that keep the kinase in close proximity to its substrates. This article will discuss the compartmentalization of the protein kinase A and other enzymes through their association with A-kinase anchoring proteins (AKAPs).

The PKA Anchoring Hypothesis

The first AKAPs that were identified remained tightly associated with the type II R subunits during purification from tissues and were therefore designated "RII-binding proteins". Over 30 AKAPs have now been identified and are recognized as a family of diverse proteins that are classified on the basis of their interaction with the PKA inside cells. It has also become apparent that most AKAPs share some other common properties (Figure 1). These include a common R subunit binding sequence (Figure 1A), localization regions that target the PKA/AKAP complex to precise intracellular environments (Figure 1B) and binding sites for other enzymes to form

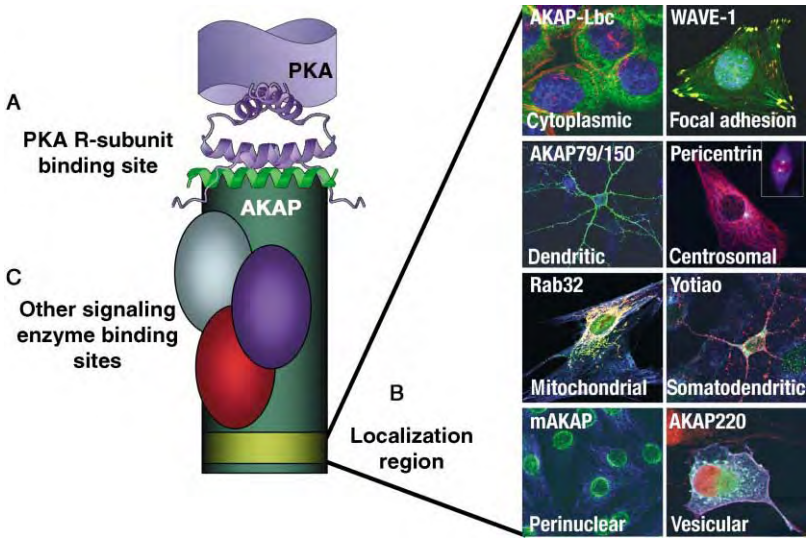

FIGURE 1 Properties of A-kinase anchoring proteins. (A) A common identifying characteristic of AKAPs is a protein–protein interaction site that binds to protein kinase A. The amphipathic helix of the AKAP (green) tightly associates with the regulatory subunit amino terminal dimer of PKA (purple). (B) The localization region of the AKAP (yellow) is responsible for the precise subcellular targeting of the scaffold. Here we show the subcellular staining pattern for eight different AKAPs (in green, or yellow and white when colocalized with other stained proteins) found at distinct locations within the cell. (C) Multiple signaling enzymes associate with an AKAP via protein–protein interactions, nucleating a unique signaling complex for efficient signal transmission.

signaling complexes (Figure 1C). Each property is discussed here.

Protein Kinase A Binding

RII Subunit Binding Sequences

Most AKAPs contain a short sequence that forms a binding site for the R subunit dimmer and was first recognized in the human thyroid anchoring protein, AKAP-Lbc. The region likely forms an amphipathic helix that slots into a binding pocket formed by the amino terminal regions of RII. This view is supported by evidence that a 24-amino acid peptide encompassing this region, called Ht31, binds RII with low nanomolar affinity. Cellular delivery of this peptide antagonizes PKA anchoring and has become a standard means to delineate a role for AKAPs in the coordination of cAMP-responsive events. Recently, a new and improved anchoring inhibitor peptide has been developed from a comprehensive analysis of 10 AKAP sequences. This 17-amino acid peptide, called "AKAP-is", selectively binds RII with subnanomolar affinity, efficiently disrupts PKA anchoring inside cells, and functions to block cAMP signaling to glutamate receptor ion channels in cells.

RI Subunit Binding

Although most AKAPs associate with the type II PKA, it is now clear that some anchoring proteins also target the type I kinase. Yeast two-hybrid screening and affinity purification techniques have identified anchoring proteins that can interact with either RI or RII (designated dual function AKAPs) and, in a few instances, RI selective AKAPs have been reported. Apparently, RI anchoring also proceeds through an amphipathic helix although other determinants may contribute to the compartmentalization of the type I PKA holoenzyme. Recently, a single nucleotide polymorphism (SNP) that causes a valine to isoleucine mutation in the anchoring helix of D-AKAP-2 has been shown to increase RI-binding affinity threefold. Although the functional ramifications of this valine to isoleucine change are unclear it is more prevalent in the aging population. Detailed structural analyses will be necessary to define the differences between type I and type II PKA anchoring.

Anchoring Protein Targeting Regions

While protein–protein interactions are responsible for the precise orientation of the kinase toward its substrates, it appears that protein–lipid interactions target the AKAP–PKA complex to the correct intracellular membranes and organelles. In the brain for example, repeat sequences that bind negatively charged phospholipids tether an AKAP called AKAP79/150 to the inner surface of synaptic membranes. In addition, protein–protein interactions with SAP97, an adapter protein that binds to the cytoplasmic tail of the AMPA

receptor ion channel, places the AKAP79/150-PKA complex in the vicinity of substrates. This elaborate molecular bridging facilitates the PKA phosphorylation of serine 845 in the cytoplasmic tail of GluR1. Serine 845 is an important regulatory site on the channel that is modified during chemically induced long term potentiation (LTP). The AKAP79/150 complex also includes the phosphatase PP2B which functions to dephosphorylate serine 845 leading to attenuation of GluR1 channels. In fact, peptide disruption of the PP2B-AKAP79/150 interaction prevents efficient dephosphorylation of the channel and suggests that targeting of the phosphatase with its substrate is necessary for modulation of channel activity. In a similar manner myristoylation and palmitoylation signals facilitate the protein–lipid tethering of another AKAP, AKAP15/18 in close proximity to PKA substrates such as calcium channels and sodium channels. AKAP15/18 may also be cross-linked to the α_1-subunit of the L type Ca^{2+} channel via a modified leucine zipper motif.

There are instances where multiple AKAPs mediate PKA targeting to the same organelle. Three anchoring proteins (D-AKAP-1/AKAP149, D-AKAP-2, and Rab32) anchor PKA at mitochondria, two AKAPs (AKAP350-450/CG-NAP and pericentrin) tether the kinase to centrosomes whereas Ezrin, WAVE-1 and AKAP-Lbc tether PKA to distinct areas of the actin cytoskeleton. One explanation for these apparent redundancies may be the need to always maintain an anchored pool of PKA at certain sites. Alternatively, each compartment specific AKAP may direct the kinase to different microenvironments where specific substrates reside. Thus, compartmentalization of PKA is likely to be a more finely organized process than was initially appreciated.

Scaffolding Complexes

Multiple Enzyme Pathways

Perhaps the most important feature of AKAPs is their ability to simultaneously interact with several signaling proteins (Figure 1C). By localizing PKA with enzymes such as protein phosphatases, phosphodiesterases, G proteins, and other protein kinases, AKAPs provide focal points for the integration and processing of distinct intracellular signals. The notion was first proposed for the AKAP79/150 family, which maintains PKA, protein kinase C (PKC) and the phosphatase PP2B at the synaptic membrane. Subsequently, it has been shown that most, if not all, AKAPs nucleate signaling protein networks. For example, Yotiao, AKAP220, and AKAP149, tether protein phosphatase 1 to oppose the action of anchored kinases. This creates an environment where protein phosphorylation is only favored when kinase activity is sufficiently stimulated to overcome these basal dephosphorylation events. One variation on this theme occurs when signal termination enzymes that act upstream of protein kinases are recruited to AKAP signaling complexes. For example, AKAP450 and mAKAP co-localize a cAMP-metabolizing enzyme, the phosphodiesterase PDE4D3, with PKA. This creates a local environment where PDE activity reduces cAMP levels in the vicinity of the kinase. Presumably, these signaling complexes not only contribute to the formation of intracellular gradients of cAMP but also confer temporal control on PKA activation by generating pulses of kinase activity.

Parallel Signaling Pathways

Other AKAP complexes are known to participate in the parallel processing of distinct intracellular signals. In the brain WAVE-1 is a scaffolding protein that principally functions to relay signals from the plasma membrane via the small molecular weight GTPase Rac to the Arp2/3 complex, a group of seven related proteins that nucleate actin polymerization and branching to facilitate remodeling events in the cytoskeleton. However, WAVE-1 also anchors PKA and binds to the Abelson tyrosine kinase (Abl). Proteomic approaches have identified additional binding partners that are positive and negative regulators of WAVE-1 function and substrates for either kinase. Thus WAVE-1 is capable of recruiting different combinations of signaling enzymes to the neuronal cytoskeleton for control of distinct protein phosphorylation and actin-remodeling events. This multifaceted role is reflected in the complex phenotype of WAVE-1 knockout mice which exhibit abnormalities in their brain morphology as well as behavioral defects that may be linked to altered signaling in the cerebellum or hippocampus.

Alternatively Spliced Scaffolds

The AKAP350/450/CG-NAP/Yotiao family arise from alternative splicing of a single gene on chromosome 7q21. At least four anchoring proteins that are targeted to three distinct subcellular locations are transcribed from this gene. Initially a cDNA was isolated that encodes a 350 kDa protein believed to be a high molecular weight AKAP previously identified in centrosomal fractions. Around the same time variants encoding AKAP450 and CG-NAP were identified. The latter protein was named CG-NAP on the basis of its detection in centrosomal and Golgi fractions. Detailed analysis of CG-NAP has identified additional binding partners that include protein phosphatase 2A, the Rho-dependent-protein kinase PKN and the protein kinase C epsilon isoform. Functional studies propose that enzymes in this signaling complex may participate in membrane trafficking, microtubule nucleation and/or cell cycle progression.

Yotiao, the shortest splice variant in this family is targeted to synaptic sites where it anchors PKA and the type 1 protein phosphatase PP1 to regulate the phosphorylation state of NMDA receptor ion channels. Tonic PP1 activity negatively regulates NMDA receptors by favoring the dephosphorylated state. However, upon PKA activation the PP1 activity is overcome and the channel is phosphorylated resulting in increased NMDA receptor currents. More recently a requirement for yotiao targeting of PKA and PP1 to GABA(A) receptors at inhibitory synapses has been demonstrated in the dopaminergic regulation of cognitive processes. Thus, AKAP350/450, CG-NAP and yotiao organize PKA and a plethora of signaling enzymes in a variety of subcellular locations. Transcriptional regulation is undoubtedly a critical determinant for location and composition of each signaling complex maintained by these AKAP gene products.

Understanding the Function of Scaffolds

An emerging area of investigation is the genetic manipulation of AKAPs. Although several anchoring proteins have been identified in genetically tractable organisms including *C. elegans*, *D. melanogaster*, and *D. rerio* (zebrafish) the most significant advances have come from the characterization of genetically modified mice. Genetic disruption of the MAP2 gene causes a redistribution of the PKA holoenzyme in neurons that limits certain cAMP responsive phosphorylation events and causes reduction in dendrite length. In a similar manner disruption of the WAVE-1 gene has apparent effects on brain morphology and effects complex neuronal behaviors including coordination, balance, learning, and memory. These observations complement previous evidence that ablation of PKA subunit genes alters hippocampal-based forms of learning and memory.

Traditionally, these anchoring molecules were thought to exclusively control cAMP responsive events. However AKAP-mediated compartmentalization of other signaling enzymes may be an equally important function. Recent reports have implicated AKAP350/CG-NAP, AKAP220 and WAVE-1 networks in the control of Rho kinase signaling, glycogen synthase kinase 3 action and Rac mediated actin remodeling respectively. As the detailed dissection of these AKAP signaling complexes progresses it seems probable that their role in the coordination of both cAMP dependent and independent signaling events will become more evident.

Glossary

cytoskeleton The complex network of actin microtubules and microfilaments in the cytoplasm that provide structure to the cytoplasm of the cell and plays an important role in cell movement and maintaining the characteristic shape of the cells.

phosphorylation/dephosphorylation The activation of an enzyme by the addition of a phosphate group to the enzyme or the inactivation of an enzyme by the removal of a phosphate group from the enzyme.

protein kinase The enzyme that catalyzes the transfer of phosphate from ATP to the hydroxyl side chains of a protein causing changes in the function of the protein.

protein phosphatase An enzyme that catalyzes the removal of phosphate from a phosphorylated protein, thereby causing changes in the function of the protein.

receptor Proteins located either on the cell surface or within the cytoplasm that bind ligand, initiating signal transduction and cellular activity.

scaffold A protein that serves as a platform to bring together a unique assortment of signaling enzymes for the efficient transmission of intracellular messages.

In 1990 he joined the faculty at the Vollum Institute at Oregon Health and Science University where he is now a Senior Scientist and an Investigator with the Howard Hughes Medical Institute.

Allosteric Regulation

Barry S. Cooperman
University of Pennsylvania, Philadelphia, Pennsylvania, USA

Allosteric regulation refers to the process for modulating the activity of a protein by the binding of a ligand, called an effector, to a site topographically distinct from the site of the protein, called the "active site," in which the activity characterizing the protein is carried out, whether catalytic (in the case of enzymes) or binding (in the case of receptors) in nature. The word allosteric, Greek for "other site," was coined to emphasize this distinctness. The modulation of protein activity is accomplished by the reversible alteration of the protein conformation that accompanies effector binding. Effectors that increase activity are called activators, while those that decrease activity are called inhibitors. For the purposes of this article we will use the term substrate to indicate a ligand bound to the active site of either an enzyme or a receptor that undergoes the characteristic activity of the protein.

Allosterism and Cooperativity

Allosteric regulation has been found to be extensive in proteins, particularly in enzymes at key branch points of metabolism and in receptors that must be sensitive to small variation in signals. Although a monomeric protein having one subunit can display allosteric regulation, the great majority of proteins regulated in this manner have multiple subunits, with changes in activity arising from changes in subunit–subunit contacts. A characteristic feature of these regulatory proteins is the occurrence of cooperative interactions for both the substrate and the regulatory ligand. This property renders their function dependent upon threshold concentrations of ligand.

Cooperative Binding of O_2 to Hemoglobin

Cooperativity may be defined as any process in which an initial event affects subsequent similar events. It was initially identified with the sigmoid plot for the binding of four molecules of O_2 to hemoglobin (Hb) (Figure 1), a pseudotetrameric protein that gives red blood cells their color. A similar cooperativity of substrate binding occurs in many allosteric enzymes, leading to sigmoid plots of enzyme activity versus substrate concentration. Hb has the subunit composition $\alpha_2\beta_2$, in which the α- and β-subunits are nearly identical to one another, with each containing a heme group to which O_2 binds. The sigmoid plot was explained by the concept that the first molecule of O_2 bound makes it easier for subsequent molecules to bind, and so is an example of positive cooperativity. In fact, if the Hb-binding curve is fitted to four successive binding constants, the affinity for the fourth O_2 bound is calculated to be 100–1000 times as high as the first O_2 bound. In contrast, O_2 binding to myoglobin (Mb), a monomeric protein found in vertebrate muscle with no possibility for site-site interaction, follows a rectangular hyperbola plot.

An essential feature of the positive cooperativity, shown in Figure 1 for Hb, is that it sharpens the responsiveness of a system to a change in substrate (or effector) concentration. Thus, to go from 10% to 90%, O_2 saturation of Mb requires an 81-fold change in O_2 concentration, whereas the corresponding change for O_2 saturation of Hb requires only a fourfold change. Such responsiveness is obviously desirable in a protein whose activity must be highly regulated.

The Hill *n*, a Measure of Cooperativity

The Hill plot linearizes saturation data over the major portion of the saturation curve (typically 10–90% saturation) yielding a slope, called the Hill n and denoted n_H, which provides a convenient empirical measure of cooperativity. If we define the saturation function Y_S as the fraction of all binding sites containing a bound ligand (i.e., $0 \leq Y_S \leq 1$) then the Hill plot is obtained by plotting $\log(Y_S/(1 - Y_S))$ versus $\log [S]$ (when enzyme activity is measured, $\log(v/(V_{max} - v))$ versus $\log [S]$ is plotted instead). The value of n_H is one for a noncooperative saturation function (e.g., O_2 binding to Mb). Positive cooperativity is defined by an $n_H > 1$, with an upper limit of n, the number of identical subunits, for a cooperative saturation function. For a tetramer, an n_H equal to its upper limit of 4 would correspond to the situation where there were only two protein species in solution, one with no ligands bound

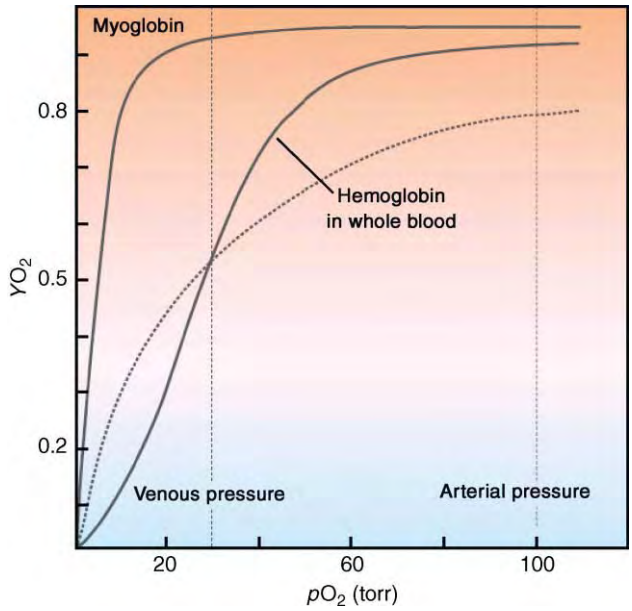

FIGURE 1 The O_2 binding curves for Hb (cooperative) and Mb (noncooperative). The dashed line represents a noncooperative curve for O_2 binding having the same value as Hb for the O_2 pressure (pO_2) required for half-saturation ($YO_2 = 0.5$). Adapted from Voet, D., Voet J. G., and Pratt, C. W. (2002) *Fundamentals of Biochemistry*. Wiley, New York.

and with ligands bound to all four sites. For Hb, a strongly cooperative tetramer, the n_H value is near 3 under physiological conditions. Some allosteric proteins have $n_H < 1$, i.e., have negative cooperativity. In contrast to positive cooperativity, negative cooperativity gives a less sensitive response over a broad range of stimulus and might be important, for example, in the response of growth or general metabolism to changes in hormone concentration.

One caveat to the use of n_H values evaluated from enzyme activity studies is that hysteresis or ligand-induced slow transitions that have the same timescale as the catalytic cycle can give rise to apparent cooperativity, even for monomeric enzymes. In addition, n_H values of < 1, whether determined by binding or enzyme activity studies, can arise from sample heterogeneity, rather than from true negative cooperativity.

Two-State Models to Explain Cooperativity in Allosteric Proteins

Two models were proposed in the 1960s to explain not only the cooperative binding of O_2 to Hb, and of substrate binding to allosteric proteins in general, but also the effects of allosteric effector molecules on substrate binding. Each of the models posits that the identical subunits within the protein can exist in two states, T and R, with the R state having higher activity for substrate. Here some definitions are in order before proceeding further. O_2 binding to hemoglobin is an example of a "positive homotropic effect," since the initial binding of O_2 increases the affinity for subsequent O_2 molecules. On the other hand, addition of the allosteric inhibitor 2,3-diphosphoglycerate reduces O_2 affinity for Hb, providing an example of a "negative heterotropic effect." In a similar fashion, an allosteric activator which increases substrate affinity gives rise to a positive heterotropic effect, whereas a negative homotropic effect is seen when initial binding of substrate decreases the affinity for subsequent substrate molecules.

The first model, proposed by Monod, Wyman, and Changeux in 1965, and known as the MWC (or symmetry) model hypothesizes that: (1) allosteric regulatory proteins, in general, are oligomers made up of a finite number of identical subunits that occupy equivalent positions and, as a consequence, possess at least one axis of rotational symmetry; (2) the allosteric oligomers can exist in two freely interconvertible and discrete conformational states (T or R) that differ in the energy of their intersubunit interactions, but in which molecular symmetry is conserved, so that all subunits are either in the T state or the R state; (3) in the absence of ligand, the pre-existing conformational equilibrium is characterized by an allosteric constant $L = (T_n)/(R_n)$, where n is equal to the number of identical subunits; and (4) ligand affinities for the active and allosteric sites carried by the oligomers may differ between the two states, allowing ligand binding to preferentially stabilize the state for which it exhibits a higher affinity. Such modulation of the conformational equilibrium by ligand binding suffices to generate positive homotropic effects and both positive and negative heterotropic effects.

The second model, proposed by Koshland, Nemethy, and Filmer in 1966, and known as the KNF (or sequential) model, hypothesizes that in the absence of ligand the protein exists in a single state, that ligand binding induces a conformational change only in the subunit to which it binds, and that cooperative interactions arise through the influence of such conformational changes on intersubunit interaction. The KNF model embodies the notion of "induced fit," whereby the binding of substrate to an active site causes conformational changes of active site residues that are necessary for the protein's function. Since conformational change only occurs on ligand binding, partially saturated protein contains a mixture of R and T states, so that the symmetry of the oligomeric protein is not preserved during the binding process.

Both the MWC and KNF models are limiting cases of the more general scheme of a two-state model, as shown for the case of substrate binding to a tetrameric protein in Figure 2. In the MWC model only species corresponding to the left-most ($T_nS_i, i = 0 - n$) and right-most

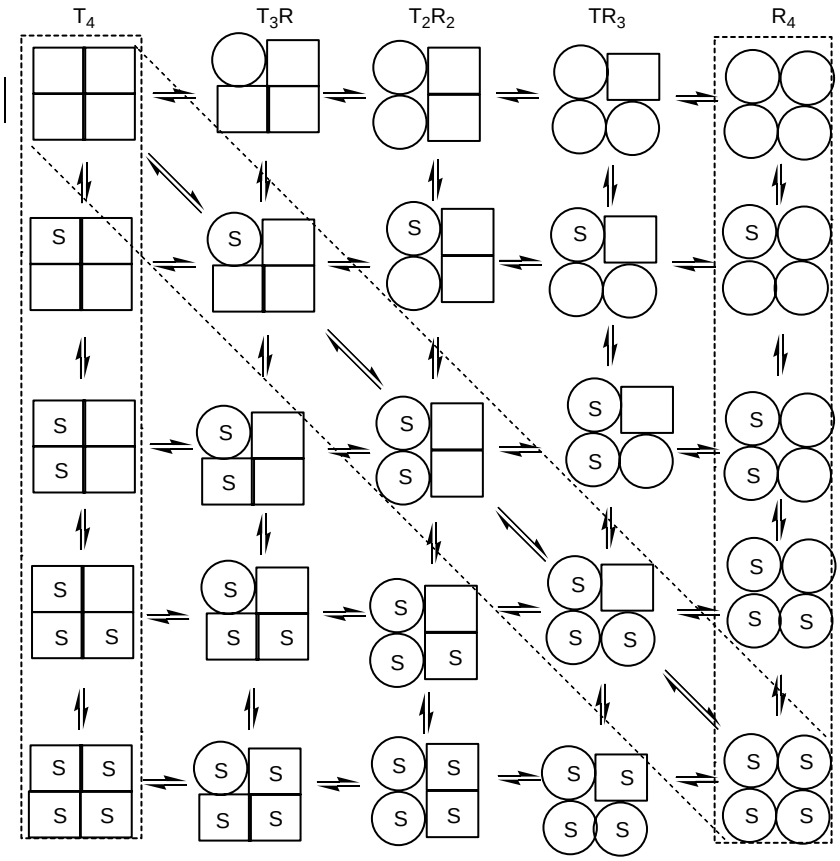

FIGURE 2 The general two-state model for substrate binding to an allosteric tetrameric protein. The columns on the left and right show the species included in the MWC model. The diagonal from upper left to lower right shows the species included in the KNF model.

($R_nS_i, i = 0 - n$) columns are considered, because it is posited that hybrid states containing both R- and T-subunits are inherently unstable and do not accumulate. In contrast, in the KNF model only species lying along the diagonal connecting T_n to R_nS_n (i.e., $T_{n-i}R_iS_i, i = 0 - n$) are considered, because of the requirement that conformational change only results from substrate binding.

Either limiting model generates the sigmoidal saturation curve for substrate binding to an allosteric protein using just three parameters. For the MWC model these are L, the allosteric constant, and K_T and K_R, the dissociation constants for S binding to the T and R states, respectively. In the KNF model the three parameters are K_SK_t (as a product), K_{RT}, and K_{RR}, where K_S is the binding constant for substrate to the R state, K_t is the equilibrium constant for changing a single, isolated, subunit from the T to the R conformation (= [R]/[T]) and K_{RT} and K_{RR} measure the relative strength of associations of $R-T$ and $R-R$ intersubunit contacts, respectively, versus the strength of association of $T-T$ intersubunit contact. In the two models, allosteric effectors exert their heterotropic effects by altering the apparent conformational equilibrium constant (L' or K_t') in each model, with inhibitors, which bind T state preferentially, increasing L' or decreasing K_t' and activators, which bind R state preferentially, decreasing L' or increasing K_t'.

Because of their relative simplicities, both the MWC and KNF models provide useful frameworks for the analysis of allosteric proteins, although, in detail, each enzyme studied may show deviations. In some cases one model may be preferred over the other. Thus, the MWC model does not account for negative homotropic effects ($n_H < 1$), whereas such effects can arise in the KNF model when K_{RT} is substantially greater than either K_{TT} or K_{RR}. On the other hand, the MWC predicts that the state function R, which measures the fraction of all subunits in the R state, will, in general, increase more rapidly as a function of substrate concentration than the saturation function Y_S, since the binding of one substrate molecule can shift all the subunits in T_n to the R_n conformation. In contrast, the KNF model demands that R is always equal to Y_S. Experimental examples have been found for both negative homotropic cooperativity and for $R \neq Y_S$. Detailed examination of structural or energetic changes on partial ligand binding have been used to differentiate between the two models.

Extensions and Modifications of Two-State Models

When ligand binding induces a change in the oligomeric state of the protein, cooperativity can result as a direct consequence of ligand binding preferentially to either the associated or dissociated form. If, for example, substrate binding favors a higher state of oligomerization, then higher enzyme concentrations will enhance activity but depress cooperativity, and, at constant enzyme concentration, allosteric ligands that favor association will be activators while those that favor dissociation will be inhibitors. The equations to account for this type of behavior are similar in form to those generated by either the MWC or KNF models, but with the addition of terms that are dependent on protein concentration.

Thus far, we have considered allosteric proteins in which the substrate and effector molecules have different affinities for the *R* and *T* states. These are the so-called *K* (binding constant) systems. In pure *K* allosteric enzymes, the *T* and *R* states have identical V_{max} values. However, allosteric enzymes can also be regulated by *V* (velocity) systems. In pure *V* allosteric enzymes, the *R* and *T* states have identical affinity for substrate but different V_{max} values. In both *K* and *V* enzymes an effector functions by binding preferentially to the *R* or *T* state. For *K* systems, such binding results in altered affinity and cooperativity of substrate binding. In *V* sytems, effector binding results in altered V_{max} values, and there is no cooperativity in substrate binding.

Structures of Allosteric Proteins

High-resolution structures have been determined for a number of allosteric enzymes in both the *R* and *T* states, permitting some generalizations to be made and allowing critical consideration of the MWC and KNF models. One common finding is that ligand-binding sites, both active site and regulatory, are located at subunit interfaces. Such placement provides an exquisite means of communicating cooperative and/or allosteric effects between subunits in an oligomeric enzyme, since sites at the interface are likely to respond to the changes in subunit interactions that are critical for allosteric regulation. For similar reasons, a second common location for ligand binding is at the interface of two domains within same subunit. Placement of the active site at either interface has as a consequence that even modest conformational changes can cause significant changes in the size and shape of the active site, thus altering the protein's activity. Allosteric binding sites also tend to be located in low-stability regions of the protein. The binding of an effector stabilizes both the region itself and specific contacts the region makes with adjacent regions, requiring the movements of polypeptide backbone and side chains, and, in particular, the alteration of salt bridges and hydrogen bonds at subunit interfaces. These movements provide a mechanism for transmission of signals to the active site and to other allosteric sites over distances of tens of angstroms. Other common features are: (1) small but critical movements at the active site; (2) the rotation of subunits with respect to one another around a cyclic axis; (3) only two modes of subunit:subunit docking, consistent with the MWC model of concerted transition; and (4) a more highly constrained and extensive subunit interface in the less active *T*-state than in the *R*-state.

Examples of Allosteric Proteins Other than Hemoglobin

Aspartate Transcarbamoylase (ATCase)

ATCase catalyzes a key step of pyrimidine biosynthesis, the condensation of carbamoyl phosphate with aspartate to form N-carbamoylaspartate. The *Escherichia coli* enzyme has been extensively studied. CTP is an allosteric inhibitor representing a classic case of feedback inhibition whereby the end product of a biosynthetic pathway inhibits an enzyme catalyzing a reaction at the beginning of the pathway. ATP is an allosteric activator, and together CTP and ATP act on ATCase to coordinate the rates of purine and pyrimidine nucleotide biosynthesis. The enzyme has the subunit composition c_6r_6, where *c* and *r* are catalytic and regulatory subunits, respectively. The *c* subunits are arranged as two c_3 s, which are complexed with three r_2 s. In the absence of *r* subunits, the *c* subunits are catalytically active, and are unaffected by ATP or CTP, which bind only to the *r* subunit. Crystal structures have shown that the c_6r_6 holoenzyme exists in two conformations, with CTP preferentially binding to the inactive *T*-state and ATP to the active *R*-state. Interestingly, ATP and CTP bind competitively to the same allosteric site in the *r* subunit. CTP binding induces a contraction in r_2, which in turn, via interactions at the $r-c$ interface, results in the c_3 s moving together by 0.5Å. This movement causes a perturbation of the active site and a loss in catalytic activity. In contrast, ATP binding results in the c_3 s moving apart by 0.4Å.

Ribonucleotide Reductase (RR)

RRs form a family of allosterically regulated enzymes that catalyze the conversion of ribonucleotides to deoxyribonucleotides and are essential for *de novo* DNA biosynthesis. Their allosteric regulation is designed to match the flux of the four deoxynucleotides produced with the base composition of the organism's DNA.

Class Ia RRs are the most widespread in nature. They accept the four common nucleoside diphosphates (NDPs) as substrates, with enzymatic activity dependent upon the formation of a heterocomplex between subunit R1, which contains the active site and three allosteric sites (the s-, a-, and h-sites), and subunit R2, which contains a stable tyrosyl-free radical that is necessary for NDP reduction at the active site. The substrate specificity of RR is determined by the allosteric ligand occupying the s-site. ATP and dATP stimulate the reduction of CDP and UDP, dTTP stimulates the reduction of GDP and dGTP stimulates the reduction of ADP. The s-site is located at the interface between R1 monomers, such that effector binding drives formation of $R1_2$. The regulation of total enzyme activity is controlled by ATP and dATP, chiefly at the level of changes in oligomerization state. Both bind to the a-site, located at the interface between two $R1_2$ s, driving formation of $R1_4$, which exists in two conformations, $R1_{4a}$ and $R1_{4b}$, with the latter predominating at equilibrium, while only ATP binds to the h-site, which drives formation of $R1_6$. Only the $R2_2$ complexes of $R1_2$, $R1_{4a}$, and $R1_6$ are enzymatically active. dATP is a universal inhibitor of RR activity due to its induction of $R1_{4b}$ formation whereas ATP is a universal activator because it induces $R1_6$ formation. Class II RRs, which are only found in bacteria, are considerably simpler, comprising only a monomeric protein containing an active site, an s-site and a B_{12} cofactor. Interestingly, the active site and s-site have the same relative orientations as in Class Ia, with the s-site located at an interdomain interface.

GroEL

E. coli GroEL is an example of a chaperonin, which mediates protein folding in an MgATP-dependent manner. GroEL consists of 14 identical subunits that form two heptameric rings. Cooperativity in ATP binding and hydrolysis by chaperonins reflects the switching of rings between protein-binding and protein-release states and is important for regulation of their reaction cycle. GroEL displays two levels of allostery: one within each ring and the second between the two rings. In the first level of allostery, each heptameric ring is in equilibrium between T and R states that interconvert in a concerted manner, in accordance with the MWC model. In the absence of ligands, GroEL is predominantly in the T_7T_7 state. In the presence of low concentrations of ATP ($<100\ \mu$M), the equilibrium is shifted toward the T_7R_7 state, displaying positive cooperativity in ATP binding and hydrolysis. A further shift in the equilibrium from the T_7R_7 state to the R_7R_7 state ($L2 = [RR]/[TR]$) takes place only at higher ATP concentrations because of inter-ring negative cooperativity. This second level of allostery is better described by the KNF model.

Cell-Surface Receptors Involved in Signal Transduction

Membrane receptors for transmitters, peptides, and pharmacological agents are central to signal transduction. They selectively recognize chemical effectors (neuronal or hormonal) and allosterically transduce binding recognition into biological action though the activation of ligand-gated ion channels (LGICs) and/or G-protein-coupled receptors (GPCRs). Various features of membrane receptors for neurotransmitters are well accommodated by the MWC model. These receptor proteins are typically heterooligomers and exhibit transmembrane polarity. In general, the regulatory site to which the neurotransmitter binds is exposed to the synaptic side of the membrane while the biologically active site is either a transmembrane ion channel, a G protein-binding site, or a kinase-catalytic site facing the cytoplasm. Interactions between the two classes of sites are mediated by a transmembrane allosteric transition. Signal transduction or activation is mediated by a concerted cooperative transition between a silent resting state and an active state. Agonists stabilize the active state and competitive antagonists the silent state, and partial agonists may bind nonexclusively to both. These receptors can also undergo a cascade of slower, discrete allosteric transitions, which include refractory regulatory states that result in the desensitization or potentiation of the physiological response.

Glossary

allosteric effector A molecule binding to a protein site other than the active site, which can either increase or decrease the activity of the protein.

heterotropic cooperativity The effect of an allosteric effector on protein activity toward a substrate.

homotropic cooperativity The effect of initial substrate binding on subsequent substrate binding.

KNF and MWC models Thermodynamic models that account for the cooperativity displayed by allosteric enzymes.

Biography

Dr. Barry S. Cooperman is a Professor of Chemistry at the University of Pennsylvania, where he previously also served as Vice Provost for Research. His broad interests are in the fields of biological and bioorganic chemistry, with a special focus on the mechanisms of action of ribosomes, ribonucleotide reductase, and serpins, and has published numerous articles in these fields. He holds a Ph.D. from Harvard University and was a postdoctoral fellow with Jacques Monod at the Institut Pasteur.

Alternative Splicing: Regulation of Fibroblast Growth Factor Receptor (FGFR)

Mariano A. Garcia-Blanco
Duke University Medical Center, Durham, North Carolina, USA

Most stable biological programs and many dynamic biological responses rely on the quantitative and qualitative regulation of gene expression. Such regulation can be accomplished by rearranging the gene, controlling transcription of the primary RNAs, regulating the processing of these primary transcripts into mature RNA species, modulating the stability and distribution of these mature RNAs, and finally, in some cases, manipulating the synthesis and stability of the protein products templated by messenger RNAs. Among these steps in the information flow of gene expression, this article focuses on the regulation of RNA processing and, in particular, alternative splicing. Alternative splicing is the process by which a single species of primary transcript undergoes differential removal of introns to yield different mature RNAs. Alternative splicing, which affects gene products from the majority of protein-coding genes, is likely one of the major engines of proteome diversity.

Premessenger RNA Splicing

The initial RNA products of transcription by RNA polymerase II (RNAPII), primary transcripts, are large molecules (averaging 30,000 nucleotides) that are divided into exons and introns. Exons, which usually average 300 nucleotides in length, are retained in mature RNAs, whereas introns, which average over 3000 nucleotides, are removed from the primary transcripts by RNA splicing. RNA splicing occurs in the nucleus and appears to be coupled to the synthesis of primary transcripts by RNAPII. RNA splicing is catalyzed by the spliceosome, an RNA-based macromolecular enzyme that recognizes and defines the exons and introns and precisely removes the latter and rejoins the exons (Figure 1). The definition of exons and introns is governed by conserved cis-acting elements: the 5′ splice site (also known as the donor site) demarcating the 5′-end of an intron and the 3′ splice site (also known as the acceptor site), a tripartite element marking the 3′-end of an intron. It should be noted that although the definition focuses on introns, all internal exons (e.g., exon M in Figure 1D) are defined by a 3′- splice site upstream and a 5′- splice site downstream.

Alternative Splicing

There are four types of alternative splicing events in which splice site choice solely determines the sequence of mature RNAs (Figures 1A–D). In rare cases, an intron is removed or retained to give two very different RNAs (A). The use of two or more alternative 5′ splice sites (B) or 3′ splice sites (C) can lead to RNA isoforms. Finally, inclusion or skipping of one or more exons is a common form of alternative splicing (D). In addition, alternative splicing of transcripts initiated at different transcription start sites leads to mature RNAs with different first exons (E). The 3′ terminal exons can also vary by coupling alternative splicing with alternative polyadenylation (F). This entry describes a slightly more complex form of the decision to skip or include an exon (D), which is observed among transcripts encoding the fibroblast growth factor receptor-2 (FGFR2).

Alternative Splicing of FGF-R2 Transcripts

The extracellular region of FGF-R2 has three immunoglobulin-like (Ig) domains and the third Ig domain determines ligand-binding specificity. This third domain comes in two forms, which differ only in the sequence of the C-terminal half of the domain. One form, predominant in cells of epithelial origin, is encoded by sequences within exons 7 and 8 (IIIb), while the other IgIII domain isoform, which is expressed in fibroblasts, is encoded by sequences within exons 7 and 9 (IIIc) (Figure 2). Alternative splicing of the same FGF-R2 primary transcript, via the mutually exclusive use of exons 8 (IIIb) or 9 (IIIc), leads to the production of FGF-R2

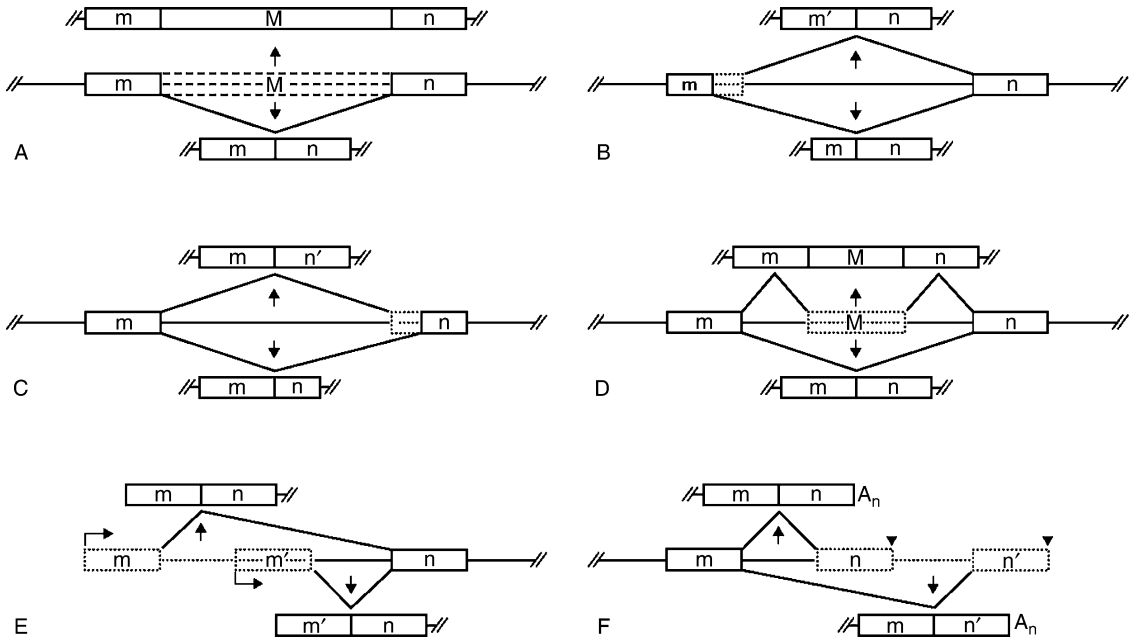

FIGURE 1 Forms of alternative splicing. (A–D) Cases in which transcript diversity is provided solely by alternative splicing. (E) A case in which alternative transcription-initiation sites coupled with alternative splicing leads to diversity of products. (F) A case in which alternative splicing and alternative 3′-end formation lead to diverse transcripts.

(IIIb) or FGF-R2 (IIIc). The importance of this alternative splicing is suggested by the following: (1) FGF-R2 (IIIb) and FGF-R2 (IIIc) bind different FGFs; (2) the expression of two isoforms is tightly regulated in different cell types; (3) the targeted disruption of exon 8 (IIIb) or exon 9 (IIIc) in transgenic animals leads to nonoverlapping defects in organogenesis and development, which are not compatible with viability; and finally (4) several genetic disorders in humans have been mapped to mutations in IgIII of FGF-R2. The regulation of the mutually exclusive use of exons IIIb or IIIc is mediated by cis-acting elements within the primary transcript and trans-acting factors, which must differ in different cell types.

Regulatory Elements and Factors

The cis-acting regulatory elements that control alternative splicing can be divided generally into four categories: exonic splicing enhancers, exonic splicing silencers, intronic activators of splicing, and intronic splicing silencers. These cis-elements mediate their function by interacting, directly or indirectly, with trans-acting activators or repressors of splicing.

Exonic Splicing Enhancers

Exonic splicing enhancers (ESEs) are cis-acting elements that activate the definition of an otherwise weak

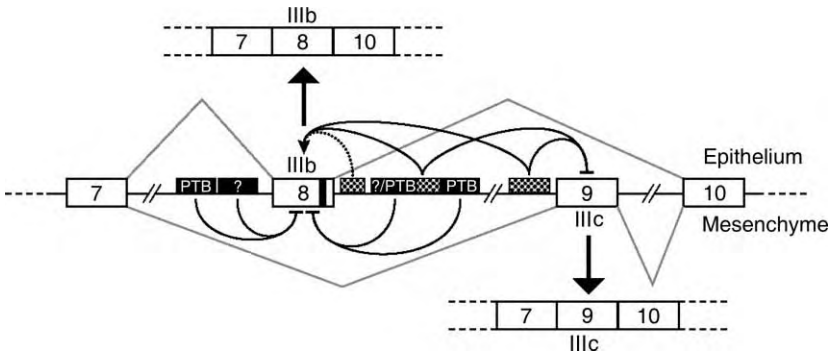

FIGURE 2 Multiple layers of combinatorial interactions result in tissue-specific alternative spliced transcripts: the example of fibroblast growth factor receptor-2. A schematic of exons 7–10 and introns 7–9 of FGF-R2 transcripts is shown indicating that in mesenchymal cells a layer of negative regulation, which includes weak splices bordering exon 8, an exonic splicing silencer (black bar in exon 8), and flanking intronic splicing silencers (black rectangles) silence exon 8 and lead to the choice of exon 9. In epithelial cells, however, a second layer of regulation combines activation of exon 8 by intronic activators of splicing (stippled rectangles) with repression of exon 9 (stippled rectangles) to ensure the use of exon 8.

exon, promoting its inclusion into mature transcripts. Several families of ESEs have been recognized, and the most common are characterized by purine-rich sequences (consensus) and mediate their action via members of the SR protein family (e.g., SC35). Although ESEs have been implicated in regulated splicing, they appear to have a role in defining many constitutive exons. The FGF-R2 IgIII alternative splicing unit does not have obvious ESEs (Figure 2).

Exonic Splicing Silencers

Exon definition can be repressed by exonic splicing silencers (ESSs). The best-characterized ESSs bind hnRNP A1, a protein originally described as an abundant heterogeneous nuclear RNA-binding protein. HnRNP A1 binding at ESSs can suppress inclusion of a weak exon, as has been noted for exon IIIb of FGF-R2 transcripts (Figure 2). HnRNP A1 and SR proteins can play counterbalancing roles in exon definition and their relative levels may determine tissue-specific alternative splicing outcomes.

Intronic Activators of Splicing

Intronic activators of splicing (IASs), which can provide constitutive or regulated enhancements of exon definition, can selectively activate weak exons. Exon IIIb definition requires IAS1, which is a long U-rich element found immediately downstream of the exon. IAS1 binds the Tia-1 (huNam8p) protein that provides ancillary activation of exon IIIb. This activation critically requires two other IASs, IAS2 and IAS3, which mediate epithelial cell-specific inclusion of the exon. Portions of IAS2 and IAS3 directly interact, forcing a double-stranded RNA stem that is required for activation (Figure 2). IAS2 and IAS3 are part of more complex elements that also mediate repression of exon IIIc in epithelial cells and are thus termed intronic splicing activators and repressors of splicing (ISARs) (Figure 2). The coordinated cell-type activation of exon IIIb and repression of exon IIIc results in the epithelial pattern of FGF-R2 splicing.

Intronic Splicing Silencers

Intronic splicing silencers (ISSs) inhibit exon definition by directly occluding cis-elements within canonical splice sites or by creating zones of silence around exons. Many times, ISSs are found flanking exons subject to silencing; this is the case for exon IIIb. Two bipartite silencers, upstream and downstream of exon IIIb, are required for repression of this exon in fibroblasts. Both ISSs mediate their action via the polypyrimidine tract binding protein (PTB), another member of the hnRNP protein family, and other unidentified factors (Figure 2). The actions of the ISSs dominate in fibroblasts; however, in epithelial cells IASs antagonize the silencers. Silencing of introns, possibly in combination with a lack of ESEs, can be important to prevent inappropriate inclusion of pseudo exons, which have canonical splice sites with proper spacing but are not used as exons. These pseudo exons can serve as silent reservoirs of genetic information.

Layers of Regulation

The alternative splicing of FGF-R2 exons IIIb and IIIc provide examples of ESSs, IAS, and ISS, and in addition reveal several general features of regulated alternative splicing units. First, regulation is mediated by the superimposition of several layers of control, starting with weakening of the canonical splice sites bordering regulated exons, followed by global silencing mediated

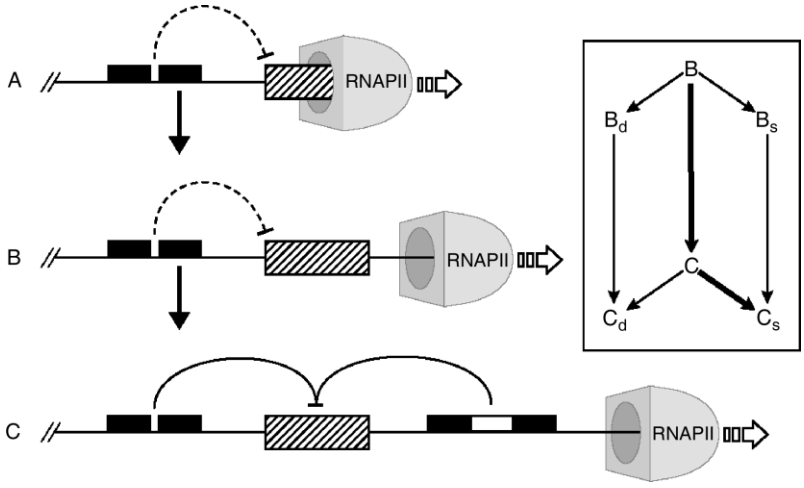

FIGURE 3 A dynamic view of exon silencing. In many exons, for example, for exon 8 (IIIb) of FGF-R2 transcripts, flanking ISSs are required for silencing. (B) During the synthesis of the transcript there is a time when the exon is fully accessible to the splicing apparatus but either is not defined or is defined reversibly. (C) Synthesis of the downstream ISS leads to full repression. The inset proposes the view that the rate of synthesis (B → C) is faster than the rate of exon definition (B → B_d).

by non-cell-type-specific ESS and ISS, and finally capped by cell-type-specific ISAR elements. Second, the layers of regulation involve antagonistic interactions between activators and repressors of exon definition. Third, each individual layer is determined by a combination of cis-elements and factors. Fourth, a general principle that is far from being understood mechanistically, regulation must be coupled with transcription of RNAPII.

A Dynamic View of Alternative Splicing

Most schematics of alternative splicing (including Figure 2) present a static splicing substrate. Although useful, this static view must give way to a more realistic representation. A dynamic representation of the silencing of exon IIIb is presented in Figure 3. This schematic focuses on the potential to define the exon, which can only proceed once the exon is synthesized and accessible to the splicing machinery (Figure 3B). Exon definition ($B \rightarrow B_d$) must be slow relative to the rate of transcript synthesis ($B \rightarrow C$). Upon the appearance of the downstream ISS full silencing can ensue (Figure 3C).

Glossary

alternative splicing The process by which a single species of primary transcript undergoes differential removal of introns to yield different mature RNAs. Alternative splicing, which affects gene products from the majority of protein-coding genes, is probably one of the major engines of proteome diversity.

exon A block of sequence within the primary transcript that is retained in the mature transcript after splicing. Internal exons average 145 nucleotides in length among protein-coding transcripts.

intron A block of sequence, which averages ~3000 nucleotides in length but can be larger than 100,000 nucleotides, that is removed during splicing.

RNA splicing One of the processes by which primary transcripts (RNAs) are converted into mature transcripts. During RNA splicing, introns are removed and exons are precisely ligated together.

Biography

Dr. Mariano A. Garcia-Blanco is Professor of Molecular Genetics and Microbiology, Professor of Medicine at Duke University Medical Center, and Co-director of the Duke Center for RNA Biology. His principal research interest is in the field of gene expression, specifically the interactions that connect transcription with pre-mRNA processing and the regulation of alternative splicing. He holds M.D. and Ph.D. from Yale University.

Alternative Splicing: Regulation of Sex Determination in *Drosophila melanogaster*

Jill K. M. Penn, Patricia Graham and Paul Schedl
Princeton University, Princeton, New Jersey, USA

Alternative splicing is a regulatory process that produces multiple mRNA transcripts from pre-mRNAs transcribed from a single gene. The net effect of alternative splicing is that diverse proteins can be manufactured from a limited amount of DNA. Often a cell contains distinct ratios of alternatively spliced mRNAs and, consequently, distinct ratios of protein isoforms. The ratio of isoforms can vary among different cell types and different stages of development. Conversely, alternative splicing can contribute to cell identity by producing tissue- or stage-specific mRNAs rather than distinct ratios. One example of this exists in *Drosophila melanogaster*, in which alternative splicing is responsible for sex-specific protein expression that functions to maintain sexual identity. Intriguingly, *Drosophila* sexual development is governed by alternative splicing at multiple levels of the regulatory hierarchy.

The Sex Determination Hierarchy in *Drosophila melanogaster*

Sexual Choice, Memory, and Differentiation

The X chromosome/autosome ratio (X/A ratio) determines the choice of sexual identity early in embryogenesis by setting the activity state of the master regulatory switch gene *Sex-lethal* (*Sxl*). An X/A ratio of 1.0 specifies female identity by turning *Sxl* on, whereas an X/A ratio of 0.5 specifies male identity by keeping *Sxl* off (Figure 1). Once *Sxl* is activated in 2X/2A animals, it functions to maintain the female determined state through a positive autoregulatory feedback loop in which Sxl protein promotes its own expression and to orchestrate female development by directing the expression of several regulatory cascades in the female mode. In 1X/2A animals, male identity is remembered by the absence of Sxl protein, while male development is specified by the expression of these same regulatory cascades in the default mode. Although the initial choice of sexual identity is controlled at the level of transcription, many of the key regulatory steps for both memory and differentiation depend on sex-specific alternative splicing.

Details of the Hierarchy

Although *Sxl* is on in females and off in males, the gene is transcribed in both sexes from a promoter, *Sxl-Pm*, which is active from the cellular blastoderm stage onwards. The critical difference between the sexes is that all *Sxl* mRNAs in males have an additional exon, exon 3, which is spliced out of the *Sxl* mRNAs in females (Figure 2A). This male-specific exon has multiple in-frame stop codons that prematurely truncate the *Sxl* open reading frame that begins at an AUG codon in exon 2. Consequently, male mRNAs do not encode functional proteins. In contrast, female *Sxl* mRNAs encode proteins that have two RNA recognition motif (RRM)-type RNA-binding domains. These proteins positively autoregulate their own synthesis by directing the splicing machinery to join exon 2 to exon 4, skipping the male-specific exon 3 (Figure 2A). Because female splicing never occurs in the absence of Sxl protein, the X/A ratio must activate the *Sxl* autoregulatory feedback loop in female embryos by a mechanism that bypasses this requirement. This is accomplished by turning on a special promoter, *Sxl-Pe*, in precellular blastoderm 2X/2A, but not 1X/2A embryos. The Sxl proteins encoded by the *Sxl-Pe* mRNAs set the autoregulatory feedback loop in motion in 2X/2A embryos by directing the female-specific splicing of the first *Sxl-Pm* transcripts. Because *Sxl-Pe* is not activated in 1X/2A embryos, the *Sxl-Pm* transcripts are spliced in the default male pattern.

The regulatory target for *Sxl* in the somatic sexual differentiation pathway is *transformer* (*tra*). The second exon of the *tra* pre-mRNA has two 3′ splice sites, the upstream default splice site and the downstream female-specific site (Figure 2B). Sxl protein turns *tra* on in

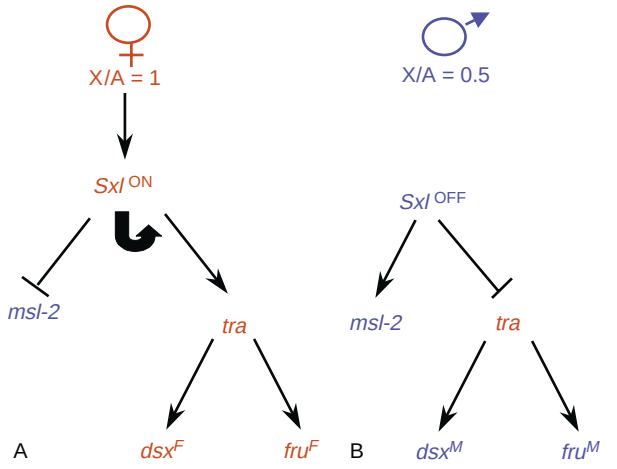

FIGURE 1 Sex determination hierarchy in *Drosophila melanogaster*. (A) Female regulatory cascade showing that *Sex-lethal* is the master regulator of sex determination because it receives the initial signal that chooses sexual identity, maintains sexual identity by a positive autoregulatory feedback loop, and regulates sexual differentiation through downstream target genes. (B) Male regulatory cascade showing the opposite events leading to male development.

females by promoting splicing to the downstream 3′ splice site of exon 2. This produces an mRNA that has an open reading frame that encodes a functional Tra protein. When Sxl protein is absent, as in males, the default 3′ splice site is used. Because there is an in-frame stop codon just downstream of the default 3′ splice site, the male *tra* mRNA does not encode a functional protein and *tra* is off.

Like *Sxl*, *tra* promotes female differentiation by regulating splicing. The two known targets of Tra, *double-sex (dsx)* and *fruitless (fru)*, encode transcription factors. In the case of *dsx*, *tra* controls the production of sex-specific isoforms that have a common N-terminal DNA-binding domain, but different C-terminal activation domains. In females Tra promotes the joining of the 5′ splice site of exon 3 to the 3′ splice site of exon 4 (Figure 2D). In males, where Tra is absent, splicing is to the default 3′ splice site of exon 5. Although Tra regulates *dsx* pre-mRNA splicing by controlling the use of alternative 3′ splice sites, it regulates *fru* pre-mRNA splicing by controlling the use of alternative 5′ splice sites. As illustrated in Figure 2E, a default upstream 5′ splice site in exon 2 is used in males, whereas in females, in which Tra is present, the splicing machinery skips this 5′ splice site and uses instead a 5′ splice spite located some 1500 bp further downstream. Although both the male and female mRNAs are predicted to encode functional protein, the female-specific mRNA does not appear to be translated.

In addition to controlling somatic sexual differentiation, *Sxl* regulates dosage compensation. To make up for the difference in dose of X-linked gene products in the two sexes, transcription from the X chromosome is hyperactivated in males by the male-specific lethal (MSL) dosage-compensation system. *Sxl* turns off the dosage compensation system in females by negatively regulating one of its components, *msl-2*. Interestingly, Sxl regulates *msl-2* by blocking the alternative splicing of an intron in the 5′-UTR and by inhibiting the translation of the message (Figure 2C).

Alternative Splicing Regulation by *Sxl*

tra: A Simple Blockage Model?

The regulation of *tra* splicing by *Sxl* is much simpler than autoregulation in that it only involves a choice between alternative 3′ splice sites (Figure 2B), and it will be considered first. In principle, Sxl could promote the use of the downstream female-specific 3′ splice site in the *tra* pre-mRNA by preventing the splicing machinery from using the upstream default 3′ splice site. Alternatively, it could activate the downstream 3′ splice site. Sosnowski *et al*. tested these models by making deletion constructs that were missing one of the two alternative 3′ splice sites of exon 2. Deletion of the default 3′ splice site led to use of the downstream female-specific 3′ splice site not only in females, but also in males in which Sxl protein is absent. This finding is inconsistent with a simple activation model because in this model Sxl protein would be required to use the downstream site even when the upstream site is missing. Deletion of the downstream 3′ splice site did not interfere with splicing in males, but led to an increased amount of unspliced mRNA in females. This result is consistent with a simple blocking model because when an alternative 3′ splice site is not present, Sxl protein still inhibits the use of the default 3′ splice site, leading to an increase in unspliced mRNA.

Biochemical studies suggest that Sxl blocks the use of the default 3′ splice site by competing with the generic splicing factor U2AF^{50}. U2AF^{50} normally binds to polypyrimidine tracts where it facilitates spliceosome assembly by interacting with the U2 small nuclear ribonucleoparticle (snRNP). Although U2AF^{50} can bind to the polypyrimidine tracts of both the default 3′ and female-specific splice site, it binds with much higher affinity to the default polypyrimidine tract. The default polypyrimidine tract is unusual in that it contains two polyuridine (poly U) runs. Poly U is the recognition sequence for the Sxl protein and mutations in the *tra* poly U runs that eliminate Sxl protein binding *in vitro* prevent *Sxl* from regulating splicing *in vivo*. Thus, the classic model of *tra* splicing is that the Sxl protein outcompetes U2AF^{50} for binding to the polypyrimidine tract of the default 3′ splice site, forcing U2AF^{50} to bind to and activate the weaker, downstream 3′ splice site.

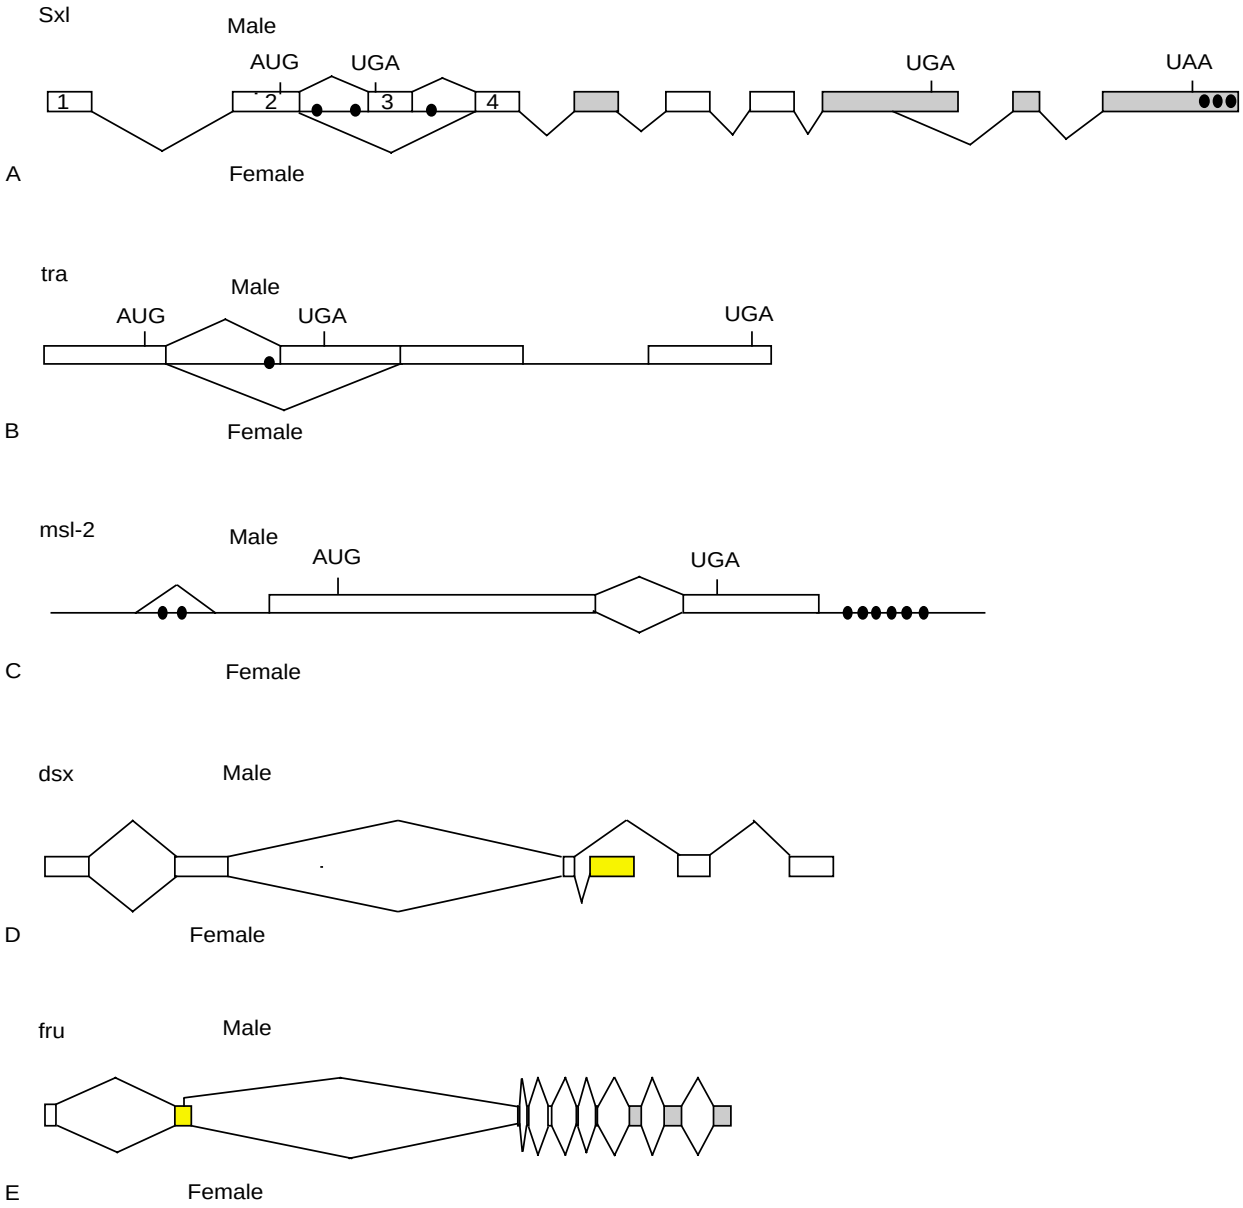

FIGURE 2 Sex-specific alternative splicing. The sex-specific splicing patterns for (A) Sxl, (B) tra, (C) msl-2, (D) dsx, and (E) fru. The male splicing pattern is shown above the gene, and the female pattern is below. Ovals indicate Sxl binding sites. Yellow exons in dsx and fru contain RE and PRE binding sites. Sxl and fru have multiple promoters, and some regions of these genes undergo non-sex-specific splicing (gray). The establishment promoter of Sxl, controlled by the X/A ratio, is not sex-specifically spliced. For fru, only transcripts from promoters that are alternatively spliced in a sex-specific manner are indicated.

Consistent with this model, when the N terminus of Sxl protein is replaced with the U2AF activation domain, the hybrid Sxl protein binds to poly U sites and activates splicing to the default 3′ splice site.

Because a protein consisting of only the two Sxl RRM domains can bind to the default polypyrimidine tract with higher affinity than U2AF[50], this competition model predicts that only the RNA-binding domain of the Sxl protein should be necessary to direct female-specific splicing of *tra*. Indeed, this is the case in *in vitro* splicing reactions. However, a Sxl protein containing the RNA-binding domains, but lacking the first 40 amino acids is unable to regulate *tra* splicing *in vivo* in transgenic animals. One explanation for this discrepancy is that the binding of Sxl to the poly U runs in the default polypyrimidine tract must be stabilized *in vivo* by protein–protein interactions involving the N-terminal domain. However, this reasoning would not explain why a protein consisting of the N-terminal 100 amino acids of Sxl fused to β-galactosidase (N-βgal) is able to weakly promote female-specific splicing of *tra* when expressed in male flies.

This N-βgal fusion protein does not have the two Sxl RNA binding domains and consequently cannot directly compete with U2AF^{50} for binding to the polypyrimidine tract of the default 3′ splice site. Taken together, these findings suggest that in addition to competing with U2AF^{50} for binding to the default polypyrimidine tract, Sxl may play a more active role in directing the splicing machinery to use the downstream female-specific 3′ splice site. As described later, Sxl is known to associate with a number of components of the splicing machinery *in vivo*, including U2AF. Potentially such interactions could provide a mechanism for directing assembly of a functional spliceosome on the weak downstream splice site.

Sxl Autoregulation

Although autoregulation is also thought to involve some type of blockage mechanism, it must be more complicated than *tra* splicing because Sxl has to regulate the use of both the 3′ and 5′ splice sites of the male exon (Figure 2A). Like *tra*, the polypyrimidine tract at the 3′ splice site of the *Sxl* male exon has a poly U run that is recognized by Sxl protein. However, because mutations in this poly U run have no effect on the splicing of *Sxl* pre-mRNAs in either tissue culture cells or transgenic animals, one can rule out a mechanism in which Sxl directs female splicing by binding to the polypyrimidine tract of the male exon and directly occluding U2AF or other generic splicing factors.

In fact, splicing regulation does not seem to pivot on controlling the use of the male exon 3′ splice site. When the male exon 5′ splice site is deleted, placing the 3′ splice sites of the male exon and exon 4 in direct competition, the male exon 3′ splice site is skipped in *both* sexes and exon 2 is spliced exclusively to exon 4. A different result is obtained when the 5′ splice sites of exon 2 and the male exon are placed in competition by deleting the male exon 3′ splice site. In males, a new male exon is generated using a cryptic 3′ splice site in the second intron and the normal male exon 5′ splice site. This deletion mutant transcript is also appropriately regulated by Sxl in females where exon 2 is spliced directly to exon 4, skipping the cryptic male exon. Other findings also argue that controlling the use of the male exon 5′ splice site is likely to be more important than controlling the 3′ splice site.

One mechanism to make the 5′ splice site of the male exon preeminent is to perturb the functioning of the male exon 3′ splice site. The male exon is unusual in that it has two 3′ splice site AGs, located 18 nucleotides apart, that compete with one another and reduce the efficiency of splicing. Use of the male exon in a heterologous context can be improved by mutating the upstream AG so that it can no longer be used. In the context of *Sxl*, inactivating the upstream AG compromises the ability of Sxl to block the inclusion of the male exon, presumably because the male exon 3′ splice site now functions much more efficiently. Finally, Lallena *et al.* have recently shown that the downstream AG is recognized by U2AF, whereas the upstream AG is recognized by the splicing factor SPF45. As would be predicted, if SPF45 is important for splicing to the upstream AG, reducing the activity of SPF45 in tissue culture cells (with RNAi) substantially increases the use of the downstream 3′-AG. The consequent improvement in efficiency of splicing of exon 2 to the male exon 3′ splice site compromises the ability of Sxl to block the inclusion of the male exon.

How does Sxl regulate the male exon 3′ and 5′ splice sites? It turns out that there are multiple poly U runs that are critical for regulation, located some 200 bp from the male exon. The deletion of the upstream or downstream poly U runs greatly compromises, but does not completely abolish, regulation by Sxl, whereas regulation is eliminated when both are deleted. Because the critical poly U runs are located far from the regulated splice sites, it is thought Sxl exerts its effect on male exon splicing indirectly through interactions with other components of the splicing machinery. Consistent with this idea, a number of proteins have been found in complexes with Sxl, and mutations in the genes encoding these proteins show genetic interactions with *Sxl*. The best characterized of these is *sans-fille* (*snf*), which encodes the *Drosophila* homologue of the mammalian U1 and U2 snRNP proteins U1A and U2B′. Although recombinant Sxl and Snf interact directly with one another *in vitro*, the immunoprecipitable complexes between Snf and Sxl seen in nuclear extracts are RNase-sensitive and do not include the U1 and U2 snRNPs unless the extracts are cross-linked prior to immunoprecipitation. Cline *et al.* proposed a snRNP-independent function for Snf in regulating *Sxl* splicing because they found that increasing the levels of *snf*, but not other genes encoding U1 or U2 snRNP proteins, could promote *Sxl* autoregulation under conditions of limiting Sxl protein. However, recent genetic experiments by Nagengast *et al.* show that Sxl interacts with the Snf protein associated with U1 snRNPs. The same study has also shown that Sxl can form an RNA-independent complex with the U1 snRNP protein U170K, and genetic interactions indicate that this protein–protein interaction is important for autoregulation.

The association of Sxl with two U1 snRNP proteins suggests that Sxl may prevent splicing between the male exon and exon 4 by blocking the assembly of a functional U1 complex at the male exon 5′ splice site. However, this would not explain how Sxl prevents exon 2 from splicing to the male exon 3′ splice site(s). An understanding of the role of Sxl in this context is becoming clearer from studies done with U2AF.

In nuclear extracts, Sxl can form a complex with U2AF^{50} and U2AF^{38}, and *Sxl* mutations interact genetically with U2AF^{38}. Naggengast *et al.* suggest that one mechanism Sxl might use to block splicing between exon 2 and the male exon would be through interactions with the U2AF heterodimer. Because U2AF recognizes the downstream AG in the male exon 3′ splice site, some other mechanism might be required to block the use of the upstream AG.

Genetic and molecular studies indicate that genes encoding two additional trans-acting factors, *fl(2)d* and *virilizer* (*vir*), are necessary for regulating the female-specific splicing of *Sxl* (and of *tra*), although how these proteins function is unclear. *fl(2)d* is homologous to *wilm*'s *tumor associated protein* (*wtap*) and encodes a protein present in human spliceosomes. In *Drosophila*, the Fl(2)d protein can form an RNA-independent complex with Sxl, and the two proteins are able to interact directly *in vitro*. Interestingly, Fl(2)d is able to form an RNA-independent complex with Snf, which would be consistent with Fl(2)d functioning with the U1 or U2 snRNP because Snf is a component of both. *vir*, on the other hand, is not homologous to any known gene involved in splicing, but Vir protein has been shown to be in a complex with Fl(2)d, suggesting that Vir might function in splicing regulation.

Alternative Splicing Regulation by Tra

Tra Protein

Tra protein is an arginine/serine domain containing splicing regulator (SR) protein. SR proteins generally function to activate splice sites, but there are examples of SR proteins that are able to block splice sites instead. In *Drosophila*, female-specific Tra protein functions with sex-nonspecific Tra-2 protein to activate splice sites in *dsx* and *fru* pre-mRNAs.

Regulation of *DSX* and *FRU*

In males, the default splicing machinery joins the 5′ splice site of *dsx* exon 3 to the 3′ splice site of exon 5. When Tra is present in females, it promotes splicing of exon 3 to exon 4 by activating the 3′ splice site of exon 4. Exon 4 contains six 13-nt repeat elements (RE) and one purine-rich element (PRE) (located between RE #5 and RE #6) that are necessary for efficient use of the female-specific splice site. When these elements are deleted, *dsx* is spliced in the male pattern irrespective of whether Tra protein is present. Conversely, when these elements are placed downstream of a heterologous 3′ splice site they can activate the splice site when Tra is present. *In vitro* experiments indicate that Tra and Tra-2, together with the SR protein RBP1, associate with the 13-nt REs, whereas the SR proteins dSRp30 and b52/dSRp55 function at the PRE. It is thought Tra and Tra-2 plus the various SR proteins form an enhancer complex in exon 4. Because Tra and Tra-2 interact with U2AF^{38}, this suggests a model in which the enhancer complexes assembled in exon 4 recruit U2AF^{38} and subsequently U2AF^{50} to the 3′ splice site.

This model is complicated by the fact that the *fru* transcript contains three similar Tra/Tra-2 binding sites within exon 2, which are necessary for activating a female-specific 5′ splice site. This is difficult to reconcile with the U2AF recruitment model because recruiting U2AF is not useful for activating a 5′ splice site. Moreover, when the six REs and the PRE within exon 4 of *dsx* are replaced with the Tra/Tra-2 binding sites found in the *fru* transcript, activation of the female-specific 3′ splice site still occurs. One explanation for this result is that recruitment of general splicing regulators by Tra, Tra-2, and other SR proteins might be context dependent. Tra, Tra-2, and specific SR proteins might be able to recruit different proteins to activate either a 3′ or a 5′ splice site. Which component of the splicing machinery is recruited may be determined by additional proteins specific to each transcript that bind to sites other than the REs and/or PREs. Alternatively, the U2AF recruitment model might be entirely incorrect and Tra and Tra-2 might use a similar mechanism to activate both 5′ and 3′ splice sites.

Alternative Splicing and Sex Determination in Other Species

Sex-lethal is produced in a sex-specific manner within the genus *Drosophila*, but in every other dipteran examined outside of this genus, *Sex-lethal* is not expressed sex-specifically nor does it appear to have a role in sex determination. By contrast, some of the downstream genes seem to maintain their role in sex determination. In *Ceratitis capitata*, *tra* seems to act as the master regulator of sex determination. *Cctra* appears to receive the initial sex-determination signal and subsequently regulates not only the necessary downstream gene(s) in the hierarchy of sexual development, but also maintains its own expression via alternative splicing. Further down the hierarchy, the gene *dsx* is much more evolutionarily conserved. In both *Megaselia scalaris* and *C. capitata*, *dsx* is structurally conserved and sex-specifically alternatively spliced. Intriguingly, the *dsx* homologue in *Caenorhabditis elegans*, *male abnormal 3* (*mab-3*), also controls sexual cell fate, thus extending the conservation beyond dipteran insects.

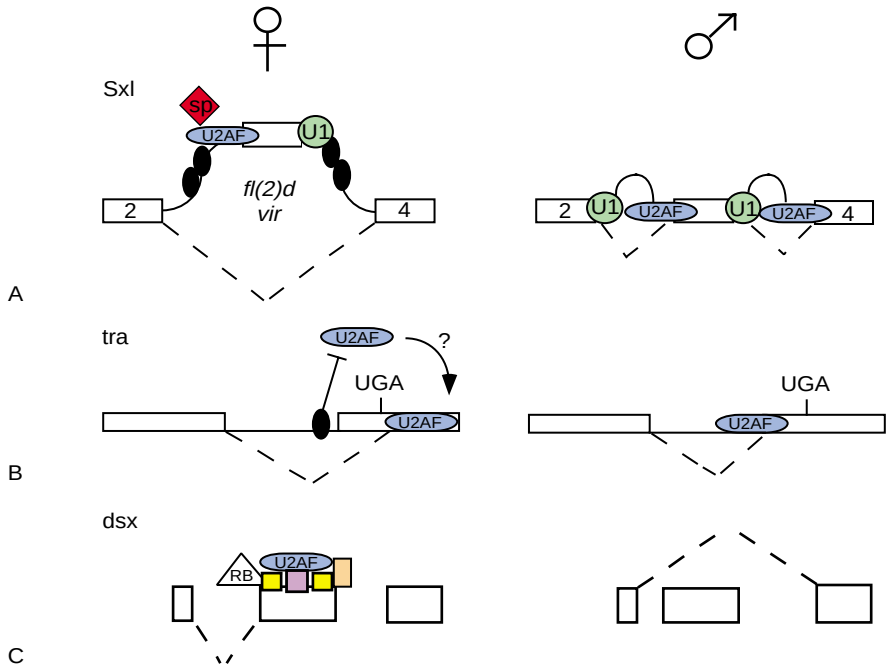

FIGURE 3 Models for regulation of alternative splicing. Splicing patterns for (A) Sxl, (B) tra, and (C) dsx mRNAs in females (left column) and males (right column). Black ovals, Sxl; green circles, Ul snRNP (including snf and U170K); red diamond, spF45; yellow squares, tra/tra2; orange rectangle, dSRp30; purple square, b52/dSRp55; white triangle, RBP1. (A) To regulate splicing of its own mRNA, Sxl may bind to components of U2AF at the male 3′ splice site and components of the U1snRNP at the male 5′ splice site, thereby preventing these splice sites from being used. When no Sxl protein is present, the male exon splice sites are available. (B) To regulate tra splicing, Sxl competes with U2AF for binding to the poly(U) tract near the upstream 3′ splice site, forcing U2AF to use the weaker downstream site. Sxl may also activate the downstream 3′ splice site. When there is no Sxl, U2AF uses the stronger site. (C) Tra/tra-2 bound with the RE and PRE elements in exon 4 of doublesex may form a complex with other factors to activate the upstream 3′ splice site. When the complex is not present, the downstream site is used.

Summary

Drosophila sex determination is a powerful and practical system in which to examine the mechanisms of alternative splicing. Studies done thus far indicate that within the *Drosophila* sex determination hierarchy are examples of several different mechanisms that control alternative splicing. *Sxl* autoregulation is controlled by blocking both the 3′ and 5′ splice sites of an exon, while female-specific *tra* expression is achieved by blocking the stronger 3′ splice site (Figure 3). Splice site activation is used for female-specific *dsx* and *fru* expression. However, a 3′ splice site is activated in *dsx*, whereas a 5′ splice site is activated in *fru*. Each of the various alternative splicing events is unique, but some of the proteins regulating these splicing reactions are shared. Sxl protein probably interacts with Fl(2)d and Vir to direct female-specific splicing of both *Sxl* and *tra*. Likewise, Tra and Tra-2 interact at similar consensus binding sites in the exons of *dsx* and *fru* pre-mRNAs. Further studies will hopefully elucidate which combinations of protein–protein interactions allow the same trans-acting factors to regulate two different alternative splicing events.

Patricia Graham is a post doctoral Fellow at Princeton University. She received her Ph.D. from the University of Wisconsin-Madison.

Dr. Paul Schedl is a Professor in the Department of Molecular Biology at Princeton University. He holds a Ph.D. degree from Stanford University and received his postdoctoral training at Biozentrun in Switzerland.

Amine Oxidases

Giovanni Floris
University of Cagliari, Cagliari, Italy

Alessandro Finazzi Agrò
University of Rome "Tor Vergata," Rome, Italy

Amine oxidases (AOs), a widespread class of enzymes, are present in all living systems, where they control the level of very active compounds, i.e., mono-, di-, and polyamines. The oxidation of these compounds may generate other biologically active substances, like aldehydes, ammonia, and hydrogen peroxide, which either directly or indirectly influence cells and tissues. Hydrogen peroxide, which is always formed in the reactions catalyzed by AOs, is more and more considered either a crucial substrate for important biochemical processes or a signal and a defense molecule, rather than a noxious waste product.

Classification

The oxidative deamination of mono-, di-, and polyamines is catalyzed by a number of AOs that exhibit different patterns of substrate specificity and inhibitor sensitivity and also differ in their action mechanism. Amine oxidases have been divided into two main categories, depending on the nature of the cofactor involved. One class is characterized by the presence of flavin adenine dinucleotide (FAD) as the redox cofactor. The enzymes belonging to this class are further subdivided into monoamine oxidases (MAO A and MAO B) and polyamine oxidases (PAOs). The second class is represented by enzymes having a tightly bound Cu^{II} ion and a carbonyl-type group identified as 6-hydroxydopa quinone (2,4,5-trihydroxyphenethylamine quinone; TPQ) at the active site (Figures 1A and 1B). TPQ is derived from the oxidation of a tyrosyl residue in a posttranslational event. It has been proposed that the bound copper itself catalyzes the process of TPQ formation by the initial insertion of an oxygen atom into the tyrosine ring to generate dihydroxyphenylalanine (Scheme 1).

Distribution, Reaction Mechanism, and Physiological Roles

FAD-Containing Monoamine Oxidases

MAO A and MAO B [amine:oxygen oxidoreductase (deaminating); EC 1.4.3.4] have subunits of M_r of 59.7 and 58 kDa, respectively. The crystal structure of human MAO B shows that FAD is covalently bound through the flavin C8α-position to a cysteine (Cys397) side chain (Figure 1C). MAOs are ubiquitous in the cells of most mammalian species, the notable exception being erythrocytes, and are tightly associated with the mitochondrial outer membrane, although both MAOs have been also found in the microsomal fraction. The distribution of MAOs has been studied principally in the brain: MAO A is found in catecholaminergic neurons, whereas MAO B is abundant in serotonergic and histaminergic neurons and glial cells. Moreover, some tissues mainly contain MAO A (human placenta and bovine tyroid), and other tissues contain predominantly MAO B (human platelets and bovine liver and kidney).

MAOs oxidize primary amino group of arylalkyl amines to form an imine product with the concomitant reduction of flavin to $FADH_2$. The imine is then hydrolyzed to the corresponding aldehyde and ammonia, and $FADH_2$ is oxidized back to FAD by oxygen with the formation of hydrogen peroxide. MAO A oxidizes preferentially dopamine, noradrenaline, and serotonin and is sensitive to the irreversible inhibitor clorgyline. MAO B oxidizes preferentially benzylamine and phenylethylamine and has a higher affinity for the inhibitor deprenyl. Adrenaline, kynuramine, tyramine, and tryptamine are substrates for both enzymes.

MAO A and B have been implicated in apoptosis, immunosuppression, cytotoxicity, cell growth and proliferation. These enzymes play a protective role in the body by preventing the entry of amines at the renal and intestinal levels or by oxidizing them in blood. In fact, liver MAOs are involved in controlling the blood level of pressor amines. MAO A can oxidize circulating serotonin thus preventing its effects on the heart and vascular system. Both MAO A and MAO B have important roles in the metabolism of neurotransmitters and other biogenic amines in the brain and are implicated in a large number of neurological and psychiatric disorders. The loss of dopaminergic neurons in the substantia nigra, which causes Parkinson's disease, has been associated

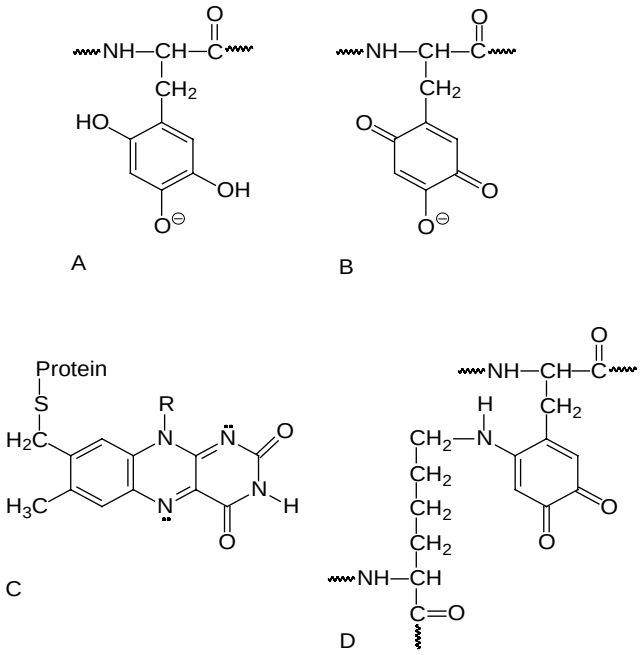

FIGURE 1 Structure of the (A) reduced and (B) oxidized form of TPQ; (C) FAD covalently bound in MAO B; (D) lysine tyrosylquinone.

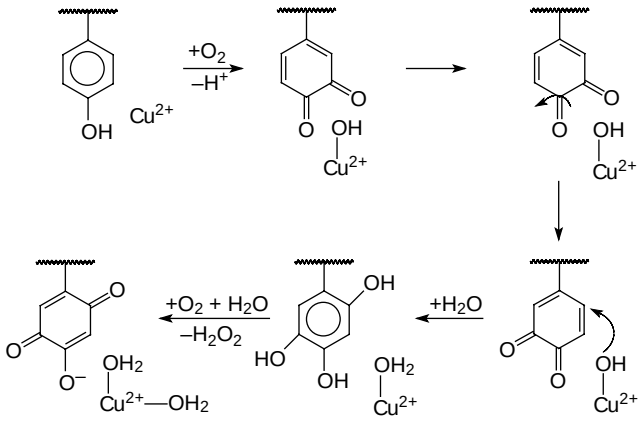
with an increased dopamine oxidation by MAO B producing high amounts of oxygen radicals responsible for oxidative damage of nigrostriatal neurons. Therefore, the pharmacological regulation of MAO activity has been shown to be important in the treatment of depression and Parkinson's disease.

FAD-Containing Polyamine Oxidases

FAD-containing polyamine oxidases (PAOs) are monomeric enzymes with a M_r ranging from 53 to 63 kDa, with 1 mol of FAD per mol of protein. The prosthetic FAD is noncovalently bound to the protein.



SCHEME 1 Postulated pathway for the biogenesis of TPQ from tyrosine.

PAOs [N^1-acetylspermidine:oxidoreductase (deaminating); E.C. 1.5.3.11] are intracellular enzymes mainly found in vertebrates and plants. PAOs with characteristics similar to vertebrate enzymes are present in yeasts and amoebae, whereas bacteria and protozoans contain enzymes similar to those of plants. Plant PAOs have been isolated and characterized, particularly from the Gramineae oat, maize, barley, wheat, and rye. The enzyme from maize seedlings has been crystallized.

The mechanism by which PAOs catalyze the oxidation of polyamines is still unknown, but the catalytic mechanism can be divided into two half-reactions: (1) flavin reduction upon polyamine oxidation followed by (2) flavin reoxidation by molecular oxygen. Polyamine oxidases catalyze the oxidation of polyamines at the secondary amino group yielding different products according to the organism considered. Mammalian PAOs oxidize preferentially acetyl spermine and acetyl spermidine: spermidine and putrescine are respectively formed as reaction products, together with 3-aminopropanal and hydrogen peroxide. Oxidation of spermine by plant PAOs gives 1,3-diaminopropane, hydrogen peroxide, and 1-(3-aminopropyl)-4-aminobutanal. The latter spontaneously cyclizes to 1-(3-aminopropyl)pyrrolinium that undergoes further spontaneous rearrangements to 1,5-diazobicyclo[4.3.0.]nonane (Scheme 2). The oxidation of spermidine by plant PAOs gives 1,3-diaminopropane, hydrogen peroxide, and 4-aminobutanal that yields 1-pyrroline by spontaneous cyclization. Contrary to the reaction of MAOs and copper/TPQ AOs, the oxidation of polyamines by PAOs does not release ammonia.

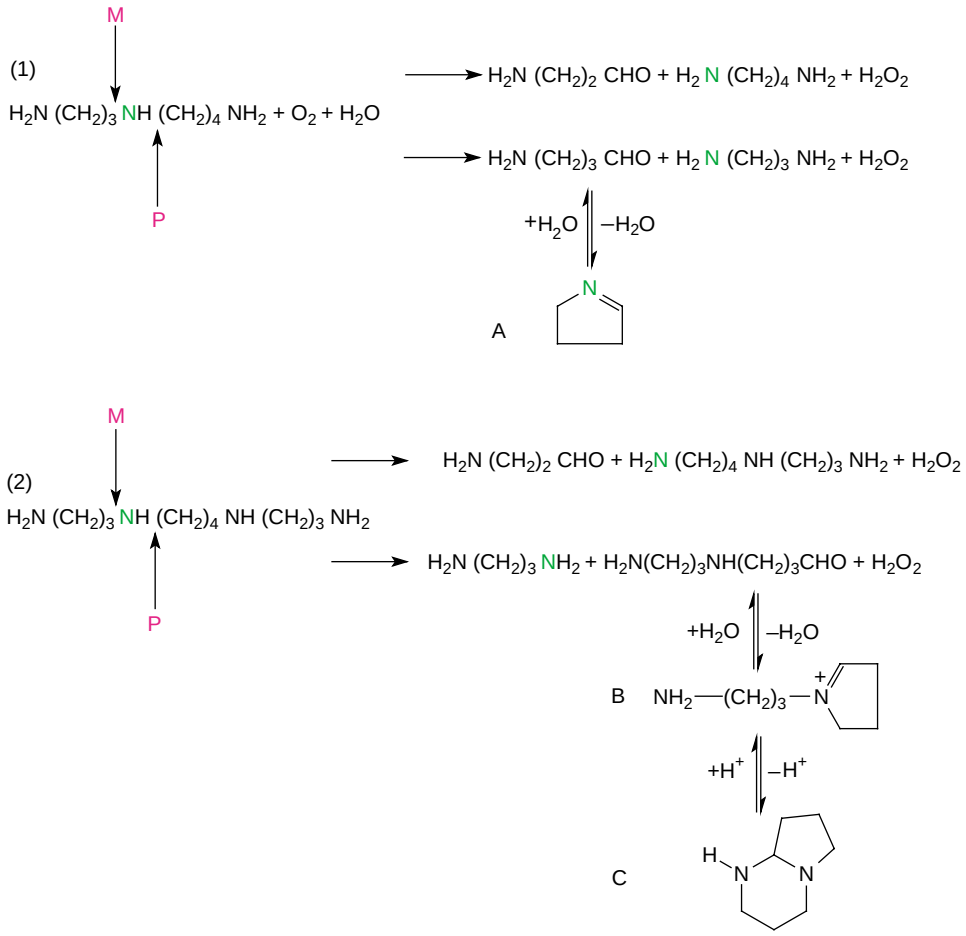
PAOs play an important role in the regulation of intracellular polyamine level, and seem to be important for homeostasis and cell survival.

Cu/TPQ Amine Oxidases

Copper/TPQ-containing amine oxidases [amine:oxygen oxidoreductase (deaminating) (copper containing); EC 1.4.3.6] are homodimers in which each subunit (M_r 70–90 kDa) contains a tightly bound type II copper ion and a quinone (TPQ). Copper/TPQ AOs catalyze the oxidative deamination of primary amino groups of mono-, di-, and polyamines, abstracting two electrons from amines and transferring them to molecular oxygen, to form the corresponding aldehyde, ammonia and hydrogen peroxide. Again, the catalytic mechanism can be divided into two half-reactions: (1) enzyme reduction at the quinone moiety (TPQ → $TPQH_2$) by substrate followed by (2) reoxidation by molecular oxygen:

$$E_{ox} + R{-}CH_2{-}NH_3^+ \rightarrow E_{red}{-}NH_3^+ + R{-}CHO \quad (1)$$

$$E_{red}{-}NH_3^+ + O_2 + H_2O \rightarrow E_{ox} + NH_4^+ + H_2O_2 \quad (2)$$



SCHEME 2 Reaction catalyzed by mammalian (M) and plant (P) PAOs. (1) Spermidine; (2) Spermine; (A) 1-pyrroline; (B) 1-(3-aminopropyl)- pyrrolinium; and (C) 1,5-diazobicyclo[4.3.0.]nonane.

Within the class of Cu/TPQ amine oxidases are included:

(i) The intracellular amine oxidases, also called diamine oxidases (DAOs), are ubiquitous enzymes occurring in microorganisms (fungi and bacteria), plants, and mammals. Some DAOs have been crystallized from bacteria, the yeast *Hansenula polymorpha*, and from pea seedlings. The crystal structure shows that the copper atom is coordinated by three histidine side chains and two water molecules, laying at approximately 6Å distance from TPQ (Figure 2). Plant DAOs from various species have been purified to homogeneity and characterized, the best known and studied being those from lentil (*Lens esculenta*) and pea (*Pisum sativum*) and from latex of the shrub *Euphorbia characias*. In mammals, the best known enzymes are those from pig kidney and intestine, and from human placenta. DAOs prefer short aliphatic diamines like putrescine (1,4 diaminobutane) and cadaverine (1,5 diaminopentane) as substrates.

The role of DAOs is difficult to define, because this class includes several enzymes with different localizations and substrates. Bacteria and yeasts can utilize amines as nitrogen and carbon sources through the reaction with amine oxidase. Plant DAOs have an important role in cell growth by regulating the intracellular di- and polyamine levels, and the aldehyde products might have a key role in the biosynthesis of some alkaloids. The function of amine

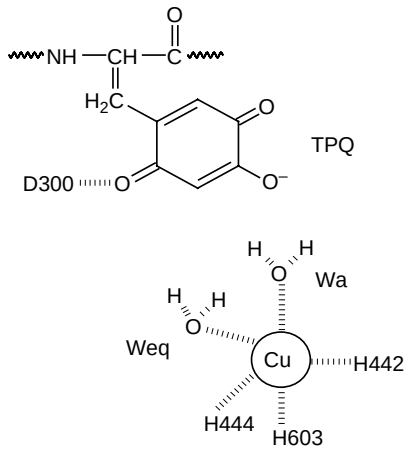


FIGURE 2 Structural arrangement of the copper center and TPQ in the active site of pea seedling amine oxidase. D300 is the base required for the catalytic mechanism.

oxidases in mammals is even more diverse and elusive. Amine oxidase activity is found in many tissues, the highest levels being in decidual cells of placenta, in kidney tubular epithelial cells, and in intestinal epithelial cells. These localizations may suggest a general barrier function for this enzyme in preventing the entrance of extracellular diamines and polyamines into circulation. Furthermore, these enzymes may keep under control the endogenous histamine, which may be responsible for several pathological conditions like allergy, peptic ulcer, and anaphylactic reactions. Several observations point to a relationship between amine oxidase activity and growth, both in normal and tumoral tissues possibly correlated with cell proliferation and differentiation. DAOs have also been proposed as immune response modulators. It has been demonstrated that human placental diamine oxidase is identical to the amiloride-binding protein and thus in some way is involved in the regulation of epithelial ion transport.

(ii) The mammalian extracellular plasma soluble and intracellular tissue-bound amine oxidases are able to metabolize mono-, di-, and polyamines, even though *in vitro* they are preferentially active toward nonphysiological amines like benzylamine. Plasma soluble AOs are generally termed either plasma and serum AOs or benzylamine oxidases (BzAOs). Tissue-bound AOs are often indicated as semicarbazide-sensitive amine oxidases (SSAOs), somewhat misleading since all Cu/TPQ AOs, at variance with FAD-dependent enzymes, are inhibited by semicarbazide and other carbonyl reagents. There has been considerable disagreement whether the extracellular plasma AO were a product of a different gene or a cleavage product of a tissue-bound amine oxidase. The better known examples of BzAOs are those from bovine, swine, and equine plasma. Intracellular SSAOs are widely distributed: smooth muscle cells of vascular tissue of all mammalian species are a good source of these enzymes, which have been also detected in uterus, ureter and vas deferens, in ox dental pulp, in human umbilical artery, in rat adipocytes, and chondrocytes.

The increased BzAO activity in blood serum of pregnant women supports the possibility that this enzyme has a protective role against the polyamines released from the fetoplacental unit. SSAOs have been also shown to be a new class of DNA-binding proteins: in the presence of polyamines they bind DNA and oxidize DNA-bound polyamines. Structural similarity between SSAOs and VAP-1, a protein involved in cellular adhesion, has been observed. SSAOs seem to be involved in the regulation of glucose metabolism (via the H_2O_2 produced?) and in the regulation of leukocyte trafficking in endothelial cells.

(iii) The extracellular matrix-bound lysyl oxidase has the best-defined role: it catalyzes maturation and aging of collagen and elastin, by oxidizing the ε-aminogroups of their lysyl residues, allowing the formation of cross-links essential for the structure of these proteins. Lysyl oxidase differs from other members of the group because lysine tyrosyl quinone (Figure 1D) rather than TPQ is the redox cofactor. The genetic or acquired decrease of lysyl oxidase activity is accompanied by severe pathological conditions like the formation of aneurisms in arteries.

Concluding Remarks

In the past few years, evidence has accumulated about the physiological relevance of hydrogen peroxide, which is generated in the catabolism of mono-, di-, and polyamines by all amine oxidases. This reactive oxygen species is toxic at high concentration. However, at lower concentrations it regulates cell number during embryonic development as well as the proliferation and adhesive properties of endothelial and smooth muscle cells. Hydrogen peroxide appears to be involved in the impairment of cell growth and proliferation, in the regulation of many genes and transcription factors, and in the transduction of cellular signals in many living species. In plants, hydrogen peroxide might be utilized by peroxidases in crucial physiological events, such as in development, in the polymerization of lignin and suberin precursors, and in the catabolism of indoleacetic acid, in response to wounding or to pathogen invasion.

Glossary

amines Hydrocarbon compounds bearing an amine group. They are called primary, secondary, or tertiary when nitrogen binds two, one, or zero hydrogen atoms.

oxidases Enzymes that oxidize substrates using molecular oxygen.

polyamines Hydrocarbon compounds bearing both primary and secondary amino groups (e.g., spermine and sperimidine) strongly interacting with nucleic acids involved in many important cellular functions.

primary amines Metabolically derived from amino acids by decarboxylation. Primary amines often show potent pharmacological or hormonal activity (e.g., histamine, serotonin, GABA, and noradrenaline).

Biography

Alessandro Finazzi Agrò is full Professor of Enzymology, Faculty of Medicine, at the University of Rome "Tor Vergata," Italy. He is currently Rector of the same University. For the past 35 years he has been studying copper proteins and copper enzymes with respect to their biochemical, physiological, and pathological roles.

Giovanni Floris is full Professor of Biochemistry and Molecular Biology, Faculty of Science, at the University of Cagliari, Italy. He is working on the purification and characterization of enzymatic proteins, particularly on plant copper/TPQ amine oxidases.

Amino Acid Metabolism

Luc Cynober
Hôtel-Dieu Hospital and Paris 5 University, Paris, France

Amino acids are major macronutrients involved in (1) protein synthesis, (2) energy requirements, and (3) specific functions either directly (as mediators) or through their metabolism into mediators or hormones. This article describes amino acid metabolism with special emphasis on tissue-specific metabolism, inter-organ exchanges, and regulation.

Structure, Functions, and Classification of Amino Acids

Amino acids (AAs) are defined as organic molecules possessing an amino moiety located at α-position to a carboxylic group. AAs therefore have the following general formula:

$$R-\alpha CH\begin{<}NH_2\\COOH\end{>}$$

where R may be an aliphatic or a cyclic structure.

Note that proline is considered as an AA even though its $-NH_2$ group is part of a heterocycle. Also, taurine is considered as an AA even though it has a sulfur moiety instead of an amino group in the α-position.

AAs can be classified in three different ways (Table I):

- *Chemical Classification* This classification is based on structure and identifies different chemical families of AAs: aliphatic (subdivided into several subgroups – see Table I for details), aromatic, heterocyclic, etc.
- *Metabolic Classification* Although in theory most AAs can be precursors of glucose, *in vivo*, because most AAs preferentially use other metabolic pathways, only alanine (ALA), glutamine (GLN), and to a lesser extent proline (PRO) and glycine (GLY) contribute significantly to gluconeogenesis.

Certain AAs can be precursors of ketone bodies (ketogenic AAs). Again, *in vivo*, only leucine (LEU) contributes significantly to ketogenesis.

Finally, some AAs can be both glucogenic and ketogenic: isoleucine (ILE) and phenylalanine (PHE).

- *Nutritional Classification* This is based on what AAs the human body can or cannot synthesize. The former are named nonessential AAs (NEAAs) and the latter essential AAs (EAAs). There are nine EAAs (Table I). Note that some NEAAs can become EAAs in specific situations, e.g., arginine (ARG) during growth, tyrosine (TYR) during renal failure, or GLN in trauma patients.

Intestinal Absorption of AAs

Digestion of proteins (beyond the scope of this chapter) releases a mixture of free AAs and short-chain peptides. Nitrogen is absorbed mainly in the jejunum and the ileum in the form of free AAs and di- and tripeptides. It is now well recognized that the latter have a kinetic advantage for uptake. To date, two peptide transporters have been cloned, PEPT-1 and PEPT-2.

AAs are taken up by systems that are rather different from those found in other cells and also from those located at the basolateral side of enterocytes. The groups of transporters are relatively specific to:

- neutral AAs,
- imino acids,
- dibasic AAs + cysteine (CYS), and
- dicarboxylic AAs.

Intestinal Metabolism

It was long thought that the gut had a single function, namely, taking up AAs from the lumen for transport in the bloodstream.

In fact, the intestine avidly consumes some AAs for its energy requirements: GLU and GLN are used to the same extent as glucose by enterocytes, producing α-ketoglutarate, which is oxidized in the Krebs cycle. After a balanced meal, at least 30% of GLU + GLN is used by enterocytes, and as a consequence ammonia is released in the portal vein. Interestingly, when GLN is taken up at the luminal side of enterocytes, its uptake at the basolateral side decreases. The reverse is true in the postabsorptive state, so that the supply of GLN to enterocytes remains roughly constant.

TABLE I

Classifications of Amino Acids.

Aliphatic	Aromatic
• Short-chain	***Phenylalanine***
Glycine	**Tyrosine**
Alanine	Heterocyclic
• Alcohol	*Tryptophan*
Threonine	Dibasic
Serine	**Arginine**
• Branched-chain	*Histidine*
Leucine	*Lysine*
Isoleucine	Diacid
Valine	**Glutamate**
• Sulfur	**Glutamine**
Methionine	**Aspartate**
Cysteine	**Asparagine**
Imino acid	
Proline	

Only AAS engaged in protein bonds are presented. Note that there are numerous other AAs: (1) intermediary metabolites: ornithine, citrulline; and (2) posttranscriptionally formed: hydroxyproline, γ-carboxyGLU acid – (a) in italics: essentials AAs; (b) in bold type: gluconeogenic AAs; and (c) underlined; ketogenic AAs.

Also, the turnover of enterocytes is very rapid, causing a strong requirement for purine and pyrimidine precursors (e.g., GLN).

Cellular Transport of AAs

Once AAs appear in the circulation, cellular transport is a critical step in AA metabolism, since it is a prerequisite for any further metabolism. In certain cases this step may even be rate limiting or rate controlling for metabolic pathways.

The systems of transport have long been classified according to their preferred substrates, their dependency towards sodium, their sensitivity to pH, and their ability to transport nonmetabolizable analogues. Based on these criteria a large number of transport systems have been identified. The most ubiquitous are system A (A for ALA-preferring), system ASC (ALA-, serine (SER-) and CYS-preferring), system L (LEU-preferring), y + (ARG being the main substrate), N (for the transport of GLN and histidine (HIS)), etc. With progress in molecular biology methods, a number of transporters have been cloned, allowing a new classification. Not surprisingly, the number of transport systems was found to be greater. For example, for ARG, four transporters have been cloned (CAT-1, CAT-2A, CAT-2B, and CAT-3) with different cell localizations, properties, and affinities for the different cationic AAs.

The organs that are most contributive to AA metabolism are the liver and muscle.

TABLE II

Some Amino Acid Functions

Function	Amino acid	Example
Constituent of proteins	20 AAs	
Hormone precursor	Phenylalanine	Tyroxine
	Tyrosine	Cathecholamines
	Tryptophan	Serotonin
Mediators	Glutamate	Glutamate, GABA
	Glutamine	Glutamine
	Arginine	Nitric oxide
Binding of calcium	Glutamate	γ-carboxyglutamate
Collagen structure	Proline	hydroxyproline

GABA: γ-aminobutyric acid.

Liver Metabolism

The liver holds a central place in the metabolism of AAs because it is responsible for the synthesis of most circulating proteins, transforms AAs as energy sources (i.e., glucose and ketone bodies) for other tissues, and eliminates surplus nitrogen.

AAs supplied via the portal vein after a meal are heavily metabolized (~50%). The carbon chain is oxidized or forms glucose, which is saved as glycogen, while the N-moiety (ies) is (are) removed in ureagenesis.

The reason for this process is that whereas the intestinal absorption of AAs is not limiting (95–99% of nitrogen is absorbed in a large range of protein intake), the brain must be protected against excessive AA exposure because several of them are neurotoxic or are the precursors of potent neuromediators (see Table II). Thus, the liver acts as a filter, limiting the amount of AAs released in the general circulation. Notable exceptions are the branched-chain AAs (BCAAs; VAL, ILE, LEU), which are almost nonmetabolized in the liver: BCAAs form ~22% of AAs in food proteins but almost 50% of AAs reaching the general circulation.

The biochemical explanation for this effect is that hepatocytes do not contain BCAA transaminase, which mediates the first step of BCAA metabolism. The physiological reason may be related to the fact that LEU plays a critical role in the stimulation of muscle protein synthesis in the postprandial phase.

In the postabsorptive state, with glycogen exhaustion, gluconeogenesis increases to maintain glucose homeostasis. As stated above, ALA is the main gluconeogenic

substrate among AAs: in healthy humans starved for 8 h, 30% of perfused ALA is metabolized into glucose, and, in these conditions, 11% of glucose formed by the liver comes from ALA. When the starvation time is increased, and in situations of hyperglucagonemia (e.g., during response to injury such as burn, trauma, or sepsis), the contribution of ALA to gluconeogenesis increases like those of other AAs, in particular GLN. In these situations, most AAs taken up by the liver come from the muscles.

During starvation, another metabolic pathway is activated: ketogenesis is mainly supported by free fatty acid metabolism, but one AA, LEU, is also contributive. This may seem paradoxical because, as stated above, hepatocytes do not express BCAA-T. However, hepatocytes express all the other enzymes required for ketone body (KB) production, in particular the highly regulated enzyme branched-chain keto-acid-dehydrogenase (BCKA-dh). Thus, as described below, the production of KB from LEU is a typical example of the importance of inter-organ exchanges in AA metabolism.

Muscle Metabolism

Muscles contain ~50% of the proteins in the human body and the largest pool of free AAs (i.e., 87 g in a male weighing 70 kg; by comparison the plasma pool is only 1.2 g).

Therefore, muscles can be considered as a reserve of AAs, either directly (i.e., as free AAs) or indirectly (i.e., in the form of proteins).

After a meal, arterio-venous measurements indicate that all AAs are taken up by the muscles to support protein synthesis.

At the postabsorptive state, all but one (GLU) are released by the muscles. It is noteworthy that ALA + GLN together represent 60% of the total AAs released by muscle, whereas they form less than 20% of protein content. This underlies the fact that most ALA and GLN comes from *de novo* synthesis in the muscle. The carbon chain required for ALA synthesis comes from anaerobic degradation of glucose, and the amino moiety comes from transamination with GLU. The resulting α-KG is retransaminated by BCAA-T releasing BCKAs from BCAAs (Figure 1). Ultimately, 18% of the glucose taken up by muscle is metabolized into ALA and 12.5% of the nitrogen contained in circulating ALA comes from LEU. For GLN, the carbon chain comes from GLU and GLU comes both from transamination and from the bloodstream. The ammonia required for the amidation of GLU comes from oxidative deamination of AAs and from the degradation of purine bases (Figure 1).

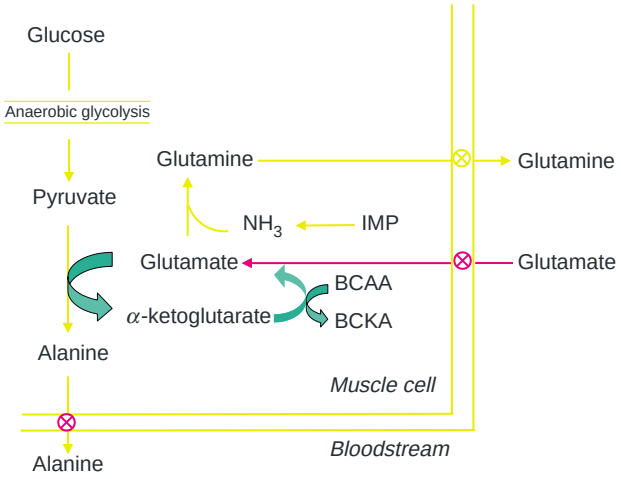

FIGURE 1 *De novo* synthesis of alanine and glutamine in muscles at the postabsorptive state. IMP, inosin monophosphate; BCAA, branched-chain amino acid; BCKA, branched-chain keto acid.

Inter-Organ Exchanges

Every tissue or organ possesses enzymatic equipment that is specific both qualitatively and quantitatively. Correspondingly, each tissue plays a specific role in nitrogen homeostasis. This explains the importance of inter-organ exchanges, each organ contributing as a provider of those AAs that others are unable (or not sufficiently able) to produce. The inter-organ exchanges are highly dependent on the feeding state (i.e., postprandial versus postabsorptive).

At the postprandial state, as mentioned above, there is major AA splanchnic sequestration. AAs appearing in the general circulation are taken up by peripheral tissues, especially muscles.

At the postabsorptive state, the body must use its stores to generate the energy required. Lipolysis and glycogenolysis are contributive to this process. However, the glycogen stores are limited and as fasting progresses, the glucose supply becomes more and more dependent on gluconeogenesis. This process implies the transfer to the liver of gluconeogenic AAs such as ALA and GLN. As described earlier in this article, the nitrogen moiety ultimately comes from BCAAs. This fact has two consequences:

1. Since BCAAs are essential AAs (i.e., no possibility of synthesis in humans), their sole source is protein breakdown. Hence gluconeogenesis in the liver results in net protein breakdown in muscle.
2. Branched-chain keto acids (BCKAs) resulting from BCAA transamination are poorly metabolized in muscles (except in severe catabolic situations where BCKA-dh is activated by proinflammatory cytokines)

and therefore released in the bloodstream. They are then taken up by the liver, where two of them (α-ketoisocaproate and α-ketomethylvalerate) contribute to ketogenesis.

Gluconeogenic AAs taken up by the liver are readily transformed into glucose and this is favored by increased glucagon levels and decreased insulin secretion. Of course, synthesis of one molecule of glucose from one molecule of AA requires the removal of the N-residues. This is the job of ureagenesis. This process has an important consequence: each molecule of glucose produced in this pathway leads to the irreversible loss of (at least) one N-residue from net muscle proteolysis. This explains why in conditions of prolonged food restriction or when energy demand increases (e.g., in injury), a characteristic sign of metabolic adaptation is loss of muscle mass.

Glucose produced by the liver is taken up by glucose-dependent tissues. In the muscle, glucose is largely used anaerobically, leading to further generation of alanine, producing an alanine–glucose–alanine cycle also called the Cahill cycle.

At the whole-body level, this cycle makes no sense energetically because anaerobic glucose consumption generates little ATP and gluconeogenesis consumes at least the same amount of ATP. However, reasoning at the tissue level casts a different light: in the postabsorptive state the liver is rich in energy owing to β-oxidation of free fatty acids from lipolysis in adipose tissue, whereas muscle is somewhat depleted in energy. Therefore, the Cahill cycle corresponds ultimately to the transfer of energy from an organ that is energy-rich (the liver) to a tissue that demands energy (muscle) at the cost of net protein breakdown.

Final Products of AA Metabolism, Elimination of Surplus Nitrogen

N-metabolic products of AAs are mostly excreted in urine. Only an average 7 mg kg^{-1} body weight in males and 8 mg kg^{-1} in females is removed daily in other ways: shed skin (5 mg kg^{-1}), nasal secretions, shed hair, menstrual losses, etc.

Elimination of nitrogen cannot be carried out directly as ammonia because this substance is toxic for the central nervous system at plasma concentrations above 50 μmol l^{-1}. Yet the equivalent of a mole of NH_3 has to be cleared every day. For this reason, in humans, the main form of nitrogen elimination is urea, a water-soluble nontoxic compound synthesized by the liver.

However, not all the ammonia must be converted into urea, because ammonia plays a key role in acid–base homeostasis, in particular in the kidney.

Ureagenesis

The urea cycle is partly cytoplasmic and partly mitochondrial. Only the liver possesses all the enzymes required to synthesize urea from ammonia, and this pathway is strictly located in periportal hepatocytes.

Five enzymes are involved: carbamoylphosphate synthase (CPS), ornithine carbamoyltransferase (OCT), arginosuccinate synthase, arginosuccinate lyase, and arginase.

Ureagenesis is governed by three different types of regulation:

1. Regulation by the availability of precursors: the rate of flux of AAs towards the liver is a key regulator of ureagenesis; the more AAs the liver takes up, the higher is the rate of ureagenesis. AAs may come from food in the postprandial phase or from muscles in the post-absorptive phase. Conversely, during prolonged starvation, urea production declines simply because the muscle efflux of AAs decreases. All the AAs are not equally ureogenic: GLN, ALA, and ARG are the most contributive.
   - GLN is hydrolyzed into GLU and ammonia by glutaminase present in large amounts in periportal hepatocytes. This reaction forms a ureagenesis amplification loop because the product of the reaction (ammonia) has the unusual property of activating glutaminase. The accumulation of GLU, the other product of the reaction, allows the synthesis of N-acetylglutamate, the regulatory role of which is described next.
   - ALA is transaminated into PYR and in parallel α-ketoglutarate gives rise to GLU. This GLU forms a pool distinct from those described above: a second transamination reaction turns oxaloacetate into aspartate, which provides the second nitrogen donor in ureagenesis.
   - ARG is very ureagenic because (1) it is the direct precursor of urea and (2) it plays a key role in the allosteric regulation of ureagenesis.
2. Allosteric regulation: role of N-acetylglutamate. This substance plays a key role in ureagenesis regulation because it is the allosteric regulator of CPS, the enzyme controlling the entry of ammonia into the cycle. N-acetylglutamate synthesis is catalyzed by N-acetylglutamate synthase, which is strongly activated by ARG. Hence the flux of substrates (GLN, NH_3, and ARG) and the allosteric regulation of CPS act synergistically to modulate ureagenesis both upstream and downstream.

3. *Hormonal Regulation* This regulation operates at two levels:

- On substrate availability: cortisol increases proteolysis and muscle efflux of AAs; glucagon promotes their transport into hepatocytes and further metabolism into ureagenesis and gluconeogenesis.
- On the activity of enzymes.

Ammoniagenesis

This pathway is located in kidney tubular cells and is 80% supported by GLN. The first step is mediated by type I phosphodependent glutaminase, an enzyme activated by acidosis; GLU can then be transaminated into α-ketoglutarate or deaminated by GLU dehydrogenase. This last reaction is strongly activated by acidosis, further increasing the flux of NH_3. NH_3 passes freely into the lumen, where it combines with protons to form the ammonium ion, which cannot return to cells.

The one-way flux of NH_3 means that during acidosis (i.e., high amount of H^+ in the lumen) the intra-cellular NH_3 level is low, derepressing GLU-dh. In turn, this favors GLU metabolism and low GLU derepresses glutaminase. Hence it appears that ammoniagenesis is an adaptative pathway that plays a fundamental role in metabolic acidosis.

Relationship between Ureagenesis and Ammoniagenesis: A Contribution to Acid–Base Homeostasis

The observations described above underline the unique role of GLN as a donor of nitrogen for both ureagenesis and ammoniagenesis. However, heavy consumption of GLN in ureagenesis is not compatible with an increased demand by the kidney in acidosis. A balance between these two almost exclusive processes is achieved, thanks to an anatomical detail – the liver contains two different hepatocyte populations:

- Periportal hepatocytes (93% of the total), which possess a glutaminase activity and enzymes of the urea cycle.
- Perivenous hepatocytes, which form only 7% of the total but have a metabolic activity 100 times higher. These cells possess GLN synthase activity.

Hence catabolism and synthesis of GLN are two processes that occur simultaneously in the liver, but at a different rates according to the situation.

- Physiologically, most of the GLN from the portal vein is taken up by periportal hepatocytes, and the liver is a net consumer of GLN.
- In acidosis, hepatic glutaminase is inhibited (note: acidosis activates kidney glutaminase and inhibits the liver isoform). Consequently, GLN remains available for amino acid metabolism.

Hormonal Control of Amino Acid Metabolism

Physiologically as well as in disease, hormones play a key role in the control of AA metabolism, with a balance between anabolic and catabolic hormones.

Anabolic Hormones

1. *Insulin* Insulin exerts actions at every level of AA metabolism:
   (a) It increases the cell transport of numerous AAs, especially in muscle and liver.
   (b) It favors net protein anabolism by decreasing protein breakdown.
   (c) It decreases gluconeogenesis both by decreasing the availability of precursors and by inhibiting key enzymes of this pathway.

2. *Growth Hormone (GH)* GH stimulates protein synthesis.

Catabolic Hormones

1. *Glucagon* Like insulin, glucagon activates the A system of AA transport, but unlike insulin, glucagon favors the use of AAs in gluconeogenesis.

In addition, glucagon favors proteolysis (through macro-autophagy) in the liver.

2. *Cortisol* Cortisol induces hyper-amino-acidemia because although it increases hepatic, intestinal and renal uptake of AAs, it increases their muscle release even more strongly. In addition, cortisol favors net protein breakdown. Hence in a stress situation, cortisol and glucagon have a synergistic action (Figure 2) leading to a unidirectional flux of nitrogen from the muscle to the liver.

3. *Cytokines* Physiologically, their role is minor. However, in disease, proinflammatory cytokines (e.g., tumor necrosis factor α, interleukins 1 and 6) are overproduced and act synergistically with glucagon and cortisol on AA metabolism.

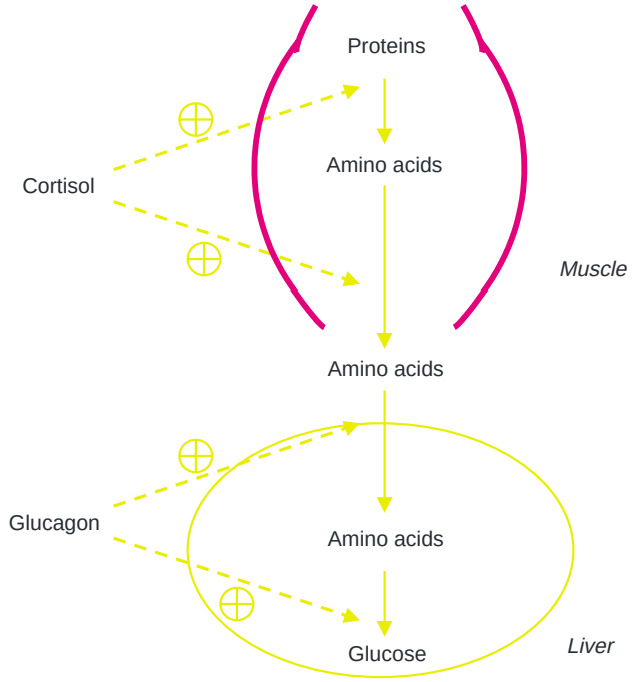

FIGURE 2 Cortisol and glucagon act synergistically to drive AAs from muscle to the liver.

Glossary

ammoniagenesis *De novo* ammonia synthesis from amino acids. The main precursor is glutamine and this process occurs mainly in the kidney. Ammoniagenesis plays a key role in acid–base homeostasis.

enterocyte A cell that ensures the transport of nutrients from the gut lumen to the bloodstream and protects the internal milieu from invasion by bacteria and others.

essential amino acid An amino acid that cannot be synthesized by humans; hence, their provision is strictly dependent upon alimentation.

gluconeogenesis Glucose synthesis from nonglucidic precursors. Main substrates are AAs (mainly alanine, glutamine, and proline), lactate, pyruvate, and glycerol. Gluconeogenesis occurs during fasting mainly in the liver and also in the kidney.

ketogenesis Synthesis of ketone bodies. Fatty acids are the main substrates. Some AAs are also involved, especially leucine. Ketogenesis occurs specifically in the liver.

ureagenesis Synthesis of urea from ammonia or from ammonia derived from amino acids. Ureagenesis allows removal of amino acid in excess and/or the incorporation of the carbon moiety of AAs into glucose (i.e., gluconeogenesis). Ureagenesis is located in the liver.

Aminopeptidases

Ralph A. Bradshaw
University of California, Irvine, California, USA

Aminopeptidases, which are widely distributed in nature, are one of the two major subclasses of the exopeptidases, proteolytic enzymes that remove amino acids from the termini of peptides and proteins (the other being the carboxypeptidases). As the name indicates, the aminopeptidases attack their substrates exclusively from the amino terminal end. Most remove one amino acid at a time, but a small group cleaves two or three residues at a time; these are known as dipeptidyl and tripeptidyl aminopeptidases, respectively. A few enzymes such as acylaminoacyl-peptidase and pyroglutamyl-peptidase remove derivatized amino acids, but generally aminopeptidases require an unmodified or free amino group.

General Description

Properties

Aminopeptidases occur in both soluble and membrane-bound forms and can be found in various cellular compartments as well as in the extracellular environment. The majority are metalloenzymes; that is, they minimally require a metal cofactor at the catalytic site for activity, which is usually zinc ion but can be a number of other metal ions, including Fe^{2+}, Mn^{2+}, and Co^{2+}. There are subclasses containing one and two metal ions. In some cases, the physiological relevant metal is uncertain. There are a few aminopeptidases, particularly of the dipeptidyl- and tripeptidyl-peptidase type, that are classified as serine or cysteine proteases. Aminopeptidases can be processive, meaning that they will continue to degrade the substrate until they reach an unfavorable residue (or combination of residues), and nonprocessive. The latter are usually highly specific for an amino acid type and do not further degrade the substrate after the initial susceptible residue is removed.

Functions

The physiologic functions of aminopeptidases can be divided into three main categories: processing/maturation, activation, and degradation. The enzymes involved in the first two areas usually are highly specific, are nonprocessive, and tailor the N terminus of proteins or peptides either co- or posttranslationally to induce activity or to allow for subsequent modifications that will, in turn, affect activity. Degradation (including inactivation) can also use specific enzymes, particularly where individual bioactive peptides are targeted, but most often involves nonspecific enzymes that participate in protein turnover by the reduction of small peptides, arising from proteosomal cleavage of targeted proteins, to amino acids or by the extracellular degradation of peptides arising from a number of sources.

N-Terminal Cotranslational Processing

One of the best understood functions of aminopeptidases is their role in N-terminal cotranslational processing. Protein synthesis that is directed by the genetic material is universally initiated by the amino acid methionine (in prokaryotes, N-formyl methionine), but the majority of the protein mass in organisms does not reflect this event; that is, most proteins (at least those commonly studied to date) do not have an N-terminal methionine residue. Extracellular proteins that are exported through the endoplasmic reticulum and proteins imported into mitochondria (as well as related organelles such as chloroplasts) lose their respective signal peptides (usually ~20–25 amino acids), including the initiator methionine, through the action of specific signal peptidases, which are endopeptidases. The removal of the initiator methionine from intracellular proteins is accomplished through the action of a specific class of aminopeptidases (clan MG of the metallopeptidases) designated methionine aminopeptidases (MetAPs). All living organisms apparently have at least one form of this enzyme, and they require this activity for vitality. There are several reasons for this: (1) methionine is a relatively scarce amino acid and failure to return a large percentage of the methionine used in the initiation process for reuse (in a variety of activities) leads to a starvation condition that is ultimately lethal; (2) many proteins are subsequently modified on the α-amino group of the newly exposed residue (but can also occur on methionine residues that are not removed) that in many cases is a requirement for their further function; and (3) a few proteins use the newly exposed penultimate residue as a

part of their active structure. The reason that methionine is not removed from all N termini is apparently due to its role as a protecting group against degradation by the N-end rule pathway.

MetAP Specificity

The substrate profile of the MetAPs, despite other distinguishing physical characteristics, is highly conserved over all living organisms, suggesting that it is a very ancient enzyme. Briefly, susceptible substrates have the seven smallest amino acids (glycine, alanine, serine, threonine, cysteine, proline, and valine) in the adjacent (penultimate) position to the methionine. In yeast, a little over one-half of the open reading frames (ORFs) are predicted to code for proteins with these N-terminal sequences, but in terms of mass the percentage of soluble proteins is much higher, perhaps as high as 80%. Because essentially all exported and transmembrane proteins (which may account for as much as one-third of the total protein in a cell) and most of the proteins imported into the mitochondrion also lose their N termini through cleavage of their signal peptides, which are in turn degraded to amino acids, there is a very high degree of recyclization of initiator methionine.

Properties of MetAPs

Structural Organization

The basic catalytic domain, first defined by X-ray analyses of the *E. coli* enzyme, is ~30 kDa in mass and contains two metal ions at the active site. It has an internal symmetry (described as a pita bread fold) suggestive of an early gene duplication event. This structure appears, with only minor variations, to be found in all eubacteria and represents the type 1 isoform. Archaebacteria contain a different but related (homologous) form of MetAP, principally characterized by an insertion of approximately 65 residues, that forms an extra highly helical domain on the surface of the protein. It is designated type 2. Eukaryotes contain both types and in addition each contains an amino terminal extension. The N-terminal segment of the type 1 enzyme contains zinc-finger domains that are thought to act as a tether to tie this enzyme to the ribosome. The corresponding segment of the eukaryotic type 2 proteins is marked by extended stretches of polyacidic and basic amino acids. The function of this domain is unknown. The overall organization of the MetAP family is shown in Figure 1.

Metal Use

These enzymes were initially characterized as using two Co^{2+}, based on early experiments with the eubacterial MetAPs. Subsequently, it was shown that multiple metals could be used in many of the forms, particularly the *E. coli* enzyme, which is active with Fe^{2+}, Zn^{2+}, Ni^{2+}, and Mn^{2+}, in addition to Co^{2+}. It is possible that, depending on availability, the eubacterial enzymes may use different metals. In recent studies in eukaryotes, Mn^{2+} has emerged as the preferred candidate for the type 2 enzyme, whereas Zn^{2+} remains the most likely metal cofactor for the type 1 enzymes under physiological conditions. Although early studies suggested that the MetAPs used a bivalent metal structure, they can clearly function with only a single metal ion present.

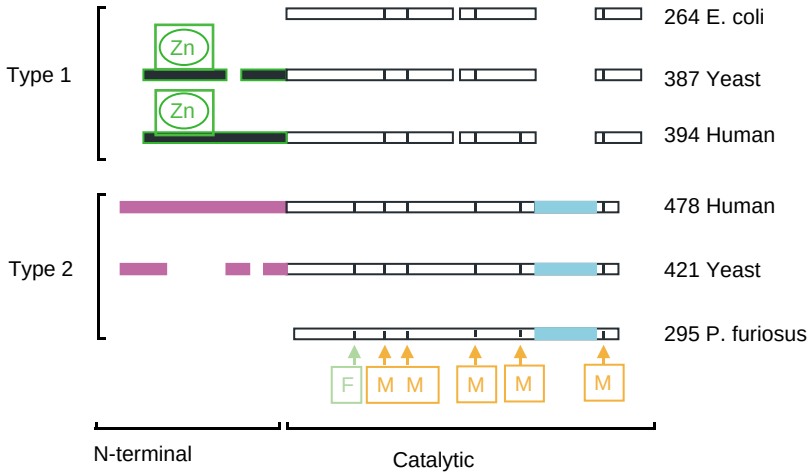

FIGURE 1 Schematic presentation of the structural organization of the MetAP family. Separate domains are indicated by color (magenta, N-terminal extension characteristic of MetAP2s; brown, N-terminal extension with putative Zn-binding domains characteristic of MetAP1s; light blue, catalytic domain insert characteristic of MetAP2s) and are presented approximately to scale. Major deletions (and insertions) deduced from sequence and structural comparisons are indicated as gaps. M denotes the site of a metal ligand; F indicates the location of the histidine modified in type 2 enzymes. The number of residues for each protein is given in the column at the right. Reproduced with permission from Bradshaw and Yi, 2002, *Essays in Biochemistry*, Vol. 38, pp. 65–77. © the Biochemical Society.

In all cases, the metal ions are bound through five amino acid side chains and these are well preserved in all the isoforms in both prokaryotes and eukaryotes.

Roles of the MetAP Isoforms

The substrate specificity of all of the isoforms is generally the same as just described and is heavily predicated on the nature of the penultimate residue. Substrate length, in *in vitro* studies, does have some effect but it is unclear whether this is of significance *in vivo*. Similarly, different metal ions could also affect substrate selection, but this has not been systematically demonstrated. Null mutations (manipulations that prevent the expression of a gene) in yeast demonstrate some measure of redundancy because cells will survive with one or the other of the isoforms but not when both are eliminated. Deletion of the single gene in prokaryotes is also lethal. Nonetheless, there is both direct and indirect evidence to support the view that the two isoforms have different cellular functions. MetAP1 is thought to function as the main processing enzyme and be physically associated with the ribosome in a position to hydrolyze the methionine from germane nascent chains during protein synthesis. MetAP2 is thought to be a soluble enzyme and to probably provide secondary processing for substrates that improperly escape the action of MetAP1. However, it is clearly involved in other activities as well. This is illustrated by a class of irreversible chemical inhibitors that are highly selective for MetAP2, which cause cell-cycle arrest in endothelial cells (but not cell death) resulting in anti-angiogenesis. These potential drugs are being refined for use in treating tumors. Presumably this inhibition results from the failure of MetAP2 to process a select protein or subset of proteins involved in mitosis of these cells, but their nature is unknown. Downstream sequences probably are responsible for rendering these select targets susceptible to MetAP2 but not MetAP1. MetAP2 also functions to inhibit the phosphorylation of eIF2α and thereby promote translation. This activity is entirely distinct from its catalytic one and is not connected to its cell-cycle functions because the inhibited protein is still fully functional as a phosphorylation inhibitor. It is thus one of many proteins known to have dual (and often unrelated) functions.

Glossary

anti-angiogenesis The process by which blood vessel formation is inhibited. Disruption of this activity is an effective way to prevent tissue proliferation, as is encountered in tumor growth.

carboxypeptidase One of two major classes of exopeptidases. They cleave protein and peptide substrates sequentially from the carboxyl terminal end.

endopeptidase One of two major classes of proteolytic enzymes (the other being exopeptidases) that cleave peptide and protein substrates at internal peptide bonds.

N-end rule pathway An intracellular pathway in which selected N termini of proteins are recognized by a specific part of the ubiquitin tagging machinery of the cell, leading to their degradation via proteosomal cleavage.

open reading frames (ORFs) Genome sequences that can be continuously interpreted in an unbroken protein sequence. They generally, but not always, correspond to true structural genes.

proteosome An intracellular suborganelle (or protein machine) composed of multiple subunits organized in a stack of four 7-membered rings. The subunits of the inner rings are proteolytic enzymes that degrade target proteins into short peptides, which are then either further broken down into free amino acids by exopeptidases action or (in the immune system) presented as cell surface antigens to elicit an antibody response. When associated with additional subunits that recognize appropriately marked proteins, it is the principal entity responsible for intracellular protein turnover.

zinc-finger domains Short amino acid sequences that contain four appropriately spaced residues capable of binding a zinc ion through their side chains. This structure, usually predictable from sequence alignments, is often involved in binding to both protein and nucleic acid partners.

Amyloid

Ronald Wetzel
University of Tennessee, Knoxville, Tennessee, USA

Amyloid is an aggregated protein structure consisting of unbranched microscopic fibrils often found in dense tissue deposits and associated with a variety of human diseases, including a number of significant neurodegenerative disorders. In its broadest usage, the term amyloid does not pertain to a specific protein molecule or sequence, but rather to a general folding pattern, or folding motif, that appears to be accessible to many, if not all, polypeptide chains. Although the three-dimensional structures of these proteins in their native states can vary enormously, the abnormal amyloid structures that they form exhibit a characteristic folding pattern, called a "cross-β" structure, that differs from that of the native state structure.

Introduction

Amyloid formation thus involves a protein misfolding reaction. Amyloid fibrils are generally very stable and quite insoluble in native, aqueous buffer. In a way, amyloid is a foreign substance composed of self-proteins, but it is not easily recognized and removed as a foreign substance by the immune system, for reasons that are not well understood. In some disease states involving amyloid deposition, the amyloid deposit is directly involved in the disease mechanism, whereas in other cases its mechanistic role is less clear. In some microorganisms, specific proteins and protein domains appear to have evolved for the purpose of making amyloid fibrils that play an important, positive role in the cell. In most cases, however, amyloid is a pathogenic structure, formed by accident under conditions of molecular, cellular, or organismic stress, from proteins that evolved to fold and function in quite different structural states. The recognition that proteins not known to be involved in amyloid disease can be induced to form amyloid fibrils, through exposure to certain nonnative conditions *in vitro*, has led to a picture of the amyloid motif as a general default structure in protein folding accessible to many, if not all, polypeptide sequences. Notwithstanding the predominant usage described above, the word "amyloid" is also occasionally found as part of the names of specific proteins. These proteins tend to be associated in some way with the amyloid phenomenon, either as proteins capable of making amyloid fibrils [such as serum amyloid A, islet amyloid polypeptide, and β-amyloid (also known as Aβ)] or as proteins that interact with amyloid fibrils (such as serum amyloid P component).

History

Waxy masses found at autopsy in the liver and spleen have been observed in humans since the 17th century. In 1854, Virchow reported that an iodine stain thought to be specific for starch generated a positive test on such material and therefore classified these structures as amyloid (starch-like). Although 5 years later Friedreich and Kekule demonstrated that these deposits contained negligible carbohydrate, the name amyloid has been retained. In 1922, Bennhold introduced the use of the dye Congo red to stain tissue amyloid deposits. After the dye binds, it exhibits an apple-green birefringence when examined by polarized microscopy that sharply distinguishes amyloid from other tissue components (Figure 1). Ever since, Congo red has been the primary method by which pathologists identify amyloid deposits in tissue samples. In 1927, Divry showed that the cores of senile plaques, the cortical structures that Alzheimer linked with early-onset senile dementia in his classic 1906 paper, exhibit the Congo red birefringence characteristic of amyloid. Amyloid plaques are recognized as one of the pathological hallmarks of Alzheimer's disease (AD) and it is believed that some aggregated form of the main protein component of the amyloid fibrils in these plaques plays a direct role in AD etiology. Although it had long been recognized that the main chemical component of amyloid fibrils is protein, it was not until the pioneering work of the Glenner and Benditt groups in the early 1970s that it was realized that amyloid fibrils are predominantly composed of *specific* protein sequences rather than a broad mixture of protein molecules. Glenner showed that amyloid extracted from primary amyloidosis patients contained the immunoglobulin light chain molecule, and Benditt found that amyloid from tissues of chronic inflammation patients consisted of a new protein called amyloid A. Other clinically distinct forms of amyloid

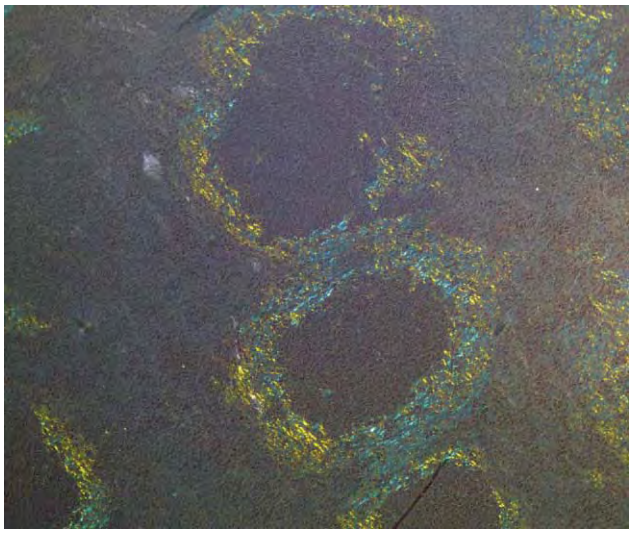

FIGURE 1 Rings of amyloid detected by Congo red staining and polarized microscopy in the spleen of a mouse with serum amyloid A amyloidosis. Courtesy of Professor Jonathan Wall, University of Tennessee.

were soon thereafter shown to have different characteristic protein constituents. In the mid-1980s, Glenner isolated and characterized by amino acid sequencing the previously unknown peptide Aβ as the principal component of AD amyloid fibrils. By the end of the 20th century, many naturally occurring amyloid proteins had been characterized and the list continues to grow with the development of more sensitive means of analysis.

Amyloid Diseases

Range of Amyloid-Related Diseases

Table I lists some of the over 30 human disease states in which amyloid fibrils have been observed, as characterized by the principal organ involved and the principal protein component of each. Amyloid diseases can occur both in the brain and in the rest of the body. The systemic amyloid diseases tend, as a general rule, to involve large deposits of amyloid that in extreme cases dramatically increase the size of the affected organ. In these cases, the toxicity of the amyloid deposit may be largely due to the mass of deposited material and its ability to disrupt normal tissue structure and function. In some peripheral amyloid diseases, the amyloid deposits are localized to a particular tissue. Such is the case in pancreatic amyloid, which is found in over 90% of adult-onset (type 2) diabetes patients (despite this high incidence, the pathogenic role of amyloid deposition in diabetes is not yet known). In contrast, in other amyloidoses, protein deposits can be found in a variety of tissues. Amyloid is also observed in a number of brain diseases. In AD, extracellular amyloid deposits are found in the cerebral cortex, usually embedded with fragments of neuronal processes and surrounded by activated glial cells. In Huntington's disease, amyloid deposits are found in both the cytoplasm and the nucleoplasm of particular neurons in the cortex and elsewhere. In Parkinson's disease, large neuronal deposits called Lewy bodies are rich in the protein α-synuclein. In each of these brain diseases, the mechanistic role of protein deposits has not yet been established.

TABLE I

Major Polypeptide Components of Pathogenic Amyloid Deposits in Humans

Polypeptide	Major disease states
Transthyretin	Heart, kidney, peripheral neuropathy
Serum amyloid A	Kidney, peripheral neuropathy
Immunoglobulin light chain	Kidney, heart
Immunoglobulin heavy chain	Spleen
β_2-Microglobulin	Carpal tunnel syndrome, osteoarthropathies
Lysozyme	Nonnaturopathic visceral amyloid
Islet amyloid polypeptide	Diabetic pancreatic islet cells
Fibrinogen α-chain	Kidney
Apolipoprotein A1	Peripheral neuropathy, liver
Atrial natriuretic peptide	Heart
Amyloid β-protein (Aβ)	Brain (Alzheimer's disease, cerebral amyloid angiopathy)
α-Synuclein	Brain (Parkinson's disease)
huntingtin polyglutamine sequence	Brain (Huntington's disease)
Prion protein (PrP)	Brain (Creutzfeldt–Jakob disease, mad cow disease)
Cystatin C	Brain (cerebral amyloid angiopathy)
Gelsolin	Brain (cerebral amyloid angiopathy)
ABri	Brain (familial British dementia)

Physiological Factors in Amyloid Formation

Although much remains to be learned about the events that trigger amyloid deposition, it is clear that a variety of factors are involved. Some well-established factors are molecular aspects of the proteins themselves. Since the rates of aggregation reactions, such as amyloid formation, depend on concentration, dramatic increases in the amount of the "amyloidogenic" precursor protein can initiate amyloid formation. This is the case for the protein serum amyloid A, which increases in concentration in response to infection and, when persistently elevated, can deposit as amyloid. Similarly, the reason Down's syndrome patients invariably develop AD may be because the extra chromosome associated with the

disease contains the gene for the amyloid β-protein precursor (APP), the protein from which the main plaque component Aβ is generated. The presence of a third active copy of the APP gene in cells results in increased levels of Aβ, which in turn serves to initiate, or "nucleate," fibril formation. One of the unsolved mysteries of amyloid disease is how nucleation of amyloid growth occurs in most disease states. When studied *in vitro*, proteins responsible for amyloid disease often require extremely high, nonphysiological concentrations for nucleation and growth of amyloid fibrils. This indicates that there are unknown specific structures and/or environments in the body that facilitate nucleation. Amyloid plaques typically contain other proteins in addition to the main fibril component and one role of some of these proteins may be to contribute to amyloid formation by helping to stabilize the fibrils and protect them from normal degradative mechanisms. Amyloid diseases are often age-related, leading to the speculation that sporadic amyloid deposition may be a not uncommon occurrence that is held in check in the young and healthy but which advances when normal surveillance mechanisms break down in the aged. This may account for the finding that, in the inherited amyloidosis associated with mutant forms of amyloidogenic precursor proteins, the diseases generally occur later in life, despite the fact that the proteins are expressed from birth.

Prions and Amyloid Enhancement Factor

In one group of amyloid-related brain diseases, a group including Creutzfeldt–Jakob disease, mad cow disease, and the sheep disease scrapie, the conditions can be transmitted by ingestion of "prion" particles, misfolded versions of a normal cellular protein, from the nervous system tissue of a previous victim. Although it is not firmly established that the actual prion particle or state is itself an amyloid fibril, the ability of prion infectivity levels to be amplified in the body bears an intriguing resemblance to the ability of amyloid fibrils to amplify themselves from a pool of precursor protein, through seeding. All mammals express a version of the prion precursor protein, PrP, which has a normal function and does not normally lead to disease. Except in rare instances of sporadic and genetic forms of the disease, prion-associated diseases are observed only when the animal has been exposed to exogenously supplied prion particles, which appear to act *in vivo* as seeds or templates for the propagation of new prions from the normal PrP pool. This scenario is reminiscent of the phenomenon that serum amyloid A amyloidosis can be accelerated in experimental animals by administration of an agent called amyloid enhancement factor (AEF). AEF extracted from the amyloidotic spleen of a mouse and injected intravenously into new mice can induce the rapid development of amyloid deposits compared to untreated controls. Biochemical studies are consistent with AEF being essentially composed of amyloid fibrils, although the presence of an important minor component is difficult to rule out. A possible strong connection between the AEF and prion phenomena has been suggested by experiments showing that AEF, as well as pure amyloid fibrils created *in vitro*, can induce amyloid disease in mice when placed in their drinking water. Thus, although most amyloid diseases are not considered to be transmissible, the results in this experimental system suggest that various amyloid fibrils might be capable of behaving as prions in some circumstances.

Toxicity of Amyloid Fibrils

Although in some peripheral conditions, amyloid can cause life-threatening disease by accumulating in such high mass that normal tissue structure and function are disrupted, in other cases, particularly in the neurodegenerative diseases, the accumulated mass of amyloid is very low compared to the surrounding cell mass. In these cases, the mechanism(s) by which amyloid fibrils cause cell death or cell dystrophy is not at all clear. Whether there is a uniform toxic mechanism in all diseases or different mechanisms for different diseases is also unknown. Toxicity mechanisms under investigation include the following: (1) collateral damage caused by immune responses to an amyloid deposit; (2) membrane depolarization resulting from channels created by amyloid fibril assembly intermediates inserted into membranes; (3) recruitment of other proteins into growing aggregates, which has the effect of denying the cell the activity of the recruited protein(s); (4) disruption or overwhelming of the normal cellular apparatus for breakdown and elimination of misfolded proteins, such as the ubiquitin – proteasome system and the molecular chaperones.

Evolved Amyloid

As far as is known, most protein sequences in evolution were selected for their abilities to efficiently access functional, folded states, while being either unselected, or selected against, with respect to the ability to make amyloid fibrils. Thus, in most cases where amyloid forms, the amyloid can be viewed as an accidental, environmentally induced structure never intended by nature. There are several examples, however, of proteins whose ability to make amyloid fibrils in microbial cells is beneficial to the organism. Yeast prions, for example, function through their ability to form and seed amyloid fibrils and in doing so they modulate the levels of the soluble form of the prion protein in the cell, the fluctuations in which play metabolic and ultimately regulatory roles. In another example, a complex system

of proteins in *Escherichia coli* is responsible for producing an extracellular amyloid fibril that plays a role in cell adhesion. The existence of functional, beneficial amyloid might be viewed as an example of nature's ability to exploit to advantage the novel properties of the products of evolution.

Amyloid Proteins

Range of Amyloid Proteins

Amyloid fibrils composed of different proteins share a number of common structural features, despite the fact that these proteins, in their native states, vary widely in structure, cellular locations, and properties. For example, the amyloid protein transthyretin is a tetramer of subunits with a total molecular weight of 55 kDa. In contrast, small peptides of approximately 40 amino acid residues, such as Aβ and islet amyloid polypeptide (IAPP), and fragments of IAPP as short as pentapeptides, are also capable of amyloid fibril formation. Proteins can grow into amyloid fibrils regardless of the nature of their normal folding patterns. In their native states, α-synuclein exhibits no stable structure in solution, transthyretin is dominated by β-sheet, lysozyme is a mixed α-helix/β-sheet protein, and serum amyloid A is essentially fully α-helical, yet all are capable of forming amyloid fibrils. Most of the peripheral amyloidoses involve secreted proteins, whereas the nine different proteins responsible for nine expanded polyglutamine diseases – including Huntington's disease – are cellular proteins (which, in turn, are found in a variety of subcellular locations). Most amyloid proteins contain significant percentages of hydrophobic residues, but polyglutamine consists entirely of the relatively polar amino acid glutamine. One of the few patterns shared among amyloidogenic protein regions is the infrequent occurrence of proline residues, which strongly disfavor β-sheet – the dominant secondary structural feature of the amyloid fibril.

Molecular Factors in Amyloid Formation

Until the early 1990s, the unusually insoluble, fibrous, quasi-crystalline amyloid fibril was generally viewed as a structural form in which the subunit building block was essentially the native state of the amyloidogenic precursor protein, in a model analogous to structural models for aggregated sickle cell hemoglobin. A significant advance in the understanding of amyloidosis was the demonstration in the mid-1990s that amyloid formation is strongly enhanced when the folded state of a protein is destabilized by mutation or by the solution environment, indicating that fibril structure involves nonnative states. These studies were later extended to show that denaturing conditions can induce amyloid formation even in some proteins not known to be pathogenic. It is clear that misfolding, i.e., the rearrangement of the complex folded shape of a protein molecule, is central to amyloid formation. Thus, protein stability – the resistance of the folded conformation to misfolding/unfolding – is an important factor in determining susceptibility to amyloid formation. Extreme environments in the body, such as acidic cell compartments, may, in some cases, facilitate protein unfolding and therefore promote amyloid formation. Proteolytic removal of a portion of a protein by an endogenous protease can also be a destabilizing factor leading to amyloid formation. Notably, mutations that alter the primary structure of proteins can affect protein stability. In fact, many of the amyloid diseases involve amino acid substitutions in an amyloid precursor protein. The most common example is familial amyloidosis, caused by a variety of single point mutations in the protein transthyretin. In addition, noninheritable, specific amino acid changes in immunoglobulin light chains are linked to a high risk of amyloidosis. Amino acid changes can contribute to the efficiency of amyloid formation not only by modifying the stability of the native state of the precursor protein, but also by modifying the stability of the amyloid fibril itself; an example of the latter is the ability of proline residues to destabilize amyloid structure.

Amyloid Assembly

The manner in which amyloid fibrils grow can be considered in terms of the kinetics of the process or in terms of the structures of assembly intermediates. Kinetically, amyloid fibril formation *in vitro* typically exhibits a lag time of hours to days, followed by a rapid growth phase. In many such cases, the lag phase can be abbreviated or eliminated if a small amount of fibril is provided as seed at the start of the reaction. Such behavior has been interpreted as evidence that fibril growth takes place by nucleated growth polymerization, a mechanism of colloidal assembly in which the initiation of aggregate growth depends on the sporadic generation of a highly unstable, highly organized nucleus state. However, it is far from clear how amyloid growth is initiated *in vivo* and it is possible, even likely, that other molecules or structures are involved, which would make the *in vivo* mechanism more akin to what in physics is referred to as heterogeneous nucleation. *In vitro*, after the nucleation (or seeding) phase has occurred, growth continues predominantly via the elongation of existing fibrils and it has been argued that this is a more realistic view of how amyloid develops *in vivo*. A number of assembly intermediates have been detected when amyloid growth is studied *in vitro*. Whether or not any of these can be considered

to be true kinetic nuclei, some of these structures may have relevance *in vivo*. Amyloid growth from monomeric proteins seems to proceed via the formation of successively larger, more complex structures, from small globular aggregates to short curvilinear filaments to isolated straight and unbranched fibrils to bundles of fibrils. The early assembly intermediates in this progression appear to be more cytotoxic than the mature fibrils, leading to the speculation that assembly intermediates are the real culprits in disease pathogenesis. Little is known, however, about whether and how these intermediates might be formed in the body and how they might kill cells.

Amyloid Structure

Amyloid ultrastructure as revealed by electron microscopy (Figure 2) or atomic force microscopy shows fibrils to be relatively straight and unbranched, with diameters in the range of 80–160Å. Fibrils have a characteristic twist, being composed of two to six protofilaments of diameter 30–40Å. X-ray fiber diffraction studies reveal that fibrils and their constituent protofilaments are rich in a type of β-sheet structure known as cross-β. In this conformational structure type, the extended chain elements of the β-sheet are perpendicular to the fibril axis and the hydrogen bonds between the strands are parallel to the fibril axis. Beyond this level of resolution, little is known about the detailed protein folding of the amyloid motif because of imposing technical barriers to their study by the standard methods of X-ray crystallography and solution-phase nuclear magnetic resonance spectroscopy. Nevertheless, a number of structural models have been proposed and important insights continue to be obtained through lower resolution studies. The structure of the amyloid folding motif is important for a number of reasons, only one of which is their association with a variety of human diseases. It is clear that misfolded, aggregated proteins are formed routinely in the cell due to fundamental inefficiencies in the protein folding process; understanding amyloid structure may help elucidate how the cell manages to recognize and eliminate the products of folding mishaps. Mapping amyloid structure and assembly will also contribute to understanding of this previously ignored aspect of the protein folding reaction – unproductive side products. Finally, better structural information may allow a rational design approach to the development of anti-amyloid therapeutics.

Glossary

folding motif The three-dimensional shape pattern exhibited by a folded protein, consisting of the secondary structural units (e.g., α-helix, β-strands) accessed by different elements of the primary sequence, and how those secondary structural units interact with one another in space. Although there are tens of thousands of protein sequences coded within the human genome, it is believed that the three-dimensional structures of these proteins will ultimately be described by perhaps only a few hundred folding motifs.

glial cells Nonneuronal, accessory cells in the brain that are responsible for maintaining brain structure and development and for fighting infection.

membrane depolarization Loss of chemical potential across a membrane.

molecular chaperones Enzymatic protein assemblies that are responsible for detecting, reversing, and, where necessary, eliminating failed products of protein folding, such as misfolded and aggregated proteins.

nuclear magnetic resonance A type of spectroscopy in which the unique covalent and noncovalent environments of atoms in molecules in solution can be assessed, allowing for construction of a high-resolution structural model of the three-dimensional relationships between atoms.

ubiquitin–proteasome system A complex pathway of enzymes responsible for marking and destroying proteins that are no longer required by the cell due to their being obsolete or defective. Such proteins are first marked by the attachment of the small protein ubiquitin, at which point they are recognized and destroyed by the proteasome, a large protein machine consisting of proteases and other enzyme activities.

X-ray crystallography A technique for determining at high resolution the spatial relationships between atoms in a molecule in the solid state, by the detailed diffraction pattern generated when a molecular crystal is exposed to X-ray beams.

X-ray fiber diffraction An intermediate-resolution version of X-ray diffraction analysis, not requiring a crystalline form, in which repeated patterns of a structure can be recognized from a limited diffraction pattern.

Biography

Dr. Ronald Wetzel is a Professor of Medicine in the Graduate School of Medicine at the University of Tennessee in Knoxville. He obtained a Ph.D. in physical organic chemistry from the University of California, Berkeley, and completed postdoctoral studies at the Max–Planck Institute for Experimental Medicine and at Yale University. He participated in the development of the modern biotechnology industry as an early employee at Genentech, Inc. Dr. Wetzel's major research focus is in the structures and assembly mechanisms of misfolded proteins and protein aggregates, in how they contribute to human disease, and in developing therapeutic interventions for these diseases.

Anaplerosis

Raymond R. Russell, III
Yale University School of Medicine, New Haven, Connecticut, USA

Heinrich Taegtmeyer
University of Texas-Houston Medical School, Houston, Texas, USA

The word anaplerosis (from the Greek, meaning "to fill up") was coined in the 1960s by Sir Hans Kornberg to describe metabolic processes that replenish intermediates in a biochemical cycle. Anaplerotic pathways are present in both eukaryotic and prokaryotic organisms. This article discusses anaplerosis as it relates to the citric acid cycle in mammalian tissues with reference to organ function. Metabolic cycles are essential for the efficient transfer of energy in the cell. In organs such as the heart and skeletal muscle, a series of moiety-conserved cycles connects the circulation with the cycling of crossbridges in the contractile elements of sarcomeres. Here we focus on anaplerotic mechanisms that maintain the intermediates of one of the most important metabolic cycles.

Introduction

Steady-state concentrations of intermediates in a metabolic pathway depend on their rates of synthesis and degradation. Substrates entering the citric acid cycle as citrate (via the condensation of acetyl-CoA with oxaloacetate) do not cause a net change in the citric acid cycle pool size. The two carbons of acetyl-CoA are lost as CO_2 in the isocitrate and the α-ketoglutarate dehydrogenase reactions. In contrast, anaplerosis supplies compounds to the citric acid cycle through reactions other than those catalyzed by citrate synthase. These compounds replenish carbon intermediates lost primarily as amino acids (glutamate or aspartate) or as oxaloacetate. The role of anaplerosis in the citric acid cycle is twofold. First, as intermediates are drained away during synthetic processes such as gluconeogenesis, glyceroneogenesis, and amino acid synthesis, anaplerosis replaces them, allowing citric acid cycle flux to proceed without impairment. This functional aspect of anaplerosis is especially important in the liver and renal cortex. Second, anaplerosis facilitates energy production in organs with high rates of energy turnover, such as the heart and skeletal muscle. The citric acid cycle operates in two spans, and flux is regulated by the α-ketoglutarate dehydrogenase reaction. Under normoxic conditions, faster energy turnover leads to an increase in the pool size of citric acid cycle intermediates. However, under hypoxic conditions, flux through a portion of the citric acid cycle provides anaerobic energy by substrate level phosphorylation.

Anaplerotic Pathways

Substrates for Anaplerosis

As a key component of all living cells, the citric acid cycle is highly organized and must be able to respond to constant changes in its environment. It is thought to be tied into a distributive system of energy transformation; however, this distributive control theory is difficult to prove experimentally, even though regulation of anaplerotic flux through a variety of pathways is part of this response (Figure 1).

The primary substrates for anaplerosis are pyruvate and alanine, although glutamate can be a physiologically significant substrate as well. In addition, the branched-chain amino acids valine and isoleucine, as well as odd-chain fatty acids and their degradation product, propionate, serve as anaplerotic substrates.

Entry at Malate and Oxaloacetate

A major anaplerotic substrate in the heart is pyruvate. Although most pyruvate is oxidatively decarboxylated and enters the citric acid cycle as acetyl-CoA, a portion is also carboxylated and enters the C4 pool of the citric acid cycle. This reaction is catalyzed by either pyruvate carboxylase (forming oxaloacetate) or by NADP-dependent malic enzyme (forming malate). Even though the NADP-dependent malic enzyme reaction is reversible, the reaction in the direction of malate production is slow and unlikely to play a significant role in anaplerosis. Aspartate can also enter the citric acid cycle as a C4 intermediate. It is transaminated with α-ketoglutarate via aspartic aminotransferase to form oxaloacetate and

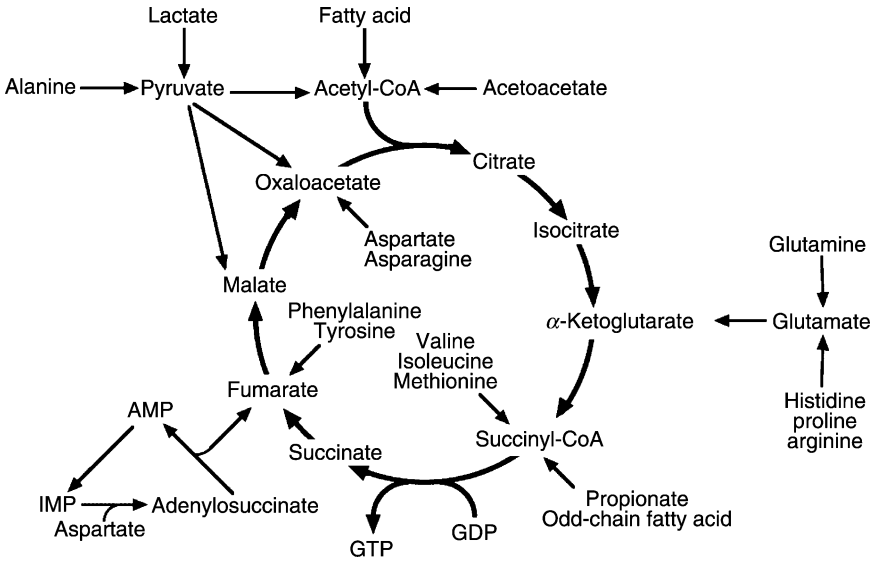

FIGURE 1 Summary of anaplerotic pathways leading to the citric acid cycle.

glutamate. In this reaction, anaplerosis balances the loss of α-ketoglutarate; however, the exact stoichiometry of these reactions has not yet been determined.

Entry via α-Ketoglutarate

In heart muscle (which has the highest rate of oxygen consumption of all mammalian organs), α-ketoglutarate dehydrogenase activity correlates with the rate of oxygen consumption. Therefore, it is likely that α-ketoglutarate dehydrogenase is rate limiting for citric acid cycle flux. Indeed, isotopomer analysis of glutamate enrichment from acetyl-CoA is a lap counter for measuring citric acid cycle flux. A fundamental assumption is that α-ketoglutarate leaves the cycle as glutamate. This reaction is readily reversible by mass action when α-ketoglutarate is formed from glutamate via transamination with pyruvate (forming alanine) or oxaloacetate (forming aspartate). Furthermore, in skeletal muscle glutamate is converted to α-ketoglutarate and NH_4^+ by glutamate dehydrogenase. This enzyme shows no activity in heart muscle.

Entry via Succinyl-CoA

The citric acid cycle intermediate succinyl-CoA plays an important role in fatty acid and amino acid metabolism because it is the entry point of odd-chain fatty acids, propionate, and the branched-chain amino acids valine and isoleucine into the citric acid cycle. Substrate entry as α-ketoglutarate or succinyl-CoA, in contrast to other anaplerotic pathways, is associated with the generation of high-energy phosphates. The reaction catalyzed by succinyl-CoA synthetase is reversed and leads to substrate-level phosphorylation of GDP to GTP. This energy-producing pathway becomes important in myocardial ischemia when ATP generation by oxidative phosphorylation is inhibited.

Entry via Fumarate

In addition to the amino acids phenylalanine and tyrosine entering as fumarate, the purine nucleotide cycle enriches the citric acid cycle based on the net reaction:

$$\text{aspartate} + \text{GTP} \rightarrow \text{fumarate} + NH_3 + \text{GDP} + P_i$$

Previous work has demonstrated that flux through the purine nucleotide cycle increases in skeletal muscle during intense exercise. This increased flux has two effects: First, it can maintain the pool of adenine nucleotides, and second, it can increase the citric acid cycle pool size via anaplerosis. Both of these effects are expected to improve energy metabolism in exercising muscle.

Exit of Intermediates: Balancing Anaplerosis

By definition, under steady-state conditions, substrates entering the citric acid cycle via anaplerotic pathways are balanced by removing an equivalent amount of citric acid cycle intermediates via pathways that maintain a constant citric acid cycle pool size. These pathways have been termed cataplerotic, although the term is a misnomer; instead, the word drainage seems more appropriate. Drainage pathways generally involve removing the citric acid cycle intermediates oxaloacetate

(as aspartate via transamination or as phosphoenolpyruvate via decarboxylation by phosphoenolpyruvate carboxykinase), citrate, or α-ketoglutarate (via transamination to glutamate). Although these drainage pathways are usually thought of as means to balance anaplerotic pathways, they play critical roles in renal gluconeogenesis and enterocyte energy production from glutamine (see later discussion).

Measuring Anaplerosis

Changes in Citric Acid Cycle Pool Size

There are two principal methods of assessing anaplerosis based on changes in citric acid cycle pool size. The amount of citric acid cycle pool intermediates can be measured enzymatically or resolved with high-performance liquid chromatography. Although both methods can reliably assess changes in the citric acid pool size, they do not provide an insight into the pathways involved in anaplerosis nor do they determine relative rates of enrichment. Furthermore, because anaplerosis is usually balanced by the exit of intermediates, changes in citric acid pool size are generally negligible.

Simply determining changes in citric acid cycle pool size provides no information on the rates of anaplerosis or on specific anaplerotic reactions. Using substrates labeled with tracer ^{14}C and measuring incorporation into specific positions in citric acid cycle intermediates is more revealing. This method can not only determine rates of anaplerosis, but also characterize the pathways involved in the process. However, the method is laborious and prone to error. It requires the sequential enzymatic degradation of intermediates and quantitation of the release of the ^{14}C label. It has been replaced by ^{13}C-nuclear magnetic resonance (NMR) spectroscopy or mass spectroscopy.

^{13}C-Nuclear Magnetic Resonance-Mass Spectroscopy

^{13}C-NMR spectroscopy is used to assess quantitatively the relative contributions of various substrates to the citric acid cycle. This method determines the anaplerotic enrichment of citric acid cycle intermediates such as the radiotracer method already discussed, but without digesting the carbon skeleton. ^{13}C-labeled compounds enter the carbon skeleton of citric acid cycle intermediates at specific positions through anaplerotic pathways or through the dilution of ^{13}C by the entry of unlabeled anaplerotic substrates. The enrichment of ^{13}C at those positions is then assessed, indicating citric acid cycle intermediate enrichment. The method is illustrated in Figure 2, in which the enrichment of the carbon skeleton

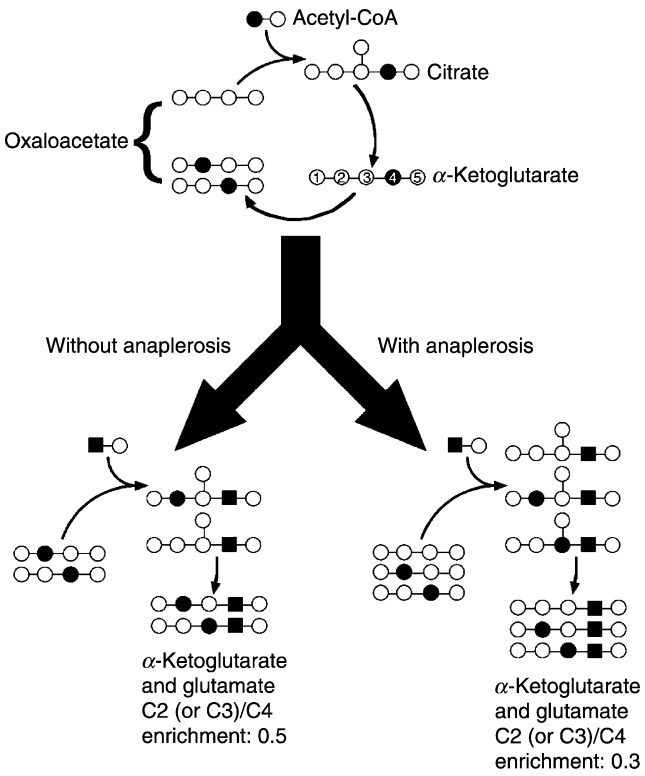

FIGURE 2 Fundamental concept of assessing anaplerotic flux using ^{13}C-NMR spectroscopy as described by Malloy *et al.* (1988). The black circles represent ^{13}C that enters the citric acid cycle pool via the first turn of the citric acid cycle. The black squares represent ^{13}C that enters the citric acid cycle pool via the second turn of the citric acid cycle.

of α-ketoglutarate (and glutamate) at the C2, C3, and C4 positions is used to quantify anaplerosis. Investigators have used the following strategy. Using [2-^{13}C]acetyl-CoA as a substrate and conditions in which there is no anaplerotic flux, one can assume that there is no dilution of the ^{13}C label in the C2 or C3 position of α-ketoglutarate. The label in these positions is generated from the randomization of the C4-position carbon in the first turn of the citric acid cycle. Therefore, the sum of the ^{13}C enrichments of the C2 and C3 carbons will be equal to the enrichment of the C4 carbon of glutamate. In contrast, with anaplerotic activity, the labeled C2 and C3 carbons will be diluted by ^{12}C arising from anaplerotic substrates, and the sum of the enrichments of the labeled C2 and C3 carbons will be less than the enrichment of the C4 carbon of glutamate.

Expression and Activity of Proteins Regulating Anaplerosis

Using the methods outlined, studies have focused on changes in enrichment of citric acid cycle intermediates to assess the activity of anaplerotic pathways and

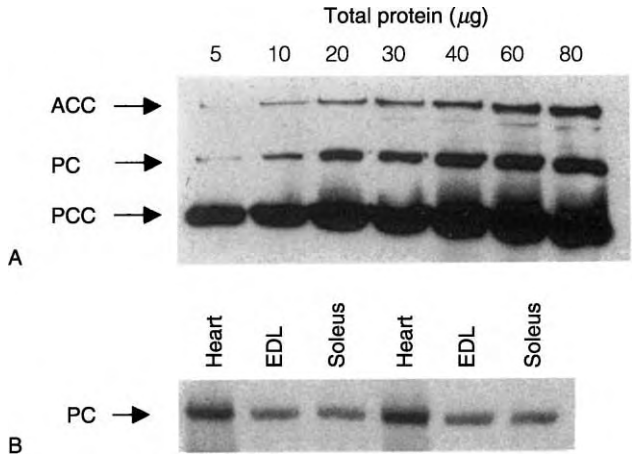

FIGURE 3 Expression of the biotin-containing carboxylases, acetyl-CoA (ACC), pyruvate carboxylase (PC), and propionyl-CoA carboxylase (PCC) in heart muscle based on (A) streptavidin blotting and (B) pyruvate carboxylase expression in rat heart and skeletal muscle. explain changes in flux in terms of mass action and allosteric regulation of key enzymes. Although this is most likely the case with acute changes in anaplerotic flux, changes in the expression and activity of enzymes responsible for anaplerosis should be taken into account when studying chronic processes such as pressure-overload-induced hypertrophy, heart failure, or diabetes. In streptozocin-treated diabetic rats, transcript levels of enzymes in anaplerosis in heart and skeletal muscle are down-regulated (Figure 3). Changes in transcript levels are paralleled by similar changes in protein expression. Although, the *in vitro* activities of the anaplerotic enzymes involved in the carboxylation of substrates (e.g., pyruvate carboxylase) can be measured by determining the incorporation of ^{14}C from $H^{14}CO_3^{-1}$, it is not known whether changes in expression correlate with changes in activity.

Changes in Anaplerosis in Response to Environmental Stress: Workload, Nutritional Status, and Disease

Ultimately, any metabolic process has functional consequences, and anaplerotic pathways are no exception. Anaplerotic pathways play important roles in regulating a wide variety of organ responses to conditions of metabolic stress ranging from exercise to inborn errors of metabolism.

Anaplerosis in Skeletal Muscle during Exercise

The transition from rest to moderate or intense exercise is associated with large increases in skeletal muscle ATP turnover, implying increases in citric acid cycle flux (up to 100-fold increases). Although, citric acid cycle intermediates increase only three- to fourfold, these relatively small increases in the citric acid cycle pool size (via anaplerosis) can reflect dramatic increases in citric acid cycle flux. It has been suggested that the increases allow skeletal muscle to adapt to the energetic demands of exercise, but, interestingly, there is no appreciable change in citric acid cycle pool size at lower levels of exercise. The majority of changes in individual intermediates occur in the second span of the citric acid cycle (i.e., from succinate to oxaloacetate) because the primary source of enrichment during acute exercise appears to be flux through the reaction catalyzed by alanine aminotransferase. This reaction results in entry of glutamate as α-ketoglutarate; however, pyruvate carboxylase and malic enzyme may contribute minor amounts to citric acid cycle enrichment in exercising muscle.

Glutamine Metabolism by the Small Intestine

Glutamine is a source of energy for a number of specialized tissues, including the small intestine. When glutamine is taken up by the small intestine, it enters the citric acid cycle as α-ketoglutarate and leaves the cycle through oxidation as CO_2. More specifically, α-ketoglutarate is converted to malate by citric acid cycle reactions and malate may be transported out of the mitochondria. In the cytosol, malate is converted to oxaloacetate. As in the liver and heart, the malate-aspartate shuttle is bidirectional. It can transport electrons from extramitochondrial NADH into the mitochondria or from intramitochondrial NADH to the cytosol.

Renal Ammonia Formation during Starvation

During starvation, when protein breakdown, renal gluconeogenesis, and hepatic ketogenesis increase, the rate of renal ammoniagenesis also increases. Ammonia is generated from amino acids, including glutamine, released by skeletal muscle. Glutamine is converted to α-ketoglutarate in renal cells; α-ketoglutarate is metabolized to malate; and malate is transported out of the mitochondria, oxidized to oxaloacetate and to phosphoenolpyruvate, and ultimately used for gluconeogenesis. Although different from glutamine oxidation by

enterocytes, this series of reactions also reflects the balance that is generally observed between anaplerotic and drainage pathways.

Ischemia and Substrate-Level Phosphorylation

Early studies assessing cardiac metabolism by measuring arteriovenous differences in amino acid concentrations revealed that, in patients with coronary artery disease and myocardial ischemia, the heart avidly takes up glutamate and releases alanine. This finding led to the hypothesis that the anaplerotic substrate glutamate enters the citric acid cycle as α-ketoglutarate via transamination with pyruvate (thereby forming the alanine that is released). Subsequently, the α-ketoglutarate is metabolized to succinate with the concomitant substrate-level phosphorylation of GDP to form GTP (Figure 4A). In this way, a span of the citric acid cycle can generate high-energy phosphates in the absence of sufficient oxygen for full citric acid cycle operation. Translational research based on this anaplerotic pathway has led to the development of glutamate-enriched solutions that increase anaerobic energy production of the heart during coronary artery bypass surgery.

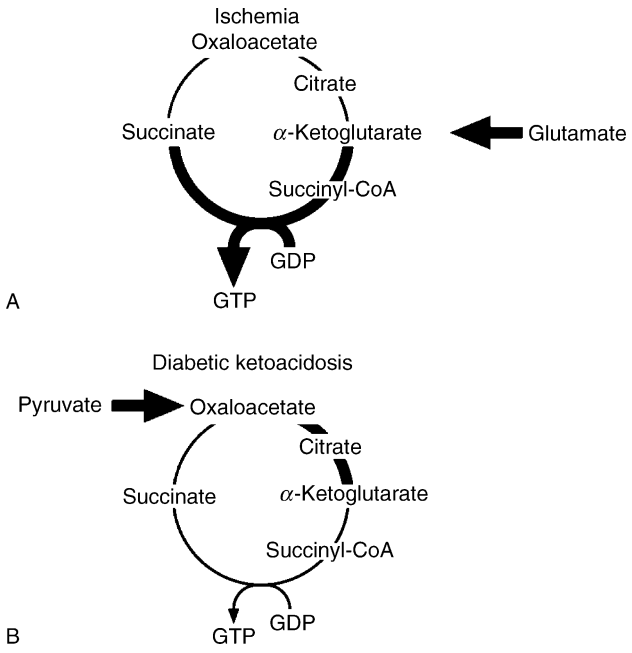

FIGURE 4 Role of anaplerosis in improving myocardial energetics in the setting of (A) ischemia and (B) diabetic ketoacidosis. Under both conditions, loss of cofactors (NAD^+/FAD^+ for ischemia, CoASH for diabetic ketoacidosis) inhibits full citric acid cycle activity. Anaplerotic pathways allow the citric acid cycle to work in spans, thereby increasing the production of high-energy phosphates. Adapted from Taegtmeyer and Passmore (1985).

Diabetes and Ketone Body Metabolism

Citric acid cycle pool size increases in the hearts of rats with experimentally induced diabetes, suggesting enrichment by anaplerotic pathways. We have suggested that an increase in anaplerotic flux, which primarily occurs through pyruvate carboxylation (via malic enzyme), plays an important role in maintaining flux through the second span of the citric acid cycle. Acutely, the metabolic derangement of ketoacidosis that occurs with diabetes inhibits flux through α-ketoglutarate dehydrogenase by sequestration of coenzyme A (CoASH). This phenomenon is associated with contractile dysfunction of the heart that can be readily reversed by the addition of glucose, lactate, or pyruvate (all of which are anaplerotic substrates). The effects of pyruvate are mediated by enrichment of malate in the citric acid cycle pool, which occurs by carboxylation of pyruvate to form malate and oxaloacetate through the actions of malic enzyme and pyruvate carboxylase, respectively (Figure 4B). The citric acid cycle is thereby able to operate once again in a span that can generate reducing equivalents to support oxidative phosphorylation of ADP to form the ATP necessary to drive the contractile machinery of the heart.

Long-Chain Fatty Acid Oxidation Defects and Myopathies

The inability to oxidize long-chain fatty acids due to deficiencies in activity of carnitine palmitoyltransferase-1 or the enzymes involved in β-oxidation is associated with contractile dysfunction due to skeletal and heart muscle damage. One proposed mechanism for the decrease in contractile activity is decreased citric acid cycle flux due to loss of intermediates from damaged myocytes. Based on this hypothesis, a recent trial treated patients with defects in long-chain fatty acid oxidation with odd-chain triglycerides (which can increase the citric acid cycle pool size by entering as succinyl-CoA) and tested the hypothesis that an increase in citric acid cycle pool size may improve muscle function. The study demonstrated beneficial effects, such as reversing left-ventricular dysfunction, decreasing muscle breakdown, and decreasing weakness.

Summary and Perspective

Efficient energy transfer in the mammalian cell is linked to a series of moiety-conserved cycles, including the citric acid cycle. Changes in the cell's environment lead to depletion and replenishment (anaplerosis) of citric acid cycle intermediates. The multiple pathways of

anaplerosis use a variety of substrates, including carbohydrates, odd-chain fatty acids, and amino acids. These pathways reflect a system of redundancy that is important for the functional survival of the cell.

Biography

Raymond R. Russell III is an Assistant Professor of Medicine (Cardiology) at Yale University School of Medicine. His laboratory investigates mechanisms of non-insulin-mediated glucose uptake, uncoupling proteins, and metabolic regulation in the heart. He received both his M.D. and his Ph.D. from the University of Texas Health Science Center at Houston in 1991 and served his residency and fellowship at Yale.

Heinrich Taegtmeyer is a Professor at the University of Texas-Houston Medical School, a cardiologist, and a biochemist. His research interests focus on the logic of cardiac metabolism. He received his M.D. from the University of Freiburg in Breisgau, Germany; was a resident on the Harvard Medical Service at the Boston City Hospital; and was a cardiology fellow at the Peter Bent Brigham Hospital. From 1978 to 1981 he studied in the Metabolic Research Laboratory at the University of Oxford (England), under the late Sir Hans Krebs and Regnal Hems, where he earned his D.Phil.

Angiotensin Receptors

Tadashi Inagami
Vanderbilt University, Nashville, Tennessee, USA

Angiotensin (Ang), initially considered as a major pressor substance, is now recognized to mediate numerous physiological and pathophysiological functions. Over the past 70 years, four different active forms of angiotensins, Ang II, Ang III, Ang IV, and Ang (1-7), have been identified. The complexity of their action was multiplied by subtypes of their respective receptors, AT_{1A}, AT_{1B}, and AT_2 for Ang II, AT_4 for Ang IV, and Ang (1-7) receptors (Table I). Each subtype of the receptors shows more than one signaling mechanism. This article presents an overview of the formation and structure, and the receptors of Ang's and representative signaling pathways that play very colorful regulatory functions, which cover wide areas such as vasoconstriction, vasorelaxation cardiovascular hypertrophy and remodeling, atherosclerosis, thrombosis, stimulation of mineralocorticoid synthesis and release, facilitation of sympathetic outflow, renal electrolyte metabolism, control of central nervous system in water drinking behavior, blood pressure regulation, memory retention, growth inhibition apoptosis, tissue differentiation, arachidonic acid and prostaglandin formation, and regulation of insulin signals.

Angiotensins (Ang) Structure and Formation

Angiotensin I

All angiotensins are derived from the amino terminus of the ~65 kDa prohormone angiotensinogen via a series of proteolytic cleavage by a variety of proteinases and peptidases. The enzyme that initiates this process is renin. This aspartyl protease is active in pH 6–7, reacts exclusively with angiotensinogen, and cleaves only one singular leucyl peptide bond of the prohormone between residues 10 and 11 generating the decapeptide Ang I (Figure 1). Ang I is hormonally inactive, thus it is prohormone as it has no specific receptor to transmit its signal. The physiological, significance of Ang I appears to confer the high degree of specificity to the angiotensin generating system in plasma or intracellular system in which there are numerous proteins.

Angiotensin II

The inactive Ang I is activated to the active Ang II by the metallo-endopeptidase, angiotensin I converting enzyme (ACE), which is identical to kininase II. This enzyme was the target for the first most successful drugs for the treatment of renin-dependent hypertension, with a minimum of side effects and complications. Starting with captopril, a series of long acting ACE inhibitors were synthesized and were found to almost completely block Ang II formation. Ang II has two subtypes of receptors, AT_1 and AT_2. The heptapeptide Ang III is the product of amino terminal cleavage of Ang II by aminopeptidases. Although Ang III is prominent in the neuronal system, it shares receptors, AT_1 and AT_2, with Ang II. The amino acid sequence of rat AT_1 and AT_2 are shown in Figure 2.

Ang (1-7)

Ang (1-7) can be formed mainly by the removal of carboxyl terminal tripeptide from Ang I or of a carboxypeptidase from Ang II. It has been shown to activate phospholipase A_2 to release arachidonic acid from phospholipids leading to the formation of prostaglandins.

Ang IV

Ang IV is the hexapeptide Ang (3-8). It was reported to stimulate the production of plasminogen activator inhibitor to stabilize blood clots and to promote atherosclerosis. Other roles in the brain have been reported.

Whereas receptors for Ang II, Ang III, and Ang (1-7) are G-protein coupled receptors, the receptor isolated and cloned from the adrenal membranes is a single transmembrane type.

Angiotensin Receptor

Ang I Binding Protein

Despite the ubiquitous distribution of Ang I binding proteins, no physiological function was found for it.

TABLE I

Angiotensin Receptors

Angiotensins	Receptors	G-proteins coupled
Ang II	AT_{1a}	$G_{q/11}$, G_i, $G_{12/13}$
	AT_{1b}	$G_{q/11}$, G_i, $G_{12/13}$
	AT_2	G_i
Ang III	The same as Ang II	The same as AT_1 and AT_2
Ang (1-7)	*Mas* oncogene product	?
Ang IV	AT_4/IRAM	Single transmembrane receptor

ANG II RECEPTORS

Receptor Subtypes

Synthesis of a series of variants of Ang II revealed the presence of an Ang II receptor, confirming the earlier finding that there are two types of Ang II receptors, one resistant to dithiothreitol and the other sensitive to the treatment. Inactive variants of Ang II were synthesized to obtain Ang II receptor antagonists. These inhibitor peptides also showed the importance of Arg^2, Tyr^4, and Arg^8 for type 1 Ang II receptors. Particularly, replacement of Phe^8 to Ile, Thr, or Ala (saralisine) greatly reduced Ang II receptor signals such as Ca^{2+} response although binding is not significantly affected. However, these peptidic analogs were partial agonists. These peptidic inhibitors did not distinguish two different receptors, AT_1 and AT_2. We had to wait until the syntheses of nonpeptide inhibitors to obtain indications for the presence of at least two receptor subtypes for Ang II that differ in biochemical and physiological responses, localization, and ontogeny.

Direct proof for the two major receptor subtypes AT_1 and AT_2 were provided by expression cloning of their cDNAs from rat and bovine tissues. Rodents were found to have three genes: AT_{1a}, AT_{1b}, and AT_2. It is likely that birds, reptiles, and amphibians may also have more than one type of receptor. Rat or mouse murine AT_{1a} and AT_{1b} share a 98% amino acid sequence identity through their respective genes and are located in different chromosomes. They can be distinguished only by Northern blot analysis or *in situ* hybridization of 3′ noncoding sequences, where a sizeable difference occurs in nucleotide sequences. In contrast, AT_1 and AT_2 share only 34% amino acid sequence homology. Noteworthy is the localization of the AT_2 gene in the X chromosome throughout species.

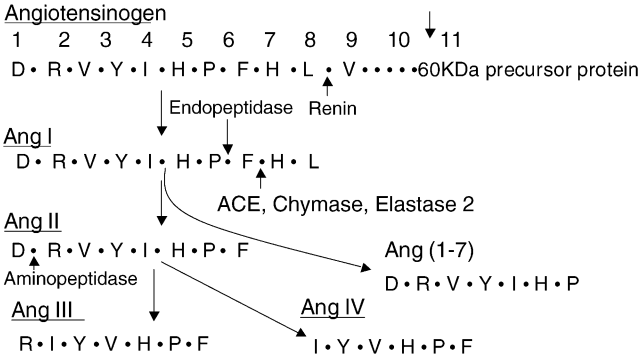

FIGURE 1 Angiotensinogen and generation.

AT_1 Receptor Signaling

Most of the signal responses considered earlier as Ang II actions seem to be mediated by AT_1. These responses are smooth muscle contraction and hypertension, mineralocorticoid synthesis, tyrosine hydroxylase gene expression in adrenal and central and peripheal adrenergic facilitation, stimulation of cellular hypertrophy, mitogenesis and migration, plasminogen activator synthesis, stimulation of fibrosis, renal sodium retentions, centrally regulated dipsogenesis, and hypertension. The major AT_1 signaling pathways are mediated by the Gq/11 mediated phospholipase β_1 activation via cellular $[Ca^{2+}]$ increase and protein kinase activation. However, AT_1 can also couple to Gi, $G_{12/13}$.

It is now well accepted that AT_1 can also activate pathways that involve tyrosine kinase activation such as epidermal growth factor (EGF) receptor through Ca^{2+}-stimulated heparin binding-EGF, and consequent activation of Ras, ERK 1/2 which will further result in $p70^{s6k}$ and phosphatidyl inositol-3-kinase and activation of immediate early gene pathways. AT1 also activates the JAK-STAT system, Src family kinases, tyrosine phosphatase SHP-2, PLC-δ, JNK, and p38 MAP kinase. Accumulating lines of evidence seem to support that some of these tyrosine kinase pathways do not involve G-proteins based on results of mutagenesis studies that eliminate key residues required for interaction of cytoplasmic loops of AT_1.

Importantly, many of the tyrosine kinase activation steps are activated by the reactive oxygen species (ROS), such as superoxide anion and hydrogen peroxide. The formation of super oxide anion is mediated by NAD(P)H oxidase, which is also activated by Ang II. Important recent additions to the knowledge of Ang II mediated smooth muscle contraction is sensitized by the Rho–Rho kinase system. This information is of particular significance for the mechanism of hypertension. On the other hand, cardiovascular hypertrophy and remodeling of resistance vessels are another important aspect for cardiac failure and diminished vascular compliance and hypertension.

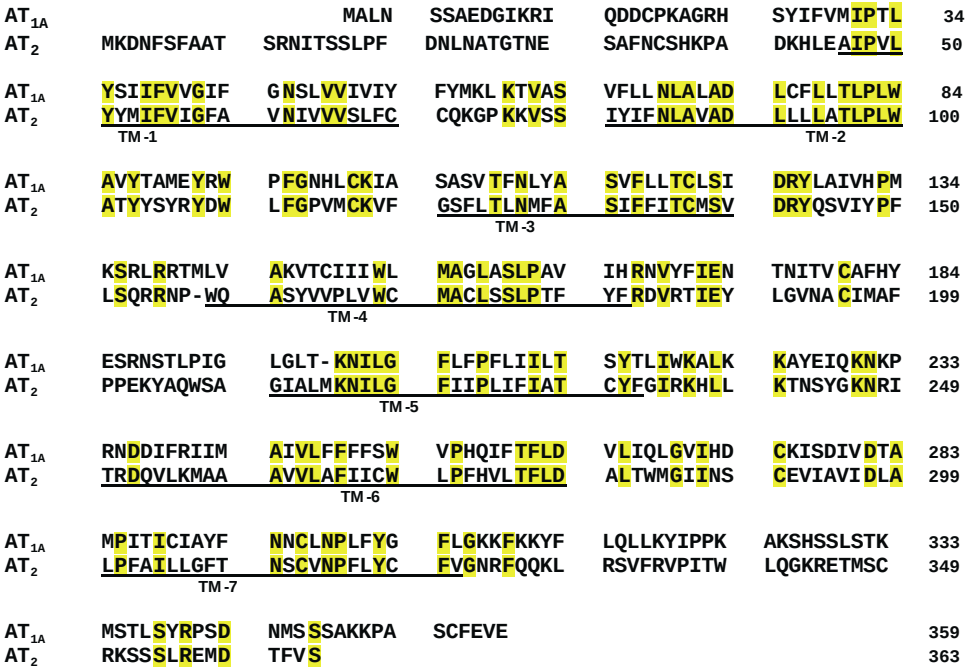

FIGURE 2 Rat angiotensin receptor AT_{1A} and AT_2.

AT_2 Receptor Signaling

Studies on AT_2 signaling, particularly using cultured cells, were not straightforward because of rapid disappearance of AT_2 receptor during repeated passage of cells and exposure to growth medium. Interpretation of results was also difficult because of rapid ontogenic change in AT_2 expression, particularly postnatal decline and increase under stress, during tissue repair or inflammation. *In vivo* studies eliminate many of these difficulties. Thus, *in vivo* studies of loss-of-function studies of AT_2 in the kidney, vasculature, heart, and brain particularly adrenal and colon, where AT_2 remains expressed in adults, are producing substantive results.

In vitro Studies on AT_2 Receptor Signals

Although AT_2 (the AT_2 receptor) is labile in cells in growth culture medium, some cells, such as PC12w, N1E115, and R3T3, maintain AT_2 expression but not AT_1 over several generations. Ang II stimulation resulted in growth inhibition via either MAP kinase phosphatase or the tyrosine phosphatase SHP1 even inducing apoptosis, but not all AT_2 expressing tissues or cells undergo apoptosis. Ovarian atretic cells express AT_2 prominently, yet Ang II treatment failed to induce apoptosis. AT_2 expressed in neuronal cells activate Ser/Thr phosphatase PP2A via a Gi-coupled mechanism and was reported to open delayed rectifier K^+ channel, a hyperpolarizing mechanism. Its growth inhibitory mechanism on endothelial cells was shown to involve the following sequence of events:

Lowering pH → Release of cycloplasmic kallikrein → generation of bradykinin → activation of NOS

This can explain relaxation or dilation of resistance arteries *ex vivo* by AT_2 and its reversal by its specific synthetic inhibitor PD123319 or PD123177 and relaxation by AT_2 partial agonists CGP24112. Although AT_2 was shown to bind specifically with Giα2 or Giα3, not all of these growth suppressing or cGMP mediated signals were inhibited by pertussis toxin.

In vivo Studies on AT_2 Signals

AT_2 gene deleted mice and AT_2 inhibitor treated mice were shown to slowly retain Na and show impaired natriuresis and markedly diminished urinary cGMP, presumably by the mechanism analogous to endothelial cells discussed above. These observations seem to indicate that the signals mediated presumably by inhibition of phosphatases work in the direction opposite to the growth-stimulating signal of AT_1. However, paradoxical observation exists in which AT_1 and AT_2 function in parallel. An increasing number of publications reported that chronic infusion of the AT_2-specific blocker PD123319 was able to inhibit chronic Ang II-induced aortic smooth muscle hypertrophy and fibrosis despite continuously elevated blood pressure. Despite a short half-lifetime of PD123319 *in vivo*, chronic infusion by osmotic mini-pump suppressed

the Ang II-infused aortic hypertrophy. AT_2 gene deleted mice also showed marked resistance against left ventricular hypertrophy induced by pressure overload or chronic Ang II infusion. Another example of parallel phenotypic effect of AT_1 and AT_2 was found in stimulation of tyrosine hydroxylase by both AT_1 and AT_2 in adrenal chromaffin cells *in vivo*.

Since all of the paradoxical results were obtained under well-controlled conditions, signaling mechanism specific tissues were investigated. It was found that the AT_2 binds a zinc finger protein and serves as a transporter to deliver the zinc finger protein to the nucleus, which activated transcription of phosphatidyl inositol 3-kinase p85α subunit (p85αPI3K). This triggers a subsequent cardiac hypertrophic pathway. These results indicate that the AT_2 mediated cardiac hypertrophy uses signals distinct from that which are activated by AT_1. The parallel phenotypic results were due to tissue specific expression of the zinc finger protein in the heart but not in the kidney, where the AT_2 signal depends on the kallikrein-NOS-cGMP mechanism. In contrast, the cardiac tissue uses a more direct activation mechanism of nuclear transcription of p85αPI3K. The p85PI3K activation has been shown to induce a variety of cardiac hypertrophy mechanisms.

Major Physiologic Roles and Morphogenesis of AT_1 and AT_2

Targeted gene deletion of AT_{1A}, AT_{1B}, or angiotensinogen in mice showed that angiotensin II has a profound effect on the maintenance of blood pressure, dual deletion of AT_{1A}, AT_{1B} resulted in hypotension by 45–50 mmHg and no pressor response to Ang II infusion. AT_{1B} was responsible for only 10% of the pressor effect. Interestingly, these animals showed profound defects in the renal papillary and medullary formation suggesting defects in Na reabsorption, an idea in agreement with the poly urea and increased Na excretion. These animals were stunted and it was difficult to keep them alive without daily saline injection. AT_2 gene deletion did not cause overt physical deficiency. However, closer examination revealed that AT_2 deficient mice show high frequency (28% penetrance) of uretero-renal pelvis ligation that is closely analogous to a human neonatal disease called Kakkut syndrome. Connection to the ureter of the renal pelvis is the last step of the kidney morphogenesis and AT_2 concentration is seen in the renal pelvis at this stage in a normal fetus.

Recently, Srivastava's group reported a very intriguing observation in which they identified families with severe mental retardation and traced their gene defect to the absence or "mis sense" mutation of AT_2 gene on the X chromosome. Thus, AT_2 function is not only limited to the renal, adrenal, and cardiovascular system, but brain function also depends on AT_2. Indeed AT_2 gene deficient mice show a pattern of fearful behavior.

Angiotensin (1-7)

Functions

Ferrario and his associate reported physiological functions of Ang (1-7). Since the heptapeptide seemed to be generated by one step of carboxypeptidase, it was not clear whether it was a part of Ang II function. However, it was shown that Ang (1-7) is generated from Ang I by an endopeptidase. Since the affinity of the heptapeptide binding to the brain plasma membrane was in the nanomolar range, it seemed to have a physiological significance. Its specific action was shown as arachidonate release and prostaglandin synthesis. Its systemic presence and function were also demonstrated. Decisive evidence of Ang (1-7) as a hormonal peptide came as the receptor was identified.

Ang (1-7) Receptor

In 1988, Hunley *et al.* presented the hypothesis that *Mas* oncogene product was the Ang II receptor. This hypothesis failed to meet the test of many investigators. AT_1 and AT_2 were cloned soon afterward as unmistakable Ang II receptors. However, the *Mas* oncogene story made a full circle recently when Santos, Walther, and their collaborators showed that the *Mas* oncogene product expressed in COS7 cells binds Ang (1-7) with a nanomolar K_D value and releases prostaglandins in an abstract form. It has a structural feature of a seven transmembrane domain receptor. Further details are awaited.

Ang IV

Harding *et al.* showed that the hexapeptide Ang IV binds to receptors in a variety of tissues and increases blood flow. Recently, Xie, Mendelsohn, and their collaborators purified Ang IV receptor from adrenal plasma membrane and succeeded in cloning the cDNA. They found that it is identical with insulin-regulated amino peptidase (IRAP) with a single transmembrane domain. Its possible interaction with insulin is of potential interest as an interface between angiotensin and insulin. However, Ang IV is not the only ligand that binds the extracellular domain. LVV hemorphin, a segment of hemoglobin, was also reported to be a binding ligand. AT_4 is expressed heavily in the hippocampus and signals to stimulate acetylcholine. Its potential role in memory retention is of great interest in relation to a possible regulatory role of this aminopeptidase.

Ang II also was shown to be involved in the regulation of long-term potentiation (LTP). Thus, the roles of angiotensin are not limited to the control of blood pressure, water drinking, and dipsogenesis in the hypothalamus and brain stem. AT_4 expressed in hippocampus, AT_2 expressed in central amygdala nucleus, and Ang II stimulation of LTP points to roles of angiotensins in normal cortical function.

AT_3

We reported non-AT_1-non AT_2 Ang II receptors in neuro 2A cells were expressed at room temperature, but not at 37 °C. Therefore, we consider it as a likely product of mycoplasm that infected the neuro 2A cell line we used. Thus, at present AT_3 is not of mammalian origin.

Biography

Tadashi Inagami obtained his B.S. from Kyoto University, Kyoto, Japan in 1953, and his Ph.D. in Chemistry from Yale University in 1958. After his postdoctoral training, he joined the Vanderbilt University School of Medicine and has been on the faculty of the Department of Biochemistry since 1966. He assumed the Stanford Moore Professorship in 1992. His research has centered on the biochemistry of vasoactive substances including renin, angiotensin receptor and signaling on intracellular angiotensin generation, cellular hypertrophy signals in vascular smooth muscle cells, and cardiac myocytes.

ara Operon

Robert F. Schleif
The Johns Hopkins University, Baltimore, Maryland, USA

The arabinose operon in the bacterium *Escherichia coli* enables uptake and catabolism of the pentose sugar L-arabinose as the cell's sole source of carbon and energy. In the presence of arabinose, the synthesis of the proteins required for these activities is increased up to 300-fold under the control of the operon's arabinose sensor and regulatory protein, AraC. Expression of the arabinose genes is also subject to catabolite repression, and the catabolite repression protein, CRP, as well as the AraC protein, both bind in the promoter regions of the arabinose gene clusters to regulate expression. In the absence of arabinose, AraC protein binds to two half-sites at the ara p_{BAD} promoter and forms a DNA loop that represses expression. The widespread phenomenon of DNA looping was discovered in the arabinose system. In the presence of arabinose, the loop opens and AraC protein acts positively to assist the binding of RNA polymerase to the p_{BAD} promoter and also speeds the conversion of bound RNA polymerase into the transcriptionally active open complex.

Genetics and Physiology

The pathway for the catabolism of L-arabinose in *Escherichia coli* includes two uptake systems and three enzymes for the conversion of arabinose into D-xylulose-5-phosphate (Figure 1). The *araE* gene codes for a low-affinity arabinose symport protein that couples arabinose uptake to proton uptake. The *araF, araG,* and *araH* genes code for three components of a high-affinity transport system that uses ATP as the source of energy. The products of the *araA*, *araB*, and *araD* genes catalyze the isomerization of L-arabinose to L-ribulose, its phosphorylation to L-ribulose-5-phosphate, and its epimerization to D-xylulose-5-phosphate, which then enters the pentose phosphate pathway and whose enzymes are not subject to direct regulation by arabinose. Expression of the *araA, B, D, E, F, G,* and *H* genes as well as a gene of unknown function, *araJ*, is under control of the *araC* gene product. Expression of the *ara* genes is also under control of the catabolite repression protein, CRP. Thus, expression is low in growth medium containing glucose. Arabinose stimulates increased initiation of *ara* operon messenger within 3 s of its addition to a growing culture.

Transcription Regulation Mechanisms

In the absence of arabinose, the dimeric AraC protein binds to the $araO_2$ and $araI_1$ half-sites, which are 210 bp apart, and forms a DNA loop (Figure 2). The presence of the DNA loop interferes with the binding of RNA polymerase to the p_{BAD} and p_C promoters. Upon the addition of arabinose, AraC protein prefers to bind to the adjacent I_1 and I_2 half-sites. Occupancy of the I_2 half-site stimulates the binding of RNA polymerase to its adjacent binding site and assists RNA polymerase in making the transition to an open complex capable of initiating transcription. Protein–protein contacts important for binding and open complex formation are made between the C-terminal domain of the α-subunit of RNA polymerase and activation region three of CRP as well as the two DNA binding domains of AraC. Contacts likely are also made between the DNA-binding domain of the AraC subunit bound to I_2 and the σ-subunit of RNA polymerase.

Control of DNA Looping

AraC protein shifts from the state of preferring to loop DNA (when arabinose is absent) to the state of preferring to bind to adjacent DNA half-sites (when arabinose is present). The mechanism by which arabinose brings about this change in DNA-binding properties is called the light switch mechanism. In the absence of arabinose, an arm of 18 residues extends from the dimerization-arabinose-binding domain of AraC and binds to the backside of the DNA-binding domain. This arm interaction, plus the covalent connection between the dimerization-arabinose-binding domain and the DNA-binding domain, holds the DNA-binding domains of AraC protein in such an orientation with respect to each other that they are well positioned for DNA looping between O_2 and I_1. Binding to the adjacent I_1 and I_2 half-sites would require extensive bending of the protein and breaking of at least one of the two arm-DNA-binding domain interactions.

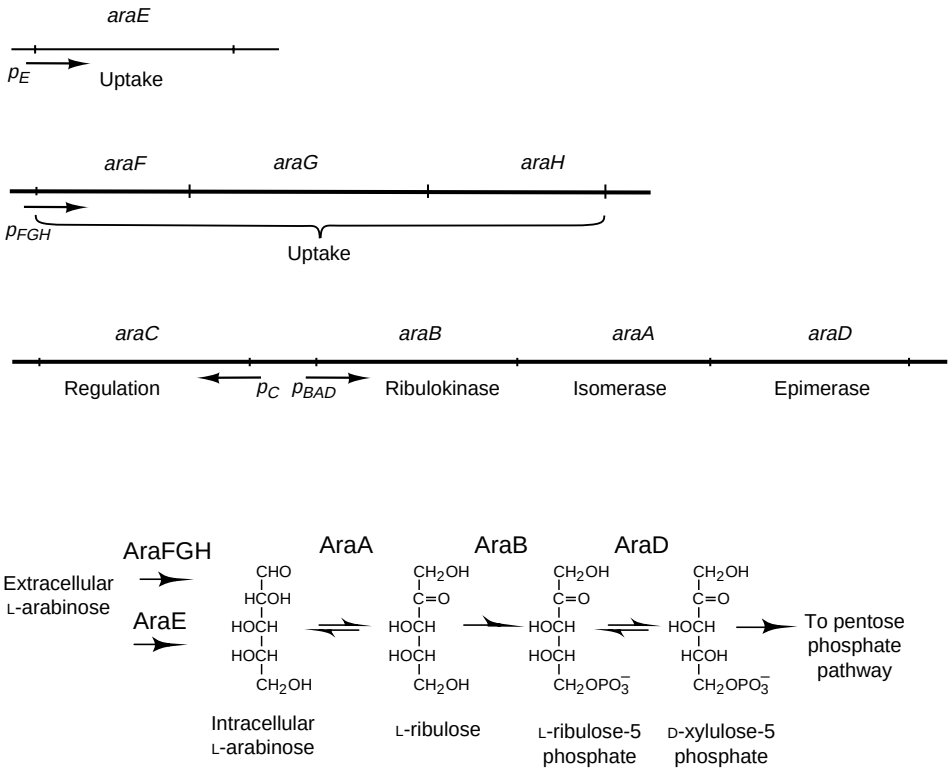

FIGURE 1 Structure of the *ara* gene clusters in *E. coli* that code for the proteins required for arabinose uptake and catabolism, the catabolic pathway, and the enzymes involved.

When arabinose binds to the dimerization-arabinose-binding domain, the arm prefers to bind over the arabinose rather than to the DNA-binding domain. Thus, the DNA-binding domains are freed from the arm-induced constraints, and they can easily position themselves for binding to the direct repeat half-sites I_1 and I_2. In this situation, it is energetically more favorable for the protein to bind to these half-sites rather than to form a DNA loop. Thus, the DNA-binding domain that formerly had been bound to O_2 repositions to I_2, and induction ensues.

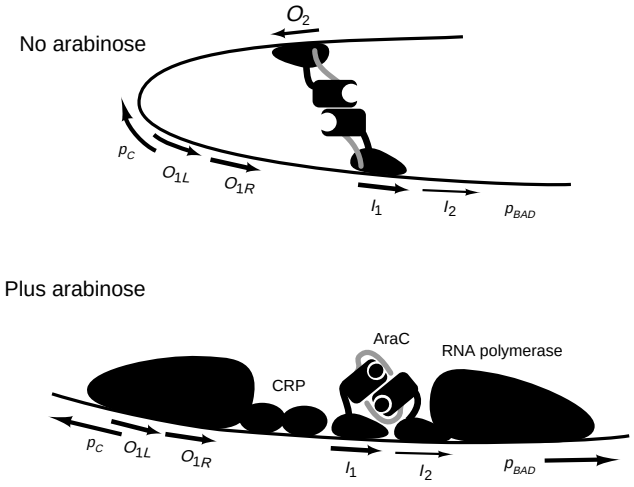

FIGURE 2 The regulatory region between the *araC* and *araBAD* genes containing the promoters p_{BAD} and p_C. In the absence of arabinose, AraC forms a loop between the O_2 and I_1 half-sites. In the presence of arabinose, AraC binds to the adjacent I_1 and I_2 half-sites. The N-terminal arm of AraC is indicated in gray. The p_C promoter is considerably less active than the p_{BAD} promoter. Its activity is further depressed by the binding of AraC to the O_{1L} and O_{1R} half-sites.

The Discovery and Demonstration of DNA Looping

Ellis Englesberg, who initiated genetic studies of the arabinose operon, isolated a deletion extending from outside the *araCBAD* region through at least part of the *araC* gene and into the promoter region. The deletion has the peculiar property that the remaining p_{BAD} promoter can still be fully induced even though the promoter has lost the ability to be repressed by AraC. This property suggested that a site that is required for repression lies upstream from all the sites required for induction. Indeed, an extensive deletion analysis by Schleif confirmed the existence of such repression from upstream and indicated that the upstream site is several hundred nucleotides ahead of all the sites required for induction. The site was definitively identified after the development of genetic engineering technology. *In vivo* footprinting showed

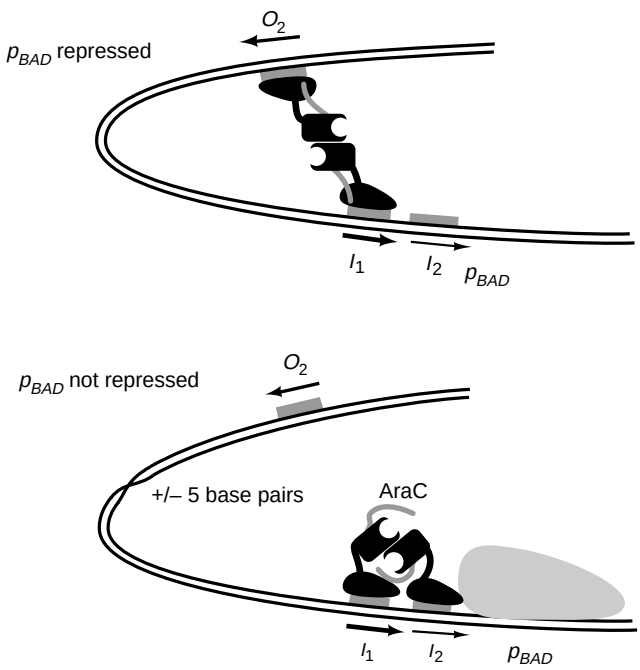

FIGURE 3 Helical twist experiment showing the involvement of the O_2 half-site in repression of p_{BAD}. Introduction of 5 bp of DNA between O_2 and I_1 rotates O_2 to the backside of the DNA and prevents loop formation. In this situation, a small fraction of AraC, even though arabinose is absent, binds at I_1–I_2 and somewhat stimulates the activity of p_{BAD}.

that both the upstream half-site, *ara*O_2, and the *ara*I_1 half-site are occupied by AraC and that mutations in either half-site abolish binding at both half-sites. Introduction of 5 bp of DNA between *ara*O_2 and *ara*I_1 blocks DNA looping and repression by AraC, but still allows induction of p_{BAD} in the presence of arabinose (Figure 3). A 5 bp insertion rotates the O_2 half-site half a turn around the helical DNA with respect to the I_1 half-site so that O_2 the half-site no longer faces toward I_1 and loop formation is not possible. The expression pattern of many additional spacing strains that were generated by inserting and deleting DNA between the half-sites reveals a cyclical pattern of repression with a period of 11.1 bp, thus measuring the helical twist of DNA *in vivo*. DNA looping in the *ara* system has also been demonstrated and studied *in vitro* with gel electrophoresis.

Related Systems

A number of bacteria – e.g., *Salmonella typhimurium, Citrobacter freundii,* and *Erwinia chrysanthemi* – contain genes with greater than 95% sequence identity to AraC, and thus it can be inferred that they contain arabinose operons that are controlled like that in *E. coli*. *Bacilus subtilis* can utilize arabinose as a source of carbon and energy, but its arabinose operon genes are negatively regulated.

At the amino acid sequence level, no close homologues are yet known to the dimerization domain of AraC. Its structure is known to consist of a jelly roll motif that binds arabinose and a coiled-coil motif that dimerizes the protein. Several homologues – including the rhamnose operon regulators, RhaR and RhaS, and the melibiose operon regulator, MelR – are likely however to possess related structures. Many sequence homologues exist to the DNA-binding domain of AraC. Typically, the level of sequence homology between two members of this family, called the AraC/XylS family, is ~20%. Because these family members are gene regulators and generally act positively, they can be inferred to possess similar structure. The structures of MarA and Rob, two proteins in the family, have been determined. Each consists of two helix–turn–helix motifs joined by a long α-helix. This provides an explanation of how each of the two DNA-binding motifs that are found in each DNA-binding domain of the dimeric AraC, contact 17 bp half-sites. For AraC these half-sites are in a direct repeat orientation. The half-sites of RhaR and RhaS, however, are in inverted orientation, illustrating how flexibly the dimerization and DNA-binding domains may be connected in this family.

History and Historical Significance

Genetic analysis of the arabinose operon was begun by Ellis Englesberg. His studies were among the first to suggest that a regulatory protein could act positively to turn on expression of a gene rather than act negatively to turn off expression as had been shown for the *lac* and lambda phage repressors. His genetic analyses also indicated that AraC protein acted negatively and that at least some of the DNA sequence required for this repression lay upstream of all the sites required for induction of expression. Subsequent genetic analysis by Schleif confirmed this result, and revealed DNA looping as the explanation. Further work by Schleif discovered the light switch mechanism by which arabinose controls the preference of AraC to loop in the absence of arabinose and to bind to adjacent DNA half-sites in the presence of arabinose.

The demonstration of positive regulation by AraC was one of the first indications of the wide diversity of regulatory mechanisms that are utilized in nature. Positive regulation is now known to occur in a great many regulation systems, both prokaryotic and eukaryotic. Similarly, DNA looping is widespread in nature. The discovery of DNA looping came at a convenient time to provide an explanation for action-at-a-distance phenomena, e.g., the way in which enhancers in eukaryotic cells can affect gene expression.

Biography

Robert Schleif is a Professor in the Biology and Biophysics Departments at Johns Hopkins University. His principal research interests are in understanding the fundamental mechanisms that govern the action of proteins, particularly those involved with regulation of gene activity. His laboratory discovered the phenomenon of DNA looping and the light switch mechanism.

ARF Family

Gustavo Pacheco-Rodriguez, Joel Moss and Martha Vaughan
National Institutes of Health, Bethesda, Maryland, USA

ARFs or ADP-ribosylation factors are highly conserved 20-kDa guanine nucleotide-binding proteins found in all eukaryotic cells from *Giardia*, the most primitive existing eukaryote, to primates. No ARFs have been found in prokaryotes, which likewise have a paucity of intracellular organelles. ARFs have critical roles in multiple cellular functions, such as protein secretion, cytoskeletal rearrangements, and signal transduction. Vesicular trafficking in eukaryotes is required for intracellular communication and cargo transportation among organelles. Membrane trafficking involves the formation, translocation, and fusion of vesicles of defined structure and composition, initiated at specific sites on intracellular membranes. Vesicles are constructed and dismantled in a step-wise fashion, beginning with initiation at the donor membrane, formation of the membrane bud, assembly of vesicle cargo, and finally, fission to release the vesicle, followed by its transport, tethering at its destination, uncoating, and fusion with the target membrane. The investigation of ARF actions has contributed significantly to understanding many of those events at a molecular level. Although information regarding the function of ARF6 in actin cytoskeleton and membrane dynamics has expanded rapidly in recent years, the mechanisms of trafficking in endoplasmic reticulum and Golgi compartments are probably still better understood and in more detail.

Molecular Characteristics of ARFs

ARFs were first identified, purified, and characterized because of their ability to enhance the cholera toxin-catalyzed ADP-ribosylation of Gαs, the GTP-binding protein activator of adenylyl cyclase. ARF action in cells requires its controlled alternation between the inactive GDP-bound and active GTP-bound forms. This property allows ARFs to regulate enzyme activities and to participate in the formation and transformation of multi-molecular complexes that effect intracellular transport and cytoskeletal rearrangements.

Mammalian ARFs have been grouped in three classes, with ARF1, 2, and 3 in class I, ARF4 and 5 in class II, and ARF6 in class III. Grouping was based on molecular size, amino acid sequence, and gene structure. The yeast *Saccharomyces cerevisiae* has one class III and two class I ARFs. ARF amino acid sequences are highly conserved among species with $>65\%$ identity among human, yeast, and *Giardia* ARFs. All ARFs contain the stereotypical sequences and specific amino acids that function in GTP binding and hydrolysis. One of the hallmarks of these molecules is the presence of the Rossman fold, a $\beta-\alpha-\beta$ structure responsible for nucleotide binding. The availability of high-resolution structures of ARFs allowed identification of other regions, such as the internal β-sheet that distinguishes ARFs from other subfamilies of GTPases. The ARF structure also determines the specificity of its interactions with other molecules, and thereby its function. ARF structure differs from those of all other ca. 20-kDa GTPases in having an N-terminal extension that ends with an N-myristoylated glycine. The fatty acid modification, plus the added amphipathic helix at the N-terminus of the ARF protein, facilitates its membrane association through interaction with phospholipids as well as proteins.

ARF-Related Proteins

In both structure and function, ARFs resemble the several subfamilies of ca. 20-kDa Ras-like GTPases that include Rho, Rac, Rab, and Rap. Each of these proteins, like the ARFs, has special, specific functions in cells. It is notable, however, that many of their actions, effects, and mechanisms of regulation are similar and may even appear to overlap. Perhaps this is because all of these GTPases function by interacting with numerous other molecules, simultaneously or sequentially, in a manner that depends on whether GDP or GTP is bound, to modify their activities or effects.

Among the ARF-related proteins, are ARF-like proteins or ARLs that appear to be more diverse in function and, as a group, differ more in structure than do the ARFs. The 181 amino acid sequences of human ARF1 and ARL1 are, however, 56% identical. There is also ARP (ARF-related protein) and the intriguing 64-kDa ARD1 (ARF domain protein 1), with an 18-kDa ARF domain at the C-terminus.

ARF Actions

With GTP bound, all of the ARFs are activators of the cholera toxin ADP-ribosyltransferase, which is secreted by *Vibrio cholerae*. They also activate the very similar *Escherichia coli* heat-labile enterotoxin (LT) that causes travelers' diarrhea. Allosteric activation of the cholera toxin A subunit (CTA), which is the ADP-ribosyltransferase enzyme, has been well established *in vitro*. The role of ARF in CTA action on cells however, is less clear. The capacity to activate CTA and LT distinguishes ARFs from other GTPases, including the ARF-like proteins or ARLs. The biochemical and/or catalytic behavior of ARFs can be markedly influenced by their interaction with specific phospholipids.

ARF-GTP can also activate mammalian phospholipase D (PLD) and phosphatidylinositol kinases that metabolize phospholipids critical in cell signaling. PLD-catalyzed hydrolysis of phosphatidylcholine produces phosphatidic acid, a molecule that alters the physical properties of membranes and can also activate specific receptors to initiate signaling. Phosphorylation of phosphatidylinositol 4-phosphate by an ARF-activated kinase likewise contributes to the modification of membrane composition and thus the molecular interactions that can be vitally important in properly controlling cell functions.

The shape of the ARF molecule differs dramatically depending on whether GDP or GTP is bound. Activation of ARF by GTP binding results from movement of the N-terminal helix with its N-myristoylated glycine away from a position close to the surface of the ARF molecule, where it resides when GDP is bound. This facilitates its interaction with other molecules and means that ARF-GTP binds membranes more effectively than does ARF-GDP (Figure 1). Membrane-bound active ARF then recruits adaptor and coat proteins to initiate vesicle formation. ARF function in vesicular trafficking probably involves interactions with phospholipids, as well as with proteins, whether they result in the activation of an enzyme like phospholipase D or in the generation of a vesicle when ARF-GTP becomes membrane-bound to begin the assembly of proteins that will become vesicle coat and cargo. Among the three types of coated vesicles, the COPI- and clathrin-coated structures require ARFs (probably class I ARFs) for formation.

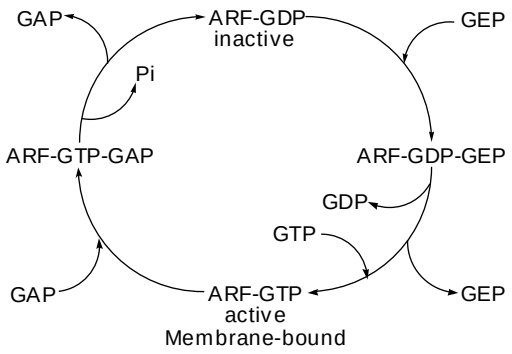

FIGURE 1 Cycle of ARF activation and inactivation mediated, respectively, by GEPs and GAPs. ARF is active in the GTP-bound form, which is produced by GEP-catalyzed replacement of bound GDP with GTP. Active ARF-GTP associates with membranes, to which it recruits adaptor and coat protein molecules. GAP-accelerated hydrolysis of ARF-bound GTP yields inactive ARF-GDP, which has a lower affinity for membranes and therefore dissociates from them.

Regulators of ARF Activity

Activation of ARF requires the replacement of bound GDP by GTP, which under physiological conditions occurs very slowly. ARF activation is regulated, therefore, by guanine nucleotide-exchange proteins, or GEPs, which accelerate the replacement process (Figure 1). The turn-off results from hydrolysis of bound GTP, the rate of which is undetectable until ARF-GTP interacts with a GTPase-activating protein or GAP to generate inactive ARF-GDP (Figure 1).

Several families of ARF GEPs with complex regulatory properties that parallel their critical functions have been described. All ARF GEP molecules are characterized by the presence of a ~190-amino acid Sec7 domain, which contains specific sites for ARF binding; also present are residues (i.e., glutamic acid) that act catalytically to accelerate the release of bound GDP and thereby the binding of GTP, which is present at higher concentration in cells than is GDP. Families of GEPs are distinguished by overall molecular size and structural elements outside of the Sec7 domain, as well as by sensitivity to inhibition by brefeldin A (BFA), a fungal fatty acid metabolite. BFA, which was first used experimentally as an inhibitor of viral replication, was later shown to inhibit protein secretion and certain pathways of intracellular membrane trafficking. BFA-inhibited GEPs include mammalian BIG1 and BIG2, yeast Gea1, Gea2, and Sec7, and the *Arabadopsis* GNOM protein.

Among the BFA-insensitive GEPs, the ca. 47-kDa cytohesin family appears to be the most numerous, with four human genes. These molecules contain a central Sec7 domain responsible for ARF activation, followed by a pleckstrin homolog (PH) domain, which binds phosphatidylinositol phosphates with notable specificity; it thereby influences intracellular localization of the protein. The cytohesins are also of interest as cell adhesion molecules. Before its role in ARF activation was recognized, cytohesin-1 had been identified and cloned because of its function in adhesion of lymphocytes to the extracellular matrix. The multiplicity of GEPs (as well as ARFs) complicates delineation of their individual physiological functions, just as the diversity

and complexity of their structures emphasizes the crucial importance to the cell of accurate and timely integration of signals from multiple sources.

There are also several families of GAPs that regulate ARF inactivation, which is just as critical as activation for maintenance of the ARF cyclical function. These proteins contain characteristic zinc-finger structures that are responsible for acceleration of ARF GTPase activity via a critical arginine residue. The diverse GAPs, like the GEP molecules, contain additional structural domains specialized for different functions and interactions, e.g., with cytoskeletal molecules. Three types of ARF GAPs have been recognized: ARF GAP type, GIT type, and ASAP type. Molecules of the last type contain multiple domains, including PH, ankyrin, proline-rich, and SH3. The multiple domains of these proteins enable them to localize at specific intracellular sites and to interact with numerous other molecules with reciprocal effects on function.

Aspartic Proteases

Ben M. Dunn
University of Florida College of Medicine, Gainesville, Florida, USA

Aspartic proteases are one of the four classes of proteolytic enzymes, which cut other proteins into smaller pieces. Proteolytic enzymes are also known as peptidases, because they cleave peptide bonds, and as proteinases, because they cleave proteins. The four classes include serine-, cysteine-, and metallo-proteases, in addition to the aspartic proteases. Each of these classes derives their name from the amino acid residue or functional group in the case of the metallopeptidases, which serves as the critical part of the catalytic mechanism. In the aspartic proteases, it is actually two aspartic acids that make up the catalytic machinery of the enzyme. The carboxylate groups of these two aspartic acid residues assist in proton transfers from a water molecule that acts as the nucleophile, to attack the peptide bond of the peptide or protein to be cleaved. Aspartic proteases are found in all forms of life and play important roles in some disease processes.

The Spectrum of Aspartic Proteases in Biology

Historically, aspartic peptidases were first found in the digestive tract of many animals. Pepsin is found in the stomach of most animals with an acidic phase of digestion. A related enzyme, gastricisin, is also present in the stomach and in some animals it is the dominant enzyme. Chymosin, a similar enzyme from the fourth stomach of the calf, is responsible for clotting milk when the young animal suckles from its mother. This helps retain the semisolid form of milk proteins in the digestive track for further processing. The presence of an activity was inferred in ancient times when milk was placed in a sack made from the stomach of an animal so that the milk could be transported on long journeys. The travelers found the milk had clotted and realized that something from the stomach lining was causing this to happen. Chymosin is now used to initiate the production of cheese. In some countries, farmers discovered that certain flowering plants also contained a substance that caused milk to clot and these flowers are used in what is termed artisanal cheese making. Other plant enzymes may be involved in digestion of stored seed protein to provide nourishment for a growing seedling. In the world of fungi, many aspartic peptidases have been found. For example, the common bakers yeast, *Saccharomyces cerevisiae*, contains several enzymes in an intracellular organelle called the food vacuole; one of these enzymes is yeast proteinase A.

Due to the progress of genome sequencing projects from 1990 to the present, sequence information is now available for 354 members of the aspartic protease family. They can be related by sequence identities as seen in Figure 1. Representative examples are given for enzymes from animals, plants, fungi, protozoa, insects, and worms. Furthermore, within one organism, different members of the family play different roles. As an example, humans have two enzymes in the stomach that are involved in the digestion of protein in the diet. In addition, an enzyme in the bloodstream, renin, is involved in regulation of blood pressure by converting a precursor molecule, angiotensinogen to angiotensin I. Subsequent conversion of angiotensin I to angiotensin II has a large effect upon blood pressure, as the latter molecule causes constriction of blood vessels and increases in blood pressure. Within cells, several aspartic proteases are found to play important roles. Cathepsin D in the lysosomes of cells acts to activate other enzymes, prohormones, and growth factors. Cathepsin E, which is found mainly in cells of the lymphoid system, seems to have a function in the response of cells to immunological stimuli. Memapsin, also known as BACE, is involved in the conversion of the β-amyloid precursor protein to a form that can aggregate and cause fibrils that are found in Alzheimer's disease. Several enzymes known as napsins have recently been discovered in humans. Their function is unknown at this point in time. In the genomes of the plant, *Arabidopsis thaliana*, the nematode, *Caenorhabditis elegans*, and the fruit fly, *Drosophila melanogaster,* a similar pattern of multiple potential functions has emerged, as multiple sequences with identities to the aspartic protease family have also been identified.

Structure

Pepsin from the stomach of the pig was one of the first proteins to be crystallized; however, the

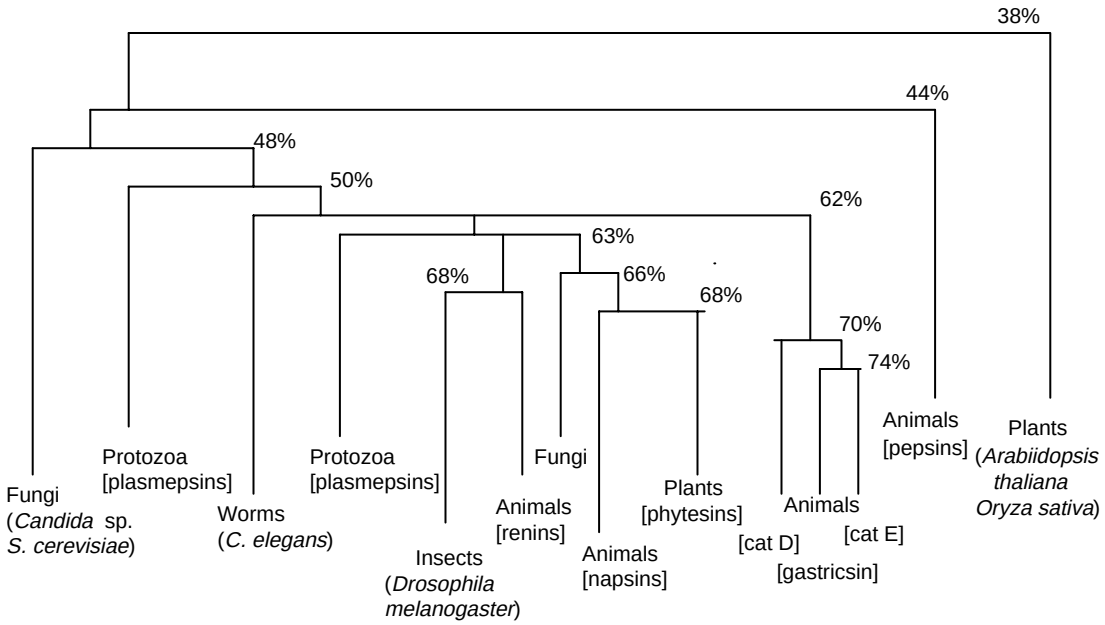

FIGURE 1 Diagrammatic representation of the relationship among several major classes of aspartic proteinases. The number at the top of each division point is the percentage identity between all species below the line. Organism names are given in italics inside parentheses and specific enzyme names are given inside square brackets. Note that different organisms are seen in different points in the diagram. This is due to the fact that different enzymes within one species play different functional roles.

three-dimensional structure of three fungal enzymes were reported before the structure of pig pepsin was solved. Since the 1970s several hundred structures have been solved by X-ray diffraction. At this point in time, we can state with certainty that all proteins that have sequence homology over 40% with the aspartic protease family will have the same overall structure.

Overall Structure

The structure of a typical aspartic protease is shown in Figure 2 in several views. The structure can be divided in two ways. First, there is a twofold axis of symmetry down the middle of the protein as seen in Figure 2A. The first ~165 amino acids of the protein (the N-terminal domain) are an independent folding unit that is mostly

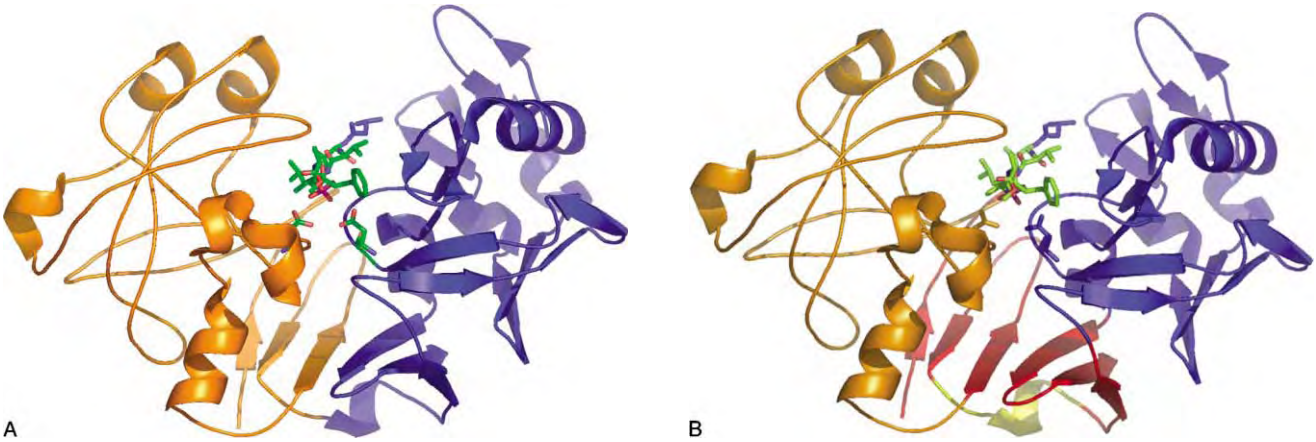

FIGURE 2 Representation of the three-dimensional structure of a typical aspartic protease. The flat arrows represent β-strand structure and the spiral shapes represent α-helices. These elements are from the backbone only and do not show the complete structure of the protein. (A) View of the enzyme looking end-on into the active site cleft at the top. In this representation, the N-terminal domain is colored orange and the C-terminal domain is colored blue. The two catalytic aspartic acid residues are shown in sticks at the bottom of the active site cleft. Above these amino acids one can see an inhibitor molecule bound in the active site. (B) Same orientation as A, with the N-terminal domain colored orange, the C-terminal domain colored blue, and the β-sheet at the bottom of the molecule colored red. A small connecting loop between the first three strands of the red β-sheet and the second three strands is colored yellow.

composed of β-strands and very little α-helical structure. The last ~165 amino acids (the C-terminal domain) are also an independent folding unit with exactly the same folding pattern. The active site cleft is located between the two domains and on one side of the molecule. Each domain contributes to the surface of the cleft, which binds substrates for cleavage or inhibitors that block cleavage. The two halves of the enzymes are believed to have arisen by a gene duplication event before divergence into the different forms shown in Figure 1. A second way to analyze the structure has the same division as described above, but also considers the β-sheet shown at the bottom of Figure 2B as an independent unit comprised of β-strands from each of the two domains. In either analysis, all the known structures are highly similar in structure. Some variation is seen in the relative orientation of the two (or three) domains with respect to each other. In addition, some variability is provided by the length of some of the β-hairpin loops that impinge on the active-site cleft. This provides diversity in the active site binding characteristics of each enzyme, which could be involved in the specific function of each member of the family.

Catalytic Residues

Each of the two domains (N-terminal and C-terminal) provides one aspartic acid, and these two amino acids are located in the 3D structure at the bottom of the active site cleft, and the carboxylic acid functional group of each of the aspartic acid side chains are within 3–5Å. In the enzyme without bound ligands, a water molecule is hydrogen bonded to the two aspartic acid residues and is the nucleophile that attacks the peptide bond of a substrate held within the active site cleft.

Flap Structure

Another significant feature of all aspartic proteases is a β-hairpin that hangs over the active site cleft. This is frequently referred to as the "flap" and movement of this is important in the binding of substrates and inhibitors in the active site. Amino acid differences on the flap, when comparing different members of the family, are important in the different activities exhibited by the enzymes.

Proenzyme Structure

Most aspartic proteases are synthesized within cells as inactive precursors known as zymogens or proenzymes. In all known cases, this involves an N-terminal extension of between 35 and 125 amino acids. In cases where the 3D structure has been determined for some of the proenzyme forms, the extra amino acid sequence acts to either block the active site cleft or to pull the two domains apart from one another, in either case this prevents activity. For many cases, conversion from the proenzyme to the mature enzyme form is self-catalyzed and occurs when the proenzyme moves from a neutral pH condition to a compartment of lower pH. Removal of the N-terminal extension results in a decrease in molecular weight of between 4 and 15 kDa. In a few known cases, the conversion requires a second enzyme.

Diseases

Efforts to understand the structure and function of aspartic proteases have been stimulated by the discovery that many disease processes involve the activity of these enzymes.

Hypertension

As mentioned above, renin is involved in a cascade of reactions that leads to elevation of blood pressure. While this is a normal function that can increase blood pressure in times of activity of an individual, when the levels of renin activity are slightly out of balance, the effects can be dangerous to health. Studies in animals have shown conclusively that giving a selective renin inhibitor, i.e., a compound that will bind to and block the activity of renin without affecting the other aspartic proteases of the human body, has a dramatic effect on blood pressure levels. This area of investigation was extremely important to the study of the whole field of aspartic proteases, as it allowed scientists to develop the tools and strategies to develop selective inhibitors. This has paid dividends in the development of antiviral inhibitors as well as in programs searching for inhibitors against many other family members.

Cancer

High levels of cathepsin D have been observed in areas surrounding tumors in both humans and animals. This has led to the hypothesis that cathepsin D is involved in the invasiveness of cancer cells. However, cathepsin D activity is normally highest at pH values well below that of tissue. Cathepsin D exhibits its activity in the lysosome, where the pH level is believed to be less than 6. In addition, cathepsin D is released when cells break open, so that the excess levels seen in necrotic tissues may be due to cellular decay. Furthermore, in some conditions, excess levels of cathepsin D are due to overloads of the secretory pathway so that the proenzyme form of cathepsin D is released rather than the mature form. Cathepsin D or the proenzyme form may act as a growth factor to stimulate the growth of cancerous cells.

AIDS

An aspartic protease is part of the causative agent for AIDS, human immunodeficiency virus. This protease acts to cut apart a viral polyprotein so that new virus particles can assemble. The HIV protease was the second target against which new antiviral drugs were developed. These compounds have had a major impact on therapy for AIDS.

Malaria

The malaria parasite, *Plasmodium falciparum*, lives during part of its complicated life cycle within human erythrocytes where it degrades hemoglobin for two reasons: one, to provide nutrients in the form of free amino acids for new protein synthesis, and, two, to create space for growth of the parasitic cell. Digestion of hemoglobin is initiated by the action of aspartic proteases. Following the sequencing of the *P. falciparum* genome, it is now known that ten different aspartic protease genes are present. Four of these are expressed and the proteins are located within a special organelle, the food vacuole. This organelle is equivalent to the lysosome of mammalian cells and a similar vacuole of *S. cerevisiae*. Complete digestion of hemoglobin requires the coordinated activity of cysteine proteases and metallo-proteases as well as the aspartic proteases. Inhibitors of aspartic proteases are able to kill the parasite in culture studies.

Fungal Infections

A number of fungi are known to cause diseases in humans and in plants. For example, *Candida albicans* is a common commensal organism, living within the human body but kept in check by a healthy immune system. In situations where the immune system is compromised, due to chemotherapy for cancer or immune suppression to avoid transplant rejection or due to suppression by diseases such as AIDS, *C. albicans* can become a life-threatening systemic infection. The fungus is also known to have a number of aspartic proteases, including several that are secreted into the extracellular environment surrounding the fungal cells. These enzymes are believed to assist in providing nutrients to the fungus by digesting proteins found in the surrounding environment. Some of these secreted enzymes may work to aid in the invasiveness of the fungus as the infection spreads.

Alzheimer's Disease

The newest target for drug discovery is the β-secretase or memapsin. This enzyme acts to cleave the β-amyloid precursor protein at a specific bond, generating a fragment that can become, with further modification by the so-called gamma secretase, a peptide that forms amyloid fibrils. This condition leads to neurofibrilary plaques in the brain, which are a hallmark of Alzheimer's disease. Due to the unique specificity of memapsin, development of specific inhibitors is possible and new therapies for this condition may develop in the next few years.

Inhibitors

Naturally Occurring Inhibitors

Unlike the serine protease family, naturally occurring inhibitors of aspartic proteases are relatively rare. A few have been described in detail and structural information obtained. By investigating the mechanism of inhibition of these protein inhibitors, it is hoped that new insights into inhibitor design will be found.

Pepstatin

Culture filtrates of the organism *Streptomyces* have been found to contain many interesting compounds. Pepstatin, discovered around 1970, was found to strongly inhibit pepsin and other members of the aspartic protease family. This compound is a relatively nonspecific inhibitor, as it seems to block most members of the aspartic protease class. Pepstatin contains an unusual amino acid, 3-hydroxy-4-amino-6-methylheptanoic acid. The 3-OH group binds to the two catalytic aspartic acids to form a transition-state analogue, which provides very tight binding. Because all aspartic proteases have the identical catalytic mechanism, pepstatin is an excellent inhibitor. This compound has been used in many studies of the 3D structure of members of the aspartic protease family and, thus provides convenient comparisons between these enzymes. Many synthetic inhibitors, mentioned below, utilize the same concept in the design of selective inhibitors.

PI-3 Pepsin Inhibitor of *Ascaris*

The nematode, *Ascaris lumbriocoides*, lives within the human digestive tract for a significant part of the life cycle. The digestive tract contains many proteolytic enzymes, including aspartic proteases. The nematode produces several proteins, each of which is able to bind to and inhibit a specific host enzyme. Several inhibitors have been purified to homogeneity, including PI-3. From a purification of the aspartic protease inhibitors, the third fraction had the highest activity in assays of the ability to inhibit pepsin, thus leading to the designation, PI-3. PI-3 is a protein of 149 amino acid residues. It inhibits pepsins and gastricsins from humans and pigs, and has been shown to inhibit the

cathepsin E from humans. The structure of PI-3 in complex with porcine pepsin has been determined and it was found that the inhibitor is a rigid protein, which makes contact with pepsin at two points, using a total of about 13 out of the 149 residues. The structure of the inhibitor does not change when interacting with pepsin.

IA-3 Yeast Protease Inhibitor of *S. cerevisiae*

The yeast *S. cerevisiae* synthesizes a 68-residue protein called IA-3, which is a strong and selective inhibitor of yeast proteinase A. The 3D structure of the complex between the two proteins shows that the inhibitor forms a near-perfect α-helix between amino acids 2 and 34 when it binds to the enzyme, while the inhibitor when free in solution has little or no organized structure. The IA-3 inhibitor does not inhibit any other member of the aspartic protease class that have been tested so far and, in fact, is cleaved by several of the other enzymes. The transition from an unstructured protein to a tightly folded one is a unique aspect of this inhibitor. This is an example of an "intrinsically unstructured protein."

Synthetic Inhibitors

Due to the importance of aspartic proteases in several disease processes, strong efforts have gone into the design and testing of compounds that could become new drugs for treatment of disease. In many cases, the observations that pepstatin was a potent inhibitor gave the initial clue to inhibitor design. Thus, the presence of a hydroxyl group within the structure of a new compound is frequently coupled with the variation in the amino acid sequence (for peptide-like compounds), or in the structural groups (for non-peptide compounds) to create a selective inhibitor. Other variations on the central hydroxyl group include replacements for the peptide bond such as –CH2NH–, –PO2–CH2–, and –CHOH–CHOH–. These replacements have proven effective in the development of new inhibitors.

His laboratory studies the enzymatic function of proteases, using kinetics and biophysical techniques including X-ray crystallography.

ATP Synthesis in Plant Mitochondria: Substrates, Inhibitors, Uncouplers

Kathleen L. Soole and R. Ian Menz
Flinders University, Adelaide, Australia

Adenosine triphosphate (ATP) is the energy carrier of the cell and in eukaryotic cells is synthesized via photosynthesis and respiration. Within respiration there is a low level of ATP synthesis associated with glycolysis in the cytoplasm; however, the majority of ATP is synthesized via oxidative phosphorylation which occurs within mitochondria, specifically via the operation of an electron transport chain (ETC) in the inner mitochondrial membrane. In mammals, flux through the respiratory pathway is tightly regulated by the ATP/ADP ratio or adenylate energy charge of the cell. Plants, unlike mammals, must synthesize all of their cellular components. In plants, the presence of a nonphosphorylating pathway in the mitochondrial ETC and an uncoupler protein in the inner membrane overcomes this restriction by adenylate control. In plants, respiration is not only important for energy production but also has a major role in biosynthesis and anabolic reactions.

Mitochondrial Electron Transport Chain in Plants

Sucrose and starch are converted to metabolites that feed into the early steps of glycolysis which occurs in the cytoplasm. The end products of glycolysis in plants can be either pyruvate or malate, the latter being formed by the action of PEP carboxylase and malate dehydrogenase, which together bypass pyruvate kinase. Once within the mitochondrial matrix, pyruvate is metabolized by pyruvate dehydrogenase and the enzymes of the citric acid cycle. Being a substrate for mitochondrial malate dehydrogenase, malate can either feed into the citric acid cycle or be metabolized to pyruvate via NAD-malic enzyme. There must be a balance between these processes, since because of the poor forward equilibrium of malate dehydrogenase, the accumulation of oxaloacetate would prevent further malate metabolism. The net result of these reactions is the production of NADH and $FADH_2$ (via succinate dehydrogenase). During a turn of the citric acid cycle, 1 ATP is produced directly by substrate level phosphorylation, not GTP as in mammalian mitochondria. Matrix NADH is oxidized by the ETC and more ATP produced via oxidative phosphorylation.

Oxidative phosphorylation occurs via the interaction of large lipo-protein complexes of the (ETC) and smaller mobile electron carriers found in the inner mitochondrial membrane (Figure 1). NADH is oxidized by complex I, which donates its electrons to a mobile lipophilic electron carrier, ubiquinone. Complex II or succinate dehydrogenase also donates electrons to the ubiquinone pool. Reduced ubiquinone (or ubiquinol) is oxidized by complex III via the Q-cycle and reduces the mobile peripheral protein cytochrome *c*. By interacting with complex IV (cytochrome oxidase), the electrons carried by cytochrome *c* are donated to the terminal electron acceptor, oxygen. During these electron transfer events, protons are translocated from the matrix side of the inner membrane to the inter-membrane space at complexes I, III, and IV, thus establishing the proton motive force (pmf or $\Delta\mu_{H+}$). If ADP is bound to the F_oF_1-ATPase in the inner membrane, then protons pass through this complex and the energy within the pmf is used to synthesize ATP. Once ATP is synthesized, it is then exported out of the matrix in exchange for another ADP via the adenine nucleotide translocase. Thus, the flow of electrons and hence oxygen consumption is tightly under control of cellular ADP levels. This is called acceptor or adenylate control.

In plant mitochondria, additional protein complexes are found associated with this ETC. They are distinct from complexes I–IV in that they participate in the transfer of electrons from NADH to oxygen, but do not contribute to the pmf. These enzymes are the alternative or nonphosphorylating NAD(P)H dehydrogenases (NDE and NDI), which donate electrons to the ubiquinone pool and the alternative oxidase (AOX), which accepts electrons from reduced ubiquinone (Figure 1).

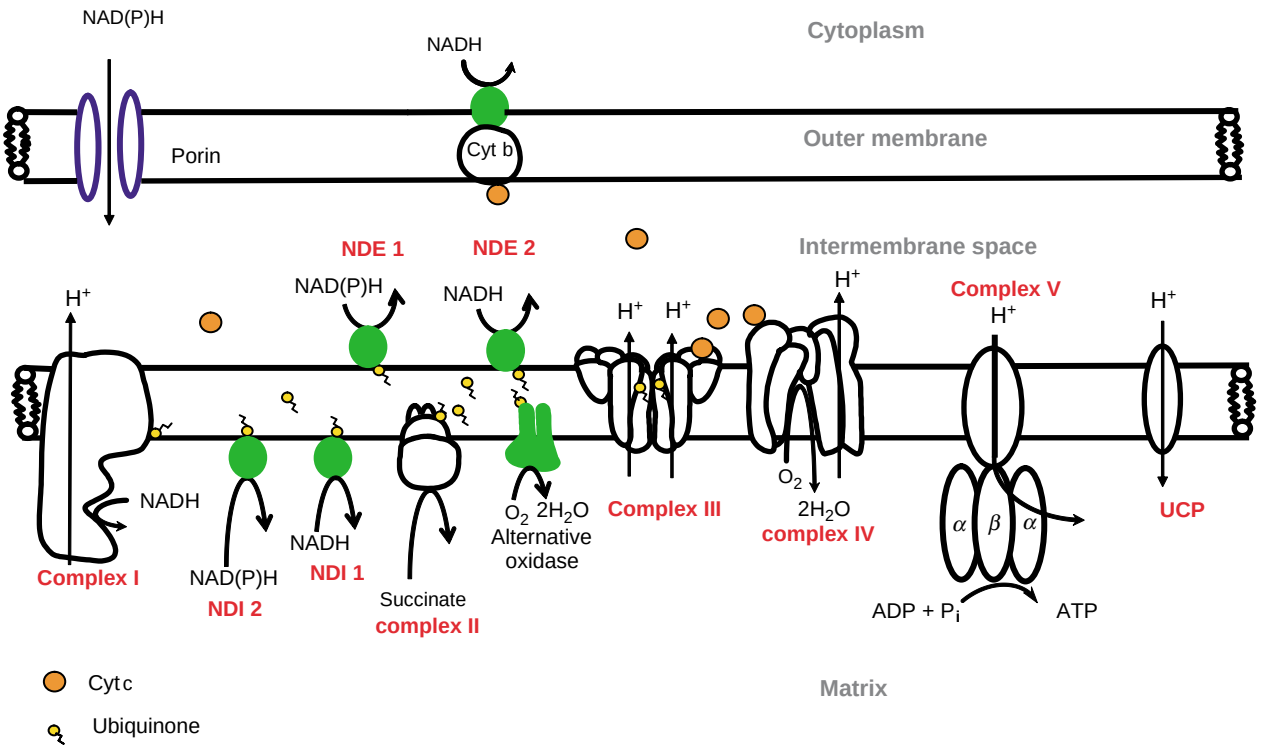

FIGURE 1 A schematic representation of the routes of NAD(P)H oxidation and the electron transport chain (ETC) of plant mitochondria. NDI refers to internal matrix-facing nonphosphorylating NAD(P)H dehydrogenase, and NDE refers to external cytosolic nonphosphorylating NAD(P)H dehydrogenase. UCP refers to the uncoupling protein. Reproduced from Rasmusson *et al.* (2004) *Annual Review of Plant Biology*, Volume 55.

Evidence for the alternative nonphosphorylating NAD(P)H dehydrogenases comes from the ability of isolated plant mitochondria to oxidize externally supplied NAD(P)H, which cannot pass through the inner membrane. The external cytosolic-facing NAD(P)H dehydrogenase (NDE) feeds directly into the ubiquinone pool, as external NAD(P)H oxidation has an ADP/O ratio equivalent to succinate of less than 2.0. Matrix NADH oxidation in plants has a component which is insensitive to inhibition by the complex I inhibitor, rotenone. This oxidation is catalyzed by NDI. The rotenone-insensitive alternative matrix NADH oxidation has an ADP/O ratio also similar to succinate indicating that NDI also feeds electrons into the ubiquinone pool, bypassing proton pumping at complex I. The alternative oxidase is a cyanide and antimycin A-resistant ubiquinol oxidase that catalyses the reduction of oxygen to water with electrons from ubiquinol and thus bypasses the proton pumps at complexes III and IV.

Thus, it is possible to have electron transport/transfer with no ATP synthesis in plant mitochondria. Therefore, due to the bypasses that exist around key regulatory sites in glycolysis, plant respiration can be totally independent of respiratory control, which gives plants great metabolic flexibility. This flexibility, which results in the loss of adenylate control of respiration by the energy status of the cell can theoretically allow the release of biosynthetic intermediates from the respiratory pathway, independent of energy charge of the cell. This role of the nonphosphorylating pathway is hypothesized and has not been clearly demonstrated *in vivo*.

Substrates for ATP Synthesis

The plant mitochondrial ETC can oxidize matrix NADH and NADPH to a much lesser extent. The source of this NADH is from pyruvate dehydrogenase and citric acid cycle, and plants have the full complement of these enzymes in addition to other unique enzymes. The presence of matrix pools of NADPH is indicative of the mitochondria's anabolic role. NADP-dependent enzymes involved in folate and thymidylate synthesis such as NADP-dihydrofolate reductase and methylene tetrahydrofolate dehydrogenase have been found in plant mitochondria and their continued operation requires the turnover of the NADPH generated via NDI2. Apart from NAD-dependent isocitrate dehydrogenase, there is also another NADP-dependent form in the matrix, however its role in plant metabolism is not yet clear. Additionally, via the action of a soluble

transhydrogenase detected recently in pea leaf matrix, the mitochondrial oxidation of any strictly NAD-linked substrates such as pyruvate would also be able to produce NADPH.

Another unique enzyme found in plant mitochondria is glycine decarboxylase, which generates NADH in the matrix, is part of photorespiratory cycle and is important in photosynthetic metabolism. It is accepted that the mitochondrial ETC operates in the light, and that ATP synthesis in the light is not exclusively generated from photosynthesis. Evidence indicates that glycine oxidation is linked to a nonphosphorylating NADH dehydrogenase, such as NDI. Recently it has been shown that NDI is regulated at the transcriptional level by light, at least in potato leaf, suggesting a link between nonphosphorylating enzymes and photorespiratory metabolism.

Plant mitochondria also have the capacity to oxidize cytosolic NADH and NADPH via the enzymes NDE1 and NDE2. Thus, ATP synthesis can also occur from the recycling of cytosolic NAD(P)H.

Inhibitors of ATP Synthesis

There are a multitude of inhibitors that act on specific components of the ETC and the use of many of these has been invaluable in elucidating the composition of the respiratory chain in different species (Table I).

The two most common and specific complex I inhibitors are rotenone and piericidin A, both inhibitors block electron flow between the final iron–sulfur center and ubiquinone. However, they display different inhibition kinetics and it is postulated that the transfer of electrons to quinone may involve more than one quinone-binding site, similar to those observed in complex III. Many other inhibitors of mammalian complex I have been discovered, such as aurachin A and B, thiangazole, phenoxan, and aureothin, and many are likely to inhibit plant complex I; however, their efficacy and specificity has not been demonstrated.

Relatively few inhibitors of plant complex II have been described (Table I), the most widely used is the competitive substrate inhibitor malonate; however, several new complex II inhibitors that are potential fungicides or pesticides have been reported recently.

The two most significant specific complex III inhibitors are antimycin A and myxothiazol, which are specific to the N-side and P-side quinone-binding sites, respectively, and have been important for developing models of the Q-cycle which is involved in proton translocation by complex III.

Complex IV is inhibited by a variety of competitive inhibitors of the oxygen-binding site, such as cyanide and azide. The most interesting of these is the rapid

TABLE I

Specific Inhibitors of Plant Respiratory Enzymes

Respiratory protein	Inhibitor	Site/mode of action
Complex I	Rotenone	Blocks between FeS
	Piericidin A	cluster N2 to quinone
Complex II	Malonate	Competitive substrate
	Thenoyltrifluoroacetone (TTFA)	Blocks FeS cluster S3
Complex III	Antimycin A	Quinone binding (N side)
	Myxathiazol	Quinone binding (P side)
	Stigamatellin	Quinone binding (P side)
Complex IV	Cyanide	Competitive inhibitors of
	Azide	O_2 binding site
	Nitric oxide	
Complex V	Oligomycin	Binds to OSCP-subunit
	Venturicidin	Proton translocation
		(c-subunit)
NDE1 (external NAD(P)H)	DPI	
	Calcium chelators	
NDE2 (external NADH)	Calcium chelators	
NDI1 (internal NADH)		
NDI2 (internal NAD(P)H)	Calcium chelator	
	DPI	
Alternative oxidase	*n*-Propylgallate	
	SHAM	

and reversible inhibition by nitric oxide, which may play an important role in regulation of oxidative phosphorylation.

There are several chemical inhibitors of ATP synthase (Table I), the most prominent being oligomycin, which is a specific inhibitor of F-type ATP synthases found in a variety of organisms. Apart from the chemical inhibitors, there are also inhibitor proteins, which play a role in regulating the activity *in vivo*. The most characterized is the mammalian inhibitor protein (IF1), whose conformation and inhibitory activity changes in response to pH. Proteins with low homology to IF1 have been found in plants, and although they can inhibit ATP synthetase activity, they do not appear to be regulated by pH. More recently, a class of phosphoserine/phosphothreonine-binding proteins, called the 14-3-3′s, have been identified in plant mitochondria and shown to regulate the ATP synthetase activity.

There are several inhibitors of the alternative NAD(P)H dehydrogenases, while a few show differential selectivity between the various alternative NAD(P)H dehydrogenases many of these such as platanetin, IACA (7-iodo-acridone-4-carboxylic acid), dicumarol, hydroxyflavaones, and sulphydryl reagents can inhibit all of the alternative NAD(P)H dehydrogenases. Interestingly, many of these were originally reported as specific inhibitors of particular alternative NAD(P)H activities. The most effective selective inhibitors are calcium chelators such as EGTA, which are potent inhibitors of the external and NADPH utilizing enzymes, which have a calcium requirement, and DPI (diphenyleneiodonium) which is more effective at inhibiting NADPH utilizing enzymes compared to NADH utilizing enzymes (Table I). SHAM (salicylhydroxamic acid) and *n*-propylgallate are the most prominent inhibitors of the alternative oxidase, the latter being more specific as SHAM can also effect other enzymes of oxidative metabolism such as peroxidases, lipoxygenase, and xanthine oxidases.

Uncouplers of ATP Synthesis

Chemical Uncouplers

Oxidative phosphorylation in plants is sensitive to chemical uncouplers such as dinitro phenol (DNP) and carbonyl cyanide *p*-(trifluoromethoxy)phenylhydrazone (FCCP) which dissipate the $\Delta\mu_{H+}$ by carrying proteins across the inner membrane, thus equilibrating the proton gradient. In heterotrophically grown tobacco suspensions cells, cellular respiration is increased by the addition of the uncoupler, FCCP, therefore under these conditions respiration is substrate limited.

Nonphosphorylating Respiration

Plants have the capacity to uncouple respiration and ATP synthesis using naturally occurring enzymes such as the alternative NDE and NDI, and AOX. Therefore, the level of "coupled" respiration will be dependent on the level and activity of these alternative ETC enzymes.

Alternative NAD(P)H Dehydrogenases

In plants, complex I has a much better affinity for NADH than NDI. This suggests that the latter route of electron flow will only be active when the matrix concentration of NADH is high. This has been clearly demonstrated in tissues like potato, which lose NAD from their mitochondrial matrix during longterm storage. In NAD-depleted mitochondria, the rate of electron flow through NDI was markedly reduced, i.e., malate oxidation in isolated mitochondria was totally sensitive to rotenone; however, this could be overcome if the mitochondria were reloaded with NAD from the bathing media. NAD enters via a specific transporter on the inner membrane. It is not clear if this level of regulation occurs *in vivo*. One of the NDI enzymes that uses NADPH as a substrate is calcium-dependent and could be regulated via matrix calcium levels. One question is whether, these alternative pathways operate as overflow for complex I or operate simultaneously during respiration *in vivo*. In a mutant where expression of one of the NDI enzymes was eliminated, the total respiration was reduced, which suggests that NDI contributes to respiration in presence of ADP along with complex I. Both the NDE enzymes are dependent on calcium for maximal activity. It has been suggested that electron flow through the NDE can be regulated by alteration of the local calcium concentration which can be facilitated by polyamines which occur naturally in plant cells, e.g., spermine and spermidine.

Alternative Oxidase

For many years, it was thought that the AOX acted as an overflow, only being used when there was an excess of reduced ubiquinone and the cytochrome pathway (via complexes III and IV) was saturated. It is now known that this is not the case, and that AOX and cytochrome pathway can operate simultaneously. Thus, the level of ATP synthesis will rely on the regulation of AOX. AOX can be regulated at both the transcriptional and posttranslational level. AOX exists as a monomer or dimer, with the monomeric form being most active. Further, AOX is activated by organics acids such as pyruvate. Pyruvate is the end product of glycolysis and thus this activation can act as a positive feed-forward mechanism of control when glycolytic flux is high. AOX is induced upon inhibition of the complexes III and/or IV

and also under various environmental stresses. It is thought that the expression of AOX is an attempt by the plant to have a flexible control of ATP synthesis and to maintain growth rate homeostasis. It is also thought to be part of the cell's defense against oxidative stress, as increased flux through the ETC would prevent the accumulation of high-energy electrons in the respiratory pathway, which could react with oxygen to form harmful, reactive oxygen species.

Uncoupling Protein

In addition to AOX, plants also have uncoupling protein (UCP), which mediates proton re-uptake across the inner membrane (Figure 1). This activity is activated by free fatty acids and inhibited by pyridine nucleotides. UCP is active during respiration in the presence of excess ADP when the free fatty acid concentration is $\sim 4\ \mu M$, and thus can divert energy from oxidative phosphorylation, impacting on the capacity for ATP synthesis. There is a reciprocal regulation between UCP and AOX as free fatty acids inhibit AOX activity. However a precise understanding of the integration and regulation of nonphosphorylating respiratory pathway, UCP and ATP synthase remains a major research challenge.

Glossary

alternative oxidase A ubiquinol oxidase located in the inner mitochondrial membrane, which accepts electrons from reduced ubiquinone and reduces oxygen to water. During this process, no protons are translocated across the inner mitochondrial membrane.

nonphosphorylating NAD(P)H dehydrogenase(s) Enzymes that accept electrons from NADH or NADPH and reduce ubiquinone, a mobile lipophilic electron carrier in the inner mitochondrial membrane with no consequent proton translocation across the membrane.

nonphosphorylating pathway A route of electron transfer with no concomitant translocation of protons across the inner mitochondrial membrane, hence this route of electron flow does not contribute to the proton motive force.

proton motive force Refers to the proton gradient that is established across the inner mitochondrial membrane during electron transfer through complexes I, II, and IV. Often referred to as $\Delta\mu_{H+}$ or pmf.

Biography

Dr. Kathleen L. Soole is a Senior Lecturer in the School of Biological Sciences at Flinders University, South Australia. Her principal research interests are in the roles that the nonphosphorylating pathways play in plant mitochondria, plant growth, and stress adaptation. She holds a Ph.D. from the University of Adelaide in South Australia and gained her postdoctoral training at the University of Newcastle-upon-Tyne, England. She has recently identified the gene in Arabidopsis that encodes the protein responsible for matrix nonphosphorylating NADH oxidation in Arabidopsis.

Dr. R. Ian Menz is a Biotechnology Lecturer in the School of Biological Sciences at Flinders University, South Australia. His research interests include the function and structural biology of respiratory proteins. He holds a Ph.D. from the Australian National University, Canberra, Australia. He worked on the structural biology of ATP synthase as a postdoctoral fellow with Sir John E. Walker at the Medical Research Council, Laboratory of Molecular Biology, Cambridge, England.

ATP Synthesis: Mitochondrial Cyanide-Resistant Terminal Oxidases

James N. Siedow
Duke University, Durham, North Carolina, USA

Mitochondria from all higher plants, most algae, many fungi, and some protozoa contain a second terminal oxidase in their electron transfer chain in addition to cytochrome *c* oxidase, the standard terminal oxidase found in all mitochondria. Functionally, this "alternative" oxidase is a ubiquinol oxidase, receiving electrons from reduced ubiquinone and transferring them to oxygen, which is reduced to water. Electron flow from reduced ubiquinone to cytochrome *c* oxidase includes two sites for transporting protons across the inner mitochondrial membrane to form a proton gradient across the membrane that drives ATP formation. Electron flow through the alternative oxidase involves no proton translocation and therefore wastes all the free energy released during electron transfer that would otherwise be conserved in the proton gradient to produce ATP. The role of such an energetically wasteful pathway has yet to be fully elucidated, but in plants it appears to be associated with response to a variety of stresses, possibly acting to prevent over-reduction of the quinone pool and the subsequent formation of harmful reactive oxygen species.

The Uniqueness of Plant Mitochondria

Plant mitochondria, like those of all other eukaryotes, contain a standard set of protein complexes that make up the electron transport chain in the inner mitochondrial membrane, complexes I–IV (Figure 1). This electron transfer chain functions as the third stage of aerobic respiration, whereby reductants (NADH, $FADH_2$) generated by operation of the TCA cycle in the mitochondrial matrix are oxidized and the resulting electrons transferred to molecular oxygen. The free energy released during electron transfer is used to translocate protons across the inner membrane from the mitochondrial matrix to the intermembrane space at complexes I, III, and IV, forming an electrochemical proton gradient across the inner membrane. Another inner membrane protein complex (complex V, ATP synthase) provides a path for protons to move back into the matrix and, in the process, couples the energy stored in the proton gradient to the synthesis of ATP from ADP and Pi. The terminal reaction of the electron transfer chain is the reduction of O_2 to H_2O by complex IV, cytochrome *c* oxidase. This standard electron transfer pathway is frequently termed the "cytochrome" (cyt) pathway because of the cytochromes present in complexes III and IV and cytochrome *c*. Specific inhibitors of each of the mitochondrial complexes are known. For example, rotenone inhibits complex I, antimycin A inhibits complex III, and cyanide inhibits cyt *c* oxidase.

In addition to the standard cyt pathway, mitochondria in plants contain a variety of additional electron transport proteins that impart flexibility to the system because they can operate without being coupled to ATP synthesis (Figure 1). On the electron input side of the ubiquinone pool are two sets of NAD(P)H dehydrogenases. One pair of dehydrogenases is found on the outside of the inner mitochondrial membrane, allowing mitochondria to oxidize cytoplasmic NADH or NADPH. A second set exists on the inner surface of the inner membrane and oxidizes matrix-derived NAD(P)H. These dehydrogenases do not contribute to proton gradient formation during electron transfer and therefore are able to operate unconstrained by it, unlike proton-pumping components such as complex I whose activity will be impaired as the proton gradient increases. These dehydrogenases are also insensitive to complex I inhibitors such as rotenone. Electrons derived from the oxidation of NAD(P)H by all these dehydrogenases are transferred to the common pool of ubiquinone that also serves as the electron sink for complexes I and II (Figure 1).

Cyanide-Resistant Respiration

Plant mitochondria also have an additional electron transport branch downstream of the ubiquinone pool due to the presence of a second terminal oxidase in addition to cyt *c* oxidase. This "alternative oxidase"

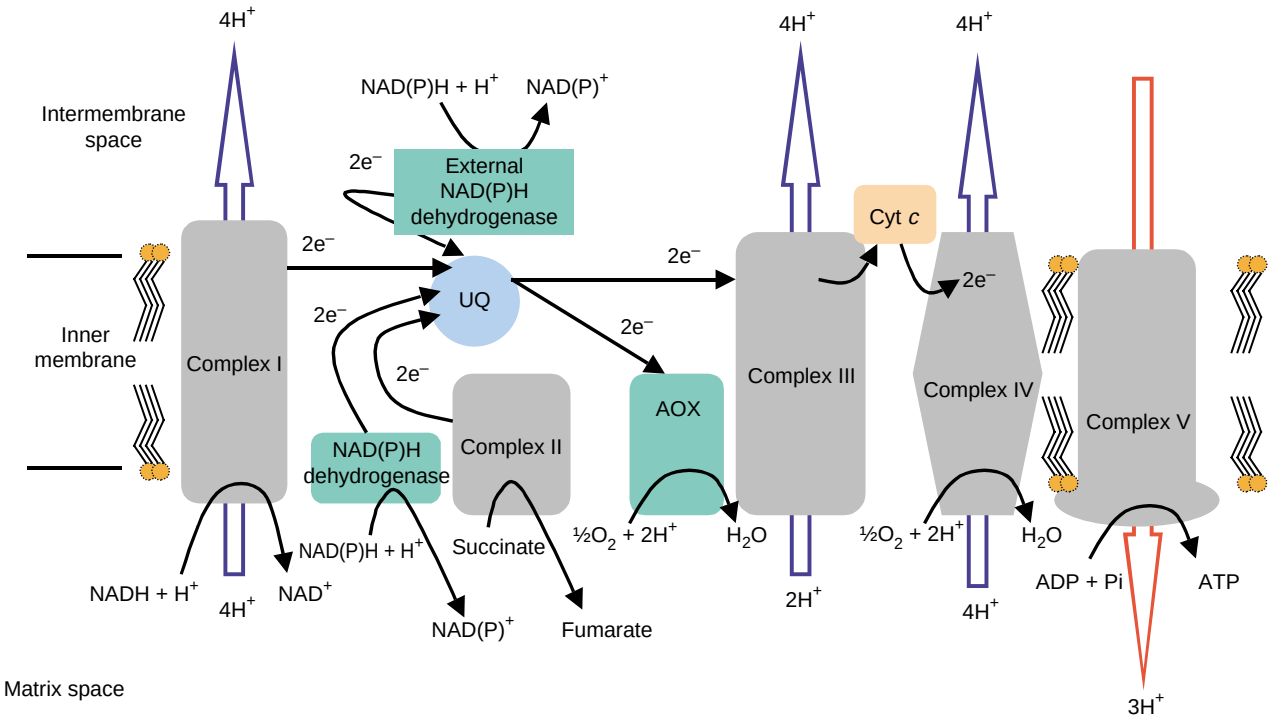

FIGURE 1 Schematic representation of the plant mitochondrial electron transfer chain.

(AOX) is a ubiquinol:oxygen oxidoreductase that accepts electrons from reduced ubiquinone and subsequently reduces O_2 to H_2O (Figure 1). AOX activity is resistant to cyanide and other inhibitors of cyt *c* oxidase but is specifically inhibited by salicylhydroxamic acid (SHAM) and n-alkyl gallate which do not affect the cyt pathway. An important feature distinguishes the two oxidase pathways. Electron flux downstream of the ubiquinone pool through the cyt pathway drives proton gradient formation at complexes III and IV, but no proton gradient formation occurs during operation of the alternative pathway. Thus, AOX would appear to be a wasteful enzyme from an energetic standpoint, eliminating a primary mitochondrial function during aerobic respiration, coupling the oxidation of reductants generated during the operation of glycolysis and the TCA cycle to the synthesis of ATP. Apart from its apparent absence in any metazoan (animal), AOX occurs widely among eukaryotic organisms. AOX has been found in all plants examined to date, but it is also present in most eukaryotic algae, many fungi, and a number of protozoa, including the bloodstream form of the organism responsible for African sleeping sickness, *Trypanosoma bruceii*.

Contemporary understanding of AOX can be traced to the development of an antibody against the plant AOX in 1989. The availability of this antibody led to the first isolation of a plant AOX gene and now dozens of AOX sequences from plants and fungi, and several protozoa and algae are present in gene databases. AOX is nuclear encoded and in plants, it occurs as a small gene family (e.g., five genes in *Arabidopsis*, three in soybean), that produces proteins from 32–35 kDa (~285 amino acids). More recently, characterization of the gene associated with a mutation leading to a defect in chloroplast biogenesis, IMMUTANS, identified a chloroplast protein having sequence similarity to AOX. IMMUTANS also functions as a quinol oxidase, leading to its general characterization as a "plastid terminal oxidase" (PTOX), and it has been shown to participate in a desaturation step during carotenoid biosynthesis in chloroplasts. As prokaryotic genome sequencing has progressed, AOX and PTOX homologues of unknown function have now been identified in an α-proteobacterium and several cyanobacteria, respectively. Phylogenetic analyses of the bacterial and eukaryotic sequences suggest that AOX and PTOX arose from a common prokaryotic ancestor, but the two activities diverged prior to the endosymbiotic events that gave rise to mitochondria and chloroplasts.

AOX Structure

AOX is integral inner membrane protein, but attempts to purify and characterize it have been hampered by the marked instability of the protein following its

solubilization from the membrane and the lack of any apparent visible (>350 nm) absorption spectrum or EPR spectral features in either its oxidized or reduced states. The observation that iron was required for induction of AOX activity in the fungus *Hansenula anomala* originally led to the suggestion that the active site contained iron. AOX sequence analyses later revealed the presence of conserved iron-binding motifs found in members of the family of diiron carboxylate proteins that include the R2 subunit of ribonucleotide reductase and the hydroxylase subunit of methane monooxygenase. This led to the initial development of a model of the AOX active site that contained a four-helical bundle forming a hydroxo-bridged diiron-binding site. The suggestion of a hydroxo-bridged iron center accounted for the absence of any visible absorbance, analogous to the diiron center in methane monooxygenase. Recently, an EPR signal associated with a mixed valence Fe(II)/Fe(III) hydroxo-bridged binuclear iron center has been reported for an *Arabidopsis thaliana* AOX expressed in *Escherichia coli*, providing direct spectral evidence for the diiron carboxylate nature of the AOX (and, by analogy, PTOX) active site.

Over time, the AOX structural model has been refined. As currently envisioned (Figure 2A), the C-terminal two-thirds of the AOX protein comprises a four-helical bundle that makes up the diiron-binding scaffold. Two short hydrophobic helical regions anchor the protein in the inner leaflet of the bilayer, with the bulk of the protein protruding into the mitochondrial matrix. This C-terminal region is relatively conserved among all AOXs, showing 85-90% sequence similarity among plants and over 55% similarity between plants and fungi.

While the C-terminal two-thirds of the AOX protein is responsible for forming the catalytic diiron site, the structure of the N-terminal third of the protein is unknown. When plant and fungal amino acid sequences in this region are compared, there is considerable sequence conservation within each organism type but marked sequence variability between them. Within the N-terminal third of the plant AOX, there is a highly conserved block of ~38 amino acids that includes a regulatory cysteine (*cf.* below). Fungal sequences initially align with plant sequences right after this block. From that point on, the plant and fungal sequences are highly similar with two exceptions: (1) an insertion of 20–25 amino acids unique to fungi just before the first of the four iron-binding helical regions and (2) an extension of the fungal C terminus 20–50 amino acids beyond that found in plants. AOX sequences in protozoa are more similar to the fungal AOX than they are to that of plants.

In plants, chemical cross-linking studies have established that AOX exists in the membrane as a dimer consisting of two AOX monomers (Figure 2B). However, the fundamental unit of catalytic activity based on radiation–inactivation analysis is the monomer. Consistent with the latter observation, AOXs dimers are not universal; cross-linking studies with AOX in both fungi and protozoa have established that they both exist in the membrane as monomers.

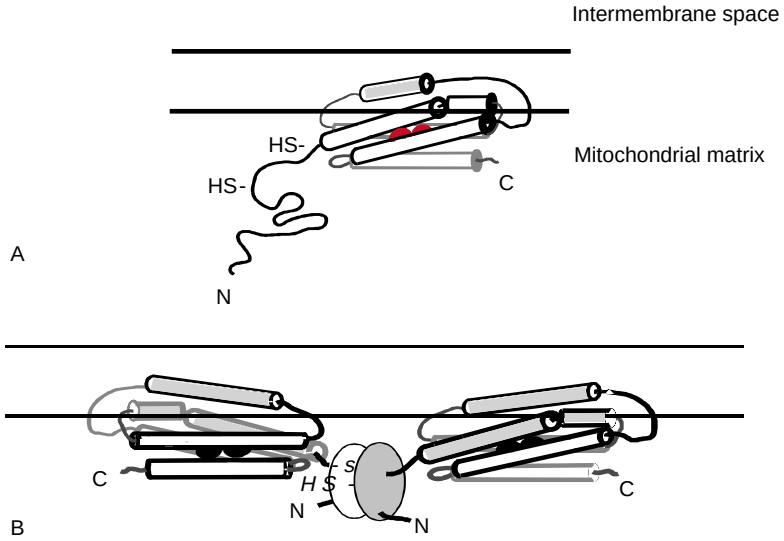

FIGURE 2 Diagrammatic representation of the structure of the AOX. (A) AOX monomer, (B) dimeric AOX structure found in plants. The two red spheres in (A) represent the diiron center (shown in black in (B)). The inner mitochondrial membrane is delimited by the set of parallel horizontal lines.

Biochemical Regulation of AOX Activity

While the N-terminal third of the AOX protein is less well characterized structurally than the remainder of the protein, this region has been found to confer regulatory features on the plant AOX. The plant AOX homodimer can exist in two forms, an oxidized state where the two monomeric subunits are covalently linked by an intermolecular disulfide bond and a reduced state where the AOX remains dimeric but the disulfide is reduced to its component sulfhydryls (Figure 3). In the oxidized state, AOX is inactive. When the disulfide is reduced, AOX remains inactive but has the ability to become activated in the presence of an α-keto acid, such as pyruvate (Figure 3). In the absence of α-keto acids, AOX has essentially no activity. AOX is activated by α-keto acids through reaction with a cysteine residue to form a thiohemiacetal. Site-directed mutagenesis of AOX has established that a single cysteine residue (termed CysI, the more N-terminal of two highly conserved cysteines located in the N-terminal region (Figure 2A)) is responsible for both the inactivating disulfide bond and interaction with α-keto acids to form the thiohemiacetal that activates AOX (Figure 3). As noted previously, CysI appears in the middle of a conserved block of amino acids in plant AOXs. Given the close proximity of the two regulatory CysIs on adjacent AOX monomers it appears that AOX activation following α-keto acid binding results from a conformational change brought about by charge repulsion between the resulting two proximal negative charges.

The regulatory features outlined above provide a facile mechanism for activating AOX under conditions when electron flow through the standard cyt pathway is restricted. Under such conditions, electron transfer would slow down leading to a buildup of reductant in the mitochondrial matrix. The more reduced environment in the matrix would bring about the reduction of the AOX regulatory disulfide, possibly via reduced thioredoxin, which is found in the mitochondrial matrix. As electron transfer becomes limiting, TCA cycle activity would become restricted causing pyruvate concentrations to increase, activating the AOX through a feed-forward regulatory system.

Biochemical regulation of AOX activity in fungi and protozoa is not as well characterized as in plants, but purine nucleotides, particularly GMP, AMP, and ADP, are known to markedly stimulate AOX activity in fungi and protozoa. No stimulation of alternative oxidase activity by α-keto acids has been seen in fungi.

Physiological Role(s) of AOX

The fact that the alternative pathway wastes much of the free energy released during aerobic respiration must be related to its metabolic role. AOX has been found in all higher plants but there is only one instance where its role is clearly established, thermogenesis during flowering in certain members of the plant family Araceae (aroids). Just prior to pollen release, high levels of mitochondria found in club-like structures on the floral inflorescence undergo very high rates of respiration, heating up the inflorescence and volatilizing aromatic compounds that serve to attract pollinating insects. Mitochondria from this thermogenic tissue have extremely high levels of AOX, allowing the high rates of respiration without having to synthesize and use comparable amounts of ATP.

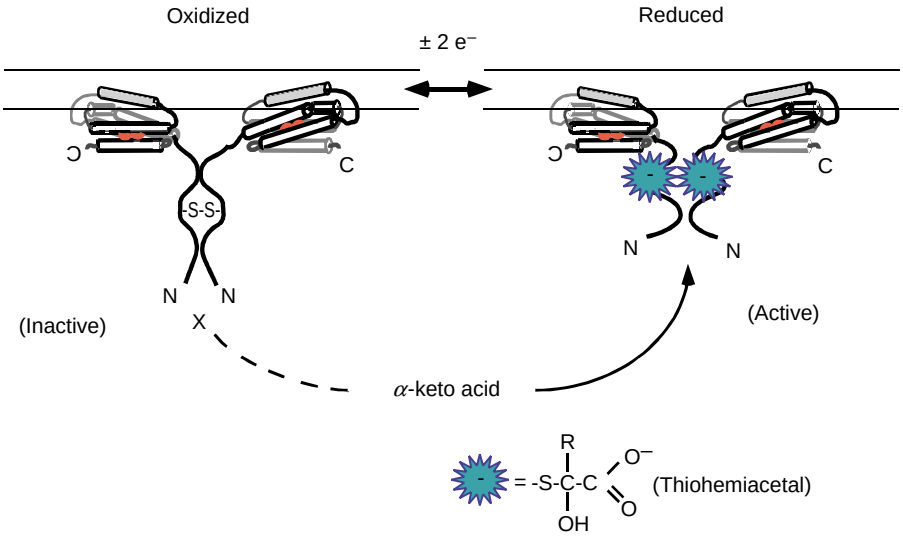

FIGURE 3 Biochemical regulation of plant AOX by the combined effects of reduction/oxidation of the redox active sulfhydryl/disulfide bond and reaction with α-keto acids to form an activating thiohemiacetal.

Most plant tissues do not respire at rates sufficient to support even modest thermogenesis, so that cannot represent its primary function in the vast majority of plant tissues. Because AOX is not involved in proton gradient generation, its activity is independent of the size of the gradient, unlike the cyt pathway, whose activity will be impaired as the proton gradient increases. Therefore, the AOX is in a position to use mitochondrial and cytoplasmic reductant in excess of that needed to maintain ATP synthesis, or when either ATP synthesis or the cyt pathway is impaired. Recognition of this fact originally served as the basis for the suggestion that the alternative pathway only operated when the activity of the cyt pathway was saturated, the so-called "energy overflow" hypothesis. Subsequent studies have established that the alternative pathway can compete with the cyt pathway for electrons from the ubiquinone pool when the cyt pathway is not saturated. This eliminated the overflow hypothesis in is purest form, but not from the standpoint of the alternative pathway helping to regulate mitochondrial electron flow and, as such maintain mitochondrial redox homeostasis.

One outcome of the ability of the alternative pathway to use excess mitochondrial reductant, resulting either from increased input to the ubiquinone pool or decreased use by the cyt pathway, is amelioration of the formation of reactive oxygen species (ROS; superoxide, hydrogen peroxide, hydroxyl radical) by the mitochondrial ubiquinone pool upon over-reduction. Operation of the alternative pathway has been shown to decrease both the reduction state of the ubiquinone pool in roots, and the formation of ROS in plant culture cells. The ability of AOX to decrease mitochondrial ROS formation is the basis of a hypothesis suggesting that AOX plays a role in plant response to environmental stresses. In several circumstances where increased mitochondrial ROS levels are predicted, including chilling stress, post-hypoxia-induced reperfusion injury, and reduced Pi availability, AOX gene expression and protein levels are observed to increase markedly.

Similarly, enhanced AOX gene expression and protein formation have been found to accompany oxidative stresses in fungi, including treatment with hydrogen peroxide. A survey of the appearance of the alternative pathway among yeasts found it was only present in so-called "Crabtree negative" yeast, that lack the presence of alcoholic fermentation as an option to the cyt pathway consistent with the concept of the alternative pathway serving as a mechanism for eliminating excess reducing equivalents in these organisms.

Glossary

aerobic respiration The biochemical process whereby reduced organic compounds are completely oxidized in three stages, glycolysis, the TCA cycle, and oxidative phosphorylation with the free energy released used to drive the synthesis of ATP.

alternative pathway The mitochondrial electron transfer pathway that goes via a cyanide-resistant, alternative oxidase (AOX) and transfers electrons from the ubiquinone pool to molecular oxygen without storing any of the released free energy in the form of a proton gradient.

cytochrome (cyt) pathway The mitochondrial electron transfer pathway that goes from the ubiquinone pool to molecular oxygen via Complex III and Complex IV (cytochrome *c* oxidase) and is coupled at each complex to the transport of protons across the membrane to produce a proton gradient that subsequently drives the synthesis of ATP.

diiron carboxylate protein Any member of a large family of proteins that contain a diiron active site formed by a four-helix bundle, two helices of which provide ligands to the two iron atoms via an E–X–X–H sequence motif, and two of which, each provide a single carboxylate ligand (i.e., Glu or Asp) to the irons. Family members include the R2 subunit of ribonucleotide reductase and the hydroxylase subunit of methane monooxygenase.

reactive oxygen species (ROS) Any of several highly reactive chemical species that can be formed following the reduction of molecular oxygen (O_2), including superoxide anion ($O_2^{\cdot -}$) hydrogen peroxide (H_2O_2) and hydroxyl radical ($OH^{\cdot}$).

Biography

James N. Siedow is a Professor in the Department of Biology at Duke University. His research interests are in oxidative processes in plants. He received his Ph.D. from Indiana University and was a Postdoctoral Fellow at Rice University. He has served as an Associate Editor of *Plant Physiology* and *Plant Molecular Biology* and on the Editorial Board of the *Journal of Biological Chemistry* and is a Fellow of the American Association for the Advancement of Science.

Autophagy in Fungi and Mammals

Daniel J. Klionsky and Ju Guan
University of Michigan, Ann Arbor, Michigan, USA

Autophagy refers to the processes by which portions of the cytoplasm are sequestered by membranes and transported into hydrolytic compartments to be degraded. This process occurs by two modes. During macroautophagy, double- or multiple-membrane vesicles, called autophagosomes, form in the cytoplasm. Upon completion, the autophagosome outer membrane fuses with the lysosome/vacuole or endosome. Subsequently the inner membrane and the enclosed cytoplasmic materials are degraded by hydrolases. Microautophagy entails the direct uptake of cytoplasm by invaginations or arm-like extensions of the lysosomal/vacuolar membrane. Autophagy is one of the major mechanisms for degradation and recycling of macromolecules. It is highly regulated by both physiological and environmental cues.

Autophagy in Mammals

Macroautophagy in Mammals

The phenomenon of macroautophagy has been observed in virtually all eukaryotic cell types. Mammalian hepatic tissues and cell cultures have been extensively studied, and in these macroautophagy accounts for the majority of macromolecular recycling once it is induced by hormonal or other signals. The content of the autophagosomes is indistinguishable from its surrounding cytoplasm and often includes recognizable structures such as mitochondria and ribosomes, suggesting that the sequestration is nonselective. There also exists evidence for selective sequestration of certain structures such as peroxisomes, particularly when these organelles are specifically induced to proliferate before the onset of autophagy. Based on morphological and immunocytochemical studies, macroautophagy proceeds through distinct steps of autophagosome formation and maturation (Figure 1). Each of these steps requires ATP.

Formation of Autophagosomes

The autophagosomes are distinct from most other intracellular vesicles in that double or multiple delimiting membranes are employed. In addition, formation of these vesicles topologically converts the sequestered cytoplasm to a lumenal or extracellular space. Although the membrane source of the sequestering vesicle has been extensively investigated, the origin is still not known. The autophagosomal membrane may be directly derived from other organelles. Immunostaining of the autophagosomal membrane identified organelle markers of the smooth endoplasmic reticulum (ER), a ribosome-free region of rough ER or the Golgi complex. However, the autophagosomal membranes are extremely poor in proteins, indicating that they do not have protein profiles typical of most endomembranes. Accordingly, it has been proposed that a novel organelle or membrane is dedicated to generating the initial sequestering membrane, termed the phagophore.

Maturation of the Phagophore

The maturation of phagophores into autophagosomes proceeds in a stepwise manner. For example, early phagophores may retain protein markers from the membrane of origin. These proteins may be lost and others acquired as the phagophore matures. Upon completion, which is marked by closure of the phagophore membrane, the cytosolic vesicle is termed an autophagosome. The autophagosomes fuse with lysosomes to acquire degradative enzymes. As a result of fusion, the inner autophagosomal membrane is released into the lysosome lumen, where it is broken down to expose the sequestered cytoplasm to the lysosomal hydrolases. The cytoplasmic cargo is subsequently degraded and recycled for use by the cell. A population of autophagosomes may fuse with endosomes to give rise to amphisomes, an intermediate compartment named for its dual role in both macroautophagy and endocytosis. The amphisome ultimately fuses with a lysosome to allow the degradation of its cargo.

Regulation of Macroautophagy in Mammals

The regulatory mechanism of macroautophagy is rather complex. Hormones and metabolites may activate or inhibit autophagy in different tissues. The intracellular signaling pathway has been studied mainly by using reagents that can alter the rates of autophagic protein degradation. It is very likely that the cellular responses to

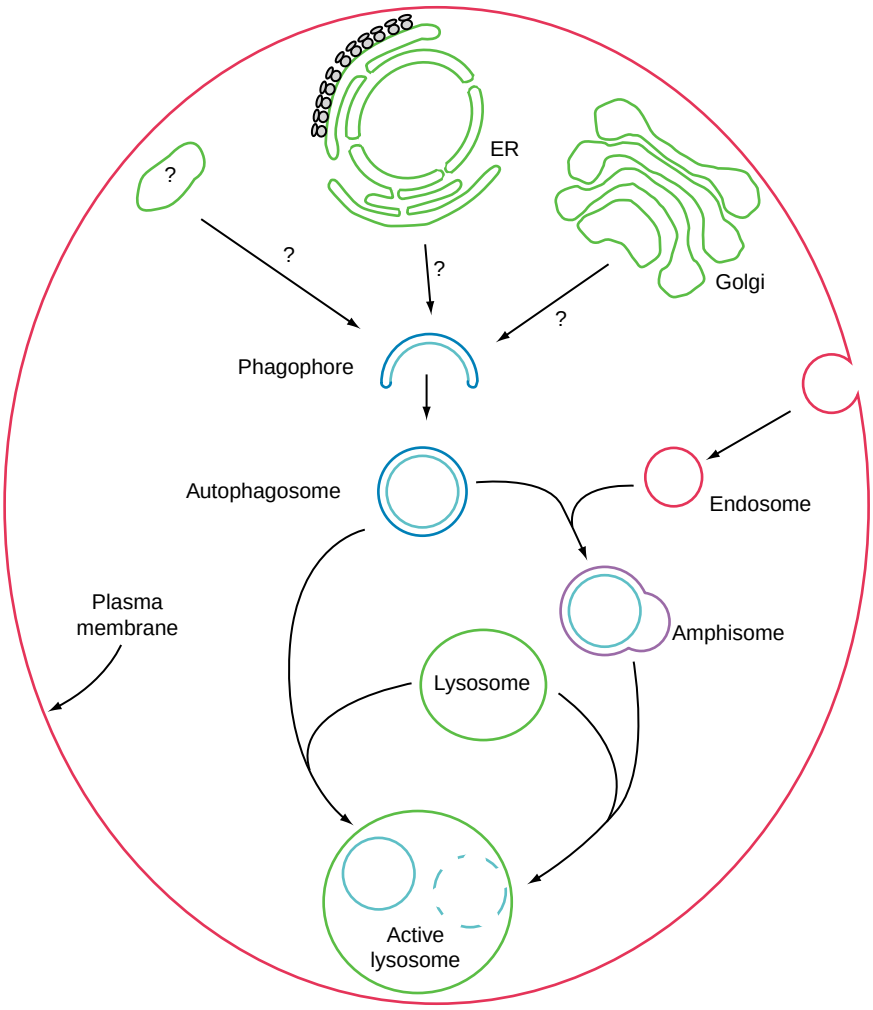

FIGURE 1 Macroautophagy in mammals. The initial sequestering membrane is termed the phagophore. Upon closure, the resulting double-membrane cytosolic vesicle is called an autophagosome. The origin of the phagophore or autophagosomal membrane is not known, but may include the endoplasmic reticulum, the Golgi complex, or a novel compartment. The autophagosome may fuse with an endosome to form an amphisome. The autophagosome or amphisome ultimately fuses with a lysosome, releasing the inner vesicle that is broken down to allow degradation and recycling of the vesicle contents.

these reagents are pleiotropic. Various proteins have been identified that play a role in regulating macroautophagy, including a phosphatidylinositol 3-kinase, heterotrimeric G proteins, protein kinases, and phosphatases. The inhibition of membrane fusion and cytoskeletal functions affects the final stages of cargo delivery. Table I lists some of the factors and chemicals that affect macroautophagy.

Microautophagy in Mammals

Microautophagy refers to the direct import of cytoplasmic materials by lysosomal membrane protrusions or invaginations. It is less well characterized in terms of its mechanisms and its contribution to overall protein degradation. In mammals, lysosomes with appendages or intralysosomal vesicles have been observed *in vivo*. Isolated lysosomes have shown the ability to uptake and degrade proteins or incorporate electron-dense markers into intralysosomal vesicles. Microautophagy is also induced by environmental cues such as nutrient deprivation.

Autophagy in Fungi

Macroautophagy in Yeast

Budding Yeast as a Model for Macroautophagy

During the last decade, autophagy has been studied using the budding yeast *Saccharomyces cerevisiae* as a model system. Nitrogen or carbon starvation induces the formation of cytoplasmic autophagosomes that have the characteristic double delimiting membranes. Similar to

TABLE I

Inhibitors of Macroautophagy in Mammals

Compounds	Effects on autophagy	Mechanism/targets
Physiological effectors		
Amino acids	Decrease	Charged tRNA, surface receptors
Anabolic hormones (insulin, IGF, EGF)	Decrease	Signaling
Catabolic factors/hormones (cyclic AMP, glucocorticoids)	Increase	Signaling
Pharmacological agents		
Okadaic acid	Decrease	Serine/threonine protein phosphatases
Wortmannin, LY294002, 3-methyladenine	Decrease	Phosphatidylinositol 3-kinase
Cycloheximide	Decrease	Ribosome
Cytochalasin B	Decrease	Microfilaments
Colchicine, vinblastine	Decrease	Microtubules

the findings in mammalian cells, yeast autophagosomal membranes are also protein-poor, as revealed by freeze-fracture electron microscopy studies. Once formed in the cytoplasm, the outer autophagosomal membrane will fuse with the vacuole (equivalent to the mammalian lysosome) membrane, leaving the inner vesicle, called the autophagic body, in the vacuolar lumen. The autophagic bodies are subsequently degraded by vacuolar hydrolases (Figure 2).

Autophagic mutants (*apg*) were isolated that failed to accumulate autophagic bodies when their vacuolar degradation was blocked by a protease inhibitor or by their decreased viability upon nitrogen starvation. An independent group of autophagic mutants (*aut*) were isolated by their inability to degrade a cytoplasmic enzyme under autophagy-inducing conditions.

The Cytoplasm to Vacuole Targeting Pathway and its Overlap with Macroautophagy

The cytoplasm to vacuole targeting (Cvt) pathway was discovered as the biosynthetic targeting pathway of a vacuolar resident enzyme, aminopeptidase I (Ape1). Precursor Ape1 (prApe1) is synthesized in the cytosol. It rapidly assembles into a dodecamer and remains in an oligomerized form during its course of transport into the vacuole (Figure 2). Cleavage of the N-terminal propeptide of prApe1 by vacuolar proteases gives rise to the mature, active form of the protein (mApe1). A group of *cvt* mutants were isolated that specifically block prApe1 maturation.

Genetic analysis revealed that the *apg* and *aut* mutants overlap with the *cvt* mutants that are defective in prApe1 targeting. Recently, a unified nomenclature has been adopted and the corresponding genes have all been termed autophagy-related (*ATG*). Morphological and biochemical studies further confirmed that prApe1 is transported to the vacuole using a vesicular mode similar to that of macroautophagy. Precursor Ape1 exists in the cytoplasm as a morphological structure that can be detected by electron microscopy. This structure, which consists of multiple prApe1 dodecamers bound to receptor proteins, is called the Cvt complex. Under vegetative growth conditions, the Cvt complex is specifically enwrapped by double-membrane Cvt vesicles. When autophagy is induced, the Cvt complex becomes a preferential cargo of autophagosomes. Thus, uptake of prApe1 represents a type of specific autophagy. Another hydrolase, α-mannosidase, is also targeted to the vacuole via the Cvt and autophagy pathways. The parallel studies of the Cvt pathway complement the analysis of autophagy by providing a specific cargo and the opportunity to study selective uptake mechanisms of autophagy.

Molecular Mechanism of the Cvt and Autophagic Pathways in Yeast

The molecular machinery was identified by cloning the genes that complement the *atg* mutants. Additional components were found by other approaches, including two-hybrid studies and the identification of homologues to pexophagy genes (see later discussion). Table II lists the Atg proteins and their proposed roles in these pathways. The molecular mechanism for the Cvt pathway and macroautophagy is briefly outlined next.

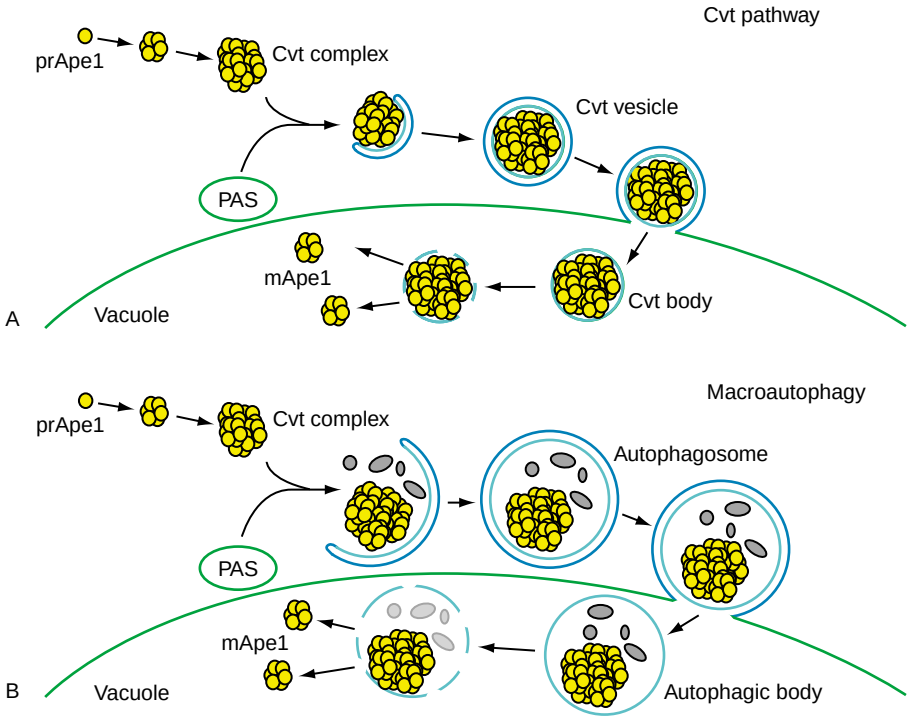

FIGURE 2 Cytoplasm to vacuole targeting (Cvt) pathway and macroautophagy in yeast. (A) Cvt pathway. Precursor Ape1 (prApe1) forms a dodecamer that assembles into a higher-order Cvt complex. Recruitment of the Cvt complex to the PAS leads to the formation of a Cvt vesicle. The completed Cvt vesicle fuses with the vacuolar membrane and releases the inner vesicle (Cvt body) into the vacuole lumen. Breakdown of the Cvt body allows the maturation of Ape1 (mApe1). (B) Macroautophagy. Under starvation conditions, the PAS is activated by specific signals resulting in the formation of autophagosomes. The Cvt complex is enclosed along with bulk cytoplasm inside autophagosomes. The inclusion of the Cvt complex is a specific process resulting from the action of receptor and adaptor proteins. Fusion between autophagosomes and the vacuole membrane and the subsequent breakdown of the inner membrane (autophagic body) release the cytoplasmic contents into the vacuole lumen for degradation and recycling or, in the case of the Cvt complex, maturation of precursor aminopeptidase I.

TABLE II

Proteins Involved in Autophagy and the Cvt Pathway

Function	Proteins	Molecular characteristics
Organization of the PAS	Atg6, Atg14	Phosphatidylinositol 3-kinase interacting proteins
	Atg9	Transmembrane protein
Localized on PAS; may control initiation of vesicle formation	Atg1, Atg11, Atg13, Atg17, Atg20, Atg24	Kinase or phosphorylated proteins PX domain proteins bind phosphatidylinositol(3)P
Localized on PAS; vesicle formation	Atg5, Atg8, Atg12, Atg16	Form conjugates or complexes conjugated to phosphatidylethanolamine
Conjugating proteins; catalyze formation of Atg12-Atg5 or Atg8-PE	Atg7, Atg3, Atg10, Atg4	E1 enzyme E2 enzymes Protease
Receptor protein of the Cvt complex	Atg19	Interacts with Atg11 and Atg8 to mediate specific enclosure of cargo
Degradation of intravacuolar vesicles	Atg15, Atg22	Lipase homologue Permease homologue
Others	Atg2, Atg18, Atg21, Atg23, Vps51	Proteins involved in vesicle formation, signaling and/or membrane retrieval

A Novel Organelle for De Novo Vesicle Formation *In vivo* fluorescence microscopy studies have colocalized the autophagosomal membrane marker protein Atg8 with several other Atg proteins on a perivacuolar structure. This structure is physiologically functional and appears to play a pivotal role in autophagosome formation; therefore, it has been termed the pre-autophagosomal structure (PAS). Localized on the PAS are two conjugates: Atg12, covalently linked to Atg5, and Atg8, covalently attached to phosphatidylethanolamine (Atg8-PE). These conjugates may directly participate in the generation of autophagosomes. Formation of the Atg12-Atg5 and Atg8-PE conjugates involves ubiquitin-like cascades. Recruitment of Atg12-Atg5 and Atg8 to the PAS depends on the function of the transmembrane protein Atg9 and an autophagy-specific phosphatidylinositol 3-kinase complex, underlying the key role of specific lipids in autophagosome formation.

Regulation of Autophagy The Cvt pathway operates under vegetative conditions, whereas autophagy is induced by starvation. Atg1 is localized at the PAS and is important in signaling Cvt vesicle or autophagosome formation, possibly via its differential association with other proteins such as Atg11 and Atg13. In particular, the Atg1-Atg13 interaction is regulated by the TOR (target of rapamycin) kinase. TOR also regulates autophagy at the transcriptional level.

Mechanism for Cargo Selection in the Cvt Pathway and Autophagy The Cvt complex is selectively sequestered by Cvt vesicles or autophagosomes. Atg19, a structural component of the Cvt complex, mediates the recruitment of the oligomerized prApe1 cargo and its recognition by the PAS though protein-protein interactions with Atg11 and Atg8. This may provide a prototype for other selective autophagic targeting pathways.

Fusion and Breakdown The fusion between the Cvt vesicles or autophagosomes and the vacuole membrane is probably similar to vacuole homotypic fusion and requires docking or tethering factors in addition to SNARE and Rab proteins. The breakdown of the inner vesicles requires the action of specific components such as the Atg15 lipase in addition to other vacuolar hydrolases.

Microautophagy and Selective Organelle Degradation in Yeasts

Nonselective Microautophagy

The morphological features of microautophagy have been observed in yeasts. Microautophagic vacuole invagination was also reconstituted *in vitro*. Interestingly, the molecular components of macroautophagy, the Atg proteins, were implicated to function at least partly in microautophagy as well.

Selective Autophagy of Peroxisomes in Methylotrophic Yeasts

Selective degradation of peroxisomes by autophagic mechanisms has been well demonstrated in methylotrophic yeasts. Peroxisomes are necessary for using methanol and are induced when methanol is the sole carbon source. Upon shift of culture medium to preferred carbon sources, superfluous peroxisomes are targeted to the vacuole via either a macro- or microautophagic mode, depending on nutrient conditions. The selective degradation of peroxisomes is termed pexophagy. The proteins involved in glucose-induced selective microautophagy of peroxisomes (Gsa proteins) are generally found to be homologous to the Atg proteins. This finding suggests that macro- and microautophagy may be more closely related at the molecular level than they appear to be morphologically. Alternatively, the Atg proteins may play a unique role in micropexophagy.

Autophagy, from Yeasts to Mammals

Most of the Atg proteins are conserved in higher eukaryotes, suggesting that the mechanism for autophagy is similar in yeasts and mammals. A few mammalian autophagy proteins have been directly demonstrated to function in macroautophagy. Future studies with mammalian cells may further benefit from the molecular model provided by yeast systems. On the other hand, abnormalities in autophagy have been connected with various human diseases such as Parkinson's disease and certain types of cancer. The importance of autophagy in developmental or pathological macromolecular turnover has yet to be directly demonstrated in higher eukaryotes, but promises to be an exciting area of future research.

Glossary

autophagy A process in which the cell undergoes membrane rearrangements to sequester a portion of cytoplasm, deliver it to a degradative organelle, and recycle the macromolecular constituents.

cytoplasm to vacuole targeting (Cvt) pathway A biosynthetic pathway that transports resident hydrolases to the vacuole through a specific autophagy-like process.

lysosome A degradative organelle in mammals that compartmentalizes a range of hydrolytic enzymes and maintains a reduced pH.

macroautophagy An autophagic process involving the formation of a double- or multiple-membrane cytosolic vesicle of nonlysosomal or nonvacuolar origin.

microautophagy An autophagic process involving direct uptake of cytoplasm at the lysosome or vacuole by protrusion, invagination, or septation of the sequestering organelle membrane.

pexophagy A selective type of autophagy involving the sequestration and degradation of peroxisomes.

vacuole A degradative organelle in fungi that compartmentalizes a range of hydrolytic enzymes and maintains a reduced pH.

Biography

Daniel J. Klionsky is the Abram Sager Collegiate Professor of Life Sciences in the Life Sciences Institute and is a professor in the Departments of Molecular, Cellular, and Developmental Biology and of Biological Chemistry at the University of Michigan, Ann Arbor. His principal research interest is the regulated targeting of proteins and organelles from the cytoplasm into the vacuole using the budding yeast as a model system. He holds a Ph.D. from Stanford University and received his postdoctoral training at the California Institute of Technology. He is a fellow of the John Simon Guggenheim Memorial Foundation and a recipient of the National Science Foundation Director's Award for Distinguished Teaching Scholars.

Ju Guan was a graduate research student in the Klionsky laboratory until 2002. She is currently a postdoctoral research scholar at the University of Michigan, Ann Arbor.

B_{12}-Containing Enzymes

Vahe Bandarian* **and Rowena G. Matthews**
University of Michigan, Ann Arbor, Michigan, USA

Vitamin B_{12}, or cobalamin, was isolated from liver extracts over 50 years ago as a red crystalline metabolite that cured pernicious anemia in humans. The X-ray crystal structure of the cofactor and various derivatives subsequently showed that it has an elaborate organometallic structure. Cobalamin is widely distributed in nature and biochemical studies have shown that it facilitates enzymatic transformations that involve methyl group transfer and radical-mediated rearrangements. The biosynthesis of cobalamin, the molecular mechanisms of the transformations that are catalyzed by cobalamin-dependent enzymes, and the inherent chemical flexibility in this organometallic cofactor that permit it to participate in these disparate reactions, have fascinated chemists and biochemists for decades. This entry highlights the chemical transformations that are catalyzed by cobalamin-dependent enzymes.

The Cobalamin Cofactor

The central feature of the cobalamin cofactor (Figure 1A) is a cobalt atom with octahedral geometry, which is centered in the corrin macrocycle by coordination to pyrrole nitrogens from the corrin in the four equatorial coordination positions of the metal ion. A nitrogen atom that is donated by a dimethylbenzimidazole moiety, which in turn is ligated to the corrin ring, coordinates the cobalt from the lower axial position. In some eubacteria and Archaea, the dimethylbenzimidazole substituent of the cobalamin is replaced by other compounds (e.g., *p*-cresol); such cofactors are referred to as corrinoids. The macrocycle is further adorned by methyl, acetamide, and propionamide side chains. The upper axial position of the cobalt ion is occupied by an alkyl substituent specific to the type of reaction catalyzed by the protein.

The upper face of the cobalamin is where the chemistry takes place in all cobalamin-dependent enzymes. The chemical versatility of cobalamin and corrinoids lies in the carbon–cobalt bond of the cofactor, which is susceptible to cleavage by heterolytic or homolytic pathways (see Figure 1B). The upper coordination position of the cobalamin, in the enzymes that catalyze methyl group transfer, is transiently occupied by a methyl group en route from a donor molecule to an acceptor molecule. In these enzymes, the cobalamin serves both as a nucleophile, accepting the methyl group from the donor, and as a leaving group, donating the methyl group to an acceptor molecule. By contrast, enzymes that catalyze radical-mediated transformations require that the cobalamin have 5′-deoxyadenosine coordinated to the cobalt on the upper face of the corrin. In these enzymes, the organometallic bond between the 5′-methylene of the deoxyadenosyl moiety and the cobalt is severed homolytically to generate a 5′-deoxyadenosyl radical, which initiates the radical cascades that lead to formation of product.

The identity of the ligand that occupies the lower axial coordination position of protein-bound cobalamin may differ significantly from that in solution. In some proteins, in addition to the network of interactions with the side chains of the corrin, the imidazole side chain of a histidine residue substitutes for the dimethylbenzimidazole of the cofactor and donates a nitrogen ligand to the cobalt. This latter form of binding is referred to as a base-off binding mode. Most of the proteins that bind the cobalamin in the base-off mode also contain a DxHxxG sequence that contains the histidine residue that donates the lower axial imidazole ligand. In other proteins, binding of cobalamin to the protein backbone is accomplished by extensive interactions with the corrin and its side chains, and the dimethylbenzimidazole remains coordinated to the cobalt atom. This is referred to as base-on binding of the cofactor.

The cobalamin cofactor can exist in three oxidation states, and each form of the cobalamin exhibits distinct ultraviolet (UV)-visible spectra that allow one to follow the course of the catalytic cycle. For instance, the cobalt in alkyl cobalamins, such as adenosylcobalamin or methylcobalamin, is in the +3 oxidation state (formally, the alkyl ligand is considered to be the anion R^-). Homolysis of the cobalamin to generate a deoxyadenosyl radical is accompanied by the formation of a reduced cobalamin, cob(II)alamin, in which the cobalt is in the +2 oxidation state, and reformation of the C–Co bond of the cofactor oxidizes the cobalt to the +3 state. Therefore, adenosylcobalamin-dependent proteins cycle

*Current address: University of Arizona, Tucson, Arizona.

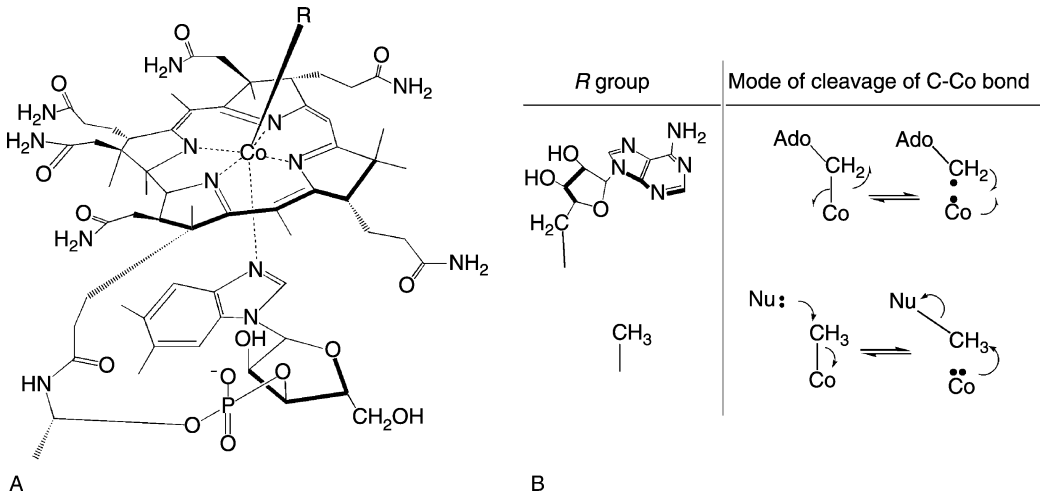

FIGURE 1 Structure and reactivity of alkylcobalamins. (A) The upper coordination position of cobalamin can be occupied by 5′-deoxyadenosine or by a methyl group. (B) Homolysis of the C–Co bond in adenosylcobalamin-dependent enzymes generates a 5′-deoxyadenosyl radical and cob(II)alamin. By comparison, the cofactor is transiently methylated in enzymes that catalyze group transfer reactions.

between the +3 and +2 oxidation states during the course of the catalytic cycle. By contrast, upon nucleophilic displacement of methyl group from the cobalamin during group transfer chemistry, the cobalamin cycles between the +3 oxidation state in the methylcobalamin form and the +1 state upon loss of the alkyl group. Remethylation of the cobalamin reoxidizes the cobalamin to the +3 oxidation state.

In this entry we summarize the reactions that are catalyzed by cobalamin-requiring enzymes, first highlighting the reactions in which cobalamin serves as a source of the highly reactive 5′-deoxyadenosyl radical and then discussing the reactions that involve methyl transfer chemistry.

Reactions Catalyzed by Cobalamin-Dependent Enzymes

Radical-Mediated Rearrangement Reactions

The enzymes that catalyze radical-mediated transformation exploit the inherent weakness of the carbon-cobalt bond of adenosylcobalamin (bond dissociation energy ~ 30 kcal mol^{-1}) to form the highly reactive 5′-deoxyadenosyl radical. Binding of the cobalamin to these enzymes accelerates the rate of homolysis of the C–Co bond $\geq 10^{12}$-fold. Homolysis of the carbon–cobalt bond is triggered by the presence of the substrate or by an allosteric effector. Presumably, the binding energy derived from substrate/effector-enzyme interactions is essential to elicit the conformational changes that are required to facilitate homolysis of the relatively weak organometallic bond. The 5′-deoxyadenosyl radical is a primary radical and readily abstracts a hydrogen atom from the substrate or from a residue on the protein. Therefore, a hallmark of catalysis by the enzymes in this group is formation of radical intermediates. Figure 2 shows the general catalytic cycles for these enzymes.

Adenosylcobalamin-dependent enzymes can be divided into four groups based on the details of the catalytic transformations (Table I). The reactions catalyzed by enzymes in each group are discussed next.

Migration and Elimination Reactions

The enzymes in this group participate in the fermentation of short-chain organic compounds such as ethanolamine, glycerol, 1,2-propanediol, and 1,2-ethanediol. The reactions catalyzed by these enzymes are formally the interchange of a hydrogen atom on one carbon with a group X (= OH or NH_3) at the adjacent position. The catalytic mechanism of these enzymes is quite similar to the mechanism of the carbon skeleton mutase enzymes discussed later. These two groups, in fact, differ only in that the mutases retain the rearranged substituent.

The catalytic mechanisms of ethanolamine ammonia-lyase and diol dehydratase have been studied extensively and a generalized mechanism for these enzymes is shown in Figure 2A. As with all cobalamin-dependent enzymes, the carbon–cobalt bond of the cofactor is homolyzed to generate 5′-deoxyadenosyl radical and cob(II)alamin in the first step of the catalytic reaction. The deoxyadenosyl radical abstracts a hydrogen atom from the substrate (S–H) to generate a substrate-like radical (S·) $\sim$ 9–12Å away from the cob(II)alamin. The rearrangement of S· to a product-like radical (P·) followed by return of a hydrogen atom from the 5′-deoxyadenosine results in the formation of the enol form of the product (P–H). The deoxyadenosyl radical recombines with cob(II)alamin to regenerate

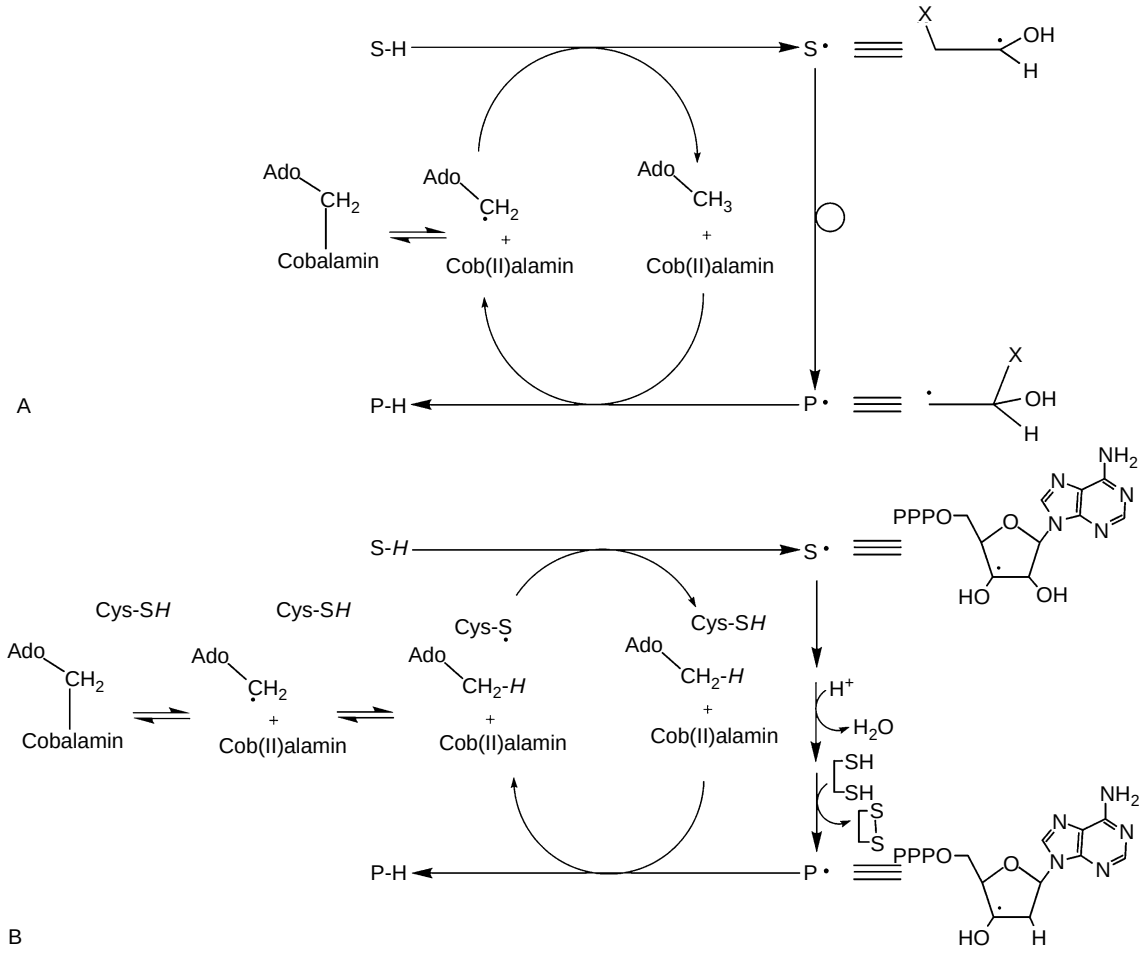

FIGURE 2 Generalized reaction cycles for enzymes that catalyze radical-mediated rearrangements. (A) The catalytic cycles for enzymes that catalyze rearrangements and eliminations, carbon skeleton rearrangements, and PLP-dependent aminomutase reactions. The structures on the right are examples of the intermediates that would be expected in the conversion of ethanolamine acetaldehyde and ammonia by ethanolamine ammonia-lyase. (B) The catalytic cycle of ribonucleotide triphosphate reductase differs from the cycle in (A) in that the 5′-deoxyadenosyl radical abstracts a hydrogen atom from an active site cysteine thiol to generate a thiyl radical that subsequently generates a substrate-based radical species. The structures on the right show some of the reaction intermediates that form in the course of conversion of ATP to dATP.

adenosylcobalamin. The initial *gem*-diol or *gem*-amino alcohol that is formed in the course of these transformations subsequently eliminates water or ammonia, respectively, to generate the corresponding aldehydes.

Diol and glycerol dehydratases have the best characterized structures in this group. Few sequence similarities exist between the diol and glycerol dehydratases and ethanolamine ammonia-lyase, despite the similarities in the reactions that they catalyze. Nevertheless, members of these groups of enzymes appear to retain coordination of the cobalamin to dimethylbenzimidazole.

Diol dehydratase and glycerol dehydratase are rapidly inactivated in the course of their catalytic cycle by side reactions that lead the formation of tightly bound inactive cofactor at the active site of these enzymes. The gene clusters that code for the structural genes for these proteins also contain open reading frames whose products have been shown to catalyze the ATP- and Mg^{2+}-dependent exchange of inactive cofactor with cofactor from solution. The generality of the reactivation mechanism remains to be determined.

Carbon Skeleton Rearrangement Reactions

As with the enzymes that catalyze rearrangement and elimination, the enzymes in this group catalyze the interchange of a hydrogen atom on one atom with an alkyl group on the adjacent carbon atom (see Table I). The reactions catalyzed by these enzymes differ from the others in several respects. First, the migrating alkyl group is not eliminated from the product. Second, the mutase reactions are *reversible*. Two significant structural differences have also been noted between these enzymes. First, spectroscopic and structural studies have shown that cobalamin binds in the base-off conformation and that the histidine residue that donates the imidazole ligand is conserved in the members of

TABLE I

Adenosylcobalamin-Dependent Radical-Mediated Transformations

Group 1	Rearrangement/Elimination reactions		Diol dehydratase	1,2-propanediol → propionaldehyde + water
		ethylene glycol → acetaldehyde + water
	Glycerol dehydratase	glycerol → 3-hydroxypropionaldehyde
	Ethanolamine ammonialyase	ethanolamine → acetaldehyde + ammonia
Group 2	Carbon skeleton mutases		Methylmalonyl-CoA mutase	(2*R*)-methylmalonyl-CoA ⇔ succinyl-CoA
	Isobutyryl-CoA mutase	isobutyryl-CoA ⇔ *n*-butyryl-CoA
	Glutamate mutase	*S*-glutamate ⇔ (2*S*,3*S*)-3-methylaspartate
	2-Methyleneglutarate mutase	2-methyleneglutarate ⇔ (*R*)-3-methylitaconate
Group 3	PLP-dependent aminomutases		Lysine 5,6-aminomutase	D-lysine ⇔ 2,5-diaminohexanoic acid
		L-β-lysine ⇔ 3,5-diaminohexanoic acid
	D-Ornithine 4,5-aminomutase	D-ornithine ⇔ (2*R*,4*S*)-diaminopentanoate
Group 4	Ribonucleotide reduction		Ribonucleotide triphosphate reductase	ribonucleotide triphosphate → deoxyribonucleotide triphosphate

the group. Second, the substrate-based radicals that are formed in the course of the reaction reside ~6Å away from the cob(II)alamin. However, despite these differences, the 5′-deoxyadenosyl radical is involved in generating a substrate-based radical and the catalytic cycle of these enzymes resembles that of the enzymes that catalyze rearrangement and elimination reactions (see Figure 2A).

PLP-Dependent Aminomutase Reactions

Pyridoxal 5′-phosphate (PLP)-dependent aminomutases catalyze the interchange of a hydrogen atom with an amino group on the adjacent carbon atom. These enzymes (see Table I) have been purified from several strict anaerobes that catabolize lysine or ornithine to organic acids and ammonia. The salient features of the generic aminomutase mechanism are the formation of a Schiff base linkage between the substrate and PLP and the use of 5′-deoxyadenosyl radical to initiate catalysis. In these enzymes, the PLP may assist in the intramolecular migration of the amino group. In addition to the presence of PLP, these enzymes differ from the enzymes that catalyze migration and elimination reactions in that aminomutases catalyze a reversible interchange of a hydrogen atom with the amino group on the adjacent carbon atom and the cofactor binds in a base-off configuration. Despite these differences, the catalytic cycle shown in Figure 2A applies to these enzymes as well.

Ribonucleotide Triphosphate Reductase Reaction

Ribonucleotide reductases catalyze the conversion of nucleotides to deoxynucleotides in all organisms. The prominent role of these enzymes in nucleotide metabolism has made them attractive targets of antiviral and antitumor therapies. Ribonucleotide reductase can synthesize all four DNA bases from the corresponding nucleosides; however, the activity of the enzymes from all sources is allosterically regulated by the ratio of the deoxyribonucleotides and nucleotides. Four classes

of reductases have been described. Although the overall reactions catalyzed by all of these enzymes are identical, they differ in two respects. First, some use nucleoside diphosphates as substrates, whereas others prefer nucleotide triphosphates. Second, these enzymes differ in the source of the species that initiates the radical turnover cascade. In fact, ribonucleotide reductases have been categorized into four classes based on the free-radical initiators. Only one of these, the class II ribonucleotide triphosphate reductase, is adenosylcobalamin-dependent. However, the catalytic transformations that ensue following the formation of the substrate radical are remarkably similar. The ribonucleotide triphosphate-specific enzyme from *Lactobacillus leichmannii* is the best-characterized example of adenosylcobalamin-dependent reductases.

The mechanistic details of the ribonucleotide reduction differ significantly from the paradigms that have been discussed in the previous sections for the group migration and elimination, aminomutase, and carbon skeleton mutase enzymes. First, ribonucleotide reductases contain a pair of active-site cysteine residues that are oxidized in the course of the reaction and must undergo reduction between each catalytic cycle. Second, a cysteine on the protein forms a thiyl radical that is directly involved in the reaction. Figure 2B shows a general catalytic cycle for the adenosylcobalamin-dependent ribonucleotide reductase, highlighting the differences between this enzyme and other radical-mediated rearrangement reactions. The carbon–cobalt bond of the cofactor is homolyzed by the protein in the presence of allosteric effector; the resulting 5′-deoxyadenosyl radical abstracts a hydrogen atom from an active-site cysteine residue to generate a thiyl radical, which in turn abstracts a hydrogen atom from C3′ of the substrate. In the course of reduction of the substrate to the product, a pair of active-site thiols is oxidized and the active-site thiyl radical is reformed. Reformation of the cofactor and reduction of the active-site thiols prepare the active site for subsequent turnover.

Methyl Transfer Reactions

Enzymes that catalyze cobalamin-dependent methyl transfer reactions use the potential for heterolytic cleavage of the carbon-cobalt bond of the cofactor (see Figure 1B). The cofactor in these enzymes serves both as a nucleophile and as a leaving group, undergoing transient methylation in the course of the reaction. Although the identities of the donor and acceptor molecules vary among the family of cobalamin-dependent methyl transferase enzymes (Figure 3), the overall catalytic cycles of these enzymes are similar. In this section, we consider methionine synthase as a prototype of the cobalamin-dependent methyltransferases, highlighting the similarities and differences among the members of the methyl transferase family of enzymes.

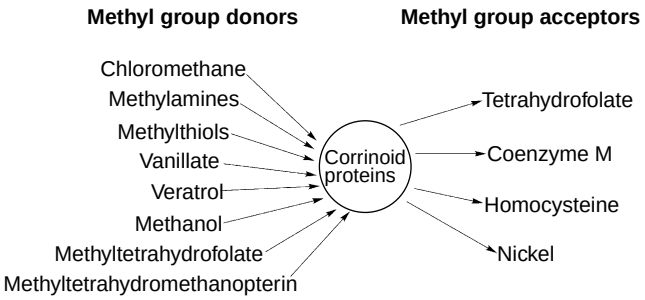

FIGURE 3 Diversity of methyl group donors and acceptors in cobalamin-dependent methyltransferase enzymes.

Cobalamin-Dependent Methionine Synthase

Cobalamin-dependent methionine synthase is found in mammals and in *Caenorhabditis elegans*, but not in insects or in plants, which neither produce nor transport cobalamin. It is also found in many prokaryotes, including *Escherichia coli*, but not in Archaea. The enzyme catalyzes the transfer of a methyl group from the tertiary amine methyltetrahydrofolate to the thiol of homocysteine, and the cobalamin cofactor serves as an intermediary in the methyl transfer. A catalytic cycle for methionine synthase is shown in Figure 4.

Methionine synthase is a large monomeric protein (1227 amino acid residues in the enzyme from *E. coli*) containing four discrete modules. The N-terminal module binds and activates homocysteine; the thiol of homocysteine coordinates to a catalytically essential zinc metal ion in this module. The next module in the sequence binds and activates methyltetrahydrofolate. Each of these substrate-binding modules communicates with the third module in the sequence, the B_{12}-binding module, to transfer methyl groups to and from the base-off cofactor. The C-terminal module is required for activation of methionine synthase when the cob(I)alamin cofactor becomes oxidized during turnover (~1 in 2000 turnovers results in oxidation *in vitro*). Activation of the inactive cob(II)alamin form of the cofactor requires both a methyl donor and an electron donor. The methyl donor is *S*-adenosyl-L-methionine. In *E. coli* the electron donor is reduced flavodoxin, and in mammals it is methionine synthase reductase, a protein containing a domain with homology to flavodoxin. To allow methyl transfer during reductive activation, the C-terminal domain must also access the cobalamin; a structure of a fragment of methionine synthase in this conformation has recently been determined.

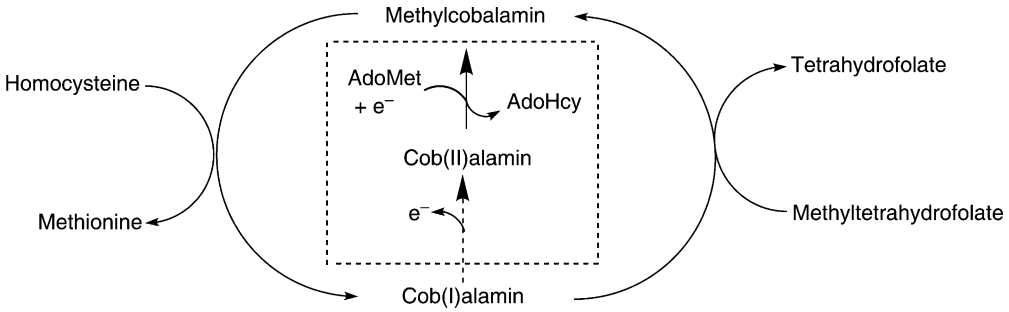

FIGURE 4 Catalytic cycle of cobalamin-dependent methionine synthase. The dashed box shows the reactivation of the oxidized cofactor by reductive methylation.

Methyl Transferases Involved in Methanogenesis and Acetogenesis

Although cobalamin-dependent methionine synthase is the only B_{12}-dependent methyl transferase in eubacteria and eukaryotes, a large number of enzymes catalyzing similar methyl transfers that employ corrinoid cofactors have been identified in Archaea and acetogenic eubacteria. The diversity in the methyl group donor-acceptor pairs is illustrated in Figure 3. In general, in methanogens, corrinoid-dependent enzymes are involved in the formation of methylcoenzyme M, the methyl thioether that provides the methyl group destined to form methane in methanogenesis. The methyl donors in these reactions include methyltetrahydromethanopterin, which is chemically similar to methyltetrahydrofolate. The methyl group of methyltetrahydromethanopterin is formed by the reduction of carbon dioxide using reducing equivalents derived from molecular hydrogen. Some methanogens can also use simple compounds such as methylamines, methanol, or methylsulfides as the source of methyl groups for methanogenesis. In contrast to cobalamin-dependent methionine synthase, in which a single protein catalyzes methyl transfer from methyltetrahydrofolate to cobalamin and from methylcobalamin to homocysteine, most of these methanogenic methyl transferase reactions require three separate proteins, a corrinoid-containing protein, a methyltransferase that transfers methyl groups from the donor molecule to the corrinoid protein, and a second methyltransferase that transfers methyl groups from the methylcorrinoid protein to the acceptor.

Eubacterial acetogenesis also involves corrinoid-dependent methyl transferases. In these organisms, carbon dioxide and hydrogen are used to generate acetyl CoA. The methyl group of acetyl CoA is generated by reduction of carbon dioxide using reducing equivalents from molecular hydrogen, as in methanogens, and is transferred to a corrinoid cofactor that serves as the direct methyl donor to the enzyme responsible for the synthesis of acetyl CoA from a methyl group and carbon dioxide. Additional acetogenic substrates include vanillate, veratrol, and halogenated aryl or alkene compounds. The precise nature of the chemistry that is promoted by cobalamin with the last substrates remains to be elucidated.

Biography

Vahe Bandarian is a postdoctoral fellow at the University of Michigan at Ann Arbor. His research interest is the mechanism of action of adenosylcobalamin-dependent enzymes. He holds a Ph.D. in biochemistry from the University of Wisconsin-Madison and is a recipient of a 2002 Burroughs Wellcome Career Award in Biomedical Sciences.

Rowena G. Matthews is the G. Robert Greenberg Distinguished University Professor of Biological Chemistry and Senior Research Scientist at the Life Sciences Institute of the University of Michigan. Research in her laboratory focuses on the role of vitamins, especially folic acid and vitamin B_{12}, in biochemical reactions, and on the regulation of folic acid-dependent metabolism. She received her Ph.D. from the University of Michigan and her B.A. from Radcliffe College, Cambridge, MA. Dr Matthews is a Fellow of the American Association for the Advancement of Science and of the National Academy of Sciences and has served on the Advisory Council of the National Institute of General Medical Sciences.

Bax and Bcl2 Cell Death Enhancers and Inhibitors

David L. Vaux
The Walter and Eliza Hall Institute, Parkville, Victoria, Australia

Apoptosis, the physiological cell death mechanism used by metazoans to remove unwanted cells, is controlled by a family of pro- and anti-apoptotic proteins that bear varying degrees of similarity to a protein called Bcl2. Some members of this family, such as Bcl2 itself, stop cells from activating their suicide mechanism, whereas other members of this family, such as Bax, activate the cell death process.

Identification of Bcl2 as a Cell Death Inhibitor

A gene at the site of chromosomal translocations associated with the common lymphoid cancer follicular lymphoma was designated Bcl2 for B-cell leukemia/lymphoma gene number 2. Rather than promoting cell growth and proliferation like most cancer genes, Bcl2 does not stimulate cells to divide but prevents them from activating their endogenous apoptotic cell suicide mechanism. The association of activation of the apoptosis inhibitor Bcl2 with lymphoma was the first evidence that cell death is required to avoid the development of cancer.

Genetics of Cell Death in *Caenorhabditis elegans*

Although Bcl2 was the first component of the apoptosis mechanism to be recognized at the molecular level in any organism, genetic analysis of programmed cell death in the nematode *C. elegans* revealed that in worms developmental cell death is controlled and implemented by a specific genetic program. Programmed cell death in *C. elegans* fails to occur in *egl-1*, *ced-4*, and *ced-3* loss of function mutants, as well as in *ced-9* gain of function mutants, implying that *egl-1*, *ced-4*, and *ced-3* encode killer proteins and that *ced-9* encodes a survival protein. The expression of human Bcl2 in the worm, and the cloning and sequencing of *ced-9*, showed that they are structurally and functionally homologous. In the worm CED-9 prevents cell death by preventing the adaptor CED-4 from activating the protease CED-3, and in mammalian cells Bcl2 stops apoptosis by indirectly preventing activation of CED-3-like proteases, termed caspases.

Bcl2 Function

Exactly how Bcl2 prevents apoptosis is unresolved, but there are two main models. In one, Bcl2 acts like CED-9 does in the worm, namely by preventing a mammalian CED-4-like adaptor molecule from activating the caspases. In the other, Bcl2 stops the release of pro-apoptotic proteins from the mitochondria that are sufficient to cause cell death and lead to the further activation of caspases.

Three Classes of Bcl2 Family Members

Several mammalian proteins have been identified that resemble Bcl2 and bear one or more Bcl2 homology domains, designated BH1-4. These proteins fall into three groups. The first group, to which belong Bcl-x, Bcl-w, and Mcl-1, for example, like Bcl2, is anti-apoptotic and carries three or more of the BH domains. Bax and Bak are members of the second group, which is pro-apoptotic and bears BH domains 1, 2, and 3. The third group of the Bcl2 family is also pro-apoptotic, but carries only the BH3 domain and is therefore often referred to as BH3-only proteins. This class includes proteins such as Bim, Bid, Bad, Bmf, Bik, Hrk, Noxa, and Puma, as well as the *C. elegans* protein EGL-1 (see Figure 1).

Structure of Bcl2 Family Proteins

Structural studies have shown that Bcl2, Bcl-x, Bcl-w, Bax, and Bid adopt similar three-dimensional folds,

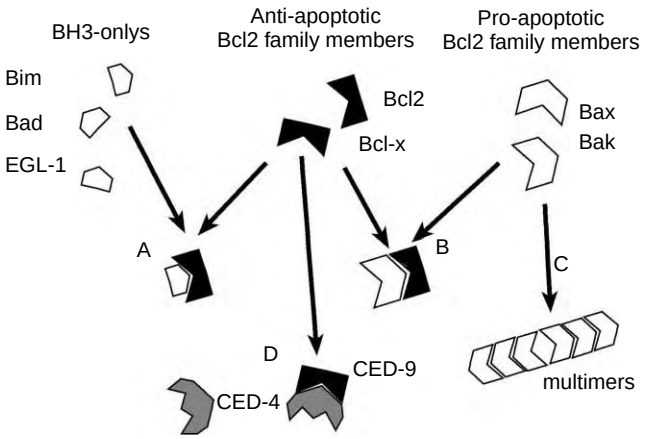

FIGURE 1 Interactions between Bcl2 family members. (A) Following death signals, BH3-only proteins (e.g., Bim, Bad, Bid, Noxa, Bik, and EGL-1) become activated and can bind strongly to anti-apoptotic family members (e.g., Bcl2, Bcl-x, Bcl-w, and CED-9). (B) In some circumstances anti-apoptotic family members can associate with Bax and Bak. (C) Apoptosis has been associated with movement of Bax to the mitochondria and the formation of multimers of pro-apoptotic Bax and Bak. (D) In *C. elegans*, the anti-apoptotic protein CED-9 can bind to and inhibit the caspase activator CED-4. CED-4 is liberated if enough of the BH3-only protein EGL-1 is present.

composed almost entirely of α-helixes. On the surface is a groove formed from parts of BH1, 2, and 3 that can be occupied either by the carboxy terminus of the protein itself or by the BH3 domain of another Bcl2 family member. Binding of the pro-apoptotic, BH3-only protein EGL-1 via its BH3 domain to the *C. elegans* cell death inhibitor CED-9 blocks its anti-apoptotic activity. In mammals, BH3-only proteins are believed to promote apoptosis by analogous interactions with other mammalian Bcl2 family members. For example, Bak can bind to Bcl-x in an interaction whereby the BH3 domain of Bak binds into the groove on the surface of Bcl-x (Figure 1).

BH3-Only Family Members

The BH3-only proteins from mammals (Bim, Bad, Bid, Hrk, Bmf, Noxa, Puma, etc.) and *C. elegans* (EGL-1) transduce pro-apoptotic signals to the core cell death machinery by binding, via their BH3 domains, to anti-apoptotic members of the Bcl2 family.

To give a pro-apoptotic signal, the BH3-only proteins can be activated in a wide variety of ways. Some are regulated transcriptionally by proteins such as p53. Others are under posttranslational control. For example, Bid is activated by proteolytic cleavage, Bad is activated by dephosphorylation, and Bim and Bmf are activated when released from sequestration by components of the cell's cytoskeleton. In this way, pro-apoptotic signals from various parts of the cell can be integrated into a common cell death effector mechanism.

Bax and Bak

Bax and Bak are pro-apoptotic proteins that bear BH1-3 domains. The deletion of genes for either Bax or Bak results in a very mild phenotype in mice, but the deletion of both has very dramatic effects, suggesting that there is a requirement for Bax or Bak for cell death in many circumstances but that the presence of one can compensate for absence of the other. Most mice lacking both Bax and Bak die perinatally. Those that do survive have persistent interdigital webs, imperforate vaginas, and accumulate excess neurons and blood cells. The fact that lymphocytes from these animals retain full sensitivity to cell death stimulated by the ligation of the tumor necrosis factor (TNF) receptor family member Fas shows that in these cells apoptosis can be activated by two independent pathways, only one of which is regulated by Bcl2 family members.

How Bax and Bak function is not certain. Cells lacking Bax and Bak are resistant to apoptosis caused by the overexpression of BH3-only proteins, and BH3-only proteins have been reported to bind to Bax and Bak, but the interactions appear to be weak and may not occur *in vivo*. Apoptosis is associated with the translocation of Bax from the cytosol to the mitochondria and the formation of multimers of Bax and Bak that can be detected by cross-linking (Figure 1). Some believe that these multimers can act as channels in the mitochondrial membranes allowing release of proteins such as cytochrome c and Smac/Diablo.

Role of the Mitochondria

In almost all cases, apoptosis is associated with the release of proteins such as cytochrome c and Smac/Diablo from the mitochondria. It has not yet been resolved whether this is necessary or sufficient for cell death. Some groups believe that Bcl2 prevents apoptosis by stopping the release of these mitochondrial proteins, whereas Bax and Bak cause apoptosis by enabling their release. Based on comparisons of their 3D structure with that of diphtheria toxin, it has been proposed that Bcl2, Bcl-xl, Bax, and Bak form or regulate channels in the mitochondrial outer membrane through which the proteins leave the mitochondria. The BH3-only proteins somehow cause Bax and Bak to form these channels. According to this model, cells subsequently die either because of the loss of mitochondrial function or because cytochrome c activates the CED-4 homologue Apaf-1, which in turn activates the caspases.

Other groups believe that Bcl2 inhibits, whereas Bax promotes, the activation of caspases that are sufficient to cause apoptosis independently of the mitochondria. According to this model, these caspases also cause

secondary damage to the mitochondria, resulting in the release of proteins such as cytochrome c and Smac/Diablo that accelerate the death process.

Roles of Bcl2 Family Members *in vivo*

To determine their essential functions, many of the genes for Bcl2 family members have been deleted in mice. The deletion of Bcl-x results in death in early embryogenesis. Mice lacking Bcl2 genes are healthy at birth but grow poorly, turn gray, and usually die of renal failure caused by cysts in their kidneys. White blood cells from these mice are very sensitive to apoptotic stimuli.

Although mice lacking Bax or Bak have no major abnormalities, mice lacking both these pro-apoptotic proteins accumulate large numbers of white blood cells and have extra neurons. Cells from these mice are resistant to apoptosis triggered by BH3-only proteins, but not that triggered by members of the TNF family of receptors.

Mice lacking genes for Bim have excess white blood cells, and these are resistant to some cell-death-inducing drugs but not others. The fact that mice lacking genes for both Bim and Bcl2 have different phenotypes from those missing one or the other indicates that, although Bim can be inhibited by Bcl2, it can also act independently of Bcl2 and, conversely, although Bcl2 can be inhibited by Bim, it can also act independently of Bim.

Therapeutic Implications

The association of Bcl2 with follicular lymphoma and the ability of antiapoptotic Bcl2 family members to inhibit chemotherapy-induced apoptosis have led to speculation that antagonizing anti-apoptotic Bcl2 family members or reducing their levels will promote the death of cancer cells. Consequently, trials are underway to use antisense against Bcl2 and to test novel drugs that mimic BH3-only proteins against a variety of cancers.

David L. Vaux is a Laboratory Head at the Walter and Eliza Hall Institute in Melbourne, Australia. His principal research interest is the molecular biology of apoptosis. He holds an M.D. and a Ph.D. from Melbourne University and received postdoctoral training at Stanford University. He was the first to recognize that Bcl2 was an inhibitor of cell death, and he linked apoptosis in mammals to programmed cell death in the worm.

B-Cell Antigen Receptor

Thomas M. Yankee and Edward A. Clark
University of Washington, Seattle, Washington, USA

B-cell functions in the immune system are dependent on their ability to recognize foreign antigens and to discriminate between foreign antigens and self-antigens. The complex of proteins responsible for the identification of foreign antigens is the B-cell antigen receptor (BCR) complex. Signals originating with the BCR can lead to a variety of cell fates, depending on the developmental stage of the B-cell and the concentration and avidity of the antigen. B-cell precursors in the bone marrow require BCR signals for survival. Once a competent signaling complex is formed, the BCR is tested to ensure that it does not react with self-antigens. If the BCR is ligated by self-antigens, it must either change its specificity or undergo cell death. Later in B-cell development, basal BCR signaling is required for the survival and homeostatic maintenance of the B-cell pool. BCR stimulation of mature B-cells initiates an immune response, characterized by the proliferation and differentiation of B-cells into either antibody-producing plasma cells or memory B-cells. Hence, a competent BCR that recognizes foreign antigens and not self-antigens is critical for the development and maintenance of B-cells and for the initiation of humoral immune responses.

Structure of the B-Cell Antigen Receptor

The BCR complex contains a membrane-bound immunoglobulin (mIg). mIg can be one of five isotypes: IgM, IgD, IgA, IgG, or IgE. The isotype of mIg expressed on a given B-cell varies with the stage of development and activation. Immature and transitional B-cells express mIgM, whereas mature resting B-cells express mostly mIgD and some mIgM. Cells that have been activated undergo a process called isotype class-switching and may then express mIgG, mIgA, or mIgE in addition to soluble IgG, IgA, or IgE. The process of isotype class-switching results in the activation of other hematopoietic cells. Each molecule of mIgM contains two heavy-chain (H) and two light-chain (L) proteins, that is H_2L_2 (Figure 1). Disulfide bonds link the heavy chains to one another and each heavy chain is disulfide-bonded to a light chain. At the membrane proximal end of the heavy chain is a transmembrane domain followed by a short intracellular domain. mIgM and mIgD contain only three intracellular residues that anchor the protein in the membrane. Other classes of mIg contain slightly longer intracellular domains and appear to mediate functions only present in B-cells that express mIgG, mIgA, or mIgE.

The short intracellular domains of mIgM and mIgD alone cannot generate a signal; mIg-associated accessory proteins fulfill this function. There are two such accessory molecules, Igα (also called CD79a) and Igβ (CD79b). The interaction between mIg and Igα/Igβ depends on the transmembrane domains of each protein. The transmembrane domains of mIg, Igα, and Igβ are α-helices and contain both polar and nonpolar regions. The polar regions are critical for protein–protein interactions among the BCR components. mIg contains polar residues on both sides of the α-helix. One side is conserved among all Ig isotypes and the other side is isotype specific. The residues that are isotype specific allow for oligomerization of the BCR complex. The degree of oligomerization varies with each Ig isotype. The side of the molecule that is conserved among all isotypes participates in the association between mIg and Igα/Igβ.

Like mIg, the transmembrane domain of Igα contains polar residues on both sides of the α-helix. In contrast, Igβ contains polar residues on only one side of the α-helix. Thus, a favored model for the structure of the BCR complex is that Igα bridges mIg and Igβ (Figure 1). According to this model, when the BCR complex is assembled, the polar residues within the transmembrane domains are masked by protein–protein interactions. This is essential for the surface expression and stability of the BCR.

B-Cell Antigen Receptor Diversity

In order to contribute to protective immunity to a range of pathogens, B-cells must be able to recognize a vast array of antigens. The diversity of the Ig repertoire is accomplished using three factors: combinatorial diversity, junctional diversity, and somatic hypermutation. Combinatorial diversity occurs through the

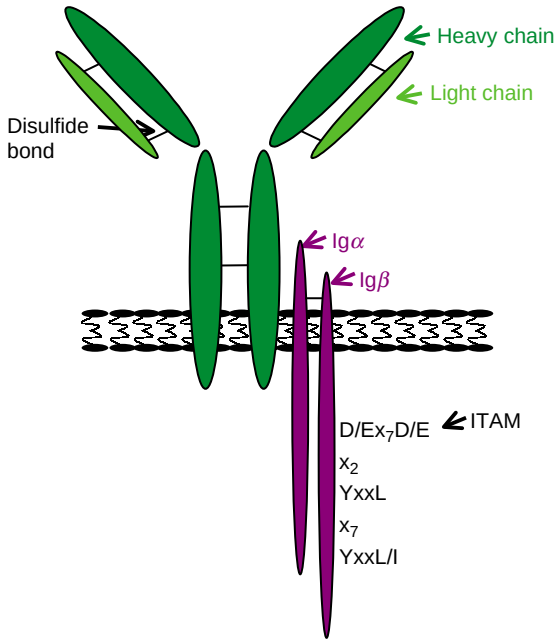

FIGURE 1 The structure of the BCR. The BCR consists of two heavy chains disulfide-bonded to one another. Each heavy chain is disulfide-bonded to a light chain. Igα and Igβ are also disulfide-linked. mIg and Igα/Igβ are noncovalently coupled. Also shown is the ITAM motif on Igβ; Igα and Igβ each have one ITAM motif.

recombination of sets of heavy- and light-chain gene segments. Three gene segments, variable (V_H), diversity (D_H), and joining (J_H), recombine to form the variable region of the heavy chain. There are many V_H gene segments, D_H gene segments, and J_H gene segments. Thus, sets of different segments recombine to form a range of different VDJ_H genes. The light chain undergoes a similar process of recombination. To generate the light chain, two gene loci, κ and λ, undergo recombination. Here, V_L and J_L gene segments recombine and result in VJ_L. The combination of heavy-chain rearrangement and light-chain rearrangement results in substantial BCR diversity.

Junctional diversity also arises from the recombination of the gene segments. When a V_H gene segment recombines, nucleotides may be added or subtracted. This results in the addition or loss of amino acids or a shift in the reading frame of the new gene. The third mechanism by which diversity is introduced to the BCR repertoire is through somatic hypermutation (discussed later).

B-Cell Antigen Receptor Signaling

Ligation of the BCR complex triggers a series of events that ultimately affects the fate of the cell. A B-cell stimulated through the antigen receptor may proliferate, differentiate, or undergo apoptosis. B-cells are also very efficient antigen-presenting cells. BCR signaling is essential for antigen internalization and processing after the BCR binds and captures antigen.

Antibody–Antigen Interactions

Antigens interact with the variable regions of mIg. Within the variable region, there are framework regions interspersed with three hypervariable regions, the areas that contain the most variability. The framework regions, folded as β-sheets, provide much of the antibody structure. The hypervariable regions are located on one edge of the β-sheets. To provide even greater repertoire diversity, the hypervariable regions of the heavy and light chain are within close proximity to one another and together create the antigen-binding site. Haptens and other small antigens bind the antibody in the grooves between the hypervariable regions of the heavy and light chains. Interactions between the BCR and larger antigens may extend into the framework region. The interactions between the antibodies and antigens are noncovalent in nature. These interactions may consist of electrostatic interactions, van der Waals interactions, hydrophobic interactions, and hydrogen bonding.

Early Signaling Events

Igα and Igβ each contains tyrosine residues that are phosphorylated following BCR engagement. Two of the tyrosine phosphorylation sites on Igα and Igβ are located within immunoreceptor tyrosine-based activated motifs (ITAMs) (Figure 1). These regions contain six conserved residues in the specific configuration, D/ExxxxxxxD/ExxYxxLxxxxxxxYxxL/I. The spacing between the tyrosine residues in the ITAM results in these residues being positioned on the same side of an α-helix, facilitating the interactions with downstream SH2-domain-containing signaling molecules. (SH2 domains are motifs that bind phosphotyrosine and the surrounding residues.)

In addition to the ITAM tyrosine residues, Igα and Igβ contain other residues that become phosphorylated. Non-ITAM tyrosine residues may also recruit SH2-domain-containing signaling proteins. Serine/threonine phosphorylation of Igα may negatively regulate phosphorylation of the ITAM tyrosine residues and, therefore, may negatively regulate downstream signaling.

Three families of protein tyrosine kinases (PTKs) play key roles in the initiation of BCR signaling (Figure 2). These kinases are Src-family PTKs, such as Lyn; the Syk/ZAP-70-family PTKs, such as Syk; and the Tec-family PTKs, such as Btk. Following BCR ligation, Lyn becomes activated and phosphorylates the ITAM tyrosines. The phosphorylated ITAM becomes the docking sites for Syk, which has two tandem SH2 domains.

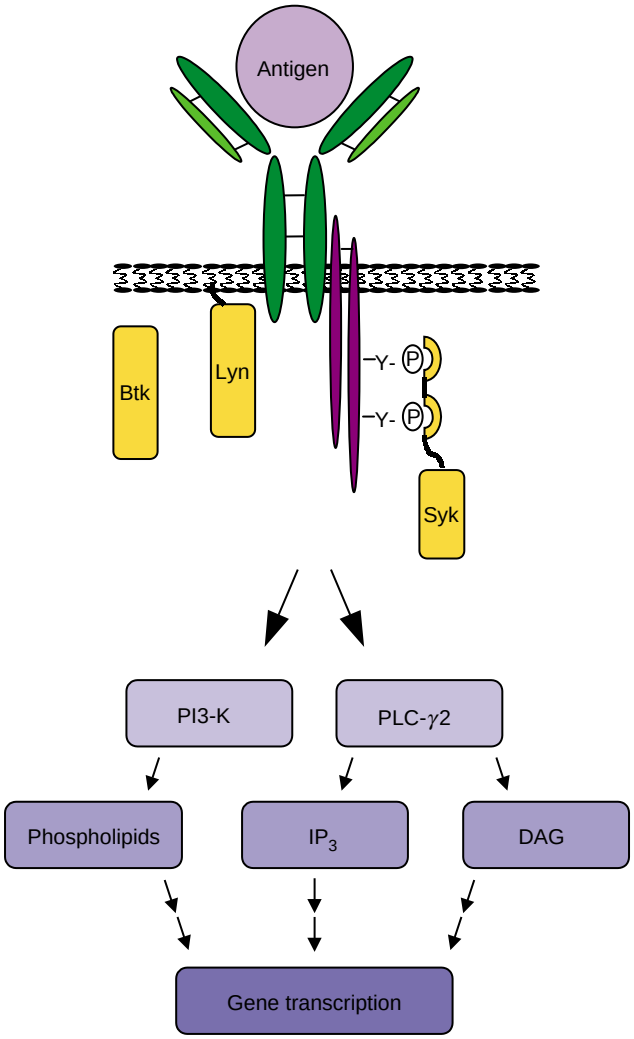

FIGURE 2 BCR-mediated signaling events. Following antigen binding to the BCR complex, tyrosine residues on Igα and Igβ become phosphorylated and bound by the tandem SH2 domains of the Syk. Lyn is also activated. The activation of these two PTKs trigger many downstream signaling cascades, including the activation of PI3-K and PLC-γ2.

The binding of the SH2 domains of Syk to the phospho-ITAM contributes to its activation. Syk can also become activated in the absence of Src-family PTKs. A small amount of Syk is constitutively associated with the BCR complex. Cross-linking the BCR leads to the clustering of Syk, which then may transautophosphorylate and become activated. Activation of Syk and Lyn, then, leads to the activation of Btk. The combination of Syk, Lyn, and Btk activity is necessary for optimal signaling through the BCR.

Downstream Signaling Events

The activation of Syk-, Src-, and Tec-family PTKs trigger a number of downstream signaling pathways (Figure 2). For example, phosphatidylinositol 3′-kinase (PI3-K) and phospholipase C-γ2 (PLC-γ2) are two enzymes that generate second messengers in BCR signaling. PI3-K is a lipid kinase important for the recruitment and activation of PH-domain-containing proteins. (PH domains are motifs that bind phospholipids.) PLC-γ2 generates inositol-1,4,5-triphosphate (IP_3) and diacylglycerol (DAG), second messengers critical for calcium influx and protein kinase C activation. The activation of these signaling pathways, along with many other pathways, leads to gene transcription and cell-fate decisions.

In addition to gene transcription, BCR signaling is also critical for antigen internalization and processing. When the BCR binds an antigen, the BCR complex is internalized. The antigen is then processed and presented on the cell surface in order to activate antigen-specific T cells.

The B-Cell Antigen Receptor and the Immune Response

When antigen and other immune cells activate a B-cell, a complex series of events takes place that can result in proliferation, somatic hypermutation, isotype class-switching, and differentiation. The BCR on mature naïve B-cells may be able to recognize more than one antigen. This multispecific nature of the BCR results in relatively low affinity to any specific antigen. Somatic hypermutation is a process by which high-affinity BCRs are generated. Under some conditions following BCR ligation, a somatic hypermutation program is induced. During somatic hypermutation mutations are introduced into the V segment of the heavy- and light-chain genes. After somatic hypermutation, B-cells expressing BCRs with high affinity are selected for further expansion. In this way, the immune system creates B-cells that have produced high affinity antibodies tailor-made for specific pathogens.

The other major changes in the BCR following B-cell activation include isotype class-switching. The genomic organization of mIg is the recombined variable region followed by the constant genes of μ, ∂, γ3, γ1, γ2b, γ2a, ε, and α in mice and μ, ∂, γ3, γ1 α1, γ2, γ4, ε, and α2 in humans. Following the activation of the B-cell through certain key receptors such as CD40, DNA recombination can occur so that the V_H joins a C_H segment of another isotype. This process is a guided repetitive DNA sequence preceding each constant domain known as a switch region. The precise mechanism of class-switching is unknown, but probably involves DNA recombination between homologous repeats in the switch regions of different constant genes.

The result of somatic hypermutation and class-switching is the generation of highly specific antibodies of an isotype that generates an effective immune response.

In particular, the constant regions of the antibody bind specific receptors on other immune cells. For example, the constant region of IgGγ1 and IgGγ3 bind Fcγ receptors on macrophages and neutrophils leading to phagocytosis of the antigen, whereas the constant region of IgE binds Fcε receptors on mast cells and basophils leading to the secretion of inflammatory agents.

Membrane-bound forms of IgG, IgA, and IgE may function differently than mIgM and mIgD. Cross-linking mIgG leads to the proliferation and antibody secretion of mIgG-expressing B-cells. Although mIgG and mIgM activate similar downstream signaling pathways, mIgG cross-linking triggers a much more robust response than does mIgM cross-linking. This may be due to the fact that mIgG is resistant to down-regulation by certain B-cell co-receptors, such as CD22. The mechanism for this resistance may be related to differences in the intracellular domains between mIgM and mIgG.

Summary

The BCR complex is a critical component of the humoral immune response. The BCR repertoire must be diverse enough to recognize an incredible number of foreign antigens, but must also avoid targeting self-antigens. Ligation of the BCR triggers a complex series of events that include the activation of PTKs, the phosphorylation of Igα and Igβ, and the initiation of multiple signaling cascades. These signaling pathways lead to cell-fate decisions, antigen presentation, and an immune response.

Biography

Dr. Thomas M. Yankee is a Senior Fellow in the Department of Microbiology at the University of Washington, Seattle. His principal interest is the regulation of cell fate in B- and T-lymphocytes. He holds a Pharm.D. degree from the University of Illinois and a Ph.D. degree from Purdue University.

Dr. Edward A. Clark is a Professor of Microbiology and Immunology at the University of Washington, Seattle. His principal interest is the regulation of B-cells and dendritic cells during immune responses. He holds a Ph.D. degree from the University of California, Los Angeles. He has helped to discover and characterize a number of receptors and signaling molecules in B-lymphocytes such as CD40, CD80, and Syk.

Bile Salts and their Metabolism

Ulrich Beuers and Thomas Pusl
University of Munich, Munich, Germany

Bile salts originate from conversion of cholesterol in the liver, a major pathway for elimination of cholesterol from the body. Bile salts together with phospholipids and cholesterol are the major organic solutes in bile and are the key driving force of bile formation being actively secreted into bile canaliculi across the apical membranes of hepatocytes. Bile salts undergo an efficient enterohepatic circulation. Their structure is amphipathic with a hydrophobic and hydrophilic side allowing them to interact with both lipids and the aqueous environment. Molecular self-aggregation occurs, by means of micelle formation, above a critical micellar concentration. Bile salt micelles can solubilize other lipophilic molecules such as cholesterol, phospholipids, and monoglycerides to form mixed micelles, acting as carriers for these lipids in bile and in the intestine. Such micelle formation promotes absorption of dietary lipids and fat-soluble vitamins in the small intestine. Bile salts may become cytotoxic when their intracellular concentrations increase beyond physiological levels due to impairment of bile secretion as observed in a variety of pathological conditions, particularly cholestatic liver diseases. Therefore, bile salt homeostasis is tightly regulated. Bile salts have recently been shown to represent potent intracellular signaling molecules that activate nuclear receptors and modulate cytosolic signaling cascades, thereby regulating their own metabolism and transport.

Bile Salt Synthesis and its Regulation

Bile salts consist of a steroid nucleus with its hydroxyl or other substituents and an aliphatic side chain of variable length. They are synthesized in pericentral hepatocytes from cholesterol by different pathways, which involve up to 17 enzymes located in the endoplasmatic reticulum, mitochondria, cytosol, and peroxisomes (Figure 1). The rate-limiting step of the classic bile salt biosynthetic pathway, also known as the "neutral" pathway, is 7α-hydroxylation of cholesterol by a microsomal cytochrome P-450 monooxygenase (CYP7A1). End products of the complex biosynthetic steps are the two major human primary bile salts, cholate (C; 3α,7α,12α-trihydroxy-5β-cholanoate) and chenodeoxycholate (CDC; 3α,7α-dihydroxy-5β-cholanoate). These primary bile salts undergo further modifications during enterohepatic cycling by bacterial enzymes in the distal intestine which lead to dehydroxylation at C-7 of C or CDC to form the secondary bile salts, deoxycholate (DC; 3α,12α-dihydroxy-5β-cholanoate) and lithocholate (LC; 3α-hydroxy-5β-cholanoate), respectively, or to epimerization of the hydroxy group at C-7 of CDC to form ursodeoxycholate (UDC; 3α,7β-dihydroxy-5β-cholanoate). A second pathway (commonly referred to as the "alternative" or "acidic" pathway) is initiated by the mitochondrial enzyme sterol 27-hydroxylase (CYP27A1), which allows for the conversion of cholesterol to both 27-hydroxycholesterol and 3β-hydroxy-5-cholestenoic acid. Although CYP27A1 is expressed also in peripheral tissues such as macrophages and vascular endothelium, the liver remains the sole site for complete bile salt formation. The acidic pathway provides a mechanism by which excess oxidized cholesterol generated in peripheral tissues can be removed through conversion to bile salts. The relative contribution of CYP7A1 and CYP27A1 to overall bile salt synthesis is unclear, but CYP7A1 has been estimated to account for 75% (mice) to 90–95% (human) of total bile salt synthesis. Cholesterol 25-hydroxylase and cholesterol 24-hydroxylase (CYP46A1) may also initiate bile salt synthesis *in vitro*, but their contribution to bile salt formation *in vivo* may be limited.

Bile salt synthesis is highly regulated and subject to feedforward and feedback control whereby bile salts down-regulate their own synthesis and oxysterols up-regulate bile salt synthesis, mainly by regulating CYP7A1 gene transcription (Figure 2). Promoter analyses of the CYP7A1 gene have identified two bile acid response elements, which are highly conserved among different species, contain hexameric repeats of an AGGTCA sequence, and are binding sites for nuclear hormone receptors. Nuclear hormone receptors are ligand-activated transcription factors with a highly conserved DNA-binding domain (DBD) in the N-terminal region and a moderately conserved ligand-binding domain (LBD) in the C-terminal region. Upon ligand binding to the LBD, nuclear receptors undergo conformational changes that allow dissociation of corepressors and recruitment of coactivator proteins to

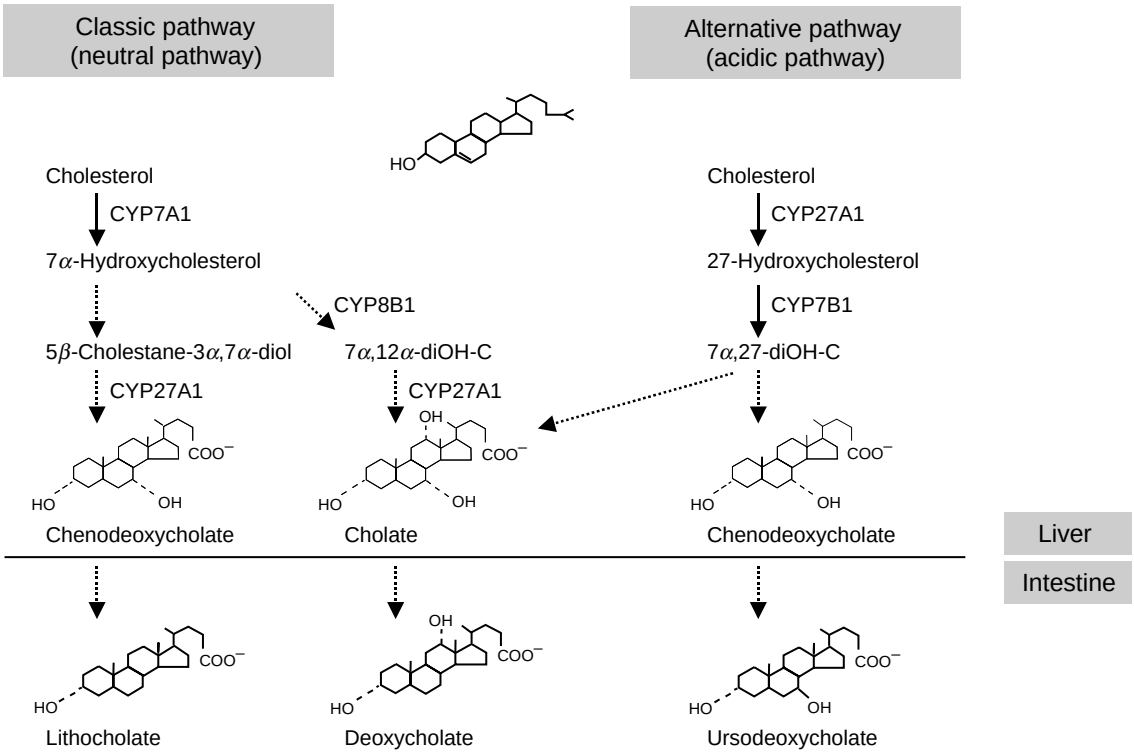

FIGURE 1 Major bile salt biosynthetic pathways in the liver. The initial and rate-determining step of the classic ("neutral") pathway is the conversion of cholesterol to 7α-hydroxycholesterol by microsomal cholesterol 7α-hydroxylase (CYP7A1) leading to formation of cholate and chenodeoxycholate. The initial step of the alternative ("acidic") pathway is the conversion of cholesterol to 27-hydroxycholesterol by mitochondrial sterol 27-hydroxylase (CYP27A1) leading to formation mainly of chenodeoxycholate. These primary bile salts undergo further structural modifications by bacterial enzymes during enterohepatic cycling resulting in the formation of the secondary and tertiary bile salts, deoxycholate, lithocholate, and ursodeoxycholate. Only major biosynthetic steps are shown. CYP7B1, oxysterol 7α-hydroxylase; CYP8B1, sterol 12α-hydroxylase; 7α,27-diOH-C, 7α,27-dihydroxycholesterol; 7α,12α-diOH-C, 7α,12α-dihydroxy-4-cholestene-3-one.

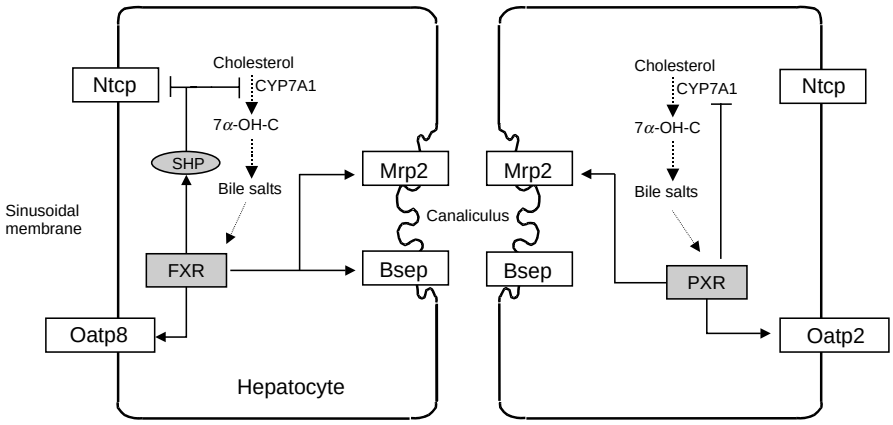

FIGURE 2 Regulation of bile salt transport and metabolism by nuclear bile salt receptors in hepatocytes. The transport of bile salts is vectorial in liver. Bile salts are taken up by the Ntcp and Oatp in the sinusoidal membrane of hepatocytes and are excreted into bile via the Bsep and the conjugate export pump (Mrp2) located in the canalicular membrane. The FXR acts as a bile salt sensor and represses the transcription of cholesterol 7α-hydroxylase (CYP7A1) and Ntcp genes via up-regulation of small heterodimer partner-1 (SHP-1), thereby inhibiting bile salt synthesis and uptake. FXR also stimulates expression of Bsep, Mrp2, and Oatp8. PXR represses bile salt synthesis by down-regulation of transcription of CYP7A1. PXR also stimulates the expression of Mrp2 and Oatp2. 7α-OH-C, 7α-hydroxycholesterol ($\rightarrow$ activation; $\dashv$ repression).

activate the expression of target genes. The nuclear hormone receptor superfamily includes receptors for steroid and thyroid hormones, retinoids and vitamin A and D, as well as different so-called orphan receptors, whose ligands were initially unknown. Analyses of orphan receptor expression patterns in enterohepatic tissue have identified bile salts, including CDC and C, as the endogenous ligands of farnesoid X receptor (FXR). In the liver, bile salt activation of FXR represses CYP7A1 transcription by an indirect mechanism involving nuclear receptors small heterodimer partner (SHP) and liver receptor homologue 1 (LRH1). Activation of pregnane X receptor (PXR), a promiscuous bile salt receptor, also results in repression of CYP7A1. The liver X receptor α (LXRα), abundantly expressed in the liver and bound by oxysterol ligands, has been shown to mediate the feedforward cholesterol catabolism to bile acids by up-regulation of CYP7A1. Nuclear hormone receptor-independent pathways may also be involved in bile salt feedback inhibition of gene transcription based on protein kinase C (PKC) and mitogen-activated protein kinase (MAPK) signaling pathways as well as bile-salt-induced release of inflammatory cytokines.

Bile Salt Transport and its Regulation

After their biosynthesis and conjugation mainly to glycine and taurine in hepatocytes, bile salts are secreted into bile and reach the intestinal lumen. More than 95% of intestinal conjugated bile salts are actively reabsorbed mainly from the distal ileum by an apical sodium-dependent bile salt transporter (Asbt) and reach the liver via the portal vein, the majority being bound to albumin. Hepatic extraction followed by resecretion into bile completes the enterohepatic circulation of bile salts. In humans, the normal bile salt pool size averages 3–4 g recirculating 5–10 times each day. The hepatocyte plays a key role in the vectorial transport of bile salts from portal vein to the bile canaliculus, with distinct bile salt transport systems at its basolateral (sinusoidal) and apical (canalicular) plasma membranes (Figure 2). Functional impairment of bile salt transport at any level of the hepatocyte may be an important cause of cholestasis, a syndrome characterized by a reduction in bile flow and retention of biliary constituents in serum, liver, and other organs leading to biochemical, morphological, and clinical alterations.

Hepatocellular uptake of bile salts at the basolateral membrane is the first step in hepatic bile salt transport, and is predominantly mediated by the Na^+-taurocholate-cotransporting polypeptide (Ntcp) and to a lesser extent by the organic anion transporting protein (Oatp) family. The 362-amino acid Ntcp with a molecular mass of 50 kDa has been cloned from human liver and mediates secondary active transport of bile salts, using an inwardly directed sodium gradient generated by Na^+-K^+-ATPase and the intracellular negative electrical potential generated in part by a potassium channel. Members of the Oatp family mediate sodium-independent uptake of organic anions and mainly unconjugated bile salts. Tissue distribution of Oatps is not restricted to the liver, where they are exclusively located in the basolateral membrane of the hepatocyte.

Little is known about the intrahepatocellular transport of bile salts. Cytosolic proteins such as a 36 kDa bile salt binding protein in human liver are considered to play a major role in the intracellular trafficking of bile salts, but rapid diffusion may also contribute to bile salt trafficking across the cell. In addition, bile salt partitioning into organelles may be observed when the intracellular bile salt load is increasing.

Under physiologic conditions, bile salt levels in the hepatocyte remain low, indicating the existence of efficient secretory mechanisms. Canalicular excretion of bile salts is predominantly achieved by the ATP-dependent bile salt export pump (Bsep), which transports monovalent bile salts against a steep gradient (up to 1000-fold) across the apical liver cell membrane into the canaliculus. This 60 kDa protein is a member of a large family of ATP-binding cassette (ABC) transporters. Mutations in the Bsep gene may lead to progressive familial intrahepatic cholestasis type 2 (PFIC 2) in childhood, a disorder with markedly elevated serum bile salt levels and low content of bile salts in bile, which carries a dismal prognosis. The conjugate export pump (multidrug resistance-associated protein 2, Mrp2) is another ABC-type transporter that has been shown to be capable of transporting divalent sulfated and glucuronidated bile salts.

In experimental animal models of cholestasis induced by application of endotoxin (model for inflammatory cholestasis), ethinyloestradiol (cholestasis of pregnancy), alpha-naphtylisocyanate (vanishing bile duct syndrome), and common bile duct ligation (extrahepatic biliary obstruction), most of the hepatic transporters are down-regulated. Recent findings of up-regulation of basolateral bile salt transporters in cholestasis such as Mrp3 and Mrp4 may provide an escape route for bile salts out of the hepatocyte when apical transport is defective. Cholestasis is also associated with retrieval of canalicular transporters to pericanalicular vesicles. Thus, the function of most hepatobiliary transport systems is presumed to decrease after exposure to cholestatic injury.

Active transport of bile salts across the canalicular membrane represents the rate-limiting step in overall transport from blood to bile and is under both short-term and long-term regulation by posttranscriptional and transcriptional mechanisms, respectively. On the

transcriptional level, hepatic transporters have been shown to be regulated by nuclear receptors (Figure 2). FXR up-regulates Bsep expression in the canalicular membrane of the hepatocyte. An FXR-dependent transactivation has also been demonstrated for the Mrp2 and Oatp8 gene promoter. PXR stimulates expression of Mrp2 and Oatp2. Short-term regulation on the post-transcriptional level occurs via signaling cascades which may involve cytosolic free calcium, adenosine 3,5-cyclic monophosphate (cAMP), phosphatidylinositol 3-kinases, PKC isoforms, and different MAP kinases.

Bile Salts in Therapy

UDC is a hydrophilic bile salt that is increasingly used for the treatment of various cholestatic disorders. It is normally present in human bile at a low concentration of about 3% of total bile salts. It is the major bile salt in black bear's bile, which has been used in Chinese traditional medicine for the treatment of liver diseases. First reports on the beneficial effects of UDC in patients with liver diseases came from Japan in the 1970s. A number of controlled trials on the use of UDC in primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) have been published in the Western literature since the early 1990s. UDC improves serum liver tests and may delay disease progression to cirrhosis and prolong transplant-free survival in PBC. In PSC, UDC improves serum liver tests and surrogate prognostic markers, but effects on disease progression must further be evaluated. Anticholestatic effects of UDC have also been reported in a number of other cholestatic conditions. After oral administration of unconjugated UDC, 30–60% of the dose is absorbed by nonionic diffusion mainly in the small intestine and to a small extent in the colon and undergoes efficient hepatic uptake and conjugation with glycine and to a lesser extent with taurine. A daily dose of 13–15 mg kg^{-1} UDC causes an enrichment of ~40–50% in biliary bile salts of patients with PBC. The mechanisms underlying the beneficial effects of UDC in cholestatic disorders are increasingly being unraveled. Experimental evidence suggests three major mechanisms of actions: (1) protection of cholangiocytes against cytotoxicity of hydrophobic bile salts, resulting from modulation of the composition of mixed phospholipid-rich micelles, reduction of bile salt cytotoxicity of bile, and possibly, decrease of the concentration of hydrophobic bile salts in the cholangiocytes; (2) stimulation of hepatobiliary secretion, putatively via Ca^{2+}- and PKC-dependent mechanisms and/or activation of p38MAPK and extracellular signal-regulated kinases (Erk) resulting in vesicular insertion of transporter molecules (e.g., bile salt export pump, Bsep, and conjugate export pump, Mrp2) into the canalicular membrane of the hepatocyte and, possibly, activation of the inserted carriers; (3) protection of hepatocytes against bile-salt-induced apoptosis, involving inhibition of the mitochondrial membrane permeability transition (MMPT), and possibly, stimulation of a survival pathway.

Biography

Ulrich Beuers is a Professor in the Department of Internal Medicine II, University of Munich, Germany. His principal research

interest is in the field of bile acids and cholestasis with a focus on bile acid-induced modulation of signaling and secretion in liver cells and treatment of chronic cholestatic liver diseases. He holds an M.D. from the University of Freiburg and received his postdoctoral training at the Universities of Göttingen (Department of Biochemistry), Munich (Department of Internal Medicine II), and the Yale University, New Haven (Section of Digestive Diseases).

Thomas Pusl is a resident in the Department of Internal Medicine II, University of Munich, Germany. His special research interests include mechanisms and effects of calcium signals in liver, and mechanisms underlying cholestasis and treatment of chronic cholestatic liver diseases. He holds an M.D. from the University of Munich and received his postdoctoral training at the University of Munich (Department of Internal Medicine II), and the Yale University, New Haven (Section of Digestive Diseases).

Biliary Cirrhosis, Primary

Marshall M. Kaplan
Tufts-New England Medical Center and Tufts University School of Medicine, Boston, Massachusetts, USA

Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease that is characterized by a continuing destruction of interlobular bile ducts, progressive fibrosis, and the eventual development of cirrhosis and liver failure. In contrast to patients seen more than a decade ago, most of whom had symptoms of fatigue, pruritus (itching), or jaundice, more than 60% of PBC patients who are diagnosed now are asymptomatic. Asymptomatic patients live longer than symptomatic ones. However, most asymptomatic patients eventually develop symptoms and their survival is reduced compared to an age- and sex-matched healthy population. There is general agreement that all patients with PBC should be treated but no agreement about the best treatment or even whether any treatment prolongs survival free of liver transplantation. Most physicians initiate treatment with ursodeoxycholic acid (UDCA), the only treatment for PBC approved by the U.S. Food and Drug Administrations (FDA). Some, including the author, believe that the addition of colchicine and/or methotrexate to those who fail to respond fully to UDCA provides an added benefit.

Epidemiology

Primary biliary cirrhosis (PBC) was once considered a rare disease. However, increased awareness of PBC has led to earlier and more frequent diagnoses. In some series, it accounted for almost 2% of deaths due to cirrhosis. In a study from England, there was an annual incidence of 5.8 cases per million population and a point prevalence of 54 cases per million. The prevalence in the United States is at least that high. Estimates place the number between 50,000 to 100,000 patients. The etiology is unknown, but may be related to altered immunoregulation. The lack of concordance of PBC in identical twins suggests that some triggering event is required to initiate PBC in a genetically susceptible individual. PBC is much more likely to occur in families of patients with an index case compared to the general population. A number of environmental causes have been implicated in the pathogenesis of PBC, including bacteria and viruses. Some of the most compelling evidence for an environmental factor has been derived from an epidemiological study that demonstrated significant geographic clustering of PBC cases in urban areas in northeast England.

Etiology

Autoantibodies and Antimitochondrial Antibody

Ninety to 95% of patients with PBC are women, a sex distribution similar to that for other autoimmune diseases such as systemic lupus. There is an increased incidence of autoantibodies including antimitochondrial antibody, antinuclear antibody, and antimicrosomal antibody. Antimitochondrial antibody (AMA) is detected in 95% of patients with PBC. The major autoantibody found in PBC patients has been called anti-M2. It is directed principally against the dihydrolipoamide acyltransferase component (E2) of the branched keto-acid dehydrogenase and pyruvate dehydrogenase complexes on the inner mitochondrial membrane. Other antimitochondrial antibodies that have been described in PBC, anti-M4, anti-M8, and anti-M9, are most likely artifacts and were not found in a study that employed highly purified human mitochondrial proteins as antigens. The relationship between antimitochondrial antibodies and immunologic bile duct injury is not clear. The mitochondrial antigens are not tissuespecific, and their intracellular location should reduce their immunogenicity. Repeated studies have shown that there is no correlation between the presence or titer of AMA and the severity or course of PBC.

Mitochondrial Antigens and the Cellular Immune System

Although there is little evidence that AMA plays a direct role in the pathogenesis of PBC, an interaction between the mitochondrial antigens and the cellular immune system appears to be important. The E2 antigens stimulate interleukin-2 production by peripheral blood mononuclear cells and by T cells cloned from liver biopsies of PBC patients. E2 antigens are recognized by both helper and cytotoxic T cells in PBC and cytotoxic

T cells appear to mediate bile duct epithelial cell necrosis. The mitochondrial antigens are aberrantly expressed on the luminal surface of biliary epithelial cells from PBC patients, but not in control subjects or patients with primary sclerosing cholangitis. These antigens are expressed in bile duct epithelial cells before two other antigens that are also required for T-lymphocyte-mediated cell destruction, human leukocyte antigen (HLA) class II antigens, and the cellular recognition factor, BB1/B7. This chronology suggests that aberrant expression of the E-2 autoantigen on the surface of biliary epithelial cells initiates lymphocytic destruction of bile ducts, the characteristic lesion in PBC.

Association with Other Autoimmune Diseases

There is an increased association of PBC with other autoimmune diseases, such as thyroiditis, rheumatoid arthritis, calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactylyl and telangiectasia (CREST) syndrome, Raynaud's disease and Sjögren's syndrome. Although circulating immune complexes have been demonstrated in some PBC patients, it is unlikely that they play a role in pathogenesis. Only a small percentage of PBC patients have immune complexes. Some PBC patients have an IgM that can fix complement in the absence of demonstrable antigen binding and will give false positive results with many of the assays used to detect immune complexes.

Pathophysiology

The signs and symptoms of PBC are due to long-standing cholestasis. There is a gradual destruction of small intrahepatic bile ducts that results in a decreased number of functioning bile ducts within the liver. This, in turn, causes retention within the liver of substances that are normally secreted or excreted into bile, such as bile acids, bilirubin, and copper. The increased concentration of some of these substances (e.g., bile acids) causes further damage to liver cells. Other substances regurgitate from the liver into the blood and soft tissues and cause symptoms such as pruritus. The identity of the substance or substances that cause pruritus is unknown. It is not any of the naturally occurring primary and secondary bile acids. Most data suggest that it is some substance that is secreted into bile and that binds tightly to cholestyramine, a nonabsorbed, quaternary ammonium resin. Possible pruritogens include the naturally occurring opioids. Serum levels of endogenous opioids (endorphins and encephalins) are increased in PBC, and opioid antagonists will relieve itching in some patients. The striking hyperlipidemia and xanthoma formations in some PBC patients are also a consequence of longstanding cholestasis. The impaired secretion of bile in patients with clinically advanced PBC causes a diminished concentration of bile acids within the intestinal lumen. The bile acid concentration may fall below the critical micellar concentration and thus be inadequate for complete digestion and absorption of neutral triglycerides in the diet. This causes the striking fat malabsorption seen in some jaundiced PBC patients, as well as malabsorption of the fat-soluble vitamins A, D, E, and K. Some PBC patients with Sicca syndrome also have pancreatic insufficiency. The pathogenesis of the osteopenic bone disease that occurs in at least 25% of PBC patients is still unclear. Some data suggest that high concentrations of serum bilirubin may impede osteoblast function. The clinically important bone disorder is osteoporosis, not osteomalacia, as was once believed.

Pathology

PBC is characterized by portal inflammation, the destruction of interlobular bile ducts, progressive fibrosis, and the eventual development of cirrhosis. PBC is divided into four histologic stages, I to IV. The disease is believed to progress from stage I to stage IV. However, the liver is not affected uniformly in PBC. One biopsy specimen may demonstrate lesions ranging from normal to stage IV. By convention, the histologic stage is the highest stage seen in a biopsy. There are two widely used staging systems, those of Scheuer and Ludwig, both well-known liver pathologists. In the Scheuer classification, stage I is defined by the presence of florid, asymmetric destructive bile duct lesions within portal triads (Figure 1). These lesions are irregularly scattered throughout the portal triads and are often seen only on large surgical biopsies of the liver. The damaged bile ducts are often surrounded by dense collections of lymphocytes, histiocytes, plasma cells eosinophils, and occasionally true giant cells, a pathologic lesion that is called a granuloma (Figure 1A). In the Ludwig classification, stage I is defined by the localization of inflammation to the portal triads. In stage II in the Scheuer classification, there are reduced numbers of normal bile ducts within some portal triads and increased numbers of poorly formed bile ducts with irregularly shaped lumens in others, a lesion called atypical bile duct hyperplasia (Figure 2). There is also mononuclear cell inflammation in portal triads and the beginning of portal fibrosis. In stage II in the Ludwig classification, the inflammation and fibrosis extends beyond portal triads and into the surrounding parenchyma. A diminished number of bile ducts in an otherwise unremarkable-appearing needle biopsy of the liver

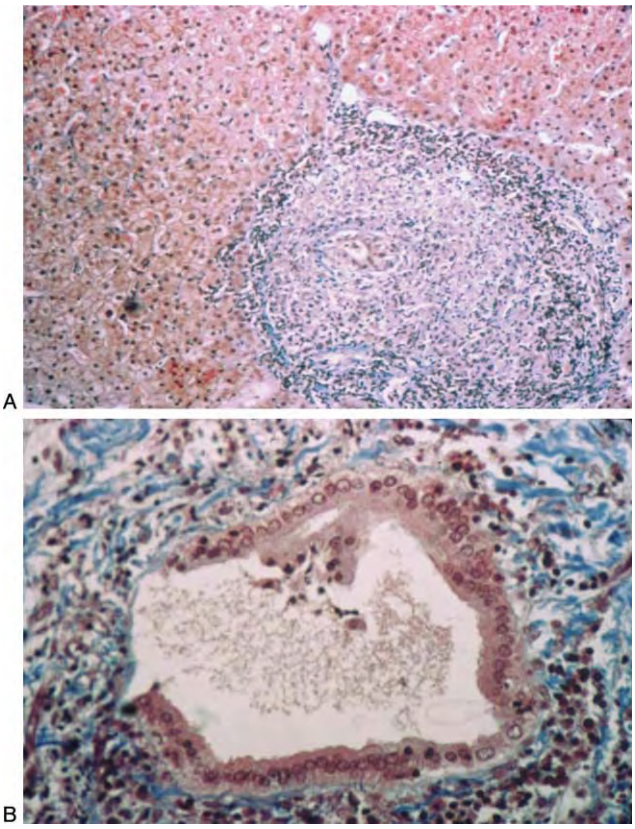

FIGURE 1 (A) Stage I florid bile duct lesion in primary biliary cirrhosis. A damaged bile duct is at the center of a granuloma (masson trichrome, ×124). (B) Stage I florid bile duct lesion in primary biliary cirrhosis. Epithelial cells have been dislodged from one quadrant of a bile duct (masson trichrome, ×310).

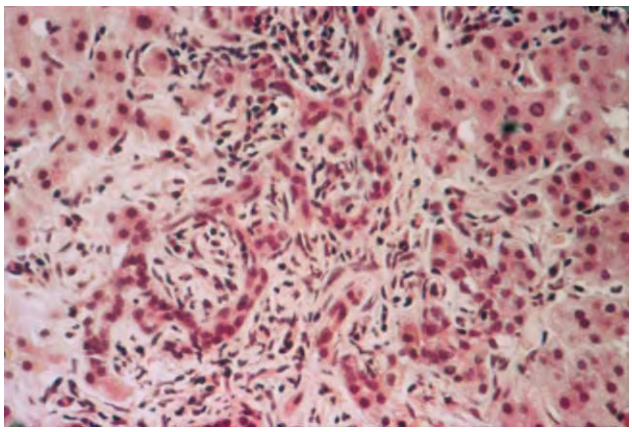

FIGURE 2 Stage II primary biliary cirrhosis. Atypical bile duct hyperplasia. Bile ducts are tortuous. None is cut in cross section, and there are no visible bile duct lumens (hematoxylin and eosin, ×310).

should alert one to the possibility of PBC. In stage III in both classifications, fibrous septa now extend beyond triads and form portal-to-portal bridges (Figure 3). The portal triads are otherwise similar to those in stage II. Stage IV represents the end stage of the

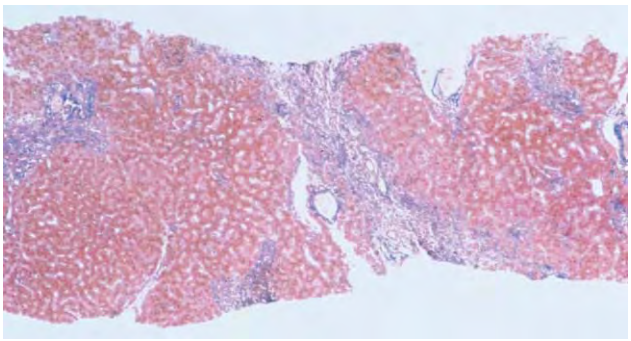

FIGURE 3 Stage III primary biliary cirrhosis. Adjacent portal triads are linked by septae that contain mononuclear inflammatory cells and scar tissue (masson trichrome, ×310).

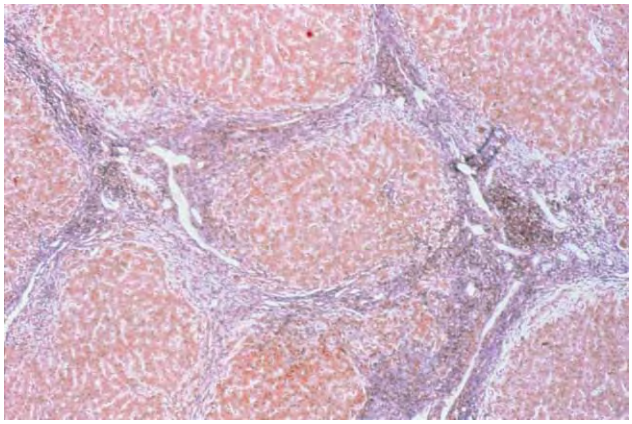

FIGURE 4 Stage IV primary biliary cirrhosis. Cirrhotic liver removed at the time of liver transplantation performed because of end-stage primary biliary cirrhosis. Nodule formation is evident and there are no visible bile ducts (masson trichrome, ×54).

lesion, frank cirrhosis, and regenerative nodules. It may be difficult to distinguish this late lesion from other types of cirrhosis. A paucity of normal bile ducts in areas of scarring suggests PBC (Figure 4).

Clinical Findings

The earliest and most common complaint is fatigue. Fatigue, however, is nonspecific and is found in many diseases. The earliest specific complaint in PBC is pruritus, usually worse at bedtime. In some patients, the pruritus begins during the third trimester of pregnancy and persists after delivery. Physical examination may reveal hepatomegaly and increased skin pigmentation. The pigment is melanin, not bilirubin, at this early stage. Excoriations, caused by intense itching and an uncontrollable urge to scratch, may be widespread. Jaundice usually presents later in the course of the disease. Kayser-Fleischer rings have been observed in a few PBC patients with long-standing jaundice.

Unexplained weight loss may also occur. Rarely, patients with PBC may go undetected until late in the course of the disease when they present with severe jaundice, ascites, or bleeding from esophageal varices. During the course of the disease, some jaundiced patients may develop malabsorption and complain of nocturnal diarrhea; frothy, bulky stools; or weight loss in the face of a voracious appetite and increased caloric intake. Fewer than 5% of patients will develop xanthomas (a cutaneous tumor composed of lipid-laden foam cells), but xanthelasmas (a planar xanthoma of the eyelids) are common. Bone pain may occur in PBC patients with osteoporosis, as well as spontaneous collapses of vertebral bodies and hairline fractures of the ribs. Fractures of the long bones are less common.

Laboratory Tests

Liver function tests reveal a cholestatic pattern. The serum alkaline phosphatase and gamma glutamyl transpeptidase (GGT) are often strikingly elevated. The serum aminotransferases are less elevated and may be normal early in the course of PBC. Serum albumin and prothrombin times are characteristically normal early in the course of the disease. whereas IgM levels are often elevated. The elevated alkaline phosphatase is usually of liver origin. 5′-Nucleotidase and GGT levels parallel the alkaline phosphatase. The serum bilirubin is normal early in the course of the disease, but becomes elevated in most patients as the disease progresses. Both direct and indirect fractions are increased. Despite strikingly high serum cholesterol values, occasionally 800–1600 mg/dl, atherosclerosis is uncommon, most likely because serum high-density lipoprotein (HDL) cholesterol levels are also elevated. Antimitochondrial antibody is positive in 95% of patients. Serum ceruloplasmin is elevated, in contrast to Wilson's disease, another disorder with increased retention of copper within the liver. There is an increased incidence of hypothyroidism in PBC that is not always reflected by routine tests of thyroid function. Elevated thyroid-stimulating hormone (TSH) levels will usually identify such individuals.

Diagnosis

The combination of a disproportionately elevated alkaline phosphatase and a positive AMA is sufficient evidence to make a diagnosis of PBC as long as the liver biopsy is consistent with this diagnosis. It is prudent to demonstrate that the bile ducts are patent. Ultrasonography is usually adequate for this purpose. Endoscopic cholangiography (ERCP) is recommended if there is a suspicion of bile duct obstruction on imaging tests or if the AMA is negative in a patient with inflammatory bowel disease. The ERCP is done in this setting to detect primary sclerosing cholangitis. A percutaneous needle biopsy of the liver will confirm the diagnosis, allow histologic staging, and provide a baseline for follow-up biopsies that are done to evaluate the efficacy of medical treatment.

Treatment

Treatment of Symptoms

Pruritus

The nonabsorbed resin, cholestyramine, 4–8 g twice daily with meals, will relieve pruritus in most patients. Commonly prescribed anti-itch medicines such as antihistamines are only helpful early in the course of PBC when itching is not severe. Rifampin, 150 mg twice daily, will control itching in most patients who fail to respond to cholestyramine. Opioid antagonists, such as naloxone and naltrexone, may be effective in the small number of PBC patients who fail to respond to ammonium resins and rifampin.

Malabsorption

Some patients with PBC and the Sicca syndrome may have concomitant pancreatic insufficiency. This can be treated with pancreatic enzyme preparations given orally. Malabsorption of fat-soluble vitamins is irregular and unpredictable, but deficiencies of vitamins A, D, E, and K may occur in patients who are chronically jaundiced. Patients with low levels of a specific vitamin should be given supplements of it orally.

Anemia and Osteoporosis

PBC patients may develop iron-deficiency anemia. This often reflects unrecognized gastrointestinal (GI) blood loss. Upper endoscopy is indicated to detect esophageal varices or congestive gastropathy. There is no proven effective medical treatment for the osteoporosis other than liver transplantation. Because bisphosphates are an effective treatment for osteoporosis in postmenopausal women and prevent steroid-induced osteoporosis, they are often used in PBC.

Treatment of the Underlying Disease Process

PBC, if untreated, is a progressive disease that eventually ends in liver failure and the need for liver transplantation. The median survival for symptomatic patients without treatment is approximately 7–10 years. Patients who are asymptomatic at the time of diagnosis have a longer life expectancy than symptomatic patients.

Medical Treatment

Ursodeoxycholic acid (UDCA), 12–15 mg/kg body weight daily, is the only drug approved by the FDA for the treatment of the PBC. It improves serum bilirubin, alkaline phosphatase, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and IgM levels in most patients. It also decreases pruritus and prolongs the time before clinical deterioration and referral for liver transplantation. It is safe and well tolerated. Colchicine 0.6 mg twice daily and/or methotrexate, 0.25 mg/kg body weight per week in three divided doses, have been effective in the author's experience when given to patients who do not respond adequately to UDCA. Combination therapy (UDCA plus colchicine and/or methotrexate) is still under study. At this time, there is still debate about the effectiveness of medical treatment, although the author's experience suggests that medical treatment is effective in most patients, particularly those with precirrhotic PBC. Initiating treatment early in the course of PBC is important because medical therapy is less likely to help once cirrhosis and portal hypertension develop. Liver transplantation is the only effective treatment in patients with clinically advanced disease. The author's current approach is based on the observation that the response to medical treatment in PBC varies among patients. Treatment is initiated with UDCA. Colchicine is added if patients have not responded adequately to UDCA after 1 year. Methotrexate is added if patients have not responded fully to the combination of UDCA and colchicine after another year. An adequate response to treatment consists of the resolution of pruritus, a decrease in serum alkaline phosphatase to values that are $<50\%$ above normal, and improvement in liver histology of at least two points on the necroinflammatory scale. Methotrexate is discontinued after 1 year if patients fail to respond to it. They are maintained on UDCA and colchicine.

Liver Transplantation

Liver transplantation has improved the survival of PBC patients with cirrhosis and liver failure. Patients who are candidates for liver transplantation are those with cirrhosis and (1) persistent jaundice that is unresponsive to medical treatment, (2) fluid retention, (3) bleeding from esophageal varices, (4) hepatic encephalopathy, or any combination of these four. One-year survival after liver transplantation is greater than 90% in most transplant centers. Survival thereafter resembles a control population matched for age and sex. Recurrence of PBC after liver transplantation is uncommon, but has been seen in a small percentage of patients. It has responded to treatment with ursodiol and colchicine in the author's experience.

Glossary

cholestasis A liver disorder in which bile flow is impeded. Clinical signs of cholestasis are a disproportionate increase in the serum alkaline phosphatase or gamma glutamyl transpeptidase compared to the serum alanine aminotransferase or aspartate aminotransferase. The symptom most characteristic of cholestasis is pruritus.

hepatic encephalopathy A disturbance in consciousness that occurs in patients with advanced liver disease. Manifestations can range from subtle changes in personality to frank coma.

micellar Pertaining to a colloid particle formed by the aggregation of small molecules. Micelles in bile contain bile acids, phospholipids, and cholesterol.

mitochondria Organelles important in energy metabolism that are found in nucleated cells throughout the body.

necroinflammatory scale A method of evaluating liver biopsies quantitatively. Scores from 0 to 4 are given for lesions, such as portal inflammation, periportal inflammation, lobular inflammation, bile duct necrosis, and fibrosis, and added together to give a final score.

Biography

Marshall M. Kaplan is the former Chief of the Division of Gastroenterology at Tufts-New England Medical Center and is a Professor of Medicine at Tufts University School of Medicine. His research interests are the etiology and treatment of chronic-cholestatic liver disease. He received his M.D. and M.A.C.P. degrees from Harvard Medical School and the American College of Physicians. He was an associate editor of the *New England Journal of Medicine* from 1993 until 2001, served as Chairman of the Subspecialty Board in Gastroenterology of the American Board of Internal Medicine, and was awarded a mastership by the American College of Physicians.

Bioenergetics: General Definition of Principles

David G. Nicholls
Buck Institute for Age Research, Novato, California, USA

"Bioenergetics" is the study of the molecular mechanisms by which energy, made available by catabolic metabolic pathways or by light capture in photosynthesis, is transformed and made available for cellular processes of growth, motility, and survival. Traditionally, the field has largely focused on studies of bacteria, mitochondria, and chloroplasts, although the principles, largely involving the generation and utilization of ion gradients across membranes, are much more generally applicable.

Thermodynamics

Two factors are required for a biochemical reaction to occur spontaneously: the process should involve an increase in the entropy of the system and its surroundings and there should be a mechanism, usually enzymatic, to lower the energy barrier sufficiently to allow the transformation to occur at a significant rate. The entropy difference is the realm of thermodynamics, whereas the energy barrier helps to define the rate of the process.

The simplest thermodynamics deals with the limiting case of isolated systems that exchange neither material nor energy across their boundaries and therefore have no influence on their surroundings. Closed systems exchange energy but not material with their surroundings, whereas real biological systems are open, i.e., exchanging both energy and material (substrates, products). The treatment of open systems is complex and requires non-equilibrium thermodynamics; however, the equilibrium thermodynamics of closed systems can be used to obtain important information, such as the conditions under which a given reaction would be at equilibrium and the extent to which the actual reaction in the cell is displaced from equilibrium. Although equilibrium thermodynamics gives no information as to the rate of a reaction, it can unequivocally exclude any process that is energetically impossible.

Gibbs Free Energy

The entropic driving force is equally valid for closed and isolated systems; however, analysis is complicated by the effects of the energy transfer across the boundaries of the system affecting the entropy of the surroundings. The Gibbs free energy change, ΔG, is a function that, under conditions of constant temperature and pressure, corrects for the entropy change in the surroundings and enables equilibrium to be calculated just using parameters for the system itself. Gibbs energy changes are used not only to study a reaction in solution, but also to quantify reduction–oxidation (redox) reactions occurring, for example, in the mitochondrial respiratory chain, to calculate the available energy in an ion gradient, and to compare the energy available from absorption of light quanta in photosynthesis.

A basic understanding of bioenergetics is considerably helped by the use of simple analogies. Figure 1 shows schematically the *content* of Gibbs energy (G) in a closed system when the reaction A = B is displaced on either side of equilibrium. The slope of the parabola at any point represents the Gibbs energy *change* (ΔG). The bottom of the parabola represents the equilibrium condition: the content of Gibbs free energy is at a minimum and the tangent to the slope, ΔG, is zero. Equilibrium is the lowest energy state and a small conversion of substrate to product at equilibrium causes no free energy change. The left side of the parabola represents reaction conditions that have not yet proceeded as far as equilibrium. The slope ΔG is negative, which indicates that the reaction can proceed spontaneously (as long as a pathway exists). The further from equilibrium, the greater the slope; i.e., the Gibbs energy change becomes more negative and more energy is available from a conversion of substrate to product at those concentrations. Beyond the equilibrium point, the slope is "uphill." Reactions cannot proceed beyond equilibrium without some independent energy input.

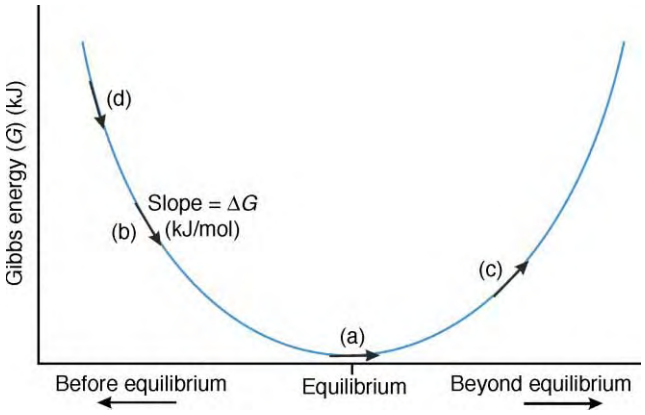

FIGURE 1 Schematic representation of Gibbs energy in relation to displacement from equilibrium. (a) Gibbs energy (G) is at a minimum at equilibrium and Gibbs energy change (ΔG), given by the slope of the parabola, is zero. (b) Before equilibrium, the slope (ΔG) is negative and the reaction can proceed spontaneously. (c) Beyond equilibrium, the slope is "uphill" and an additional energy input would be required. (d) The further the reaction is displaced from equilibrium, the greater the slope; i.e., ΔG becomes more negative. Adapted from Nicholls, D. G., and Ferguson, S. J. *Bioenergetics* 3 Copyright 2002, with permission from Elsevier.

The Gibbs free energy change can be quantified as a function of the displacement from equilibrium

$$\Delta G(\text{kJ/mol}) = -2.3RT\log_{10}\left(\frac{K}{\Gamma}\right), \qquad (1)$$

where R is the gas constant, T is the absolute temperature, K is the equilibrium constant under the conditions of the determination, and Γ is the mass-action ratio of the concentrations of substrates and products measured in the cell or assay mixture. Put more simply, ΔG changes by approximately 5.7 kJ/mol for each 10-fold displacement from equilibrium. Note that this equation corresponds to the more familiar form that involves standard free energy, e.g.,

$$\Delta G = \Delta G^0 + 2.3RT\log_{10}\left(\frac{[C]^c[D]^d}{[A]^a[B]^b}\right), \qquad (2)$$

but is more logical and symmetrical, emphasizing displacement from equilibrium, rather than the frequently misused abstract concept of standard free energy.

ATP

ATP synthesis from ADP and phosphate (P_i) and the reverse hydrolysis reaction are the dominant reactions in the distribution and utilization, respectively, of Gibbs free energy in the cell. The ATP synthesis reaction is held up to 10^{10}-fold beyond its equilibrium and thus requires an input of Gibbs free energy of approximately $10 \times 5.7 = 57$ kJ/mol. Conversely, the hydrolysis of 1 mol of ATP can yield up to 57 kJ/mol. There is no magic property associated with ATP (such as the myth of the "high-energy" bond) that fits it for this universal role, except that the equilibrium constant of the reaction is such that a sufficient concentration of ADP remains in a functioning cell to bind to the ATP synthase (see below).

The ATP synthesis reaction is usually expressed in short-hand form, ignoring water, ionization, pH, and chelating ions such as Mg^{2+}; i.e.,

$$\text{ADP} + \text{P}_\text{i} = \text{ATP}$$

This may only be used as the basis for thermodynamic calculations if the equilibrium constant is known under *exactly* identical conditions, in which case the common factors cancel out of the ratio Γ/K in Eq. (1).

Redox Potentials

Redox reactions are those that involve coordinate oxidation of one substrate and the reduction of another. An example of a redox reaction occurring in the cytoplasm is that catalyzed by lactate dehydrogenase:

$$\text{Pyruvate} + \text{NADH} + \text{H}^+ = \text{Lactate} + \text{NAD}^+. \qquad (3)$$

Redox reactions can be considered hypothetically as the sum of two linked half-reactions:

$$\text{NADH} = \text{NAD}^+ + \text{H}^+ + 2e^- \qquad (4)$$

and

$$\text{Pyruvate} + 2\text{H}^+ + 2e^- = \text{Lactate}. \qquad (5)$$

All biological redox reactions can be considered to involve primary electron transfer, although in many cases the increased negative charge on the reduced component leads to the subsequent binding of one or more protons; thus, ubiquinone reduction to ubiquinol in the respiratory chain involves the addition of two electrons followed by two protons, whereas NAD^+ reduction to NADH requires the addition of two electrons followed by one proton [Eq. (5)].

A reduced/oxidized pair, such as NADH/NAD^+, is a redox couple and the equilibrium of the half-reaction can be defined in terms of its half-reduction redox potential (the potential at which the concentrations of oxidized and reduced species are equal). A redox couple with a more negative redox potential will tend to oxidize one with a more positive potential. Zero is defined as the potential of a $\frac{1}{2}H_2/H^+$ couple at pH 0 when H_2 is 1 atm. Important half-reduction potentials include those for NADPH/$NADP^+$ and NADH/NAD^+ (both -320 mV), fumarate/succinate ($+30$ mV), ubiquinol/ubiquinone ($+60$ mV), and reduced/oxidized cytochrome c ($+220$ mV). The important $H_2O/\frac{1}{2}O_2$ couple has a redox potential

of + 820 mV when O_2 is present at 1 atm and water is 55 *M*.

Redox potentials are not constants, but vary with the state of reduction of the couple. The redox potential of a one-electron reduction couple becomes 60 mV more negative for each 10-fold increase in the reduced/oxidized ratio. Thus, although the *standard* hydrogen electrode at pH 0 has a redox potential of zero, at pH 7 when the proton concentration is only 10^{-7} *M*, the redox potential is −420 mV. Two electron reductions change by 30 mV per decade; thus, the NADH/NAD^+ couple in mitochondria is typically 10% reduced and thus has a redox potential of approximately −320 + 30 = −290 mV, whereas the NADPH/$NADP^+$ pool is at least 90% reduced and so operates at approximately −350 mV.

Although the historical origin of redox potentials (in electrochemistry) may obscure the relationship, redox changes are governed by Gibbs free energy principles; indeed, the ΔG associated with the difference in redox potential between two couples can be simply calculated as

$$\Delta G = -nF\Delta E_h, \qquad (6)$$

where n is the number of electrons transferred and F is the Faraday constant (0.965 kJ/mol/mV). As a rough rule of thumb, a "mole" of electrons falling through a potential of 1 V makes 100 kJ of Gibbs free energy available, and 2 mol of electrons passing from NADH to O_2 through the respiratory chain corresponds to a ΔG of −224 kJ. Note that this is compatible with the formation of approximately 3 mol of ATP.

Ion Electrochemical Potential Differences

The concept of Gibbs free energy as displacement from equilibrium can be extended to gradients of ions and solutes across biological membranes. Two components must be considered: that due to a difference in concentration between the two aqueous compartments and (if the species is charged) that due to the difference in electrical potential between the compartments (usually termed the membrane potential, not to be confused with any surface charge on the membrane itself). The Gibbs free energy is simply the sum of the two components (hence "electrochemical"),

$$\Delta G(\text{kJ mol}^{-1}) = -mF\Delta\psi + 2.3RT\log_{10}\frac{[X^{m+}]_B}{[X^{m+}]_A}, \qquad (7)$$

where m is the charge on the ion, $\Delta\psi$ is the membrane potential in millivolts, and X^{m+} is the concentration of the ion in compartment A or B.

The ion of most interest in bioenergetics is the proton. The equation for the proton electrochemical gradient ($\Delta\mu_{H^+}$) is rather simple, due to the logarithmic nature of pH:

$$\Delta\mu_{H^+}(\text{kJ/mol}) = -F\Delta\psi + 2.3RT\Delta\text{pH}. \qquad (8)$$

The mitochondrial convention is that ΔpH is the pH outside *minus* that in the matrix and is usually negative.

The proton electrochemical gradient is usually expressed in units of voltage. This "proton-motive force," Δp, is defined as:

$$\Delta p(\text{mV}) = -(\Delta\mu_{H^+})/F = \Delta\psi - 60\Delta\text{pH}. \qquad (9)$$

Photons

The Gibbs free energy available from a single photon is equal to Planck's constant times frequency, i.e., $h\nu$, where ν is the frequency of the radiation. A mole (Avagadro's number) of photons corresponds to a ΔG of 120,000/λ kJ/mol, where λ is the wavelength in nanometers. For 600 nm red light, this corresponds to 200 kJ/mol. Note that the absorption of such a photon would theoretically be capable of lowering (making more negative) the potential of an electron by 2 V.

The Thermodynamics of Bioenergetic Interconversions

The bioenergetic processes occurring in mitochondria involve the sequential conversion of redox energy into proton-motive force and of proton-motive force into the Gibbs free energy of the ATP pool. Since each is based on Gibbs free energy, the interconversion is very simple. Consider a respiratory chain complex that transfers two electrons through a redox span of ΔE_h mV. If the complex pumps n protons against a proton-motive force of Δp mV, equilibrium would be reached when $n\Delta p = 2\Delta E_h$. For the complex to work in the forward direction, therefore, $n\Delta p = 2\Delta E_h$. Roughly speaking, the forward rate of the complex is proportional to the disequilibrium for small displacements, which is why respiration accelerates when the proton gradient is lowered.

The equilibrium condition for the ATP synthase, where Δp is expressed in kilojoules per mole and Δp is expressed in millivolts, requires the Faraday constant, $\Delta G_{ATP} = mF\Delta p$, where m represents the number of protons required to generate 1 mol of ATP. Since the ATP synthase is reversible, it can operate in the forward direction (ATP synthesis) when $\Delta G_{ATP} < mF\Delta p$ and in the reverse direction (ATP hydrolysis) when $G_{ATP} > mF\Delta p$.

Mitochondrial Respiration Rate: The Proton Circuit

A simple but immensely powerful aid to understanding the relationships between proton-motive force, respiration, and proton re-entry pathways is to use a simple electrical analogy (Figure 2). Because there is a fixed stoichiometry between electron flow (and hence respiration) and proton translocation, and because protons must re-enter the mitochondrial matrix at exactly the same rate that they are pumped out, the "proton current," J_{H^+}, circulating around the "proton circuit" will equal the rate of respiration times the H^+/O (protons pumped divided by oxygen utilized) stoichiometry of the respiratory chain.

Because the current and potential (Δp) in the proton circuit are known, Ohm's law can be used to calculate the resistance (or its reciprocal, i.e., the conductance, $C_M H^+$) of the inner membrane to proton re-entry:

$$C_M H^+ = J_{H^+}/\Delta p \qquad (10)$$

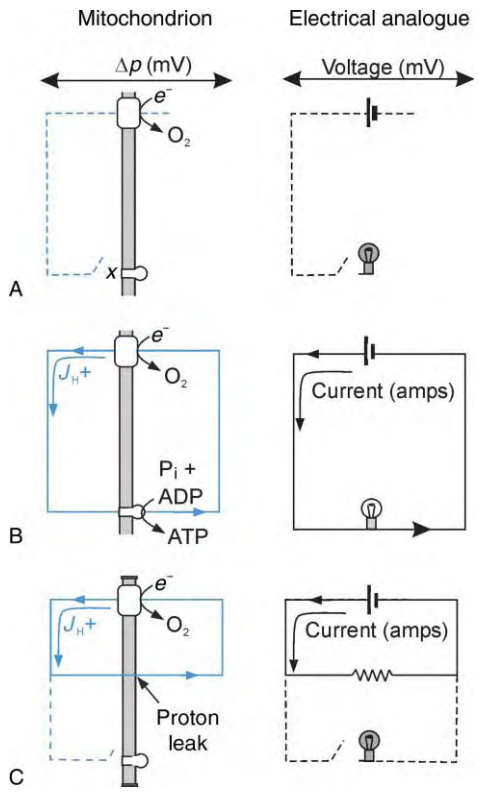

FIGURE 2 The analogy between the proton circuit and a simple electrical circuit. (A) Open circuit. Zero current (no respiration), potential (Δp) maximal. (B) Circuits completed, current flows (respiration). Useful work done (ATP synthesized). Potential (Δp) less than maximal. (C) Short-circuit introduced; energy dissipated, potential low, respiration maximal. Adapted from Nicholls, D. G., and Ferguson, S. J. *Bioenergetics* 3 Copyright 2002, with permission from Elsevier.

Two major components of proton conductance are that which occurs through the ATP synthase, which is tightly coupled to the rate of ATP synthesis, and an endogenous proton leak possessed by all mitochondria. One specialized tissue, brown adipose tissue, possesses an additional controllable proton leak catalyzed by an uncoupling protein that allows respiration, and heat production, to occur without concomitant ATP synthesis.

Glossary

electrochemical gradient The driving force inherent in an ion gradient across a membrane, made up of two components: the membrane potential and the ion concentration gradient.

Gibbs free energy A thermodynamic term that expresses the extent to which a process is displaced from equilibrium and hence defines its capacity to do work.

proton circuit The closed cycle comprising protons pumped across, e.g., the mitochondrial inner membrane and re-entering via the ATP synthase or a leak pathway.

proton conductance The conductance of a membrane to protons calculated by applying Ohm's law to the proton circuit.

redox couple A reduced/oxidized pair, such as $NADH/NAD^+$.

redox potential A thermodynamic measure of the tendency of a redox couple to gain or lose electrons.

Biotin

Steven W. Polyak and Anne Chapman-Smith
The University of Adelaide, Adelaide, Australia

Biotin, or Vitamin H, is a member of the water-soluble class of vitamins. It has been appreciated for some time that biotin is an essential cofactor for a family of enzymes known as the biotin-dependent enzymes. These enzymes are found in all living organisms and catalyze several important metabolic reactions. The cofactor actively participates in the binding and transfer of carbon dioxide between metabolites. Biotin is specifically attached to these enzymes through the activity of another ubiquitous enzyme, biotin protein ligase (BPL). In bacteria, this protein also behaves as a transcriptional repressor of the biotin biosynthetic operon, where biotin itself is an integral component required for DNA binding.

Historical Perspective

At the end of the nineteenth century it was observed that extracts from liver and meat could serve as effective treatments for skin lesions induced by a diet of raw egg. Earlier studies had identified a heat stable factor in the same extracts that was also required for yeast growth. In 1935 Kogl and Tannis isolated this factor from egg yolk and called it biotin. The essential growth factor present in the meat extracts, which had become known as Vitamin H (*Haut*, German = skin), was found to be identical to biotin. Later, it was discovered that avidin, a biotin-binding glycoprotein, was the toxic component of raw eggs. The structure of biotin was determined in 1942 and confirmed by chemical synthesis and X-ray analysis.

During the 1950s it became evident that biotin is involved as a cofactor for a class of enzymes that catalyze a variety of carboxyl transfer reactions. It was first demonstrated that β-methylcrotonoyl-CoA carboxylase, a biotin-requiring enzyme that catalyzes a step in the degradation of leucine, was capable of carboxylating free biotin. It soon became apparent that, in the cell, biotin functions as a cofactor only when bound to protein and that biotin is covalently attached to the ε-amino group of a specific lysine residue of propionyl CoA carboxylase. Subsequently, it was demonstrated for other biotin enzymes that the biotin prosthetic group is attached in the same way.

Biotin

Biotin, a member of the water-soluble B-complex group of vitamins, is synthesized by higher plants and most fungi and bacteria. Humans, other mammals, and birds cannot synthesize biotin *de novo* and therefore must obtain this essential micronutrient from material synthesized by intestinal microflora and from dietary sources. In mammals, absorption of biotin occurs in the small intestine. Other important sites that play a role in normal biotin physiology include the liver (the principal site of biotin utilization), the kidney (the site of reabsorption of filtered biotin), and the placenta (the site of transport of biotin from the maternal circulation to the developing embryo). Biotin obtained from dietary sources exists in both free and protein-bound forms. Protein-bound biotin is digested by gastrointestinal proteases and peptidases to biocytin and biotin-containing short peptides. Biotin present in these compounds is recycled through the action of biotinidase to release free biotin.

Biotin Enzymes

Biotin enzymes are a family of enzymes ubiquitously found throughout nature. It appears that all organisms contain acetyl coA carboxylase, reflecting the essential role this enzyme plays in the synthesis of fatty acids required for membrane biogenesis. While some organisms, such as bacteria, possess only one biotin enzyme, other organisms have multiple biotin enzymes. For example, mammalian cells express pyruvate carboxylase, propionyl-CoA carboxylase, and methylcrotonyl-CoA carboxylase in addition to two isoforms of acetyl-CoA carboxylase. These enzymes catalyze key metabolic reactions in gluconeogenesis and amino acid metabolism, in addition to fatty acid metabolism.

The members of this enzyme family utilize biotin as a mobile carboxyl carrier in a conserved reaction

mechanism that requires three domains: a biotin carboxylase domain, a transcarboxylase domain, and a biotin domain containing the covalently attached biotin moiety. As shown in Figure 1, these enzymes catalyze reactions in two partial reactions carried out at spatially separate sites on the protein where biotin itself carries a carboxyl group between the two sites. Biotin enzymes can be divided into three classes depending on the nature of the original donor and final carboxyl acceptor. These are the carboxylases (Class I), decarboxylases (Class II), and transcarboxylases (Class III). All eukaryotic enzymes belong to Class I, while prokaryotes contain enzymes from all three classes

The mechanism of biotin carboxylation in the Class I enzymes has been extensively investigated. Experiments on propionyl CoA carboxylase and pyruvate carboxylase showed that the source of CO_2 in the reaction is bicarbonate and the reaction is dependent upon the presence of ATP:

$$\text{MgATP} + \text{HCO}_3^- + \text{Enz-biotin} \rightleftharpoons \text{MgADP} + \text{Pi} + \text{Enz-biotin-CO}_2^- \quad (1)$$

At the first partial reaction site, biotin is carboxylated at the 1′-nitrogen probably after the formation of a very labile enzyme-bound carboxyphosphate intermediate that donates the activated carboxyl group to biotin. Although no direct evidence of this reaction mechanism has been reported, several observations suggest this as the most likely scheme. Most notable are the similarities between the biotin enzymes and carbamoyl phosphate synthetase; an enzyme known to utilize a carboxyphosphate intermediate.

Subsequently, in the second partial reaction, the transfer of the carboxyl group from carboxybiotin to the acceptor molecule occurs. It has been proposed that the decarboxylation of carboxybiotin proceeds along a pathway where CO_2 and the enolate of biotin are formed. Following protonation, carboxylated biotin can again be formed at the first reaction site under physiological conditions:

$$\text{Enz-biotin-CO}_2 + \text{acceptor metabolite} \rightleftharpoons \text{Enzyme–biotin} + \text{Carboxylated acceptor} \quad (2)$$

The Class II decarboxylases differ from the Class I carboxylases in that the reactions are ATP-independent. The decarboxylases of anaerobic prokaryotes all catalyze decarboxylation of a specific β-keto acid or acyl-CoA coupled to sodium ion export against a concentration gradient. Thus, this class of enzyme serves as an important energy transducer that does not require ATP. There is only one known member belonging to the Class III biotin enzymes: *Propionibacterium freudenreichii subsp. shermanii* transcarboxylase (TC). TC catalyzes the formation of methylmalonyl-CoA from propionyl-CoA using oxaloacetate as a carboxyl donor, and it exists as a multimeric complex composed of 30 polypeptides of three different types.

Biotin Domains

The biotin prosthetic group is covalently attached via the ε-amino group of one specific lysine residue within the biotin enzymes. This biotin-accepting lysine is found in a tetrapeptide sequence, Ala–Met–Lys–Met, which is extremely conserved among all biotin enzymes (Figure 2). Additionally, the primary structure surrounding the target lysine residue shows a high degree of homology between a wide range of enzymes and species (Figure 2). Deletion studies have revealed that 30–35 amino acid residues either side of biocytin are necessary to specify biotinylation. Collectively, these structures, able to incorporate biotin *in vivo*, are termed *biotin domains*. The removal of determinants necessary to define the structure of a biotin domain by truncation or mutation results in a molecule that is unable to be biotinylated.

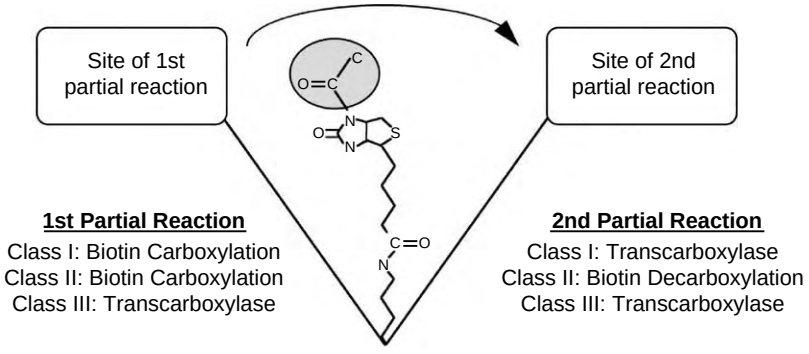

FIGURE 1 Biotin mediated carboxyl transfer between reaction subsites of biotin enzymes. The biotin group attached to the target lysine is shown located in the cleft of the biotin enzyme. The carboxylate anion, complexed to the biotin, is shown in the shaded circle. The arrow represents movement of the mobile cofactor between the two partial reaction subsites during catalysis. The reactions performed at the separate subsites are indicated for the three classes of biotin enzymes.

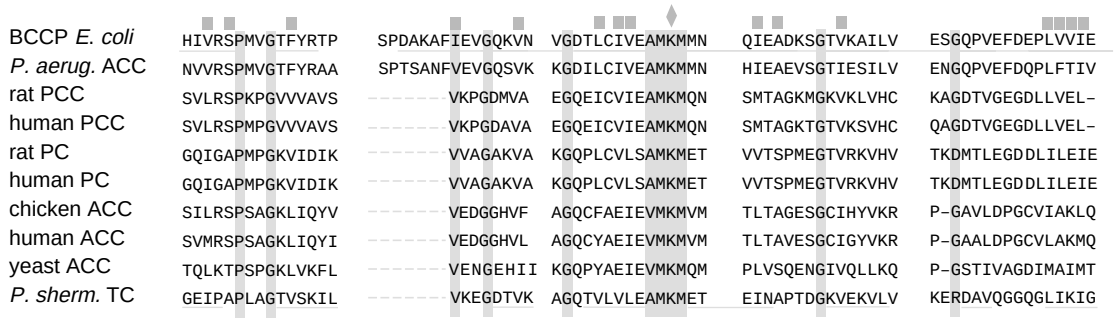

FIGURE 2 Sequence alignment of the biotin domains of biotin carboxylases from diverse organisms. Residues forming β-strands in the three-dimensional structures of *Escherichia coli* biotin carboxyl carrier protein (BCCP) and *Propionibacterium freudenreichii subsp. shermanii* transcarboxylase (TC) are underlined, and hydrophobic core residues are indicated by (■). The biotinylated lysine is marked (◆). Shading indicates residues very highly conserved in all biotin domains for which sequence data is available. Reproduced with permission from Chapman-Smith and Cronan (1999), *J. Nutr.* 129, 447S–484S.

The biotin domain participates in a number of heterologous protein:protein interactions in the cell. First, it serves as a substrate in the biotinylation reaction. Here, the biotin prosthetic group is covalently attached to the biotin domain through the enzymatic action of biotin protein ligase (BPL). Subtle conformational changes to the biotin domain that occur upon biotinylation are thought to signal dissociation of the two proteins and yield the biotinylated product. The biotinylated or holo biotin domain is then free to interact with each of the two partial reaction sites in the carboxylase, shuttling carboxyl groups between substrates in the enzyme complex.

The formation of multimeric protein complexes, characteristic of all biotin enzymes, is not necessary for substrate recognition by BPLs. Enzymatic biotinylation experiments, performed using the biotin accepting subunit of the *P. shermanii* TC or the biotin carboxyl carrier protein (BCCP) of *E. coli* acetyl CoA carboxylase, have shown that these domains function equally well as BPL substrates as do the intact or multimeric protein complex. Therefore, the information required for association with BPL is present within the structured biotin domain. BPLs from various sources have been found to recognize and biotinylate acceptor proteins from very different sources.

In 1966, McAllister and Coon first showed that extracts containing BPLs from rabbit liver, yeast, and *P. shermanii* were able to activate enzyme substrates from rabbit and bacteria via the attachment of the biotin prosthetic group. Evidence of cross species recognition *in vivo* was demonstrated when the 1.3S subunit of TC was recombinantly expressed in *E. coli* and shown to be a substrate for the *E. coli* BPL. Truncation analysis of the 1.3S TC subunit revealed that the minimum amount of information required to specify biotinylation was present in the 75 C-terminal amino acid residues. This minimal peptide, fused to β-galactosidase, was biotinylated *in vivo* by the BPL from *E. coli*. Similarly, the C-terminal 87 amino acid residue of BCCP (BCCP-87) was shown to be a stable protein that can function as a substrate for *E. coli*, insect, yeast, and human BPLs. Together, these studies suggest that all biotin domains fold into an essentially common tertiary structure recognized by all members of the BPL enzyme family.

Biotin Domain Structure

The structures of two biotin domains have been determined: that of the *E. coli* BCCP-87 (Figure 3) and the 1.3S subunit of *P. shermanii* transcarboxylase. These proteins are structurally related to the lipoyl domains of 2-oxo acid dehydrogenase multienzyme complexes, which also undergo an analogous posttranslational modification. These domains form a flattened β-barrel structure comprising two 4-stranded β-sheets with the N- and C-terminal residues close together at one end of the structure. At the other end of the molecule, the biotinyl- or lipoyl-accepting lysine resides on a highly exposed, tight hairpin loop between β-strands four and five. The structure of the domain is stabilized by a core of hydrophobic residues, which are important structural determinants. Conserved glycine residues (Figure 2) occupy β-turns linking the β-strands.

BCCP-87 contains a seven amino acid insertion common to prokaryotic acetyl-CoA carboxylases but not present in other biotin domains. This region of the peptide adopts a "thumb" structure between the β2 and β3 strands and, interestingly, forms direct contacts with the biotin moiety in both the crystal and solution structures. The significance of this interaction is not understood, but structural studies on the 1.3S subunit of TC, which is a "thumbless" biotin domain, have revealed that biotin also interacts with the protein. Residues in the N-terminal region of the TC subunit, independent of the biotin domain, functionally compensate for the thumb structure by binding to biotin only when the cofactor is in its carboxylated state.

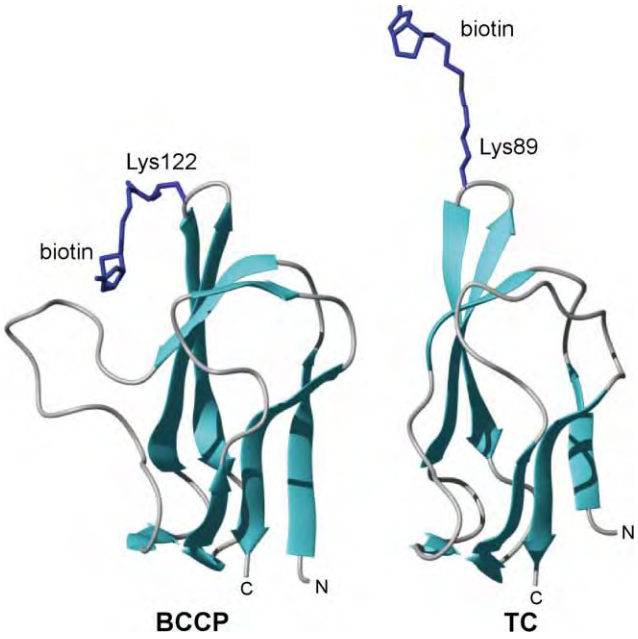

FIGURE 3 Three-dimensional structures of two biotin domains. The structures of the biotin domains from the biotin carboxyl carrier protein (BCCP) of (left) *Escherichia coli* acetyl CoA carboxylase and (right) the 1.3S subunit of *Propionibacterium freudenreichii subsp. shermanii* transcarboxylase (TC) have been determined. The holo forms of the two proteins with the biotin moiety specifically attached to the target lysine residues at position 122 and 89, respectively, are depicted. Solid arrows represent the β-strands in the fold. The amino (N) and carboxyl (C) termini of the domain are indicated. The molecules have been orientated to highlight the interaction of biotin with the "thumb" structure in BCCP.

Therefore, it is possible that the mechanism employed by the biotin-enzymes may involve non-covalent interactions between the protein and the prosthetic group.

Biotin Ligase

Reaction Mechanism

All BPLs catalyze biotinylation through the same reaction mechanism:

$$\text{Biotin} + \text{MgATP} \rightleftharpoons \text{Biotinyl-5}'\text{-AMP} + \text{PPi} \quad (3)$$

$$\text{Biotinyl-5}'\text{-AMP} + \text{apo-protein} \rightarrow \text{biotinylated protein} + \text{AMP} \quad (4)$$

In the first partial reaction, BPLs bind biotin and ATP in an ordered manner (depending on the species) to form an enzyme:biotinyl-5′-AMP complex or holo-BPL. At this stage, the carboxyl group of inert biotin is activated by the addition of an adenylate group forming the intermediate biotinyl-5′-AMP. In the second partial reaction, holo-BPL complexes with an apo-biotin domain. Nucleophilic attack upon the activated biotin by the amine group of the biotin-accepting lysine residue results in the transfer of biotin from the adenylate onto the biotin domain with AMP acting as the leaving group. This two-step process is analogous to the tRNA synthetase catalyzed linkage of amino acids to the 3′ hydroxyl group of tRNAs.

E. coli Biotin Ligase, BirA

The best characterized BPL is the 35.3 kDa protein BirA from *E. coli*. This protein is a bifunctional molecule which, in addition to biotin protein ligase activity, acts as the transcriptional repressor of the biotin biosynthetic operon. By combining regulation of biotin synthesis and metabolism through the actions of a single protein, bacteria have evolved an exceptional mechanism for maintaining biotin homeostasis. Recent structural studies of BirA, together with enzymatic and genetic studies, have provided powerful insights into BirA action. The crystal structure of BirA shows that the protein is composed of three domains: a DNA binding N-terminal domain, a central catalytic domain, and a C-terminal domain (Figure 4). The central domain contains several poorly defined loops that become more ordered upon binding of biotin or biotinyl-5′-AMP.

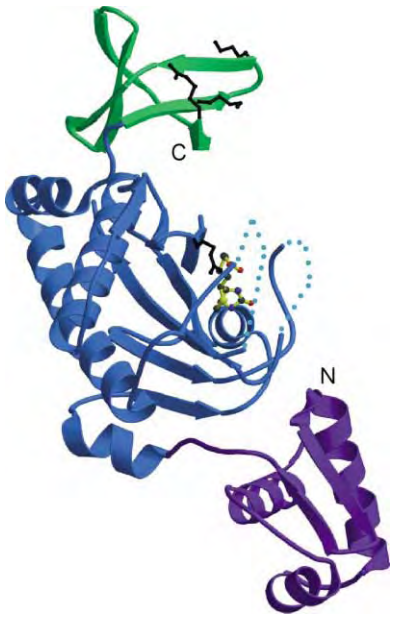

FIGURE 4 The three-dimensional structure of BirA. The diagram shows the structure of *Escherichia coli* biotin protein ligase, BirA, determined by X-ray crystallography. This figure highlights the three functional domains in the bifunctional protein. The N-terminal domain (N), shown in purple, contains a helix-loop-helix fold to facilitate DNA binding. The central catalytic domain (shown in blue) is depicted with biotin (ball and stick representation) bound at the active site. Dots represent the unstructured loops around the active site that become ordered during the reaction. The function of the C-terminal (C) domain (shown in green) is not fully understood. Modified with permission from Chapman-Smith *et al.* (2001), *Protein Sci.* 10, 2608–2617.

Ordering of these loops in the complex results in the generation of an extended β-sheet which is required for the interaction with other proteins. Thus, when complexed with biotinyl-5′-AMP, BirA is competent to participate in one of two competing interactions: either with apo-BCCP or with the 40 base pair operator sequence within the biotin synthesis operon. In the presence of apo-BCCP, monomeric BirA preferentially interacts with this protein substrate and catalyzes biotinylation. In the absence of apo-BCCP, the BirA complex forms the homodimer structure required for DNA binding and thus functions as a transcriptional repressor. Therefore, when *E. coli* needs to produce additional active acetyl-CoA carboxylase, its biotin biosynthetic pathway can be derepressed by the expression of apo-BCCP, thereby allowing the bacteria to balance its nutritional requirements.

Glossary

biocytin Biotinylated lysine which is formed between the carboxyl group of biotin and the epsilon amino group on the side chain of lysine.

biotin A small, water soluble vitamin belonging to the B-complex group; it is also known as vitamin H.

biotinidase A mammalian enzyme that can hydrolyze biotin from either biocytin or short biotin-containing peptides thus facilitating recycling of the vitamin.

biotin protein ligase The enzyme [E.C. 6.3.4.15] responsible for covalent attachment of a biotin moiety onto a biotin-enzyme; it is also known as the biotin inducible repressor (BirA) in some prokaryotes and holocarboxylase synthetase in mammalian cells.

Biography

Steven Polyak completed his graduate studies on biotin protein ligase at The University of Adelaide, Australia, in 1999 before commencing a postdoctoral position at The Hanson Institute. He returned to The University of Adelaide in 2001, where he continues to investigate the protein structure and relationships of BPL.

Anne Chapman-Smith completed a Ph.D. working on pyruvate carboxylase in the early 1980s. Since 1990, she has studied the structure and function of the biotin domains of the biotin carboxylases and their interaction with biotin ligase at the University of Adelaide and the University of Illinois at Urbana – Champaign.

Biotinylation of Proteins

Ronald A. Kohanski
The Johns Hopkins University, Baltimore, Maryland, USA

The biotinylation of proteins is the covalent coupling of biotin to an amino acid or carbohydrate moiety of the protein. Biotinylation occurs in a specific group of proteins known as carboxylases. These are enzymes that are important in several metabolic pathways, including amino acid metabolism, fatty acid biosynthesis, and gluconeogenesis. Each of these carboxylases is biotinylated on a single lysyl residue through the action of a biotin:protein ligase, and are found in all organisms (bacteria, plants, and animals). Biotinylation of proteins is also done by *in vitro* chemical synthesis, whereby biotin can be covalently coupled to any reactive functional group on the protein, and is not necessarily restricted to a single amino acid residue.

Analytical and Clinical Applications

Chemically biotinylated proteins are important tools in cell biology, and biochemistry, and have clinical applications. The uses of chemically biotinylated proteins have evolved from the strong interaction between biotin (and its derivatives) and avidin or streptavidin. The medical importance of biotinylated proteins is twofold: (1) life-threatening diseases result from failure to produce adequate levels of endogenous biotinylated proteins. These diseases are particularly serious in newborns and early childhood and (2) the diagnosis and treatment of tumors has been greatly facilitated by chemically biotinylated proteins. As an analytical reagent in cell biology and biochemistry, chemical biotinylation of proteins is in widespread use not only primarily for protein detection and assay, but also for purification. These are considered in greater detail in this article.

Biosynthesis and Degradation of Natively Biotinylated Proteins

The biotinylated proteins native to cells are the biotin-dependent carboxylases: acetyl CoA carboxylase, beta-methylcrotonyl CoA carboxylase, proprionyl CoA carboxylase, and pyruvate carboxylase. The first is a cytosolic protein and the latter three are in the mitochondria. In bacteria, the biotinylated protein is biotin carboxyl carrier protein which is a subunit of bacterial carboxylases. The biosynthesis of naturally biotinylated proteins occurs in two steps. Biotin is activated by reaction with adenosine triphosphate (ATP), releasing pyrophosphate and biotinyl $5'$-adenosine monophosphate. The hydrolysis of pyrophosphate makes this step essentially irreversible under physiological conditions. The transfer of biotin to an ε-amino group of a specific lysyl residue in the acceptor protein is catalyzed by holocarboxylase synthetase (HS) in eukaryotes, and biotin protein ligase (BPL) in bacteria. The specific lysyl residue that is biotinylated is found within a highly conserved structural motif of the apoprotein – the biotin domain – that ranges in length from 67 to 85 amino acids. The biotin domain is an independently folding motif with a core structure of eight β-strands forming two apposing antiparallel β-sheets. Conservation of the catalytic portions of the HS/BPL enzymes and of the biotin domains are so high across evolution that bacterial BPL can recognize and biotinylate mammalian biotin domains, and mammalian HS can recognize and biotinylate bacterial biotin domains. The consensus amino acid sequence surrounding the acceptor lysyl residue is Glu-Ala-Met-Lys-Met, but only the Met-Lys-Met residues are invariant. The conservation of the methionyl residues appears to be dictated by evolutionary pressure to retain a catalytically active carboxylase rather than a recognition site for the synthetase, since Thr or Val can be substituted for these Met residues with little loss of biotinylation but more significant losses in catalytic efficiency of the biotinylated product. In general, it appears that conservation of the β-sheet structure of the biotin domain is as critical for recognition by the ligase as the consensus sequence, but the latter is governed by the need to conserve optimal enzymatic activity in the biotinylated proteins. Thus the two aspects controlling specificity of protein biotinylation are: first, recognition by the ligase and second, enzymatic activity of the biotinylated protein. Biotinylated proteins are degraded by cellular proteases and the biotinylated lysyl residue (biocytin) is the product of that degradation. Biotinidase is the enzyme that cleaves biocytin to biotin and lysine.

Medical Importance of Biotinylated Proteins

Diseases caused by deficiencies in the biotin-dependent carboxylases fall into two general categories based on whether biotin administration is an effective treatment. Those not treatable with biotin are due to genetic lesions in the biotin-dependent carboxylases (OMIM 200350, 210200, 232050, 232000, and 266150 which are described at the National Institutes of Health website http://www.ncbi.nlm.nih.gov/omim), whereas those treatable with biotin are the result of genetic lesions in the synthetase (multiple carboxylase deficiency; OMIM 253270) or biotinidase (OMIM 25360). Clinically the synthetase and biotinidase deficiencies are distinguished by the early (up to three months post-partum) versus late onset of symptoms, respectively. Mutations in holocarboxylase generally cause a raised Michaelis constant for biotin. Thus the treatment with pharmacological doses of biotin is probably successful because the enzyme only requires higher concentrations of biotin for efficient biotinylation of the apoprotein carboxylases. The success of biotin administration when biotinidase is lost indicates the biological importance of recycling biotin from biocytin to maintain sufficient levels of carboxylase activity. The other clinically significant aspect of biotinidase is its ability to degrade radiolabeled biotin derivatives, which are used in conjunction with biotinylated antibodies to image and/or treat tumors.

Chemical Synthesis of Biotinylated Proteins

The usual goal of protein biotinylation is to detect the modified protein with avidin, where the avidin is itself linked to a reporter group (a radionuclide, chromophore, fluorophore, or an enzyme). The detection of biotinylated proteins has been important in Western blots in order to determine the expression of proteins in diverse cells exposed to different stimuli or growth conditions, for the immunocytochemical and immunohistochemical localization of proteins within subcellular compartments or in tissues, and for the identification and tracking of surface-biotinylated proteins. In addition, the immobilized avidin (and derivatives) can be used for affinity capture and purification of biotinylated proteins, or in the capture of receptors using biotinylated ligands. Biotinylation of proteins can be achieved through covalent attachment of a biotin derivative to any freely reactive functional group on a protein. The most commonly used sites include primary amines (α- or ε-amino groups of the N-terminal or lysyl residues, respectively, as illustrated in Figure 1B), thiol

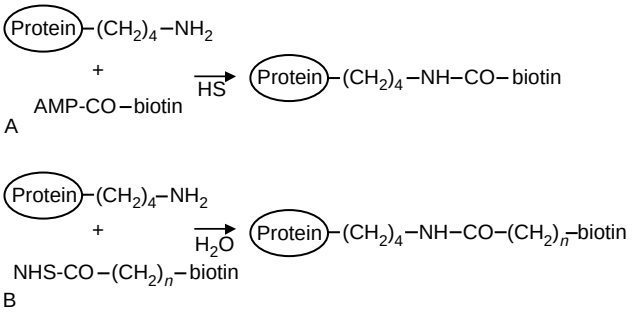

FIGURE 1 Biotinylation of proteins by enzymatic and chemical reactions. (A) The transfer of biotin from AMP to the ε-amino group of a lysyl residue in a protein, catalyzed by holocarboxylase synthetase (HS) forming an amide linkage. (B) The transfer of biotin, with a hydrocarbon spacer of "n" methylene groups from an N-hydroxysuccinimide ester (NHS) to an ε-amino group of a protein in water.

groups (of cysteinyl residues), and carbohydrate groups. The reactive derivatives of biotin for these reactions use N-hydroxysuccinmide esters, iodoacetyl, or disulfide derivatives of biotin, and hydrazide derivatives of biotin, respectively. The critical factor in the useful biotinylation of proteins is allowing avidin to bind the biotinyl group after conjugation. This requires sufficient distance between the surface of the biotinylated protein and avidin, since biotin is bound in a fairly deep pocket in avidin. This problem was solved by Klaus Hofmann, who found that an ε aminocaproyl group offered a sufficiently long spacer group for this purpose, as illustrated in Figure 1. The use of sulfo-N-hydroxysuccinimidyl-esters (sulfo-NHSH esters) for biotin derivitization introduced by James Staros further simplified the use of biotin derivatives because it increased the water-solubility and amine-specificity of the reactive ester. Importantly, the sulfo-NHS esters cannot cross cell membranes, and this permits the selective labeling of cell surface proteins through biotinylation of their extracellular domains.

Clinical Application of Biotinylated Antibodies

Clinically, biotinylated antibodies are in current use for the detection and treatment of tumors, with success in many cases. The multistep procedure can be summarized as follows: biotinylated antibodies against a tumor-specific antigen are introduced into circulation. Binding to the antigen concentrates the biotinylated antibody at the site of the tumor. Avidin or strepavidin is introduced, which binds the pretargeted antibody. Because these are tetramers, at least one biotin-binding site is expected to remain unoccupied in the avidin:biotinylated antibody complex.

A biotin derivative that chelates a radionuclide is then introduced, which is trapped by the open biotin-binding sites on avidin at the site of the tumor. This protocol can be used to visualize the tumor *in vivo* by immunoscintigraphy or positron emission tomography. With the appropriate radionuclide, radiotherapy of the tumor is also achievable. In such protocols, circulating biotinidase plays a counter-productive role, since it can and does break down biocytin analogues. Thus knowledge of the "biotin cycle" of endogenously biotinylated proteins has been important in the clinical application of chemically synthesized biotinylated proteins.

Glossary

avidin A protein that binds "avidly" to biotin ($K_d < 10^{-15}$ M) and is found in egg whites. A related bacterial protein is streptavidin, from *Streptomyces avidinii*.

biocytin A biotin derivative formed between biotin and lysine. It is formed by the catabolism of carboxylases, and is itself degraded to biotin and lysine by the enzyme biotinidase.

biotin A water-soluble vitamin that is used by carboxylases for transfer of CO_2 groups in biosynthesis. It is bound tightly by the proteins avidin and streptavidin.

Bradykinin Receptors

Ronald M. Burch
AlgoRx Pharmaceuticals, Inc., Cranbury, New Jersey, USA

Bradykinin is an inflammatory nonapeptide, whose generation in tissues and body fluids elicits numerous physiological effects including vasodilation, edema, smooth muscle contraction, as well as pain and hyperalgesia, by stimulating A- and C-neurons. Bradykinin contributes to inflammatory responses in acute and chronic diseases including allergic reactions, arthritis, asthma, sepsis, viral rhinitis, and inflammatory bowel diseases.

Overview

Most G protein agonists are hormones or neurotransmitters synthesized intracellularly and stored in secretory granules prior to release. In contrast, bradykinin is a member of the kallikrein–kininogen–kinin system, a complex of two substrates (kininogens) activated by two enzymes (kallikreins) to produce four inflammatory mediators (kinins) that bind to two bradykinin receptors (Figure 1). The substrates, high molecular weight (HMW) kininogen and low molecular weight (LMW) kininogen, are α_2 macroglobulins produced by alternative splicing of the same mRNA. HMW kininogen circulates in blood in a 1:1 complex with plasma prekallikrein. Upon tissue injury, factor XII, a component of the coagulation cascade, cleaves plasma prekallikrein to activate it. Plasma kallikrein acts on HMW kininogen to release bradykinin (plasma kallikrein also activates LMW kininogen to produce bradykinin). Tissue kallikrein is synthesized by many types of epithelial cells and secretory cells. Thus, unlike plasma kallikrein, it acts locally. Tissue kallikrein acts only on LMW kininogen and cleaves it one residue to the amino terminus of the site of cleavage of plasma kallikrein to produce a decapeptide, kallidin (or Lys-bradykinin). Bradykinin and kallidin are equipotent agonists of bradykinin B2 receptors and are usually referred to generically as bradykinin or kinins. It should be noted that bradykinin and kallidin are chemically heterogeneous since the proline residues within the peptides may be partially hydroxylated.

Kinins are metabolized further by a variety of enzymes, most of which inactivate them. The major inactivating enzyme is kininase II, especially prevalent in the lungs and in vascular beds, and its activity is largely responsible for the very short half-life of the kinins, about 15 seconds. Kininase II removes the carboxyterminal dipeptide from both bradykinin and kallidin. Kininase II is also known as an angiotensin-converting enzyme because it converts angiotensin I into the vasoconstrictor angiotensin II. Of importance to the present discussion, another enzyme, kininase I, removes the carboxyterminal Arg from bradykinin and kallidin to produce the other two inflammatory mediators, the bradykinin B1 receptor agonists desArg^9-bradykinin and desArg^{10}-kallidin, respectively. Like the agonists of B2 receptors, bradykinin and kallidin, the desArg metabolites have similar potency as agonists of B1 receptors.

Nearly all tissues express B2 receptors, and bradykinin-induced activation of B2 receptors is implicated in many disease states. B1 receptors are expressed in only a few tissues under normal conditions and only in very small numbers. Several disease states are associated with rapid induction of B1 receptors in specific tissues.

B1 Receptor

The existence of a B1 receptor activated by what had been considered an inactive bradykinin metabolite, desArg^9-bradykinin, was a provocative proposal. This receptor was not found in normal tissues, but was found to be induced during incubation of tissues *in vitro*. Identification of a synthetic B1 receptor antagonist, desArg^9, Leu^8-bradykinin, added credence to the existence of a physiologic receptor. Later, induction of B1 receptors was found pharmacologically to be associated with specific disease processes *in vivo*, and in 1994, the existence of the B1 receptor was conclusively confirmed with the cloning of the receptor protein.

B1 receptors have been implicated in hyperalgesia, plasma extravasation, white blood cell activation and accumulation, and in the control of blood pressure. However, it seems certain that complete understanding of the roles of this inducible receptor in pathophysiology is not at hand. B1 receptors from several species have been cloned. They are typical G protein-coupled

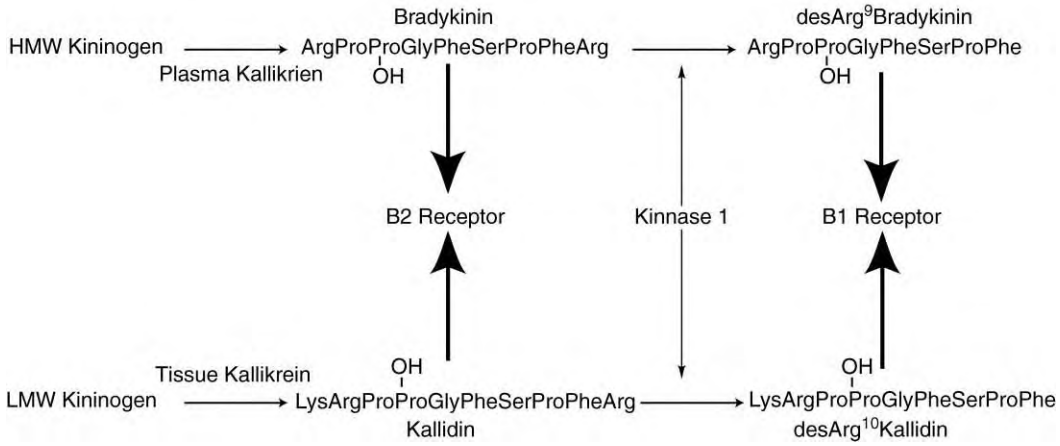

FIGURE 1 Formation of endogenous bradykinin receptor ligands. Bradykinin and kallidin bind to B2 receptors, whereas, desArg^9-bradykinin and desArg^{10}-kallidin bind to B1 receptors. Both bradykinin and kallidin may contain some proline residues that are hydroxylated. If hydroxylated, the most common residue is Pro^3 in bradykinin and Pro^4 in kallidin (shown hydroxylated in the figure).

receptors in sequence. The human receptor has a predicted sequence of 353 amino acids and is only 36% homologous to B2 receptors. The B1 receptor activates phosphatidylinositol-specific phospholipase C and possibly phospholipase A_2.

The B1 receptor gene is composed of three exons. The entire coding region for the receptor is contained within the third exon. A variety of polymorphisms have been identified. One, a G/C single nucleotide polymorphism in the promoter region has been associated with disease. Expression of the C allele is higher than the G allele, and patients with the G allele have greater incidence of inflammatory bowel disease and end-stage renal disease.

B1 Receptor Regulation

Most G protein-coupled receptors are internalized quickly after the binding of their ligands. B1 receptors, however, are not internalized following binding of desArg-kinins. This results in very prolonged activation of signal transduction, which translates into rather few receptors per cell being necessary for biological activity when compared to many other G protein-coupled receptors. Ligand binding studies in a variety of tissues reveal only hundreds to a few thousand B1 receptors per cell, whereas most G protein-coupled receptors, including B2 receptors, are found in the tens of thousands per cell.

In contrast to prolonged phosphatidylinositol turnover, B1 receptor-mediated arachidonic acid release and prostaglandin synthesis is short-lived, which is similar to B2 receptors. The mechanism for this differential desensitization is unknown, but it may be linked to sequestered pools of arachidonate-containing phospholipids or phosphorylation of an intracellular binding site for a transduction protein.

B1 receptors have been shown by immunoprecipitation studies to couple to $G\alpha q$ and $G\alpha i$. These G proteins commonly couple receptors to phosphatylinositol-specific phospholipase C and elevation of intracellular free calcium activity. Activation of B1 receptors leads to elevation of intracellular free calcium activity by increasing calcium entry into the cell; this is in contrast to the B2 receptor which acts primarily to release bound intracellular calcium.

Regulation of B1 Receptor Induction

Unlike many G protein-coupled receptors, the primary regulation of the B1 receptor number appears to occur by transcriptional induction. Biological studies have found that B1 receptor expression is induced by a variety of cytokines including endotoxin, interleukin 1β, and tumor necrosis factor. The specific domains affected by these stimulating ligands have not been identified, but activation of B1 receptor transcription has been correlated to activation of the transcription factor NF-κB.

The regulation of the B1 receptor gene has also been shown to be regulated by stabilization of mRNA. Interleukin 1 treatment of cells has been demonstrated to double the half-life of B1 receptor mRNA. In addition, protein synthesis inhibitors increase B1 receptor gene stability, suggesting the existence of a short-lived protein that causes destabilization. This protein may interact with the 3′ untranslated region, since experimentally altering the 3′ untranslated region results in B1 receptor mRNA's with varying half-lives.

B1 Receptor Knockout Animals

B1 receptor knockout mice have been reported to develop normally and to have normal blood pressure. In contrast, when inflammatory stimuli are applied, a dramatic reduction in accumulation and apoptosis of neutrophils have been reported, as well as hypoalgesia; this is consistent with pharmacological evidence presented in the past.

B2 Receptors

B2 receptors mediate bronchoconstriction, local blood flow regulation, hypotension, acute inflammatory reactions, pain, and hyperalgesia. B2 receptors from several species have been cloned. Like B1 receptors, they are typical G protein-coupled receptors in sequence. The human receptor has a predicted sequence of 364 amino acids. Both B1 and B2 receptors are found on chromosome 14 in humans, only about 12 kb apart. Like B1 receptors, B2 receptors activate phosphotidylinositol-specific phospholipase C. In addition, in most tissues, B2 receptor activation results in the production of prostaglandins and other arachidonic acid metabolites.

The B2 receptor gene is composed of three exons, of which exon 2 and exon 3 provide the coding region for the receptor. Bradykinin has been implicated in hypertension for decades. To date, nearly 80 single nucleotide polymorphisms have been identified for the B2 receptor. The promoter region for the B2 receptor contains a single nucleotide polymorphism, T/C. The C allele has been demonstrated to be an independent risk factor for essential hypertension in several ethnic groups. Several other alleles have been reported and were found to be differentially associated with several disease states. Expansion of these observations promises the potential to define the role of bradykinin in a variety of physiologic and pathophysiologic states.

B2 Receptor Regulation

In contrast to the B1 receptor, B2 receptor number does not seem to be significantly regulated by inducible gene expression. Instead, B2 receptors are constitutively expressed, as is the case for many G protein-coupled receptors. Activation of the B2 receptor by binding of bradykinin results in rapid internalization of the receptor protein by endocytosis, occurring within a few minutes. Internalization results in cessation of the biological activity of the receptor. Thus, activation of a particular B2 receptor results in a transient increase in intracellular calcium activity and transient prostaglandin release. Receptors are recycled intracellularly, with stripping of bradykinin and the return of a reactivated B2 receptor to the cell surface where it may be reactivated. Most G protein-coupled receptors are internalized following attachment to arrestin and dynamin-dependent clathrin-coated vesicles. In contrast, the B2 receptor becomes associated with caveolae.

B2 Signal Transduction

B2 receptors have been demonstrated to activate all of the signal transduction mechanisms described for G protein-coupled receptors (Figure 2). Any given cell type supports only a few of the transduction pathways, and these are primarily controlled by the specific G proteins expressed by the given cell type. B2 receptors have been shown by immunoprecipitation studies to couple to Gαq, which mediates interaction with phosphatidylinositol-specific phospholipase C. B2 receptors have also been shown by immunoprecipitation to couple to Gαi. G protein depletion studies have suggested that Gαi(2) and Gαi(3) couple B2 receptors to arachidonic acid release, presumably through the activation of phospholipase A_2. In contrast to B1 receptors, activation of B2 receptors results in increased intracellular calcium activity from the release of calcium from intracellular stores.

B2 Receptor Knockout Animals

Studies with B2 receptor knockout mice have shown that the animals develop normally. However, one study found that when animals are fed a high-salt diet, severe hypertension occurs. It has also been reported that the

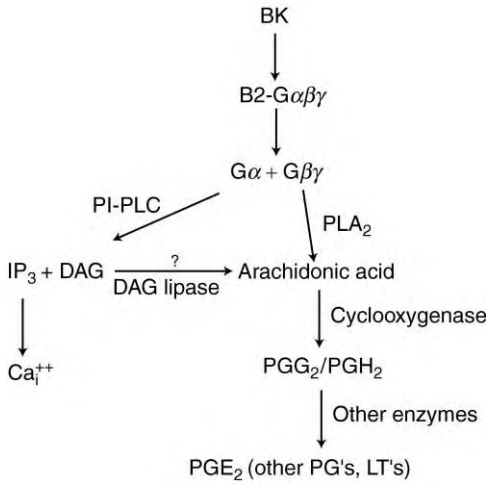

FIGURE 2 Signal transduction elicited by B2 receptors: BK, bradykinin or kallidin; PLA_2, phospholipase A_2; IP_3, inositol trisphosphate; DAG, diacylglycerol; PG, prostaglandin; LT, leukotriene. Not shown is phospholipase D, which in some cells provides a shuttle for arachidonic acid to appropriate subtrates for hormone-sensitive phosphlipase A_2. In most cells, bradykinin does not directly alter cAMP concentration; often, this occurs as a consequence of PGE_2 binding to its receptor.

renin–angiotensin system was abnormal (the kallikrein–kinin system and the renin–angiotensin system are antagonistic hemodynamic regulatory systems that play important roles in blood pressure homeostasis) and abnormal renal development occurred. A variety of cardiac defects have also been reported as well as chronically elevated heart rate.

Other Bradykinin Receptors

Many pharmacologic studies using bradykinin analogs have yielded data suggestive of additional bradykinin receptors, or at least heterogeneity of bradykinin receptors. For example, in smooth muscle preparations there is evidence for expression of different B2-like receptors expressed by the smooth muscle and the neuronal endings in the smooth muscle. Similarly, "B3" receptors have been reported in trachea, and "B4" and "B5" receptors have been reported in opossum esophagus. A criticism of all of these studies is the use of rather weak bradykinin analogs, with dissociation constants of several nM, compared to pM dissociation constant for bradykinin itself. No genetic evidence for additional receptors beyond B1 and B2 has been obtained to date.

Bradykinin Receptor Antagonists in Clinical Medicine

While highly potent peptide antagonists for B1 receptors have been described, none to date have been evaluated in clinical trials. In contrast, several peptide antagonists for B2 receptors have been evaluated as anti-inflammatory agents, including NPC 567 and Hoe 140. In addition, several nonpeptide antagonists of B2 receptors have been described. An issue that has slowed clinical development of such antagonists is the observation that bradykinin appears to play an important role in coronary artery function. It has been suggested that antagonism of B2 receptors in patients with coronary artery disease may have deleterious effects during ischemic events, perhaps even triggering myocardial infarction.

Glossary

angiotensin Peptide produced by the action of the enzyme renin on the protein angiotensinogen.

G protein Trimeric complex of α, β, and γ subunits. Activation of a G protein-coupled receptor results in dissociation of the Gα subunit, which in turn activates signaling proteins such as adenylyl cyclase, certain ion channels, and phospholipases. The activity of the Gα subunit is terminated by endogenous GTPase activity, followed by reassociation of the Gα with G$\beta\gamma$ subunit.

ischemia Loss of blood flow with resultant metabolic insufficiency of a tissue bed.

myocardial infarction Death of heart muscle following prolonged, complete ischemia.

prostaglandin Autocoid (local hormone) produced by the action of cyclooxygenase 1 or cyclooxygenase 2 on arachidonic acid. A variety of prostaglandins may be produced, each with specific biological actions elicited by binding to cell-surface receptors.

single nucleotide polymorphism Difference at a specific place in a DNA sequence of a single nucleotide. The two gene variants are alleles.

He holds a Ph.D. in pharmacology and M.D., both obtained from the Medical University of South Carolina.

Branched-Chain α-Ketoacids

David T. Chuang
University of Texas Southwestern Medical Center, Dallas, Texas, USA

The branched-chain α-ketoacids (BCKAs) comprise α-keto-isocaproate (KIC), α-keto-β-methylisovalerate (KMV), and α-ketoisovalerate (KIV) that are derived from branched-chain amino acids (BCAAs) leucine, isoleucine, and valine, respectively, through reversible transamination. The oxidative decarboxylation of these three BCKAs is catalyzed by a single branched-chain α-ketoacid dehydrogenase (BCKD) complex to give rise to various branched-chain acyl-CoAs (reaction [1]).

$$\text{R–CO–COOH} + \text{CoA-SH} + \text{NAD}^+ \rightarrow \text{R–CO–S–CoA} + \text{CO}_2\uparrow + \text{NADH} + \text{H}^+ \quad [1]$$

In patients with the inherited Maple Syrup Urine Disease (MSUD), the activity of the BCKD complex is deficient. This metabolic block results in the accumulation of BCAAs and BCKAs. Clinical manifestations include neonatal or later onset of often-fatal ketoacidosis, encephalopathy and other acute and chronic neurological dysfunction as well as mental retardation in survivors. A distinct phenotype is the strong maple syrup odor in the urine of patients, and hence the name of the disease. There are currently five clinical phenotypes associated with MSUD: classic, intermediate, intermittent, thiamin-responsive and E3-deficient. The prevalence of MSUD is one in 185 000 live births worldwide.

Degradative Pathways of BCAAs

The oxidation of BCAAs leucine, isoleucine, and valine begins with the transport of these amino acids into cells through the Na^+-independent L transporter in the plasma membrane. In the cell, the BCAAs undergo the first transamination step catalyzed by BCAA aminotransferases (BCATs), which are either cytosolic or mitochondrial, to produce BCKAs (Figure 1). The second step, i.e., the oxidative decarboxylation of BCKAs catalyzed by the mammalian BCKD complex, occurs exclusively in mitochondria. The reaction products of KIC, KMV, and KIV are isovaleryl-CoA, α-methylbutyryl-CoA, and isobutyryl-CoA, respectively. These branched-chain acyl-CoAs subsequently undergo the third step, i.e., dehydrogenation by specific acyl-CoA dehydrogenases. The dehydrogenation of isovaleryl-CoA is catalyzed by isovaleryl-CoA dehydrogenase; and of α-methylbutyryl-CoA as well as isobutyryl-CoA is carried out by α-methyl branched-chain acyl-CoA dehydrogenase. After these three steps, the degradative pathways for each of BCKAs diverge. Leucine yields acetyl-CoA and acetoacetate as end products, and is therefore a ketogenic amino acid. Valine produces succinyl-CoA, and is accordingly glucogenic. Succinyl-CoA enters the Krebs cycle, and is eventually converted to glucose by gluconeogenesis. Isoleucine is both ketogenic and glucogenic since it is metabolized to acetyl-CoA and succinyl-CoA.

Interorgan Relationships

Oxidation of BCAAs involves extensive interplay of metabolites between muscle and liver in the rat. This is due to the nonuniform distribution of BCATs and the BCKD complex among organs and tissues. In rat skeletal muscle, BCAT activity is high, but the BCKD complex activity is low. A reverse situation exists in rat liver with respect to levels of the two enzyme activities. Both rat liver and heart degrade BCKAs at high rates, but in hepatectomized rats leucine oxidation is decreased. This led to the prevailing view, based on the rat model, that the primary role of muscle is transamination of BCAAs, which provides the major source of circulating BCKAs. BCKAs are transported to liver, kidney, and heart, where they are oxidized. However, the interorgan shuttling of BCAA metabolites may not occur in humans. It was shown recently that the BCKD complex activity in human liver is similar to that in skeletal muscle. The results confirm an earlier observation that BCKD complex activity in human liver and kidney was markedly lower than in the rat counterparts, but activity in skeletal muscle was similar between two species. The human liver exhibits twice as high BCAT activity as human skeletal muscle. This finding suggests that human liver is capable of oxidizing BCAAs *in situ* and does not depend on BCAT activity in skeletal muscle for the conversion of BCAAs to BCKAs. Since skeletal muscle comprises 40% of the body mass, this tissue is likely the major site for BCAA oxidation in humans.

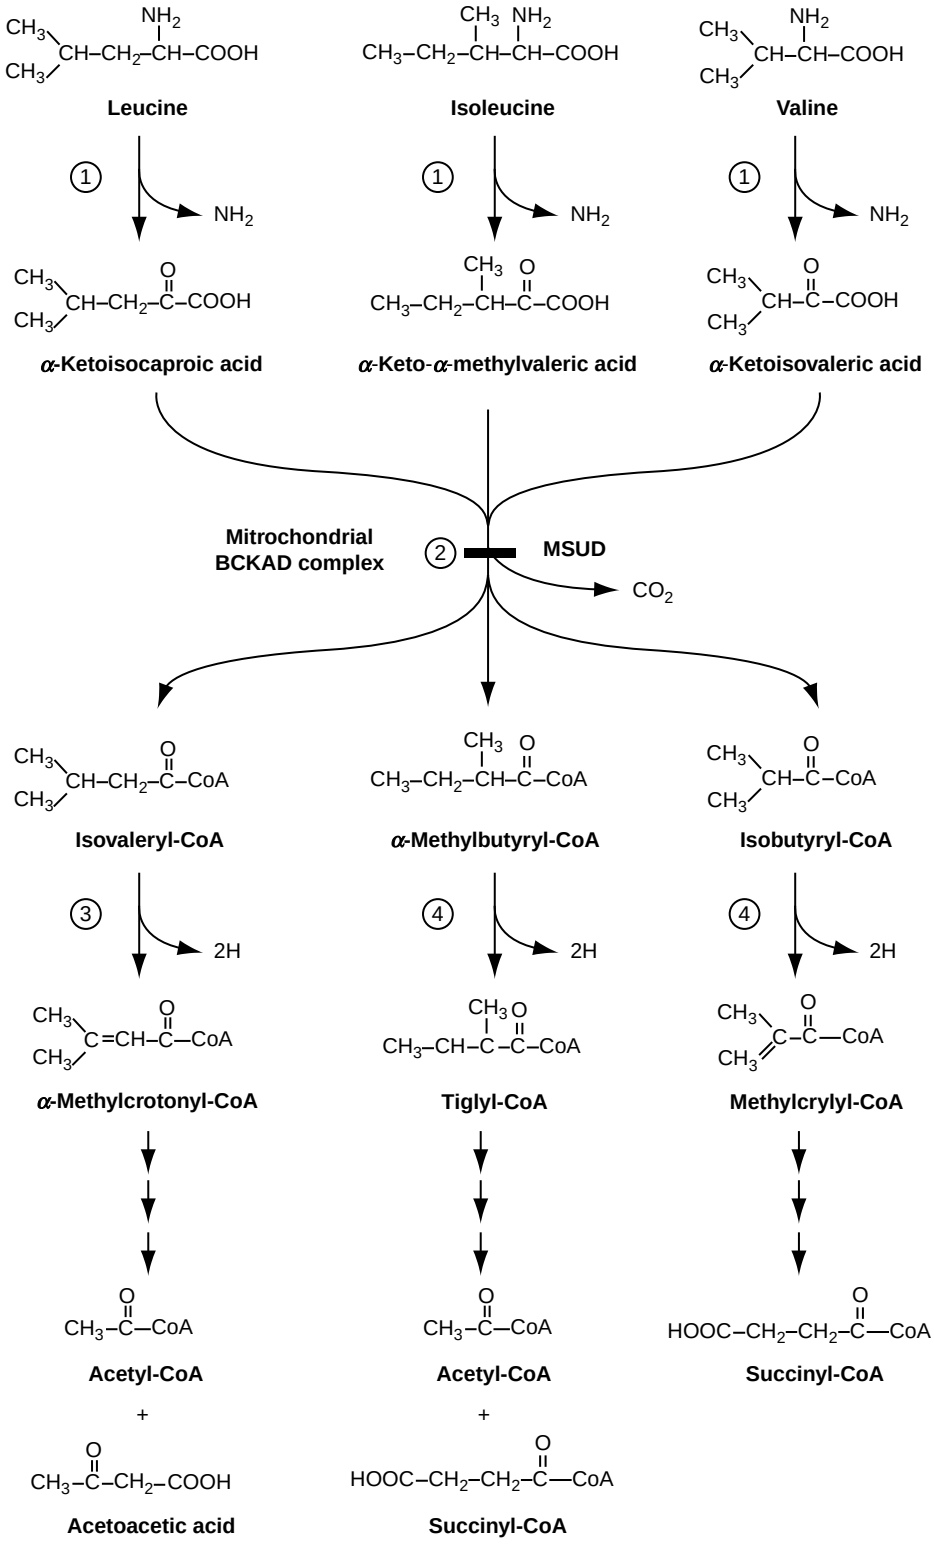

FIGURE 1 Catabolic pathways for the branched-chain amino acids (BCAAs) leucine, isoleucine, and valine. The first three common reactions are catalyzed by the following enzymes: reversible transamination by BCAA aminotransferases (1), oxidative decarboxylation of BCKAs and esterification of CoASH by the single mitochondrial branched-chain α-ketoacid dehydrogenase (BCKD) complex (2) and dehydrogenation by isovaleryl-CoA dehydrogenase (3) or α-methyl branched-chain acyl-CoA dehydrogenase (4). After these steps the degradation pathway for each amino acid diverges. As end products, leucine yields acetyl-CoA and acetoacetic acid; isoleucine produces acetyl-CoA and succinyl-CoA; and valine is converted exclusively to succinyl-CoA. The solid horizontal bar (center) depicts the metabolic block imposed by Maple Syrup Urine Disease mutations in the BCKD complex.

Regulation of BCAA and BCKA Oxidation

The oxidation of BCAAs and BCKAs is tightly regulated but exhibits tissue-specific patterns. The plasma concentrations of BCAAs and BCKAs are elevated in starvation and in clinical conditions such as diabetes mellitus, obesity, and MSUD. Paradoxically, BCAA oxidation is accelerated in muscles from fasted and diabetic rats. Epinephrine (10^{-5}–10^{-6} M) and glucagon (2×10^{-8}–5×10^{-9} M) were shown to also stimulate BCAA oxidation in the heart and hemidiaphragms of rats. Insulin decreases the oxidation of BCKAs in striated muscle of fed rats, whereas the same hormone increases oxidative decarboxylation of the ketoacids during starvation. Clofibrate administration augments BCAA oxidation in muscle, but inhibits their degradation in liver. Carnitine, ketone bodies, hexanoate, and octanoate increase the oxidation of leucine by skeletal muscle, while pyruvate and decanoate exert inhibitory effects. The metabolism of KIC in isolated rat hepatocytes is inhibited by fatty acids, KIV, KMV, and pyruvate. The mechanism of regulation for BCAA and BCKA oxidation was not fully elucidated in the above earlier studies. However, it has now become clear that these controls are through alteration in activity state or the degree of de-phosphorylation of the BCKD complex.

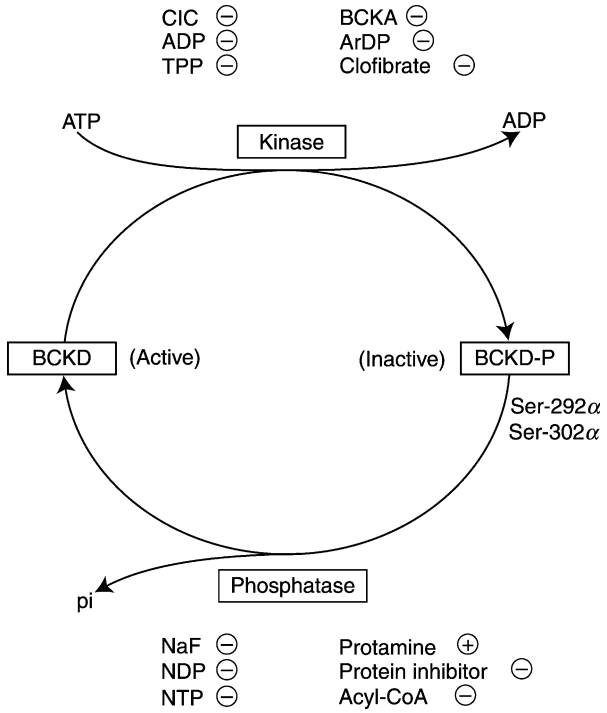

FIGURE 2 Regulation of the BCKD complex by the phosphorylation–dephosphorylation cycle. Phosphorylation at Ser-292 and Ser-302 of the E1α subunit by BCKD kinase in the presence of ATP results in the inactivation of the BCKD complex. Removal of the phosphate group on E1 converts the BCKD complex back to the active form. Inhibitors (−) and activators (+) for each enzyme are shown. CIC, α-chloroisocaproate; ArDP, arylidene pyruvate; NDP, nucleoside diphosphate; NTP, nucleoside triphosphate.

The Macromolecular Organization of the BCKD Complex

The mammalian BCKD complex is a member of the highly conserved α-ketoacid dehydrogenase complexes comprising pyruvate dehydrogenase complex (PDC), α-ketoglutarate dehydrogenase complex (α-KGDC), and the BCKD complex with similar structure and function. The mammalian BCKD multi-enzyme complex consists of three catalytic components: a heterotetrameric ($\alpha_2\beta_2$) branched-chain α-ketoacid decarboxylase or E1, a homo-24 meric dihydrolipoyl transacylase or E2, and a homodimeric dihydrolipoamide dehydrogenase or E3. The E1 and E2 components are specific for the BCKD complex, whereas the E3 component is common among the three α-ketoacid dehydrogenase complexes. In addition, the mammalian BCKD complex contains two regulatory enzymes: the specific kinase and the specific phosphatase that regulate activity of the BCKD complex through phosphorylation (inactivation)/dephosphorylation (activation) cycles (Figure 2). The six subunits with their cofactors and prosthetic groups that make up the mammalian BCKD complex are shown in Table I. Three-dimensional structures for the E1 and kinase components and the lipoyl-bearing and subunit-binding domains of the E2 component of the mammalian BCKD complex have been determined. The BCKD complex is organized around a cubic E2 core, to which 12 copies of E1, up to six copies of E3, and unknown numbers of the kinase and the phosphatase are attached through ionic interactions (Figure 3). The molecular mass of the BCKD multienzyme complex is estimated to be 4×10^6 Da. The purified bovine E1–E2 subcomplex has a sedimentation coefficient ($S_{20,w}$) of 40 S. The E3 component has low affinity for the E2 core, and was mostly lost during purification of the mammalian BCKD complex.

The reaction steps catalyzed by the three enzyme components are also shown in Figure 3. The E1 component catalyzes a thiamin diphosphate (ThDP)-mediated decarboxylation of the α-ketoacids and the subsequent reduction of the lipoyl moiety, which is covalently bound to E2. The reduced lipoyl moiety and the lipoyl domain serve as a "swinging arm" to transfer the acyl group from E1 to CoA giving rise to acyl-CoA. Finally, the E3-component with tightly bound flavin adenine dinucleotide (FAD) reoxidizes the dihydrolipoyl residue of E2 with NAD^+ as the ultimate electron

TABLE I

Component Enzymes and Subunit Composition of the Mammalian Branched-Chain α-Ketoacid Dehydrogenase (BCKD) Complex

Component	Molecular mass (Da)	Prosthetic group (P) and cofactor (C)
BCKA decarboxylase (E1)	1.7×10^5 ($\alpha_2\beta_2$)	ThDP (C)
α-Subunit	46 500	Mg^{2+} (C)
β-Subunit	37 200	K^+
Dihydrolipoyl transacylase (E2)	1.1×10^6 (α_{24})	Lipoic acid (P)
Subunit	46 518[a]	
Dihydrolipoyl dehydrogenase (E3)	1.1×10^5 (α_2)	FAD (C)
Subunit	55 000	
BCKD kinase	1.8×10^5 (α_4)	Mg^{2+} (C)
Subunit	43 000	
BCKD phosphatase	4.6×10^5 (?)	None
Subunit	33 000	

BCKA, branched-chain α-ketoacid; ThDP, thiamin diphosphate.
[a]Calculated from the amino acid composition deduced from a bovine E2 cDNA. The E2-subnit migrates anomalously as a 52 kDa species in SDS-PAGE.

acceptor. The net or overall reaction is the production of a branched-chain acyl-CoA, CO_2 and NADH from a α-ketoacid, CoA and NAD^+ (see reaction [1]).

Dietary and Hormonal Regulation of the BCKD Complex

The regulation of BCKA oxidation was shown to be at the BCKD complex step by using inhibitors such as oleate and palmitoyl carnitine. The mammalian BCKD complex is predominantly regulated by the reversible phosphorylation of the Ser-292 and Ser-302 residues in the E1α subunit. The activity state of the BCKD complex in different tissues is the ratio of the actual activity of a partially de-phosphorylated form to the maximal activity of the fully de-phosphorylated form. Thus, the activity state represents the percentage of the total BCKD complex that is active in a given tissue or cell type. Recent studies showed that the activity state of the BCKD complex in human tissues is 40% in heart, 26% in skeletal muscle, 28% in liver, and only 14% in kidney. Rats fed with low-protein diets show a reduction in the activity state, but not the amount, of the BCKD complex in hepatocytes, compared to chow-fed rats. The decrease in activity state inversely correlates with an increase in the amounts of the BCKD kinase protein and mRNA in rat liver. Starvation, exercise, and diabetes stimulate the activity of the BCKD complex in skeletal muscle by increasing the proportion of active or de-phosphorylated enzyme. Recently, it was shown that glucocorticoids cause a marked reduction in the BCKD kinase mRNA level in rat hepatoma cells and rat liver with a concomitant increase in the activity state of the BCKD complex. Glucocorticoids and acidification also significantly increase the activity state of the BCKD complex in pig kidney cells expressing the hormone receptor.

Brain Neuropathology of BCKAs

The BCAAs, in particular leucine, are rapidly transported into the brain and actively metabolized. It was proposed that a leucine–glutamate cycle which plays an important role in maintaining a steady supply of glutamate, a major excitatory neurotransmitter for inter-neuronal communication. The BCAAs are nitrogen donors for glutamate synthesis in astrocytes, a major site of BCAA transamination. The amino group is transferred to α-ketoglutarate to yield glutamate. This amino acid, in turn, is converted to glutamine. ^{15}N-labeled BCAA studies showed that at least one-third of the amino groups of brain glutamate are derived from BCAAs. The BCKAs may be released from astrocytes to the extracellular fluid and taken up by neurons. Although neurons can oxidize KIC, it is preferentially reaminated to leucine. The flux of the reverse transamination in rat cortical synaptosomes is several times greater than the rate of nitrogen transfer from leucine to glutamate. This is in contrast to the flux in astrocytes which is mainly for glutamate synthesis. In the leucine oxidative pathway, acetoacetyl-CoA is generated for ketone synthesis or for cleavage to acetyl-CoA to enter the tricarboxylic acid cycle.

In the classic form of MSUD, the excess BCAAs and BCKAs are likely to interfere with the neuronal and astrocytic metabolism. BCKAs accumulated in MSUD compromise brain energy metabolism by blocking the respiratory chain and inhibiting creatine kinase activity. Perfusion by microdialysis with leucine and KIV has created a microenvironment similar to that found in MSUD. The infusion of leucine resulted in an increase of large neutral amino acids in the extra-cellular space, thereby a decreased concentration in neurons. The infusion of KIC caused an 11-fold increase in leucine and two- to threefold increase in other large neutral amino acids in the extracellular space. This pattern is consistent with active transamination of KIC to leucine. These changes could affect biosynthesis of serotonin and catecholamines, and alter the homeostasis of the leucine/glutamate cycle and the glutamate/glutamine cycle in brain.

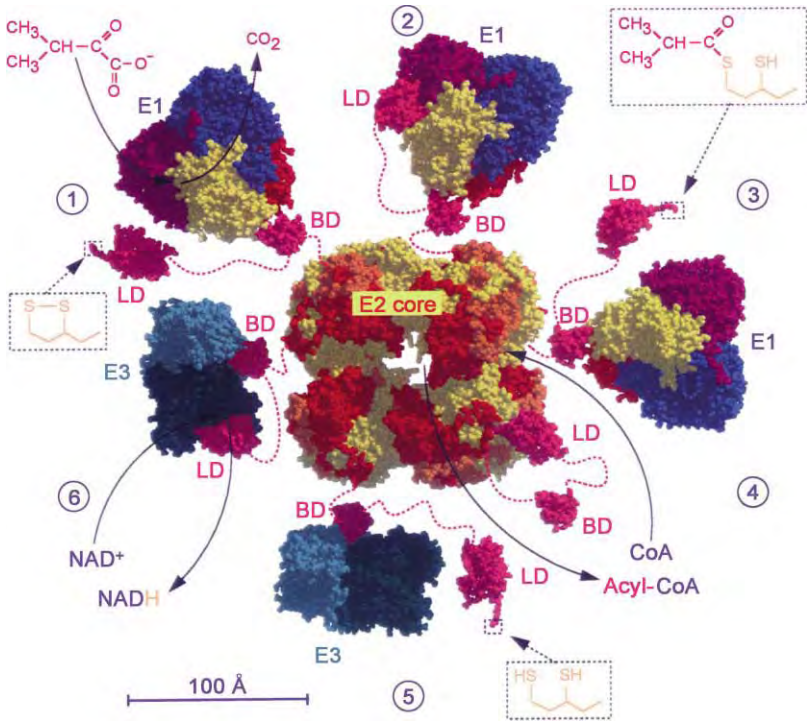

FIGURE 3 Model for structural organization and individual component reactions of the BCKD complex. The macromolecular structure (4×10^6 Da in size) is organized about a cubic transacylase (E2) core (based on the structure of *Azotobacter* pyruvate dehydrogenase E2), to which a decarboxylase (E1) (based upon *Pseudomonas* BCKD E1 structure), a dehydrogenase (E3) (according to the structure of *Azotobacter* pyruvate dehydrogenase E3) are attached through ionic interactions. E2 of the BCKD complex contains 24 identical subunits with each polypeptide made up of three folded domains: lipoyl (LD), E1/E3-binding (BD), and the E2 core domains that are linked by flexible regions (represented by dotted lines). E1 $\alpha_2\beta_2$ heterotetramers or E3 homodimers are attached to BD. The BCKD kinase and BCKD phosphatase (not shown) bind to LD. E1 catalyzes the ThDP-mediated oxidative decarboxylation of α-ketoacids. The ThDP-hydroxyacylidene moiety is transferred to a reduced lipoyl prosthetic group (in the box) on LD. The flexible LD carries S-acyldihydrolipoamide to the active site in the E2 core to generate acyl-CoA. The reduced lipoyl moiety on LD is oxidized by E3 on BD with the concomitant reduction of NAD^+. The sum of the above component reactions is the oxidative decarboxylation of BCKAs (reaction [1] in the text).

Glossary

activity state The ratio of the actual (partially de-phosphorylated) activity to the maximal (fully de-phosphorylated) activity of the mammalian mitochondrial branched-chain α-ketoacid (BCKD) complex. The activity state represents % of the total BCKD complex that is active in a tissue under defined physiological conditions.

ketoacidosis A clinical condition associated with the accumulation of the branched-chain α-ketoacids derived from branched-chain amino acids leucine, isoleucine and valine present in dietary proteins. This pathological state is presented by patients with the Maple Syrup Urine Disease caused by congenital defects in the BCKD complex.

oxidative decarboxylation The removal of a CO_2 group from a molecule by a decarboxylase/dehydrogenase with a concomitant transfer of electrons from the substrate to a biological electron acceptor. For the branched-chain α-ketoacids, this reaction is catalyzed by the BCKD complex coupled with the reduction of NAD^+.

phosphorylation The posttranslational modification of a protein or enzyme molecule by a specific kinase, in which the γ-phosphoryl group from ATP is incorporated into a serine, threonine or tyrosine residue of the protein/enzyme as a means to regulate its biological activity.

transamination A reversible enzymatic reaction that converts an amino acid into a corresponding α-ketoacid. For branched-chain amino acids, this reaction is carried out by the distinct isozymes of branched-chain aminotransferase both in the cytoplasm and the mitochondrion.

His principal research interests are in the structure/function and molecular genetics of the human branched-chain α-ketoacid dehydrogenase (BCKD) complex. His laboratory determined three-dimensional structures for components and domains of the human BCKD complex, and characterized mutations in the BCKD genes of patients with the inherited Maple Syrup Urine Disease.

Brassinosteroids

Steven D. Clouse
North Carolina State University, Raleigh, North Carolina, USA

Brassinosteroids (BRs) are endogenous plant growth-promoting hormones that function at low concentrations to influence cellular expansion and proliferation, while interacting with other plant hormones and environmental factors to regulate the overall form and function of the plant. BRs are found throughout the plant kingdom in seeds, pollen, and young vegetative tissue, and the examination of the phenotype of mutants affected in BR biosynthesis or signaling provides genetic evidence that BRs are essential for normal organ elongation, vascular differentiation, male fertility, timing of senescence, leaf development, and responses to light. BRs are unique among plant hormones in their close structural similarity to vertebrate and invertebrate steroid hormones, which have well-known roles in regulating embryonic and postembryonic development and adult homeostasis in mammals and insects.

Brassinosteroid Structure and Natural Occurrence

BRs have been identified throughout the plant kingdom as naturally occurring compounds in monocot and dicot angiosperms, gymnosperms, algae, and pteridophytes. At least 40 free BRs and four conjugates have been rigorously characterized from plant tissue by a variety of biochemical approaches.

Discovery and Chemical Structure of Brassinolide

The discovery of brassinolide, the most active natural BR currently identified, was preceded by three decades of experiments at the United States Department of Agriculture (USDA) in which organic extracts of pollen from over 60 species were applied to a variety of crop plants to identify new compounds with growth-promoting properties. An extract from *Brassica napus* pollen was extremely potent in promoting cell elongation and division in bean second internodes and enhanced overall growth of radishes, leafy vegetables, and potatoes when young seedlings were sprayed in greenhouse experiments. USDA researchers identified the active component of the *B. napus* extract in 1979 and named the novel compound brassinolide. It was determined by single-crystal X-ray analysis to be a polyhydroxylated derivative of 5α-cholestane, namely (22*R*,23*R*,24*S*)-2α,3α,22,23-tetrahydroxy-24-methyl-B-homo-7-oxa-5α-cholestan-6-one (Figure 1).

Other BRs differ from brassinolide by variations at C-2 and C-3, the presence of a ketone or de-oxo function instead of a lactone at C-6, various substitutions at C-24, and the stereochemistry of the hydroxyl groups in the side chain. Known BR conjugates include glycosylated, myristylated, and laurylated derivatives of the hydroxyls at C-2 and C-3 or in the side chain. Many BRs are biosynthetic precursors or metabolic products of brassinolide, although some of these BRs are believed to have independent biological activity in specific plants.

Endogenous Levels of BRs in the Plant Kingdom

Endogenous levels of BRs vary according to plant organ type, tissue age, and species, with pollen and immature seeds containing the highest levels, followed by young growing shoots. Pollen and immature seeds generally show BR levels of 1–100 ng g^{-1} fw; shoots and leaves typically have lower amounts, 0.01–0.1 ng g^{-1} fw. BRs are isolated from plant tissues by organic solvent extraction followed by reverse-phase high-performance liquid chromatography (HPLC). Accurate quantification of endogenous levels involves spiking with deuterated forms of the BR of interest followed by gas chromatography–mass spectrometry with selected ion monitoring (GC–MS–SIM) analysis of derivatized BR samples.

Brassinosteroid Biosynthesis

The BR biosynthetic pathway can be divided into general sterol synthesis (cycloartenol to campesterol) and the BR-specific pathway from campesterol to brassinolide. Details of the pathway have been obtained by following the fate of labeled intermediates fed to cell-suspension cultures and whole plants, and by measuring

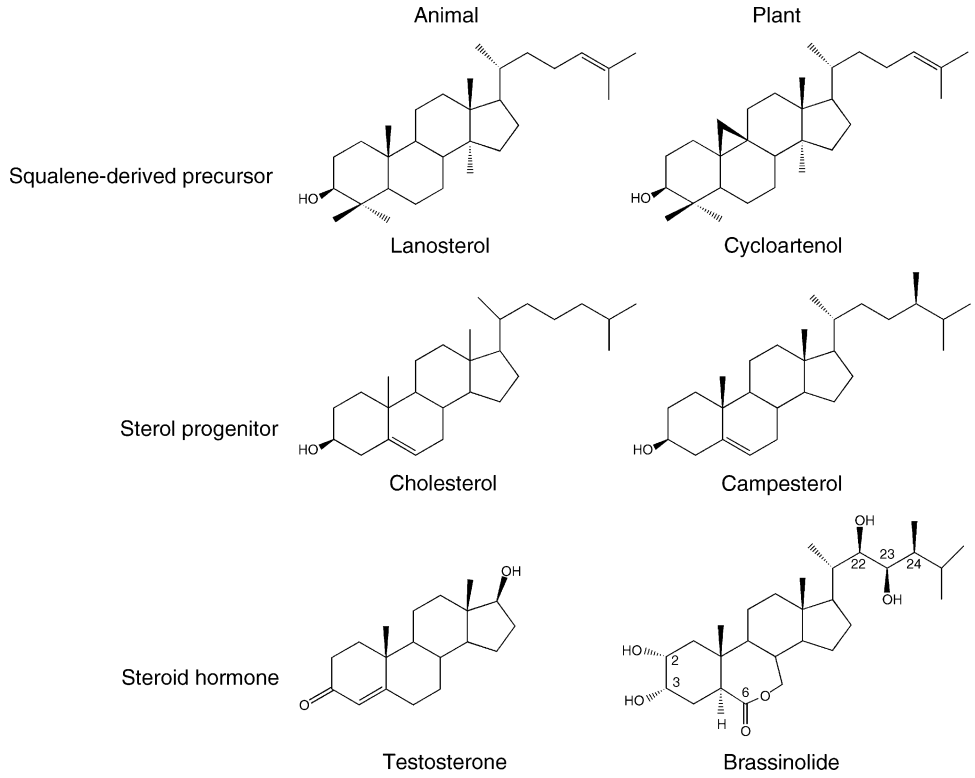

FIGURE 1 Structure of brassinolide and its sterol progenitor is compared with the animal steroid hormone testosterone and its sterol progenitor.

endogenous sterol and BR levels in biosynthetic mutants blocked at various steps of the pathway.

Mevalonic Acid to Cycloartenol

Like animal steroids, BRs are products of the isoprenoid biosynthetic pathway beginning with acetyl-CoA and proceeding through intermediates such as mevalonate, isopentenyl pyrophosphate, farnesyl pyrophosphate, and squalene-2,3-epoxide. It appears that the biosynthetic steps from mevalonate to squalene-2,3-epoxide are conserved among the phyla, but in animals and fungi squalene-2,3-epoxide is converted to lanosterol, the precursor of cholesterol, whereas in plants it is converted to cycloartenol, the progenitor of the plant sterols campesterol, stigmasterol, and sitosterol (Figure 1).

Cycloartenol to Campesterol

The conversion of cycloartenol to campesterol begins with C-24 alkylation of the side chain catalyzed by the enzyme sterol methyl transferase 1 (SMT1) in the presence of S-adenosylmethionine. The product, 24-methylenecycloartenol, is converted to 24-methylenelophenol in a series of steps including a C-14 sterol reductase and a Δ^7–Δ^8 sterol isomerase, encoded in *Arabidopsis* by the *FACKEL* and *HYDRA1* genes, respectively. Mutants in the *SMT1*, *FACKEL*, and *HYDRA1* genes show dwarfism and severe defects in embryogenesis and vascular development that are not rescued by BR treatment, possibly because the early sterol pathway may produce a non-BR signaling molecule that is critical for these developmental processes.

The conversion of 24-methylenelophenol to campesterol involves a Δ^7-C-5-desaturase, encoded by *DWARF7* (*DWF7*); a Δ^7-sterol reductase, encoded by *DWARF5* (*DWF5*); and a C-24 sterol reductase, encoded by *DWARF1* (*DWF1*). *Arabidopsis dwf7*, *dwf5*, and *dwf1* mutants are intermediate dwarfs with altered vascular development and have reduced BR levels. These developmental defects can be rescued by treatment with exogenous BRs.

Campesterol to Brassinolide

Four reactions lead from campesterol to campestanol via reduction of the C-5 double bond (Figure 2). One of these steps requires a 5α-steroid reductase (encoded by the *DE-ETIOLATED2*, *DET2*, gene) that is an orthologue of the mammalian enzyme that catalyzes the NADPH-dependent reduction of testosterone to dihydrotestosterone. From campestanol, two biosynthetic routes are possible: early C-6 oxidation, in which a ketone is introduced at C-6 before the hydroxylation of the side chain, and late C-6 oxidation, in which the side chain is

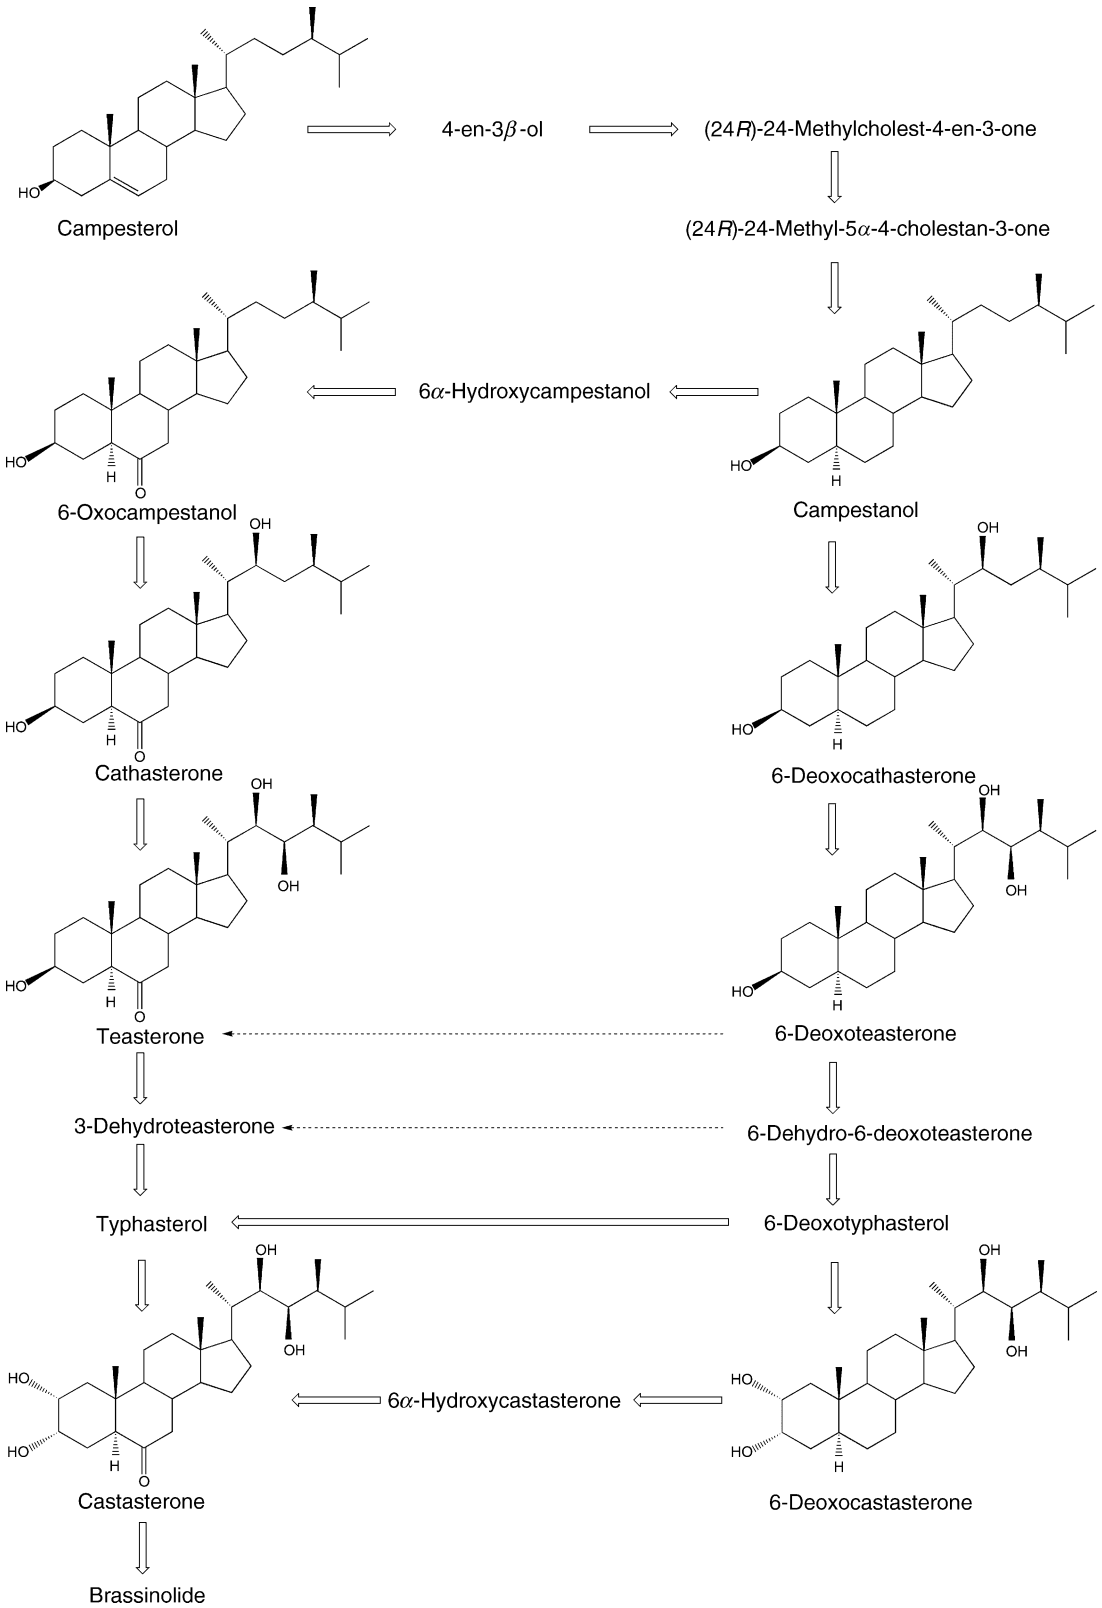

FIGURE 2 Biosynthetic pathway leading from the plant sterol campesterol to brassinolide. From campestanol, two alternative pathways exist, early C-6 oxidation (left) and late C-6 oxidation (right). Several points of interconnection are possible between the two pathways.

modified first and the ketone is introduced in the penultimate step. Many plants, including *Arabidopsis*, have both pathways functional, whereas others, such as tomato, appear to use only late C-6 oxidation. Hydroxylation of the side chain in either pathway occurs via successive steps involving the cytochrome P-450 steroid hydroxylases DWARF4 (DWF4) and CONSTITUTIVE PHOTOMORPHISM AND DWARFISM (CPD).

The *det2*, *dwf4*, and *cpd* mutants of *Arabidopsis* are extremely dwarf in stature; have dark-green, rounded, and downward-curling leaves; and exhibit a prolonged life span with reduced fertility and altered vascular development. In the dark, these mutants show some of the features of light-grown plants, including shortened hypocotyls and open cotyledons. All these phenotypic alterations can be rescued to wild type by exogenous application of brassinolide or BR intermediates downstream of the biosynthetic block caused by the mutant.

Brassinosteroid Physiology

BRs have a dramatic positive effect on stem elongation, promoting epicotyl, hypocotyl, and peduncle elongation in dicots and enhancing coleoptile and mesocotyl growth in monocots. Exogenous BRs also stimulate tracheary element differentiation and numerous studies *in vivo* suggest that endogenous BRs are essential for normal vascular development. In many systems, BRs increase rates of cell division, particularly under conditions of limiting auxin and cytokinin. BRs also promote seed germination, accelerate senescence, cause hyperpolarization of membranes, stimulate ATPase activity, and alter the orientation of cortical microtubules. In addition to effects on growth, BRs also mediate the effects of abiotic and biotic stresses, including salt and drought stress, temperature extremes, and pathogen attack.

Brassinosteroid Signal Transduction

Recently it has been shown that animal steroids can be recognized by cell-surface receptors. However, the classic signaling pathway for these hormones involves binding the steroid to an intracellular receptor consisting of a variable N-terminal domain, a highly conserved DNA-binding domain with two zinc-fingers, and a multifunctional domain that mediates ligand-binding, dimerization, and ligand-dependent transcriptional activation. The completed genome sequence of *Arabidopsis thaliana* indicates that plants do not contain members of this superfamily of intracellular steroid receptors, suggesting that cell-surface recognition is the primary, if not only, form of plant steroid perception. Thus, plant and animal steroid hormones share many structural and functional features, but differ in their primary signaling pathways.

Receptor Kinases and BR Perception

The best characterized component of BR signal transduction is *BRASSINOSTEROID INSENSITIVE 1* (*BRI1*), a single genetic locus in *Arabidopsis* encoding a leucine-rich repeat receptor kinase. Homologous genes have been identified in rice, tomato, and pea. Numerous *bri1* mutant alleles have been identified by various genetic screens, most of which exhibit the extreme dwarfism and other phenotypic characteristics of severe BR-deficient mutants. In contrast to the biosynthetic mutants, *bri1* mutants cannot be rescued by BR treatment, consistent with their role in signal transduction.

The BRI1 protein consists of a putative signal peptide followed by the extracellular domain proper including a leucine zipper and 25 leucine-rich repeats that are flanked by short sequences containing paired cysteines. A 70-amino-acid island that is critical for biological function is embedded between repeats 21 and 22. Downstream of the extracellular domain lies a short hydrophobic single-pass transmembrane domain, followed by the juxtamembrane region and the cytoplasmic Ser-Thr kinase domain. Binding studies with radiolabeled brassinolide and microsomal fractions of wild-type, mutant, and transgenic *Arabidopsis* plants clearly shows that BRI1 is an essential component of the BR receptor complex. Whether it binds BR directly or in association with other sterol-binding proteins is currently unclear.

The mechanism of action of many animal receptor kinases involves ligand-mediated homo- or heterodimerization of the receptor followed by autophosphorylation of the intracellular kinase domain. This activation of the kinase results in the recognition and phosphorylation of downstream signaling components, leading ultimately to the regulation of specific gene expression. Plant receptor kinases appear to follow the same general paradigm of receptor kinase action, and mutational analysis shows that both a functional extracellular domain and an active cytoplasmic kinase are essential for BRI1 function.

With respect to BRI1 and BR signaling, recent evidence suggests that heterodimerization with another leucine-rich repeat receptor kinase may play an important role. BAK1 (BRI1 associated receptor kinase 1) shares similar structural organization to BRI except that it has only five leucine-rich repeats in its extracellular domain and lacks the 70-amino-acid island of BRI1. BAK1 is expressed in all tissues of the plant, similar to the global expression pattern of BRI1, and confocal laser

microscopy of transgenic plants expressing fusion proteins shows plasma membrane localization for both BRI1 and BAK1. Direct physical interaction between BRI1 and BAK1 was confirmed in yeast cells and *Arabidopsis* plants by co-immunoprecipitation experiments and genetic studies strongly suggest that BAK1 plays an important role in BR signaling.

Downstream Components

Both BRI1 and BAK1 have been shown to possess kinase activity *in vitro*, and they can autophosphorylate themselves and transphosphorylate one another. Other *in vitro* substrates of the BRI1 kinase have been identified, but no *in vivo* cytoplasmic substrates of either BRI1 or BAK1 have been characterized thus far. An element further downstream from BRI1/BAK1 is the BIN2 (brassinosteroid insensitive 2) kinase, a negative regulator of BR signal transduction. BIN2, which is homologous to insect and mammalian shaggy-like kinases involved in the Wingless/Wnt signaling pathways, most likely acts by phosphorylating two related cytoplasmic proteins, BZR1 and BES1. Phosphorylation by BIN2 targets BZR1 and BES1 for proteasome-mediated degradation. In the presence of BR, BIN2 activity is apparently inhibited and the nonphosphorylated forms of BZR1 and BES1 accumulate and move to the nucleus where they interact with unknown transcription factors to regulate the expression of specific genes involved in the BR response. Our current knowledge of BR signal transduction is summarized in Figure 3.

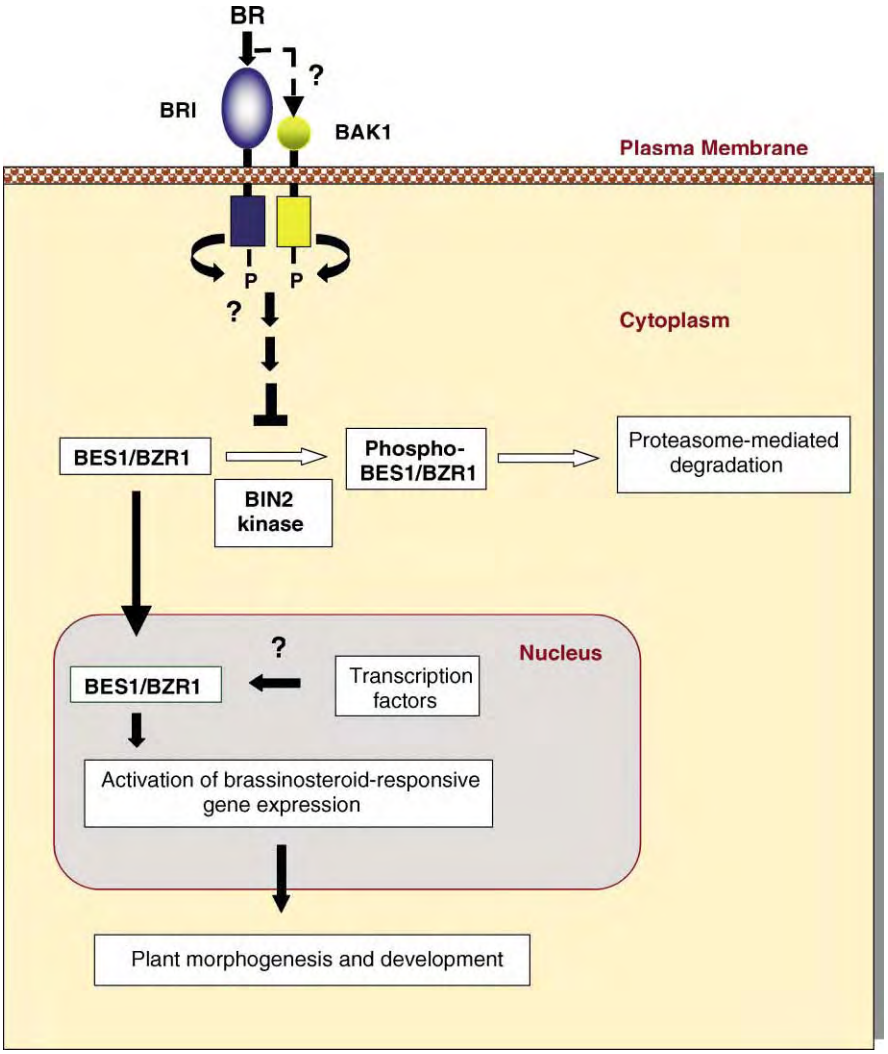

FIGURE 3 A model for BR signal transduction in *Arabidopsis*. BR binds to BRI1 or the BRI1/BAK1 heterodimer and initiates a signaling cascade that inactivates the BIN2 kinase. This allows accumulation and nuclear localization of the unphosphorylated forms of the positive regulators BES1 and BZR1. Question marks indicate proposed but uncharacterized steps. Biography

Steven D. Clouse is a Professor in the Department of Horticultural Science at North Carolina State University in Raleigh. His principal research interests are brassinosteroid signal transduction and the regulation of gene expression by plant steroids. He holds a Ph.D. from the University of California, Davis and received his postdoctoral training at the Salk Institute for Biological Studies in La Jolla, California. His group cloned some of the first BR-regulated genes and was the first to identify the *bri*1 mutant, which is the focus of much current BR signal transduction research.

Cadherin Signaling

David B. Sacks and Jonathan M.G. Higgins
Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts, USA

The associations of cells with one another regulate many cellular processes. Adherens junctions are specialized adhesive structures between cells that are formed by cadherin-dependent interactions. Cadherins are a family of Ca^{2+}-dependent intercellular adhesion molecules linked to the cytoskeleton. Cadherins are also signaling molecules that convey information from the environment to the interior of the cell. In addition, signals from inside the cell can modulate adhesion through cadherins. These forms of cadherin signaling, together with their ability to support adhesion, allow cadherins to participate in coordinating many aspects of cellular organization.

The Cadherin Family

The cadherin superfamily includes six main subfamilies. These are type-I (or classical) cadherins, type-II (atypical) cadherins, desmocollins, desmogleins, protocadherins, and Flamingo cadherins.

Classical and Atypical Cadherins

Classical cadherins like E-, N-, and P-cadherin are components of adherens junctions between cells. The most highly characterized is E-cadherin, which is predominantly expressed in epithelium. The classical cadherins are single-span transmembrane proteins with a highly conserved carboxy-terminal cytoplasmic domain and five extracellular domains, termed cadherin repeats. Ca^{2+} binding to the extracellular domain induces homophilic adhesion with cadherin molecules on adjacent cells. The cytoplasmic tail of cadherin associates with the actin cytoskeleton via proteins called catenins. Cadherin binds β-catenin or γ-catenin (also termed plakoglobin), which in turn bind to α-catenin (Figure 1). The interaction of α-catenin with the actin cytoskeleton strengthens the intercellular adherens junction. Another catenin, termed $p120^{ctn}$, also binds to the cadherin tail in the cytoplasm. The closely related atypical cadherins have similar properties.

Desmosomal Cadherins

Desmocollins and desmogleins are components of desmosomes, which are sites of cell–cell adhesion in tissues subjected to mechanical strain (e.g., epidermis and the myocardium). The overall structure of these desmosomal cadherins resembles that of the classical cadherins, but their cytoplasmic tails are linked to the intermediate filaments of the cytoskeleton.

Protocadherins

The protocadherin family members have as many as seven extracellular Ca^{2+}-binding domains, a transmembrane region and divergent cytoplasmic domains. They appear to participate in development, and may have a particularly important role in the central nervous system.

Other Cadherins

Other cadherins range from those with seven transmembrane segments (such as Flamingo) to T-cadherin, which lacks both transmembrane and cytoplasmic regions.

Functions of Cadherin Signaling

Originally described exclusively as cell adhesion proteins, cadherins have been shown to influence multiple aspects of cell behavior. Indeed, cadherins can transmit signals across the cellular membrane into the interior to modulate cell function. While many members of the cadherin family are likely to share this capacity, to date only members of the classical and atypical cadherin families have been studied in detail and they will be the focus of this article.

Signaling Triggered by Cell–Cell Contact

Signaling can be triggered when cadherins attach to other cadherins on adjacent cells, allowing information about the external environment to be conveyed into the cell. For example, most normal cells grown in culture dishes will reproduce until they form a single continuous layer. A process known as "contact inhibition" then prevents further cell division. Cadherin–cadherin junctions

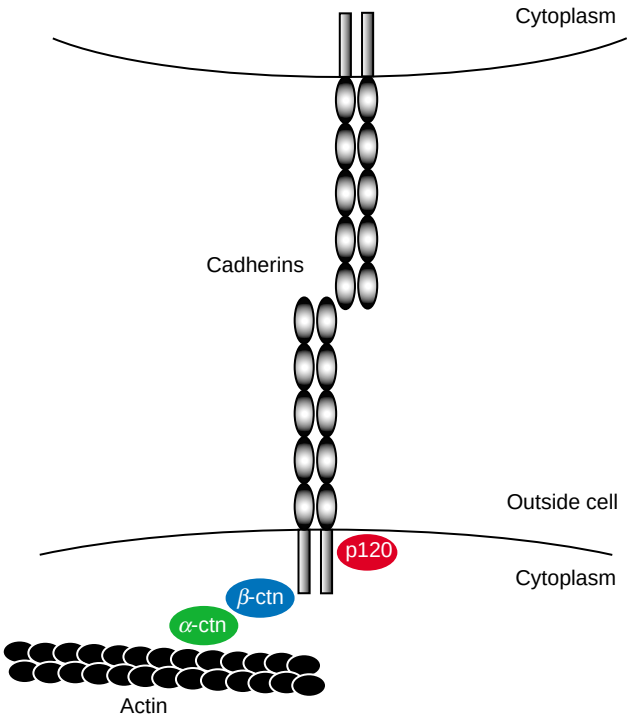

FIGURE 1 Schematic model of a cadherin-mediated adherens junction. Cadherins on adjacent cells interact with one another to provide intercellular adhesion. The terminal portion of the cytoplasmic tail of cadherin binds to β-catenin (β-ctn) or γ-catenin (not shown), which in turn binds to α-catenin (α-ctn). The interaction of α-catenin with the actin cytoskeleton stabilizes the adherens junction. Another catenin, $p120^{ctn}$ (p120), interacts with the cytoplasmic portion of the cadherin tail near the cell membrane.

between cells produce a signal that leads to contact inhibition and renders the cells insensitive to the stimulatory effects of growth factors. Signals generated by interactions between cadherins are also implicated in the formation of desmosomal cell junctions, nerve outgrowth, establishment of cell polarity, cytoskeletal organization, tissue formation, cell differentiation, cell movement, and regulation of gene expression.

Influence of Cadherin Level on Signaling

The amount of cadherin present on the cell surface may influence the signals generated. For example, expression of high levels of E-cadherin can inhibit cell motility and cell division and induce cell polarity. These effects have led to the description of E-cadherin as a tumor suppressor. In fact, loss of functional E-cadherin is often associated with epithelial tumor progression and invasion. Regulation of E-cadherin gene transcription alters the total amount of E-cadherin protein in cells during morphogenic processes such as hair follicle development. The level of E-cadherin on the cell surface also can be specifically regulated. These changes are likely to modulate not only the adhesive properties of the cell, but also the signals that the cell receives through contacts with other cells. In some cases, alterations in the level of cadherin may regulate cellular function even in the absence of cadherin–cadherin interactions between cells.

Different Signaling Properties of Various Cadherins

It is notable that the different types of cadherins induce different changes in cell behavior. For example, while E-cadherin usually reduces the motility of a cell, the presence of N-cadherin or cadherin-11 has the opposite effect, enhancing the ability of cells to crawl over surfaces and invade tissue. It is clear that the various cadherins trigger different signaling pathways. These differences are likely to play a critical role in the regulated changes in cell behavior that occur during early animal development ("embryogenesis"). A striking example of this sort of change occurs when cells undergo "epithelial–mesenchymal transitions." This process occurs during tissue remodeling when relatively sedentary epithelial cells with stable adherens junctions transform into more motile and invasive mesenchymal cells in order to migrate and form new tissue structures. These events are frequently accompanied by a switch in cadherin expression, for example, from E-cadherin to N-cadherin. Similar changes occur during malignant transformation. Most human cancers arise from epithelial cells. These cells normally express E-cadherin. In many cases, expression of functional E-cadherin is lost during malignant transformation, and anomalous expression of N-cadherin or cadherin-11 occurs. These changes may contribute to the increased growth rate, and increased migratory and invasive capacity of cancer cells.

Inside-Out Cadherin Signaling

It is also apparent that the adhesiveness of cell surface cadherins can be modulated from within the cell in the absence of changes in the level of cadherin expression. Therefore, cadherins are able to transduce both "outside-in" and "inside-out" signals. Feedback between these two types of signals is critical to allow the correct formation and disassembly of cadherin–cadherin junctions during morphogenesis and for the continuous remodeling of adherens junctions that occurs even in sedentary cells.

Mechanisms of Cadherin Signaling

Considerable progress has been made in describing cadherin signaling. Classical and atypical cadherins

interact with several signaling molecules, but the molecular mechanisms that constitute the signaling pathways are not completely understood. Three major signaling pathways have been described.

Rho Family GTPase Signaling

An important target of cadherin signaling is the cytoskeleton. This dynamic scaffold of rod-like actin must be rearranged to allow cells to form junctions with other cells and for cells to move. Members of the Rho family of small GTPases are vital regulators of these events, and they are activated in response to the formation of cadherin-mediated cell junctions. Changes in the activity of the Rho family GTPases also lead to alterations in the adhesive capacity of cadherins. Thus, communication between cadherin and Rho GTPases is bidirectional. In general, GTPases serve as switches that are "on" when bound to GTP and "off" when the bound GTP is hydrolyzed to GDP. The best-characterized members of the Rho family are Cdc42, Rac1, and RhoA.

Cdc42 induces the formation of filopodia or microspikes, small finger-like projections from the cell that are needed for the first steps of adherens junction formation by cadherins. Cdc42 is activated upon the assembly of E-cadherin-mediated cell junctions (Figure 2). This mechanism perhaps allows E-cadherin to initiate signals that in turn further stimulate adherens junction formation. Cdc42 also activates the so-called PAR/atypical protein kinase (aPKC) complex and thereby stimulates cell polarity and tight junction formation.

Rac1 is activated rapidly in response to cadherin binding. Active Rac1 stimulates remodeling of the actin cytoskeleton that leads to the formation of cell membrane protrusions known as lamellipodia. This change in morphology may help extend the contact zone between cells, enhancing formation of stable adherens junctions. Activated Cdc42 or Rac1 can also influence the function of a protein known as IQGAP1. High levels of IQGAP1 in a cell decrease E-cadherin-mediated adhesion, perhaps by binding β-catenin, thus displacing α-catenin from the E-cadherin–β-catenin complex.

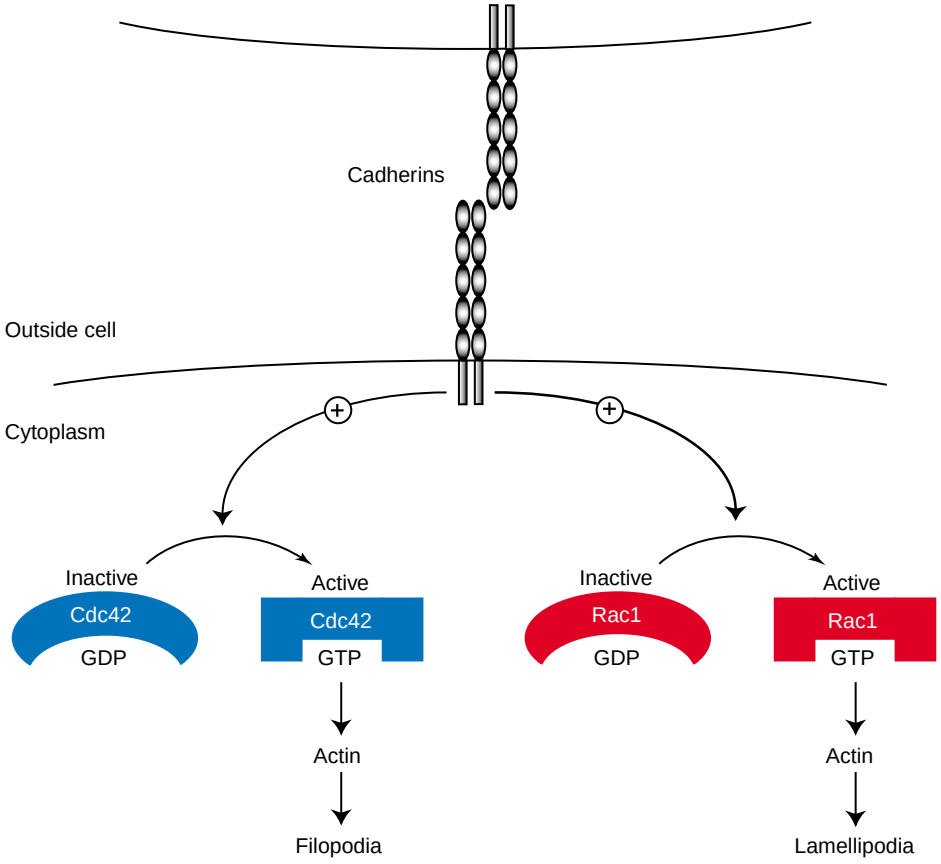

FIGURE 2 Cadherin-mediated adhesion activates Rho family GTPases. The formation of cadherin contacts between cells leads to the activation of Cdc42 and Rac1 (i.e., generation of GTP-bound forms). In the active state, Cdc42 and Rac1 cause alterations in the actin cytoskeleton that lead to the generation of finger-like filopodia and membrane ruffles known as lamellipodia, respectively. These events lead to changes in both the ability of cells to adhere to their surroundings and in cell migration, and can increase the stability of the cadherin-mediated junctions themselves.

Activated Cdc42 or Rac1 can bind to IQGAP1 and counteract this activity, thereby increasing the adhesive capacity of cadherins.

Activation of RhoA leads to the formation of stress fibers. Active RhoA influences E-cadherin function and appears necessary for maintenance of adherens junctions. Moreover, cadherin signals can modulate the activity of RhoA. Thus, cadherin can regulate the actin cytoskeleton by multiple mechanisms.

The transition from the off to the on state of GTPases can be brought about by guanine nucleotide exchange factors (GEFs) that cause the displacement of GDP from the GTPase, and replacement with GTP. Conversely, GTPase activating proteins (GAPs) enhance the conversion of GTP to GDP, so inactivating the GTPase. It is likely that cadherin-mediated adhesion leads to the activation of GEFs, or perhaps the inactivation of GAPs, for Cdc42 and Rac1. RhoA may be regulated by direct interactions with $p120^{ctn}$.

Wnt/β-Catenin Signaling

In addition to linking the cytoplasmic tails of cadherins to the actin cytoskeleton (see Figure 1), β-catenin is an important component of a signaling pathway involved in both normal development and cancer. Normally, β-catenin molecules not attached to cadherins are degraded in the cytoplasm. When cells are exposed to an extracellular growth factor known as Wnt, β-catenin is protected from degradation and accumulates in the nucleus (Figure 3). There, in association with the TCF/LEF family of DNA-binding proteins, β-catenin activates the transcription of genes that stimulate cell proliferation. Thus, the extent to which β-catenin is "soaked up" by binding to

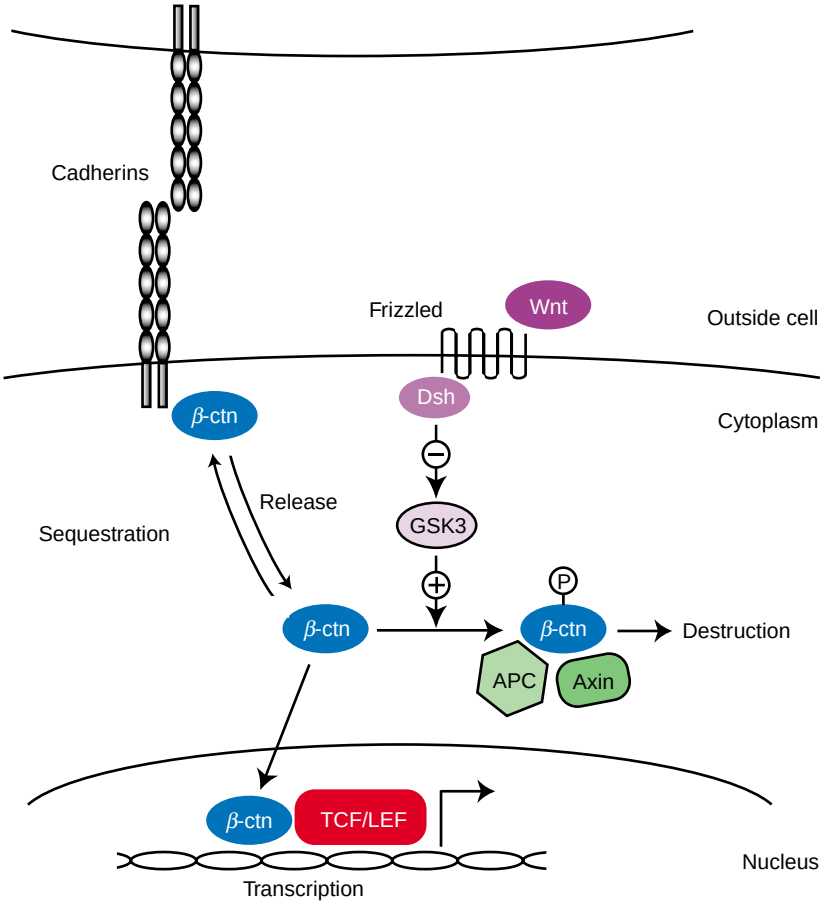

FIGURE 3 Cadherins modulate Wnt/β-catenin signaling. In addition to its role as a component of adherens junctions, β-catenin (β-ctn) increases the activity of the TCF/LEF transcription factor in the nucleus. The extent to which β-catenin accumulates in the nucleus depends in part upon the level of free β-catenin in the cytoplasm. The amount of free β-catenin is normally low due to its phosphorylation by glycogen synthase kinase-3 (GSK3), binding to adenomatous polyposis coli (APC) and Axin proteins, and subsequent destruction (P indicates the added phosphate group). GSK3 activity is decreased by Disheveled (Dsh) when the growth factor Wnt binds to its receptor frizzled on the cell surface. Therefore, Wnt can reduce degradation of β-catenin and increase the amount of β-catenin in the nucleus, thereby promoting transcription. In contrast, the formation of cadherin–cadherin junctions, or an increase in the amount of cadherin, can lead to the sequestration of β-catenin due to its interaction with cadherin tails. In this way, cadherins are thought to decrease the amount of nuclear β-catenin, and act in opposition to Wnt signals.

cadherins can potentially modulate the signal generated by activation of the Wnt pathway. High expression levels of E-cadherin can substantially reduce the amount of free β-catenin, and lower the cellular response to Wnt. In the absence of Wnt, increased adherens junction formation recruits β-catenin, decreasing the nuclear pool of β-catenin, and attenuating β-catenin-mediated transcription. Conversely, disruption of cell–cell adhesion may release β-catenin, thereby enhancing transcription. It is noteworthy that mutations of proteins that regulate turnover of β-catenin have been found in several human cancers.

Phosphorylation and Dephosphorylation

The phosphorylation of proteins (i.e., addition of phosphate groups) by kinase enzymes is a common mechanism for regulating numerous cellular processes. Although the cadherins themselves do not have kinase activity, a number of examples of cross talk have been observed between cadherins and growth factor receptors that contain intrinsic tyrosine kinases (Figure 4). For example, N-cadherin interacts with the fibroblast growth factor receptor FGFR1 and can boost the phosphorylation cascade triggered by binding of fibroblast growth factor-2 to FGFR1. Analogous interactions may occur between E-cadherin and the epidermal growth factor receptor, as well as VE-cadherin and the vascular endothelial growth factor receptor-2. In this way, cadherins can modulate changes in the survival, proliferation and motility of cells in response to a variety of growth factors.

Conversely, phosphorylation can modulate inside-out signals to regulate cadherin activity. The association between growth factor receptor tyrosine kinases and cadherins allows growth factors to promote the phosphorylation of several adherens junction proteins (Figure 4). A number of non-receptor kinases, including Src, also can phosphorylate junction components. Phosphorylation of β-catenin on tyrosine residues is believed to induce dissociation of β-catenin from cadherins and decrease adherens junction stability. Phosphorylation of the cadherins themselves, and of γ-catenin and $p120^{ctn}$, also modulates adherens junction assembly. In particular, the interaction of $p120^{ctn}$ with the cytoplasmic domain of cadherins appears to be an important regulator of cadherin activity, perhaps by influencing the clustering of cadherins in the cell membrane. Cadherins are also found in a complex with selected protein phosphatases. These enzymes, which are activated by cadherins, dephosphorylate (i.e., remove phosphate from) β-catenin, allowing reversible regulation of cadherin adhesive capacity (Figure 4).

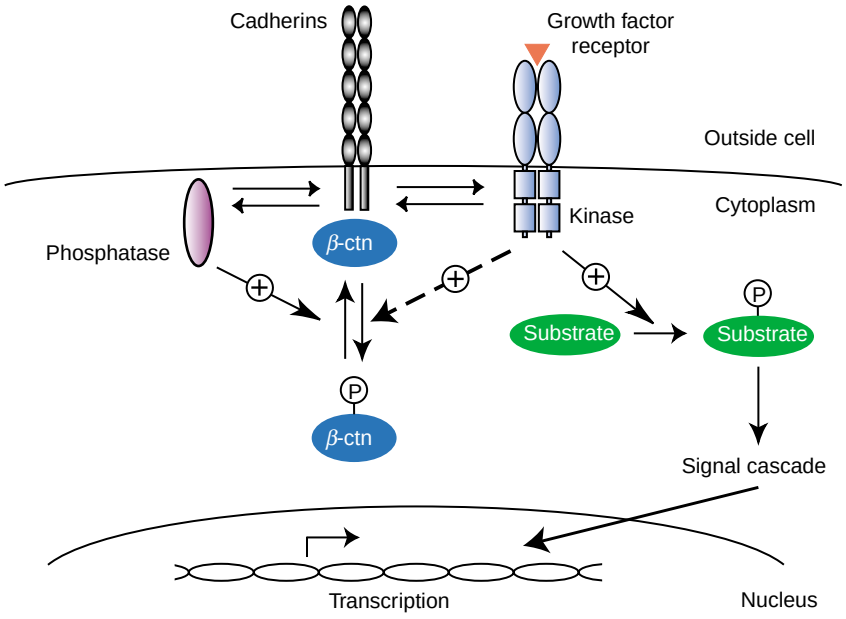

FIGURE 4 Cadherin crosstalk with kinases and phosphatases. Cadherins interact with a number of growth factor receptors that have intrinsic kinase activity. By this mechanism, cadherins can modulate the signaling cascades triggered by growth factors that lead, for example, to the activation of gene transcription. In addition, activation of receptor kinases can promote the phosphorylation on tyrosine residues of β-catenin (dotted line; P indicates the added phosphate group), its dissociation from cadherin tails, and disassembly of the adherens junction (not shown). Cadherins are also found in a complex with a number of protein phosphatases that can dephosphorylate β-catenin. In this way, cadherins can modulate the reversible phosphorylation of adherens junction components that alter the activity of cadherin itself.

Cadherin-Mediated Cell–Cell Adhesion

Frauke Drees and W. James Nelson
Stanford University, Stanford, California, USA

Cell–cell adhesion is the process of establishment and maintenance of contacts between adjacent cells in tissues and organs of multicellular organisms. Cadherins comprise a superfamily of transmembrane glycoproteins that mediate calcium-dependent cell–cell adhesion and are found in all metazoans. Cadherins are involved in a wide variety of biological processes including development, tissue morphogenesis, and tumor metastasis. The cadherin family consists of four major subfamilies: classical cadherins, desmosomal cadherins, protocadherins, and atypical cadherins. Members of the cadherin superfamily share a conserved extracellular, calcium-binding domain (CD repeat) involved in specifying cell–cell adhesion, but the number (5–34) and arrangement of these domains differ between subfamily members.

Cadherin Subfamilies

Classical Cadherins

Classical cadherins comprise a small subfamily of proteins with the simplest, prototypic organization of cadherins: an extracellular domain comprising five EC repeats, a single transmembrane domain, and a conserved cytoplasmic domain that binds specific cytosolic proteins that link cadherins to the actin cytoskeleton. They are also the best understood of all cadherins in terms of structure, mechanism of adhesion, and function. Generally, classical cadherins are expressed in specific tissues, from which they were originally named (e.g., epithelia, E-cadherin; nervous system, N-cadherin; placenta, P-cadherin) although it is now recognized that each is broadly expressed in most tissues. Classical cadherins have been implicated in a variety of developmental processes, particularly in cell sorting during tissue remodeling. They are the major components of adherens junctions, an ultrastructurally defined adhesion site between opposing cells; note that other adhesion proteins such as nectin, a member of the immunoglobulin superfamily of adhesion proteins, have also been shown to localize and contribute to the formation and maintenance of adherens junctions. Classical cadherins mostly form homotypic adhesions between the same type of cadherin on adjacent cells (e.g., E–E, N–N, P–P).

Desmosomal Cadherins

Desmosomal cadherins, termed desmocollin and desmoglein, are found in desmosomes, a structure morphologically distinct from the adherens junction. Desmosomal cadherins have five EC domains, a single transmembrane domain, and a cytoplasmic domain that interacts with cytosolic proteins different from those that bind classical cadherins that link desmosomal cadherins to the intermediate filament network. Desmosomes and desmosomal cadherins are typically found in tissues that have to withstand high mechanical stress, such as epithelia, and are well conserved throughout most higher metazoans, but are absent in flies and worms. There are three subtypes of desmocollins and desmogleins, which are expressed in a tissue- and differentiation-specific manner. Desmosomal cadherins form heterotypic interactions, in contrast to the homotypic interactions of classical cadherins. Desmosomal cadherins can initiate and maintain cell–cell adhesion in the absence of classical cadherins, but adherens junctions containing classical cadherins are generally assembled before desmosomes in development.

Protocadherins

Protocadherins constitute the largest cadherin subfamily, but its members are far less well characterized than either classical or desmosomal cadherins. Protocadherins are highly expressed in the mammalian brain and nervous system. Genomically, they are organized in three large gene clusters with a very large number of exons encoding "variable" extracellular domains, and three exons encoding "constant" intracellular domains; combinations of extracellular and intracellular domains can be assembled to potentially generate thousands of different protocadherins. This has prompted speculation that protocadherin genes might reorganize in a manner

similar to that of immunoglobulins (hence the analogy to immunoglobulin "variable" and "constant" domains), and their resulting diversity might contribute to specifying cell–cell connections during development of the nervous system. This is substantiated by the fact that protocadherins show distinct spatio-temporal expression patterns during brain development. However, a clear role for protocadherins in cell–cell adhesion has not yet been demonstrated.

Atypical Cadherins

Atypical cadherins comprise the fat-like cadherins (e.g., fat, dachsous, two related proteins expressed in *Drosophila*), cadherins with a seven-pass transmembrane domain (e.g., flamingo), protein kinase cadherins, Dcad102F-like cadherins, and T-cadherin. Fat-like cadherins are a heterogeneous subfamily of proteins with very large extracellular domains that contain up to 34 EC repeats, in addition to EGF and laminin-G domains. They have a single transmembrane domain, and the cytoplasmic domains of fat and dachsous have predicted binding sites for cytoplasmic proteins that bind classical cadherins. The seven-pass transmembrane cadherins, such as flamingo, were first identified in *Drosophila*. The extracellular domain contains eight or nine EC domains and EGFR- and laminin-like domains, and mediates homotypic cell–cell adhesion. Amino acid sequence analysis predicts seven transmembrane domains, which show similarity to G protein-coupled receptors (GPCR). The cytoplasmic domain is different from those of classical and fat-like cadherins, and interacting cytosolic proteins have not been found, but due to their similarity to GPCR, flamingo-like cadherins have been implicated in cell signaling pathways. In *Drosophila*, flamingo-like cadherins are required for establishment of planar cell polarity. T-cadherin differs from all other cadherins because it lacks transmembrane or cytosplasmic domains, but instead associates with the membrane via a glycophosphidylinositol-anchor that inserts directly into the outer leaflet of the plasma membrane lipid bilayer. T-cadherin can mediate calcium-dependent cell–cell adhesion, but does not cluster in cell–cell contacts. T-cadherin has been implicated in signaling events and might constitute a negative guidance cue for neurons in the nervous system. Little is known about the other members of this subfamily, protein kinase cadherins, and Dcad102F-like cadherins.

Regulation of Cadherin Adhesion: Role of the Extracellular Domain

Although it is broadly accepted that the main role of cadherins is to mediate adhesion between cells, the exact mechanism of how the adhesive contact forms is not fully resolved. Analysis of this problem has focused primarily on the classical cadherins: N- and E-cadherin. Classical cadherins are believed to form two types of dimers, lateral or *cis*-dimers between two cadherin molecules on the same cell, and *trans*-dimers between cadherins on opposite cells (Figure 1).

Mechanisms of Cadherin Specificity in Cell Sorting

Specificity of adhesion appears to be determined in two ways. Early cell-sorting experiments showed that when two cell lines expressing N- and E-cadherin were mixed the cells sorted out and formed separate aggregates each of which expressed the same cadherin. In this case, homotypic *trans* adhesion between extracellular domains of the same cadherins appears to mediate adhesion specificity. The specificity for homotypic recognition is thought to be encoded in the EC1 extracellular domain, because when the EC1 domain of N-cadherin is swapped onto EC domains 2–5 of E-cadherin for example, the resulting chimeric protein sorts like N-cadherin in the experiments described earlier. More recent experiments showed that cells also sort from each other in aggregates formed between cells expressing different levels of the same cadherin. Thus, cell sorting may also be mediated by differences in adhesion strength that is proportional to the amount of cadherin expressed. The exact mechanism involved in adhesion specificity remains to be elucidated, but it will probably be a combination of spatio-temporal expression patterns of different cadherins, as well as differences in adhesive properties (strengths) between different cadherins.

Extracellular Domain Structure (*cis*- and *trans*-Dimers)

These early studies indicated that the outermost, N-terminal cadherin domain (EC1) is important in adhesion of E- and N-cadherin, and that a specific tripeptide, histidine–alanine–valine (HAV), and a conserved trytophan residue at position 2 (W2) in EC1 formed cadherin-binding motifs. Short peptides comprising the HAV sequence block adhesion in cell aggregation assays, and mutations of W2 also decrease adhesion. Both the EC1 domain and the EC1–EC2 domain of E- and N-cadherin have been crystallized. The crystal structures reveal that EC domains comprise an immunoglobulin-like fold with a seven-strand β-sheet, and that 6 Ca^{2+}-ions associate with residues in the linker region between EC1 and EC2. Calcium binding stabilizes the extracellular domain into a rigid bent rod-like structure that is resistant to proteolytic

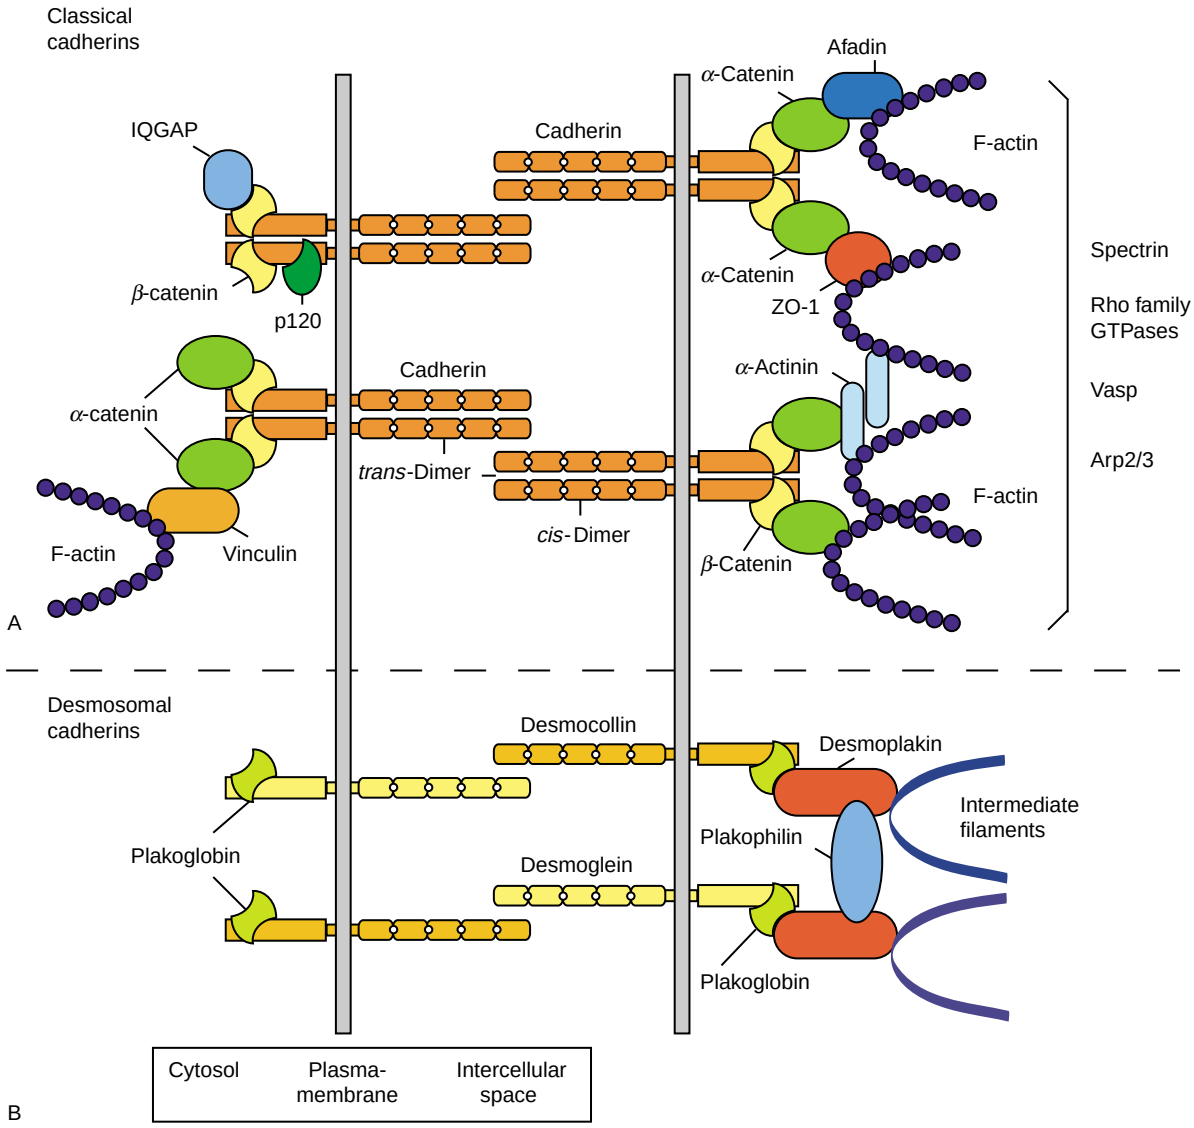

FIGURE 1 Schematic model of the linkage of protein–protein interactions between cadherins and cytoplasmic proteins. (A) Classical cadherins form *cis*- and *trans*-dimers to mediate Ca^{2+}-dependent adhesion. The cytoplasmic domain interacts directly with p120 and β-catenin. β-catenin in turn binds α-catenin, which links the complex to the actin cytoskeleton both directly through interaction with actin filaments and indirectly through the actin-binding proteins vinculin, ZO-1, α-actinin, and afadin. Other actin-associated proteins such as Rho-family GTPases, Vasp, Arp2/3, and spectrin have been shown to localize at adherens junctions, but the molecular nature of their interactions is less well defined. IQGAP binds β-catenin and has been suggested to negatively regulate adhesion by causing α-catenin to dissociate from β-catenin. (B) The desmosomal cadherins, desmocollin and desmoglein, form heterodimers and are linked to the intermediate filament network through interaction with plakoglobin, desmoplakin, and plakophilin.

cleavage, which may explain why cadherin adhesion is dependent on extracellular Ca^{2+}. Several models have been proposed for *cis*- and *trans*-dimerization. Mechanisms involved in *cis*-dimerization are poorly understood. Early models favored *trans*-dimerization through interaction between two opposing EC1 domains, but biophysical studies argue for *trans*-interaction involving contact between several EC domains. Further analysis of cadherin extracellular domains and their interactions will be required to resolve the mechanism of interaction and adhesion.

Regulation of Cadherin Adhesion: Role of the Cytoplasmic Domain

Linkage To β-Catenin Family Members

Classical and desmosomal cadherins are linked to the cytoskeleton via their intracellular domains through a class of cytosolic proteins collectively called catenins: β-catenin, plakoglobin (γ-catenin), and p120 (Figure 1). There are different binding sites on the cadherin

cytoplasmic domain for p120 catenin, and β-catenin and plakoglobin. p120 interacts directly with the juxtamembrane region of the cadherin intracellular domain, but its role in adhesion is not clearly defined; it may negatively modify adhesive strength of cadherin interaction, or regulate cadherin clustering. β-catenin and plakoglobin bind a conserved C-terminal domain of classical cadherins in a mutually exclusive manner and, in turn, interact with α-catenin to link the complex to the actin cytoskeleton (Figure 1). Desmosomal cadherins also bind plakoglobin, but not β-catenin; plakoglobin in turn binds cytosolic proteins termed plakophillin and desmoplakin that link desmosomal cadherins to the intermediate filament cytoskeleton (Figure 1). How different catenins specifically bind to different members of the cadherin superfamily is poorly understood, but it may be dependent on structural recognition between different β-catenin family members and the cytoplasmic domain of different cadherin subtypes.

Linkage to the Cytoskeleton

When cells initiate cell–cell contact, additional proteins are rapidly recruited to the cadherin-β-catenin/plakoglobin-α-catenin complex, which results in clustering of cadherins and strengthening of cell–cell adhesion. α-catenin binds directly to actin filaments, but also interacts with several actin-binding proteins including α-actinin, vinculin, ZO-1, and afadin (Figure 1). Afadin also binds the transmembrane adhesion protein nectin, which is localized with cadherins to the adherens junction, thereby interlinking the cadherin and nectin adhesion complexes. Other proteins such as VASP, IQGAP, fodrin, and members of the Rho family of small GTPases are localized to cadherin-based adhesion junctions and these proteins may further regulate actin assembly and organization at sites on the plasma membrane involved in cadherin-mediated adhesion (Figure 1). The importance of these cytosolic proteins to cell–cell adhesion is illustrated by the fact that α-catenin-deficient tumor cell lines or cell lines expressing E-cadherin lacking the intracellular domain adhere very poorly despite the expression of E-cadherin and other adherens junction proteins. Reintroduction of α-catenin causes these cells to form fully developed adhesion junctions.

Regulation by Phosphorylation

Cadherin complex assembly and disassembly is a highly regulated process. Both cadherin and β-catenin can be phosphorylated on serine/threonine and tyrosine residues, which modifies their binding affinity for each other. Serine/threonine phosphorylation by casein kinase II increases the binding affinities between cadherin/β-catenin and β-catenin/α-catenin, thereby stabilizing the cadherin/catenin complex and strengthening adhesion. Conversely, tyrosine-phosphorylation of either cadherin or β-catenin appears to destabilize the adhesion complex and weaken adhesion.

Functions in Signaling

In addition to the role as linkers between cadherins and the cytoskeleton, β-catenin, plakoglobin and p120 function as co-activators of gene transcription with members of the LEF/Tcf family of transcription factors in the Wnt/*wingless* pathway. Whether functions of β-catenin in the cytoplasm (cell–cell adhesion) and nucleus (gene expression) are interchangeable or separate is not known.

Roles of Cadherins in Cell and Tissue Morphogenesis

Classical cadherins are essential for embryonic development and have long been implicated in cell sorting, and in tissue formation and integrity. As noted above, two cell populations expressing different types, or protein levels of cadherins form separate aggregates when mixed together, and in development cell populations sort from one another by the same mechanism. To obtain evidence of morphogenic roles of cadherin in development, several cadherin genes have been deleted (Table I). E-cadherin knockout mice exhibit the most severe phenotype with very early lethality due to inability of pre-implantation embryos to fully compact and to develop into blastocysts. The N-cadherin knockout results in embryonic death at embryonic days 9–10 due to heart defects and malformation of the neural tube. In contrast, P-cadherin knockout mice are viable and fertile with only slight abnormalities in mammary glands. This demonstrates that while specific cadherins are important in development and morphogensis, some cadherins can be substituted by another. While the phenotype of the E- and N-cadherin knockout mice can be explained by adhesion defects, it is an open question as to whether there are defects in induction of tissue differentiation due to lack of a specific cadherin. In this context it is noteworthy that embryonic stem (ES) cells derived from E-cadherin −/− embryos form different tissues depending upon which cadherin is used to rescue cell–cell adhesion. When injected subcutaneously into mice, wild-type ES cells form benign teratomas that are highly differentiated and show a variety of tissue subtypes. By contrast, the E-cadherin null ES cells formed teratomas with no organized tissue structures. Interestingly, null cells rescued with overexpressed E-cadherin formed teratomas of almost exclusively epithelia, whereas overexpression of N-cadherin in the

TABLE I

Effects of Gene Deletions of Selected Cadherins and Adherens Junction Components on Mouse Development

Gene/protein	Subfamily	Genetic defect	Phenotype
E-cadherin	Classical cadherin	Knockout, deletion of extracellular Ca^{2+}-binding and adhesion motif	Embryonic lethal at time of implantation, embryonic compaction occurs, probably due to maternally deposited E-cadherin, but embryos fail to form trophectoderm or blastocyst cavity.
N-cadherin	Classical cadherin	Knockout	Embryonic lethal E9–10, major heart defects and malformed neural tube and somites.
P-cadherin	Classical cadherin	Knockout	Viable and fertile, despite high expression of P-cadherin in placenta. Virgin P-cadherin-null females exhibit precocious differentiation of mammary gland. Hyperplasia and dysplasia of mammary epithelium with age.
R-cadherin	Classical cadherin	Knockout	Viable and fertile, dilated proximal kidney tubules, defects in development of ureteric bud- and metanephric-mesenchymal-derived cells during nephrogenesis.
Cadherin-6	Classical cadherin	Targeted gene disruption (deletion of membrane targeting sequence)	Viable and fertile, transition of fraction of mesenchymal aggregates into epithelial structures in nephrogenesis is delayed.
β-Catenin	AJ component	Knockout	Embryonic lethal E7–9, at day 7 cells detach from ectodermal cell layer, the three germlayers and amniotic folds fail to form, and epithelial organization of ectoderm is completely lost.
Desmocollin Dsc1	Desmosomal cadherin	Knockout	Normal at birth, epidermal fragility and barrier defects, hyperproliferation and abnormal differentiation of epidermis, hair loss, hair follicle degeneration, mice develop ulcerating lesions resembling chronic dermatitis.
Desmoglein Dsg3	Desmosomal cadherin	Knockout	Normal at birth, disintegration of epidermis (Acantholysis), hair loss, runting (probably due to oral lesions). Phenotype resembles pemphigus vulgaris (caused by autoantibodies against Dsg3).
Desmoplakin	Desmosome component	Knockout	Embryonic lethal E6.5 due to defects in extra-embryonic tissues and failure of egg-cylinder expansion, abnormal desmosomes. Animals rescued with wild-type chimeras in extra-embryonic tissue die at E10 with major defects in heart muscle, neuro-, and skin epithelium.
Plakoglobin	Desmosome component	Knockout	Embryonic lethal E10.5–15 due to heart failure. Reduction in number and size of desmosomes and abnormal structure. Some genetic backgrounds delayed embryonic lethality, epidermal blistering.

ES cells led to the formation of neuroepithelia and cartilage in the teratomas.

A crucial and reoccurring step during development and tissue morphogenesis is the role of cell–cell adhesion in the structural and functional polarization of cells. One example is the development of polarized epithelial cells. Cadherin-mediated cell–cell adhesion between simple epithelial cells generates a cell monolayer that separates two biological compartments and regulates homeostasis by vectorial transport of ions and solutes between those compartments. This function requires cells to generate and maintain two functionally and structurally distinct plasma membrane domains, termed apical and basal-lateral, which face these different compartments. Cell–cell adhesion initiates structural and biochemical asymmetries at the cell membrane, through assembly of cytoskeleton and vesicle docking complexes that initiate formation of the (basal-) lateral membrane domain. Studies in *Drosophila* have shown that cadherins play additional roles in establishing planar polarity of ommatidia in the eye and wing hairs (fat-like cadherins), and a role for cadherins in migration has been proposed in oocyte border cell migration.

Consequences of Disruption of Cadherin Functions: Disease States and Cancer

Loss of cell–cell adhesion, changes in cytoskeletal organization, and aberrant adhesion-mediated signaling are hallmarks of malignant transformation, tumors, and cancer. Disruption of cell–cell adhesion might contribute to increased proliferation and migration of tumor cells, thereby leading to invasion of surrounding tissue and metastasis. Alterations of cadherin-mediated cell–cell adhesion arise mainly through three mechanisms: loss of adhesion complex function, most commonly through inactivation of E-cadherin or α-catenin expression or function; aberrant cadherin function due to "cadherin switching"; and changes in cell signaling through cadherins or catenins (Table I).

First, inactivating mutations in the E-cadherin gene CDH1 are frequently found in certain carcinomas such as gastric or breast lobular carcinomas, and germ-line mutations in CDH1 strongly predispose individuals to gastric cancer. Loss of E-cadherin expression requires inactivation of both CDH1 alleles, as would be expected for a tumor suppressor gene, and reintroduction of E-cadherin into tumor cell lines can reverse transformation from an invasive to a benign, epithelial tumor cell phenotype in culture. In addition to genetic mutation or gene deletion, down-regulation of E-cadherin at the transcriptional level has been observed in certain tumors, for example through DNA hypermethylation of the CDH1 promoter and/or up-regulation of transcriptional repressors of E-cadherin.

Second, up-regulation of nonepithelial cadherins, such as N-cadherin and cadherin-11, either with or without loss of E-cadherin, may contribute to the transformation and invasiveness of tumor cells. This change in cadherin expression pattern is termed "cadherin switch" and has been found in primary tumors. In tissue cancer cell lines, it causes an epithelial to fibroblast-like transition of cellular phenotype.

Third, alterations in cell signaling pathways through cadherins or catenins contribute to cancer formation. Mutations in β-catenin generally inhibit β-catenin degradation and thereby inappropriately activate the Wnt signaling pathway. In addition, tyrosine phosphorylation of E-cadherin and β-catenin destabilizes the adhesion complex and, therefore, changes in this signaling pathway, for example by activation of tyrosine kinases, might contribute to tumor cell invasiveness by decreasing the amount of cell–cell adhesion.

Mutations in desmosomal cadherins and other protein components of desmosomes, such as plakoglobin or plakophilin, give rise to specific diseases of the skin and, in some cases, heart defects, thereby illustrating the importance of desmosomal adhesion in tissues exposed to high mechanical stress. Patients with the skin conditions Darier–White and Hailey–Hailey disease suffer from defects in keratinocyte adhesion due to breakdown of desmosomal adhesion. In the blistering diseases pemphigus vulgaris and pemphigus foliaceus, which affect skin and mucous cell membranes, auto-immune antibodies against desmoglein 1 and 3, respectively, interact with the extracellular domain of these cadherins, thereby functionally blocking adhesion and leading to the disassembly of desmosomes in the skin.

In summary, the cadherin superfamily of adhesion proteins plays important roles in development, and cellular reorganization and polarization, and abnormalities in cadherins and associated proteins are characteristic of disease states and cancer. While cadherins are known to regulate calcium-dependent cell–cell adhesion, and many associated proteins that link cadherins to the cytoskeleton have been identified, there remain many unanswered questions about the way cadherins form cell–cell contacts, regulate assembly of the cytoskeleton, and determine cell differentiation.

Glossary

adaptor proteins Cytosolic proteins that link protein complexes together and allow for regulation of physiological responses. In the example of cell adhesion proteins, adaptor proteins (catenins) provide the linkage between cell adhesion transmembrane proteins and the cytoskeleton.

cell–cell adhesion Process of establishment and maintenance of contacts between adjacent cells in tissues and organs of multicellular organisms.

cell–cell adhesion molecules Transmembrane glycoproteins that mediate cell–cell binding. There are three major protein families: selectins, immunoglobulin superfamily, and cadherins.

cell–cell junctions Specialized regions on the cell surface by which cells are joined to each other. Tight junctions in epithelial cell layers form a ribbon-like seal between compartments. Gap junctions are protein-lined channels between two cells that allow diffusion of small molecules from one cell to the next. Adherens junctions and desmosomes are dense protein plaques connected to cytoskeletal networks that link two adjacent cells together.

cytoskeleton Network of fibrous proteins found in the cytosol of eukaryotic cells that provides structural support for the cell, determines cell shape and motility, and allows directional movement of organelles and vesicles inside the cell. There are three major classes of cytoskeletal filaments: actin microfilaments, microtubules, and intermediate filaments.

Biography

W. James Nelson is the Rudy J. and Daphne Donohue Munzer Professor in the School of Medicine, Professor of Molecular and Cellular Physiology, and Biological Sciences (by courtesy). Professor Nelson's research focuses on basic cellular mechanisms involved in generating cell asymmetry, particularly in epithelia and neurons. His research has uncovered a hierarchy of cellular events initiated by cell–cell adhesion that leads to cellular remodeling and the generation of structurally and functionally polarized cells.

Calcitonin Gene-Related Peptide and Adrenomedullin Receptors

Debbie L. Hay, Alex C. Conner and David R. Poyner
Aston University, Birmingham, UK

Calcitonin gene-related peptide (CGRP) and adrenomedullin are abundant, related peptides that share many biological actions. Most prominently, both are very potent vasodilators. CGRP is a neurotransmitter in sensory neurons and adrenomedullin is a hormone that is locally released from tissues including vascular endothelium and smooth muscle. Together with calcitonin and amylin, they form a peptide family. For some time, there was considerable controversy about the nature of the receptors for this family. It has been established that they define a new paradigm among G protein coupled receptors (GPCRs), in that they are heterodimers of a seven-transmembrane-spanning protein that resembles a classical GPCR and a member of the single-transmembrane-spanning receptor activity-modifying protein (RAMP) family. Although there is still much to be learned, this discovery has clarified the pharmacology of these peptides and may have implications for other GPCRs.

The Pharmacology of CGRP and Adrenomedullin

The Structure of CGRP and Adrenomedullin

The primary sequences of CGRP and adrenomedullin (Figure 1) share a low level of homology but the secondary structure of these peptides is conserved. For both peptides, an amino-terminal ring is important for receptor activation; peptides that lack this structure ($CGRP_{8-37}$ and $adrenomedullin_{22-52}$) are antagonists.

The Pharmacology of Endogenous CGRP and Adrenomedullin Receptors

CGRP Receptor-Selective Drugs and their Pharmacological Properties

There are few high-affinity, selective drugs that can be used to define CGRP and adrenomedullin receptors. For CGRP, the only widely available antagonist is $CGRP_{8-37}$. This has only limited selectivity. A number of high-affinity nonpeptide antagonists have been developed. The most interesting of these appears to be BIBN4096BS (Figure 2), which shows marked selectivity for primate over rodent CGRP receptors and has very little affinity for non-CGRP receptors. Largely on the basis of work with $CGRP_{8-37}$, it has been suggested that CGRP receptors should be divided into two subtypes. $CGRP_1$ receptors have a high affinity for $CGRP_{8-37}$ ($pA_2 > 7$); $CGRP_2$ receptors have a lower affinity for this antagonist. A number of linear CGRP analogues have been suggested to be $CGRP_1$-selective agonists, but their usefulness has been questioned.

The $CGRP_1/CGRP_2$ classification has proved controversial. $CGRP_{8-37}$ reveals marked heterogeneity in receptors that respond to CGRP in assays of physiological function. However, this is not apparent in radioligand-binding studies. The heterogeneity may reflect the existence of bona fide receptor subtypes, it may be due to cross-reactivity of CGRP at receptors for other peptides, or it may be caused by other factors,

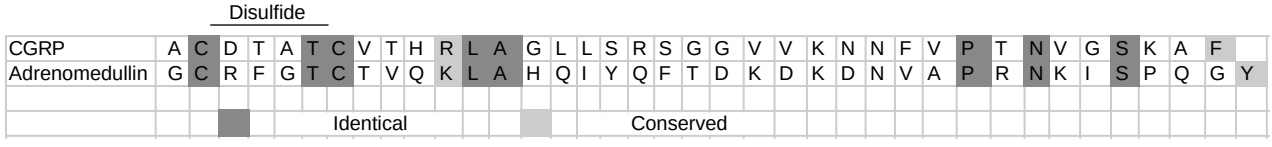

FIGURE 1 A comparison of the structure of human CGRP and $adrenomedullin_{15-52}$. Note the disulfide bond in both peptides, indicated by a bar over the sequences. The first 14 amino acids of adrenomedullin are not required for biological activity and are not shown.

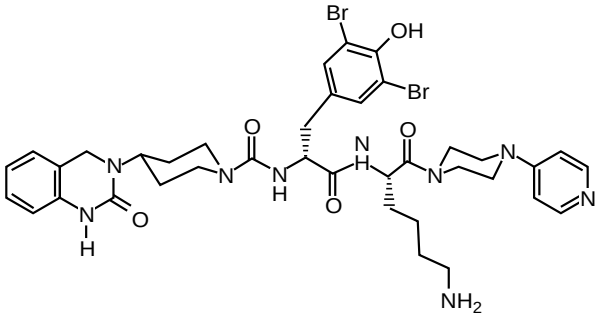

FIGURE 2 The structure of BIBN4096BS.

such as differential peptidase activity. The issue is likely to be resolved with progress in the molecular characterization of CGRP receptors hand-in-hand with the development of CGRP antagonists.

Adrenomedullin-Selective Drugs and their Pharmacological Properties

The only adrenomedullin antagonist that has been widely used is adrenomedullin$_{22-52}$. This is not particularly potent ($pA_2 \sim 7$) and does not antagonize all adrenomedullin-mediated responses. Nonetheless, it has proved useful in some circumstances in defining adrenomedullin receptors.

The Molecular Structure of CGRP and Adrenomedullin Receptors

CRLR and RAMPs

CGRP and adrenomedullin receptors display a very unusual molecular architecture. Both are composed of a common seven-transmembrane-spanning protein called calcitonin receptor-like receptor (CRLR or CL; Figure 3). This is a member of the B-family of GPCRs (related to other receptors, such as those for secretin and calcitonin). Human CRLR is 461 amino acids long and has 55.5% sequence identity with the human calcitonin receptor. It has three potential glycosylation sites, although only two appear to be utilized in the mature protein. By itself, CRLR does not function as a receptor for any peptide. However, when associated in a dimer with a RAMP, it functions as a high-affinity receptor for either CGRP or adrenomedullin. The RAMPs are a family of three proteins (Figure 4), each with an extracellular amino terminus of approximately 100 amino acids, a single transmembrane section, and a very short carboxy terminus of approximately 10 amino acids.

CRLR/RAMP1; A CGRP$_1$ Receptor

CRLR and RAMP1 associate intracellularly and this facilitates their transport to the cell surface. There, the heterodimer functions as a CGRP$_1$ receptor, with a high affinity for CGRP, CGRP$_{8-37}$, and BIBN4096BS. The complex binds adrenomedullin with an approximately 10-fold lower affinity than CGRP. Little is known about the mechanism of ligand binding and receptor activation. CGRP can cross-link to both CRLR and RAMP1, showing that both components create the peptide-binding site. However, it is not clear whether CGRP has specific contacts with both proteins or whether RAMP1 indirectly contributes to the ligand-binding site by modifying the structure of CRLR. Based on studies with other members of the B-family of G protein coupled receptors, it is likely that CGRP makes contacts with both the extracellular domain of CRLR/RAMP1 and the membrane–extracellular loop interfaces of CRLR. The selectivity of BIBN4096BS for primate over rodent CGRP receptors is due to a single amino acid at position 74 in RAMP1; this is tryptophan in humans and lysine in rats.

CRLR/RAMP2 and CRLR/RAMP3 are Adrenomedullin Receptors

The heterodimers formed by RAMP2 and RAMP3 with CRLR produce adrenomedullin receptors. Their formation is very similar to that of the CRLR/RAMP1 complex; in the absence of CRLR, they are not expressed at the cell surface. It was initially thought that RAMP2 might work by modulating the glycosylation state of CRLR. However, it is now thought that adrenomedullin and CGRP both bind to the fully glycosylated form of CRLR. As with the CRLR/RAMP1 complex, there is little detailed information on mechanisms of adrenomedullin binding to either the CRLR/RAMP2 or the CRLR/RAMP3 complexes. Both complexes exhibit higher affinity for adrenomedullin than CGRP. It has been proposed that the CRLR/RAMP2 complex should be designated as the AM$_1$ receptor and the CRLR/RAMP3 complex as the AM$_2$ receptor. The CRLR/RAMP2 complex has high affinities for adrenomedullin and adrenomedullin$_{22-52}$ but low affinity for CGRP. The CRLR/RAMP3 complex has not been extensively characterized but has high affinity for adrenomedullin and an intermediate affinity for CGRP, leading to the suggestion that it may function as a mixed adrenomedullin/CGRP receptor.

Cellular Signaling and RCP

The CRLR/RAMP complexes all couple to stimulation of adenylate cyclase production via the G protein known as G_s. However, as is the case with many related GPCRs,

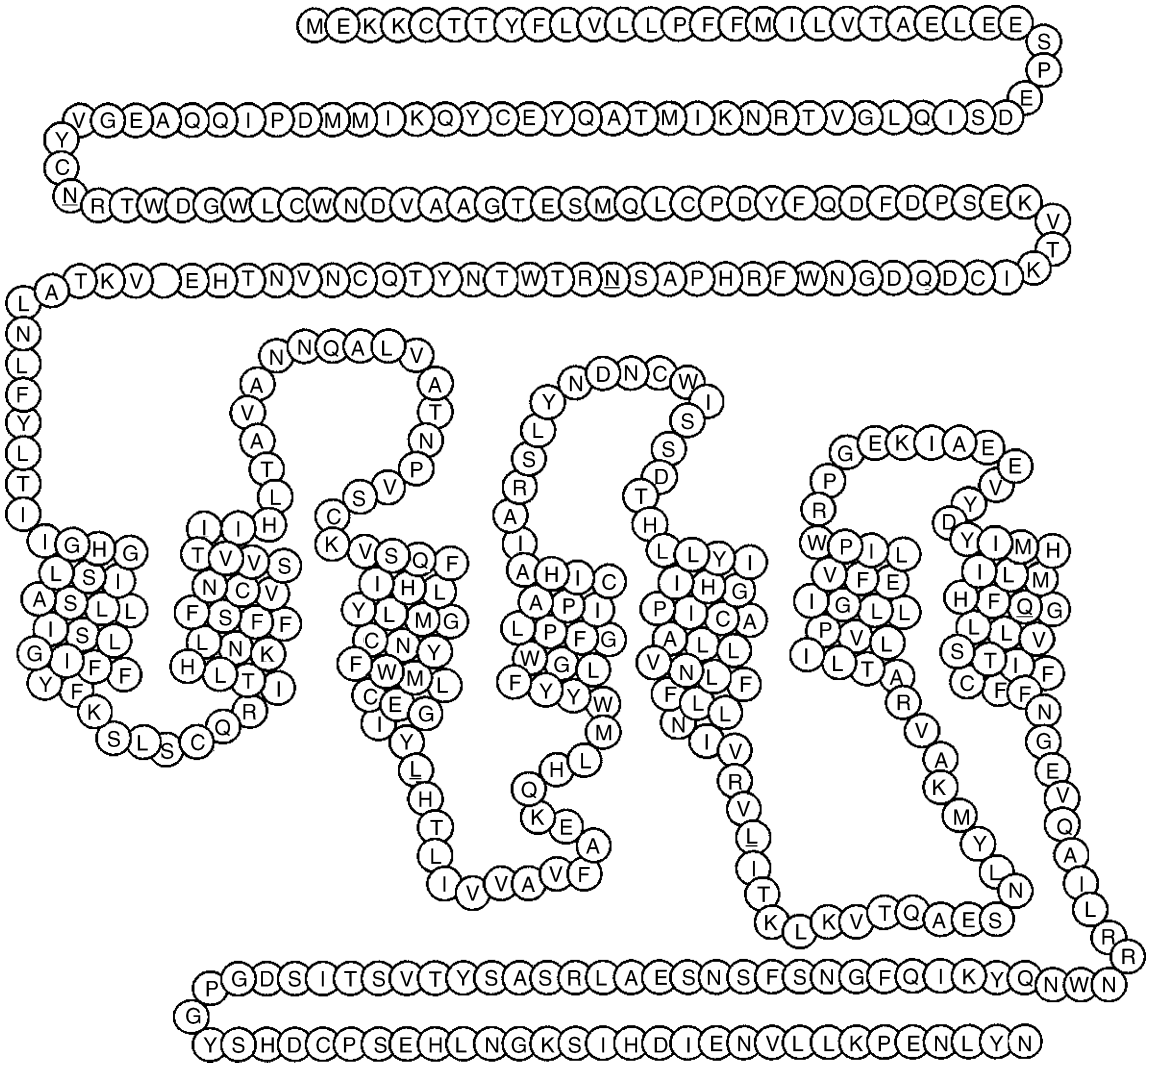

FIGURE 3 The structure of human CRLR, showing the postulated seven-transmembrane helices. The residues that are likely glycosylation sites on the amino terminus are underlined.

coupling to G_i/G_o and the G_q family of G proteins (leading to changes in ion channel activity and elevation of intracellular calcium) has also been reported.

A novel protein called receptor component protein (RCP) is reportedly essential for coupling the CRLR/RAMP complexes to stimulation of G_s. Immunoprecipitation studies suggest that RCP is physically associated with the CRLR/RAMP heterodimer. It has been reported that inhibiting RCP expression disrupts signaling mediated via CRLR/RAMP complexes. RCP is very widely distributed in cell lines but a broader role has not yet been demonstrated.

Other Receptors that Respond to CGRP and Adrenomedullin

There is pharmacological evidence for heterogeneity among endogenous receptors for both CGRP and adrenomedullin. However, the molecular basis for this remains unclear. Adrenomedullin receptor heterogeneity may be explained at least in part by CRLR/RAMP2 and CRLR/RAMP3 dimers. As the CRLR/RAMP3 complex shows appreciable affinity for CGRP, it may also contribute to the appearance of $CGRP_2$-like pharmacology. RAMPs can also dimerize with calcitonin receptors. These complexes are usually considered to be amylin receptors; however, the RAMP1-containing dimer shows an appreciable affinity for CGRP. In addition, the presence of completely novel receptors for CGRP and adrenomedullin cannot be excluded.

The Distribution and Physiology of CGRP and Adrenomedullin Receptors

The Distribution of Binding Sites for CGRP and Adrenomedullin

CGRP-binding sites are present in both the central nervous system (CNS) and peripheral tissues. In some of the earlier literature, there was confusion due to cross-labeling of what would now be considered amylin receptors. Specific CGRP receptors show the potency order: CGRP > adrenomedullin > amylin. In the rat CNS, the highest densities of CGRP binding are in the nucleus accumbens, caudate putamen, amygdaloid body, pontine nuclei, cerebellum, spinal cord, and inferior olive. In the periphery, CGRP receptors are particularly associated with the cardiovascular system, on blood vessels and in the atria. There are high densities of these receptors in the spleen. However, receptors are also found on nonvascular cells, for example, in the vas deferens and secretory cells in the gastrointestinal tract. In tissues, adrenomedullin receptors show a high level of specificity for adrenomedullin over CGRP or other peptides. Binding in the CNS is highest in the spinal cord, but moderate to low levels are seen in many other brain regions. In the periphery, it is closely associated with the cardiovascular system, with very high levels in the heart and lungs.

Distribution of RAMPs and CRLR

Almost all information on the distribution of CRLR and RAMPs comes from mRNA measurements. Generally, there is fair agreement between the distribution of RAMPs and CRLR and binding sites for CGRP and adrenomedullin. Often RAMP2 appears to be more abundant than RAMP1, with RAMP3 being expressed at the lowest levels. However, there are many exceptions; RAMP1 is the most abundant transcript in the brain and the pancreas and RAMP3 predominates in liver. There are some anomalies; the nucleus accumbens has strong CGRP binding and RAMP1 expression but little CRLR; by contrast, the frontal cortex has very little binding for CGRP, adrenomedullin, or amylin, but has high levels of RAMP expression. It is unclear whether this reflects problems of inferring protein expression from mRNA abundance or whether it indicates additional complexity in the field. There is some preliminary evidence that RAMPs can associate with other receptors in addition to those for calcitonin and CRLR.

Changes in Expression of CGRP and Adrenomedullin Receptors

There is good evidence for changes in CGRP and adrenomedullin receptors during various (patho)physiological processes. For example, adjuvant-induced arthritis in rats leads to a decrease in CGRP binding in the spinal cord. Changes in CRLR and RAMP expression have also been noted in disease. In a mouse model of sepsis, CRLR mRNA and RAMP2 mRNA show large decreases but RAMP3 expression increases in the lung. In a rat model of ischemic heart failure, RAMP2 expression is increased in the ventricles.

The Pathophysiology of CGRP and Adrenomedullin Receptors

Changes in receptor expression suggest that both CGRP and adrenomedullin receptors are of importance during normal physiological processes and also in disease. Although receptor knockout models have not yet been described, mice in which the gene for adrenomedullin has been inactivated die *in utero*, showing gross defects in their cardiovascular systems. Heterozygote knockout mice, in which adrenomedullin

production has been reduced, show an elevated blood pressure. Thus, adrenomedullin appears to be vital for normal operation of the cardiovascular system. Similar studies on αCGRP-deficient mice have produced less dramatic effects, although some workers have noted an increased blood pressure, decreased pain sensitivity, and reduced hypersensitivity to antigens in airways. The data are consistent with roles for CGRP in the cardiovascular system and also as an inflammatory mediator, involved in pain perception and the activation of cells of the immune system. Adrenomedullin and CGRP receptors are potentially important therapeutic targets in cardiovascular and inflammatory diseases.

Biography

David Poyner is a Senior Lecturer in Pharmacology at Aston University. Debbie Hay and Alex Conner are postdoctoral fellows at the same institute. The Aston group has been researching the pharmacology of CGRP and adrenomedullin for over 10 years and in that time has produced over 40 publications in these fields.

Calcitonin Receptor

Samia I. Girgis, Niloufar Moradi-Bidhendi, Lucia Mancini and Iain MacIntyre
Imperial College and William Harvey Research Institute, London, UK

The calcitonin receptor (CTR) is a cell-surface receptor on which the peptide hormone calcitonin binds with high affinity to exert its bio-effects. Calcitonin (CT) has a wide range of effects, the most obvious of which is its effect on bone. CT is a powerful inhibitor of bone resorption. It directly inhibits the activity of the osteoclast (special bone cell responsible for bone resorption). CT receptors are widely distributed and CT has a much broader range of biological activities, including the effects on the central nervous system (CNS), gastrointestinal tract, and vascular and immune systems. Peptides that are structurally similar to CT, known as the CT peptide family bind with lower affinities to the CT receptors. The CTR has seven transmembrane-domains, and belongs to the G protein-coupled family of receptors (GPCRs).

Calcitonin Peptide Family

The calcitonin family of peptides comprises five known members, which are structurally similar (Figure 1). They have some overlapping biological effects due to cross-reactivity at each other's receptors. The CT peptide family includes calcitonin, two calcitonin gene-related peptides, amylin, and adrenomedullin, which are discussed next.

Calcitonin

Calcitonin (CT) is a peptide hormone secreted mainly by special type of cells within the thyroid gland in mammals, called C cells. CT was first identified as a calcium-lowering factor. This calcium-lowering effect of CT is mainly due to inhibition of osteoclast activity, and to a lesser extent to increasing calcium excretion by the kidney. As mentioned previously, CT also has a wide range of biological activities, including its analgesic effect, suppression of gastric acid secretion, and appetite.

Two Calcitonin Gene-Related Peptides (CGRP 1 and CGRP 2)

These are neuropeptides widely distributed throughout the CNS and in peripheral nerves associated with the cardiovascular system. The tissue distribution suggests a role in the transmission of sensory impulses and in the regulation of vascular tone. Both are very potent vasodilators.

Amylin

This is found in secretory granules in β-cells of the pancreas (cells that secrete insulin) and is co-secreted with insulin in response to a high blood glucose, e.g., after a meal. Amylin is a potent inhibitor of gastric emptying and food intake. It also opposes the metabolic actions of insulin in skeletal muscle.

Adrenomedullin (ADM)

This is produced predominantly by the vascular endothelium. It is a potent vasodilator.

The CT Receptor (CTR)

Distribution

Calcitonin receptors (CTRs) are widely distributed. They are particularly numerous in osteoclasts, where there are $\sim$1.3 million receptors per cell. They are found in lower amounts in the CNS, in areas involved in the control of appetite, pain perception, and lactation, e.g., hypothalamus and pituitary. CTRs are also found in peripheral tissues, e.g., in cells of the distal nephron of the kidney, testes, placenta, lung, prostate, and lymphocytes. Receptors for CT have been identified in some human cancer cells, including those of lung, breast, bone, and prostate.

Protein Structure

The CTR was initially cloned from a pig kidney cell line. Analysis of the predicted 482 amino acid sequence demonstrated seven hydrophobic regions that could generate transmembrane (TM)-spanning domains. The CTR is a member of a subset of the G protein-coupled receptors (GPCRs) family termed GPCR$_B$. Members of this family typically recognize regulatory peptides, including parathyroid hormone (PTH), glucagon, and secretin.

FIGURE 1 The CT peptide family. The peptides share a six/seven amino acid ring structure, formed by a disulphide bridge at or close to the N terminus. The peptides also have C-terminal amides, which are essential for full biological activity. (This material is from Calcitonin Gene-related Peptide (CGRP), Girgis, S. I., and MacIntyre, I. (2002). In *Encyclopedia of Molecular Medicine* (T.E. Creighton ed.), Vol. 5, John Wiley & Sons Inc.

This family of receptors is characterized by seven TM segments connected by three extracellular and three intracellular loops (Figure 2). They all have an extracellular amino (N)-terminal sequence and an intracellular carboxy(C)-terminal sequence. The extended extracellular N-terminal region contains multiple potential glycosylation sites and conserved cysteine residues. Glycosylation is important for recognition and high-affinity binding of CT. While the TM domain sequences are conserved (40–60% identical), the N-terminal domains are generally less than 25% identical. The N-terminal domain fulfills the role for ligand binding and receptor specificity.

Multiple Forms

The human CTR gene is localized to chromosome 7. The CTR gene has a complex structural organization with several CTR protein isoforms derived from alternative splicing of transcripts from a single gene. These isoforms are functionally distinct in terms of ligand-binding specificity and signal transduction pathway utilization, and tissue distribution. In humans at least five splice variants have been described whereas two splice variants have been identified in rodents (C1a and C1b), which differ by the presence or absence of an additional 37 amino acids in the second extracellular domain. The C1a is more widely distributed and is the predominant isoform found in osteoclasts. C1b isoform is primarily localized in the central nervous system.

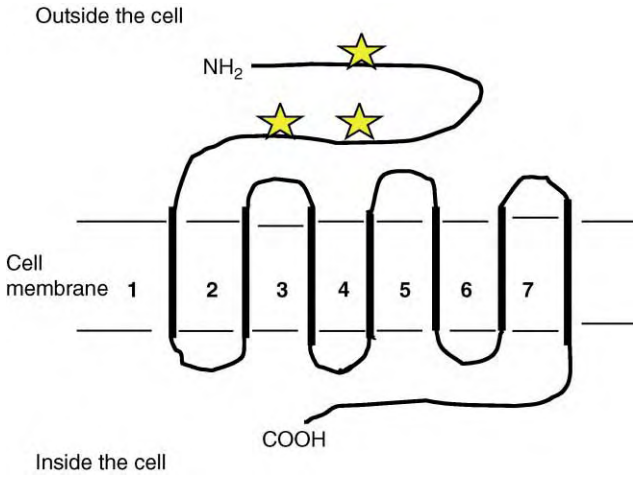

FIGURE 2 Schematic representation of the porcine CTR. Seven transmembrane regions span the cell membrane, and are connected by three extracellular and three intracellular loops. The amino-terminal extracellular loop contains three glycosylation sites (indicated by stars) and is involved with CT recognition and binding. The intracellular domain is involved with G protein coupling.

Signaling

The CTR is coupled to multiple signal pathways through interaction with different members of the heterotrimeric G protein family. These are a family of plasma membrane regulatory proteins that many activated receptors interact with and alter. The main signal pathways are the adenylate cyclase/cAMP/protein kinase A and the phosphoinositide-dependent phospholipase C (PLC) pathway, which are discussed next.

The Adenylate Cyclase/cAMP/Protein Kinase A

The binding of CT to its receptor induces conformational change in the receptor that allows it to bind to an adjacent membrane G-protein, known as G_s (the subscript s denotes stimulation). The binding causes the G_s protein to activate the membrane enzyme called adenylate cyclase. The activated adenylate cyclase, whose catalytic site is on the cytosolic site of the plasma membrane, then catalyses the conversion of cytosolic ATP to cyclic 3′,5′ adenosine monophosphate (cAMP). Cyclic AMP can diffuse throughout the cell to trigger the sequence of events leading to the cell's ultimate response to CT.

The Phosphoinositide-Dependent Phospholipase C (PLC) Pathway

The PLC pathway results in both an increase in intracellular Ca^{2+} and protein kinase C (PKC) activation via G_q protein. Both cAMP and intracellular Ca^{2+} are important second messengers for mediating the actions of CT on the osteoclast.

While adenylate cyclase, PLC and PLD are established effectors for CTR, recently CTR mediated activation of the mitogen-activated protein kinase (MAPK) pathway has been described. MAPKs are a group of serine/threonine protein kinases that are activated by several distinct classes of cell surface receptors including G-protein coupled receptors and tyrosine kinases.

Regulation

Regulation of the level or affinity of cell-surface receptors is a key component in the response to either endogenous or administered agents. The CTR is subject to both homologous (CT-induced) and heterologous regulation. Although CT effectively inhibits osteoclast-mediated bone resorption after acute administration, continuous exposure to CT results in a loss of responsiveness due to receptor down-regulation. Continuous treatment of osteoclast-like cells with CT results in the decrease in steady state levels of CTR mRNA and down-regulation of CTR binding.

It is also known that glucocorticoids stimulate CTR expression.

CTR-Like Receptor (CTRLR)

This receptor has a significant sequence homology (55%) with the CTR and share similarities in general structure and length. The CTRLR is expressed in a variety of tissues, being most prevalent in the brain, and in high densities in the pulmonary and cardiovascular system (especially in blood vessels). It is also expressed

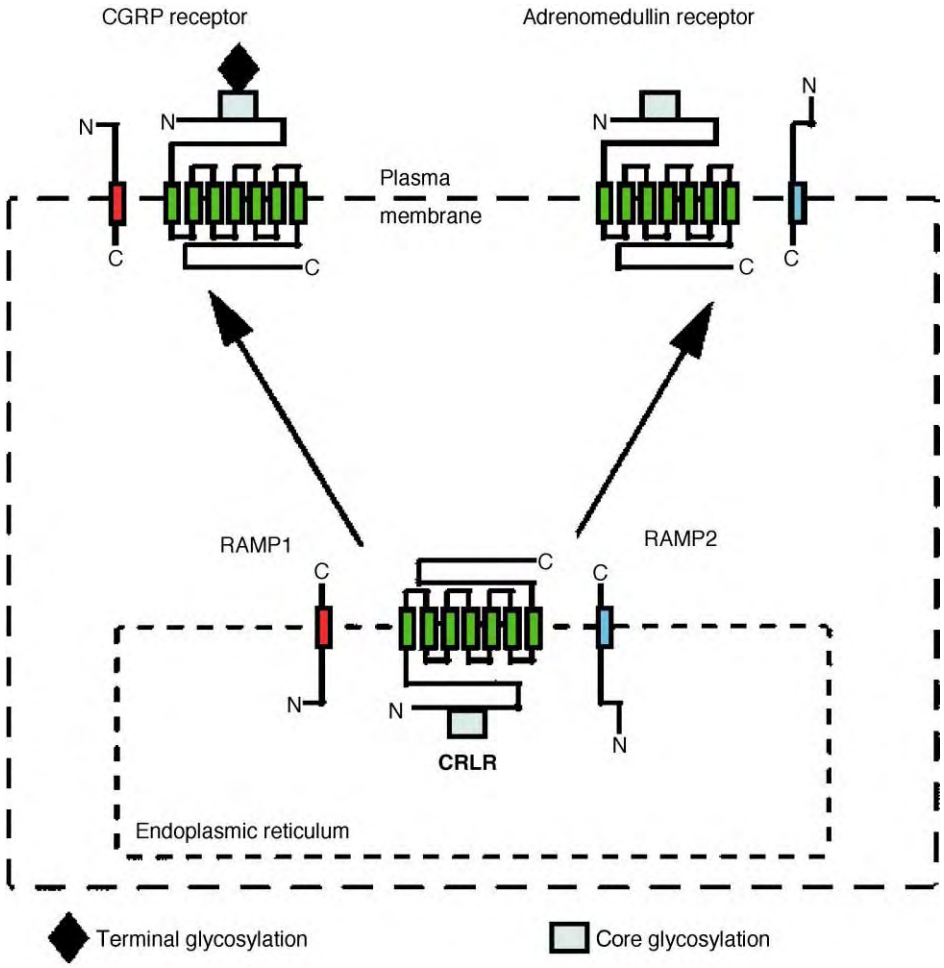

FIGURE 3 The role of RAMPs 1 and 2 and CRLR in generating CGRP or ADM receptors. (Reproduced from McLatchie L.M., Fraser, N.J., Main, M.J., Wise, A., Brown, J., Thompson, N., Solari, R., Lee, M.G., and Foord, S.M. (1998). RAMPs regulate the transport and ligand specificity of the CRLR. *Nature* (*Lond.*) **393**, 333–339.)

in the adrenal and pituitary glands, exocrine pancreas, kidney, and bone. Surprisingly, it does not bind with high affinity to any of the members of the CT peptide family. It requires other cell membrane proteins called receptor activity-modifying proteins (RAMPs) to modify its affinity for the different peptide of the CT peptide family (Figure 3).

RAMPs are single TM proteins. There are three members: RAMP1, RAMP2, and RAMP3. RAMP I acts to modify the glycosylation of CTRLR, enhance the transport of the receptor protein to the cell surface and potentially contribute to the cell surface phenotype of the receptor. RAMP I-transported CTRLR is a CGRP receptor. RAMP 2 and 3 also enhance the transport of CTRLR to the cell surface, but do not alter the pattern of glycosylation of the receptor. RAMP 2 or 3-CTRLR is an ADM receptor (Figure 3). They also act to modify the affinity of the CTR for the different peptide ligands of the CT peptide family.

Glossary

affinity The strength with which a chemical messenger binds to its receptor.

calcitonin (CT) A small peptide hormone and a potent inhibitor of bone resorption.

down-regulation A decrease in receptor number resulting from prolonged exposure to high concentration of the message.

G proteins A family of plasma membrane regulatory proteins that many activated receptors interact with and alter.

osteoclast A large multinucleated bone cell that can destroy bone.

phospholipase C Enzyme that catalyzes the breakdown of a plasma membrane phospholipid known as phosphatidyl-inositol bisphosphate (PIP_2) to inositol triphosphate (IP_3) and diacylglycerol (DAG).

protein kinases Enzymes that phosphorylate other proteins by transferring to them a phosphate group from ATP. Introduction of a phosphate group alters the activity of the protein, often itself an enzyme.

receptor-activity-modifying proteins (RAMPs) Single transmembrane-domain proteins that alter the phenotype of the calcitonin receptor-like receptor.

second messengers Substances that serve as the relay from the plasma membrane to the biochemical machinery inside the cell.

Biography

Samia I. Girgis is a Senior Lecturer in the Department of Metabolic Medicine at Imperial College London, Hammersmith Campus, and an Honorary Consultant Chemical Pathologist at the Hammersmith Hospitals NHS Trust. For many years, her research interest has been concerned with the calcitonin gene peptide family. This included the isolation, characterization and measurement of these peptides. Her recent research interest has focused on biochemical markers of bone metabolism, their potential role in diagnosis and monitoring of patients with metabolic bone diseases.

Niloufar Moradi-Bidhendi is a Post-doctoral Research Assistant in the William Harvey Research Insitute. In 2001 she was awarded a Ph.D. on "The Interrelation of Nitric Oxide and 17ß-Oestradiol in Bone Cells." Her research interests have focused mainly on bone metabolism although her more recent studies have included work on the role of nitric oxide in wound healing.

Lucia Mancini is a Post-doctoral Research Assistant in the William Harvey Research Institute. In 2000 she was awarded a Ph.D. on "Nitric Oxide Regulation of Bone Metabolism." She is currently working in the Centre of Biochemical Pharmacology on a project examining the effect of calcitonin on the regulation of the RANK/OPG system.

Iain MacIntyre is Director of Research in the William Harvey Research Institute. After qualifying in medicine in Glasgow he trained in biochemistry as a demonstrator in Professor Hans Krebs' laboratory in Sheffield and thereafter he became Director of the Endocrine Unit at Hammersmith. His research interests have always centered on calcium and after the co-discovery of calcitonin and the definition of the thyroid as its gland of origin, he contributed many research papers on the chemistry, physiology, and clinical relevance of calcitonin. His more recent interests have focused on nitric oxide and its interaction with estrogen.

Calcium Buffering Proteins: Calbindin

Willi Hunziker
Frimorfo SA, Fribourg, Switzerland

Igor Bendik
DSM Nutritional Products, Kaiseraugst, Switzerland

The calbindins, calbindin D-9k and calbindin D-28k, belong to a large family of intracellular Ca^{2+}-binding proteins of more than 300 members classified in 45 distinct EF-hand subfamilies. Their names relate to their early discovery based on calcium binding and vitamin-D responsive expression. The calbindins are mainly localized in the cytosolic compartment of the cells and exert their action after binding ionized calcium (Ca^{2+}). Calcium ions are important biological regulators that trigger a wide array of processes. Therefore, the handling of Ca^{2+}, i.e., the Ca^{2+}-absorption, -transport, -buffering, -storage, -distribution, -signaling, and -sensing are fundamental for higher life. Functionally, the large family of EF-hand calcium-binding proteins can be classified into (1) calcium-sensing proteins, which propagate a cellular signal, (2) calcium transport proteins which are involved in the cellular calcium transport, and (3) calcium buffer proteins, that are believed to buffer the intracellular free calcium, to prevent it from damaging the cells. The calbindins are believed to be involved in some of these essential processes but their exact physiological function remains still to be determined.

Calbindin D-9k

History

Originally, calbindin D-9k and calbindin D-28k have been identified during the study of vitamin-D-dependent calcium absorption. In 1966 Wassermann and Taylor reported an intracellular vitamin D-dependent calcium-binding protein in the chicken intestine. One year later, Kallfelz and colleagues observed that this 28 kDa protein was not present in the mammalian intestine, but instead they identified a vitamin D-regulated 9 kDa intestinal calcium-binding protein that was later on called calbindin D-9k. Calbindin D-9k seems to be an evolutionary younger protein, since it does not seem to exist in birds. In mammals calbindins D-9k and D-28k have a dissimilar tissue distribution. Calbindin D-9k is highly abundant in the small intestine, whereas calbindin D-28k is absent, but it is predominant in brain and kidney. Vitamin D-induced calbindin expression is only observed in organs involved in Ca^{2+} homeostasis like intestine and kidney, in the brain calbindin D28 is present independent of vitamin D.

After its identification in 1967 calbindin D-9k was initially called calcium-binding protein 9 kDa, CaBP9k, or intestinal calcium binding protein (ICBP). Five years later the first polyclonal antibodies were generated that allowed localization and tissue distribution studies of calbindin D-9k. In 1983 the rat cDNA clone of calbindin D-9k was isolated, whereas the human counterpart was identified later in 1993. The calbindin D-9k protein is characteristic for mammals but seems to be absent in birds. It consists of two calcium-binding domains and is more closely related to S100 proteins than to calbindin D-28k. Members of the S100 protein family, a subfamily of intracellular Ca^{2+}-binding protein family, are typically small, acidic proteins containing two Ca^{2+}-binding sites. Each member of the S100 protein family has a unique spatial and temporal expression pattern. The structural relatedness seems not to coincide with its location and function.

Distribution and Localization

Calbindin D-9k is only found in mammals where it is highly abundant in the small intestine, and at lower levels also in placenta, uterus, kidney, yolk sac, fallopian tube, lung, cartilage, bone, and teeth. In the intestine the highest calbindin D-9k concentration is found in the cytoplasma of duodenal villus enterocytes. The expression levels in juvenile tissues are substantially higher than in adult ones. Antisera raised against intestinal calbindin D-9k from one species generally do not crossreact with calbindin D-9k from other species. This is likely due to the lower amino acid sequence conservation of calbindin D9 in evolution as compared to that of calbindin D28.

Gene and Sequence

The human calbindin D-9k is a heatstable and acidic ($pI = 4.52$) protein consisting of 79 amino acid (9016 Da). The human protein has an amino acid sequence identity of 78% and 74% to that of the rat and that of the mouse, respectively. The first cDNA clone was identified in 1983 by differential *in situ* ybridization in the rat system. The structural organization of the calbindin D-9k gene was determined five years later. The chromosomal location was assigned to Xp22.2 and the gene name was defined to CALB3. The CALB3 gene is a small gene of 5.5 kb comprising three exons, the coding region is contained in the exons two and three, which code for the two Ca^{2+}-binding sites, respectively.

Calcium Binding

The X-ray structure of the Ca^{2+}-binding sites of calbindin D-9k was first resolved for the bovine protein. Calbindin D9-k contains two helix-loop-helix structures of 29 and 31 amino acids called EF-hands, each binding one Ca^{2+} ion. These EF-hand structures are similar to those found in the S100 proteins and thus, calbindin 9k is considered to be a member of the S-100 protein family. Characteristic for the S100 protein family members is the atypical second EF-hand with a 14 amino-acid loop, which is different to the prototype EF-hand having a loop of 12 amino acids. Calbindin D-9k reportedly binds Ca^{2+} without a significant change in conformation. The equilibrium binding constant for calbindin D-9k is in the high nanomolar range.

Regulation

Calbindin D-9k is believed to play an important role in the Ca^{2+} absorption by transporting and/or buffering cytoplastic Ca^{2+}. Vitamin D plays a pivotal role in this regulation. The hormonally active metabolite of vitamin D, $1,25(OH)_2D_3$ (calcitriol), rapidly induces calbindin D-9k synthesis in the mammalian intestine. Calcitriol regulates the expression of calbindin D-9k not only at the transcriptional but also at the translational level. For transcriptional regulation calcitriol binds the nuclear vitamin D receptor (VDR), which is a DNA-binding protein that belongs to steroid receptor superfamily. The liganded VDR recognizes a specific VDR-response element in the promoter of the calbindin D-9k gene and activates its expression. A similar regulation of expression is believed to take place in the kidney, placenta, bone, and teeth. In the uterus calbindin D-9k is regulated by estradiol but not by vitamin D. Expression of calbindin D-9k is undetectable in the uterus in the absence of estradiol. If estradiol is present, it binds to the estrogen receptor and activates expression of the calbindin D-9k gene in a mechanism similar to that described above for vitamin D. In the lung calbindin D-9k is expressed independent of vitamin D and estradiol.

Summary and Outlook

Calbindin D-9k is a calcium-binding protein with two calcium-binding domains which belongs to the S-100 EF-hand protein family. It has a characteristic tissue distribution in mammals and does not seem to exist in birds. Its expression is regulated by calcitriol, the active metabolite of vitamin D, mainly in intestine and kidney, whereas it is regulated by estrogens in the uterus. It is thought to be involved in the transport of calcium. To our knowledge, gene knockout mice have thus far not yet been generated and no human genetic disease based on a calbindin D-9k defect has been described, both of which would allow to gain further insight on the function of this protein.

Calbindin D-28k

History

In the chicken intestinal mucosa Wassermann and co-workers identified a vitamin D-inducible 28 kDa protein that makes up from 1% to 3% of all cytosolic proteins. This protein was referred to vitamin D-dependent calcium-binding protein or CaBP. Heat treatment to 80°C did not result in significant alterations of its immunological, electrophoretical, or calcium-binding properties. As a matter of fact, a heating step was used in some of the early calbindin D-28k purification protocols. It took 20 years from its original discovery until the calbindin D-28k cDNA was cloned and sequenced. The amino acid sequence implied a 6 EF-domain structure of which two domains have lost their Ca^{2+}-binding function. This finding confirmed previous observations that calbindin D-28k binds 3–4 moles of Ca^{2+}. Calbindin D-28k shares only minimal sequence homology with calbindin D-9k and the S-100 family, but is rather closely related to calretinin, another 6 EF-hand domain calcium-binding protein expressed mainly in neuronal tissues. Calbindin D-28k is highly conserved during evolution suggestive of an important physiological function that allows only little sequence divergence. The exact physiological function, however, remains still unclear.

Distribution and Localization

Calbindin D-28k is expressed in brain, kidney, bone, pancreas, and less in some other tissues (pituitary gland, salivary gland, adrenal gland, stomach, thymus, bladder, ovary, heart, liver). The expression level between tissues varies from 0.1% to 1.5% of the total soluble protein. Calbindin D-28k is expressed in specific

regions throughout the central nervous system. The highest calbindin D-28k levels are present in the cerebellar Purkinje cells where it is located in the cell bodies, axons, and dendrites, but not or to a much lesser extent in the adjacent granular cell layer. Furthermore, calbindin D-28k is localized in specific cells of the sensory pathways in mammalian cochlear and vestibular hair cells in the inner ear, as well as in the basilar papilla of the chick cochlea. Calbindin D-28k concentrations of up to 2 mM were reported to be present in the auditory neurons. In the kidney, calbindin D-28k is exclusively localized in the tubular regions of the distal nephron (distal convoluted tubule, the connecting tubule, and the cortical collecting tubule), where reabsorption of calcium is known to occur. Calbindin D-28k is also found to be expressed in the insulin-producing B cells of the avian and mammalian pancreas.

Calbindin D-28k is expressed in the avian but not in the mammalian intestine, where it is found by immunocytochemical techniques to be present in the intestinal absorptive cells whereas globlet cells are negative. The subcellular distribution of calbindin D-28k was determined in chick duodenum by electron microscopy using the protein A-gold technique. Calbindin D-28k was found in the cytosol and the nuclear euchromatin of the intestinal absorptive cells, but not in the mitochondria, the lysosomes, or the cysternal spaces of the rough endoplasmic reticulum nor in the Golgi apparatus.

An antiserum raised to chick intestinal calbindin D28 was found to also crossreact with calbindin D-28k from other species. The antiserum revealed the presence of calbindin D-28k in intestinal homogenates of duck, robin, and Japanese quail and with a protein in the duodenum of reptiles but not fishes and amphibia. Similarly, calbindin D-28k was also identified in the kidney and brain of amphibia, reptiles, birds, and mammals and also in the nervous system of fish and several mollusks. Since calbindin D-28k is found in fish brain but not in fish intestine and kidney, one might speculate that it was originally a neuronal protein.

Gene and Sequence

The rigid structure of calbindin D-28k is acidic ($pI = 4.54$) and contains 261 amino acids (30 025 Da). The chicken cDNA sequence was the first to be cloned (1986). The deduced amino acid sequence of this calbindin D-28k cDNA revealed surprisingly the presence of six EF-hand domains. Of these predicted six EF-hand domains only four were considered to be functional due to mutations within the conserved calcium coordination sites in the loop regions of domains 2 and 6. A protein sequence comparison of calbindin D-28k showed a high degree of conservation over all species. The human calbindin D-28k gene was localized to the human chromosome 8q21.3–q22.1 and the gene name was annotated to CALB1. CALB1 spans 24 kb interspersed by 10 introns and 11 exons.

Calcium Binding

EF-hand proteins play a crucial role to guide and sustain the calcium signal. The designation "EF hand" is derived from the structural orientation of the two α-helices (E and F) that form together with the calcium-binding loop of 12 amino acids the highly conserved metal-binding consensus sequence. The loop contains five oxygen-containing amino acids at defined positions that are important for coordinating the calcium ion. Da Silva and Reinach proposed to classify the EF-hand members into proteins with regulatory roles called Ca^{2+} sensor proteins and those involved in Ca^{2+} buffer and transport were entitled Ca^{2+} buffer proteins. The Ca^{2+}-binding affinities of EF-hand proteins have a wide equilibrium constant range ($K_d = 10^{-4}$–10^{-9} M). This large binding range is coded in the amino acid sequence, in particular within the 12-residues consensus loop that directly coordinates the Ca^{2+} ion. The four EF-hands domains of calbindin D-28k bind calcium with high affinity. The binding is Ca^{2+}-specific with marginal Ca^{2+}/Mg^{2+} antagonism. Therefore, under resting intracellular calcium concentrations (<100 nM) the calcium-binding sites of calbindin D-28k are largely empty and are thus immediately available for a fast buffering of nerve stimulation evoked Ca^{2+} transients. Two K_d values have been determined calbindin D-28k. The first $K_d(1)$ value ranges from 175 to 237 nM and the second $K_d(2)$ ranges from 411 to 513 nM, respectively. Ca^{2+} binding seemingly causes a conformational change in the molecule, which could trigger an interaction with another protein, thereby propagating a calcium signal.

Knockout Animals

The evaluation of the physiological role of calbindin D-28k has been facilitated by the recent generation of mouse strains deficient in this protein. Calbindin D-28k-nullmutant (−/−) mice are viable and appeared phenotypically normal in their general development. There was no evidence of any major changes in the histology neither of their nervous system nor of any other organ. However, calbindin D-28k knockout mice showed a distinct motor coordination problem that could not be overcome by continuous learning. These animals lack the calbindin D-28k in the Purkinje cells of the cerebellum, a center for motor coordination. This result points towards a critical physiological role of calbindin D-28k in controlling Purkinje cell-dependent motor behavior.

Due to its presence in Purkinje cells calbindin D-28k was also thought to be associated with other neurological disorders such as ataxia. Patients with spinocerebellar ataxia type 1 (SCA1) show a decreased calbindin D-28k staining in Purkinje cells and an aggregation of ataxin-1 in the nucleus, leading eventually to Purkinje cell death. A similar decrease in calbindin D-28 staining of Purkinje cells was found in transgenic mice overexpressing mutant ataxin-1, an animal model for SCA1. Calbindin D-28k knockout mice on the other hand did not show any Purkinje cell loss, suggesting that the lowered calbindin D-28k levels in SCA1 patients are unlikely the cause but rather the consequence of the Purkinje cell damage due to the high ataxin-1 levels. The fact that the Purkinje cells and other calbindin D-28k positive neurons of wild type mice also survive in the calbindin knockout mice, shows that the lack of calbindin D-28k is not per se detrimental to these cells. Thus, this finding argues against a general calcium-mediated excitotoxicity preventive role of calbindin D-28k. The functional data available thus far suggests that in the cerebellum calbindin D-28k plays a role in motor coordination. To our knowledge, no human genetic disease is known where the root cause is a calbindin D-28k gene defect.

Regulation

Calbindin D-28k has a unique tissue-specific expression pattern indicating a highly specialized function. Calbindin D-28k is regulated in a vitamin D-dependent fashion in kidney and pancreas, whereas its presence in the specific brain regions is independent of the vitamin D status. There are, however, reports showing a brain region-specific regulation by gluccocorticoids, by sex steroids and by nerve growth factor.

The initial finding that calbindin D-28k is induced by vitamin D in tissues involved in calcium transport, suggested that calbindin D28 might have an important role in vitamin D regulated calcium absorption. The intestine, the kidney, and the bone are target organs for the biologically active form of vitamin D, the 1α, 25-dihydroxyvitamin D3, that is known to regulate the calcium demand of the body. The active vitamin D metabolite regulates the expression of calbindin D-28k in these tissues by the steroid hormone mechanism of action as described earlier for calbindin D-9k.

Summary and Outlook

The fact that antibodies to chicken calbindin D-28k crossreact with calbindin D-28k of evolutionary far-diverged species suggest a high conservation of this protein in evolution. This finding is further evidenced by sequence comparison among the different species. The four intact and the two degenerated EF-hands show similarly a high degree of conservation, suggesting, apart from Ca^{2+}-binding, an additional functional conservation pressure. Such an additional function could be triggered by protein–protein interaction in a Ca^{2+}-dependent manner. Indeed, there is increasing evidence that similar to calmodulin, also calbindin D-28k could act as calcium sensor, undergoing a conformational change upon Ca^{2+}-binding. Such a conformational change could unmask new domains and allow calbindin D-28k to interact with other yet to be identified intracellular effectors thereby propagating the Ca^{2+}-signal.

Another intriguing question regarding calbindin D-28k function is the partial substitution during evolution by calbindin D-9k. In mammals calbindin D-9k substitutes for calbindin D-28k in the intestine and in part in the kidney. This raises the intriguing hypothesis that in the evolutionary older species calbindin D28k could have a dual function, one for calcium absorption in the intestine (vitamin D dependent), the other as calcium sensor in neurons (vitamin D-independent). With the evolution of mammals, the calcium absorption function apparently was delegated the "newly invented" calbindin D-9k.

Glossary

EF-hand calcium-binding site A specific protein sequence constisting of two α-helices connected by a sequence of 12–14 amino acids that constitute a high affinity calcium-binding site (K_d in the nM range). Depending on the protein sequence, the binding site is either specific for calcium (e.g., calbindin) or can also accept magnesium (e.g., parvalbumin).

gene family A number of closely related genes that arose by a series of gene duplications during evolution. Gene families can have from only very few up to several hundred members. The EF-hand family of calcium-binding proteins has more than 300 members grouped in several subfamilies.

His research interests are calcium metabolism and regulation of gene expression by steroids, retinoic acid, and vitamin D.

Igor Bendik obtained his Ph.D. from the University of Basel, Switzerland. During his Ph.D. thesis he was interested in calbindin D-28k and the vitamin D receptor. At the Burnham Institute in La Jolla, California, he expanded his knowledge on nuclear receptors. Back in Basel he was a group leader in the medical faculty working on tumor suppressor genes. He is currently employed by DSM, a company active in life sciences, performance materials, and industrial chemicals.

Calcium Buffering Proteins: ER Luminal Proteins

Jody Groenendyk and Marek Michalak
University of Alberta, Edmonton, Alberta, Canada

Ca^{2+} buffering endoplasmic reticulum (ER) proteins are ER resident proteins that bind Ca^{2+} with a high capacity. They play an important role in the maintenance of resting free Ca^{2+} concentration in the lumen of ER and subsequently in the modulation of cellular Ca^{2+} homeostasis. This is critical because Ca^{2+} is a universal intracellular signaling molecule, which controls numerous developmental and cellular pathways. Changes in Ca^{2+} concentration affect processes as diverse as learning and memory, secretion, contraction and relaxation, membrane excitability, cell motility, cytoplasmic and mitochondrial metabolism, protein and lipid synthesis, cell cycle, apoptosis, organellar trafficking, and protein folding and quality control. Therefore, it is of the utmost importance that Ca^{2+} homeostasis is tightly regulated in all cells. This is accomplished by a variety of Ca^{2+} transporting, binding, and buffering proteins, which are found in many cellular compartments.

The Endoplasmic Reticulum and Ca^{2+} Homeostasis

The ER is one of the most important intracellular Ca^{2+} buffering and storage organelles. In response to a variety of external stimuli, Ca^{2+} is released from the lumen of the ER into the cytosol, via the inositol-1,4,5-triphosphate receptor ($InsP_3R$) and/or the ryanodine receptor (RyR) Ca^{2+} channels. Some Ca^{2+} also enters the cytosol from the extracellular environment, via Ca^{2+} channels in the plasma membrane. Most of the released Ca^{2+} is taken up back into the lumen of the ER via the sarcoplasmic–endoplasmic-reticulum Ca^{2+}-ATPase (SERCA). Some of the Ca^{2+} is also removed from the cytosol by the plasma membrane Ca^{2+}-ATPase and the Na^{+}–Ca^{2+} exchanger. Within the ER, Ca^{2+} is bound to and buffered by high concentrations of luminal Ca^{2+} binding proteins.

Ca^{2+} Buffering in the ER Lumen

In total, the lumen of the ER contains 1–3 mM Ca^{2+}, a concentration similar to that in the extracellular space. A small portion of this ER lumenal Ca^{2+} is not buffered by Ca^{2+} binding to proteins and is considered free. Resting free Ca^{2+} concentrations in the ER vary from 100 to 400 μM, while those in the cytosol are in the nanomolar range. The actual resting free Ca^{2+} concentration in the ER is determined by the balance between the rates of Ca^{2+} uptake and Ca^{2+} leak and by the extent of buffering by the resident Ca^{2+} binding proteins.

Most Ca^{2+} in the lumen of the ER is bound to the Ca^{2+} binding molecular chaperones that are resident there. These proteins maintain specific concentration gradients of Ca^{2+} in the ER and localize Ca^{2+} to the sites of release. They also directly affect both the Ca^{2+} storage capacity of the ER and the free Ca^{2+} concentration under resting conditions and after cellular stimulation. Table I shows a list of ER proteins that are involved in buffering Ca^{2+} in the ER lumen. There are two major classes of ER Ca^{2+} binding proteins. Class I, the larger of the two, represents proteins which bind Ca^{2+} with relatively high capacity and low affinity. These proteins contain a large proportion of acidic amino acid residues that are involved in the high capacity and low affinity Ca^{2+} binding. Their Ca^{2+} binding capacity varies from as little as 2 moles of Ca^{2+} per mole of protein to as much as 50 moles of Ca^{2+} per mole of protein. The high capacity Ca^{2+} binding sites have a relatively low affinity for Ca^{2+} ($K_d = 1–2$ mM), which parallels the relatively high content of Ca^{2+} in the ER lumen. These Ca binding proteins are responsible for Ca^{2+} storage in the lumen of the ER/sarcoplasmic reticulum (SR), and they effectively determine the capacity of these intracellular organelles for Ca^{2+}. In contrast, class II represents Ca^{2+} binding proteins in the lumen of the ER that bind Ca^{2+} with relatively high affinity and low capacity. The function of these high affinity binding sites is not obvious, given the high concentrations of Ca^{2+} in the lumen of the ER. It is thought that they might play a structural role, or that they might be responsible for the regulation/maintenance of specific protein–protein interactions. Several of the class II proteins contain a classic EF-hand

TABLE I

Ca^{2+} Binding Proteins of the Endoplasmic Reticulum Lumen

PDI	20
ERp72	12
ERCalcistorin/PDI	20
P5	binds Ca^{2+}
ERp57	not investigated
ERp44	not investigated
ERp29	not investigated
Calsequestrin	50
CLASS II proteins (contain EF-hand Ca^{2+} binding motifs and bind 6–7 moles of Ca^{2+}/mole of protein with high affinity)	
Reticulocalbin	
Cab45	
Calumenin	
ERC55	
Crocalbin/CBP-50	

Ca^{2+} binding site, previously identified in many cytoplasmic proteins that bind Ca^{2+} with high affinity.

A characteristic common to proteins in both classes is that they contain an N-terminal signal sequence that targets them to the lumen of the ER. They also terminate with a KDEL-like amino acid sequence that is responsible for their continual retrieval back to the ER lumen. Finally, most of the proteins resident in the lumen of the ER are multifunctional, regardless of their Ca^{2+} binding properties. They are involved in maintaining Ca^{2+} homeostasis and they assist in both protein folding and assembly, and lipid synthesis and transport.

Class I Ca^{2+} Binding Proteins in the ER Lumen

The class I ER luminal proteins are those that bind Ca^{2+} with high capacity and low affinity. In most of these proteins, specific regions of the amino acid sequence contain a high proportion of acidic residues, and it is these acidic residues that are involved in the high capacity Ca^{2+} binding. The following ER proteins belong to class I: calreticulin, Grp94, BiP, the PDI-family, and calsequestrin.

Calreticulin

Calreticulin (46 kDa) is a major Ca^{2+} storage protein in the ER lumen, which contains both high affinity/low capacity *and* low affinity/high capacity Ca^{2+} binding sites. Specifically, it binds up to 25 moles of Ca^{2+} per mole of protein with $K_d = 1$ mM (low affinity) and 1 mole of Ca^{2+} per mole of protein with a $K_d = 1\ \mu M$ (high affinity). Calreticulin, one of the most extensively studied ER luminal proteins, is responsible for binding approximately 50% of the Ca^{2+} stored in the lumen of the ER. As observed for other ER luminal proteins, the expression of calreticulin is up-regulated by stress, Ca^{2+} depletion, and metabolic starvation. The overexpression of calreticulin in the ER significantly affects the ER Ca^{2+} storage capacity, Ca^{2+} uptake via SERCA, and release via $InsP_3$ receptor, indicating an important role for calreticulin in ER Ca^{2+} buffering.

Calreticulin is composed of three structural and functional domains. The N-domain has the most conserved amino acid sequence and binds both Zn^{2+} and ATP. In conjunction with the central, P-domain of the protein, it enables calreticulin's chaperone function. The central, P-domain of the protein is very rich in proline residues and contains several repeated amino acid sequences. It forms a highly unusual hairpin-like structure that involves the entire proline-rich region, and it is stabilized by a three-strand antiparallel B-sheet that is formed by the amino acid repeat sequences. The P-domain binds Ca^{2+} with high affinity and low capacity. It also interacts with other ER chaperones and their substrates. The carboxyl-terminal C-domain of calreticulin contains a large number of acidic amino acid residues, and it is responsible for the high capacity Ca^{2+} binding behavior of calreticulin.

In addition to binding and buffering Ca^{2+} in the lumen of ER, calreticulin also plays a significant role as a molecular chaperone with a specificity for glycosylated proteins. Specifically, calreticulin binds N-linked, monoglucosylated carbohydrates on newly synthesized proteins. In conjunction with calnexin, an integral membrane protein and also a chaperone in the ER, calreticulin facilitates protein folding and oligomerization, and it supports quality control in protein folding processes. As components of the calreticulin/calnexin cycle, calreticulin might prefer secretory proteins and calnexin integral membrane proteins. Calreticulin and calnexin both form heterodimeric complexes with ERp57 and other chaperones. The formation of these chaperone–chaperone and chaperone–substrate interactions is regulated by changes in Ca^{2+} concentration in the lumen of the ER.

Grp94 (Glucose-Regulated Protein)

Grp94 (94 kDa) is another major Ca^{2+} binding protein, and one of the most abundant proteins in the lumen

of the ER. It binds 8–10 mol of Ca^{2+} per mol of protein with low affinity ($K_d = \sim 600\ \mu M$). Like calreticulin, Grp94 contains an acidic C-terminal region that comprises the low affinity Ca^{2+} binding site. Because of their relatively high capacity for Ca^{2+} binding and their abundance, Grp94 and calreticulin are the most significant Ca^{2+} binding/buffering proteins in the ER lumen. The expression of Grp94 is up-regulated upon glucose starvation, hence its name (glucose-regulated protein). It binds ATP, but has only very low ATPase activity. It also functions as a molecular chaperone but binds to limited numbers of nascent proteins, most of them advanced folding intermediates or misfolded proteins that have been previously associated with other chaperones; it has a relatively low affinity for early folding intermediates. It appears that Grp94 is a chaperone specific for advanced intermediates in protein biosynthesis and that it works downstream of, or in conjunction with, other chaperones. Ca^{2+} binding to Grp94 may play a role in the *in vivo* interactions of the protein with other chaperones and with its substrates.

BiP (Immunoglobulin Binding Protein)

BiP is a 78-kDa ER chaperone that binds immunoglobulins. It is a monomeric protein with two distinct functional domains, an ATP-binding domain and a peptide-binding domain. While it has a relatively low capacity for binding Ca^{2+} (1–2 mole of Ca^{2+} per mole of protein), it contributes possibly as much as 25% of the total Ca^{2+} storage capacity of the ER, and its elevated expression causes an appreciable increase in ER Ca^{2+} storage capacity. BiP assists in the folding of newly synthesized polypeptides by binding to exposed hydrophobic side chains and subsequently coordinating the formation of their correct tertiary and quaternary structure. BiP binds ATP and has high ATPase activity essential for its chaperone function. Its association with nascent polypeptides is stabilized by the high concentrations of Ca^{2+} in the ER lumen and likely involves Ca^{2+} binding. The expression of BiP is up-regulated by a variety of stress conditions, including ER Ca^{2+} depletion.

The Protein Disulfide Isomerase (PDI) Family of Proteins

Several members of the protein disulfide isomerase (PDI) family are well-characterized. Each is folded similarly to thioredoxin, with a "typical" sequence of α helices and β strands. PDI proteins also contain one or more active sites (typically two), again similar to that of thioredoxin. The main function of the PDI family of proteins is to catalyze the oxidation of disulfide bonds and to isomerize incorrectly formed disulfide bonds in newly synthesized polypeptides. Recent studies indicate that some members of this family (PDI, ERp72, and ERcalcistorin/PDI) also contribute to Ca^{2+} buffering in the ER lumen.

PDI

PDI is a 58-kDa Ca^{2+}-binding chaperone. It binds 19 mol of Ca^{2+} per mol of protein with low affinity ($K_d = 2–5$ mM). The C-terminus of the protein contains numerous pairs of acidic residues that form the low affinity, high capacity Ca^{2+} binding sites. PDI is an abundant and widely distributed ER luminal protein. Its major function is to catalyze disulfide bond formation in newly synthesized proteins and, importantly, high concentrations of Ca^{2+} augment this activity. PDI contains a typical thioredoxin active site, which contains two cysteines separated by two other amino acid residues (the CXXC motif).

ERp72

ERp72 is a 72-kDa member of the PDI family that binds 12 mol of Ca^{2+} per mol protein with low affinity. Its amino acid sequence includes an acidic C-terminus that is involved in the high capacity Ca^{2+} binding. ERp72 contains 3 thioredoxin-like active sites and has PDI-like activity. The expression of ERp72 is induced under stress conditions, including ER Ca^{2+} depletion.

ERcalcistorin/PDI

ERcalcistorin/PDI, a 58-kDa protein, also has high Ca^{2+} binding capacity and low affinity. ERcalcistorin/PDI binds 23 mol of Ca^{2+} per mol of protein with low affinity ($K_d = \sim 1$ mM). Like other class I ER Ca^{2+} binding proteins, the high-capacity Ca^{2+} binding sites in ERcalcistorin/PDI are localized to a C-terminal stretch of acidic amino acid residues. As noted previously for members of the PDI family, high concentrations of Ca^{2+} augment the protein's isomerase activity. ERcalcistorin/PDI has 55% amino acid sequence identity to PDI, and it shows PDI-like chaperone activity.

Other PDI Family Members

Other members of the PDI family have also been identified. While information regarding their Ca^{2+} binding properties is limited, it has been established that they play a role in protein folding and posttranslational modification. P5, a 44-kDa polypeptide also known as CaBP1, contains two internal thioredoxin-like domains and a C-terminal KDEL retention/retrieval signal. While it does bind Ca^{2+}, it is unclear what role it plays in Ca^{2+} buffering in the ER lumen. ERp57, a 57-kDa protein, carries out disulfide bond exchange

in conjunction/complex with calreticulin or calnexin. Ca^{2+} binding to this protein has not been investigated. PDIR has the three CXXC motifs typically found in proteins within the PDI superfamily that are responsible for their oxidoreductase activity. PDIR is preferentially expressed in cells that actively secrete proteins, and its expression is stress-inducible. PDIp is a PDI-like protein expressed specifically in the pancreas. ERp44 and ERp29 are two other proteins of PDI family each containing a single thioredoxin-fold domain but no thioredoxin-like active site.

Calsequestrin

Calsequestrin is a high-capacity Ca^{2+} binding protein found in the SR of cardiac and skeletal muscle. It binds 40–50 moles of Ca^{2+} per mole of protein with low affinity ($K_d = \sim 1–2$ mM). Small quantities of calsequestrin are also present in the ER of smooth muscle and the cerebellum. There are two isoforms of calsequestrin that are encoded by distinct genes: a 55-kDa cardiac form and 63-kDa skeletal muscle form. These proteins have very similar amino acid sequences with a C-terminal stretch containing over 100 acidic amino acids that are involved in the high-capacity Ca^{2+} binding. Calsequestrin is localized to the terminal cisternae of the SR, where it acts as a Ca^{2+} buffer. It lowers the concentration of free Ca^{2+} inside the SR, thereby decreasing the concentration gradient against which the Ca^{2+}-ATPase must work as it transports Ca^{2+} from the cytosol back into the SR. During the initiation of muscle contraction, Ca^{2+} is released from the terminal cisternae of the SR into the cytosol via the ryanodine receptor. Ca^{2+}-induced conformational changes in calsequestrin affect the junctional face of these membrane proteins and this, in turn, regulates the opening and closing of the Ca^{2+} channel. Interestingly, the crystal structure of calsequestrin shows that it contains three similar domains that contain a thioredoxin-like region. The thioredoxin-like fold may, therefore, be a common structural feature of ER/SR luminal proteins.

Class II Ca^{2+} Binding Proteins in the ER Lumen

Class II Ca^{2+} binding proteins in the ER lumen are those that bind Ca^{2+} with high affinity ($K_d = 1\ \mu M$ or less). Much less is known about this class of Ca^{2+} binding proteins, which includes: reticulocalbin, Cab45, calumenin, ERC-55/TCBP-49/E6BP, crocalbin/CBP-50, and calreticulin. Calreticulin's structure, function, and Ca^{2+} binding properties have been discussed already, with the class I ER proteins. The class II Ca^{2+} binding proteins have also been found in the Golgi and may, therefore, play an important role in the secretory pathway. With the exception of calreticulin, they all contain six or seven EF-hand type, high-affinity Ca^{2+} binding sites, and they are considered to be members of the reticulocalbin family. This family is a new subset of the EF-hand superfamily of proteins. The function of the high-affinity Ca^{2+} binding sites in these proteins is not clear, but they may be involved in Ca^{2+}-dependent processes. They may also play an important structural role in the proteins.

Reticulocalbin is a 44-kDa protein that contains six EF-hand motifs. The difference between the amino acid sequences of these domains and EF-hand consensus sequences suggests that some of the domains may have lost their Ca^{2+}-binding capability. Cab45 is a 45-kDa, ubiquitously expressed protein. It contains six EF-hand Ca^{2+} binding motifs. In contrast to reticulocalbin and ERC-55, which are soluble components of the ER, Cab45 is localized to the Golgi. Cab45 is the first calcium-binding protein that has been localized to the lumen of the Golgi, a post-ER compartment. Calumenin is a 39-kDa member of the reticulocalbin family. It is highly homologous to other family members, including reticulocalbin, Cab45, and ERC55. It is localized to the lumen of the ER and has a KDEL-like (HDEF) ER retrieval signal. ERC-55 (55 kDa) comprises an amino-terminal signal sequence followed by six copies of the EF-hand Ca^{2+} binding motif.

The Functional Significance of Ca^{2+} Buffering in the ER

There are many Ca^{2+}-binding proteins in the ER lumen that both bind and buffer Ca^{2+} and that also assist in protein folding and posttranslational modification. Ca^{2+} buffering within the ER lumen is an essential component of proper cellular Ca^{2+} homeostasis. Furthermore, it has a profound effect on other ER functions including protein and lipid synthesis and stress response. For example, reduction of Ca^{2+} concentration in the ER leads to the accumulation of misfolded proteins, increased expression of ER chaperones, and ER to nucleus/ER to plasma membrane signaling, which inhibits protein synthesis and facilitates protein degradation. Overall, disruption of ER Ca^{2+} homeostasis has profound effects on intracellular communication and cell growth, resulting in organellar diseases, and it has detrimental effects at cellular and systemic levels.

Biography

Jody Groenendyk is a graduate student in the Department of Pediatrics, Faculty of Medicine, and the University of Alberta. For several years she has been involved in studies on Ca^{2+} and buffering proteins for the ER. She is supported by the Alberta Heritage Foundation for Medical Research and by the Canadian Institutes for Health Research.

Marek Michalak is a Professor of Biochemistry at the University of Alberta, Edmonton, Alberta. He obtained his Ph.D. at the Nencki Institute for Experimental Biology, Warsaw, Poland. Michalak's laboratory has been studying ER luminal proteins for almost 20 years. The major focus of this work is on Ca^{2+} buffering and chaperone protein, with a special emphasis on calreticulin. He has published over 150 papers in the area of ER Ca^{2+} binding chaperones. He has authored and edited books on the structure and function of calreticulin and calnexin.

Calcium Oscillations

Marisa Brini
University of Padova and Venetian Institute of Molecular Medicine (VIMM), Padova, Italy

Cellular signaling mechanisms are designed to transmit information from the cell surface to specific targets within the cell. Usually, the information is transmitted by intracellular messengers, of which the calcium ion, Ca^{2+}, is one of the most important. Generally, extracellular stimuli are converted in a transient increase in the cytosolic Ca^{2+} concentration, $[Ca^{2+}]_c$, which, in turn, activates cellular functions. The specificity of the activated signal is guaranteed by the complex spatial and temporal organization of the changes in Ca^{2+} concentration, which increases the versatility of this messenger. Different cell types use distinct Ca^{2+} signals, as appropriate to their physiology. The ability to use Ca^{2+} in different modes helps cells to vary the amplitude, frequency, kinetics, and localization of the signal. It is now recognized that periodic $[Ca^{2+}]_c$ changes (i.e., oscillations) probably represent the typical response of cells to physiological agonists concentrations.

General Considerations

It has been known since the 1950s that the periodic opening of plasma-membrane Ca^{2+} channels, such as induced, for example, by the rhythmic changes of the plasma membrane potential of the heart or by burst of action potential in neurons, can produce fluctuations in cytosolic $[Ca^{2+}]$. The idea that $[Ca^{2+}]_c$ oscillations may also occur in nonexcitable cells has emerged much later, thanks to seminal observations by Cobbold and coworkers in the mid-1980s on the fertilization of oocytes and on hormone-stimulated hepatocytes. Surprisingly, these oscillations were not dependent on the periodic opening and closing of plasma membrane Ca^{2+} channels, but rather on cycles of Ca^{2+} release and uptake from the intracellular compartment sensitive to the second messengers inositol (1,4,5)-trisphosphate ($InsP_3$), which is the endoplasmic reticulum. Later, Ca^{2+} oscillations were observed in other animal as well as plant cells, even if many of these cells do not have an obvious oscillatory biological function.

A question that immediately arises is the reason for the transmission of the Ca^{2+} signal by oscillations rather than by a stationary change in Ca^{2+} concentration. It is generally assumed that the oscillatory behavior has physiological advantages. This is so because the elevation of Ca^{2+} concentration over a long period is known to be lethal to the cell: the oscillatory behavior would prevent this negative effect, while still permitting optimal activation of Ca^{2+} sensing enzymes. The oscillatory regime would also prevent long-lasting receptor desensitization thus increasing the sensitivity of sensing enzymes to Ca^{2+}, i.e., $[Ca^{2+}]$ would be permitted to periodically exceed the threshold for enzyme activation, even its level would remain below the threshold. Another advantage is the wide range of temporal and spatial aspects that oscillations can assume, allowing different signals to be transmitted within cells and from cell to cell.

Usually, Ca^{2+} oscillations are characterized by rather constant amplitude and by a variable frequency, which ranges from 5 to 60 s depending to the cell type, and on the nature and the strength of the stimulus (Figure 1). These characteristics have led to the concept of frequency-modulated Ca^{2+} signaling, which reflects the ability of cells to interpret changes in the frequency of the oscillations.

Mechanism of $[Ca^{2+}]_c$ Oscillations

The mechanism of Ca^{2+} oscillation has received much experimental and theoretical attention, but is still largely debated. A first distinction considers the origin of the Ca^{2+} spikes, for which two major mechanisms exist: one is linked to the periodic opening of plasma membrane channels and another to cycles of Ca^{2+} release and uptake from intracellular stores (Figure 2). However, this distinction is incomplete since very often the contributions of intracellular Ca^{2+} release and of extracellular Ca^{2+} influx cannot be clearly separated. An obvious example is that of cardiac myocytes, where the periodic contraction of the cells is directly promoted by the release of Ca^{2+} from the sarcoplasmic reticulum (SR), which is triggered by localized influx of Ca^{2+} through plasma-membrane voltage-operated Ca^{2+} channels (VOCs), a process known as Ca^{2+}-induced Ca^{2+} release (CIRC).

In excitable cells such as neurons, heart, and neuroendocrine cells, the transient $[Ca^{2+}]$ elevation is

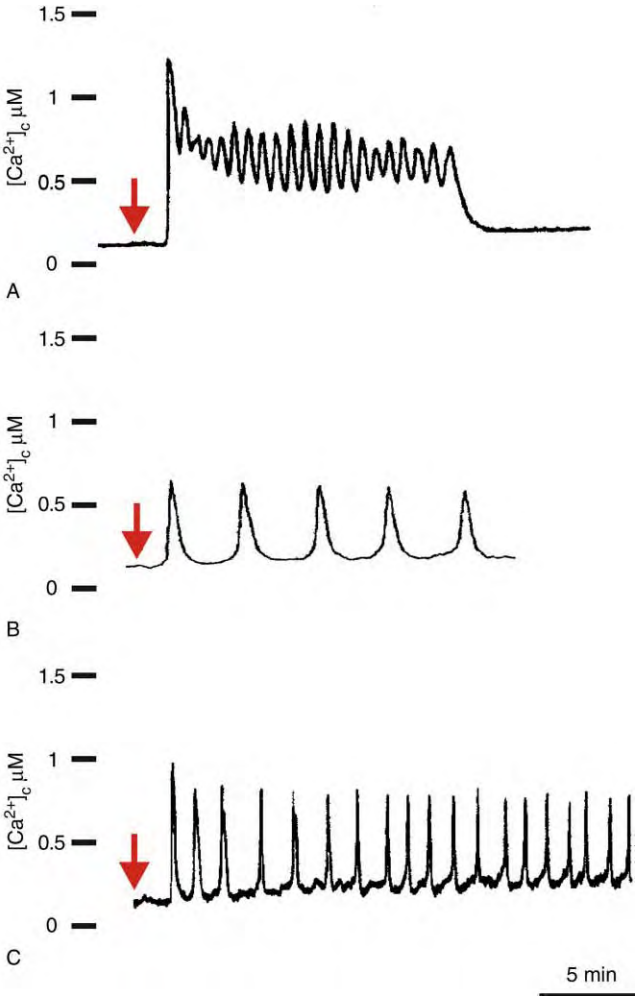

FIGURE 1 Examples of different oscillatory pathways. A, parotid gland; B, hepatocyte; C, endothelial cell. The pattern of oscillations may vary with respect to amplitude and period. The red arrow indicates agonist stimulation.

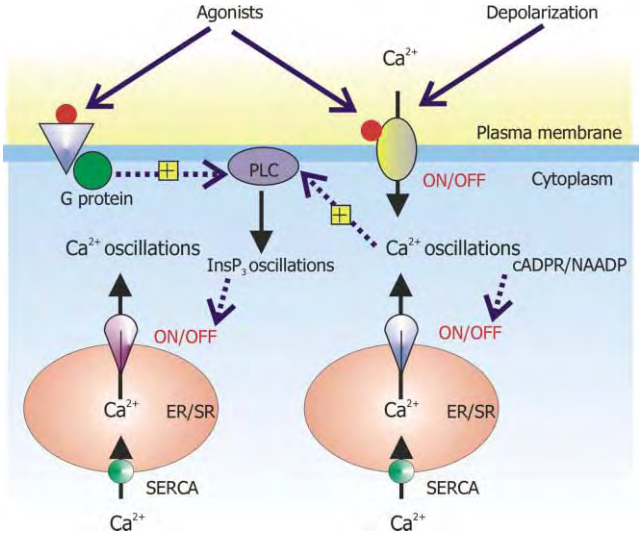

FIGURE 2 Signaling pathways that participate in the generation of Ca^{2+} oscillations. Three models are proposed. In excitable cells Ca^{2+} oscillations are evoked by rhythmic oscillatory changes in membrane potential. In nonexcitable cells they are induced either by the oscillatory production of $InsP_3$, or following the oscillatory inactivation of $InsP_3$ receptors (ON/OFF). ER/SR, endoplasmic/sarcoplasmic reticulum; PLC, phospholipase C; SERCA, sarco/endoplasmic reticulum calcium ATPase; $InsP_3$, inositol 1,4,5-trisphosphate; cADPR, cyclic ADP-ribose; NAADP, nicotinic acid adenine dinucleotide phosphate.

due to Ca^{2+} entry through voltage-operated Ca^{2+} channels or receptor-operated Ca^{2+} channels (ROCs) activated in response to neurotransmitters. In these cells the oscillatory behavior is secondary to the oscillatory nature of the trigger itself. For example, cortical and cerebellar neurons in primary cultures exhibit spontaneous oscillations that occur in synchrony with adjacent neurons and are dependent on synaptic activity, i.e., changes of membrane potential.

In nonexcitable cells the predominant mechanism of $[Ca^{2+}]_c$ elevation is through the activation of plasma membrane receptors coupled to G proteins and the phosphoinositide pathway. Activation of membrane phospholipase C (PLC) generates the second messenger $InsP_3$ from phosphatidylinositol 4,5-bisphosphate, mobilizing Ca^{2+} from stores, associated with the endoplasmic or sarcoplasmic reticulum. The pattern of the Ca^{2+} signals is often complex but $InsP_3$-linked agonists frequently give rise to repetitive $[Ca^{2+}]_c$ transients.

Other molecules (i.e., cyclic ADP-ribose, cADPR, and nicotinic acid adenine dinucleotide phosphate, NAADP) have recently also been shown to mobilize Ca^{2+} from internal stores generating Ca^{2+} oscillations. Studies using Ca^{2+} indicator dyes targeted to the lumen of intracellular stores of intact cells have shown that agonist-induced cytosolic Ca^{2+} oscillations are accompanied by inverse oscillations of stored Ca^{2+}.

Recent works suggest at least two possible mechanisms for the generation of oscillatory Ca^{2+} signals: either an oscillatory production of $InsP_3$ or oscillatory inactivation of $InsP_3$ receptors. Both mechanisms appear to operate in different cell types, the common denominator being the positive and negative feedback by Ca^{2+} on the release system, e.g., in hormone-stimulated hepatocytes, oscillations are driven by the cycling of the $InsP_3$ channels between a fully open and a largely closed state, rather than by oscillations in $InsP_3$. Similarly, in pancreatic acinar cells, the pulsatile calcium release does not depend on fluctuations in $InsP_3$ concentration, but in kidney epithelial cells spatiotemporal changes in the concentration of $InsP_3$ appear to be synchronous with Ca^{2+} oscillations, and intracellular $InsP_3$ waves accompany Ca^{2+} waves.

The fluctuations in $InsP_3$ may be controlled by Ca^{2+} itself through the regulation of PLC activity or through

regulatory proteins which act directly on G proteins, thus affecting the downstream $InsP_3$ production. Alternatively, the activity of the $InsP_3$-sensitive Ca^{2+} channels may be controlled by Ca^{2+} itself both at the cytosolic and the luminal side, and, possibly, by kinase-mediated phosphorylation/dephosphorylation cycles. Thus, low concentrations of cytosolic Ca^{2+} increase the open probability of the channels, whereas higher concentrations favor their closure, generating the oscillatory Ca^{2+}-signaling pattern.

Role and Functional Significance of $[Ca^{2+}]_c$ Oscillations

Ca^{2+} oscillations have been implicated in the control of different cell processes, among them oocyte activation and fertilization, growth-cone migration and tuning, axonal growth of cortical neurons, neuronal-cell migration, development of neurotransmitter phenotypes, formation of nodules in plant root hairs, developmental of muscle, release of cytokines from renal epithelial cells, and disassembly of adhesive structures during cell migration (Figure 3).

Numerous experimental protocols modulate the amplitude and the frequency of Ca^{2+} spikes in living cells. In general, cells choose the shape of Ca^{2+} signals according to the type of process that must be activated: single Ca^{2+} transients are used to activate processes such as muscle contraction, repetitive signals are used when information must be relayed over long time periods, as in fertilization and in the triggering of the developmental program. Furthermore, oscillations can be directed to discrete subcellular domains to generate large local $[Ca^{2+}]_c$ increases required to couple $[Ca^{2+}]_c$ to secretion and to mitochondrial metabolism. They can also propagate through entire cells, or even through coupled cells to coordinate the activities in intact tissues and organs.

The most obvious mechanism for the regulating of specific functions would seem to be modulation of the amplitude of Ca^{2+} signals. However, the efficiency of the activating stimulus is frequently related to the frequency rather than to the amplitude of the $[Ca^{2+}]_c$ oscillations.

A particularly illustrative example of decoding of the Ca^{2+} signal through the frequency of the oscillations is the Ca^{2+}-regulated gene expression.

Dolmetsch and colleagues have recently reported that Ca^{2+} oscillations in T-lymphocytes reduce the effective Ca^{2+}-threshold for activating some transcription factors, more effectively than the sustained Ca^{2+} increase. The efficacy is encoded by the oscillation frequency: rapid oscillations stimulate three transcription factors (NF-AT, Oct/OAP, and NF-κB), while lower-frequency oscillations only activate NF-κB. Thus, Ca^{2+}-modulated gene transcription is a frequency-sensitive process. Another elegant example of the correlation between the frequency of the $[Ca^{2+}]$ spikes and cellular function is the translation of repetitive cytosolic Ca^{2+} spiking through mitochondrial Ca^{2+} oscillations in primary cultures of rat hepatocytes in the final and sustained elevation of NAD(P)H production. This coupling allows the coordination of mitochondrial ATP production, linked to the sustained activation of mitochondrial Ca^{2+}-sensitive dehydrogenases, with the level of energy demand, at the same time avoiding the deleterious effects of the prolonged increase in $[Ca^{2+}]$.

In polarized cells, such as those of pancreatic acini, the receptor-evoked Ca^{2+} signal initiates at the apical pole, generating agonist-specific Ca^{2+} oscillation patterns. Acetylcholine stimulation evokes repetitive local spikes, which remain confined to the secretory apical pole. Cholecystokin instead induces local Ca^{2+} spikes

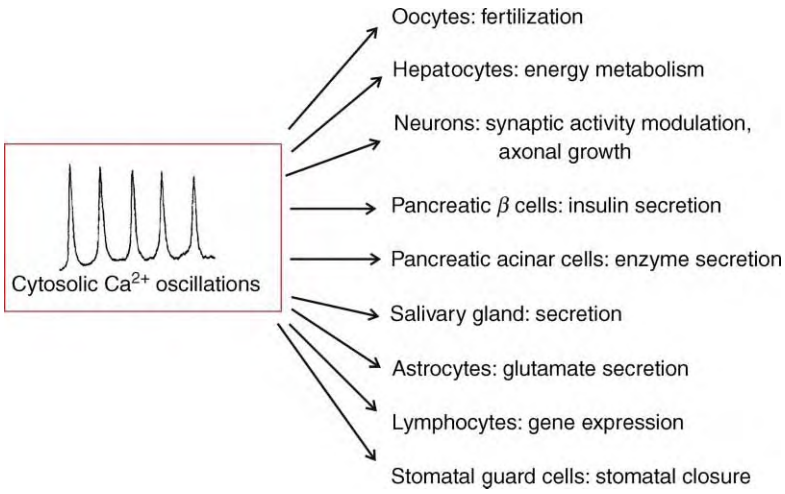

FIGURE 3 Scheme of the main cellular events modulated by the oscillatory behavior of Ca^{2+} signal.

that end in longer-lasting Ca^{2+} transients that spread to the whole cell.

Last but not least, in considering the functional significance of Ca^{2+} oscillations it is necessary to empathize their role in the central nervous system. In neurons, the sequential openings of plasma membrane Ca^{2+} channels lead to rhythmic Ca^{2+} spikes that, in turn, are linked to synaptic communication within and among neuronal circuitries, i.e., by inducing the release of neurotransmitters. A peculiar role has recently been attributed to the spontaneous and synchronous Ca^{2+} oscillations that occur independently from synaptic activity in developing neurons, such as those in rat visual cortex. It was suggested that these oscillations could propagate through different cells and determine a common developmental pattern of cells from the same domain.

A sophisticated example of the role of Ca^{2+} oscillation in the coordination of the activity of neuronal circuits has been described in glial astrocytes, a cell type of the central nervous system, which plays a number of important functions. Very recently, it has been proposed that they work as detectors of synaptic activity: by changing the frequency of Ca^{2+} oscillations evoked by the synaptic release of glutamate, these astrocytes acquire the ability to discriminate between different levels and patterns of synaptic activity.

How Are $[Ca^{2+}]_c$ Oscillations Decoded?

Although the frequency of Ca^{2+} oscillations seems critical for the induction of selective cellular functions, the mechanisms by which the cell decodes the oscillatory signal remain unclear.

In 1998 De Koninck and Schulman showed that the oscillation frequency modulates the activity of Ca^{2+}-calmodulin Kinase II (CaMKII) *in vitro*. This enzyme is tuned to respond optimally to Ca^{2+} oscillations with high frequency. The multimeric structure of the enzyme, coupled to its autophosphorylation properties, has led to the suggestion that it can act as a frequency decoder of $[Ca^{2+}]_c$ oscillations. The enzyme is now considered of special importance to the nervous system, where it regulates the process of memory formation and storage.

More recently, the advent of the green fluorescent protein (GFP) technology has shown that protein kinase C (PKC), one of the most important enzymes in cell signaling, undergoes an oscillatory plasma membrane association in phase with receptor-mediated oscillations in $[Ca^{2+}]_c$. Each $[Ca^{2+}]_c$ oscillation induces the transient membrane association of PKC leading to a transient burst of PKC substrate phosphorylation. It was suggested that the detachment of PKC from the membrane, which occurs as Ca^{2+} returns to the basal level between oscillations, results in a pause of PKC activity, allowing substrate dephosphorylation. In this respect, the Ca^{2+}-mediated regulation of PKC differs from that of CaMKII, since the latter does not fully deactivate between spikes as the frequency of $[Ca^{2+}]_c$ oscillations increases.

Biography

Marisa Brini is an Assistant Professor of Biochemistry at the University of Padova. Her main interest is in the study of calcium signaling defects occurring in human genetic diseases and/or transgenic animal models (malignant hyperthermia, mitochondrial disorders, and various cardiopathies) in which the homeostasis of Ca^{2+} in muscle is altered.

Calcium Sensing Receptor

Jacob Tfelt-Hansen and Edward M. Brown
Brigham and Women's Hospital, Harvard University, Boston, Massachusetts, USA

The calcium sensing receptor (CaR) is a membrane-bound, G protein-coupled receptor that is expressed in all tissues that regulate extracellular calcium homeostasis – the parathyroid glands, thyroidal C cells, bone, kidney, and intestine. The CaR senses the level of calcium in the blood and acts, therefore, as the body's thermostat for calcium (or calciostat). When the level of calcium changes by even a few percent from its normal level, the CaR senses this change and then modulates the functions of the cells expressing it so as to restore the level of blood calcium to normal. The CaR-mediated regulation of the secretion of parathyroid hormone plays a particularly important role in calcium homeostasis because it directly or indirectly modulates the functions of all tissues involved in regulating blood calcium.

Background

The body maintains the level of extracellular calcium (Ca_o^{2+}) within a narrow range (1.1–1.3 mM) because both high and low levels of Ca_o^{2+} are dangerous and can be life-threatening. Very small changes in Ca_o^{2+}, on the order of a few percent, lead to immediate physiological responses that restore the level of Ca_o^{2+} to normal. These fast responses are essential because rapid changes in Ca_o^{2+} are more dangerous than those that develop more slowly. The calcium sensing receptor (CaR), which was cloned almost a decade ago, plays a central role in this delicate homeostatic system. The CaR acts like a thermostat, but instead of measuring changes in temperature it measures alterations in the level of Ca_o^{2+}, thereby functioning as a calciostat. This means that the CaR tells the chief cells of the parathyroid glands the exact level of Ca_o^{2+}. The CaR is a seven-transmembrane-domain receptor that is coupled to G proteins – called a G protein-coupled receptor (GPCR). The importance of the CaR is illustrated by the diseases caused by naturally occurring mutations in it that lead to either loss of function or gain of function. Heterozygous (one-allele) loss-of-function mutations give rise to familial hypocalciuric hypercalcemia (FHH, also called familial benign hypocalciuric hypercalcemia, FBHH), in which most patients have asymptomatic hypercalcemia. The homozygous variant of inactivating CaR mutations, in contrast, is a much more severe, potentially fatal disease if left untreated; it is called neonatal severe primary hyperparathyroidism (NSHPT). The mouse model of FHH (e.g., heterozygous knockout of the CaR gene) has a phenotype comparable to that of the human condition, suggesting that the number of receptors on the cell surface is the determining factor for the clinical expression of the disease. Gain-of-function mutations give rise to autosomal-dominant hypoparathyroidism (ADH). Most patients with this condition have asymptomatic hypocalcemia. Although the principal role for the CaR is in calcium homeostasis, other functions of the receptor have been elucidated in the wide variety of cell types expressing it. The CaR can modulate the cell cycle, regulate ion channels, and control peptide secretion. This entry provides a broad overview of the CaR's biochemical features, a discussion of its functions in normal and pathophysiologic states, and a discussion of new drugs that have been developed that target the CaR.

Biochemical Features of the CaR

The CaR is a seven-transmembrane-domain GPCR whose gene is located on chromosome 3q. Other receptors in the superfamily of GPCRs that are related structurally to the CaR include the $GABA_B$ and metabotropic glutamate receptors (mGluRs), which recognize gamma aminobutyric acid (GABA) and glutamate, respectively, as their ligands, as well as putative pheromone and odorant receptors.

Structure

The human CaR has a very large N-terminal extracellular domain (ECD) of 612 amino acids (Figure 1). The ECD contains binding sites for calcium and is thought to have a bilobed venus flytrap structure that closes upon binding its principal physiological ligand, extracellular calcium ions. The binding of Ca_o^{2+} is very weak compared to many other receptors. These weak forces between the ECD and Ca_o^{2+} are crucial for the receptor to act as a calciostat. The CaR has a central core of

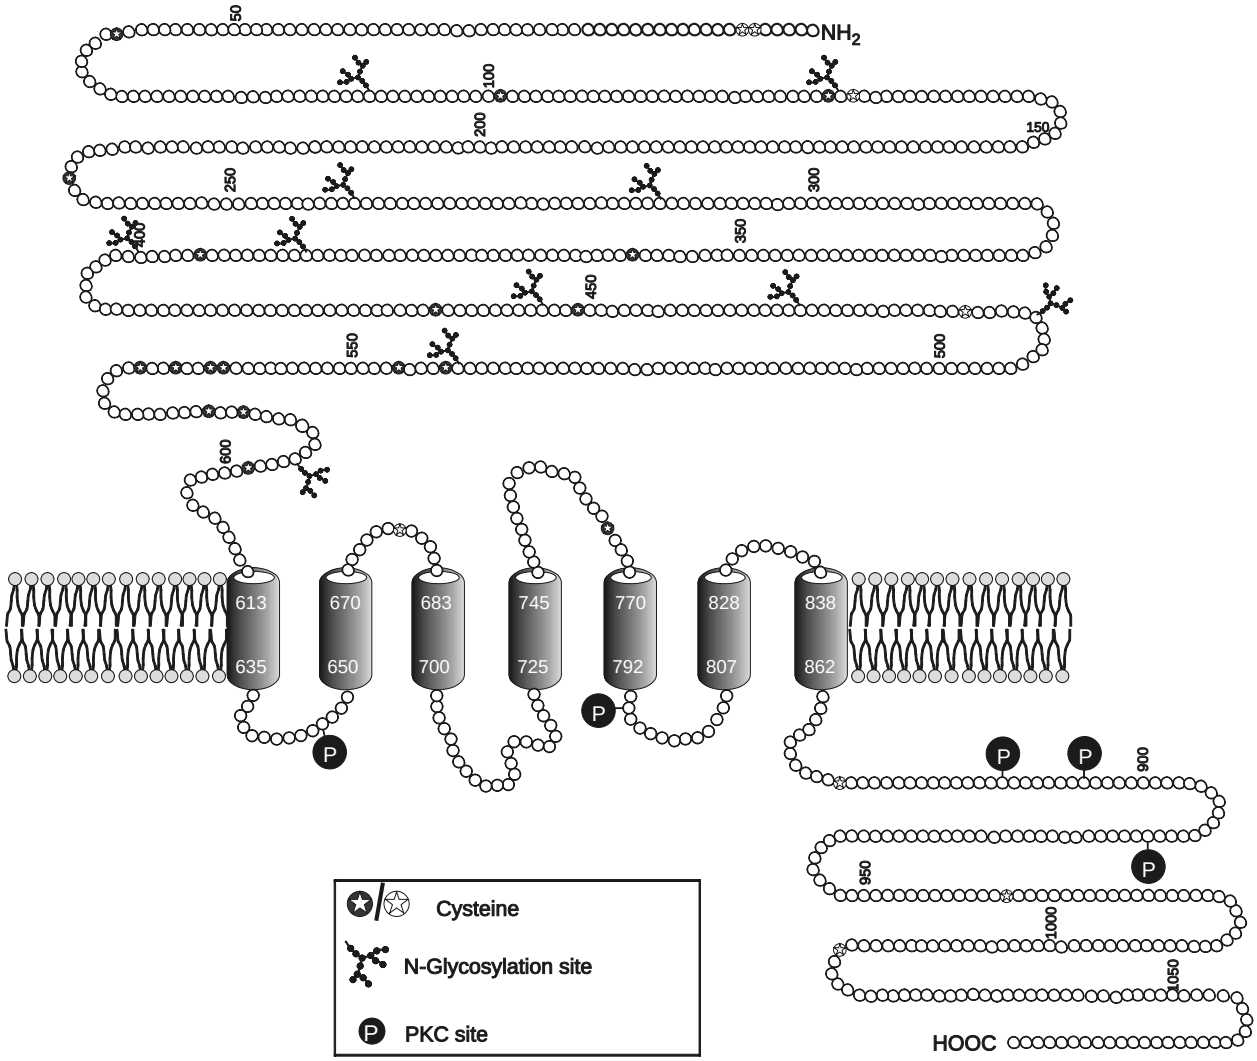

FIGURE 1 Representation of the predicted topological features of the human extracellular Ca^{2+} sensing receptor. The extracellular domain contains 612 amino acids, and the transmembrane domains and intracellular C tail each contain approximately 200 amino acids. Also shown are the PKC sites, N-glycosylation sites, and cysteine residues conserved with the metatropic glutamate receptors.

250 amino acids with seven transmembrane domains (TMDs), which is characteristic of the GPCRs. The TMDs serve as the target for newly developed drugs (discussed later). The intracellular carboxy (C) terminus of the receptor consists of 216 amino acids and has an important role, along with the CaR's intracellular loops, in the transduction of the Ca_o^{2+} signal to inside the cell.

N-Glycosylation with Carbohydrates is Crucial for Cell Surface Expression

The CaR has several N-linked glycosylation sites that are important for its expression on the cell surface. Western blotting of the CaR shows several bands between 120 and 200 kDa. A minor band at 120 kDa represents the nonglycosylated CaR, whereas major bands at 140 and 160 kDa correspond to the immature, high mannose and mature, fully N-glycosylated forms of the CaR, respectively. If the degree of glycosylation of the receptor is reduced to a significant extent by site-directed mutagenesis of its N-linked glycosylation sites, less of the receptor reaches the cell surface.

CaR Functions as a Dimer on the Cell Surface

Additional immunoreactive bands observed on Western blot analysis of the CaR at >200 kDa represent CaR dimers or even larger species. The dimer is the major form of CaR on the cell surface and is thought to be the active form of the receptor. Two monomers of the CaR are linked covalently by two disulfide bonds between cysteine residues 129 and 131 as well as by noncovalent interactions. The disulfide bonds constrain the receptor

in its inactive form; disrupting them produces a receptor that responds to lower than normal levels of Ca_o^{2+}. Moreover, heterodimerization of a normal CaR monomer with a monomer harboring an FHH mutation can interfere with the function of the wild-type CaR monomer, documenting that there are functional interactions between the monomers of the dimeric CaR.

Amino Acids in Intracellular Loops are Pivotal for Activation of Intracellular Signaling by the CaR

Amino acids in intracellular loops 2 and 3 are key players in determining selective coupling of the CaR to G proteins. For example, two amino acids residues within intracellular loop 2 and eight residues in intracellular loop 3 have been shown to be important for the G protein-dependent activation of phospholipase C (PLC) – one of the major intracellular signaling pathways used by the CaR.

The C Tail of the CaR is Important for its Function

The amino acid sequence of the proximal portion of the C tail of the CaR is highly conserved among species, suggesting its functional importance. In addition, naturally occurring mutations in the C tail have been shown to cause the diseases mentioned earlier (e.g., FHH and ADH). Furthermore, certain truncation and deletion mutations of the receptor's C tail up-regulate the expression of the receptor on the cell surface, thereby causing gain of function. Other truncations have been shown to cause loss of function, demonstrating that there are discrete elements within the C tail that modulate both the cell surface expression and function of the receptor.

Functionally Important Mutations in the CaR as Experiments in Nature

Approximately 100 naturally occurring mutations have so far been described that cause either a loss of function of the CaR in FHH and NSHPT or a gain of function in ADH. Deletion, nonsense, insertion, missense, truncations, and splice-site mutations have been described throughout the whole CaR gene. They have not only proven the physiological importance of the CaR in Ca_o^{2+} homeostasis, but have also provided an important source of information about the structure-function relationships of the receptor, as noted previously.

Agonists of the CaR

As previously mentioned, the CaR can detect very small changes in the level of $Ca_{o,}^{2+}$ on the order of a few percent. The receptor's principal physiological agonist, Ca_o^{2+}, regulates its activity at millimolar concentrations, implying an extremely low affinity compared with those of other receptors for their respective agonists. Calcium has been shown to interact with the ECD of the CaR. This has been established elegantly through the creation of a chimeric receptor containing the ECD of the CaR and the TMDs and C tail of an mGluR. The chimeric receptor responds to Ca_o^{2+} but not to glutamate. The CaR's Hill coefficient is typically 3–4, implying the presence of several binding sites for Ca_o^{2+}, but the steepness of the physiological response of the parathyroid glands to Ca^{2+} is even more extreme. Suppression of parathyroid hormone (PTH) release *in vitro* is minimal at 0.75 mM and maximal at ~2 mM. Unlike many receptors, the CaR is resistant to desensitization; this optimizes the CaR's capacity for continuous surveillance of extracellular Ca^{2+} levels. Although Ca_o^{2+} is the major ligand for the CaR, a variety of other agonists have been identified. Mg^{2+}(another biologically important divalent cation whose extracellular level is maintained within a narrow range) has been shown, like Ca_o^{2+}, to inhibit PTH secretion. Although this effect seems to be at supraphysiological levels, magnesium's action on the CaR in the kidney may regulate its renal reabsorption and contribute to Mg_o^{2+} homeostasis. Other well-established agonists acting on the ECD are gadalinium, neomycin, and spermine; all exhibit positive cooperativity with regard to their interactions with calcium in activating the receptor. These three agonists, as well as Mg_o^{2+}, are defined as type 1 agonists, which bind to the ECD and activate the CaR regardless of whether Ca_o^{2+} is present. Type 2 agonists, in contrast, are allosteric activators that require calcium to exert their effects. Certain L-amino acids, particularly aromatic amino acids, have been shown to be type 2 agonists, binding to a site within the ECD of the CaR. It is possible that they function in this manner in the gut, where the CaR is widely distributed, enabling the CaR to act, in effect, as a nutrient receptor. The CaR also senses ionic strength, as illustrated by the fact that exposing dispersed bovine parathyroid cells to a 40-mM increment in NaCl shifts the EC_{50} for high Ca_o^{2+}-evoked inhibition of PTH release by at least 0.5 mM. Ionic strength may exert physiologically relevant actions on the CaR in select regions of the gastrointestinal (GI) tract and kidney, where the levels of ionic strength can vary greatly.

Intracellular Signaling Pathways Used by the CaR

CaR agonists activate phospholipases C, A_2, and D in parathyroid as well as in CaR-transfected but not in nontransfected human embryonic kidney (HEK293) cells. The high Ca_o^{2+}-evoked, transient rise in the cytosolic calcium concentration (Ca_i^{2+}) in bovine parathyroid and CaR-transfected HEK293 cells is mediated

by activation of PLC and the resultant inositol triphosphate (IP_3)-mediated release of Ca^{2+} from intracellular stores. In parathyroid and CaR-transfected HEK293 cells, the activation of PLC is insensitive to pertussis toxin and probably involves $G\alpha_{q/11}$. In contrast, the CaR-mediated increase in inositol phosphates observed in the mouse pituitary AtT-20 cell line is sensitive to pertussis toxin, showing that the CaR can also activate PLC through pertussis toxin-sensitive G proteins (i.e., $G\alpha_i$). The CaR also stimulates the p42/44 mitogen-activated protein kinases (MAPKs) by a pathway that involves cytoplasmic tyrosine kinases (e.g., c-Src) and inhibits adenylate cyclase via $G\alpha_i$ in parathyroid and some kidney cells. In other cells, the CaR inhibits the accumulation of cAMP by increasing Ca_i^{2+}, which then inhibits the activity of a Ca^{2+}-inhibitable isoform of adenylate cyclase.

Feedback Regulation of the CaR by Protein Kinase C

The CaR has two protein kinase A (PKA) and five protein kinase C (PKC) phosphorylation sites within its intracellular domains. Phosphorylation of these PKC sites, especially the one located at threonine 888, inhibits the receptor's coupling to PLC, one of the CaR's principal intracellular signaling pathways. This serves as a negative feedback loop because PKC is activated downstream of PLC.

The Importance of the CaR in Calcium Homeostasis

The level of calcium is regulated by three calciotropic hormones: PTH, calcitonin (CT), and $1,25(OH)_2$ vitamin D_3. There is an inverse sigmoidal relationship between PTH, a key calcium-elevating hormone, and Ca_o^{2+} (Figure 2), whereas there is a positive relationship between Ca_o^{2+} and CT, the calcium-lowering hormone, both of which are mediated by the CaR. These features confer on the CaR the role of the gatekeeper to normal calcium homeostasis. The additional Ca_o^{2+}-elevating hormone, $1,25(OH)_2$ vitamin D_3, like PTH, displays an inverse relationship with Ca_o^{2+}, although whether this is CaR-mediated is currently unknown. In addition to the effects of the CaR on calciotropic hormone production and secretion, the receptor also directly modulates the function of target tissues for PTH, especially the kidney and perhaps in bone and intestine. In this way, Ca_o^{2+} functions as a first messenger, serving as the body's major Ca_o^{2+}-lowering hormone (described later).

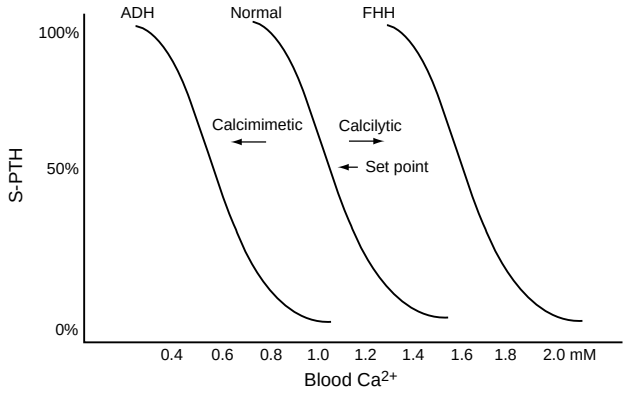

FIGURE 2 Sigmoidal relationship between the blood Ca^{2+} and serum PTH (S-PTH) levels in normal individuals (eucalcemia), in autosomal dominant hypoparathyroidism (ADH) (hypocalcemia), and in familial hypocalciuric hypercalcemia (FHH). The arrows represent the effects of calcimimetics (shifting the set point to the left) and calcilytics (shifting the set point to the right). Set point is defined as the calcium level that produces one-half of the maximal inhibition of the PTH secretion.

CaR in Hypercalcemia

The responses of the CaR to hypercalcemia provide an accurate picture of its role in calcium homeostasis. An increase in Ca_o^{2+} is sensed by the chief cells in the parathyroid gland, which within seconds lowers the rate of PTH secretion. The impact of this reduction in PTH secretion and in the direct actions of Ca_o^{2+} on cellular function occur in several target tissues.

Bone

The high Ca_o^{2+}-elicited lowering of PTH decreases the rate of release of calcium ions from bone – an action mediated through its action on the PTH receptor (PTHR) on the osteoblast. The production of $1,25(OH)_2$ vitamin D_3 is likewise inhibited by hypercalcemia – and this fall in $1,25(OH)_2$ vitamin D_3 also reduces bone resorption. High Ca_o^{2+}, by itself, also exerts negative effects on osteoclast formation and function and increases osteoblast activity, thereby reducing the net release of calcium from bone. Taken together, the effects of PTH, $1,25(OH)_2$ vitamin D_3, and Ca_o^{2+} on bone all lower the level of blood calcium.

Kidney and Intestine

The high Ca_o^{2+}-elicited decrease in the circulating level of PTH also promotes rapid excretion of calcium by the kidney. This action is thought to take place through a reduction in the PTH-induced stimulation of calcium reabsorption in the thick ascending limb of the loop of Henle as well as the distal convoluted tubule. However, high Ca_o^{2+} also directly inhibits calcium reabsorption by virtue of the presence of the CaR on the basolateral

surface of the epithelial cells of the thick ascending limb, where the receptor antagonizes the stimulatory action of PTH on calcium reabsorption. Both the high Ca_o^{2+}-elicited decrease in PTH and the direct inhibitory action of high Ca_o^{2+} on the 1-hydroxylation of 25-hydroxy-vitamin D_3 inhibit the production of $1,25(OH)_2$ vitamin D_3, thereby reducing the absorption of Ca_o^{2+} by the intestine. All these effects of hypercalcemia on the kidney reduce the level of Ca_o^{2+} toward normal. When combined with the effects of a reduction in PTH and an increase in Ca_o^{2+} on bone, the Ca_o^{2+} homeostatic system provides an elegant mechanism for maintaining near constancy of Ca_o^{2+}.

Nonhomeostatic Functions of the CaR

Although the physiological role of the CaR in cells that do not participate in mineral ion homeostasis still remain to be fully defined, studies of the CaR's functions in these diverse cell types have widened the range of functions that the CaR is known to regulate. These CaR-modulated processes include (1) secretion of peptides, for example, ACTH, gastrin, insulin, growth hormone, and PTHrP; (2) ion channel/transporter activity, for example, aquaporin-2 water channels, nonselective cation channels, voltage-dependent Ca^{2+} channels, and calcium-activated potassium (K^+) and other K^+ channels; (3) gene expression, for example, of the vitamin D receptor and the CaR; (4) proliferation of colonic and ovarian surface epithelial cells, fibroblasts, and keratinocytes; (5) differentiation of keratinocytes, goblet cells, and mammary epithelial cells; (6) apoptosis of fibroblasts, HEK-293 cells stably transfected with the CaR, and prostate cancer cells; and (7) chemotaxis of preosteoblastic cells and macrophages. Thus Ca_o^{2+} may serve as an extracellular messenger regulating diverse cellular functions, not only in cells directly involved in Ca_o^{2+} homeostasis but also in the variety of additional cell types expressing the CaR that play no apparent role in this process.

Pharmaceutical Aspects

The CaR has become a drug target as a consequence of its central role in calcium homeostasis and the evidence given earlier that it contributes to hyper- and hypocalcemic states. There are two classes of drugs acting on the CaR. One group activates the receptor; these drugs are called calcimimetics. The other group inhibits the effect of Ca_o^{2+} on the CaR; these agents are called calcilytics.

Calcimimetics

Calcimimetics are type 2 activators that bind to the receptor's TMDs and potentiate the action of Ca_o^{2+} on the CaR. NPS R-568 and AMG073 are two such agents that shift the curve for Ca_o^{2+}-regulated changes in Ca_i^{2+} and PTH release to the left without affecting the maximal or minimal responses (Figure 2). Ongoing clinical trials suggest that calcimimetics may prove to be useful in the treatment of hyperparathyroidism, such as in the secondary hyperparathyroidism that occurs in end-stage renal disease.

Calcilytics

This group of agents has the opposite effect, inhibiting the receptor and thereby stimulating PTH secretion (Figure 2). This class of drugs could potentially be useful in the treatment of osteoporosis by providing brief pulses of endogenous PTH secretion. The resultant transient increase in PTH mimics that caused by the once-daily administration of exogenous PTH, which is known to exert anabolic actions on bone and has recently been approved for use in the treatment of osteoporosis.

Biography

Jacob Tfelt-Hansen is a Postdoctoral Fellow at Harvard University. His research interests are calcium homeostasis and the non-calcium-homeostatic effects of the CaR. He received his M.D. degree from Copenhagen University, Denmark.

Edward M. Brown is a Professor of Medicine at Harvard Medical School and Brigham and Women's Hospitals. He has worked in the field of calcium homeostasis for nearly 30 years. He received his M.D. degree from Harvard University in 1972. He led the team that cloned the CaR and also played a key role in the identification and characterization of inactivating and activating mutations in the CaR.

Calcium Signaling: Calmodulin-Dependent Phosphatase

Claude Klee, Hao Ren and Shipeng Li
National Cancer Institute, Bethesda, Maryland, USA

Calcineurin (also called protein phosphatase-2B) is a eukaryotic protein phosphatase whose activity is dependent on Ca^{2+} and calmodulin. Ten years ago, the identification of calcineurin as the target of the immunosuppressive drugs, cyclosporin A (CsA) and tacrolimus (FK506), revealed the key role of calcineurin in the transduction pathway from the plasma membrane to the nucleus leading to T cell activation. Since then, the inhibition of calcineurin by FK506 and CsA complexes with their respective binding proteins, FKBP12 and cyclophilin A (CyPA), together with the overexpression of a truncated derivative of calcineurin, not dependent on Ca^{2+} or calmodulin (CaM), have been widely used to probe the involvement of calcineurin in the regulation of cellular processes. These are as diverse as gene expression, ion homeostasis, muscle differentiation, embryogenesis, secretion, and neurological functions. Alteration of calcineurin activity has been implicated in the pathogenesis of many diseases such as cardiac hypertrophy, congenital heart diseases, and immunological and neurological disorders.

Subunit Structure and Isoforms

Calcineurin is a heterodimer of a 58–64 kDa catalytic subunit, calcineurin A (CnA), tightly bound to a 19 kDa Ca^{2+}-binding regulatory subunit, calcineurin B (CnB). This subunit structure, unique among protein phosphatases, is conserved in all eukaryotes. Three mammalian isoforms (α, β, γ) of CnA have been identified at the mRNA level. The corresponding human genes (PPP3CA, PPP3CB, PPP3CC) are located on human chromosomes 4, 10, and 8 respectively. Additional isoforms, products of alternative splicing, have only been detected at the mRNA level. Two mammalian isoforms of CnB, CnB1, and CnB2 (expressed only in testis), are the products of two genes (PPP3R1 located on chromosome 2, and PPP3R2). Although expressed in most, if not all tissues, calcineurin is particularly abundant in the brain where the α-isoform of CnA is predominant. The β-isoform is broadly distributed whereas the γ-isoform is expressed specifically in the testis. Calcineurin has been identified in many other eukaryotes including plants, fungi, and the budding yeast, *Saccharomyces cerevisiae*. Another calmodulin-stimulated protein phosphatase with a CnB-like structure covalently bound to the catalytic subunit has been identified in *Drosophila melanogaster*'s retina.

Structure

The domain structure of calcineurin is well conserved. In all species the catalytic domain located in the N-terminal two-thirds of CnA, is followed by a CnB-binding domain. The C-terminal regulatory domain is composed of CaM-binding and autoinhibitory subdomains. In the absence of CaM the native protein is inactive. The catalytic and CnB-binding domains, severed from the regulatory domain by limited proteolysis, constitute the Ca^{2+}-independent, truncated, form of calcineurin routinely used in overexpression experiments. CnB is an "EF-hand" Ca^{2+}-binding protein of the CaM family. It binds four Ca^{2+}, two with high affinity ($K_d < 10^{-7}$ M) and two with moderate affinity ($K_d \geq 10^{-6}$M). The N-terminal glycine of CnB is myristoylated. This perfectly conserved posttranslational modification of CnB, apparently not involved in membrane association or required for enzymatic activity, may serve as a stabilizing structural element.

The crystal structure of the recombinant α-isoform of human calcineurin as expressed in *E. coli* is illustrated in Figure 1A. The architecture of the catalytic domain is similar to those of protein phosphatases-1 and -2A. It consists of a β-sandwich surrounded on one side by seven α-helices and on the other by a mixed α/β structure. The catalytic site contains a Fe^{3+}–Zn^{2+} binuclear metal center. The catalytic domain extends into a five-turn amphipathic α-helix whose top face is covered by a 33Å groove formed by the N- and C-terminal lobes and the C-terminal strand of CnB. A short helical segment, corresponding to the autoinhibitory domain, blocks the catalytic center. With the exception of this segment, the C-terminal regulatory domain is not visible in the electron density map, and is flexible and highly sensitive to proteolysis, in the absence of CaM. The crystal

(B) Truncated calcineurin complexed with FKBP12-FK506 [PDB code 1TCO Griffith, J. P., Kim, J. L. Kim, E. E., Sintchak, M. D., Thomson, J. A., Fitzgibbon, M. J., Fleming, M. A., Caron, P. R., Hsiao, K., and Navia, M. A. (1995). X-ray structure of calcineurin inhibited by the immunophilin-immunosuppressant FKBP12-FK506 complex. *Cell* **11**, 507–522. CnA is shown in yellow, CnB in blue. Iron and zinc are shown as light gray and blue spheres respectively. The four calcium bound to CnB are shown as red spheres. FKBP12 is shown in red.

structure of the proteolytic derivative of calcineurin, lacking the regulatory domain, when bound to FK506/FKBP12, is similar to that of the full-length protein (Figure 1B). The bottom face of the CnB-binding helix of CnA and CnB form the site of interaction with the FKBP–FK506 and CsA–CyP complexes. The key role of CnB in forming the drug-binding site provides a molecular basis for the specificity of FK506 and CsA as calcineurin inhibitors.

Enzymatic Properties

Ca^{2+}/Calmodulin-Dependent Stimulation and Inactivation

Calcineurin is a protein phosphatase with a binuclear iron–zinc active center. The purified enzyme, partially depleted of its metal cofactors, is activated by 0.1 mM Mn^{2+} or 6 mM Mg^{2+}. Purified calcineurin, that has retained stoichiometric amounts of Fe^{3+} and Zn^{2+}, is inactive and not activated by exogenous metal ions. Activation requires treatment under anaerobic conditions with the reducing agent, ascorbate, which converts Fe^{3+} to Fe^{2+}. The phosphatase activity of calcineurin is also dependent on the presence of Ca^{2+} and calmodulin. A small activation is observed upon addition of Ca^{2+} ($K_{act} = 0.5\ \mu M$). Supplementation with CaM results in a 50–100-fold increase of the V_{max} without affecting the value of the K_m. The highly cooperative stimulation of the enzyme by CaM (Hill coefficient of 2.5–3) allows calcineurin to respond to narrow Ca^{2+} thresholds following cell stimulation. Because of its high affinity for CaM ($K_{act} < 10^{-10}$ M) the activation of calcineurin in response to a Ca^{2+} signal can precede the activation of all known CaM-regulated kinases.

Enzymatic Assays

A 19-residue synthetic peptide containing the phosphorylation site of the RII subunit of cAMP-dependent protein kinase (PKA) and *p*-nitrophenylphosphate are used routinely to measure the phosphatase activity of calcineurin. In crude tissue extracts calcineurin activity is distinguished from that of other neutral serine–threonine protein phosphatases by its (1) Ca^{2+} dependence; (2) inhibition by CaM-binding peptides and inhibitors; (3) resistance to the inhibitors of protein phosphatases-1 and -2A (Inhibitor-1, DARPP32, Inhibitor-2, okadaic acid, microcystin, and calyculin); and (4) specific inhibition by FK506 (but not rapamycin) and CsA in the presence of saturating amounts of their respective binding proteins, FKBP12 and CyPA. The *p*-nitrophosphatase activity of calcineurin, which is stimulated by FK506 and CsA, cannot be used to measure calcineurin activity in crude extracts. Unlike protein phosphatase-2C, which requires Mg^{2+} for activity, calcineurin that has retained its natural metal cofactors does not require Mg^{2+}.

Substrate Specificity

Calcineurin is a dual protein phosphatase. It dephosphorylates both phosphoseryl/threonyl and phosphotyrosyl peptides. Peptides with a basic residue on the

N-terminal side of the phosphorylated amino acid and lacking acidic residues on the C-terminal side are preferentially dephosphorylated by calcineurin. The substrate specificity of calcineurin also depends on an extended N-terminal stretch. In addition to the recognition of the sequence surrounding the phosphorylated residues, the presence of docking domains greatly decrease the K_m values. A major substrate of calcineurin, the transcription factor NFAT (Nuclear Factor of Activated T cells), contains two such domains responsible for its Ca^{2+}-dependent and phosphorylation-independent anchoring to calcineurin. The anchoring of NFAT allows its dephosphorylation, despite its low intracellular concentration, and the nuclear cotranslocation of calcineurin and NFAT.

Regulation

Ca^{2+} Regulation

Two structurally similar but functionally different Ca^{2+}-binding proteins, CaM and CnB mediate the Ca^{2+} regulation of calcineurin. CnB is tightly bound to CnA even in the absence of Ca^{2+}, and plays both structural and functional roles. It is required to confer enzymatic activity to the catalytic subunit. The recombinant α- and β-isoforms of CnA expressed in bacteria and SF9 cells require CnB for activity. Ca^{2+}-binding to CnB is required for the interaction of calcineurin with immunosuppressive drugs bound to their binding proteins.

Ca^{2+}-dependent binding of CaM to calcineurin induces a conformational change of the regulatory domain accompanied by the displacement of the autoinhibitoy domain. The resulting exposure of the catalytic center allows substrate binding and results in activation of the phosphatase activity. Prolonged exposure of the catalytic center facilitates the oxidation of Fe^{2+} and results in inactivation of calcineurin that is prevented by superoxide dismutase and reversed by ascorbate. Thus, CaM can both activate and inactivate calcineurin depending of the length of the Ca^{2+} signal. The calmodulin-dependent oxidation of Fe^{2+} and inactivation of calcineurin is a potential mechanism to regulate its activity during oxidative stress.

Endogenous Regulatory Proteins

Endogenous protein inhibitors or activators, whose expression varies from tissue to tissue, can also modulate the activity of calcineurin activity *in vivo*. A family of 22–24 kDa proteins, identified in both yeast (RCn1p) and mammalian cells (calsuppressins, MCPs), act as feedback inhibitors of calcineurin. The mammalian proteins, whose expression is up-regulated by a calcineurin/NFAT-dependent mechanism, are identical to the proteins encoded in the Down's syndrome Critical Region 1 gene, ZAK1–4, DSCRIL1, and DSCRIL. These inhibitory proteins inhibit both calcineurin expression and activity. They interact with calcineurin in the absence of Ca^{2+} through a highly conserved ISPP × SPP motif, similar to the SP motifs of NFAT, and inhibit calcineurin activity *in vitro* as well as NFAT activation *in vivo*.

A 240 kDa nuclear protein, Cain/Cabin1 has been identified as a non-competitive inhibitor of calcineurin. Binding of Cabin1 to calcineurin requires Ca^{2+} and protein kinase C activation and is inhibited by FK506/FKBP, suggesting that it binds at the drug interaction site. A basic domain in the C terminus of Cabin1 has been identified as the calcineurin-binding site. A third group of proteins, including the PKA scaffold protein, AKAP79 in brain, and calsarcins in skeletal and cardiac muscles may serve to anchor calcineurin to its sites of action. They all inhibit calcineurin activity but their mechanism of action is not yet fully understood.

Functions

Regulation of Gene Expression

The elucidation of the Ca^{2+}/calcineurin/NFAT pathway of T cell activation opened the way to uncover the important role of calcineurin in the regulation of gene expression in many other cell types. As illustrated on Figure 2, in T cells, when Ca^{2+} is released from the inositol trisphosphate (IP_3)-sensitive stores following occupancy of the T cell receptor, calcineurin is activated and dephosphorylates the transcription factor NFAT. Dephosphorylation of NFAT is accompanied by the exposure of a nuclear localization signal and NFAT is translocated to the nucleus. Calcineurin, anchored to NFAT through an anchoring domain (P × I × IT), is translocated to the nucleus as well. Dephosphorylation of NFAT not only results in its nuclear translocation but also in an enhancement of its DNA binding and transcriptional activity. This is also dependent on the activation of the Ras/protein kinase C (PKC) pathway. Nuclear export depends on NFAT rephosphorylation upon removal of Ca^{2+} and calcineurin inactivation. Several kinases, including glycogen synthase kinase 3 (GSK3) and casein kinase 1 have been implicated in this process.

Four NFAT isoforms (NFAT1–4) are expressed in many tissues. These isoforms share a highly conserved regulatory domain composed of two calcineurin-binding motifs, multiple phosphorylation sites, and a nuclear localization signal. The two motifs bind calcineurin with an affinity in the micro molar range. In skeletal

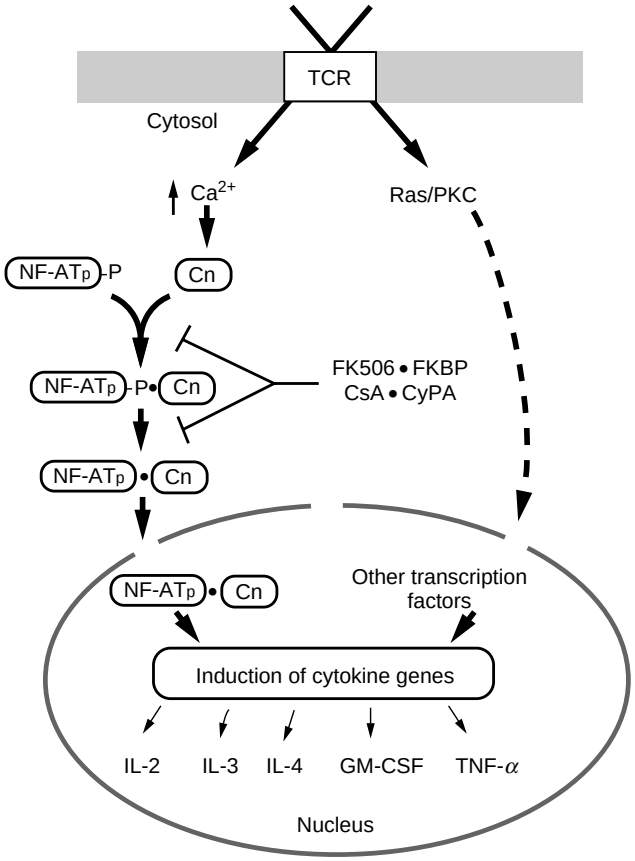

FIGURE 2 Calcineurin-mediated signal transduction from the T cell receptor to the nucleus leading to the induction of the cytokine genes (IL-2, -3, -4), granulocyte-macrophage stimulating factor (GM-CFS), and tumor necrosis factor (TNF-α). Gene activation requires the concomitant activation of the Ras/protein kinase C (PKC) pathway. [Reproduced from Klee, C. B., Wang, X., and Ren, H. (1999). Calcium-regulated protein dephosphorylation. In *Calcium as a Cellular Regulator* (Carafoli and Klee, eds.) with permission of Oxford University Press, Inc.]

muscle calcineurin-mediated dephosphorylation of the transcription factors, NFAT-3 and the myogenic enhancing factor (MEF2) plays a critical role in the switch from fast-to-slow oxidative fibers induced by sustained tonic contraction. In the heart, the calcineurin-mediated activation of NFAT3 and MEF2D, in conjunction with the cardiac specific transcription factor GATA4, has been implicated in the development of cardiac hypertrophy in response to stress. Transgenic mice lacking the β-isoform of calcineurin (the predominant isoform in heart) have impaired ability to develop cardiac hypertrophy in response to hypertrophic agonists while severe hypertrophy and cardiac heart failure is induced by overexpression of constitutively active calcineurin. The calcineurin/NFAT pathway is also essential for the development of heart valves and the vascular developmental pattern during embryogenesis. In the brain, Ca^{2+} homeostasis is itself regulated by calcineurin. Activation of NFAT increases the expression of the IP_3 receptors, the plasma membrane Ca^{2+} pumps and the Ca^{2+} exchanger. The increasing number of genes whose expression is induced by NFAT suggests a potential role of calcineurin in the regulation of gene expression during cell differentiation and apoptosis. The importance of calcineurin in the regulation of these cellular processes and its involvement in the pathogenesis of many diseases based on overexpression and knock out models is well documented. To fully assess the contribution of calcineurin in the transduction of so many diverse signals, we must understand how different pathways interact with each other.

In budding yeast, the calcineurin-mediated dephosphorylation of a transcription factor (Crz1p/Tcn1p) plays a major role in the regulation of genes involved in ion homeostasis. The mechanism is similar to NFAT-mediated transcriptional control in mammalian cells. In yeast, genetic analysis adds strong support to the physiological significance of this calcineurin signaling pathway in response to exposure to abnormal concentrations of ions or prolonged exposure to mating pheromones. It not only illustrates the important role of calcineurin in the regulation of gene expression but also reveals the participation of many other factors in this complex signaling pathway.

Neuronal Functions

Calcineurin is 1% of the total protein and broadly distributed in brain. There are few neuronal functions which are not modulated by calcineurin. A major role of calcineurin in brain is to trigger a protein phosphatase cascade initiated by the dephosphorylation of two other major substrates of calcineurin, the endogenous inhibitors of protein phosphatase-1, Inhibitor-1, and DARPP32. This cascade counteracts the stimulatory effects of cAMP and Ca^{2+}-regulated kinases. It explains the antagonistic effects of Ca^{2+} release induced by glutamate binding to the NMDA receptor and dopamine binding to some dopamine receptors in striatal neurons. Whether it activates protein phosphatase-1, or dephosphorytes an increasing number of specific substrates, calcineurin has been implicated in the regulation of neuronal processes as diverse as the expression and activity of ion channels, the synthesis of nitric oxide, the release of neurotransmitters, synaptic vesicle recycling, and neurite outgrowth. Calcineurin inhibitors and transgenic animals lacking the calcineurin genes or overexpressing the constitutive form of calcineurin have been widely used to study the involvement of calcineurin in the storage of long and short memory. How calcineurin and other protein kinases and phosphatases affect learning and memory remains one of the most challenging problems in neurobiology.

Glossary

calmodulin A unique member of a class of calcium-binding proteins that acts as sensors of changes in intracellular concentration of calcium induced by external signals. It modulates the activity of a large number of enzymes involved in the regulation of cellular processes, particularly those involved in protein phosphorylation.

EF-hand Structural motif composed of 30 contiguous amino acids forming two helices joined by a Ca^{2+}-binding loop.

immunosuppressive drugs (FK506 and CsA) Fungal natural products used to prevent organ rejection after organ transplant operations and treatment of autoimmune diseases.

NFAT Broadly distributed transcription factor originally identified as a nuclear factor of activated T cells required for the coordinated induction of several cytokine genes.

Biography

Claude B. Klee is Scientist Emeritus in the Laboratory of Biochemistry at the National Cancer Institute in Bethesda, MD. Her principal research interest is in Ca^{2+} signaling with emphasis on the mechanism of action of calmodulin using as a model system the activation of the calmodulin-dependent protein phosphatase, calcineurin. She holds an M.D. from the University of Marseille, France, and is a member of the Institute of Medicine and the American Association of Arts and Sciences.

Hao Ren and Shipeng Li are long time associates of Dr. Klee. They developed in her laboratory the procedures to express human calcineurin in bacteria, and to characterize the enzymatic activity and calcium regulation of the recombinant proteins.

Calcium Signaling: Cell Cycle

Luigia Santella
Stazione Zoologica "Anton Dohrn," Naples, Italy

Because calcium controls the most important cellular functions, it is not surprising that it should also have a role in a process as vital as the ability of cells to divide and multiply. Eukaryotes from yeasts to humans have similar division cycles, which are carefully regulated and coordinated with both cell growth and DNA replication to ensure the formation of a progeny of cells containing intact genomes. This is made possible by the existence of a system of checkpoints and feedback controls that prevent the entry of cells into the next phase of the cycle if the preceding phase has not been successfully completed.

A large number of regulatory elements have a function in the various stages of the cell cycle, among them, a variety of kinases, phosphatases, proteases, and a number of second messengers that control them. Among second messengers that have a role in the regulation of the cycle, calcium is a relatively late entry, but is now attracting increasing attention. This short article will offer a succinct survey of its role, paying attention to the meiotic cycle as well. For more detailed information, readers may consult a number of comprehensive reviews that deal with the general topic of cell-cycle regulation.

The Mitotic Cycle

The cell division is conventionally subdivided into four stages: G_1, S, G_2, and M. The M phase usually ends with the formation of two daughter cells (cytokinesis) (Figure 1). The G_1 phase corresponds to the interval gap that starts at the completion of mitosis and extends to the initiation of DNA synthesis. During this phase, the cell grows continuously and synthesizes the histones necessary for the new chromatin. G_1 is also the phase in which the cell responds to external signals by becoming committed irreversibly to enter the replicative process. This occurs at a point of no return called the restriction point (R) (in yeast it is named start). When proliferating cells are deprived of the appropriate medium they exit from the cycle after having reached the G_1 phase and enter a quiescent state termed G_0 in which they stop growing. DNA replication occurs in the S phase. The G_2 phase is the time-gap between the completion of DNA synthesis and the beginning of chromosome condensation. During G_2 phase, mRNAs and proteins are synthesized in preparation for the M phase (M), which consists of four steps: prophase, metaphase, anaphase, and telophase. The beginning of prophase is marked by the appearance of condensed chromosomes with the two sister chromatids. During prophase, in addition to chromosome condensation, changes leading to the development of the mitotic spindle also occur in the cytoplasm. The centrosomes, which had duplicated during interphase and which serve as the two poles of the mitotic spindle, separate and move to opposite sides of the nucleus. The breakdown of the nuclear envelope then allows spindle microtubules to attach to the kinetochores of chromosomes. At the metaphase stage the chromosomes align in the center of the spindle, and the sister chromatids separate, to move to opposite poles of the spindle during the anaphase stage. Chromosomes decondensation and nuclear envelope reformation take place during telophase, after which cytokinesis yields two interphase daughter cells.

Cell-Cycle Regulators

The central actor in the initiation and progression of the cell cycle is a well-conserved family of serine/threonine protein kinases (CDKs), which become activated by associating with cyclins. This binding is strictly necessary for CDKs activity and cyclin protein levels are tightly controlled during the cell cycle. Various cyclins become synthesized and degraded at specific phases of the cycle. In mammalian cells, three cyclins (C, D1, and E) that are essential for entering S phase are synthesized during the G_1 phase. The D-cyclins, which control the restriction point R, form complexes with CDK4 and CDK6, and are regulated by external signals, such as growth factors, anti-mitogenic factors, etc. Cyclin E is synthesized late in G_1 and once the active complex CDK2/cyclin E is formed the active kinase triggers the onset of DNA replication. Cyclin A and B, that are essential for M-phase entry, are synthesized during G_2. At the end of M phase, the ubiquitin-dependent proteasome pathway, which is required to inactivate CDK1 and to allow cells to enter G_1, degrades mitotic cyclins. However, it has been claimed that one of the cylins (D1) is processed by calpain.

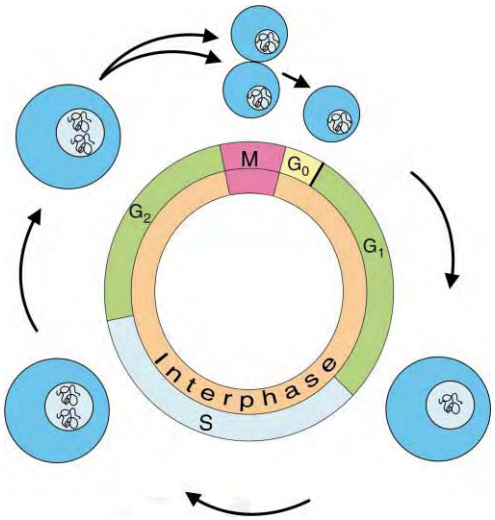

FIGURE 1 Cell-cycle phases. The cell grows throughout interphase, which includes G_1, S, and G_2. Once the cell has passed through the restriction point, it is committed to proceed through S and the rest of the cycle. If growth factors are not available during G_1, the cell stops growing and protein synthesis becomes depressed. S phase is the period during which DNA replication occurs. During G_2 mRNAs and proteins are synthesized in preparation for the mitosis (M) that ends with the two daughter cells.

Calcium and Mitosis

Although the mechanisms responsible for the activation of the cell-cycle kinases are still incompletely understood, increasing evidence now strongly suggest that changes in intracellular calcium may have an important role. During the early embryonic cell cycle in the sea urchin, cyclic increases in inositol 1,4,5-trisphosphate trigger the release of Ca^{2+} from intracellular stores that generate mitotic events. Blocking of the calcium increase prevents the dissolution of the nuclear envelope and stops mitosis. Calcium transients are associated with chromosome movement during anaphase in plants and mammalian cells. Calcium and the principal decoder of its signal, the calcium-binding protein, calmodulin (CaM), are intimately connected to the events of the cycle. Anti-CaM drugs block the G_1–S transition and the onset of DNA replication. The CaM level increases as the cell progress into mitosis, correlating nicely with the detection of CaM in the mitotic apparatus in yeast. Local activation of CaM occurs near the nuclear envelope just before its breakdown and the onset of anaphase. CaM is also involved in the phosphorylation of the retinoblastoma protein, the product of the Rb1 tumor suppressor gene (which is responsible for a rare inherited childhood eye tumor) that modulates a set of regulatory proteins that promote cell proliferation. The retinoblastoma protein is one of the key regulators that control R in G_1, past which the cells become irreversibly committed to enter S phase. The multifunctional Ca^{2+}/CaM-dependent protein kinase II (Ca^{2+}/CaMKII) is a potential transducer of the effect of CaM on cell-cycle progression. Inhibition of the G_2/M transition, and thus of the nuclear envelope breakdown, occurs upon injection of a Ca^{2+}/CaMKII specific peptide inhibitor or of Ca^{2+}/CaMKII antibodies. The involvement of Ca^{2+}/CaMKII at mitosis and meiosis entry is due to the activation of a Cdc25, a phosphatase that is a Ca^{2+}/CaMKII substrate that dephosphorylates and which activates, the M-phase promoting factor (MPF). The kinase induces multiple nuclear and cytoplasmic changes at the onset of the M phase by activating other protein kinases, and by phosphorylating structural proteins such as histone H1, nuclear lamins, proteins of the endoplasmic reticulum (ER) and Golgi membranes, and microtubule and actin-associated proteins. Once the metaphase spindle has been formed the cell proceeds to initiate anaphase and complete meiosis. Progression from metaphase to anaphase is triggered by the activation of an ubiquitin-mediated proteolysis system (proteasome) that degrades cyclin B and thereby inactivates MPF. In turn, phosphorylation of the proteasome by activated Ca^{2+}/CaMKII promotes cyclin degradation. As mentioned Ca^{2+} may also intervene in the degradation of cyclins by activating the Ca^{2+}-dependent protease calpain, that has been shown to degrade cyclin D1.

The Meiotic Cycle

Oocyte Prophase and Metaphase Arrest

Oocytes have long been used to study the meiotic cycle. In the gonads their growth is arrested at a specific phase of the meiotic cycle (prophase I). Following growth, a hormonal signal causes oocytes to mature. During maturation oocytes undergo a number of morphological, electrical, and biochemical changes that are a necessary preparation for successful fertilization. At the onset of maturation, the envelope of the germinal vesicle (nucleus) of prophase I-arrested oocytes disassembles (GVBD), the nucleoplasm mixes with the cytoplasm and the ER undergoes a structural reorganization that will ensure a normal Ca^{2+} response at fertilization: data indicate that MPF plays an important role in the restructurating of the ER. In addition to the dissolution of the nuclear envelope, resumption of meiosis entails the condensation of chromatin and the extrusion of the first polar body. The latter results from an unequal cell division that leaves most of the cytoplasm with half of the DNA. Following the release of the first polar body, oocytes enter the second mitosis of the meiotic cycle with the

extrusion of the second polar body and the formation of the pronucleus.

Although the pathway leading to the release from prophase I differs significantly among species, its ultimate common goal is to activate MPF. The experiments that have contributed to the identification of MPF as the agent responsible for the mitotic and meiotic cycle regulation have been performed on frog and starfish oocytes. Arrested oocytes could be induced to enter the M phase of meiosis by microinjecting cytoplasm from oocytes that had been hormonally stimulated, i.e., the cytoplasmic factor generated in hormone-treated oocytes was evidently sufficient to trigger the transition from G_2 to M in oocytes that had not been exposed to the hormone.

Calcium and Meiosis

Abundant evidence links the meiotic division cycle to calcium. For example, prophase I arrested starfish oocytes release calcium in the cytoplasm and in the nucleus following the resumption of meiosis promoted by the maturation-inducing hormone 1-methyladenine. A role of calcium during maturation is indicated by the inhibition of meiosis progression by the injection of CaM antagonists or of CaM antibodies directly into the oocytes nucleus. MPF activation could thus occur in the nuclear compartment, and could be linked to the Ca^{2+}/CaMKII-dependent stimulation of the Cdc25 phosphatase, which dephosphorylates two inhibitory (Th-14 and Tyr-15) MPF sites. In line with this, both MPF and Cdc25 have been shown to migrate to the nucleus once the re-initiation of meiosis has started. In some species in which fertilization triggers the release from prophase I, oocytes complete meiosis and enter mitosis directly without arrest. However, in most species in which hormonal stimuli rather than fertilization trigger the release from prophase I, the oocytes become arrested again at either metaphase I, metaphase II, or the pronucleus stage (depending on the species), until fertilization (Figure 2). For instance, *Xenopus* oocytes become arrested for a second time after maturation at the metaphase of the second meiotic division: The cytoplasmic activity that causes metaphase II arrest is termed the cytostatic factor. Injection of cytoplasm from metaphase-arrested oocytes that contains the cytostatic factor into a dividing blastomere results in the arrest of the recipient at metaphase. A serine/threonine kinase termed Mos was first identified as an essential component of the cytostatic factor. Mos is specifically synthesized in oocytes at about the time of completion of meiosis I and is responsible for the maintenance of MPF activity during the metaphase II arrest. Mos can readily arrest a dividing blastomere, and its

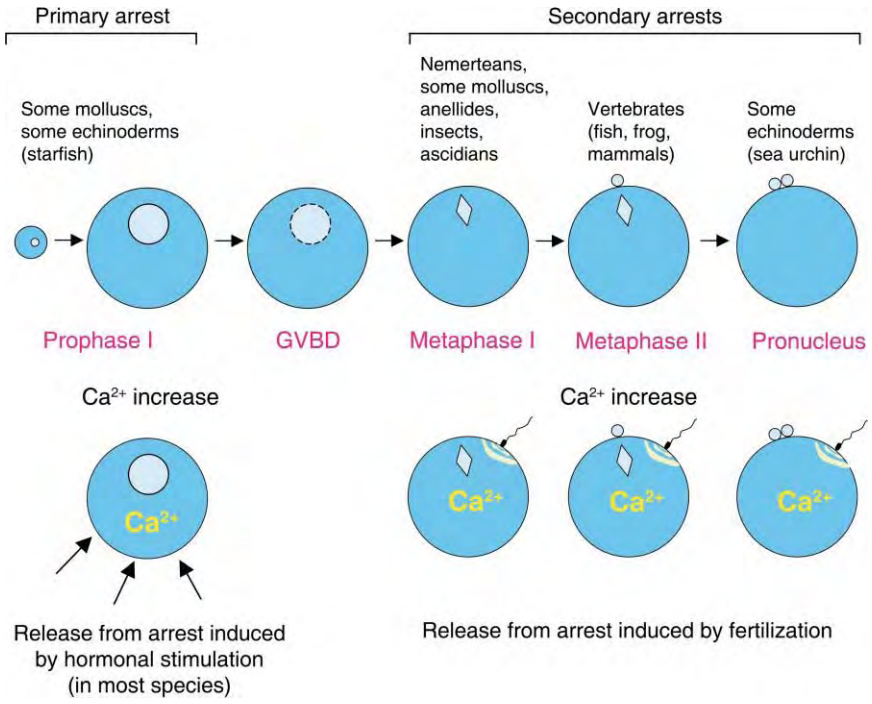

FIGURE 2 Release from meiotic arrest in different animal oocytes. In most species prophase I-arrested oocytes at the germinal vesicle (nucleus) stage (GV) re-initiate the meiotic cycle following the intracellular Ca^{2+} increase induced by hormonal stimulation. In a minority of species, however, fertilization may induce the release from prophase I arrest in the absence of hormonal stimulation. Then, in the species in which the release is induced by the hormone, a secondary arrest may occur (however, not in starfish oocytes) at metaphase I and II that is released by the intracellular Ca^{2+} increase promoted by sperm entry at fertilization.

immunodepletion removes cytostatic factor activity. The release of the secondary arrest is promoted by the entry of the sperm at fertilization and by the associated Ca^{2+} wave produced by the emptying of the intracellular stores. The Ca^{2+} increase inactivates both the cytostatic factor and the MPF, inactivation of MPF occurring through the ubiquitin-dependent proteolysis of the regulatory cyclin B. At variance with the oocytes in which the entry of the sperm induces a single Ca^{2+} transient (a Ca^{2+} wave), e.g., those of *Xenopus*, sea urchin, and starfish, in other oocytes species fertilization triggers, instead, repetitive Ca^{2+} transients. This occurs in nemertean, ascidian, and mammalian oocytes, which become fertilized at metaphase I and II when MPF activity is very high. In these species, Ca^{2+} fails to inactivate MPF, whose activity remains high and might actually regulate the Ca^{2+} oscillations induced by the sperm.

Luigia Santella is a Senior Scientist in the Laboratory of Cell Biology of the Stazione Zoologica "A. Dohrn", Naples, Italy. Her principal research interest is the spatio-temporal dynamics of Ca^{2+} signaling during the cell cycle and fertilization in invertebrate marine animals. She has also contributed to the clarification of the role of the actin cytoskeleton in modulating the intracellular Ca^{2+} increase.

Calcium Signaling: Motility (Actomyosin–Troponin System)

Takeyuki Wakabayashi
Teikyo University, Utsunomiya, Japan

Setsuro Ebashi
National Institute for Physiological Sciences, Myodaiji, Japan

Muscle contraction is regulated by the level of intracellular Ca^{2+}. In skeletal or cardiac muscles of vertebrate, Ca^{2+} regulation is mediated at the level of thin filaments, which consist of troponin, tropomyosin, and actin. Because actin filaments themselves are Ca^{2+}-insensitive, troponin and tropomyosin, which form a Ca^{2+}-sensitive switch, are required. When the cytosolic Ca^{2+} concentration increases to a micromolar level, Ca^{2+} binds to troponin and triggers a series of conformational changes in the thin filaments that lead to a sliding interaction between actin-containing thin filaments and myosin-containing thick filaments.

Structure of Thin Filaments and their Components

Thin filaments are based on a helical arrangement of actin monomers (F-actin), which can be thought of as two strands of globular actin monomers (G-actin) twisted around one another, staggered by ~27.3Å (2.73 nm) (Figure 1). One crossover (half pitch) containing approximately 13 monomers is ~360Å in length. Actin can be divided into the outer domain (subdomains 1 and 2) and the inner domain (subdomains 3 and 4) (Figure 1B). The inner domain is nearer to the helix axis. Myosin binds mainly to the subdomain 1.

In the generally accepted model of the thin filament, tropomyosin molecules are located in the two grooves of actin. Troponin binds to each of tropomyosin molecules as shown schematically in Figure 1A. The native thin filaments also contain nebulin molecules (not shown in Figure 1). One tropomyosin–troponin unit corresponds to exactly seven actin monomers, and the troponin molecules on the opposite strands are staggered with respect to one another by 27.3Å. This had been assumed for the sake of simplicity, but was recently shown to actually be the case. Tropomyosin is a rod-shaped coiled-coil dimer (~400Å, M_r ~35,000 × 2). Tropomyosin molecules form continuous ropes by longitudinal association through head-to-tail contact. Troponin consists of three subunits: troponin-T (TnT, M_r~31,000) binds to tropomyosin, troponin-I (TnI, M_r~21,000) binds to actin and inhibits the actin-activated myosin ATPase, and troponin-C (TnC, M_r ~ 18,000) binds calcium ions and neutralizes the inhibitory activity of TnI. Troponin, therefore, can bind to both tropomyosin and actin (Figure 2). Troponin can be dissociated into its three subunits in the presence of urea and Ca^{2+}-chelating reagents and can be reassembled by removing urea.

Tropomyosin Shift and Steric Blocking Model

The thin filament model shown in Figure 1A suggests that Ca^{2+}-induced changes of troponin can be transmitted to actin monomers through tropomyosin. The simplest hypothesis in calcium regulation has been the steric blocking model, in which the azimuthal position of tropomyosin on actin filaments is considered to be critical.

The increase in the second-actin-layer line intensity of the X-ray diffraction pattern from living muscle and the concomitant decrease in the third-actin-layer line intensity take place during the activation of muscle contraction. These changes in X-ray intensity can be explained if tropomyosins are located near the grooves of the actin double strands in the contracting state but dislocated more from the grooves due to the influence of Ca^{2+}-deprived troponin. If the tropomyosins in the off-groove position are located where they block sterically the myosin-binding sites of actin but the tropomyosins in the in-groove position do not, the tropomyosin shift can explain why tropomyosin is required for Ca^{2+}-regulation: Tropomyosin transmits the Ca^{2+}-induced changes in one troponin to the seven actin monomers. Three-dimensional image reconstruction from electron micrographs showed more directly the changes in thin filament

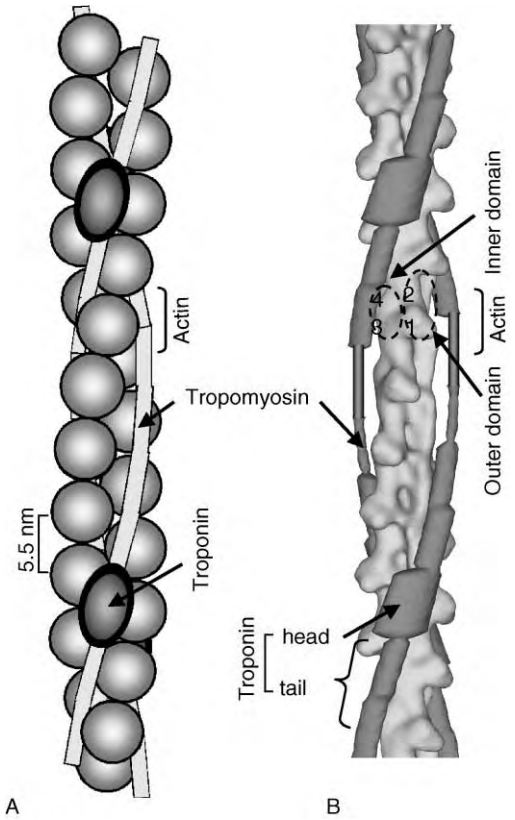

FIGURE 1 (A) Schematic illustration of a thin filament based on the model shown in (B). One tropomyosin molecule binds seven actin monomers and one troponin. The model in (B) is a composite illustration – the actin part is based on the atomic model of actin, and the troponin and tropomyosin part is based on the three-dimensionally reconstituted image of the actin–tropomyosin–troponin complex (reconstituted thin filament). Smoothing along the actin helix was applied to the tropomyosin and troponin part to simplify it. The four subdomains of actin are indicated by numerals, and the approximate location of the head and tail domains of troponin are indicated. Tropomyosin is ~400Å in length. Reprinted from Narita, A., Yasunaga, T., Ishikawa, T., Mayanagi, K., and Wakabayashi, T. (2001). Ca^{2+}-induced switching of troponin and tropomyosin on actin filaments as revealed by electron cryomicroscopy. *J. Mol. Biol.* **308**, 241–261, copyright 2001, with permission from Elsevier.

structure – the addition of TnT–TnI complex (which inhibits actin–myosin interaction irrespective of Ca^{2+} concentration) to the actin–tropomyosin complex induces the tropomyosin shift. It was later shown that the three-dimensional images of reconstituted thin filaments containing actin, tropomyosin, and troponin were changed by the addition of Ca^{2+}, and the structural changes were interpreted to be the result of the tropomyosin shift induced by Ca^{2+}. The addition of TnI–TnC complex (without TnT) to the actin–tropomyosin complex also induces the tropomyosin shift in a Ca^{2+}-dependent manner. There are indications that troponin movement and conformational changes of actin are also involved in Ca^{2+} regulation, and the changes in the X-ray diffraction pattern therefore could be explained solely by the shift of troponin instead of tropomyosin. The positions of tropomyosin determined by modeling or helical image reconstruction are therefore not unambiguous and are biased by changes in the other components of thin filament, especially troponin, as described next.

Three-State Model for Ca^{2+} Regulation

Biochemical studies showed that the simple steric blocking model, which proposes that only the position of tropomyosin is responsible for Ca^{2+} regulation, is an oversimplification. The binding of the myosin head (subfragment-1, S1) to the reconstituted thin filaments (actin–tropomyosin–troponin complex) is cooperative irrespective of Ca^{2+} concentration and the Ca^{2+} binding to troponin alone is not sufficient for the full activation of actin-activated myosin ATPase.

The cooperative/allosteric model, or three-state model, emphasizes the importance of conformational changes in actin. At low Ca^{2+} concentrations, the thin filament is in a blocked state, in which myosin cannot bind to actin. There are two states at high Ca^{2+} concentrations: an open state (called R state in the allosteric model), in which myosin bound with ADP-phosphate can interact with actin weakly and the weak binding can be converted to a strong binding by releasing phosphate; and a closed state (called T state in the allosteric model), in which myosin with bound ADP-phosphate can bind to actin but no phosphate release step can follow. Thus, the transition to the strong binding of myosin with bound ADP or nucleotide-free myosin does not occur in a closed state. These three states are illustrated in Figure 3. Moreover, the closed state is favored against the open state, with an allosteric constant L (the ratio of T state to R state, or closed/open) of ~10. The open state is achieved fully only when the concentration of the myosin head is high enough to shift the allosteric equilibrium from a closed state (T state) toward an open state (R state). When the positions of tropomyosin are determined by electron microscopy in the absence of the myosin head (S1), the position at low Ca^{2+} and high Ca^{2+} concentrations should represent the position at a blocked and a closed state, respectively. The biochemical studies showed that the thin filament is only ~67% blocked even in the absence of Ca^{2+}.

Molecular Organization of Troponin and its Ca^{2+}-Induced Changes

Troponin is a target protein of Ca^{2+} signaling and its Ca^{2+}-induced changes are important to understanding

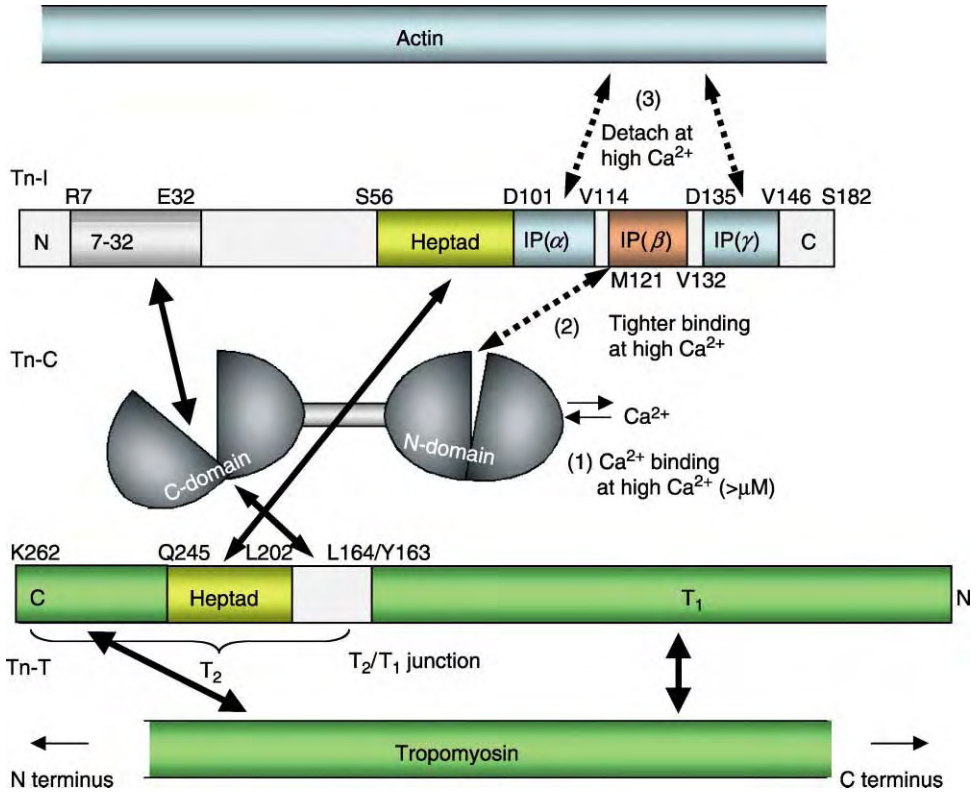

FIGURE 2 The three steps of Ca^{2+}-induced changes in interactions among actin, troponin subunits, and tropomyosin. The interactions indicated by dashed arrows are Ca^{2+}-sensitive, whereas those indicated by solid arrows are Ca^{2+}-insensitive and constitutive. The numbering shown is for chicken skeletal troponin; skeletal TnI differs from cardiac TnI by ~30 due to the insertion in the N-terminal region of cardiac TnI.

how the muscle contraction is triggered. Such changes have been revealed by ultracentrifugation, X-ray scattering, neutron scattering, circular dichroism, infrared and ultraviolet spectroscopy, fluorescence resonance energy transfer, and chemical cross-linking.

TnC is dumbbell-shaped with two globular domains connected by a long helix. Each domain possesses two EF-hand helix–loop–helix Ca^{2+}-binding motifs. The N-terminal domain (N domain in Figure 2) of TnC from skeletal muscle binds two Ca^{2+} specifically but with lower affinity (with a dissociation constant, K_d, of a few micromolars), whereas the C-terminal domain (C domain in Figure 2) binds either Ca^{2+} or Mg^{2+} (two Ca^{2+}/Mg^{2+} sites) with higher affinity ($K_d \sim 0.01$ μM). Only one of the EF-hand motifs in the N domain of cardiac TnC binds Ca^{2+}. The metal-binding sites of the C domain are occupied always by either Ca^{2+} or Mg^{2+}, and the hydrophobic pocket of the C domain is always exposed and binds the N-terminal region (the residues 7–32) of TnI. The corresponding hydrophobic pocket of the N domain becomes open only at high Ca^{2+} (step 1 in the Figure 2).

TnT binds to tropomyosin. Many isoforms have been isolated for TnT. TnT can be divided into TnT_1 and TnT_2 by chymotryptic cleavage at the carboxyl side of Tyr158 (chicken skeletal TnT), which follows two seryl residues (S156 and S157). TnT_1 and the C-terminal region of TnT_2 bind to tropomyosin. TnT_2 also binds to the C domain of TnC. The primary structures of TnI and TnT show the heptad-repeat pattern – in a heptad the first and the fourth residues are almost always hydrophobic. Two such regions (the residues 56–101 of TnI and 202–245 of TnT) associate and form a coiled coil. Thus, TnT_2 binds to tropomyosin, TnI, and TnC.

TnI binds to actin and inhibits the actin-activated ATPase. Its inhibitory activity is neutralized by Ca^{2+}-loaded TnC. The residues 97–117 and the peptide corresponding to the residues 96–116 were shown to be responsible for the inhibitory activity and are called the inhibitory region, which approximately corresponds to IP(α) in Figure 2, and the inhibitory peptide (IP), respectively. The numbering shown in Figure 2 is for skeletal troponin, which differs from cardiac TnI by ~30 due to the insertion at the N-terminal region of cardiac TnI. The minimum sequence necessary for inhibition (but not sufficient for full inhibition) is residues 104–115 (GKFKRPPLRRVR), which approximately corresponds to IP(α). There are two other regions with a homologous

sequence, called IP(β) and IP(γ) (Figure 2). The region near residues 117–127, which forms a helix according to the prediction of the secondary structure and the preliminary report of the crystal structure of the cardiac TnT_2–TnI–TnC complex at high Ca^{2+} concentrations, follows the inhibitory region and is identified as the target of the hydrophobic pocket in the N domain of TnC; it is called the second TnC-binding site and corresponds approximately to region IP(β).

When Ca^{2+} binds to the N domain of TnC and the hydrophobic pocket becomes open (step 1 in Figure 2), the association between the second TnC binding site of TnI and the N domain of TnC becomes tighter (step 2 in Figure 2). Then, the inhibitory regions IP(α) and IP(γ) detach from actin (step 3 in Figure 3). This detachment step is key for triggering the activation of muscle contraction. Thus, the N domain of TnC, the C-terminal region of TnI, and actin make up the regulatory machinery. Actin is therefore not just a *target* of Ca^{2+} regulation but is an important *component* of the Ca^{2+} switch.

Ca^{2+}-Induced Troponin Shift on the Thin Filaments

The first event of muscle contraction is the binding of Ca^{2+} to TnC and the detachment of TnI from actin, which is followed by the changes in the location of troponin on the thin filaments. Several parts of TnI have been known to change their positions on the thin filaments. Recent electron cryomicroscopic work shows that troponin changes its shape and shifts toward the inner domain of actin during activation (Figure 3A–B).

The region near Cys117 between the IP(α) and IP(β) of TnI and the region near Cys133 between the IP(β) and IP(γ) are nearer to the C terminus of actin at low Ca^{2+} concentrations. The details of the troponin shift, however, have been difficult to visualize because troponin does not follow the helical symmetry of actin filament. In 2001, the location of troponin was visualized by the three-dimensional reconstruction from electron cryomicrographs of thin filaments using single-particle analysis. The troponin head (Figure 1B) is gourd-shaped and at high Ca^{2+} concentrations it is located over the inner domain of actin (Figure 3B), whereas at low Ca^{2+} concentrations it is shifted by ~30Å toward the outer domain and bifurcated, with a troponin arm (Figure 3B) covering the N- and C-terminal regions of actin in subdomain 1 (Figure 1B). The troponin arm disappears at high Ca^{2+} concentrations. This might be the consequence of the detachment of the IP(α) and IP(γ) of TnI from actin. According to the analysis of the data from fluorescence resonance energy transfer experiments, the position of the C domain of TnC seems to change more than that of the N domain. Presumably, the association between the troponin arm and subdomain 1 of actin pulls the C domain of TnC toward ubdomain 1 at low Ca^{2+} concentrations. At high Ca^{2+} concentrations, however, such interactions disappear and the C domain of TnC returns to its original position over the inner domain of actin.

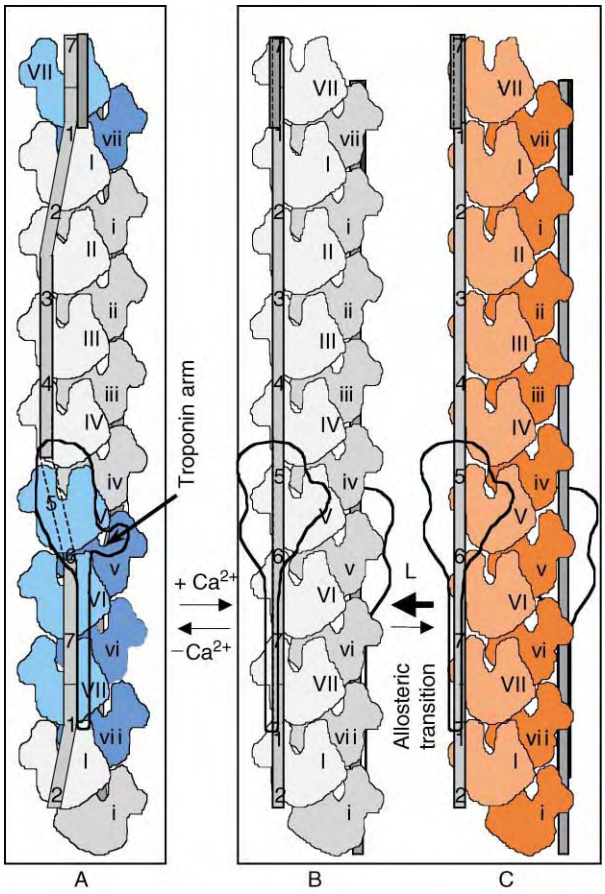

FIGURE 3 A model for Ca^{2+} regulation. (A) blocked state (T * state); (B) closed state (T state); (C) open state (R state). For simplicity, the two strands of actin are shown untwisted, so that they are parallel, and in different colors. The uppercase roman numerals label the outer domain of actin, and the lowercase ones label the backside of the inner domain. The arabic numerals label the seven segments of tropomyosin, with the segment 5 being the binding site of a troponin head. At high Ca^{2+} concentrations, there are two states, with the T or closed state (B) ~10 times higher in population than the R or open state (C) (L =~10). Myosin favors the transition from the T state to the R state (actin colored orange; myosin can bind and release phosphate to fully support contraction). At low Ca^{2+} concentrations (A), a troponin arm emerges and tropomyosin shifts differentially. Only the actin colored blue is blocked (myosin cannot bind); the actin colored gray is in a closed state (myosin can bind weakly and cannot release bound phosphate). Reprinted from Narita, A., Yasunaga, T., Ishikawa, T., Mayanagi, K., and Wakabayashi, T. (2001). Ca^{2+}-induced switching of troponin and tropomyosin on actin filaments as revealed by electron cryo-microscopy. *J. Mol. Biol.*, **308**, 241–261, copyright 2001, with permission from Elsevier.

Ca^{2+}-Induced Tropomyosin Shift

Since the Ca^{2+}-induced tropomyosin shift was first proposed, there has been controversy over the locations of tropomyosin, which were determined by assuming helical symmetry. It was found that the thin filaments deviate from helical symmetry; the extent is greater at low Ca^{2+} concentrations than at high Ca^{2+} concentrations. Thus, the locations of tropomyosin were determined by three-dimensional reconstruction without assuming such symmetry.

Tropomyosin follows a smoothly curved path in crystals and in thin filament at high Ca^{2+} concentrations (Figure 1B). At low Ca^{2+} concentrations, however, tropomyosin does not seem to follow a smooth path; it shifts differentially (Figure 3A) at the N-terminal half and the C-terminal third. There is evidence suggesting that the C-terminal third of tropomyosin may not always be in a rigid coiled-coil conformation and is sensitive to the changes in environment (e.g., the changes in troponin). The X-ray crystallographic studies showed that residues 160–220 of tropomyosin are mobile and that its mobility increases at higher temperatures, with the N-terminal half being immobile and almost insensitive to temperature. The region around residue 220 of tropomyosin shows low scores for coiled-coil structure, and the secondary structure prediction of sequence 214–218 of tropomyosin is ambivalent.

The myosin-binding site is located mainly in subdomain 1 in the outer domain of actin. At low Ca^{2+} concentrations, the myosin-binding sites of three actin monomers (colored blue in Figure 3A) out of seven are blocked by the C-terminal third of tropomyosin or troponin. The myosin-binding sites of the remaining four actin monomers (colored gray in Figure 3A), however, are not blocked because the N-terminal half of tropomyosin does not shift much. This is consistent with the biochemical study that found that the thin filament is only 67% blocked even at low Ca^{2+} concentrations. Thus, the simple steric blocking hypothesis is only partially correct.

Molecular Mechanism of Ca^{2+} Regulation

The relationship between the three states of actin and the location of tropomyosin is presented in Figure 3. When tropomyosin is located on the outer domain, actin monomers are in a blocked state. When tropomyosin is located on the inner domain, there are two states of actin monomers.

Figure 3A–B illustrates the three-dimensional structure of the thin filaments reconstructed from electron cryomicrographs. For clarity, the double helix of thin filament has been untwisted so that two strands are parallel and the strands are colored. The uppercase roman numerals label the outer domains of actin, and lowercase ones label the back side of the inner domains. Arabic numerals label the seven segments of tropomyosin, with segment 5 as the binding site of a troponin head.

At high Ca^{2+} concentrations (Figure 3B), the troponin head looks gourd-shaped and is located over the inner domain of actin (subdomains 3 and 4). Tropomyosin is also located entirely over the inner domain of actin, allowing greater access of myosin to the outer domain, where the myosin-binding site of actin is located, for the generation of force. Thus, all actin monomers are in a closed state (colored gray in Figure 3B).

At low Ca^{2+} concentrations, however, the troponin head shifts toward the outer domain and bifurcates, with a troponin arm covering the N- and C-terminal regions in subdomain 1 of actin. The C-terminal third of tropomyosin also shifts, together with a troponin tail, toward the outer domain of actin and the myosin-binding sites are blocked (colored blue in Figure 3A), but the N-terminal half of tropomyosin shifts only small amount and these myosin-binding sites are still accessible in a closed state (colored gray in Figure 3A). Thus, the myosin-binding sites of only three actin monomers are blocked by tropomyosin and troponin at low Ca^{2+} concentrations.

According to the three-state model, tropomyosin should shift further toward the inner domain of actin to achieve full activation of actin-activated myosin ATPase (Figure 3C). The mutagenesis introduced in residue 230 in subdomain 4 of actin facilitates the actin activation of myosin ATPase in the presence of tropomyosin, with the activation by pure actin being unchanged. Such mutagenesis increases the accessibility of the hydrophobic pocket in subdomain 4 of actin. It is conceivable that tropomyosin shifts further to bind to the exposed hydrophobic pocket to achieve an open state (colored orange).

This model predicts that the full activation of contraction is a two-step process: (1) a Ca^{2+}-dependent transition from a blocked state (T^* state) to a closed state (T state) and (2) a Ca^{2+}-independent allosteric transition from a closed state (T state) to an open state (R state), facilitated by the binding of myosin to actin. The model also explains why complete relaxation is difficult to achieve in skeletal and cardiac muscles – not all the myosin-binding sites of actin monomers are blocked at low Ca^{2+} concentrations. This may be on purpose; unlike smooth muscles, striated muscles must be always on standby. Ca^{2+} regulation appears to be the result of the delicate balance of interactions among calcium ions, troponin, actin, tropomyosin, myosin, and nucleotides. Such delicateness is consistent with the large number of

reports of mutations that cause familial hypertrophic myocardiopathy.

Glossary

actin A globular protein (G-actin, $M_r \sim 42,000$) that forms filaments (F-actin) that bind tropomyosin and troponin. Actin filaments activate myosin ATPase, which supplies the free energy for contraction. The folding pattern of actin is homologous to RNase H.

myosin (Myosin II) A motor protein, for example, ATPase, which is activated by an actin filament by approximately 100 times. Myosin consists of two head domains and a tail domain. Tail domains assemble to form thick filaments. A head domain (subfragment 1) can bind to actin and hydrolyze ATP. The myosin head, kinesin, and ras protein share a common folding pattern.

thin filament A structure formed by F-actin, tropomyosin, and troponin; native thin filaments also contain nebulin. At high Ca^{2+} concentrations, thin filaments interact with myosin-containing thick filaments to generate force.

tropomyosin A fibrous protein ($\sim$400Å, $M_r \sim 35,000 \times 2$) that polymerizes in a head-to-tail manner. When the myosin concentration is low, tropomyosin inhibits actin-activated myosin ATPase. Tropomyosin and troponin are essential for Ca^{2+} regulation.

troponin A protein complex formed from troponin-T (TnT, $M_r \sim 31,000$, tropomyosin-binding), troponin-I (TnI, $M_r \sim 21,000$, inhibitory), and troponin-C (TnC, $M_r \sim 18,000$, Ca^{2+}-binding). TnT can be divided into TnT_1 and TnT_2. TnT_2, TnI, and TnC form a troponin head, from which a troponin arm emerges at low Ca^{2+} concentrations. TnT_1 forms a tail domain.

Biography

Dr. Setsuro Ebashi is a Professor Emeritus of the University of Tokyo and a former director of the National Institute of Physiological Sciences. His research interest is the regulatory mechanism of muscle contraction. He holds an M.D and a Ph.D. from the University of Tokyo. He discovered the relaxation induced by Ca^{2+}-uptake by sarcoplasmic microsomes, discovered Ca^{2+} regulation of muscle contraction, and isolated troponin.

Dr. Takeyuki Wakabayashi is a Professor of Teikyo University and a Professor Emeritus of the University of Tokyo. His interest is the structural basis of Ca^{2+} regulation of muscle contraction. He holds an M.D. and a Ph.D. from the University of Tokyo. He determined the three-dimensional location of troponin on thin filaments, the myosin-binding site of actin, and the ATP-binding site of myosin; and he showed the differential tropomyosin shift by Ca^{2+}.

Calcium Signaling: NO Synthase

Zhi-Qiang Wang and Dennis J. Stuehr
The Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, Ohio, USA

Nitric oxide (NO) is an important signal and effector molecule in animal physiology. NO is generated from L-arginine by the NO synthases (NOSs). Three NOSs have been characterized in animals: neuronal NOS (nNOS, type I), cytokine-inducible NOS (iNOS, type II), and endothelial NOS (eNOS, type III). Importantly, the activities of all three depend on their binding calmodulin (CaM). CaM binds reversibly to eNOS and nNOS in response to elevated Ca^{2+} concentrations and so their activities are regulated by intracellular Ca^{2+}. In contrast, iNOS binds CaM independent of Ca^{2+} concentrations and is therefore continuously active after it is expressed. Because it is unusual for a redox enzyme like NOS to be controlled by a Ca^{2+} binding protein, the NOS–CaM interaction has provided new insight into some aspects of protein structure and function.

NO Synthases

To become active each NOS enzyme must assemble into a dimer of two subunits. Each subunit in the NOS dimer contains a N-terminal "oxygenase domain" that binds iron protoporphyrin IX (heme), the cofactor 6R-tetrahydrobiopterin (H_4B), and the substrate Arg, and a C-terminal "reductase domain" that binds FMN, FAD, and NADPH. Between oxygenase and reductase domains there is a 20–25 amino acid CaM binding motif (Figure 1).

NO synthesis depends on electron transfer to the heme, and this process only occurs when CaM is bound. In a CaM-bound NOS dimer, the electrons from NADPH load into the FAD and FMN groups in one subunit, and then transfer from the FMN to the heme that is located in the partner subunit (Figure 1). In general, CaM activates electron transfer in NOS at two points: electron transfer into the flavins (intradomain) and between the FMN and heme (interdomain). Intradomain transfer is associated with enhanced catalysis by the NOS reductase domain, as measured by rates of NADPH-dependent ferricyanide or cytochrome c (Cyt c) reduction. CaM activation of the interdomain electron transfer in NOS results in reduction of the ferric heme iron, which is a prerequisite for oxygen binding to the heme and for NO synthesis.

Calmodulin Interactions with Ca^{2+} and with NOS

CaM is a small Ca^{2+} binding protein (molecular weight 17 kDa) consisting of two similar globular domains (called lobes) that each contain two E–F hands. An E–F hand includes a N-terminal helix (E helix), a centrally located Ca^{2+} coordinating loop, and a C-terminal helix (F helix). Upon Ca^{2+} binding, CaM is able to bind to and activate more than 30 target enzymes, enabling it to regulate numerous second messengers and cell functions. Binding and full activation of target proteins by CaM typically requires occupancy of all four Ca^{2+} binding sites in CaM. The carboxy-terminal lobe contains two high affinity Ca^{2+} binding sites, while the amino-terminal lobe contains two sites with lower Ca^{2+} affinity. Conformational changes that occur in CaM after it binds Ca^{2+} expose its hydrophobic surface residues in order to form critical van der Waals interactions with the hydrophobic face of the target peptide recognition site.

CaM binds to each NOS subunit in a 1:1 stoichiometry with reasonably high affinity. Binding affinity studies with peptides that correspond to NOS CaM recognition sequences show that the three NOSs display different affinities toward CaM with the general order being iNOS $\gg$ nNOS $\approx$ eNOS. The iNOS peptide binds well to CaM both in the presence and absence of Ca^{2+}, but eNOS and nNOS peptides bind to the CaM only in the presence of Ca^{2+}.

Each lobe of CaM binds to NOS independently and displays different affinities toward NOS. The CaM–nNOS interaction has been investigated using CaM mutants and plant CaM proteins. nNOS displays a high degree of structural specificity toward CaM domains 1, 3, and possibly 4 regarding activation of heme reduction and NO synthesis. The CaM–nNOS interactions are particularly important for electron transfer and involve the latch region of CaM (formed by CaM domains 1 and 3) and a methionine residue in domain 4. These regions of CaM appear to interact with as yet unknown regions on nNOS that are distinct from its CaM binding sequence. Ca^{2+} dissociation from

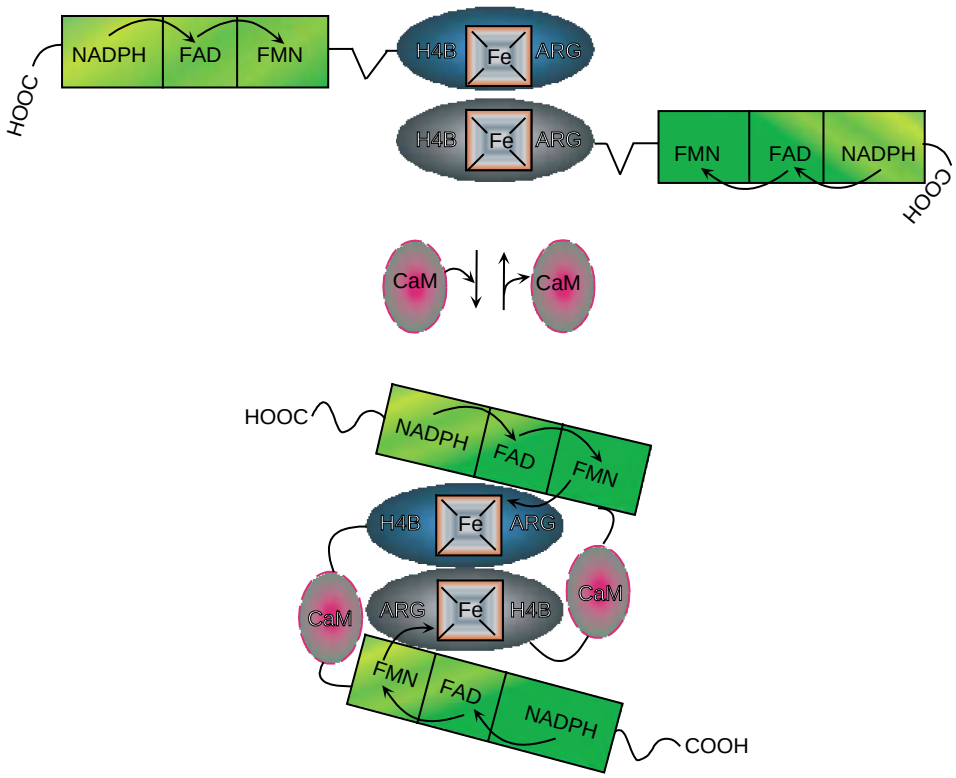

FIGURE 1 CaM-induced electron transfer in nNOS. CaM binding in response to elevated Ca^{2+} concentrations enables electron transfer between FMN and the heme located in adjacent subunits of the NOS dimer.

NOS-bound CaM has also been investigated. It occurs in two sequential steps: rapid Ca^{2+} dissociation from the N-terminal lobe occurs first and corresponds with inactivation of NO synthesis, followed by a slower Ca^{2+} dissociation from the C-terminal lobe, which leads to the dissociation of CaM from NOS.

Conformational changes occur in the NOS CaM binding peptides when they bind CaM. Typically, the peptides acquire an α-helical conformation upon interaction with Ca^{2+} bound CaM. A CaM-induced conformational change in the NOS reductase domain also occurs as indicated by changes in protein and flavin fluorescence and by a change in the trypsin proteolysis pattern.

A crystallographic structure of Ca^{2+}-loaded CaM bound to a 20-residue peptide corresponding to the eNOS CaM recognition sequence is available. The structure revealed that the α-helical eNOS peptide binds to CaM in an antiparallel orientation through extensive hydrophobic interactions: the N-terminal and C-terminal lobes of CaM wrap around the bound peptide, interacting with the C- and N-terminal halves of the peptide, respectively. Specific CaM residues in the latch region and domain 4 were positioned in a manner consistent with their importance as determined by mutagenesis studies. The crystal structure also suggested a basis for tighter CaM binding in iNOS: because iNOS contains a greater number of hydrophobic residues within its corresponding CaM recognition sequence, it was argued that these would support more extensive van der Waals contacts with CaM and minimize unfavorable solvent exposure of hydrophobic residues in order to favor tighter association between CaM and the iNOS CaM recognition sequence.

Ca^{2+}/CaM Regulation of NOS

How Ca^{2+}/CaM regulates NO synthesis and heme reduction in NOS is not entirely clear. CaM binding does not appear to change the thermodynamic driving force for electron transfer in NOS and instead may control the electron transfer primarily via structural rearrangement. CaM binding likely induces a relatively large conformational rearrangement which then enables the FMN subdomain to get close enough to the NOS oxygenase domain heme to make electron transfer between them more efficient.

Some cellular proteins that bind to NOS can regulate its response to Ca^{2+}/CaM. These include caveolins, dynamin, the bradykinin β-2 receptor, and heat shock protein-90. In addition, several different structural elements that are present in NOS regulate its interaction and response to Ca^{2+}/CaM (Table I, Figure 2). These

TABLE I

NOS Structural Elements Involved in Its Ca^{2+}/CaM Response

NOS structural element	Role
CaM binding site	Binds CaM to NOS; is inhibitory in the absence of CaM
Autoinhibitory loop	Impacts Ca^{2+} concentration response, represses NOS activity in absence of CaM, also required for full CaM response
C terminal extension	Impacts Ca^{2+} concentration response, represses NOS activities in absence of CaM, also required for full CaM response
Amino acid 484–726 in the FMN subdomain of iNOS	Required for Ca^{2+}-independent CaM-binding to iNOS
CD2 loop in reductase domain of eNOS	Impacts Ca^{2+} concentration response, represses NOS activities in absence of CaM
Phe1395 in FNR subdomain of nNOS	Helps to repress NOS activities in absence of CaM, also required for CaM to fully relieve the repression
Phosphorylation sites in eNOS	
S1179	Phosphorylation impacts Ca^{2+} concentration response and increases enzyme activity
T497	Dephosphorylation increases enzyme activity
S635	Phosphorylation may impact enzyme activity
S617	Phosphorylation impacts Ca^{2+} concentration response, no change in enzyme activity

include the canonical CaM binding site in each NOS and at least four other structural elements within the reductase domain. Initially, it was imagined that the CaM interaction with each NOS isoform might depend solely on its CaM recognition sequence. However, subsequent studies showed that other sequence elements are important. For example, substitution of the eNOS CaM-binding sequence by that of iNOS, and vice versa, yielded proteins whose Ca^{2+} dependence were intermediate between those of iNOS and eNOS. Other studies showed that both eNOS and nNOS, after having their CaM binding sequences replaced with the corresponding sequence from iNOS, still required added Ca^{2+} for full CaM binding and activity. Other more specific deletion studies have identified short regions within the iNOS and eNOS reductase domains that modulate the NOS Ca^{2+} requirement and CaM affinity in a positive or negative manner (Table I). Finally, there are several amino acids that can undergo phosphorylation within the NOS reductase domains and CaM binding sites (Figure 2). Phosphorylation at these individual or combined sites in NOS alters the CaM response with regard to its Ca^{2+} concentration requirement and may also alter the maximal level of enzyme activation that is achieved.

One regulatory element that is unique to NOS is the autoinhibitory loop insert (Figure 2). Constitutive NOSs (for example, eNOS and nNOS) contain a 40–50 amino acid insert in their FMN binding module that is not shared with iNOS or with other related flavoproteins. Similar autoinhibitory loops have been reported in a number of CaM-dependent enzymes, including CaM-dependent protein kinase II, smooth muscle myosin light chain kinase, and calcineurin. Peptides based on the eNOS insert sequence inhibited NOS enzymatic activity by altering their CaM binding. Subsequent studies showed that deleting the insert in eNOS or nNOS decreased their EC_{50} for Ca^{2+}, confirming that the insert was inhibitory (i.e., causes the enzyme to require a higher Ca^{2+} concentration to enable its CaM response). Deletion of the autoinhibitory peptide also enables some NO synthesis in the absence of CaM and increases the intrinsic catalytic activity of CaM-bound eNOS. Thus, the insert contributes to the Ca^{2+}-dependence of the constitutive NOS, and also regulates the electron transfer between its FMN and heme centers.

How the autoinhibitory insert participates in Ca^{2+}/CaM regulation is still unclear. One model has the insert docking on a site in NOSs that impedes both CaM binding and the structural rearrangement that is expected to be required for enzymatic activation. Upon binding, the Ca^{2+}/CaM, a conformational change that displaces the autoinhibitory insert from its docking site would then relieve the inhibitory effect and facilitate activation of the enzyme. A two-stage model seems reasonable to explain the Ca^{2+}/CaM activation in NOSs: CaM binding is largely determined by the recognition sequence and some other interactions with the enzyme. However, activation of the enzyme is fully dependent on a movement of the autoinhibitory insert, which could only be affected by the Ca^{2+}-saturated CaM. The conformational change induced by Ca^{2+}/CaM is passed on to the autoinhibitory insert, and this in turn presumably enables the enzyme reductase and oxygenase domains to adopt

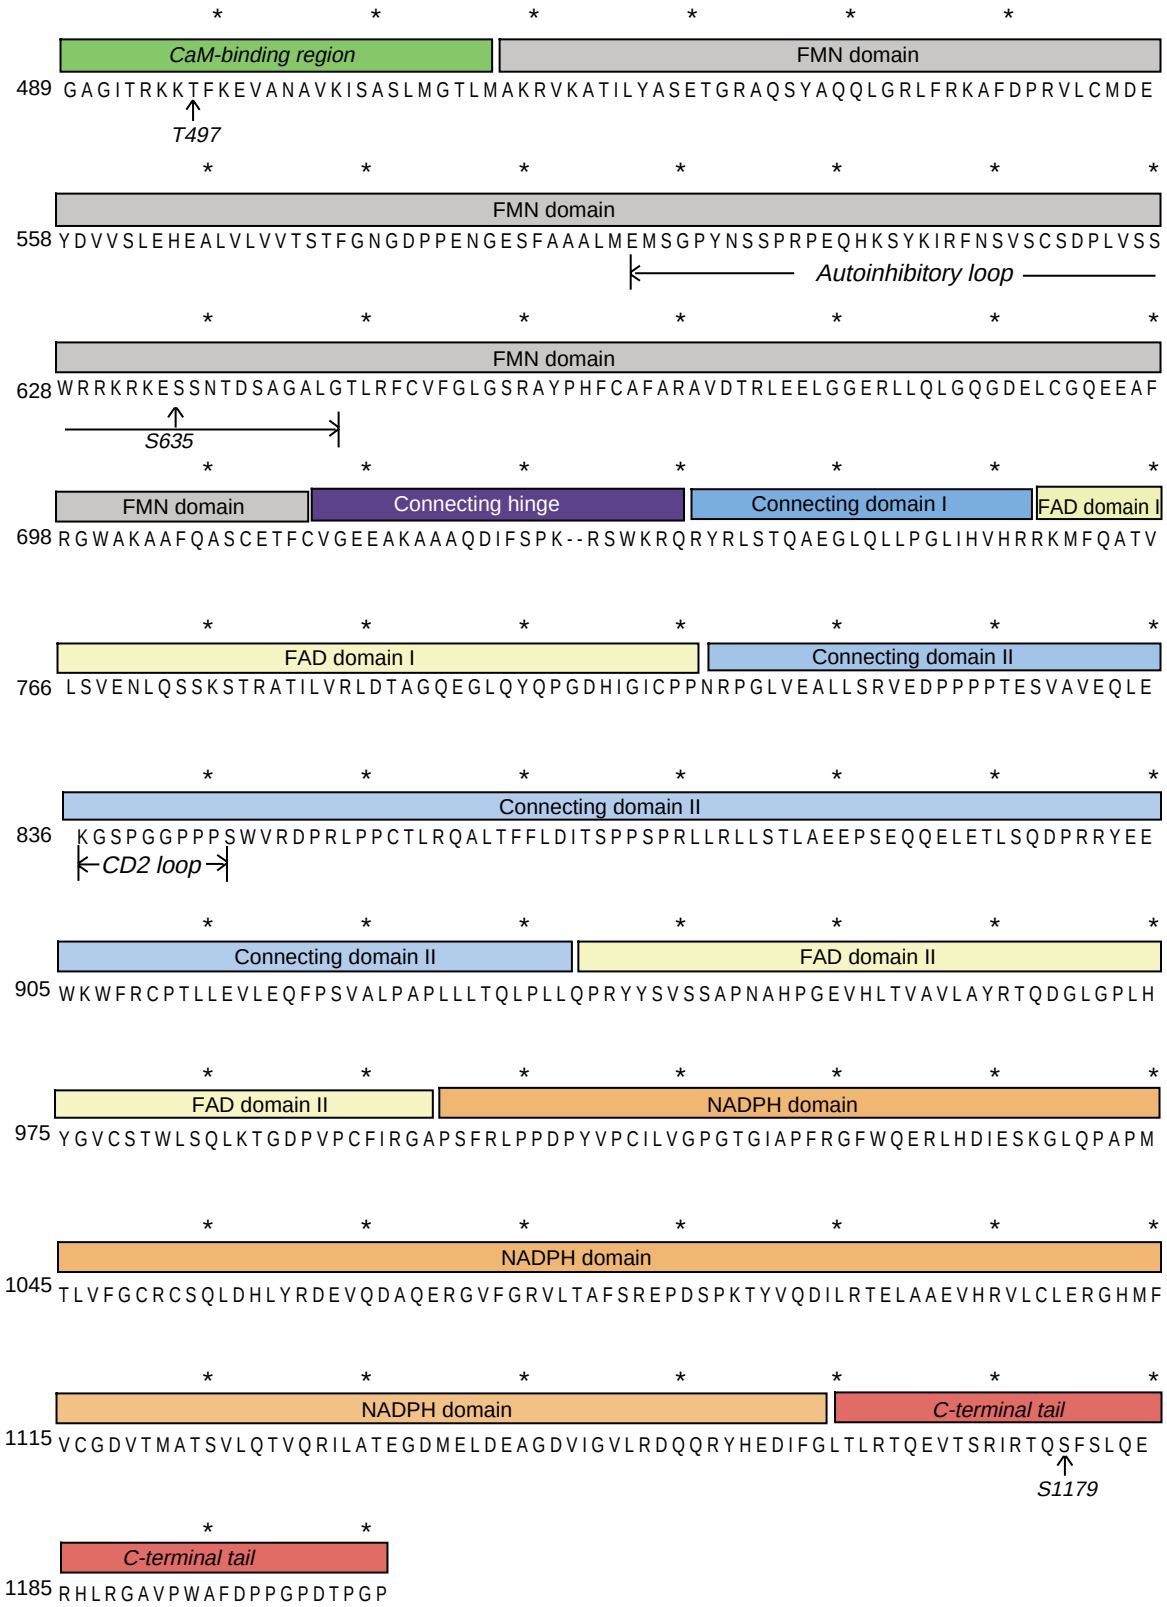

FIGURE 2 Sequence of eNOS CaM binding site and reductase domain. Colored rectangles indicate subdomains that make up the reductase domain. Structural elements and phosphorylation sites that impact Ca^{2+}/CaM regulation of NOS are noted in italics.

conformations that lead to productive electron transfer between the FMN and heme redox centers.

Another regulatory element that is unique to NOS is the C-terminal extension. The protein sequences of NOS reductase domains closely resemble that of NADPH-cytochrome P450 reductase (CPR). However, all NOS isoforms have an additional 20–40 residue extension in their C terminus, forming a "tail" that is absent in CPR. Deletion of 33 or 42 C-terminal residues from nNOS or eNOS speeds electron transfer into the flavins, implying that the C-terminal extension is a negative regulator. Another NOS mutant with a partial deletion of the C-terminal extension (Δ27 eNOS) exhibited a lower Ca^{2+} concentration response and an increase in some of its catalytic activities. Importantly, there is an Akt-dependent phosphorylation site located in the C-terminal tail of the constitutive NOS enzymes that modulates their regulation by Ca^{2+}/CaM (Figure 2). Phosphorylation at this site relieves some of the repression attributed to the C-terminal tail in the absence of CaM. It also lowers the Ca^{2+} concentration that is required for CaM binding and increases the NO synthesis activity of eNOS (but not of nNOS). When the autoinhibitory loop is present (as in nNOS and eNOS), the C-terminal tail is also needed to enable full activation in response to Ca^{2+}/CaM. This indicates that it functions as a positive regulatory element under this circumstance.

Ca^{2+}/CaM regulation of NOS may involve the two regulatory elements in the following manner. In the absence of CaM, the C-terminal extension helps to cover the NADPH-FAD and FMN subdomain interfaces, and this inhibits (but does not completely prevent) the FMN subdomain from transferring electrons to redox partners like cytochrome c or the NOS heme. This repression by the C-terminal tail requires that the enzyme NADPH binding site be occupied. Under this condition, the autoinhibitory insert is positioned in a way that antagonizes CaM binding and prevents the FMN subdomain from interacting productively with the NOS oxygenase domain. Upon CaM binding, the autoinhibitory loop swings away and this conformational change enables interactions between the FMN subdomain and the oxygenase domain that are productive for electron transfer to the heme. Specific interactions between the C-terminal extension and the autoinhibitory insert are likely to occur within the CaM-bound NOS. Such interactions between the two regulatory elements are likely to enable full activation of electron transfer by Ca^{2+}/CaM. Thus, the autoinhibitory loop and C-terminal tail repress enzyme function in the absence of CaM, and help to positively modulate function when Ca^{2+}/CaM is bound. Other structural elements that are present in the NOS reductase domain (Table I) along with protein phosphorylation events also help to regulate Ca^{2+}/CaM binding and to tune its activation of enzyme catalysis.

Calcium Transport in Mitochondria

Rosario Rizzuto
University of Ferrara, Ferrara, Italy

Marisa Brini
University of Padova and Venetian Institute of Molecular Medicine (VIMM), Padova, Italy

Mitochondria have long been known to accumulate Ca^{2+} down the electrical gradient established by the respiratory chain. Recent work has shown that, despite the low affinity of their Ca^{2+} transporters, Ca^{2+} uptake into mitochondria always follows the stimulation of cells with agonists causing an increase of cytoplasmic Ca^{2+} concentration. This process can modulate cellular events as diverse as aerobic metabolism, cytoplasmic diffusion of Ca^{2+} signals, and induction of apoptotic cell death.

The Origins and the Fundamental Principles

Studies of Ca^{2+} transport in isolated mitochondria began in the 1960s when evidence was provided that isolated, respiring mitochondria accumulate Ca^{2+} in the presence of inorganic phosphate. Ca^{2+} uptake was inhibited by respiratory chain blockers, but not by the ATP synthesis inhibitor oligomycin, and during Ca^{2+} uptake no ADP phosphorylation took place. In the presence of ATP no respiratory chain activity was necessary. Thus, the process of Ca^{2+} uptake was regarded as an alternative pathway to ADP phosphorylation for the use of the respiratory chain energy. In this scenario, mitochondria were thought as large stores of Ca^{2+}, which could be accumulated together with inorganic phosphate and precipitate in the matrix, leaving the matrix Ca^{2+} concentration virtually unchanged.

The general picture became clearer when the chemiosmotic theory solved the mechanism allowing mitochondria to store the energy obtained from metabolite breakdown and couple it to ATP synthesis. Indeed, the concept that the respiratory chain establishes a gradient ($\Delta\mu_H$), given by the Nernst equation $\Delta\mu_H = zF\Delta\psi + RT\ln[H^+]_i/[H^+]_o$, has major implications for Ca^{2+} transport and distribution. The gradient, composed of an electrical potential ($\Delta\psi$) and a concentration ratio (ΔpH), results by pumping protons across the ion-impermeable inner membrane. In actively respiring mitochondria, considering the buffering capacity mostly provided by weak acids, the gradient is supposed to be maintained mostly in the form of electrical gradient across the inner membrane ($\sim$180 mV). This implies a strong thermodynamic force in favor of the accumulation of cations (in the case of a divalent cation, such as Ca^{2+}, thermodynamic equilibrium is attained when in the matrix the concentration is $\sim 10^6$ higher than in the inter-membrane space). Based on these simple considerations, much attention was focused in the 1960s and 1970s on the capacity of mitochondria to accumulate Ca^{2+}, and on the biochemical and thermodynamic properties of this transport. Through the contribution of numerous laboratories and a large body of experimental work carried out in isolated, respiring mitochondria, these organelles were shown to possess separate accumulation and release pathways for the cation along with defined characteristics. Accumulation was shown to depend on the activity of an electrogenic "uniporter," which transports Ca^{2+} down the electrical gradient established by the respiratory chain. Inhibition of the respiratory chain or collapse of the electrical gradient (e.g., by the use of a protonophore) abolishes the capacity of mitochondria to accumulate Ca^{2+}. Ca^{2+} uptake is also directly inhibited by the compound Ruthenium Red (or its recently identified subcomponent Ru360) or lanthanides. Unfortunately, none of the inhibitors is highly specific, thus no selective tool has aided the purification of the transporter. Indeed, through the years this as well as the other mitochondrial Ca^{2+} transporters were not purified, and thus, despite the renewed interest, no molecular information on this process is available. As for the release pathways, two sets of exchangers have been shown to extrude Ca^{2+} from mitochondria: a Na^+/Ca^{2+} exchanger, mostly expressed in excitable cells (muscle and brain) and a H^+/Ca^{2+} exchanger, that represents the prevailing route in most other tissues. Both exchangers (although with different K_d) are inhibited by verapamil, diltiazem and other Ca^{2+} channel blockers.

More recently, much attention has been drawn to the potential role of a large-conductance channel, commonly referred to as the permeability transition pore (PTP). It is supposed to be a multiprotein complex (the putatively essential components being the voltage dependent anion channel, VDAC, of the outer membrane, the adenine nucleotide transporter, ANT, of the inner membrane and cyclophilin D) activated by various pathophysiological conditions (e.g., Ca^{2+} increases in the mitochondrial matrix and oxidation of critical cysteins). However, its role in mitochondrial Ca^{2+} homeostasis still remains elusive: it appears to play no role in Ca^{2+} efflux (as expected, considering that, unless an almost complete collapse of the electrical gradient occurs, the driving force is for Ca^{2+} accumulation, not release) and there is no clear evidence for its participation in mitochondrial Ca^{2+} uptake.

The Middle Ages

In the 1980s mitochondrial participation in intracellular Ca^{2+} homeostasis rapidly lost support, as the focus in calcium signaling was largely diverted to the endoplasmic reticulum (ER). In these years, the chain of events that couples the stimulation of plasma membrane receptors to the induction of a rise in cytoplasmic Ca^{2+} concentration was clarified, and it became clear that the ER and not mitochondria, were the main sites of action. Indeed, stimulation of receptors coupled through a G_q protein to the activation of phospholipase C induces the hydrolysis of the plasma membrane phospholipid phosphatidylinositol 4,5bisphosphate (PIP2) into diacylglycerol (DAG) and inositol 1,4,5trisphosphate (IP3). IP3 diffuses into the cytosol and interacts with Ca^{2+}-permeant channels of the ER membrane, causing their opening and the release of Ca^{2+} into the cytoplasm. The ER (and its specialized version of muscle cells, the sarcoplasmic reticulum, SR) was shown to be endowed with a molecular repertoire allowing it to act as a highly reactive intracellular Ca^{2+} store: pumps (that accumulate Ca^{2+} at the expense of ATP hydrolysis, and maintain a standing gradient between the lumen and the cytosol), low-affinity Ca^{2+} binding proteins (that increase the net amount of cation that can be accumulated, but promptly make it available when the concentration in the lumen decreases), and channels (opening, with different mechanisms, after stimulation of plasma membrane receptors).

What was left for mitochondria? In principle, given the large thermodynamic force for Ca^{2+} accumulation, they could take up most of the Ca^{2+} released by the ER. However, in the same years the availability of powerful and versatile Ca^{2+} indicators, the intracellularly trappable fluorescent dyes (e.g., quin2, fura-2, etc.) allowed for the careful estimation of cytosolic Ca^{2+} concentration ($[Ca^{2+}]_c$) of living cells and further reduced the possible roles of mitochondria. Indeed, these indicators showed that both at rest (0.1 μM) and upon stimulation (1–3 μM) the $[Ca^{2+}]_c$ is well below the affinity of the mitochondrial uniporter, and thus very little Ca^{2+} is supposed to be accumulated in mitochondria during the brief pulse of a physiological stimulation. Thus, the general consensus incorporating this series of information was that mitochondria acted as a low-affinity sink that could accumulate large Ca^{2+} loads, but only if the cell was exposed to challenges (most likely pathological events) that induced sustained, large $[Ca^{2+}]_c$ increases. In other words, mitochondria were mostly intended as salvage mechanisms against deleterious Ca^{2+} overloads.

The Renaissance

In this situation, the only opportunity for mitochondria to reobtain credit in the calcium field was to directly demonstrate in intact, living cells changes in mitochondrial $[Ca^{2+}]$ occurring in physiological conditions. This became possible in the early 1990s when novel experimental tools allowed to specifically measure the Ca^{2+} concentration in the mitochondrial matrix ($[Ca^{2+}]_m$): positively charged fluorescent indicators, which are largely accumulated in the mitochondria and molecularly engineered chimeras of the Ca^{2+}-sensitive photoprotein aequorin that include mitochondrial targeting sequences, and are thus exclusively localized in the mitochondrial matrix. Using these probes, it was possible to demonstrate that, in a variety of cell systems (ranging from epithelial cells to skeletal and cardiac myocytes, from hepatocytes to neurons), the $[Ca^{2+}]_c$ rises evoked by physiological stimulations are always paralleled by rapid $[Ca^{2+}]_m$ increases, which reach values well above those of the bulk cytosol (up to ~500 μM in chromaffin cells). The obvious discrepancy between this prompt response and the low affinity of the calcium uniporter was reconciled by the demonstration that mitochondria are exposed to microdomains of high $[Ca^{2+}]$ that largely exceed the values reported in the bulk cytosol and meet the low affinity of the uniporter. This is achieved through a close interaction between the mitochondria and the ER, the intracellular Ca^{2+} store, which could be directly demonstrated using targeted chimeras of a fluorescent recombinant protein (GFP) and a high-resolution imaging system. A consequence of this morphological arrangement is the capacity of mitochondria to "sense" the microenvironment at the mouth of the IP3-sensitive channel (and/or the plasma membrane Ca^{2+} channels), and thus the high $[Ca^{2+}]_c$ generated by their opening upon cell stimulation (Figure 1).

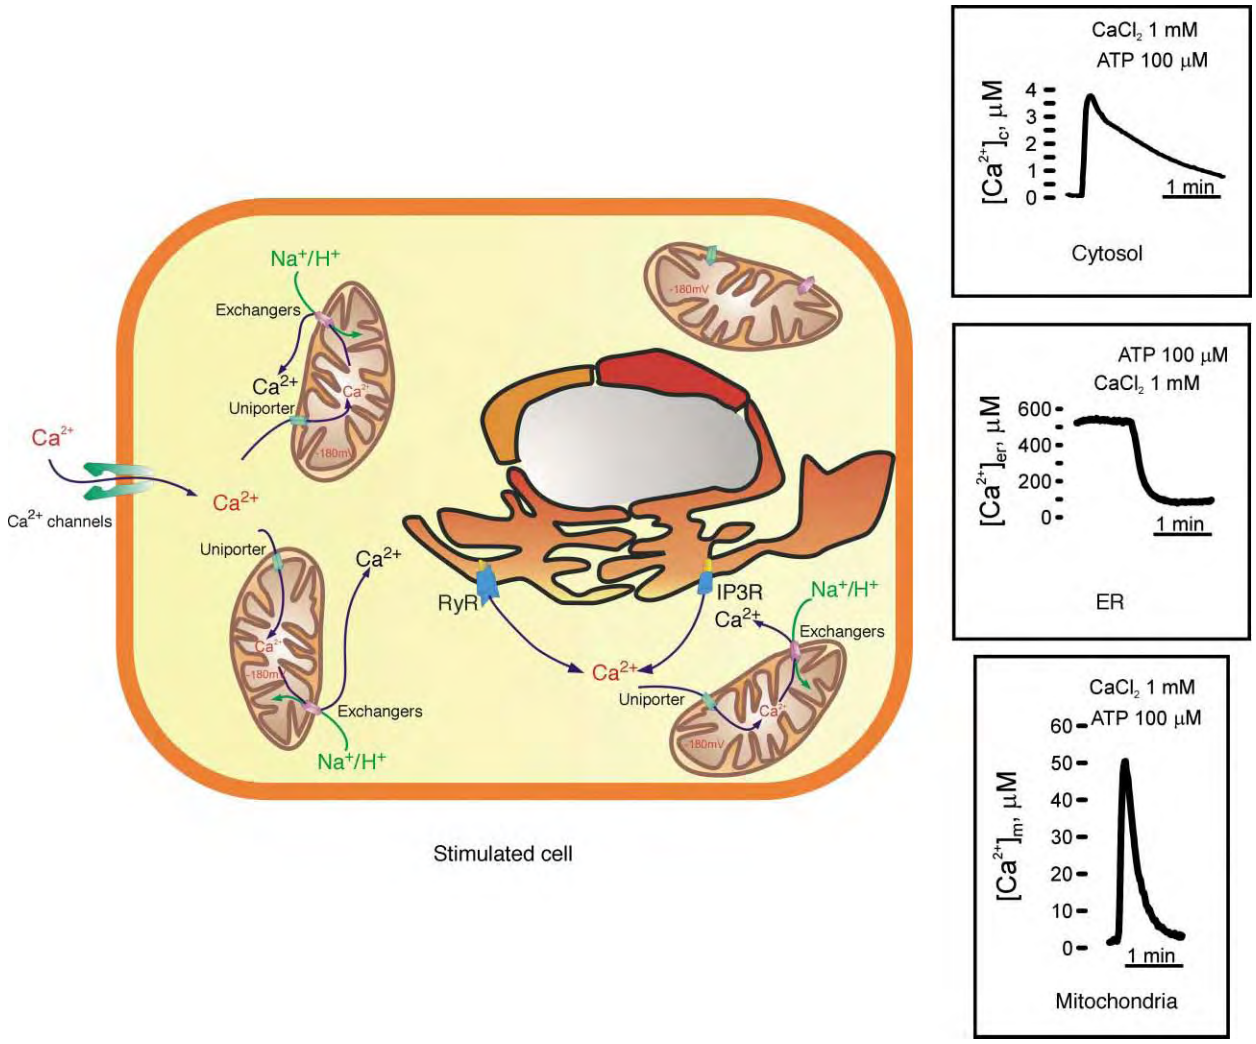

FIGURE 1 Mitochondrial Ca^{2+} transport. Cell stimulation induces the opening of plasma membrane Ca^{2+} channels and ER Ca^{2+} channels (IP3R and RyR), which, in turn, generates "hot spots" of Ca^{2+} concentration. Mitochondria located in the Ca^{2+} channels proximity could rapidly take up Ca^{2+} since their low-affinity uniporter could experience high local Ca^{2+} concentrations. The three traces represent measurements of $[Ca^{2+}]$ in the three cellular compartments shown, performed with suitably targeted aequorin.

One (or Many) Roles?

What is the functional significance of the re-evaluated mitochondrial Ca^{2+} transport? An obvious answer again stems from biochemical work by Denton, McCormack and Hansford in the 1960s, who could demonstrate that three key metabolic enzymes (the pyruvate, α-ketoglutarate and isocitrate dehydrogenases) are activated by Ca^{2+}, by different mechanisms: in the case of pyruvate dehydrogenase through a Ca^{2+}-dependent dephosphorylation step, and in the latter two cases through the direct binding of Ca^{2+} to the enzyme complex. Thus, the extension of a Ca^{2+} signal originated in the cytoplasm to the mitochondria would serve the purpose of transmitting an activatory signal to the energy powerhouse of the cell. In conjunction with the triggering of energy-consuming processes in the cytosol (contraction, secretion, etc.), mitochondrial dehydrogenases are stimulated, thus adapting aerobic metabolism to the increased needs of an active cell. Using the luciferase-based probe for ATP, it was possible to demonstrate that a rise in mitochondrial ATP levels parallels the $[Ca^{2+}]_m$ increase evoked by cell stimulation, and strictly depends on the $[Ca^{2+}]_m$ rise; if the latter is prevented by the use of Ca^{2+} chelators, such as 1,2-Bis(2-aminophenoxy) ethane-N, N, N′, N′-tetracetic acid (BAPTA), the [ATP] rise does not occur.

However, recent work by different groups has clarified that the role of mitochondrial Ca^{2+} uptake is not limited to the control of organelle function, but has a direct impact on the Ca^{2+} signals evoked by agonist stimulation in the cytosol. Two different mechanisms concur in this effect. The first occurs in the microdomains where mitochondria and ER get in

close contact. Here, the efficiency of mitochondrial Ca^{2+} accumulation accounts for the rapid clearing of the high $[Ca^{2+}]$ at the mouth of the release channel of the ER, and thus reduces the (positive or negative) feedback effect of the cation on the channel itself. Such a mechanism has been shown in a variety of experimental systems ranging from Xenopus oocytes (in which the diffusion properties of Ca^{2+} waves correlates with the energization state of mitochondria) to mammalian cells such as hepatocytes and glial cells, where it was demonstrated that the kinetics of Ca^{2+} release from the ER, and thus the spatio-temporal properties of the $[Ca^{2+}]_c$ rise are influenced by the process of mitochondrial Ca^{2+} uptake.

The second mechanism by which mitochondrial Ca^{2+} uptake affects cytosolic Ca^{2+} signals has been demonstrated in pancreatic acinar cells, which are endowed with a defined polarized morphology and the occurrence of cellular Ca^{2+} signals with different cellular locations and physiological consequences.

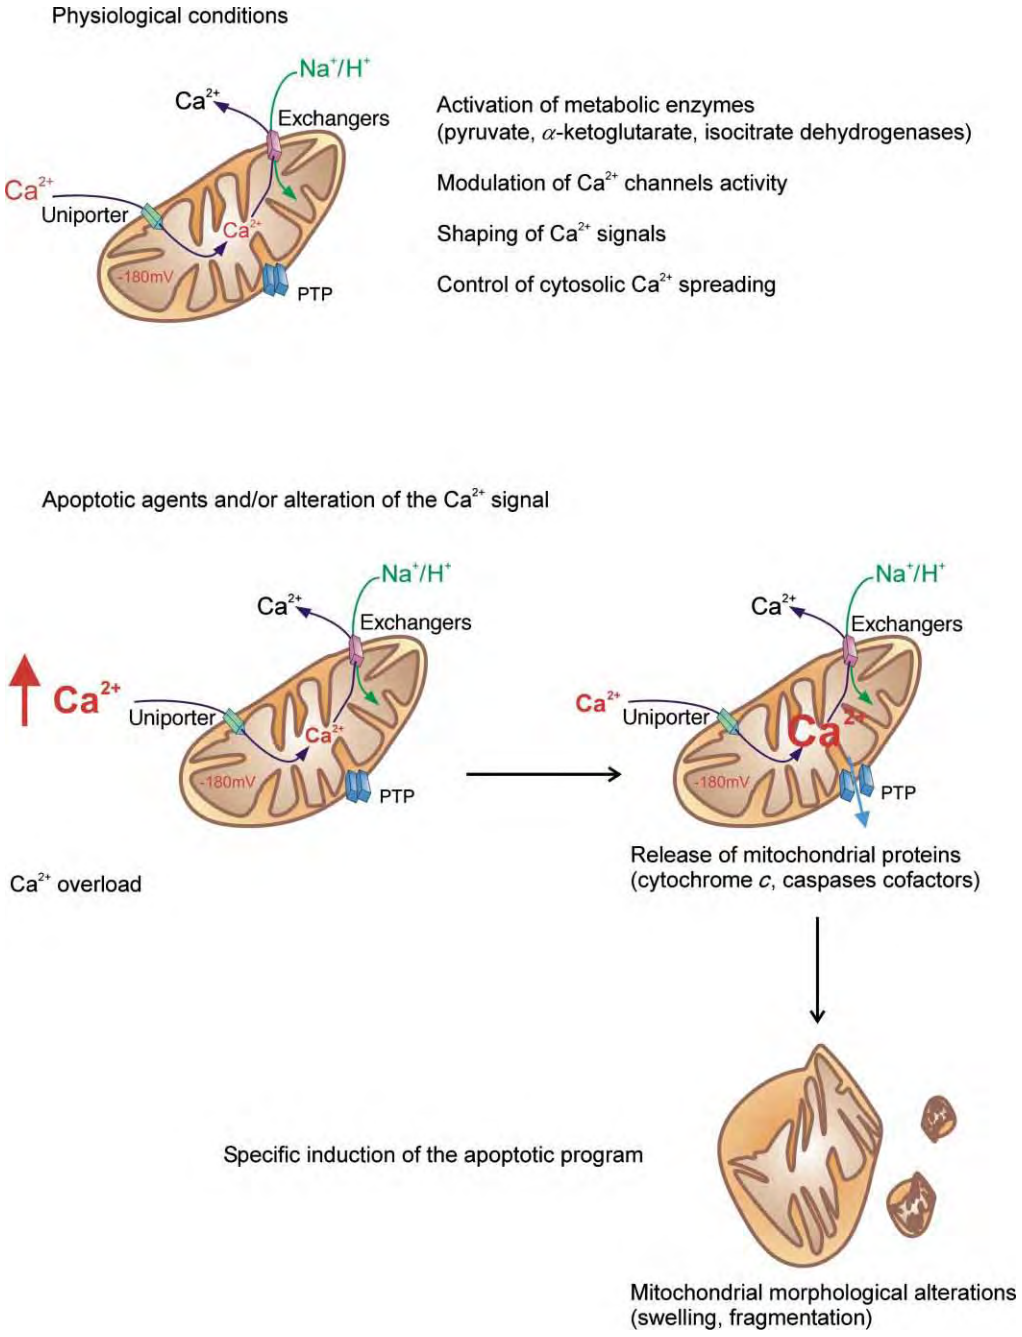

FIGURE 2 Physiological and pathological role of mitochondrial Ca^{2+} signaling.

At lower doses of agonists (e.g., colecystokinin) the $[Ca^{2+}]_c$ rise is restricted to the apical pole and causes granule secretion, at higher doses the $[Ca^{2+}]_c$ rise extends to the basal pole (where the nucleus is located), thus causing activation of gene expression and long-term alterations of cell function. The restriction mechanism was shown to be dependent on Ca^{2+} uptake by mitochondria clustered below the apical region that act as a "firewall" preventing the spread of the $[Ca^{2+}]_c$ rise. When the mitochondrial "belt" is overwhelmed (e.g., upon intense stimulation, or when the Ca^{2+} uptake capacity of mitochondria is experimentally impaired), then the Ca^{2+} signal can freely diffuse to the rest of the cell.

Finally, in the past years a more "dangerous" role for mitochondrial Ca^{2+} uptake has emerged. Work from various labs has revealed that the alteration of the Ca^{2+} signal reaching the mitochondria and/or the combined action of apoptotic agents or pathological conditions (e.g., oxidative stress) can induce a profound alteration of organelle structure and function. As a consequence, proteins normally retained in the organelle (such as an important component of the respiratory chain, cytochrome *c*, as well as newly discovered proteins, such as AIF and Smac/Diablo) are released into the cytoplasm, where they activate effector caspases and drive cells to apoptotic cell death. Different effects have been described: in hepatocytes, upon treatment with suboptimal doses of the lipid mediator of apoptosis ceramide, the repetitive spiking of cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_c$) rather than triggering the activation of matrix dehydrogenases (and thus the stimulation of aerobic metabolism), causes the opening of the permeability transition pore, the swelling of mitochondria, and the release of cytochrome *c*. Thus, a mechanism of "coincidence detection" of physiological agonists and apoptotic stimuli allows the specific induction of the apoptotic program (the mitochondria acting as the site where this "differential decoding" is operated). In addition, apoptotic stimuli can induce the impairment of the Ca^{2+} clearing mechanism of the cell (the plasma membrane Ca^{2+}-ATPase) thus potentiating Ca^{2+} loading. In this scenario, it can be easily understood how the partial depletion of Ca^{2+} from the ER, induced by the oncogene Bcl-2, has a protective effect toward some apoptotic stimuli (those involving mitochondria in the signaling pathway). Both in neurons and in hepatic cells it was observed that apoptotic signals cause mitochondrial Ca^{2+} overload, thus resulting in apoptotic morphological and functional alterations. A general scheme of the physiological role of mitochondrial Ca^{2+} signaling, and the potential alterations occurring in pathological conditions (modifying the final outcome) is summarized in Figure 2.

Conclusions

Recent work has greatly re-evaluated mitochondrial Ca^{2+} homeostasis as a key event not only for the maintenance of ion balance within the organelle (avoiding deleterious short-circuitry of the chemiosmotic machinery), but also as a control mechanism for physiological and pathological processes occurring in mitochondria, or activated by mitochondrial factors. Thus, both in basic and applied research there is an expanding interest on this topic, that contrasts with the paucity of molecular information. Neither the transporters nor the regulatory elements (and the crosstalk with other signaling routes) have been characterized, leaving a stimulating challenge (and much work to do) for scientists joining the field.

Biography

Rosario Rizzuto is a Professor of General Pathology at the University of Ferrara. He developed a new method for measuring Ca^{2+} concentration in specific cell domains, based on the targeting of the Ca^{2+}-sensitive photoprotein aequorin. His research interest is the role of calcium ions as intracellular second messengers with special emphasis on the mechanism and functional role of mitochondrial Ca^{2+} homeostasis.

Marisa Brini is Assistant Professor of Biochemistry at the University of Padova. Her main interest is the study of calcium signaling defects occurring in human genetic diseases and/or transgenic models affecting the homeostasis machinery of muscle. These include malignant hyperthermia, mitochondrial disorders, and cardiopathies due to mutations in the Ca^{2+} ATPase modulator phospholamban.

Calcium Waves

Lionel F. Jaffe
Marine Biological Laboratory, Woods Hole, Massachusetts, USA

Calcicum waves are actively propagated increases in intracellular calcium that carry signals within all organisms above the bacterial level. They occur in four main classes with characteristic speeds that vary over a range of a billionfold. Fast calcium waves move at 10 to 30 micrometers per second along endoplasmic reticula and include fertilization waves and brain injury waves. Slow calcium waves move at 0.1 to 1 micrometer per second and are surface contraction waves such as those that cleave dividing cells. Ultrafast calcium waves move at 10 to 40 centimeters per second along cell membranes and are electrical ones which underlie calcium action potentials in nerves and muscles. Ultraslow calcium waves move at 0.1 to 10 nanometers per second during development and include waves of DNA replication and of floret formation. Their mechanism is unknown.

Fast Calcium Waves

History, Roles, and Visualization

Calcium waves occur in four main classes with characteristic speeds that vary over a range of a billionfold. This speed spectrum is shown in Figure 1.

Calcium waves were discovered in 1978 by Gilkey *et al.* as the giant 10 μ/s fast wave or tsunami that crosses a medaka fish egg as it is fertilized and serves to start its development or activate it. This was done by injecting the eggs with the chemiluminescent calcium reporter, aequorin, and observing the wave of luminescence with an ultralow light imaging system (Figure 2). The American, Ernest Just first grasped the significance of fertilization waves and first measured their speeds accurately (in sea urchin eggs) in 1919. Just believed that such waves were restricted to the cell cortex, but they are now known to traverse the whole cytoplasm including the nucleus. The role and speed of such fertilization waves through medaka eggs was discovered by Tok-io Yamamoto during the Second World War in Japan. Moreover, he correctly predicted that they would prove to be calcium waves. Whereas sea urchin and fish eggs are activated by a single fast calcium wave, many other eggs – including human ones – can only be fully activated by a long series of fast calcium waves that start every few minutes. Aequorins still provide the best way to visualize calcium waves because these reporters are nondisturbing and provide quantitative information over a far larger dynamic range than the more widely used fluorescent indicators. Other roles of fast calcium waves include the control of contraction within muscle cells isolated from whole hearts, the control of contraction within isolated uterine muscle cells, the control of spreading depression or convulsion in the injured brain, the control of neuroglial waves in various vertebrate retinas, and the control of secretion in isolated rat livers.

Among brain injury waves are those that propagate migraine attacks and stroke. As early as 1941, the propagation of fast waves through the visual cortex of the brain during migraine attacks was inferred by Karl Lashley from the wave of visual blurring that sometimes accompanies migraine attacks.

Mechanisms

The initiation of fast calcium waves is best understood during fertilization. The interaction of eggs and sperm starts when contact of the sperm with the jelly coat around the egg induces a flow of calcium ions into the sperm from the medium. The influx ceases only when the sperm dies of calcium poisoning approximately 1 hour later. When the gametes fuse, this influx is diverted into the egg to help initiate a calcium wave. In most creatures, initiation is also speeded up by small molecules (sometimes called second messengers), such as nicotinic acid adenine dinucleotide phosphate (NAADP) or nitric oxide, that diffuse into the egg along with calcium ions.

Fast calcium waves are propagated within cells by a reaction–diffusion cycle or cycles that travel along the endoplasmic reticulum (ER). In the best understood of these cycles, the only reaction is one that opens calcium channels within the ER membrane. Calcium ions then move through such a channel from the lumen of the ER to the region just outside it. There they diffuse along the outside of the ER to other calcium channels a few microns away so as to induce their own release; a reaction called calcium-induced calcium release (CICR). In this way, a fast calcium wave is relayed from channel to channel so as to traverse a cell. Successful relay also requires a high enough level of channel sensitizers.

FIGURE 1 Main classes of natural calcium waves based on speeds at room temperature. Fast waves through active cells refers to all such waves in this speed class except for the slightly slower ones that activate eggs and are marked f. Fast waves are reaction–diffusion waves propagated by the short-range diffusion of calcium ions between relay points in the endoplasmic reticulum (ER). Slow waves are a second coherent class of calcium waves and seem to be stretch propagated. Ultrafast waves are electrically propagated waves or action potentials that are primarily dependent on an influx of calcium, rather than sodium, ions. Ultraslow waves are developmental. Reproduced with permission from L.F. Jaffe (1999). *BioEssays* **21**, 657–677. Copyright 1999, John Wiley & Sons.

In various cells these include cyclic AMP (cAMP), inositol trisphosphate (IP_3), cyclic adenosine 5′-diphosphate-ribose (cADPR), as well as NAADP. One way that fast calcium waves are carried between cells is by the diffusion of calcium ions through minute cytoplasmic bridges called gap junctions. Reaction–diffusion waves can also be seen in dishes containing a complex mixture of nonbiological chemicals such as the brominated ones that support the Bielozov–Zhabotinsky (BZ) reaction.

However, they may also be propagated along the interiors or lumens of ER strands by a reaction–diffusion cycle in which calcium induces its own release from a luminal calcium-binding protein such as a calsequestrin, a calreticulin, or a calcistorin/PDI. The two cycles mutually reinforce one another like the riders of a tandem bicycle; this is called a tandem wave mechanism.

Slow Calcium Waves

History, Roles, and Visualization

Slow calcium waves (like fast ones) were discovered in medaka fish eggs with the aid of aequorin. They were seen as two successive waves, both of which move at 0.5 μm/s within the forming second furrow of the cleaving medaka egg. The first of these accompanies elongation of the second furrow, whereas the second accompanies the subsequent, sequential apposition, or zipping together, of the newly formed blastomeres. This discovery was made in 1991 and the results of calcium buffer injections into Xenopus eggs (which likewise exhibit slow calcium waves during cleavage) soon showed that these waves do more than accompany furrowing. They are needed for it to start, to continue, and to remain. Moreover, by 1998, 30 apparently similar slow surface contraction waves had been recognized. An especially vivid one is the repeated gross contractile waves that traverse the barnacle egg from pole to pole before its first mitotic division. Its discoverers called these barnacle egg waves peristaltic in the plausible belief that they serve to drive morphogens to the vegetal pole via intracellular peristalsis. Another remarkable one is the surface contraction wave that accompanies primary neural induction in the axolotl egg.

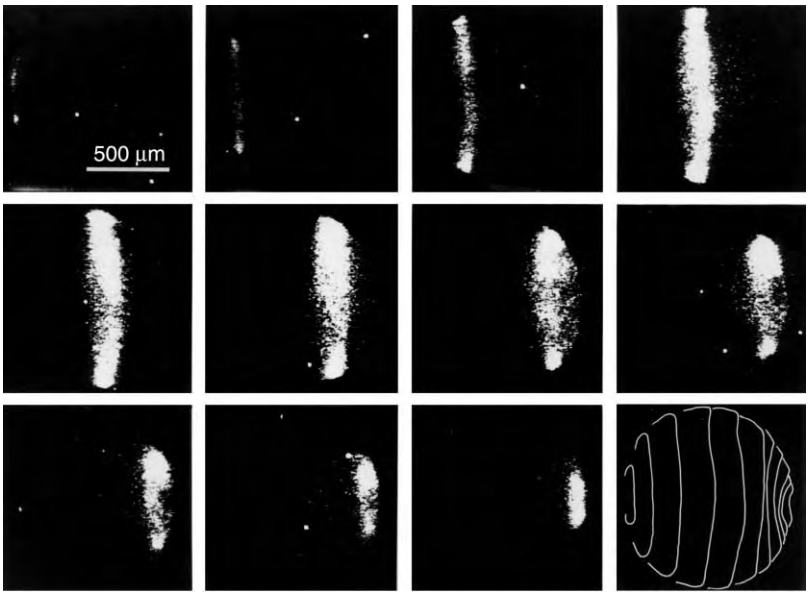

FIGURE 2 A free calcium wave propagating across a sperm-activated medaka egg. Successive photographs are 10 seconds apart. The last frame is a tracing showing the leading edges of the 11 illustrated wave fronts. Reproduced from Gilkey, J. C., Jaffe, L. F., Ridgway, E. B., and Reynolds, G. T. (1978). A free calcium wave traverses the activating egg of the medaka, *Oryzias latipes*. *J. Cell Biol.* **76**, 448–466, by copyright permission of the Rockefeller University Press.

Mechanisms

Slow calcium waves are thought to be propagated mechanically. Local surface contraction opens stretch-activated calcium channels in the subsurface ER of nearby regions. This releases calcium ions, which induces contraction in these nearby regions and thereby relays the wave. If the initial contraction is along a line, then the wave spreads along a line as in a cleavage furrow; however, if the initial contraction acts to shrink a small disk, then the wave spreads over the entire surface, as in the precleavage surface contraction waves of axolotl eggs.

Ultrafast Calcium Waves

Action potentials are electrical waves that are propagated by voltage-gated ion channels in the plasma membranes of nerve, muscle, and other cells. In the best-understood action potentials, sodium ions flow in through these ion channels to extend the electrical field along a cell; however, in another important class of action potentials, calcium ions flow in; these are called calcium action potentials or ultrafast calcium waves. The speeds of calcium action potentials have been measured along neurons within systems that range from jellyfish up to guinea pig brains, along muscles that range from moth hearts up to guinea pig hearts and even along an insectivorous plant. Unlike sodium action potentials, whose speeds vary over a thousandfold range, calcium action potential speeds vary over a range of approximately 10–40 cm/s (at 20°C) and thus over only a fourfold range. Moreover, unlike the speeds of sodium action potentials, the speeds of calcium ones are unrelated to cell diameter.

Why do calcium action potentials, or ultrafast calcium waves, have such a limited range of speeds? Perhaps evolution has driven them to be the fastest waves of calcium influx that avoid subsurface poisoning of the cell.

Ultraslow Calcium Waves

Ultraslow calcium waves are the least understood class of calcium waves. They include waves of formation of the morphogenetic furrow in developing Drosophila eyes, of floret formation in sunflowers, of DNA replication in certain protozoa, and of growth-cone-like bulges along certain growing mammalian brain neurons, as well as, perhaps, waves of cell division in rat lenses as they heal after a wound. The propagation mechanism of ultraslow calcium waves is completely unknown.

Biography

Lionel F. Jaffe is a Senior Scientist at the Marine Biological Laboratory in Woods Hole and at Brown University. His principal research interest is in the broad field of developmental physiology, including calcium waves and calcium gradients, electrical field and polarized light effects, and interactions via chemiluminescent signals. He holds a Ph.D. from the California Institute of Technology.

Calcium, Biological Fitness of

Robert J. P. Williams
University of Oxford, Oxford, UK

Calcium has a special cation, Ca^{2+}, in cellular activity. It is rejected by all cell cytoplasm either to the outside of cells or to the inside of resides. From these stores it is released by events outside eukaryote cells to the cytoplasm and organells were it activates many processes. Thus calcium is the dominant messenger, relaying information concerning the environment to activities such as contraction of muscles, release of digestive jucies from the pancreas, to hormone release from glands. It is also the major cation in organizing external protein structures and in formation of biological mineral – shells and bones.

Calcium: The Element and its Ion, Ca^{2+}

Calcium, atomic number 20 lies in group 2 in the third row of the periodic table and before the first row of transition metals. It resides below magnesium and above strontium and then barium in its group. It has low ionization potentials, giving a rather large calcium ion, Ca^{2+} (radius 1.0Å), which is a rather poor Lewis acid and hence a somewhat poor acid catalyst. However, it can bind quite strongly to certain anion centers. Within its group, the chemistry of the Ca^{2+} ion has close resemblance to that of the larger strontium ion, Sr^{2+}, but differs markedly from the smaller magnesium ion, Mg^{2+}, which is a better Lewis acid.

Calcium, like magnesium, is an abundant element in the universe and on Earth, and its salts are quite soluble in water. Hence, calcium is available in the sea, 10^{-2} M, compared to magnesium at 5×10^{-2} M, whereas in fresh water it, like magnesium, is often as high as 10^{-3} M. It is against these background levels in water, especially in the sea, that life evolved.

The calcium ion has three major mass isotopes, 40, 42, and 44, which can be used to follow the reactions of its ions. It can also be followed in biological systems through association with fluorescent organic dyestuffs.

The Aqueous Calcium Ion

The free aqueous calcium ion has a variable fluctuating number of water molecules around it, exceeding six but not exceeding nine. This loose hydration sphere is common to all cations of a radius greater than 0.8Å. In this way the calcium ion differs from the magnesium ion, radius 0.6Å, which has a fixed, rather rigid coordination of six water molecules. The differences in structure are reflected in the rates of exchange of the water molecules from their respective coordination spheres, that of magnesium being rather slow, $10^6\ s^{-1}$ and that of calcium being close to the diffusion limit of $10^9\ s^{-1}$.

Insoluble Salts

The binding of calcium, a large ion, is less than that of magnesium when the in-coming anion is small (e.g., fluoride or hydroxide) and these magnesium salts tend to be the more insoluble. However, larger groups, which include the vast majority of anions (e.g., carbonate, sulfate, and phosphate anions), are more readily accommodated around the larger calcium ion. Hence, we observe that the vast majority of calcium salts are more insoluble than the corresponding magnesium salts. This becomes a feature in organisms, where we find calcium carbonate in shells and calcium phosphate in bones, whereas in plants calcium oxalate is often precipitated. Aberrant precipitation causes stones in animal organs. Among minerals, calcium and magnesium often occur together, as, for example, in dolomite.

Soluble Complex Ions and their Binding Strengths

Calcium ions do not bind strongly to simple anions in water at pH 7. Thus, complexes with carbonate, sulfate, hydroxide, and phosphate are not of great importance in organisms. However, binding to ligands with several donor atoms can be strong because despite their bulkiness they can be fitted around the large calcium ion. By contrast, the Mg^{2+} ion fails to bind strongly, so these chelating ligands selectively bind calcium relative to magnesium by at least a thousandfold. Typical examples are proteins both inside cells and in external circulating fluids. The use of the calcium buffer (ethylene tetra-acetate (EGTA)) depends on this quite strong

binding to calcium but weak binding to magnesium at pH 7.

Structures of Calcium Salts and Complexes

The structures of many calcium salts have been determined, and the extremes of their variation are shown even within the allotropic forms of its carbonates. Whereas calcite has a six-coordinate lattice, aragonite has a nine-coordinate structure. These salts have no water of crystallization and both are found in shells. More frequently, when calcium ions are bound to bulky chelating organic ligands in solution, calcium has seven near-neighbors, but the distances from the metal ion to the nearest ligand atom are very irregular, from 2.2 to 3.0Å. Bound to saccharides or proteins, the ion has this structure, but it fluctuates. It is usual for one or two water molecules to remain bound. The binding ligand atoms are invariably oxygen from such centers as oxyanions, carboxylates, alcohols, carbonyls, and ethers.

Rates of Exchange

The rate of loss of water molecules from around Ca^{2+}, $10^9\ s^{-1}$, is the rate at which ligands can bind, k_{on}. The rate of leaving is related to the ligand binding constant, $K = k_{on}/k_{off}$, so for $K = 10^6\ M^{-1}$ the leaving rate is $10^3\ s^{-1}$. This binding constant is close to that found for several proteins inside cells. The combination of such a protein (e.g., calmodulin) with calcium then provides a response time of $10^3\ s^{-1}$, as is seen in fast muscle cells. It is the rates of exchange together with the *selective* binding constants that make calcium an incomparable messenger in aqueous solution.

Biological Salts and Ligand Complexes

The major insoluble calcium salts found in organisms are the fluoride (in krill), carbonates (in shells in at least three allotropic forms), phosphates (in bone), and oxalates (in many plants). There are variable amounts of other metal ions and anions in these salts, so their exact nature is far from simple; for example, bone, hydroxy apatite, does not have an ideal stoichiometric formula and easily incorporates other elements including magnesium and fluoride. The apatite structure is somewhat different in bones of different organisms and even in the teeth and bones of one species (e.g., humans). Calcite is also found in the ears of animals, with a balance function.

In cellular complexes, calcium is bound, seven-coordinate, to oxygen (O-) donor groups of proteins and polysaccharides through both side chain and main chain atoms (e.g., $-OH$, $>CO$, CO_2^-, ether, and SO_4^{2-}). There is little or no binding to DNA or RNA in cells, in marked contrast to the essential function of magnesium in the structures of these nucleotides. The selective binding arises from the differences in concentration and binding ability.

Concentrations and Selectivity of Binding in Organisms

The ability of calcium ions to precipitate many organic anions including DNA required that one primary necessity of the original life forms, prokaryotes, was the rejection of calcium. Consequently, all organisms hold Ca^{2+} concentrations at 10^{-6} M or below in their cytoplasm using calcium outward pumps. Magnesium ions do not precipitate organic anions and are found at 10^{-3} M in all cell cytoplasms. Hence, for Ca^{2+} to bind selectively inside cells, its binding constant must be close to $10^6\ M^{-1}$, whereas that of Mg^{2+} has to be less than $10^3\ M^{-1}$. This selectivity between the two ions is found for many cytoplasmic messenger proteins, for example, calmodulin, troponin and S-100. Meanwhile, Ca^{2+} fails to bind to such molecules as ATP and DNA, $K = 10^4$, but Mg^{2+} can bind with the same binding constant. Outside cells, both Mg^{2+} and Ca^{2+} are $> 10^{-3}$ M and in eukaryotes the cell vesicles hold Ca^{2+} at this concentration also. Ca^{2+} can again bind selectively if its binding constant to proteins or now saccharides is $\geqslant 10^3\ M^{-1}$, whereas that of Mg^{2+} is less than $10^2\ M^{-1}$, because both ions are present outside cells at 10^{-3} M. These constants are found for some coat, blood-clotting, and immune-response proteins and for some vesicle proteins. Note that in higher organisms the free Ca^{2+} concentration in external fluids and vesicles is extremely well controlled and in the extracellular fluid of humans is nearly in equilibrium with the precipitated bone. The further requirement for a messenger activity, that the rate of exchange to the internal proteins be fast, at least $10^3\ s^{-1}$ for calcium, is also met.

Consider now a cytoplasmic concentration in a resting cell of Ca^{2+} of 10^{-7} M and an external or vesicle concentration of 10^{-3} M. Any influx of Ca^{2+} to the cytoplasm from outside through channels will increase Ca^{2+} to 10^{-6} M, which will trigger activity through cytoplasmic protein binding. On closing the channel, the outward pumps will restore rest conditions quickly. The calcium ion is therefore able to act as a pulsed messenger. Hence, the combination of sufficiency of binding, of selectivity, of concentration control, and of rates of on/off reactions give optimal messenger character to this elementary ion. No other ion or molecule could be better.

Overall Functional Fitness of Calcium Ions in Evolution

The properties of the calcium ion, its fast on/off reactions reflecting the structural flexibility of its coordination sphere and its quite strong binding to selected organic ligands, have made it an extremely valuable partner to organic chemicals in almost all forms of life. In the most primitive forms of life, this value is seen in protective external constructs (walls) and mineralization, but also in the use of bound calcium in external digestive catalytic enzymes. These functions are found in all other organisms but the most striking feature of the use of calcium appeared at the time the eukaryotes developed from the prokaryotes. At that time, the problem of coordinating activities of different compartments (vesicles) and the need for an increasing recognition of the environment became critical for the survival of the large eukaryote cells. Cooperation between compartments and sensing required the rapid transfer of information between cellular compartments and from the outside environment, and there is no better possible mode of communication in cellular biology than that which can be derived from the happy coincidental values of the high availability with concentration control and the response properties of the calcium ion. Hence, it was an evolutionary requirement that led to a messenger system in which the calcium ion was the best of all available carriers (Table I). The protein receptors in the cytoplasm acted as mechanical triggers of action, changing conformation upon binding calcium. They include all muscle responses (troponins), fertilizations, many metabolic responses (calmodulins), genetic activations (possibly S-100 and other proteins), and immune responses (calcineurin). The necessary refinement of the homeostasis of the calcium concentrations increased all the way up to humans and included the control over both the internal cytoplasmic and the external circulating fluid concentrations. In the external fluids, there arose various novel functions that used the calcium ion, including further immune responses and blood-clotting controls in addition to digestive actions. Finally, we must remember that the messenger system from outside to inside the cell

TABLE I

Calcium-Controlled Events in Cells

Activity	Controlled events or systems
Photosynthesis	Dioxygen release
Oxidative phosphorylation	Dehydrogenases
Receptor responses	Nerve synapse; IP_3-linked reactions
Contractile devices	Muscle triggering (actomyosin); cell filament controls (tubulins)
Phosphorylation	Activation of kinases, e.g., in fertilization
Metabolism	Numerous enzymes inside cells
Membrane/filament organization	Annexin-like proteins modulate tension
Cell division	S-100 proteins, immune system
Cell death (apotosis)	Internal proteases
Hormone/transmitter release	Homeostasis
Binding to membranes	C2 domains of enzymes
Cross-linking	Outside cells
Enzyme-activation	Outside cells; in membranes

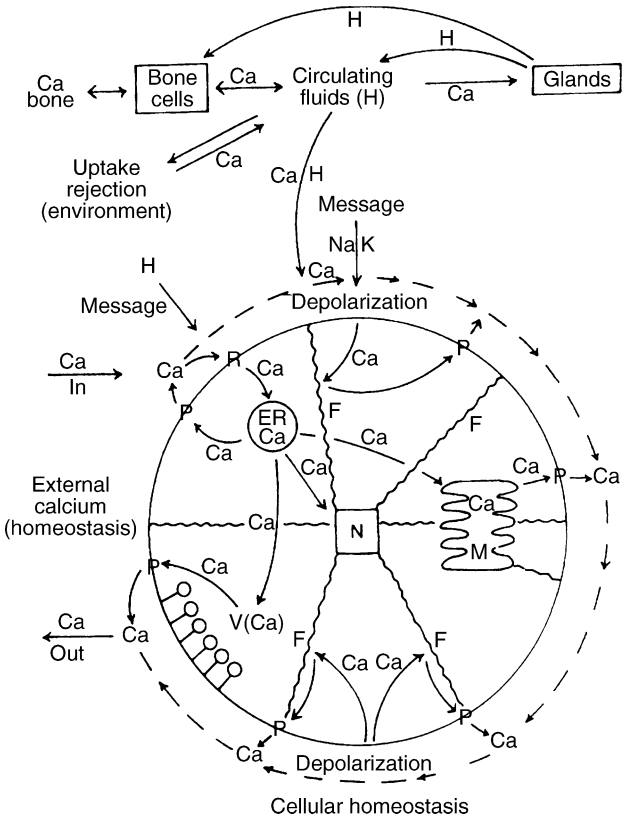

FIGURE 1 The generalized way in which calcium ions act as a messenger in advanced animal cells. The top of the figure shows the connection between the calcium in the external fluids, bone, and glands and uptake and rejection systems (e.g., the epithelial cells of digestion and the rejection cells of the kidney). H is a hormone. Calcium ions from the circulating fluids together with hormones and Na/K nerve messages activate a large range of cells. The calcium entry is controlled by channels R responding to perturbations. On entering the cell, calcium can release further calcium from vesicles such as the endoplasmic reticulum (ER). The calcium in the cytoplasm can act directly on filaments (F), on mitochondria (M) (or chloroplasts), through transcription factors on the nucleus (N), and on vesicles (V). The vesicles act to release transmitters, hormones, or enzymes. The calcium is removed by pumps (P). The bottom of the diagram shows the effect of general depolarization rather than specific channel activation. This allows calcium entry by electrically operated channels, as, for example, at nerve synapses of the heart.

was augmented by the further responses, releases due to calcium pulses of chemicals, which caused release from internal vesicles and organelles to both the cytoplasm and the external fluids. Thus, the pulsed calcium ion input to the mitochondria and chloroplasts stimulates the release of energy (ATP) to the cytoplasm, and the release of this ion from vesicles to the external fluids stimulates the release not only of enzymes (e.g., for digestion, general to many organisms) but also of hormones and synaptic messengers, leading to overall homeostatic control. Hence, calcium signaling is central to a huge variety of communication modes leading up to and including synaptic action in the brain. In this homeostasis, we must not forget the buffer action of the bone. The overall fitness of calcium for a multitude of functions is very clear (see Figure 1).

Biography

Robert J. P. Williams is Emeritus Professor at Oxford University, having been a Royal Society Research Professor there for many years. He holds an M.A., D.Phil. (Oxford), F.R.S. (London), Hon. D.Sc. (East Anglia, Leicester, Keele) and is a Fellow of the Academies of the Czech Republic, Belgium, Sweden and Portugal. His research interests are in bio-energetics and the roles of inorganic ions in organisms. He has received many honors: four honorary doctorates and more than ten medals from chemical and biochemical societies. He is an academy member of four national bodies. His founding contribution was to biological inorganic chemistry including the development of the protein chemistries of elements such as Ca, Fe, Cu, Zn, Co, and Mg; he also proposed the use of protons as intermediates in bio-energetics. He is the author of four leading books in these areas.

Calcium/Calmodulin-Dependent Protein Kinase II

Andy Hudmon
Yale University, New Haven, Connecticut, USA

Howard Schulman
Mountain View, California, USA

Calcium/calmodulin-dependent protein kinase II (CaMKII) is a multifunctional serine/threonine (Ser/Thr) protein kinase involved with a diverse array of cellular functions. From metabolism and cytoskeletal organization to gene expression and the cell cycle, CaMKII phosphorylation of key substrates transduces a transient rise in free calcium (Ca^{2+}) induced by neurotransmitters, hormones, or other signaling molecules, into complex cellular functions. CaMKII is particularly important in the nervous system, where neurogenetics (knockouts, knockins, and transgenics) have directly implicated it in behavior and learning/memory. It is strategically localized in both pre- and postsynaptic compartments, where it regulates Ca^{2+}-dependent processes central to neuronal communication, including neurotransmitter synthesis and release and ion flux through voltage and ligand-gated channels. In addition, CaMKII possesses autoregulatory properties that may enable it to function as a "molecular switch" to translate neuronal activity into specific alterations in synaptic connectivity, such as long-term potentiation (LTP), a cellular correlate of learning and memory. Autophosphorylation can be considered as a form of molecular memory, as it generates a form of persistent activity (autonomous) that is temporally uncoupled from the Ca^{2+} signal. This autoregulation also enables CaMKII to function as a Ca^{2+} spike integrator – the ability to generate graded levels of autonomous activity that is differentially sensitive to the frequency of Ca^{2+} transients. Thus, its direct action on neuronal substrates and its complex autoregulation enables CaMKII to function as a cognitive kinase with both short- and long-term consequences on complex behaviors, such as learning and memory.

Neuronal CaMKII: Localization and Substrates

CaMKII is highly concentrated in the nervous system. At roughly 1–2% of the total protein in the brain, it is the predominant Ca^{2+}/calmodulin (Ca^{2+}/CaM) regulated kinase in the central nervous system. CaMKII has a diverse intracellular localization, including the postsynaptic density (PSD), a cytoskeletal specialization replete with signaling molecules (e.g., ligand and voltage gated receptors, kinases, phosphatases, and anchoring and structural proteins) that lies immediately across the presynaptic terminal below the postsynaptic membrane. Biochemical cascades at the PSD regulated by CaMKII are likely central to the function of this highly specialized signaling network for the following reasons: (1) CaMKII constitutes a significant fraction of the total PSD protein, (2) it is recruited to the PSD in an activity-dependent manner, (3) it anchors to multiple PSD proteins (e.g., densin-180, α-actinin, and NMDA-receptors), and (4) it regulates the activity of multiple PSD proteins through phosphorylation. One prominent PSD substrate of CaMKII is the GluR1 subunit of the AMPA-subtype of glutamate receptor. CaMKII phosphorylation of a specific serine (Ser^{831}) in this channel increases its conductance by favoring the open probability of its high conductance state. CaMKII was also shown by Malinow and his colleagues to regulate the targeting or insertion of AMPA-receptors into the PSD. Although both effects may underlie long-term potentiation, CaMKII regulation of AMPA receptor function and targeting has obvious implications for postsynaptic function; further studies will be required to determine how the 28 CaMKII substrates in the PSD recently identified using mass spectrometry contribute to PSD structure and function.

In addition to the postsynaptic compartment of neurons, CaMKII is also present in the presynaptic compartment, where it regulates neurotransmitter synthesis, neurotransmitter vesicle availability and release by its phosphorylation of vesicle proteins (e.g., Synapsin I) cytoskeletal regulating proteins (e.g., MAP2), membrane channels (e.g., calcium channels), and other enzymes (e.g., Tyrosine Hydroxlyase). CaMKII is also present in the nucleus, where it phosphorylates key

substrates (e.g., CREB) involved in the regulation of gene transcription and long-term changes in neuronal function. Thus, CaMKII is strategically positioned throughout the neuron to transduce and coordinate a host of calcium mobilizing stimuli into the appropriate alterations in neuronal function (see Figure 1).

Activation, Autoregulation, and Structure of CaMKII

CaMKII is composed of a family of highly conserved isoforms (α, β, γ and δ that are encoded by unique genes and differentially expressed throughout the body (see Figure 1). Although the δ and γ isoforms are ubiqitous, the α and β isoforms are brain specific. The molecular weights of these subunits range from 54 to 72 kDa, with α-isoform being the smallest subunit at 54 kDa. This size difference is due primarily to domain insertions in the region between the regulatory and association domains, because each of these genes encode protein products possessing a catalytic, regulatory, and association domain. A proto-typical α-subunit of CaMKII, illustrating the relative positions of these domains, is shown in Figure 2. Like all protein kinases, the catalytic domain serves to bind substrates and catalyze the phosphotransferase reaction from Mg^{2+}/ATP to the protein substrate.

CaMKII is coupled to the Ca^{2+} stimulus via CaM, a small dumbbell-shaped protein that, following Ca^{2+} binding, is competent to bind and activate multiple target proteins, including CaMKII. The autoregulatory domain is composed of a CaM binding domain and a region that resembles a protein substrate. This pseudo-substrate and the surrounding sequence of the regulatory domain (including the CaM binding domain) interacts with the catalytic domain to inhibit kinase activity in the absence of Ca^{2+}/CaM. C-terminal to the autoregulatory domain, the association domain produces the supramolecular association of kinase subunits into a multimeric complex, termed the holoenzyme.

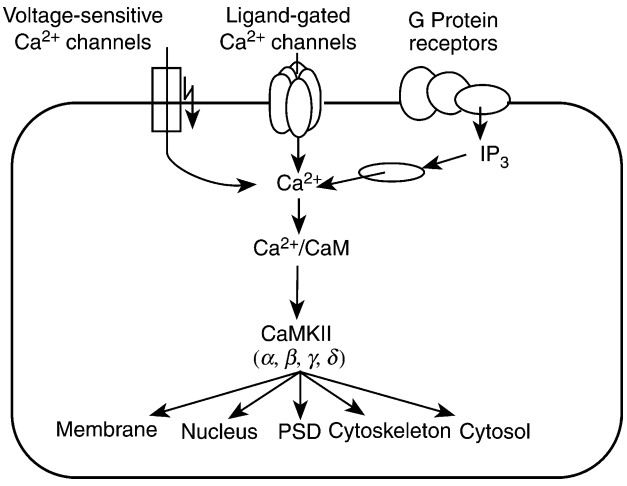

FIGURE 1 A variety of extracellular signals (e.g., depolarization, neurotransmitters, and hormones) function to elevate intracelular Ca^{2+} levels through the action of ligand and voltage-gated channels and IP_3 operated intracellular stores. Activation of CaMKII (α, β, γ, and δ isoforms) throughout the neuron via Ca^{2+}/CaM leads to phosphorylation of substrates at the membrane, cytoskeleton, postsynaptic density (PSD), nucleus, and in the cytosol. Adapted with permission from *Annu. Rev. Biochem.* **71**, 473–510 by Annual Reviews.

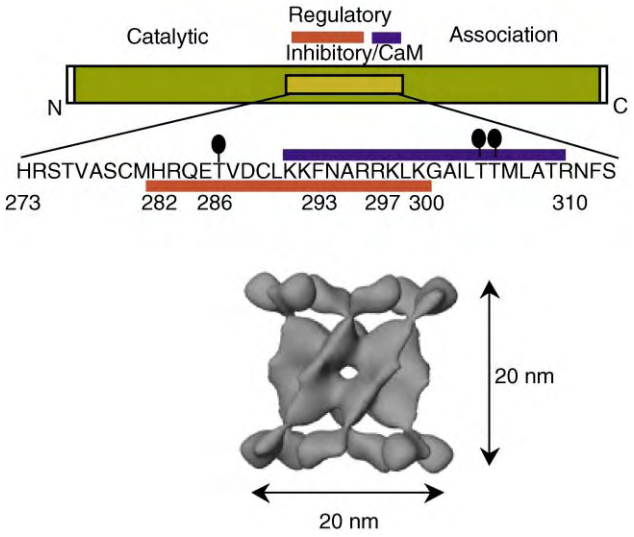

FIGURE 2 Linear diagram of α-CaMKII illustrating the catalytic, regulatory, and association domains. Like all kinases, the catalytic domain is composed of both an ATP and a protein substrate binding region. Adjacent to the catalytic domain is an autoregulatory region (shown in yellow): a bifunctional sequence that serves to inhibit kinase activity through an inhibitory region (red) and to activate the kinase via the calmodulin binding domain (blue). The association domain drives subunit multimerization and holoenzyme assembly. A computer assisted reconstruction of α-CaMKII obtained from images produced using transmission electron microscopy indicates a dodecameric structure, with 12 catalytic heads radiating out form the top and bottom of the central core.

A computer-assisted reconstruction of α-CaMKII obtained from images using transmission electron microscopy indicated that the catalytic heads extend from the gear-shaped central core via delicate stalk in a dodecameric (12 subunits) arrangement (Figure 2). The structure of the core hub-like assembly was recently resolved in a crystal obtained from a truncated form of CaMKII. In this structure, the association domain appeared as a tetradecameric structure (14 subunits) with extensive contacts between neighboring subunits in a head-to-head orientation. Variance in the number of subunits forming the holoenzyme may be expected, as native CaMKII isolated from forebrain varies greatly in its apparent molecular weight (450–650 kDa). In addition, CaMKII isolated from brain may be homo- and heteromeric in its isoform composition.

The isoform composition of the holoenzyme may afford CaMKII with the properties and regulation unique to each isoform. For example, in addition to the α and β isoforms being differentially expressed throughout the brain and during development, recent evidence indicates that neuronal activity favors the expression of the α-isoform whereas, a lack of activity favors the β-isoform. One functional consequence of altering the subunit composition is in its regulation of the subcellular localization of CaMKII. For example, unlike the α-isoform, the β-isoform possesses an F-actin binding domain that targets this isoform to cytoskeletal structures, where it participates in regulating the sprouting and stability of neuronal dendrites.

The Structure/Function of CaMKII Autophosphorylation

In addition to phosphorylating protein substrates throughout the cell (see Figure 1), CaMKII is a substrate for its own catalytic activity via *auto*phosphorylation reactions. CaMKII undergoes both Ca^{2+}/CaM-dependent as well as Ca^{2+}/CaM-independent forms of autophosphorylation. These modes of autophosphorylation occur at distinct sites within different regions of the autoregulatory domain and, importantly, have both been implicated in both the cellular correlates of learning and memory (i.e., LTP), as well as the behavior itself.

Ca^{2+}/CaM-Dependent Autophosphorylation

Following CaM activation, autophosphorylation may occur at Thr^{286} (Thr^{287} of the β, γ and δ), a phosphoamino acceptor that resides just N-terminal to the pseudo substrate anchor and CaM binding domain (see Figure 2). Autophosphorylation at Thr^{286} is not necessary for enzyme activation, because nonphosphorylatable amino acids (e.g., Ala) substituted at position 286 are similar to wild-type enzyme in regards to both CaM activation and substrate phosphorylation. The autophosphorylation reaction is dominated by an intraholenzyme inter-subunit reaction that requires CaM bound to both the subunit acting as kinase as well as the subunit behaving as substrate (Figure 3). Three functional consequences associated with Thr^{286} autophosphorylation are (a) the generation of

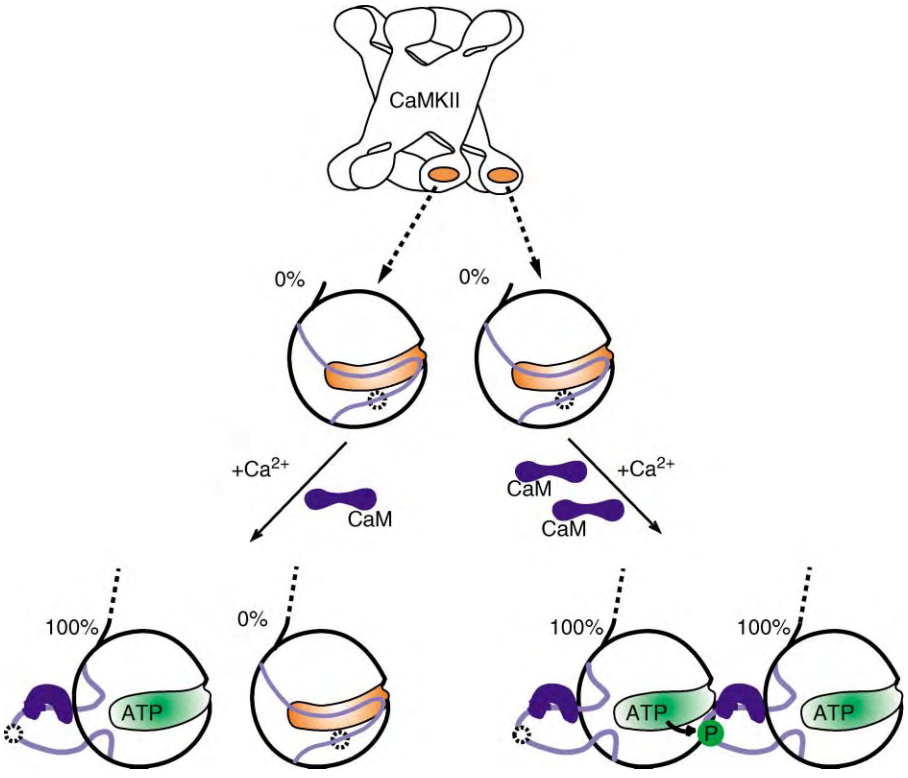

FIGURE 3 Autophosphorylation requires coincident Ca^{2+}/CaM binding between neighboring subunits within CaMKII. Catalytic/regulatory regions are depicted from subunits within the same holoenzyme (i.e., intraholoenzyme) and CaM is depicted as the purple dumbbell. Ca^{2+}/CaM binding displaces the autoinhibitory domain to activate subunits within the holoenzyme. Coincident binding of Ca^{2+}/CaM exposes the autonomy site (Thr^{286}), represented as a dashed circle, of one subunit for phosphorylation by an active neighboring subunit in an intersubunit reaction. Adapted with permission from *Annu. Rev. Biochem.* **71**, 473–510 by Annual Reviews.

autonomous activity, (b) an increase in the binding affinity of CaM (CaM trapping) and (c) exposure of a site on the catalytic domain that functions as a binding site to anchor CaMKII to its substrates.

Autonomous Activity

Autonomous activity (Ca^{2+}/CaM-independent activity) has intrigued neurobiologists and enzymologists since its discovery almost 20 years ago in the marine mollusc, *Aplysia californica* – a well-characterized animal model for studying the molecular mechanisms of learning and memory. Autonomous activity can be described as the "residual" activity attributed to an autophosphorylated subunit after CaM dissociation. At the structural level, the mechanism of autonomous activity is likely attributed to the negative charges associated with phospho-Thr^{286} preventing reassociation and inactivation of the catalytic domain by the autoregulatory domain following CaM dissociation.

CaM Trapping

Among the various CaM target proteins reported, CaMKII possesses a relatively low binding affinity for CaM (K_d 15 nM). However, following autophosphorylation, the CaM binding affinity is decreased by over a 1000-fold (K_d 20 pM), thus attaining one of the highest CaM binding affinities reported to date. The autophosphorylation of Thr^{286} is thought to indirectly produce CaM trapping, because a peptide designed from the Ca^{2+}/CaM binding domain of CaMKII (290–309) possesses high affinity Ca^{2+}/CaM binding, even though Thr^{286} is not contained within the peptide sequence (see Figure 2). This is mechanistically consistent with steric constraints or an inaccessibility of the binding site for Ca^{2+}/CaM in the nonautophosphorylated state. In support of the peptide binding studies, mutant cycle analysis studies designed to delineate the amino acid contacts responsible for high affinity binding between CaM and CaMKII supports a model for CaM trapping whereby Thr^{286} autophosphorylation exposes amino acids (Phe^{293} and Arg^{294}) within the N-terminal part of the CaM target sequence to thermodynamically stabilize and expose the target sequence for optimal Ca^{2+}/CaM binding.

Substrate Anchoring

The subcellular targeting of multifunctional kinases (e.g., CaMKII, cAMP-dependent protein kinase, and protein kinase C), is thought to be an integral component in generating the kinetics of the phosphorylation reaction and substrate specificity. Ca^{2+}/CaM binding and autophosphorylation of Thr^{286} exposes a binding site on CaMKII to permit anchor proteins and substrates to directly associate with the enzyme. Protein targeting may also afford new modes of regulation for CaMKII. For example, CaMKII targeting to the NR2B subunit of the NMDA-type glutamate receptor requires Ca^{2+}/CaM to induce binding. However, once the interaction is formed, the enzyme is active and remains bound *even* in the absence of Ca^{2+}/CaM and Thr^{286} autophosphorylation. Binding of the NR2B subunit to the catalytic domain may act as a wedge to prevent the autoregulatory domain from reforming its contacts subsequent to CaM dissociation.

Autophosphorylation at Thr^{305}/Thr^{306}

Ca^{2+}/CaM-independent autophosphorylation occurs at amino acids Thr^{305}/Thr^{306} with the CaM binding domain. Often referred to as inhibitory or "burst" autophosphorylation, Ca^{2+}/CaM-independent autophosphorylation is initiated once Ca^{2+}/CaM dissociates from a kinase phosphorylated at Thr^{286}. Autophosphorylation within the CaM binding domain (Thr^{305} or Thr^{306}) disrupts CaM from rebinding to this subunit. Autophosphorylation in the Ca^{2+}/CaM binding domain has also been reported in the basal state (autoinhibited), a process that appears to occur by an intrasubunit mechanism and is likely a result of this regions proximity to the substrate binding pocket on the catalytic domain. Basal autophosphorylation preferentially occurs at Thr^{306}, and like burst autophosphorylation, it functions to block Ca^{2+}/CaM binding.

Autophosphorylation as an Index of Neuronal Activity

In neurons, like in other excitable cells, Ca^{2+} signaling is a balance between homeostatic mechanisms (e.g., Ca^{2+} binding proteins and membrane extrusion pumps) designed to maintain and buffer the intracellular free Ca^{2+} concentration at roughly 20,000-fold below extracellular levels and a transient rise in free Ca^{2+} induced by hormones, neurotransmitters, or other signaling molecules. Autonomous activity is a form of persistent activity that is temporarily uncoupled from Ca^{2+} signaling. In addition to possessing the capacity to potentiate its activity beyond the Ca^{2+} transient, CaMKII is also capable of translating the temporal dynamics (e.g., frequency) of Ca^{2+} signaling. Immobilized CaMKII subjected to Ca^{2+}/CaM pulsed at varying frequencies by a high pressure computer controlled valve assembly generates distinct graded levels of autonomous activity *in vitro*. Two factors identified in computer simulations as key for frequency decoding are the effective cooperativity in the Thr^{286} autophosphorylation reaction and the availability of CaM for this reaction. In cells, CaM is thought to be largely bound to a variety of cellular proteins and presumably not available to maximally activate all of its targets. CaMKII

activation and autophosphorylation are particularly sensitive to limiting CaM levels as its relatively high affinity for CaM would predict that a transient rise in Ca^{2+} would lead to only a few of the subunits in each holoenzyme being activated (Figure 4). Under these conditions, a minority of activated subunits would actually undergo Thr^{286} autophosphorylation and trap CaM due to the requirement of coincident CaM binding for the autophosphorylation reaction. Higher Ca^{2+} spike frequencies produce shorter Ca^{2+} spike intervals that increase the CaM remaining associated between Ca^{2+} transients and the probability of autophosphorylation. Because autophosphorylation further prolongs CaM association, a feed-forward process ensues at a threshold level of autophosphorylation to produce the nonlinear Ca^{2+} spike frequency function for CaMKII activation/autophosphorylation illustrated in Figure 4. The frequency response function of CaMKII could also be influenced by autophosphorylation within the CaM binding domain, because inhibitory autophosphorylation could function to limit activated/autonomous subunits from subsequently competing with nonactivated subunits for the available free CaM.

CaMKII in LTP and Learning and Memory

Neuronal information in the brain is propagated and encoded through synaptic activity and multiple lines of evidence indicate that CaMKII is necessary and sufficient to induce long-lasting changes in synaptic efficacy, such as long-term potentiation (LTP). LTP is a long-lasting enhancement in the strength of neurotransmission that is believed to represent a cellular correlate of learning. Synaptic stimulation protocols that produce LTP in the hippocampus also produce long-lasting changes in the activation and autophosphorylation of CaMKII. Importantly, peptide inhibitors of CaMKII are potent inhibitors of LTP induction and viral introduction of a

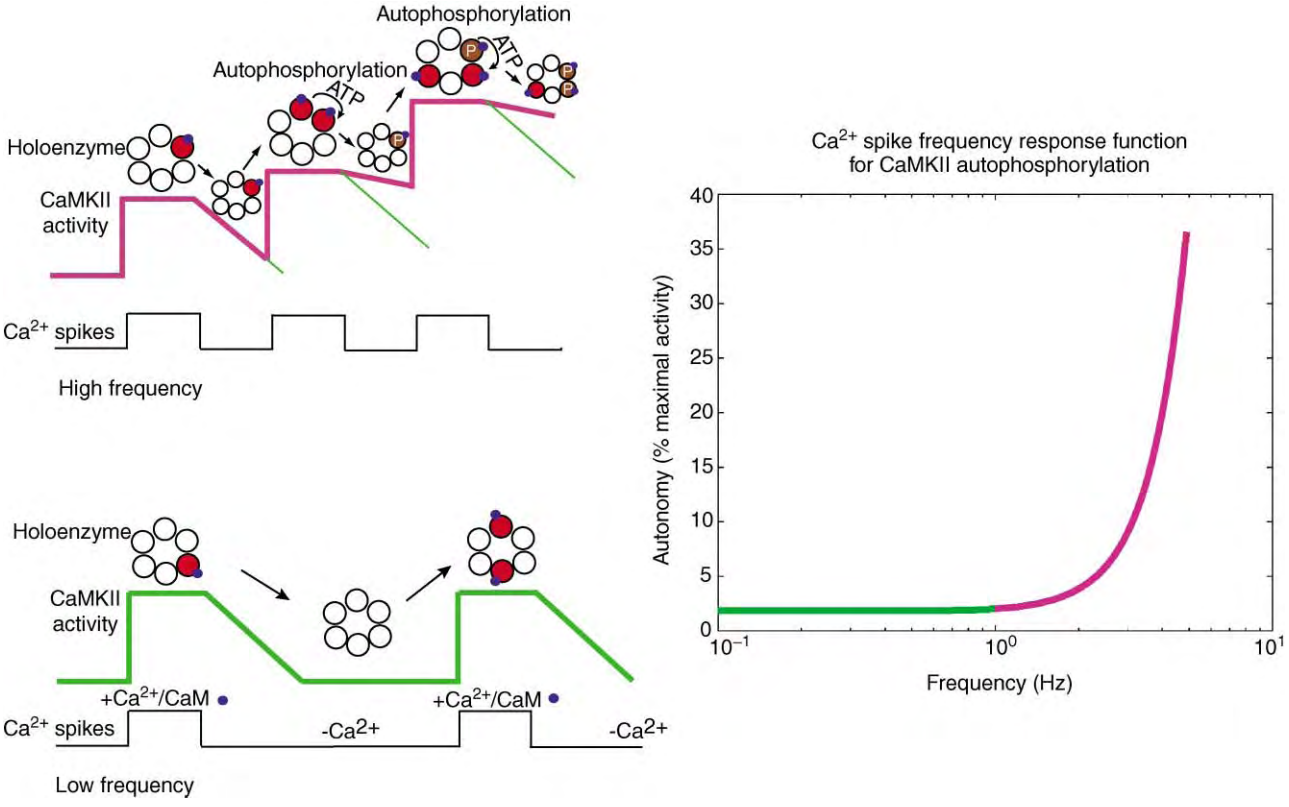

FIGURE 4 (Left) The role of coincident CaM binding, autophosphorylation, and CaM trapping in Ca^{2+} spike frequency detection. Inactive subunits within CaMKII (holoenzymes are shown as 6 mers for simplicity) are represented by open circles. Ca^{2+}/CaM (blue circle) binding activates a given subunit (shown in red) and coincident Ca^{2+}/CaM binding results in autophosphorylation and CaM trapping ("P" inside a filled dark red circle). During low frequency Ca^{2+} spikes, CaM completely dissociates between Ca^{2+} spikes, effectively producing "naïve" CaMKII subunits at each inner spike interval. However, at high Ca^{2+} spike frequencies, CaM does not completely dissociate between Ca^{2+} spikes; this increases the probability that coincident CaM binding, autophosphorylation, and CaM trapping may occur – a process that effectively increases the probability that a neighboring subunit will also bind Ca^{2+}/CaM during successive spikes to produce the nonlinear increase in autonomous activity illustrated by a computer simulation encompassing the biophysical and enzymatic characteristics of CaMKII (Right). Adapted with permission from *Biochem. J.* **364**, 593–611 © the Biochemical Society.

constitutively active form of CaMKII occludes LTP generated by the high frequency stimulation protocols typically used to induce LTP. In addition to being implicated in synaptic plasticity, the activity and autophosphorylation of CaMKII are also important for learning and memory.

In the field of neuroscience as in other areas of biology, genetic approaches in flies, worms, and mice have greatly advanced our understanding of the molecular mechanisms involved in behavior and learning. Although we will focus on the role of CaMKII in mammalian learning, disrupting the activity of CaMKII induces behavioral or cognitive defects in *all* of these organisms. The genetic deletion in the α-isoform of CaMKII was a pioneering study aimed at understanding the role of CaMKII in mammalian learning and memory. These CaMKII knockout mice displayed deficits in hippocampal LTP and possessed severe learning impairments in spatial learning tasks, such as the Morris Water Maze. These knockout mice directly implicated CaMKII and hippocampal LTP in mammalian learning and memory.

The use of knockin genetics permitted researchers to introduce mutant forms of CaMKII into both wild-type and knockout mice. This technology permitting further dissection of the role of CaMKII in learning, as mutant mice could be created that had altered autoregulatory properties without ablating kinase activity. A knockin mouse in which Thr^{286} (α-isoform) was mutated to Ala^{286} to prevent autophosphorylation displayed deficient LTP and spatial learning, directly implicating Thr^{286} autophosphorylation in synaptic plasticity and learning. Recent knockin technology has also permitted temporal control of transgene expression with inducible promoters. In experiments with a transgenic mouse in which Thr^{286} was replaced with a charged residue (e.g., Asp^{286}) in order to mimic an autophosphorylated state of the enzyme, enhanced LTP at low levels of transgene expression and deficient LTP at higher levels occurred, suggesting complex interactions between the level of activated CaMKII and its function in regulating synaptic strength. Autophosphorylation within the CaM-binding domain (Thr^{305}/Thr^{306}) has also been implicated in regulating CaMKII targeting and function. Knockin mice that cannot undergo inhibitory autophosphorylation (Ala^{305}/Ala^{306}) have increased levels of CaMKII in the PSD and a lower threshold for LTP. Mimicking inhibitory autophosphorylation (Asp^{305}/Asp^{306}) lowers the CaMKII content in the PSD and blocks LTP induction and hippocampal learning. Finally, in addition to CaMKII autophosphoryation regulating synaptic plasticity and behavior, a knockin mouse with an intact coding region for α-CaMKII yet possessing an altered mRNA targeting was created. Disrupting mRNA localization into dendrites was found to impair LTP and learning, suggesting that local translation and delivery of CaMKII to its site of action at the synapse is important for synaptic plasticity learning.

The Tao of Neuronal CaMKII

The function of CaMKII in synaptic plasticity and learning and memory appears to be tightly linked to its unique structure and autoregulation. The multimeric structure of CaMKII permits different isoforms to associate into a macromolecular signaling complex to provide specific targeting information essential for its subcellular localization as well as an intersubunit autophosphorylation reaction. Key autoregulatory features following autophosphorylation include the ability to (1) reduce its Ca^{2+}/CaM dependence following dissociation of CaM (autonomous activity), (2) increase its affinity for Ca^{2+}/CaM by over 1000-fold (CaM trapping), (3) enable activity-dependent substrate targeting, and (4) enable it to function as a Ca^{2+} spike frequency detector. Thus, the designation of a kinase as a cognitive kinase (i.e., based on its requirement in learning and memory) possesses a double meaning for CaMKII. Because of this enzyme's complex autoregulation and autophosphorylation, CaMKII activity may directly function as a molecular representation of synaptic activity: a molecular memory that is expressed as a persistent form of activity temporarily uncoupled from the Ca^{2+} stimulus. Thus, the role of CaMKII in transducing synaptic activity into the complex neuronal changes associated with learning appears to be an intimate dance between its autoregulation and its capacity to phosphorylate key protein substrates integral to neuronal function.

Glossary

Ca^{2+} transient A temporary rise in the intracellular levels of free Ca^{2+} ($\approx$100 nM to 1 μM) induced by a variety of extracellular signals (hormones, neurotransmitters, and depolarization) that may vary in its localization, duration, frequency, and amplitude.

hippocampus Part of the limbic system of the brain that is involved in spatial learning; because of its laminar architecture, it is routinely used for electrophysiological studies designed to evaluate synaptic connectivity and plasticity.

long-term potentiation A long-lasting increase in synaptic strength that could function to strengthen synaptic connectivity; it is considered to represent a cellular correlate of learning and memory.

Morris water maze An apparatus that is routinely used to assess spatial learning and memory in rodents. In this task, a mouse is placed in a large tub of an opaque liquid and assayed both for its ability to find a visible platform as well as a submerged

platform – tasks that evaluate the general function and ability to learn the task as well as its spatial learning, respectively.

pre- and postsynaptic elements of neurons Components of typical neuronal synapse: the presynaptic terminal releases neurotransmitter that diffuses across a synaptic cleft to bind and activate ligand-gated channels along the postsynaptic specialization.

pseudosubstrate A component of the autoregulatory domain that binds to the substrate binding pocket on the catalytic domain to prevent kinase activity in the absence of calmodulin.

Biography

Andy Hudmon is currently a research scientist at the PVA-EPVA Center for Neuroscience and Regeneration Research in the Department of Neurology at Yale University where he is studying the calcium-dependent regulation of voltage gated sodium channels in models of pain and spinal cord trauma. As a postdoctoral fellow in the laboratory of Dr. Howard Schulman at Stanford University, he studied the targeting and function of the multi-functional Ca^{2+}-calmodulin-dependent protein kinase II in regulating voltage-gated calcium channels in the heart and nervous system. He received his M.S. in physiology at Auburn University in the laboratory of Dr. Jim Sartin, and he holds a Ph.D. from the University of Texas Health Science Center at Houston, where he trained in the laboratory of Dr. Neal Waxham.

Howard Schulman is a Professor in the Department of Neurobiology at Stanford University and currently is Vice President of research at Surromed (MountainView, CA). His principle research interest is in how the structure/regulation of protein kinases decode and translate the calcium signal during neuronal function and plasticity. He holds a Ph.D from Harvard University, where he trained under Dr. Eugene Kennedy. Dr. Schulman received his postdoctoral training in the laboratory of Dr. Paul Greengard at Yale University.

Calcium/Calmodulin-Dependent Protein Kinases

J. Robison and Roger J. Colbran
Vanderbilt University, Nashville, Tennessee, USA

The Ca^{2+}/calmodulin-dependent protein kinase (CaMK) enzyme family is activated by increases in intracellular calcium ions (Ca^{2+}) and transfers phosphates from ATP to specific serine or threonine residues in other proteins. Family members vary in expression level, subcellular location, and substrate specificity. They are essential for signal transduction in all cells and modulate a variety of physiological processes including learning and memory, metabolism, gene transcription, and motor function.

Ca^{2+} Signaling

Modulation of the concentration of Ca^{2+} is used as an intracellular signal to allow hormones and neurotransmitters to control numerous processes in virtually all cell types. In general, cells have a resting Ca^{2+} concentration of 50–100 n*M*, but this concentration can "spike" above 1 μ*M* in an activated cell. Interestingly, these changes in Ca^{2+} concentration can activate extremely disparate signaling cascades not only in different cell types but also in different areas of the same cell. For instance, Ca^{2+} elevation in the nucleus of a neuron activates gene transcription, whereas a similar elevation at the synapse causes neurotransmitter release. These responses are possible because of the hundreds of different molecules that are directly or indirectly responsive to Ca^{2+}, the numerous mechanisms for increasing Ca^{2+}, and the variation in duration, frequency, amplitude, and localization of Ca^{2+} spikes. Ca^{2+} can enter the cell through channels in the membrane or be released from internal stores. The resulting Ca^{2+} spikes can occur on the millisecond level in neurons or be separated by days in the mitotic cell and modulate diverse enzymes and/or alterations in the shape of structural molecules. Many of the intracellular effects of Ca^{2+} are mediated by calmodulin, a small protein that undergoes dramatic conformational changes when bound to Ca^{2+} ions. Among the many enzymes activated by Ca^{2+}/calmodulin (Figure 1), members of the CaMK family mediate diverse physiological responses in most, if not all, cell types.

Protein kinases are enzymes that catalyze the addition of phosphates onto specific residues in target proteins, thereby regulating them in some way. Substrate proteins include other enzymes, gene transcription factors, scaffolding proteins, receptors, and many other cellular proteins. Thus, kinases can regulate such diverse cellular events as intercellular signaling, cell motility and shape, cell cycle, metabolic pathways, and gene transcription. In addition, kinases themselves may be regulated by intracellular signals, including Ca^{2+} acting via calmodulin. Most cells contain multiple representatives from the diverse family of CaMKs (Figure 2). Generally, CaMKs contain an autoinhibitory domain (AID) that interferes with catalysis by blocking or disrupting the catalytic site. This inhibition is relieved by the binding of Ca^{2+}/calmodulin to a domain that overlaps the AID (Figure 2), thus activating the kinase.

CaMKs phosphorylate specific serine or threonine residues in substrate proteins based in part on the surrounding amino acid sequence. Each of the kinases favors target serines or threonines in specific consensus sequences, although their substrate specificities can overlap. For instance, Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) and Ca^{2+}/calmodulin-dependent protein kinase IV (CaMKIV) recognize the consensus sequences Hyd-X-Arg-NB-X-Ser/Thr-Hyd and Hyd-X-Arg-X-X-Ser/Thr-X (where Hyd is a hydrophobic residue, NB is a nonbasic residue, and X is any residue), respectively; however, some peptide substrates that fit both of these sequences are phosphorylated by the two kinases with similar affinity. In addition, the catalytic domains of most CaMKs contain acidic residues that are important for interaction with the basic residues in their specific substrates (exceptions are noted below). Based on their substrate specificity, CaMKs can be divided into two general groups: those with narrow substrate specificity and those with broad substrate specificity.

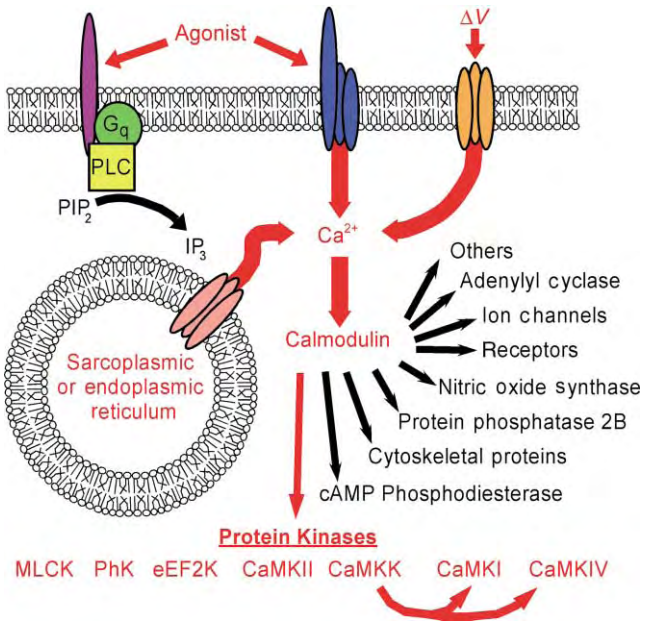

FIGURE 1 Modulation and effects of intracellular Ca^{2+}. Ca^{2+} enters cells via ligand-gated (blue) or voltage-gated (orange) Ca^{2+} channels in the plasma membrane or can be released from sarcoplasmic or endoplasmic reticulum stores via inositol 1,4,5-triphosphate (IP_3 (pink)) receptors and/or ryanodine receptors (not shown). IP_3 is generated from phosphatidyl-inositol 4,5-bisphosphate (PIP_2) by phospholipase C (PLC), which is activated by ligand binding to specific G_q protein coupled receptors (magenta) in the plasma membrane. Cytosolic Ca^{2+} is rapidly extruded from the cell or taken up by the intracellular stores (not shown). The combined actions of these pathways result in spatially localized and transient changes in intracellular Ca^{2+}. The ubiquitous Ca^{2+}-binding protein calmodulin senses the changes in Ca^{2+} and mediates the activation of multiple intracellular enzymes and other processes, including the family of CaMKs.

Narrow-Specificity Ca^{2+}/Calmodulin-Dependent Protein Kinases

Myosin Light Chain Kinase

Myosin is the only known *in vivo* substrate of myosin light chain kinase (MLCK), which is found in all vertebrate muscle cells and many nonmuscle tissues. Distinct genes encode two MLCK isoforms. Skeletal muscle MLCK (SkMLCK) is found only in skeletal muscle and contains a catalytic core, an AID, a calmodulin-binding domain, and a short N-terminal extension. The smooth muscle MLCK (SmMLCK), which is expressed in multiple tissues, also contains an actin-binding domain, a fibronectin domain, a PEVK repeat, and a number of immunoglobulin domains that can be varied by alternative splicing. MLCK is normally activated by Ca^{2+} release from the sarcoplasmic reticulum (SR) or endoplasmic reticulum and phosphorylates the regulatory light chain of the molecular motor myosin II, which is sufficient to initiate contraction in smooth muscle or to potentiate the force and speed of contraction in skeletal muscle. Although both forms of MLCK are tightly regulated by calmodulin binding, SmMLCK can be further regulated by phosphorylation. Many kinases, including CaMKII, cyclic AMP-dependent protein kinase (PKA), cyclic GMP-dependent protein kinase, p21-activated kinase, and protein kinase C, can phosphorylate SmMLCK *in vitro* at two serine residues in the calmodulin-binding domain and thus decrease the affinity for calmodulin. In addition,

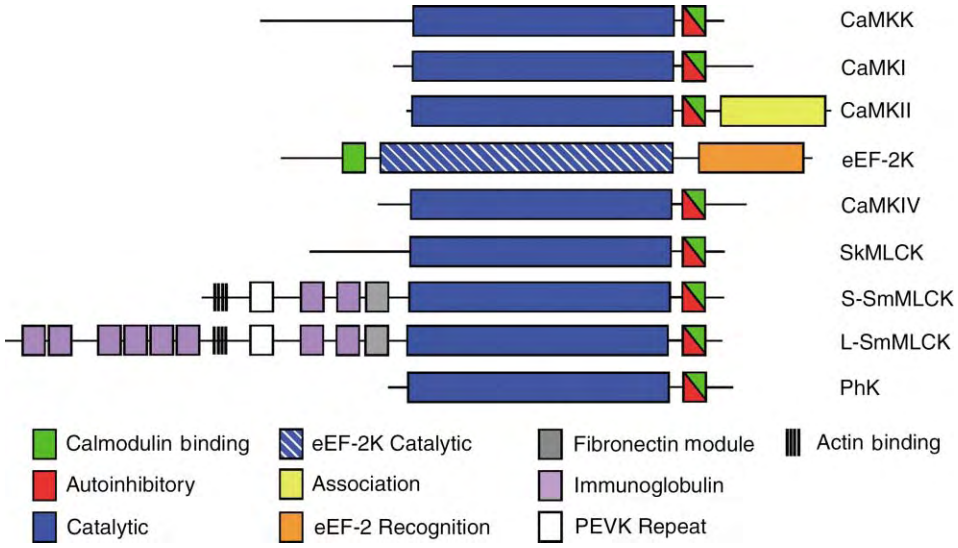

FIGURE 2 Schematic representation of CaMK domain structures. The key depicts various domains. The kinase domain of eEF-2K, formerly known as CaMKIII, bears no homology to those of the other CaMKs and thus is represented with white hatching. Most family members have multiple isoforms (not shown). Modified from Soderling, T. R., and Stull, J. T. (2001). Structure and regulation of calcium/calmodulin-dependent protein kinases. *Chem. Rev.* **101**, 2341–2351.

two sites outside the catalytic and regulatory regions of SmMLCK can be phosphorylated by members of the mitogen-activated protein kinase family, resulting in an increase in V_{max} but no change in K_{CaM}. SmMLCK, but not SkMLCK, is targeted to actin/myosin filaments through interaction with actin subunits.

Phosphorylase Kinase

Phosphorylase kinase (PhK) phosphorylates and activates glycogen phosphorylase, thus accelerating glycogen degradation. Splice variations and gene duplications result in multiple isoforms, many of which are tissue-specific. Isoforms of PhK are found in muscle, brain, heart, liver, intestines, and many other cell types. The highly abundant liver and muscle enzymes contribute to blood-glucose homeostasis and provide an energy source to facilitate muscle contraction, respectively. Four catalytic γ-subunits form a 1.3 mDa holoenzyme complex with α, β, and δ regulatory subunits, each of which is present at four copies per holoenzyme. The three regulatory subunits inhibit the phosphotransferase activity of the catalytic subunit. The δ-subunit is in fact calmodulin, which, unusually, is stably associated with the holoenzyme even at low Ca^{2+} concentrations. Ca^{2+} binding to δ partially activates PhK and phosphorylation of the α- and β-subunits by PKA potentiates activation. Binding of additional Ca^{2+}/calmodulin molecules, or Ca^{2+}-bound troponin C, to the holoenzyme maximally activates PhK. PhK associates with a protein termed PTG (protein targeted to glycogen) in muscle, which may facilitate phosphorylation of glycogen phosphorylase *b*, which is also associated with glycogen. PhK also interacts with other proteins in a tissue-specific manner, such as tubulin in rat brain lysates, and is found in membrane preparations from various tissue types.

Eukaryotic Elongation Factor 2 Kinase

The ubiquitous 90 kDa eukaryotic elongation factor 2 kinase (eEF-2K), also known as CaMKIII, phosphorylates Thr-56 in eEF-2, a protein elongation factor that promotes ribosomal translocation along mRNA during translation. Since eEF-2 is inactivated by this phosphorylation, eEF-2K was initially proposed as a link to reduced global protein synthesis following Ca^{2+} elevation. The eEF-2K contains a calmodulin-binding domain and an eEF-2 recognition domain. However, the catalytic domain of eEF-2K bears no homology to conventional kinases and is a member of the α-kinase family. Regulation of eEF-2K is both subtle and complex. In the presence of Ca^{2+} and calmodulin, autophosphorylation of eEF-2K occurs at several serine residues and confers a partially Ca^{2+}-independent activity. In addition, phosphorylation by a variety of kinases *in vitro* can both up- and down-regulate eEF-2K activity. Phosphorylation by PKA confers Ca^{2+} independence. Thus, stimulation of β-adrenergic receptors and subsequent cyclic AMP elevation causes eEF-2K activation and inhibition of protein synthesis in cultured mammalian cells. In addition, studies suggest that slight drops in cellular pH (such as those caused by hypoxia and ischemia) cause activation of eEF-2K. In combination, these data suggest that this kinase may not be a simple, direct link between Ca^{2+} and translation, but rather may function to integrate multiple intracellular signals.

Broad-Specificity Ca^{2+}/Calmodulin-Dependent Protein Kinases

Ca^{2+}/Calmodulin-Dependent Protein Kinase I

Ca^{2+}/Calmodulin-dependent protein kinase I (CaMKI) is a ubiquitous cytoplasmic enzyme enriched in brain, liver, and intestine. Three isoforms of the kinase, α, β, and γ, have been reported and are products of separate genes, each of which may be alternately spliced. CaMKI is an approximately 42 kDa monomer and its catalytic domain shows sequence and structural homologies with those of other serine/threonine kinases. A kinase originally termed CaMKV has been shown to be a splice variant of CaMKI. Goldberg *et al*. crystallized CaMKI, demonstrating that the AID binds and distorts the ATP-binding pocket in the basal state. Binding of Ca^{2+}/calmodulin presumably disrupts these interactions. This is the only known structure of a CaMK. A threonine residue in the catalytic domain (activation loop) of CaMKI is then phosphorylated by an upstream kinase, Ca^{2+}/calmodulin-dependent protein kinase kinase (CaMKK), resulting in a 10- to 20-fold increase in CaMKI catalytic activity without conferring Ca^{2+}/calmodulin independence. However, this phosphorylation can occur only when both CaMKK and CaMKI are bound by Ca^{2+}/calmodulin, perhaps permitting synergism in kinase activation. CaMKI phosphorylates synapsin I and cAMP Response Element Binding protein (CREB) *in vitro* and expression of truncated forms of CaMKI activates CREB-dependent gene transcription. However, the physiological substrates and roles of CaMKI remain elusive.

Ca^{2+}/Calmodulin-Dependent Protein Kinase II

CaMKII is a ubiquitous kinase that has been implicated in the regulation of diverse physiological processes, such

as gene transcription, neuronal plasticity, exocytosis, and metabolism. Four separate genes encode the α-, β-, γ-, and δ-isoforms of CaMKII. Each isoform is subjected to alternative mRNA splicing, resulting in over 20 known variants of the kinase, many of which have specific cellular and tissue distributions. In addition to catalytic, AID, and calmodulin-binding domains, most CaMKII isoforms contain a C-terminal association domain that facilitates the formation of a holoenzyme structure. The α-isoform forms a double hexameric ring-shaped holoenzyme and other isoforms appear to form similar multimeric holoenzymes, which may contain multiple isoforms or splice variants. The holoenzyme structure of CaMKII facilitates complex regulatory properties. Each subunit is independently activated by Ca^{2+}/calmodulin binding. When adjacent subunits in a holoenzyme bind Ca^{2+}/calmodulin, there is a trans-autophosphorylation at Thr-286, resulting in Ca^{2+} independence and also a 1000-fold increase in affinity for calmodulin. The kinase can be inactivated only by the actions of cellular protein phosphatases. Additional autophosphorylation at Thr-305 and Thr-306 in the calmodulin-binding domain occurs in the absence of Ca^{2+}/calmodulin. Thr-305/Thr-306 phosphorylation interferes with calmodulin binding, blocking Ca^{2+}/ calmodulin-dependent activation.

The number of subunits in a holoenzyme that become active and autophosphorylated at Thr-286 is directly related to the Ca^{2+} concentration. Thus, CaMKII is able to "decode" the frequency and amplitude of Ca^{2+} spikes. This unique capacity has been proposed to play an important role in prolonged signaling after transient changes in Ca^{2+}, such as may be involved in learning and memory. Consistent with this idea, transgenic mice in which the CaMKIIα gene has been mutated such that the kinase cannot autophosphorylate at Thr-286 are deficient in spatial learning tasks.

CaMKII can be found in the cytosol, in the nucleus, and associated with various organelles or membranes, depending on the cell type examined. The identity of CaMKII splice variants expressed is believed to play a role in modulating subcellular localization, although few specific examples have been documented. For example, one variant of CaMKIIδ contains a nuclear localization sequence and has been shown to regulate gene transcription in cardiac myocytes. Variable subcellular localization can also be attributed in part to the large number of proteins with which CaMKII may associate, including several neuronal proteins (e.g., *N*-methyl-D-aspartate (NMDA) receptor, α-actinin, synapsin I, and densin-180) and contractile/motor proteins (e.g., actin and myosin V). Binding of CaMKII to these proteins may position the kinase close to Ca^{2+} sources, and/or close to specific substrates, and may modulate its availability to cellular phosphatases, thereby affecting the rate of inactivation. One splice variant of the CaMKIIα gene (αKAP) functions as a CaMKII anchoring protein. αKAP lacks a catalytic domain but forms hetero-multimers with the conventional isoforms through an intact association domain and associates with the SR in muscle via an N-terminal hydrophobic region.

At last count, CaMKII phosphorylates at least 50 distinct proteins *in vitro* and many of these are likely to be physiologically relevant. However, relatively few of these have been formally shown to be phosphorylated in intact cells under physiologically relevant conditions. One of the best characterized substrates is the neuronal L-alpha-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA)-type glutamate receptor; phosphorylation of this receptor at Ser-831 by CaMKII plays an important role in the regulation of synaptic transmission. In neuronal presynaptic terminals, phosphorylation of synapsin 1 by CaMKII modulates synaptic vesicle movement. In the heart, CaMKII plays a critical role in feedback regulation of Ca^{2+} dynamics by regulating Ca^{2+} entry via L-type voltage-gated Ca^{2+} channels, by phosphorylating ryanodine receptors to regulate SR Ca^{2+} release, and by phosphorylating phospholamban at Thr-17, thereby regulating SR Ca^{2+} uptake via the Ca^{2+}-ATPase.

Ca^{2+}/Calmodulin-Dependent Protein Kinase IV

αCaMKIV is a monomeric kinase expressed largely in neuronal tissues, testes, and T cells, whereas the βCaMKIV splice variant is differentially expressed in the cerebellum during development. Like CaMKI, CaMKIV is initially activated by calmodulin binding and is further activated when phosphorylated by CaMKK in its activation loop. However, combined with a subsequent N-terminal autophosphorylation, the activation by CaMKK eventually leads to Ca^{2+}-independent activity of CaMKIV. An additional autophosphorylation at Ser-332 of the calmodulin-binding domain prevents further Ca^{2+}/calmodulin binding in a manner analogous to CaMKII autophosphorylation at Thr-305 and Thr-306. CaMKIV contains a nuclear localization sequence and it is thought to be responsible for Ca^{2+}-dependent phosphorylation of a variety of transcription factors (e.g., CREB, serum response factor, and myocyte enhancer factor 2 (MEF2)) and regulatory factors, such as the CREB-binding protein. In the cytosol, CaMKIV phosphorylates oncoprotein 18, preventing its association with tubulin. Protein phosphatase 2A (PP2A), a ubiquitous multimeric protein phosphatase, associates with and dephosphorylates CaMKIV, forming a

self-regulating complex that may be a prototype for phosphatase–kinase cross-talk in cell signaling.

Ca^{2+}/Calmodulin-Dependent Protein Kinase Kinase

CaMKK, originally characterized as an "activating factor" from brain extracts, can dramatically increase the activity of CaMKI and CaMKIV when incubated in the presence of Ca^{2+}/calmodulin, Mg^{2+}, and ATP. Two isoforms (α and β) of CaMKK have been cloned and their domain organization and function are similar to those of other Ca^{2+}/calmodulin-dependent kinases. However, CaMKK is unique in its method of substrate recognition, lacking acidic residues to recognize basic residues near its preferred phosphorylation sites. Instead, this kinase contains an arginine- and proline-rich (RP) insert that is important for phosphorylation of CaMKI and CaMKIV and Ca^{2+}/calmodulin must be bound to both CaMKK and the substrate (CaMKI or CaMKIV) for phosphorylation to occur. CaMKK also phosphorylates protein kinase B both *in vitro* and in cultured cells, although this does not require the RP domain. Regulation of CaMKK also occurs via other kinases, such as PKA, which phosphorylates CaMKK in its calmodulin-binding domain, resulting in the inhibition of Ca^{2+}/calmodulin-induced activity.

Summary

Repetitive transient changes in Ca^{2+} concentration in every mammalian cell are sensed by a number of different Ca^{2+}/calmodulin-dependent protein kinases. Although many of these kinases share a great deal of functional homology, there are diverse regulatory nuances. Moreover, some of these kinases phosphorylate a number of different substrates, whereas others have only one principal substrate. The specific response of individual cells to changes in intracellular Ca^{2+} concentration likely depends on the subset and specific isoforms of Ca^{2+}/calmodulin-dependent kinases expressed in that cell. For example, in hippocampal neurons, synaptic activity increases Ca^{2+} levels in dendritic regions. In the short term, dendritic Ca^{2+} locally activates CaMKII, which phosphorylates pre-existing synaptic glutamate receptors. However, over a longer time frame, Ca^{2+} signals the activation of nuclear CaMKIV and thus the transcription of specific genes. It is the

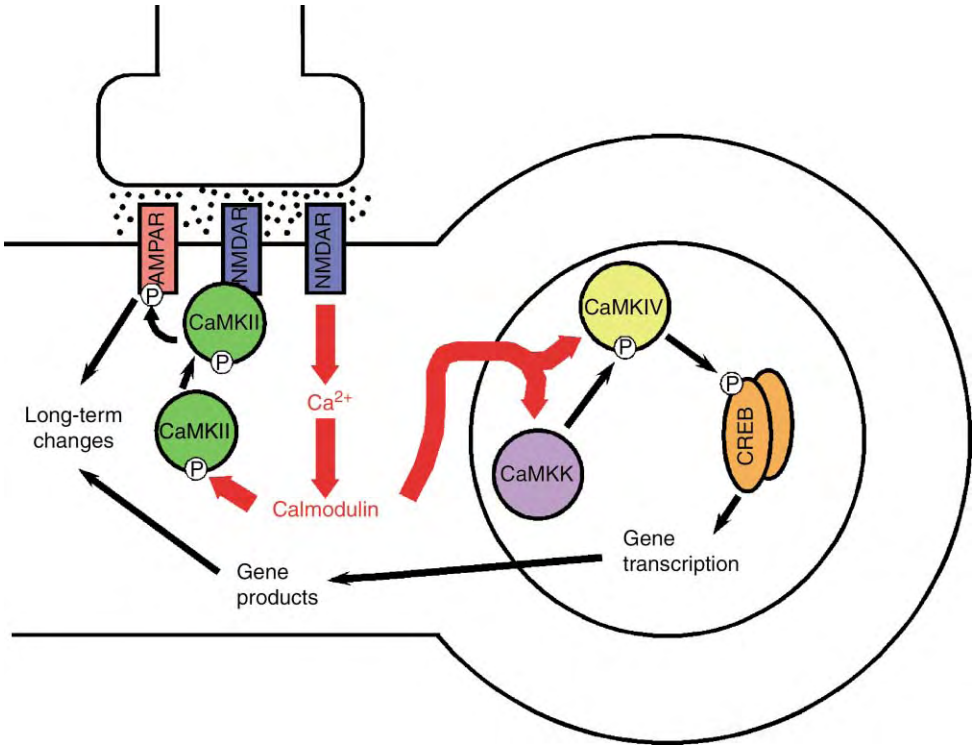

FIGURE 3 Modulation of neuronal function by activation of CaMKII and CaMKIV. Glutamate release from presynaptic terminals activates NMDA- (blue) and AMPA- (red) type glutamate receptors on the postsynaptic neuron. The NMDA receptor (NMDAR) is a ligand-gated Ca^{2+} channel. The elevated local intracellular Ca^{2+} in the dendrites activates CaMKII, which phosphorylates AMPA-type glutamate receptors, potentiating synaptic transmission. Ca^{2+} elevation via NMDA- and voltage-gated Ca^{2+} channels (not shown) also signals to the nucleus to activate CaMKK and CaMKIV, driving the transcription of specific genes. The dual CaMKII and CaMKIV signals combine to promote long-term changes in synaptic function. AMPAR, AMPA receptor.

combined actions of CaMKII and CaMKIV that result in long-lasting changes in the synaptic response of these neurons that may underlie learning and memory (Figure 3). However, much work remains to be performed in identifying substrates and physiological roles of the various Ca^{2+}/calmodulin-dependent protein kinases in other cells and tissues.

Glossary

autoinhibitory domain (AID) The region of a Ca^{2+}/calmodulin-dependent protein kinase that binds and inhibits the catalytic domain. Inhibition is relieved by interaction with calmodulin and in some cases is prevented by subsequent autophosphorylation.

calmodulin A small cytosolic protein that binds four Ca^{2+} ions and subsequently associates with and modulates many important proteins, including some protein kinases.

catalytic domain The region of an enzyme responsible for activity; in protein kinases, this domain transfers the γ-phosphate from ATP to the target residue.

protein kinase An enzyme that transfers the terminal (γ) phosphate from ATP to a serine, threonine, or tyrosine residue of a substrate protein.

protein phosphatase An enzyme that hydrolyzes a phosphate group from a serine, threonine, or tyrosine residue of a phosphoprotein substrate.

Biography

A. J. Robison is a graduate student in the Molecular Physiology and Biophysics Department at Vanderbilt University. He received a B.S. in biology with honors from Rhodes College in 1999. He is studying the subcellular anchoring of neuronal CaMKII in the laboratory of Dr. Roger Colbran.

Roger. J. Colbran is an Associate Professor of Molecular Physiology and Biophysics, a member of the Center for Molecular Neuroscience, and an Investigator at the John F. Kennedy Center for Research on Human Development at Vanderbilt University. He earned a Ph.D. from the University of Newcastle upon Tyne (United Kingdom) and received postdoctoral training at Vanderbilt University. His principal research interest is in understanding calcium-dependent signaling events in neurons, especially as this relates to the regulation of synaptic transmission, and in cardiomyocytes.

Calcium-Binding Proteins: Cytosolic (Annexins, Gelsolins, C_2-Domain Proteins)

Joachim Krebs
Swiss Federal Institute of Technology, Zurich, Switzerland

Calcium is one of the most common elements on Earth, and it is the fifth most abundant element of the human body. Inside cells, calcium is a very versatile second messenger involved in the regulation of a variety of different cellular processes. This pivotal role of calcium is made possible due to the binding of Ca^{2+} to a great variety of different calcium-binding proteins. Next to the well-studied family of the so-called EF-hand containing proteins, a number of other calcium-binding proteins became known in recent years. These proteins are composed of a number of repeat units containing a variety of different Ca^{2+}-binding sites. The families of annexins, gelsolins, and C_2-domain containing proteins described in this article bind to different membranous or cytoskeletal structures in a Ca^{2+}-dependent manner, and are involved in a number of different cellular functions.

Annexins

The family of intracellular Ca^{2+}-binding proteins called annexins is soluble, amphipathic proteins that bind to membranes containing negatively charged phospholipids in a Ca^{2+}-dependent manner. They are called annexins since they bring or hold together different cellular structures, in particular membranes. The close to 200 different annexin proteins known to date are widespread in the animal and plant kingdoms, and have been claimed to be involved in a variety of cellular functions such as interaction with the cytoskeleton, membrane fusion, anticoagulation, signal transduction, or phospholipase inhibition. The primary structure of the annexins contains four or eight (annexin VI) conserved repeat units of ~75 amino acids in length, the protein core, which are separated by intervening sequences of variable length. These repeat units probably originated from gene duplications, a view which is corroborated by the evolutionary conservation of the intron–exon boundary positions. Most annexins containing four repeat units are comprised of 12–15 exons resulting in a quite variable amino-terminal part of the different annexins. Most alternative splicing sites have been located within exons encoding the variable amino-terminal parts of annexins. Since these parts are also the locations containing motifs for binding partners or for post-translational modifications, thus alternative splicing may contribute to the regulation of annexin function.

After the first determination of an annexin crystal structure (annexin V) by Huber and his co-workers, a number of additional annexin structures from different sources (including those from lower eukaryotes and plants) have been reported. From these structures it can be concluded that the conserved repeat units are packed into an α-helical disk, as first described for annexin V, which is almost entirely α-helical. It consists of five α-helices bundled into a right-handed super-helix. On the basis of this structure it was proposed that annexin V functions as a calcium channel, and some experiments using an *in vitro* reconstituted system seem to support a voltage-gated mechanism. This property is connected with the structure of the annexin core, which is shared by most annexins. Meanwhile, for most annexins a Ca^{2+} channel activity has been demonstrated in artificial bilayer systems, but never *in vivo*; therefore, the physiological relevance of these observations is questionable.

In contrast to the EF-hand containing Ca^{2+}-binding proteins, the ligands coordinating calcium in the annexins are not adjacent in sequence. Several calcium-binding sites seem to exist in annexins, two invariably in repeats II and IV, one in either repeat I or III, but annexins may contain as many as 10–12 Ca^{2+}-binding sites along the membrane-binding surface of the protein. The sites with the highest Ca^{2+} affinity are structurally related to the Ca^{2+}- and phospholipid-binding site of phospholipase A_2. The calcium ion is heptacoordinated with ligands organized in a pentagonal bipyramidal arrangement with ligating oxygens provided mainly from peptide carbonyls and water molecules, together with a single side-chain oxygen from a distant part of the sequence. Replacement of this latter

"capping" residue, which is usually acidic, with alanine precludes Ca^{2+} binding at the site. Once bound to membranes, many annexins oligomerize to form highly ordered two-dimensional arrays that have been shown to strongly influence *in vitro* membrane properties, e.g., increased rigidity.

An interesting feature is the role of Trp185 in the Ca^{2+}-binding site of repeat III of annexin V (see Figure 1). As suggested by Seaton and others, a Ca^{2+}-dependent exposure of Trp185, which is buried within the protein core in the absence of calcium, may facilitate the interaction between annexin V and the phospholipid bilayer. This view has been supported by fluorescence data and by mutagenesis experiments in which replacement of Trp185 by alanine decreased the annexin V membrane-binding affinity.

Annexins have long been known as targets for post-translational modifications. In fact, annexin II was originally isolated as a major substrate of the *src*-encoded protein kinase, and annexin I was long known to be phosphorylated by the tyrosine kinase activity of the epidermal growth factor (EGF) receptor, suggesting that annexins I and II could be used as coupling factors between growth factor receptors and their cellular targets, since these phosphorylations alter the Ca^{2+}-dependent binding of annexin I and II to membranes. In addition to the phosphorylation by different tyrosine kinases, also serine/threonine kinases have been identified to phosphorylate annexins. As a result, annexin phosphorylation often leads to an altered susceptibility towards proteolysis. On the other hand, phosphorylation of annexin II by different kinases interferes with its ability to form stable heterotetrameric complexes with p11, a member of the S100 family (S100A10), since these phosphorylation sites are located – like in the other annexins – within the variable amino-terminal domain, which comprises also binding motifs to interact with other proteins. Due to the binding of p11 (S100A10) the Ca^{2+}-sensitivity of the complex is increased by 3 orders of magnitude, and enables the heterotetrameric complex to bind simultaneously to two different membrane surfaces through the two annexin II cores. Next to the interaction between annexin II and S100A10 (p11) two other complexes between an annexin and an EF-hand containing protein of the S100 family may exist, i.e., interactions between annexin XI and S100A6 and annexin I and S100A11, respectively, but in contrast to annexin II/S100A10 the existence of the latter complexes *in vivo* has not been described to date.

In spite of extended studies in many laboratories over the years, the precise function of individual annexins is not yet understood. The accumulated data suggest that due to the many ways that annexins interact with different membranes in a Ca^{2+}-dependent manner, annexins may participate in Ca^{2+} signaling as effectors, mediators or even as regulators, but to clarify their biological activities unambiguously, this has to await further experiments. However, *in vivo* experiments from knockout and transgenic mice are beginning to shed some light on annexin function.

Gelsolin

Gelsolin belongs to the superfamily of actin-binding proteins (ABPs) expressed in all eukaryotes. It is a multifunctional protein-binding actin in a Ca^{2+}-dependent

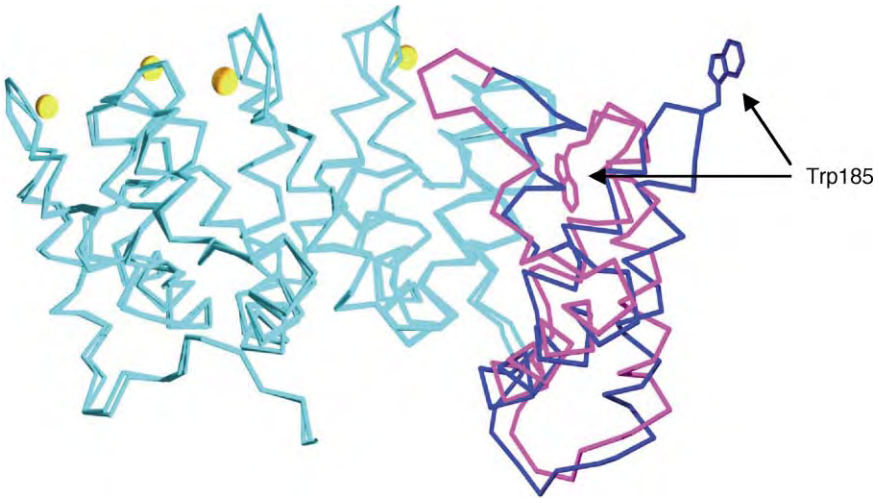

FIGURE 1 Superposition of α-carbon backbones of annexin V in the Ca^{2+}-free and the Ca^{2+}-bound form. Domains 1, 2, and 4 are light green, both in the Ca^{2+}-free and in the Ca^{2+}-bound form. Domain 3 is shown in magenta (Ca^{2+}-free, trp185 buried) and in blue (Ca^{2+}-bound, trp185 exposed). (Courtesy of Barbara Seaton.)

manner, and is composed of up to six repeats of 120–150 amino acids. To the gelsolin family belong proteins such as villin, adseverin, CapG, flil, and others. Villin, for example, is a six gelsolin-domain ABP regulating actin assembly in microvilli, whereas CapG is a smaller, three-domain gelsolin analogue that responds to Ca^{2+} and phosphatidylinositol-(4,5)-diphosphate under conditions where gelsolin is ineffective.

Alternative transcription initiation and selective RNA processing produces two isoforms of gelsolin from the same gene. One isoform of 80 kDa is located intracellular, whereas the other extracellular, slightly larger (83 kDa) protein is derived by alternative splicing, which results in a short amino-terminal elongation of the protein. The intracellular gelsolin is involved in cell motility regulating actin function, whereas extracellular gelsolin can act as an actin-scavenging system to prevent the polymerization of actin released after cell death.

Gelsolin consists of six repeat units (G1–6). The units are organized in two clusters of similar architecture, and are connected by a flexible linker of ~50 amino acids that may be cleaved by caspase-3, thereby cleaving the actin-binding domain of gelsolin from its calcium-binding domain. Caspase-3 cleavage and separation of subdomains of gelsolin coincides with plasma membrane blebbing, one of the characteristics of apoptosis. Apoptosis could also be induced by the overexpression of the amino-terminal half of gelsolin, whereas neutrophils of gelsolin-null mice have a delayed onset of apoptosis.

The structure of gelsolin in the absence of Ca^{2+} has been determined at 2.5Å resolution by Robinson and his co-workers (Figure 2). The amino-terminal half can bind to two actin monomers independent of calcium, whereas the carboxy-terminal half binds a single actin in a Ca^{2+}-dependent manner.

A detailed mechanism for the regulation of gelsolin activity by Ca^{2+} has recently been proposed. This was made possible by comparing the Ca^{2+}-free structure of nonactive gelsolin (Figure 2) with the recently solved structure of the active form of Ca^{2+}-bound gelsolin complexed to actin (see Figure 3). In this latter structure consisting of the C-terminal half of gelsolin, i.e., G4–6, bound to monomeric actin two classes of Ca^{2+}-binding sites have been identified: type-1 sites bind calcium in a coordination sphere shared by actin and gelsolin, whereas type-2 sites are identified only in gelsolin, i.e., located within G5 and G6. Due to conservation of the ligating residues within all gelsolin repeats, type-2 Ca^{2+}-binding sites should exist in all six domains of gelsolin. In total, gelsolin should be able to bind eight calcium ions in the active gelsolin–actin complex, i.e., two in type-1 sites and six in type 2.

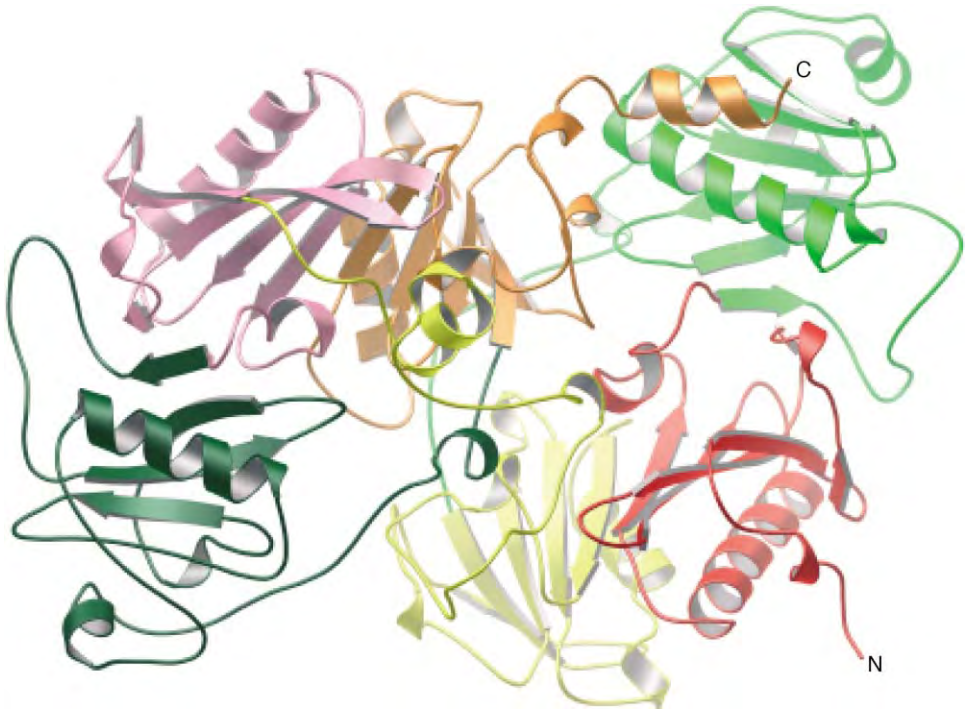

FIGURE 2 A ribbon diagram of the structure of gelsolin in the absence of calcium. The following color code for the different segments (G1–6) has been used: G1 (containing the amino terminus) red; G2, light green; G3, yellow; G4, magenta; G5, dark green; G6, (containing the carboxy terminus) gold. (Reproduced from Burtnick, L. D., Koepf, E. K., Grimes, J., Jones, E. Y., Stuart, D. I., McLaughlin, P. J., and Robinson, R. C. (1997). The crystal structure of plasma gelsolin: Implications for actin severing, capping and nucleation. *Cell* **90**, 661–670, with permission from Elsevier.)

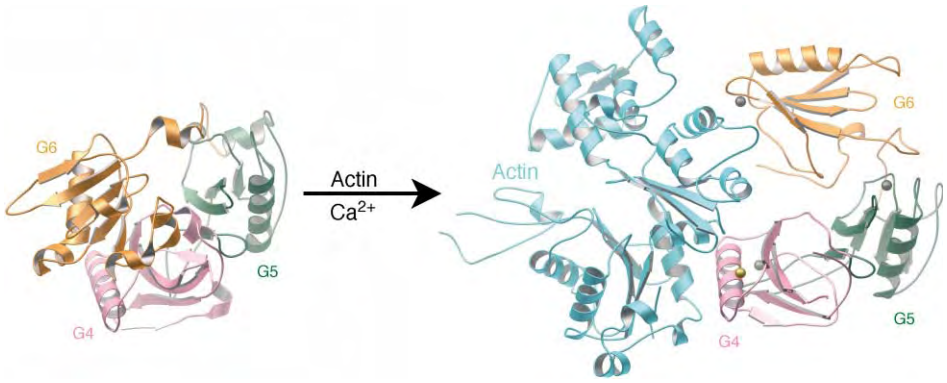

FIGURE 3 Ribbon diagram of gelsolin domains G4–G6 demonstrating the influence of binding Ca^{2+} and actin (shown in cyan) on the conformational changes of the protein. The same color code as in Figure 2 is used for domains G4–G6. The left-hand panel shows G4–G6 in a Ca^{2+}-free conformation (see Figure 2), whereas the right hand panel depicts the actin and Ca^{2+}-bound form of G4–6. (Reproduced from Choe, H., Burtnick, L. D., Mejillano, M., Yin, H. L., Robinson, R. C., and Choe, S. (2002). The calcium activation of gelsolin: Insights from the 3Å structure of the G4–G6/actin complex. *J. Mol. Biol.* **324**, 691–702, with permission from Elsevier.)

The latter are proposed to facilitate structural rearrangements within gelsolin as part of the activation and actin-binding process.

In the absence of Ca^{2+} the six repeat units of gelsolin provide a very compact globular structure, thus blocking the actin-binding helices of the appropriate sub-domains. Therefore, in a first step, this compact globular arrangement of the six sub-domains has to be opened up. As suggested by H. Choe and co-workers in 2002, binding of Ca^{2+} first to G6 should induce a conformational rearrangement in which G6 is flipped over G5 to tear apart the continuous β-sheet core of G4 and G6, thereby unmasking the actin-binding site on G4, and hence permit binding to actin strands (see Figure 3). Similar events should also occur in the N-terminal half of gelsolin, i.e., Ca^{2+}-binding to G3, flipping over G2 to open up the actin-binding site of G1. Finally, to tighten up the gelsolin–actin complex, Ca^{2+} binds to the two type-1 sites shared between actin and gelsolin, which might explain the very high affinity of gelsolin to actin (K_d 50 nM).

Gelsolin-null mice show normal embryonic development, but suffer subtle changes. This suggests the need of gelsolin for cell motility during processes such as hemostasis leading to reduced platelet function, inflammation leading to delayed neutrophil migration, or during wound healing, which would lead to reduced movement of fibroblasts. In this context it is interesting to note that it was demonstrated that during development of zebrafish embryos gelsolin is required for dorsoventral patterning. Inhibition of gelsolin expression that starts to be expressed already at the two-cell stage resulted in ventralized phenotypes, some of which lacked brain or eyes. These phenotypes could be rescued by injecting zebrafish gelsolin mRNA or even by injecting human gelsolin protein. These data indicate that gelsolin may have at least two separate functions: a structural role for the cytoskeletal/cell motility apparatus, and a regulatory role during development.

C_2-Domain Proteins

Interaction of proteins, intracellularly or extracellularly, often occurs via different binding modules or domains such as SH2, SH3, WW, PDZ, or C_2-domains. These modules are formed by folding domains consisting of 100–150 residues with different binding properties, that is, SH2-domains interact with phosphotyrosine-containing sequences, SH3- and WW-domains with proline-rich sequences, PDZ-domains with C-terminal sequences to link multiprotein complexes to the cytoskeleton, and C_2-domains with phospholipids, some in a Ca^{2+}-dependent, some in a Ca^{2+}-independent, manner. C_2-domains consist of about 120–130 amino acid residues. They were first identified in protein kinase C. More than 100 C_2-domain containing proteins can now be identified in current data banks.

Most proteins containing C_2-domains are linked either to signal transduction pathways or are involved in membrane traffic. The former proteins either generate lipid second messengers (e.g., phospholipase A2, phospholipase C, or phosphatidylinositol-3-kinase), phosphorylate proteins (e.g., protein kinase C), or ligate ubiquitin (e.g., Nedd4). Those proteins involved in membrane traffic include, for instance, the Rab-binding proteins rabphilin and RIM, which are involved in regulating the exocytosis of secretory vesicles. However, the best-characterized protein of

this category is synaptotagmin, which will be discussed in more detail.

Synaptotagmin I is a transmembrane protein belonging to a family of more than ten members which contain two C_2-domains, C_2A and C_2B, comprising most of the cytoplasmic region of synaptotagmins. The C_2-domains contain Ca^{2+}-binding domains of non-EF-hand character. Synaptotagmin I is found in synaptic vesicles, and is believed to act as the major Ca^{2+}-sensor of exocytosis and neurotransmitter release. Important in this respect is the Ca^{2+}-dependent binding of synaptotagmin to syntaxin, a member of the SNARE family of membrane proteins, involved in vesicle transport mechanisms.

C_2-domains have been suggested to be responsible for binding to membranes in response to Ca^{2+}. Sudhof and his co-workers determined the first structure of a C_2-domain, the C_2A-domain of synaptotagmin I (see Figure 4). The C_2-domain consists of a β-sandwich of two four-stranded β-sheets (Figure 4A). The eight β-strands are connected by three loops at the top that bind Ca^{2+} in the form of a cluster, primarily through oxygen of aspartate side chains serving as bidentate ligands, and by four loops at the bottom lacking

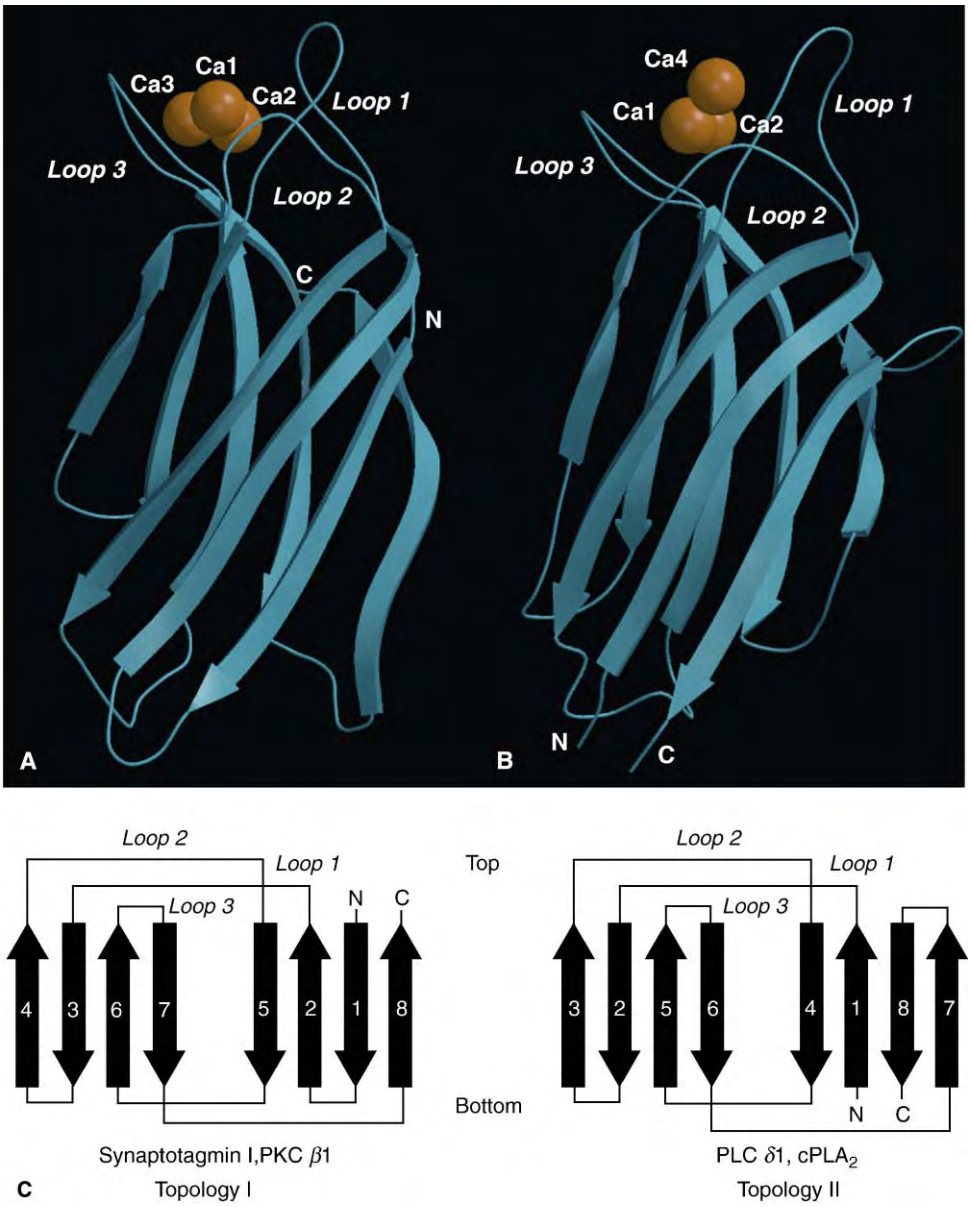

FIGURE 4 Ribbon diagrams of the structures of the C_2A-domain of synaptotagmin I (A) and of the C_2-domain of phospholipase Cδ1(B). (C) A schematic drawing of the β-strand topologies of the two structures. The locations of the Ca^{2+} clusters (orange) are indicated. (Reproduced from Rizo, J., and Südhof, T. C. (1998). C_2-domains, structure and function of a universal Ca^{2+}-binding domain. *J. Biol. Chem.* **273**, 15879–15882, with permission of the American Society for Biochemistry & Molecular Biology.)

Ca^{2+}-binding sites. In contrast to Ca^{2+}-binding to EF-hand type of sites, which causes substantial conformational changes, Ca^{2+}-binding to sites of C_2-domains leads to structural stabilization rather than backbone rearrangements.

Structural determination of other C_2-domains revealed similar designs, but significant differences in the topology of the arrangement of the β-strands (see Figure 4C). It could be shown that the structure of the C_2-domain of protein kinase Cβ is very similar to synaptotagmin I (topology I), whereas the topological arrangement of the structure of the C_2-domain of phospholipase Cδ is significantly different (topology II) (see Figure 4C). Phospholipase Cδ contains several protein modules including EF-hand Ca^{2+}-binding domains, which provides evidence for the existence of proteins containing EF-hand and non-EF-hand Ca^{2+}-binding sites.

An interesting finding concerning important functional differences between Ca^{2+}-binding sites of C_2A- and C_2B-domains of synaptotagmin has recently been reported. It has been shown that by mutating an aspartate essential for Ca^{2+}-binding to the C_2A-domain into an asparagine, this domain lost its Ca^{2+}-dependent binding to phospholipids or to syntaxin. However, introducing such a mutated synaptotagmin into the germline of *Drosophila* lacking synaptotagmin I that were severely impaired in neurotransmitter release, the mutated synaptotagmin I could fully rescue this defect, indicating that Ca^{2+}-binding to the C_2A-domain of synaptotagmin is not essential for neurotransmitter release. However, by replacing an aspartate for asparagine essential for Ca^{2+}-binding in the C_2B-domain, this mutated protein could not rescue such a defect in a similar set of experiments suggesting a significant functional difference in Ca^{2+}-binding between the C_2A- and C_2B-domains of synaptotagmin I.

In another C_2-domain containing protein, Nedd4, it was demonstrated that binding of Ca^{2+} to the C_2-domain was responsible not only for the localization of the protein but also for part of its function. Nedd4, the neuronal precursor cell-expressed developmentally down-regulated four protein, is a multimodular ubiquitin protein ligase. This enzyme is involved in controlling the turnover of membrane proteins. It was shown that localization of Nedd4 to the apical region of polarized epithelial cells was dependent on the Ca^{2+}-binding to its C_2-domain. Here an important target of Nedd4 is the Na^+-channel (ENaC), which plays a critical role in Na^+ homeostasis of epithelial cells. However, the C_2-domain of Nedd4 was not required to inhibit EnaC. On the other hand, it was shown that Nedd4 lacking its C_2-domain was still able to ligate ubiquitin to appropriate membrane protein targets such as Gap1, the general amino acid permease, but subsequent internalization by endocytosis, a prerequisite for the downregulation of membrane receptor proteins, was impaired.

Glossary

actin A eukaryotic protein that has the capability to form thin helical filaments.

alternative splicing Alternate usage of particular exons to create isoforms of a given protein.

amphipathic proteins Proteins composed of helices containing both hydrophobic and hydrophilic amino acid residues.

apoptosis Apoptosis (or programmed cell death) is derived from a Greek word describing the shedding of leaves from trees. During apoptosis, the cell responds to specific physiological or developmental signals undergoing a regulated, well-programmed series of events which will lead to its death and its removal from the organism.

cytoskeleton Complement of actin filaments, microtubules, and intermediate filaments forming a network in the cytoplasm.

EF-hand proteins Term coined by R.H. Kretsinger to describe the helix–loop–helix calcium-binding domains of specific proteins. The highly conserved motif (first described on the basis of the crystal structure of parvalbumin containing six helices, A–F) in which certain amino acids are invariant consists of two helices enclosing the Ca^{2+}-binding loop. As a model, the forefinger and the thumb of the right hand can resemble the two helices (e.g., E and F of the second Ca^{2+}-binding domain of parvalbumin) and the bent midfinger the enclosed loop, hence the EF-hand.

exon Segments of a eukaryotic gene preserved in the mature messenger RNA.

intron Segments of a gene transcribed into the precursor RNA but excised by RNA splicing before the mature RNA is exported from the nucleus into the cytoplasm.

post-translational modification Enzymatic modification such as acetylation, phosphorylation, myristoylation, or ubiquitination of proteins regulate their activity, topology, or degradation.

second messenger Intracellular small molecules (e.g., cyclic nucleotides or inositol polyphosphates) or ions such as Ca^{2+} or gases such as NO, indispensable for the transduction of signals converting extracellular stimuli – e.g., raised by hormones (= primary messengers) – into intracellular responses.

splicing Removal of introns from the precursor messenger RNA and joining of exons in mature messenger RNA; positions of boundaries between introns and exons are often conserved in homologous proteins of different species.

Biography

Joachim Krebs has been working in the field of calcium-binding and calcium-transporting proteins for many years. After receiving his Ph.D. from the University of Tuebingen, Germany, he spent 2 years as a postdoctoral fellow at the Institute of Inorganic Chemistry of the University of Oxford, UK, before joining the Institute of Biochemistry at the Swiss Federal Institute of Technology (ETH) in Zurich, Switzerland. He has authored, co-authored, and edited numerous articles in international journals and books in the field of calcium biochemistry.

Calcium-Modulated Proteins (EF-Hand)

Robert H. Kretsinger
University of Virginia, Charlottesville, Virginia, USA

Many different proteins – extracellular, membrane, and intracellular – bind calcium more or less selectively. Those calcium binding proteins in the cytosol or bound to membranes facing the cytosol are inferred to be calcium modulated. That is, when the cell is quiescent, the concentration of free calcium ion is less than 10^{-7} M (pCa > 7) and the calcium-modulated protein is in the apo- or magnesi-form. Following stimulus, the concentration of calcium rises (pCa < 5.5), and the protein binds calcium. The attendant change in structure is involved in the transduction of the information of a pulse or wave of Ca^{2+} ions to an ultimate target enzyme or structure. Most of these calcium-modulated proteins contain from 2 to 12 copies of the EF-hand domain. There are other proteins in the cytosol that bind calcium and appear to be modulated by calcium; these include the annexins, proteins that contain one or several C2 domains, such as protein kinases C or synaptotagmin, and calcium pumps.

Calcium Coordination

Many of the functional characteristics of calcium and of calcium-modulated proteins can be rationalized from the geometry of calcium coordination.

Pentagonal Bipyramid

In proteins, the Ca^{2+} ion (atomic radius 0.99Å) is usually bound by seven oxygen atoms in an approximately pentagonal bipyramid conformation at average Ca–O distance 2.3 ± 0.3Å; the oxygen atoms have some lateral flexibility. The Mg^{2+} ion (atomic radius 0.65Å) is usually coordinated by six oxygen atoms at the vertices of an octahedron with Mg–O, 2.0Å; these oxygens are in tight van der Waals contact with one another. Although many small molecules bind magnesium with greater affinity than they bind calcium, most intra- and extra-cellular proteins bind calcium with much greater affinity than they bind magnesium.

Kinetics of Calcium and Magnesium Binding

The dissociation constant is the ratio of the off rate to the on rate: K_d (M) = k_{off} (s^{-1})/k_{on} ($M^{-1}s^{-1}$). The rate limiting dehydration of $Ca(H_2O)_7^{2+}$ is fast, $\sim 10^{8.0}\ s^{-1}$; while that of $Mg(H_2O)_6^{2+}$ is slow, $\sim 10^{4.6}\ s^{-1}$. This reflects the loose pentagonal bipyramidal vs the tight octahedral packing of the oxygen ligands. The cation must be (partially) dehydrated before it can bind to the protein. These rates are extremely important for modeling the flux of Ca^{2+} ions through the cytosol and the attendant binding of proteins. The increase in affinity of most proteins for calcium relative to magnesium derives primarily from this difference in k_{on} (e.g., see Table I).

Temporal Buffering

It is intriguing that most EF-hand proteins bind calcium ~10,000 times more strongly than they bind magnesium. This reflects strong evolutionary selection and cannot yet be mimicked by protein designers. The cytosolic concentration of the free Ca^{2+} ion is $\sim 10^{-7.2}$ M and that of the Mg^{2+} ion is $\sim 10^{-2.8}$; in contrast, both pCa_{out} and pMg_{out} are ~ 2.8. This means that a cytosolic protein, such as parvalbumin, that binds calcium with high affinity, e.g., $pK_d(Ca^{2+})$ ~8.0, will also bind magnesium with relatively high affinity, e.g., $pK_d(Mg^{2+})$ ~4.1, and, in the resting cell, will be in the magnesium state. In contrast, lower affinity sites, such as EF-hands 1&2 of troponin C have lower affinities for divalent cations, $pK_d(Ca^{2+}) \sim 6.5$ and $pK_d(Mg^{2+}) \sim 2.3$, and are apo in the resting state. This leads to the counterintuitive situation in which a pulse of messenger calcium first binds to the weaker apo sites in domains 1 and 2 of troponin C, misleadingly referred to as calcium specific. The Ca^{2+} ion, whose concentration during the pulse reaches $10^{-6.0}$ M, can bind to the apo site only after the Mg^{2+} ion diffuses off the strong site of parvalbumin. Parvalbumin, with higher affinity for divalent cations, binds calcium after the weaker

TABLE I

	K_d (M)	k_{off} (s^{-1})	k_{on} ($M^{-1}s^{-1}$)
Parvalbumin/Ca^{2+}	$10^{-8.0}$	$10^{0.0}$	$10^{8.0}$
Parvalbumin/Mg^{2+}	$10^{-4.1}$	$10^{0.5}$	$10^{4.6}$
Troponin C (domains 1&2)/Ca^{2+}	$10^{-6.5}$	$10^{1.5}$	$10^{8.0}$
Troponin C (domains 1&2)/Mg^{2+}	$10^{-2.3}$	$10^{2.3}$	$10^{4.6}$

troponin C and thereby helps to relax the muscle and prevent tetany. Such temporal buffering surely plays a significant role in the propagation and transduction of calcium waves observed in many cell types. The information encoded in the frequencies, durations, and amplitudes of calcium waves and spikes might be decoded by a corresponding matching of k_{off} and k_{on} rates for calcium and for magnesium in calcium-modulated proteins.

EF-Hand Containing Proteins

The structure of the EF-hand provides insight into its evolution and function.

Structure of the EF-Hand

The canonical EF-hand (Figure 1) consists of α-helix E, (forefinger, residues 1–10), a loop around the Ca^{2+} ion (clenched middle finger, 10–21), and α-helix F (thumb, 19–29). Residue 1 is often Glu; the insides of the helices (palmer surfaces) usually have hydrophobic residues that contact the insides of the other EF-hand of the pair (Figure 2). The side chains of five residues, approximating the vertices of an octahedron (X, residue 10; Y, 12; Z, 14; $-X$, 18; and $-Z$ 21), provide oxygen atoms to coordinate Ca^{2+}; residue 16 at $-Y$ bonds to Ca^{2+} with its carbonyl oxygen. The positions of these ligands within the loop are often referred to as 1, 3, 5, 7, 9, and 12. The Ca^{2+} ion is actually 7 coordinate in a pentagonal bipyramid with major axis, X, $-X$. There are five oxygen atoms in the Y, Z plane; since, the $-Z$ ligand (residue 21, usually Glu) coordinates Ca^{2+} with both oxygen atoms of its carboxylate group. A Gly at 15 permits a tight bend; residue 17 has a hydrophobic side chain that attaches the loop to the hydrophobic core of the pair of EF-hands.

Several variations to this canonical calcium coordination scheme have been inferred from amino acid sequence and confirmed in crystal structures of other EF-hand proteins. Nearly one-third of all known EF-hands do not bind calcium; those with no indels

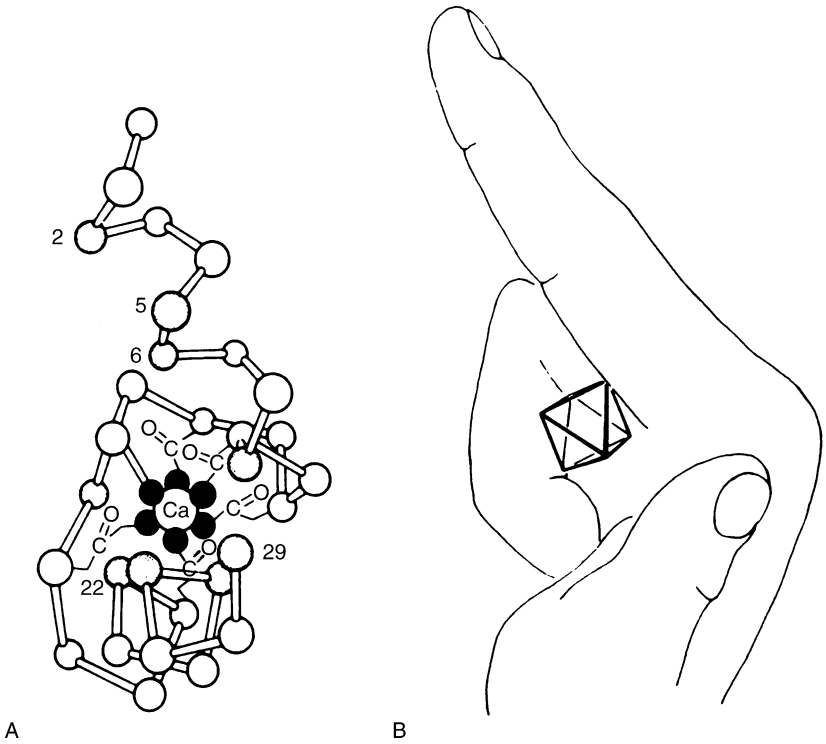

FIGURE 1 The EF-hand. (A) The spheres represent α-carbons. Residues 2, 5, 6, and 9 of helix E and residues 22, 25, 26, and 29 of helix F are usually hydrophobic and face the hydrophobic surface of the other EF-hand of the pair. Five residues—10, 12, 14, 18, and 21—coordinate the Ca^{2+} ion with an oxygen from a side chain. Residue 21 is usually Glu and contributes both oxygen atoms of its carboxylate to the pentagonal bipyramid coordination of calcium. Residue 16 coordinates with its carbonyl oxygen. (B) Helix E, the loop around the Ca^{2+} ion, and helix F are represented by the forefinger, clenched middle finger, and thumb.

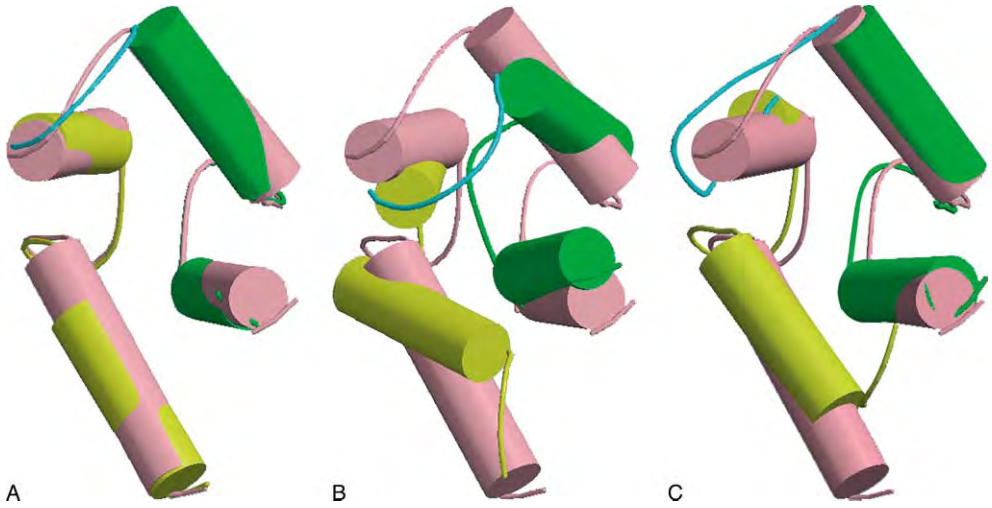

FIGURE 2 Conformations of pairs of EF-hands. Calmodulin consists of two pairs (1&2 and 3&4) of EF-hands. A flexible tether, seven residues long, connects helix F2 to helix E3. In the crystal structure, F2, the tether, and E3 form a single continuous helix. Calmodulin is widely distributed and interacts with at least 30 different target proteins. Furthermore, calmodulin's four EF-hands are all canonical; hence, it serves as a reference point for many evaluations and comparisons. (A) The backbone of the pair calmodulin-3&4 in its dicalci form is shown as a cylinder when it is α-helical and as a strand elsewhere. It is viewed down its approximate twofold axis and is shown in light salmon color; the calcium binding loops are far from the viewer. Dicalci-parvalbumin-CD&EF (CD, yellow; linker, light blue; EF, green) is superimposed on dicalci-calmodulin-3&4; their conformations are very similar. (B) Apo-calmodulin-3&4 (yellow, blue, green) is superimposed on dicalci-calmodulin-3&4 (salmon); the binding of calcium opens the cleft between the two helices of each EF-hand and between the two EF-hands of the pair. This is supposedly a necessary step permitting calmodulin to interact with its numerous targets. The structure of apo-parvalbumin is not known. (C) Dicalci-calmodulin-3&4 (yellow, light blue, and green) as complexed with the target peptide from myosin light chain kinase (not shown) is superimposed on dicalci-calmodulin-3&4 (salmon). Both the 3&4 and the 1&2 pairs of calmodulin undergo little additional change in conformation to bind their targets. The binding of a target peptide facilitates binding of calcium and vice versa. (Courtesy of Hiroshi Kawasaki, Yokohama City University, Yokohama, Japan.)

(insertions or deletions), have a non-oxygen-containing side chain substituted at position 10, 12, 14, 18, or 21. Other EF-hands have indels; most notable is EF-hand 1 of the S-100 subfamily (Table II), in which several carbonyl oxygens, instead of side chain oxygens, coordinate Ca^{2+}.

Evolution of the EF-Hand Family

All members of a protein homolog family are inferred to have evolved from a common precursor domain in a single ancestral organism. The most parsimonious interpretation is that all of the EF-hand domains listed in Table II are homologs; however, the statistics are weak since the domains are only 30 residues long. We employ other criteria, such as the fact that nearly all EF-hands occur in pairs (Figure 2) and that in nearly all EF-hand proteins at least one of the EF-hands binds calcium. Many domains have been suggested to resemble the EF-hand. They are not included in Table II unless they have passed a Hidden Markov Model test based on unambiguous EF-hands of known structure. Most EF-hand containing proteins have been found in eukaryotes; however, there are several examples in eubacteria. EF-hand proteins, e.g., calmodulin, have been found in all eukaryotes subject to thorough investigation. This distribution might reflect an origin in the bacterium that gave rise to eukaryotic cells; other bacteria may have lost their EF-hands. Or, the precursor EF-hand may have arisen in an early eukaryote and been transferred to a few bacteria by some sort of transduction or transformation.

Distribution of EF-Hand Domains

Most of the calcium-modulated proteins contain 2 to 12 tandem copies of the EF-hand domain. EF-hands occur in pairs and are related by an approximate twofold axis of rotation (Figure 2). Although about one-third of all EF-hands are known or inferred not to bind calcium, usually at least one EF-hand domain in any protein does bind calcium with $pK_d(Ca^{2+}) \sim 7.0$. The protein, such as archetypical calmodulin, is in the apo or magnesium form prior to stimulation of the cell; following a rise in $[Ca^{2+}]_{cyt}$, the competent EF-hand binds calcium with attendant change in conformation of itself and probably of the paired EF-hand of the two-domain lobe. If the protein is hetero-chimeric with a non-EF-hand catalytic portion, the change in conformation of the EF-hand region activates the enzyme. If the EF-hand protein itself is not catalytic, the change in conformation causes the EF-hand protein to activate a target enzyme or structural protein.

The characteristics of 77 distinct EF-hand proteins are summarized in Table II. The functions of only 26 of

Note. The 77 known EF-hand homolog subfamilies are described in several groups: CTER, those that are congruent with calmodulin, troponin C, essential, and regulatory light chains; CPV, those that are congruent with calcineurin B, p22, and visinin (recoverin); Pairings, those closely related between or among themselves but not closely related to other subfamilies; Self, those (some of) whose EF-hands are most closely related to other EF-hands within the same subfamily; and Miscellaneous, those whose domains do not show a strong and consistent pattern of similarity with other EF-hand subfamilies. The first domain of (pre)parvalbumin is inferred to have been deleted; hence, its domains are listed as 2(AB), 3(CD), and 4(EF). In congruent subfamilies, all of the EF-hands 1 (or *n*) resemble one another more closely than they resemble other EF-hands within their own protein. For 26 subfamilies, only one sequence is available; this is indicated by inclusion of genus name in parentheses or as part of the name of that subfamily. APFP refers to whether the protein is found in Animals, Plants, Fungi, and/or Protists. Five subfamilies are found in prokaryotes (bact) and one in a virus. The Func/Struct columns indicate whether a function is known + or not ? and whether a crystal structure is available X or not ?. The symbol *** before the first EF-hand column or after the last column indicates a protein with the non-EF-hand domain(s) to either the N-side or C-side of the EF-hands. For P26 and for EP15 *** indicates another domain between EF-hands 1 & 2 and EF-hands 3 & 4. Thirty-four, including the nine enzymes, of the 77 subfamilies are hetero-chimeric. For AEQ and PPTS, **−*** indicates that domain is not recognizable as an EF-hand by analysis of its sequence; however, its proximity to an otherwise unpaired EF-hand suggests that it may be an EF-hand and is inferred not to bind calcium. For each EF-hand is indicated whether calcium binding is observed (or inferred from sequence) + or not −. For some EF-hands there are instances of both binding and not binding calcium +/−. There are four examples—a, b, c, and d—of noncanonical EF-hand loops that bind calcium. Some loops inferred not to bind calcium may provide additional examples of noncanonical calcium binding loops. EF12 has 12 and LPS has 8 EF-hands; for ease of formatting EF-hands, 7 and on are listed under EF-hands 1 and on. Of the 77 distinct EF-hand proteins 56 have been found in animals. The functions of only 27 of the 77 are known. Nine of these are enzymes and have been demonstrated or inferred to be activated by the binding of calcium. Many, but certainly not all, of the remaining 50 function in the information transduction pathway summarized for calcium modulated proteins, such as calmodulin.

the 77 are known. Nine of these are enzymes and have been demonstrated or inferred to be activated by the binding of calcium. Many, but certainly not all, of the remaining 51 function in information transduction pathways as summarized for calcium-modulated proteins, such as calmodulin. However, others such as intestinal calcium binding protein, probably facilitate the diffusion of calcium through the cytosol; parvalbumin appears to function as a temporal buffer. Thirty-one, including the nine enzymes, of the 77 subfamilies are hetero-chimeric. In addition to their EF-hands, they contain other domains of different evolutionary origin and conformation. It is not unusual for a basic protein domain to find many uses, often spliced together with other domains; however, the EF-hand is one of the most widely distributed domains in eukaryotes, perhaps reflecting the range and subtlety of calcium signaling. The downstream regulation element antagonist modulator (DREAM) upon binding calcium dissociates from a DNA binding regulatory element that otherwise functions as a gene silencer. Whether this might provide a precedent for long-term potentiation remains to be seen.

Calmodulin

Calmodulin is probably present in all cells of all eukaryotes. It consists of four EF-hands and is highly conserved in amino acid sequence. The second (F2) α-helix of domain 2, the eight residue linker between domains 2 and 3 and the first (E3) α-helix of domain 3 form a single continuous α-helix ~28 residues long, thereby giving calmodulin a dumbbell shape as seen both in the crystal and in solution. Upon binding calcium, the relative orientations of the four helices in both lobes change, thereby exposing hydrophobic regions and permitting the interaction of calmodulin with target enzymes and structural proteins. Over 30 calmodulin targets have been reported. The structures of calmodulin complexed with α-helical regions of several targets, such as myosin light chain kinase (MLCK), reveal what appears to be a general pattern for the interactions of four domain EF-hand proteins, such as calmodulin, troponin C, and the essential and regulatory light chains of myosin, with their respective targets. MLCK is self-inhibited by its own peptide 796–813; limited proteolysis removes this peptide. The 1–795 MLCK is then constitutively active. *In vivo*, calmodulin binds calcium, undergoes a change in conformation, binds α-helix 796–813 of MLCK, and thereby removes the self inhibition of MLCK. Calmodulin assumes a near spherical shape when complexed with its target, as opposed to the elongated dumbbell shape of uncomplexed calmodulin. The eight-residue linker is flexible, permitting calmodulin to assume a broad range of conformations. Among these conformations are some that grasp the MLCK target peptide; other conformations fit other targets.

Biography

Robert Kretsinger is Professor of Biology at the University of Virgina, Charlottesville, Virginia. He received his Ph.D. in biophysics from the Massachusetts Institute of Technology and carried out his post-doctoral training at the Medical Research Council Laboratory of Molecular Biology in Cambridge, England. He determined the first crystal structure of an EF-hand protein, parvalbumin, in 1970, and he has continued his research in various aspects of protein structure, evolution, and structure prediction.

Calpain

Hiroyuki Sorimachi and Yasuko Ono
University of Tokyo, Tokyo, Japan

Calpain (Clan CA, family C02, EC 3.4.22.17) is a ubiquitous intracellular Ca^{2+}-dependent cysteine protease that displays limited proteolytic activity at neutral pH. Calpain acts by proteolytically processing, rather than digesting, substrates to transform and modulate their structures and activities. Thus, calpain is viewed as a representative "modulator protease" that governs various cellular functions such as signal transduction and cell morphogenesis. Calpain belongs to the papain superfamily and constitutes one of the three distinct kingdoms, i.e., calpain-, papain-, and bleomycin-hydrolase-sub-superfamilies. The human genome has 14 genes that encode a calpain-like protease domain. These generate diverse types of calpain homologues possessing combinations of several functional domains such as a Ca^{2+}-binding domain (C2-type and EF-hand-type) and a Zn-finger domain. Furthermore, calpain homologues are increasingly being found in other organisms including insect, nematode, trypanosome, plant, fungus, yeast, and even some bacteria, thus constituting a superfamily possessing versatile functions. The importance of the physiological roles of calpains is reflected by the fact that particular defects in calpain functionality cause a variety of deficiencies in many different organisms. These include muscular dystrophies, diabetes and tumorigenesis in humans, embryonic lethality in mice, neurogenesis deficiency in flies, incomplete sex determination in nematodes, defects in aleurone cell development in maize, and alkaline/osmotic stress susceptibility in yeast.

History and Nomenclature

Calpain was described as early as 1964. After several "re-identifications," calpain, which was called CANP (calcium activated neutral protease) at that time, was finally purified into homogeneity in 1978. Both names, "calpain" and "CANP," were unified as calpain in 1991. In 1984, the cDNA for the catalytic subunit of calpain was cloned for the first time, revealing that calpain is a chimeric molecule consisting of a cysteine protease and a calmodulin-like Ca^{2+}-binding module. In the two decades following this event, hundreds of calpain-related molecules, including its endogenous specific inhibitor protein, calpastatin, have been identified through the use of cDNA cloning and genome/EST projects.

Two major ubiquitous calpains are found in mammals, μ- and m-calpains. Since most of the studies carried out concerned μ- and m-calpains, they are referred to as the "conventional" calpains. As the names suggest, μ-calpain and m-calpain are activated by μM and mM levels of Ca^{2+} *in vitro*, respectively. They are both hetero-dimers and consist of a common calpain small regulatory subunit (30K, ca. 28 kDa) and large distinct μ- and m-calpain catalytic subunit (μCL and mCL, respectively, ca. 80 kDa), which have ca. 60% amino acid identity. Fourteen human calpain homologues have been numbered as in the case of caspases as shown in Table I and Figure 1. As an example, μCL is now called "calpain 1," i.e., μ-calpain is a hetero-dimer consisting of a 30K subunit and calpain 1. To avoid unnecessary confusions, however, the original name and the gene product name are adopted in this section, e.g., μCL/CAPN1, mCL/CAPN2, p94/CAPN3, 30K/CAPNS1, hTRA-3/CAPN5.

Structure and Function of Conventional Calpains

In general, potential substrates for calpain are very limited and specific. Most oligopeptides investigated are poor substrates for calpain. Although casein is not an *in vivo* substrate of calpain, it is a very good *in vitro* substrate and is used to assay calpain activity. Although the rules governing substrate specificity remain unclear, calpain is thought to recognize a large scope of 3D substrate structures rather than a particular primary amino acid sequence. For example, protein kinases, phosphatases, phospholipases, cytoskeletal proteins, membrane proteins, cytokines, transcription factors, lens proteins, and calmodulin-binding proteins are just some of the proteins suggested to be *in vivo* substrates. There has been no report suggesting differences in substrate specificity between μ- and m-calpains.

Calpain has a very specific proteinaceous inhibitor *in vivo* called calpastatin. Calpastatin has four repeats of an inhibitor unit, each of which inhibits calpain. Both μ- and m-calpains possess similar susceptibility

TABLE I

Human Calpain Related Genes[a]

Gene	Chr.	Originally described names(s) of the gene product	Other name(s) used	Name in number	Domains				Expression	Note
					Protease activity[b]	C2-like	5EF-hands	C2 (T)		
The large subunits										
CAPN1	**11q12-13.1**	μCANP[c]/calpain-I large subunit	μ-calpain large subunit(μCL), μ80K	Calpain 1	+	+	+	−	ubiquitous	+30K/CAPNS1 = μ-calpain
CAPN2	**1q32-41**	mCANP/calpain-II large subunit	m-calpain large subunit (mCL), m80K	Calpain 2	+	+	+	−	ubiquitous except for mammalian erythrocytes	+30K/CAPNS1 = m-calpain
		p94	calpain 3, nCL-1	Calpain 3a	+	+	+	−	skeletal muscle	binds to connectin/titin termination codon in the human
CAPN3	**15q15**	Lp82, Lp85, etc.	—	Calpain 3b, 3c etc.	+	+	+	−	lens, retina	first exon
CAPN5	**11q14**	calpain 5, hTRA-3	nCL-3	Calpain 5	+	+	−	+	testis, brain	nematode TRA-3 homologue
CAPN6	**Xq23**	calpain 6	calpamodulin, CANPX	Calpain 6	−	+	−	+	placenta, embryonic muscles	nematode TRA-3 homologue, but no Cys at the active site
CAPN7	**3p24**	calpain 7, PalBH	—	Calpain 7	n.d.	+	−	−	ubiquitous	Aspergillus PalB homologue
		nCL-2	—	Calpain 8a	+	+	+	−	stomach	
CAPN8	**1q32-41**	nCL-2′	—	Calpain 8b	+	−	−	−	stomach	Ca^{2+}-dependent
CAPN9	**1q42.1-43**	nCL-4	—	Calpain 9	+	+	+	−	digestive tracts	30K is required for activity
CAPN10	**2q37.3**	calpain 10a–h	—	Calpain 10a–h	n.d.				ubiquitous	SNP is related to NIDDM
CAPN11	**6p12**	calpain 11	—	Calpain 11	n.d.				testis	
CAPN12	**19q13**	calpain 12a–c	—	Calpain 12a–c	n.d.	+	+	−	hair follicle	
CAPN13	**2p21-22**	calpain 13	—	Calpain 13	n.d.	+	+	−	ubiquitous	mRNA not detected
CAPN14	**2p21-22**	calpain 14	—	Calpain 14 n.d.	n.d.	+	−	−	n.d.	
CAPN15	**16p13.3**	SOLH	—	Calpain 15	n.d.	−	−	−	ubiquitous	drosophila SOL homologue
The small subunits										
CAPNS1	**19q13**	CANP/calpain small subunit	30K, ccs1	CAPNS1	–	−	+	−	ubiquitous	regulatory subunit for μCL and mCL
CAPNS2	**16q13**	CAPNS2	30K-2, ccs2	CAPNS2	−	−	+	−	ubiquitous	intron less gene
The calpain inhibitor										
CAST	**5q15-21**	CANP inhibitor/ calpastatin	—	–	−	−	−	−	ubiquitous	specific inhibitor for μ-, m-calpains, and nCL-4

[a] Human disease and results of knock-out mice were taken together.

[b] (+) indicates that it was experimentally shown to have protease activity, and (−) in calpain 6 means that it has no active site cysteine residue.

[c] Abbreviations: n.d., not yet determined; CANP, Ca^{2+}-activated neutral protease; nCL, novel calpain large subunit; LGMD2A, limb-girdle muscular dystrophy type 2A; TRA-3, transform genotypic hermaphrodites; PalB, phosphatase mutants: loss in activity at alkaline pH but normal or increased activity at acidic pH; PalBH, PalB homologue; SNP, single nucleotide polymorphism; NIDDM, non-insulin-dependent diabetes mellitus; SOL, small optic lobes; SOLH, SOL homologue; ALG-2, apoptosis-linked gene-2; PDCD6, programmed cell death 6.

[d] The corresponding mammalian gene does not exist.

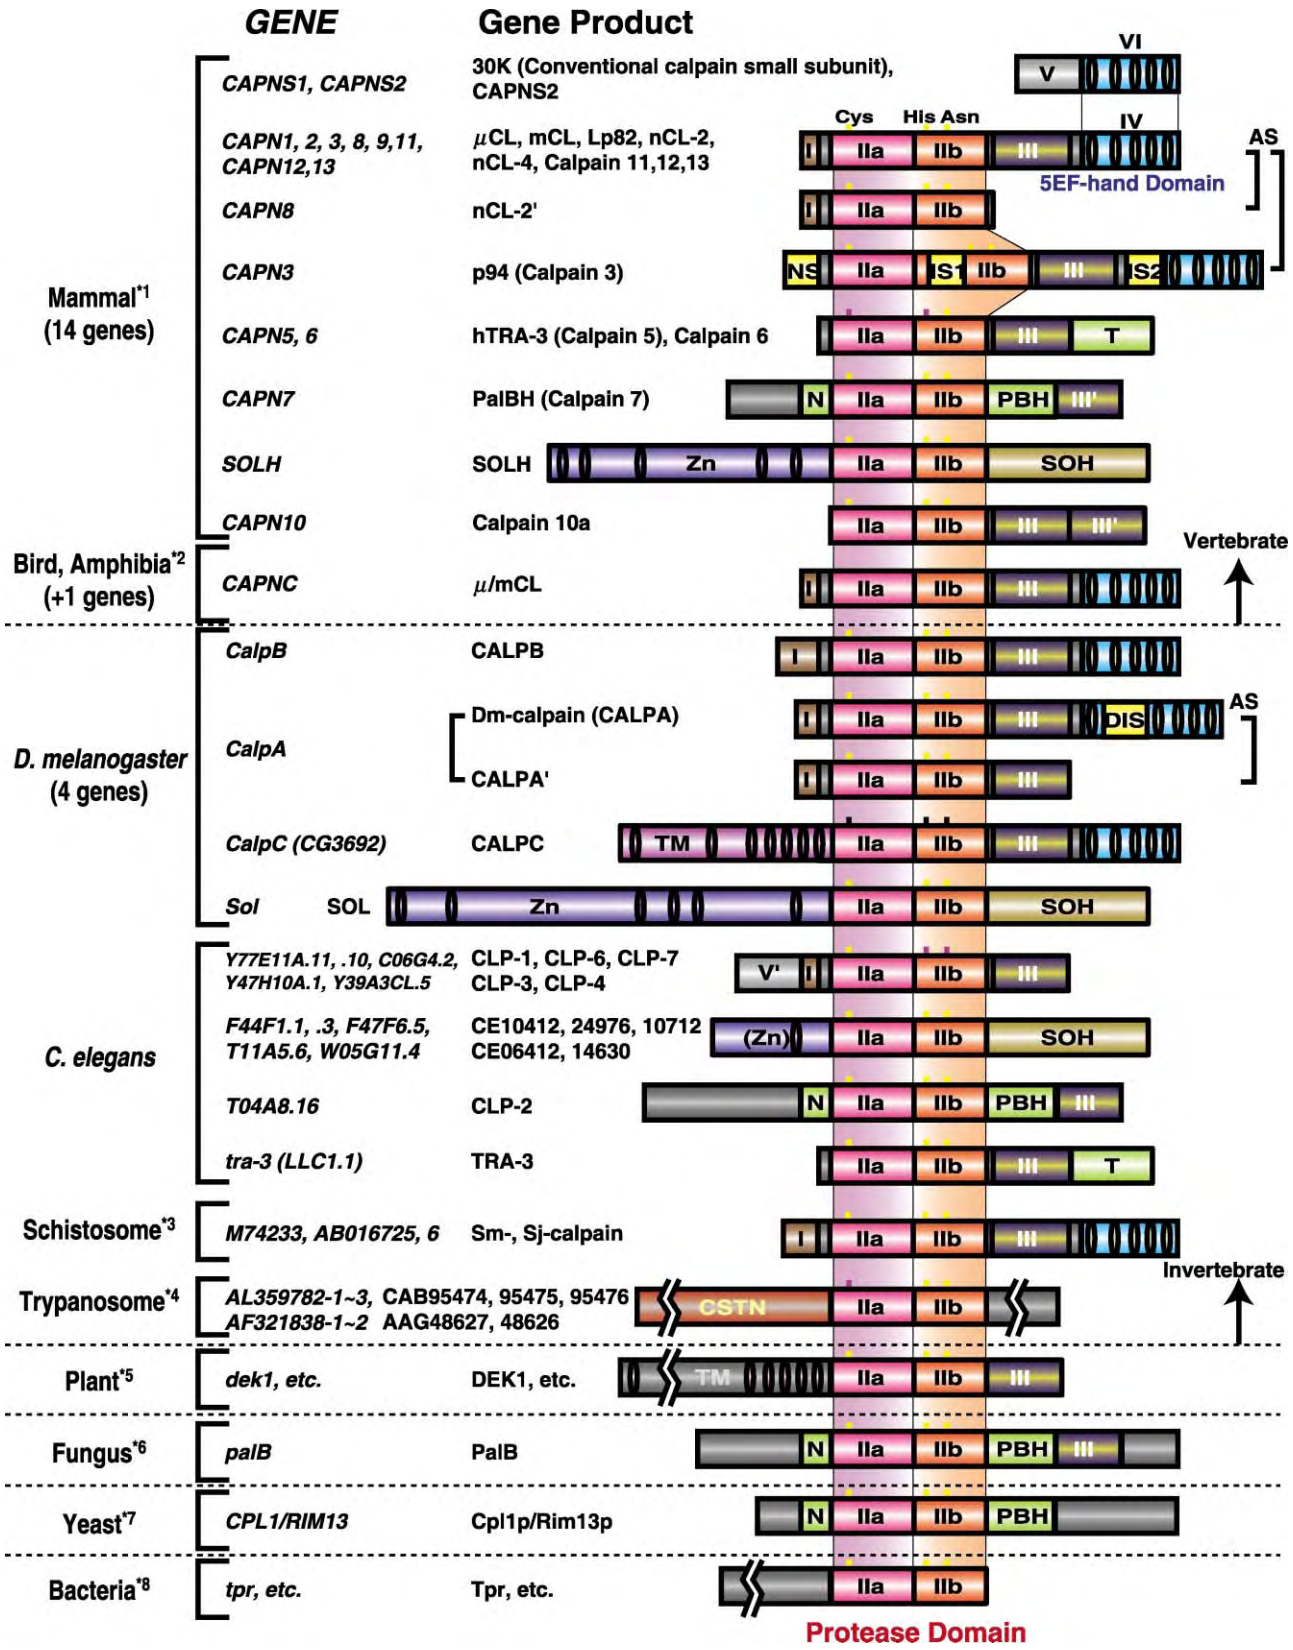

FIGURE 1 Schematic structures of calpain. Calpain homologues have been identified in Mammals (*1: human, mouse, rat, rabbit, porcine, bovine, ovine), birds (*2: chicken and quail), amphibians (*2: *X. laevis*), flies, nematodes, schistosomes (*3: *S. mansoni* and *S. japonicum*), trypanosomes (*4: *Leishmania major* and *Trypanosoma brucei*), plants (*5: *A. thaliana*, maize, rice, and loblolly pine), fungi (*6: *A. oryzae* and *E. nidulans*), yeasts (*7: *S. cerevisiae*, *Y. lipolytica*, and *C. alabicans*) and bacteria (*8: *Porphyromonas gingivalis*, *Cyanobacterium Anabaena*, etc.). I,

to calpastatin. μ- and m-calpains are ubiquitously expressed in mammalian and avian cells. Thus, their function is thought to be fundamental and essential. Many functions including the regulation of signal transduction systems, cell motility and apoptosis have been suggested, although they have not yet been completely clarified. *CAPN1* knock-out mice showed almost no phenotype, while *CAPNS1* knock-out mice resulted in embryonic lethality, indicating the indispensable roles of conventional calpains and, at the same time, differentiating between μ- and m-calpain functionality.

As shown in Figure 1, the catalytic and regulatory subunits of conventional calpains can be divided into 4 and 2 domains, respectively. The N-terminus of domain I of the large subunit is autolyzed upon activation by Ca^{2+}. This results in a lower requirement for Ca^{2+} and the dissociation of both subunits. Therefore, autolysis is involved in the regulation of calpain activity and specificity.

Three-D structural studies revealed that the protease domain in the absence of Ca^{2+} is divided into two subdomains—domains IIa and IIb, which are folded into one domain upon Ca^{2+} binding. This domain is highly conserved among calpain family members, suggesting the functional importance of this domain (Figure 1). Surprisingly, only the protease domain of μ- and m-calpains showed Ca^{2+}-dependent protease activity. This is supported by the 3D structural studies of the protease domain in the presence of Ca^{2+} that showed Ca^{2+} bound to domains IIa and IIb. Thus, the whole calpain molecule mediates Ca^{2+}-dependency since all of the domains IIa, IIb, III, IV, and VI bind at least one Ca^{2+} with varying affinities.

The 3D structure of domain III consists of 8 antiparallel β-strands (β-sandwich structure), a structure very similar to TNF-α and the C2-domains found in several Ca^{2+}-regulated proteins such as PKCs and synaptotagmins. Although the primary structure of domain III is highly conserved in calpain homologues, it has no similarity to any other proteins including TNF-α and C2-domains. This domain actually binds Ca^{2+}, and may play an important role in the Ca^{2+}-dependent membrane translocation of calpains.

Domain IV is very similar to domain VI of the small subunit, and each contains 5 EF-hand motifs. Thus, these domains are referred to as 5-EF-hand, or penta EF-hand (PEF) domains. *In vitro* experiments together with 3D structural studies showed that only the first, second, and third EF-hands bind Ca^{2+}. The fifth EF-hand motif is involved in the dimerization of both subunits.

Domain V of the calpain regulatory subunit contains clusters of Gly making it hydrophobic. This domain is thought to interact with membrane and/or membrane proteins through hydrophobic interactions. Most of this domain is cut off by autolysis, indicating no involvement of this region in protease activity. In humans, the *CAPNS2* gene encodes a regulatory subunit homologue, whose physiological roles remain unclear.

Calpain Superfamily and Its Members

Classifications

As for calpain homologues other than conventional calpains, domains other than the protease domain are not necessarily conserved amongst homologues (Figure 1). Amino acid sequence identities of the protease domains vary, depending on the molecules, from less than 30% to more than 75%. Several kinds of domains, putatively originated from independent genes, exist in both N- and C-terminal parts of the protease domain. These include C2 and C2-like domains, a 5-EF-hand domain, a transmembrane domain, as well as conserved domains with unknown functions (SOH, PBH, etc). These features, together with the organization of mammalian calpain genes, strongly suggest that calpain molecules are the result of the combination of the gene for the ancestral calpain-type cysteine protease with genes encoding other functions.

These calpain homologues can be divided into two categories. The first group consists of molecules having domains II, III, and IV (the protease domain), and the C2-like and 5-EF-hand Ca^{2+}-binding domains. In other words, these group members have a "typical" structure highly similar to conventional calpain catalytic subunits. Beside mammalian μCL/CAPN1 and mCL/CAPN2, typical calpains include p94/CAPN3, nCL-2/CAPN8, nCL-4/CAPN9, CAPN11, and CAPN12. Chicken and *Xenopus laevis* are reported to additionally have μ/mCL. In invertebrates, only five typical calpains have been identified thus far. Three are found in *Drosophila melanogaster* as Dm-calpain (CALPA), CALPB, and CG-3692. *Schistosome mansoni* and

the N-terminal domain with little homology; IIa and IIb, the protease subdomains containing the active site Cys and His residues, respectively; III, the C2-like Ca2 + -binding domain; IV and VI, the 5-EF-hand Ca2 + -binding domain; V, Gly-rich hydrophobic domain; NS, IS1 and IS2, p94-specific sequences; T, TRA-3 subfamily-specific C2 domain; PBH, PalB subfamily homology domain; N, PalB subfamily N-terminal conserved domain; Zn, Zn-finger motif containing domain; SOH, SOL subfamily homology domain; DIS, CALPA-specific insertion sequence; TM, transmembrane domain; CSTN, the domain weakly similar to calpastatin.

S. japonicum also have at least one typical calpain (Sm-, and Sj-calpain). No typical calpain homologues have been found in *Caenorhabtisis elegans*, plants, fungi, trypanosomes, and *Saccharomyces cerevisiae*.

The second group contains various molecules that have the protease domain but do not have domains III or IV. Instead, some possess an extra domain(s) distinct from the known domains I to VI. Thus, these molecules are "atypical" calpain homologues. These atypical calpains are thought to have somewhat different functions compared with those of typical calpains. Atypical calpains include the TRA-3, SOL, and PalB subfamilies, the alternative splicing products of *Capn8* (nCL-2′) and *CalpA*, and others.

In addition to the structural features, independent classification is possible according to the localization of the expression. In mammals, μCL/CAPN1, mCL/CAPN2, PalBH/CAPN7, CAPN10, and CAPN13 are ubiquitously expressed, whereas p94/CAPN3, nCL-2/CAPN8, nCL-4/CAPN9, hTRA-3/CAPN5, CAPN6, 10, 11, and 12 are predominantly expressed in specific organs (Table I).

Structure and Functions of Calpain Superfamily Members

Skeletal Muscle-Specific Calpain, p94/CAPN3

p94/CANP3, the first tissue-specific calpain found in 1989, is ca. 60% identical to the large subunits of μ- and m-calpains, and has a conserved domain structure (Figure 1). Given that p94/CAPN3 contains three specific regions, NS, IS1, and IS2, it is often referred to as "calpain 3."

mRNA for p94/CAPN3 is expressed predominantly in skeletal muscle, and the amount expressed is approximately 10 times larger than that of conventional calpain. p94/CAPN3 possesses several unique properties. For example, p94/CAPN3 protein undergoes extremely rapid autolysis (half-life *in vitro* is less than 10 minutes), and this autolysis is obviated by deletion of the p94-specific region, IS1 or IS2. Specific inhibitors of μ- and m-calpains such as calpastatin, E-64, and leupeptin have no effect on autolysis. Furthermore, p94/CAPN3 possesses a nuclear localization signal-like sequence in IS2 and is localized in the nucleus in addition to the cytosol. p94/CAPN3 binds to gigantic muscle protein, connectin/titin, specifically through IS2. The protease activity of p94/CAPN3 should be regulated *in vivo*; however, the mechanism remains unclear. Connectin/titin is a candidate as a suppressor of p94/CAPN3 proteolytic activity.

Some alternative splicing products (Lp82) of *CAPN3* are specifically expressed in lenses. Lp82 showed Ca^{2+}-dependent protease activity against βA3 and αB crystallins. The activity is inhibited by E-64, but not by calpastatin. Some other splicing variants are expressed in embryonic skeletal muscles, although the physiological functions of these variants remain clear.

In 1995, mutations in *CAPN3* were shown to be responsible for limb-girdle muscular dystrophy type 2A (LGMD2A). Positions of the mutation found in the LGMD2A patients were distributed widely within *CAPN3*, with more than half of the mutations being missense mutations. No "hot point" was found, making its diagnosis very difficult. A primary cause of LGMD2A is a defect in protease activity, and not structural property, of p94.

nCL-2 and nCL-2′ (CAPN8)

nCL-2 and nCL-2′ are alternative splicing products of *CAPN8*, with and without C2-like and 5-EF-hand domains, respectively. They are predominantly expressed in the stomach. nCL-2 is highly similar to mCL/CAPN2 along the whole molecule (ca. 62% identical). Moreover, *CAPN8* and *CAPN2* are closely located, and their transcripts have overlap, i.e., complementary sequences. Recombinant nCL-2 and nCL-2′ proteins were expressed in *E. coli* and showed Ca^{2+}-dependent caseinolytic activities. *X. laevis* possesses an nCL-2 orthologue, xCL-2, the disruption of which causes severe developmental defects.

nCL-4/CAPN9

nCL-4/CAPN9 is a typical calpain homologue that is predominantly expressed in the digestive tract. It possesses overall similarity to μCL/CAPN1 and mCL/CAPN2, and requires 30K/CAPNS1 for its activity. Recombinant human nCL-4 + 30K protein showed Ca^{2+}-dependent caseinolytic activity, which was inhibited by calpastatin and other cysteine protease inhibitors, as in the case of conventional calpains. Involvement of nCL-4 in anti-tumorigenesis was reported in human gastric cancer and NIH3T3 transformation.

TRA-3 and Its Orthologues (TRA-3 Subfamily)

TRA-3 is involved in the sex determination cascade of *C. elegans*. Although enzymatic characterization of the purified enzyme has not yet been reported, protease activity of TRA-3 is Ca^{2+}-dependent and necessary for female development in XX hermaphrodites through the processing of TRA-2A membrane protein. Mammals possess two orthologues of TRA-3, hTRA-3/CAPN5, and CAPN6, whose amino acid sequences are more than 30% identical to that of TRA-3. The T domain, which is conserved in all three molecules, has weak similarity to the C2-domain. Surprisingly, CAPN6 apparently has no

active site residues (active site Cys is substituted with Lys), strongly suggesting that CAPN6 has no proteolytic activity.

Cpl1p, PalB, and its Orthologues (PalB Subfamily)

Cpl1p is the only calpain homologue found in *S. cerevisiae* and is considered both structurally and functionally to be the orthologue of Aspergillus PalB, which plays important roles in the adaptation of fungi to alkaline conditions. *CPL1*, also referred to as *RIM13*, is involved in both the alkaline adaptation and sporulation process of yeast through its processing activity. Rim101p and the Aspergillus orthologue PacC, are probable *in vivo* substrates for Cpl1p and PalB, respectively. Several other yeasts also have a Cpl1p orthologue. Cpl1p, PalB, and their orthologues share a somewhat conserved domain, the PalB homology domain (PBH). Mammals have one orthologue, PalBH/CAPN7, whose physiological functions are unknown.

Calpain 10/CAPN10

This homologue was identified by reverse genetics of non-insulin-dependent diabetes mellitus (NIDDM, type 2 diabetes). The single nucleotide polymorphism (SNP) in intron 3 of *CAPN10* is statistically related to a risk of NIDDM. This SNP probably affects transcription levels of *CAPN10*. *CAPN10* generates several alternative splicing products. The longest, CAPN10a, has two C2-like domains moderately and weakly similar to that of domain III. The physiological functions of calpain 10/CAPN10 are unclear.

SOL and its Orthologues (SOL Subfamily)

The Drosophila gene responsible for a defect in neuronal cells (small optic lobes) was positionally cloned and shown to encode a calpain homologue with several Zn-finger motifs located at the N-terminus. Mammals possess one orthologue, SOLH/CAPN15, while *C. elegans* has several. They share a conserved C-terminal structure called the SOL homology domain (SOH).

DEK1 and its Orthologues (DEK1 Subfamily)

The maize *defective kernel 1* gene required for aleurone cell development in the endosperm of maize grains revealed that it encodes a plant calpain homologue with 21 transmembrane regions located at the N-terminus and a C2-like domain, significantly similar to domain III, located at the C-terminus. Rice, Arabidopsis, and loblolly pine have very conserved orthologues (above 70% identity), and the whole genome sequence of Arabidopsis has revealed that DEK1 is the only calpain homologue in the genome. The structure and function of the DEK1 subfamily members are quite intriguing, and investigations have just begun.

Other Calpain Homologues

As described with the TRA-3 subfamily, some of the calpain homologues possess substituted residues in one of the very conserved active site residues, Cys, His, and Asn. Besides CAPN6 and Drosophila CG3692, some of the *C. elegans* homologues, and all of the trypanosome homologues, do not possess one or more of the active site residues. These molecules are thought not to possess Cys protease activity. Some of the *C. elegans* calpain homologues possess Gly-rich sequences, which is a characteristic of domain V of the calpain regulatory subunits (CAPNS1 and CAPNS2). Trypanosome calpains have N-terminal domains weakly similar to calpastatin. The physiological significance of these structural features has yet to be determined.

Carbohydrate Chains: Enzymatic and Chemical Synthesis

Thomas J. Tolbert and Chi-Huey Wong
Scripps Research Institute, La Jolla, California, USA

Carbohydrate chains play many important roles in biology, covering the surfaces of cells, mediating cell–cell recognition events, and forming major classes of biologically active molecules. Though carbohydrate chains are very important in biology, their study is frequently problematical because *in vivo* biosynthesis of carbohydrate chains often produces heterogeneous mixtures that are hard to purify in sufficient quantities for biochemical and structural studies. The *in vitro* enzymatic and chemical synthesis of carbohydrate chains offers another route to these interesting biomolecules that allows sufficient quantities of homogeneous oligosaccharides to be produced for biological studies.

Difficulties in the Synthesis of Carbohydrate Chains

The synthesis of oligosaccharides can present several technical difficulties that do not occur in the synthesis of other biopolymers. Unlike nucleic acids and proteins, the linkage between each subunit, i.e., sugar, of a carbohydrate chain forms a chiral center at the sugar's anomeric carbon that has two possible configurations, termed the α- or β-anomer (Figure 1B). Each time a sugar is joined to a carbohydrate chain through a glycosidic linkage, the stereochemistry of the bond that is formed must be controlled or directed in some manner to insure that the correct anomer is produced. In addition, carbohydrate chains are not just simple linear chains as DNA and proteins are, but can also be branched chains with increased complexity. Glycosidic linkages can be formed through each hydroxyl of a sugar, and when multiple hydroxyls on a single sugar form glycosidic linkages, branched oligosaccharide structures result. Distinguishing between the different hydroxyl moieties on sugars is another difficulty of carbohydrate chain synthesis. Each sugar of a carbohydrate chain can have several hydroxyl moieties that are nearly equivalent in chemical reactivity, making them difficult to differentiate from one another and adding several steps to most chemical syntheses. To overcome these difficulties, several enzymatic and chemical methods have been developed.

Enzymatic Synthesis of Oligosaccharides

Enzymes have frequently been employed to synthesize carbohydrate chains, because they offer a few technical advantages over traditional organic synthesis. Enzymes generally do not require protecting groups to select the correct chemical moiety on their substrates, and in carbohydrate chain synthesis this is a great advantage. The many nearly chemically equivalent hydroxyl moieties of sugars make selective chemical protection of sugar hydroxyls a laborious task. The use of enzymes in carbohydrate chain synthesis can eliminate the need for both selective hydroxyl protection before forming the glycosidic linkage, and removal of the protecting groups after forming the glycosidic linkage, greatly reducing the number of steps required for synthesis of an oligosaccharide. Another advantage of the use of enzymes in carbohydrate chain synthesis is the stereoselectivity of glycosidic bond-forming enzymes, which often produce a single anomer during the formation of a glycosidic bond. In contrast, chemical methods frequently produce mixtures of anomers during glycosidic bond formation, which must be purified from one another after formation of the glycosidic bond. Though enzymatic synthesis of oligosaccharides has many advantages, it is often limited by the availability of specific enzymes needed to form certain types of carbohydrate structures, but with the increased number of enzymes being discovered by genomic research this should improve in the future. Two classes of enzymes that have been used to form carbohydrate chains will be discussed further below, glycosidases and glycotransferases.

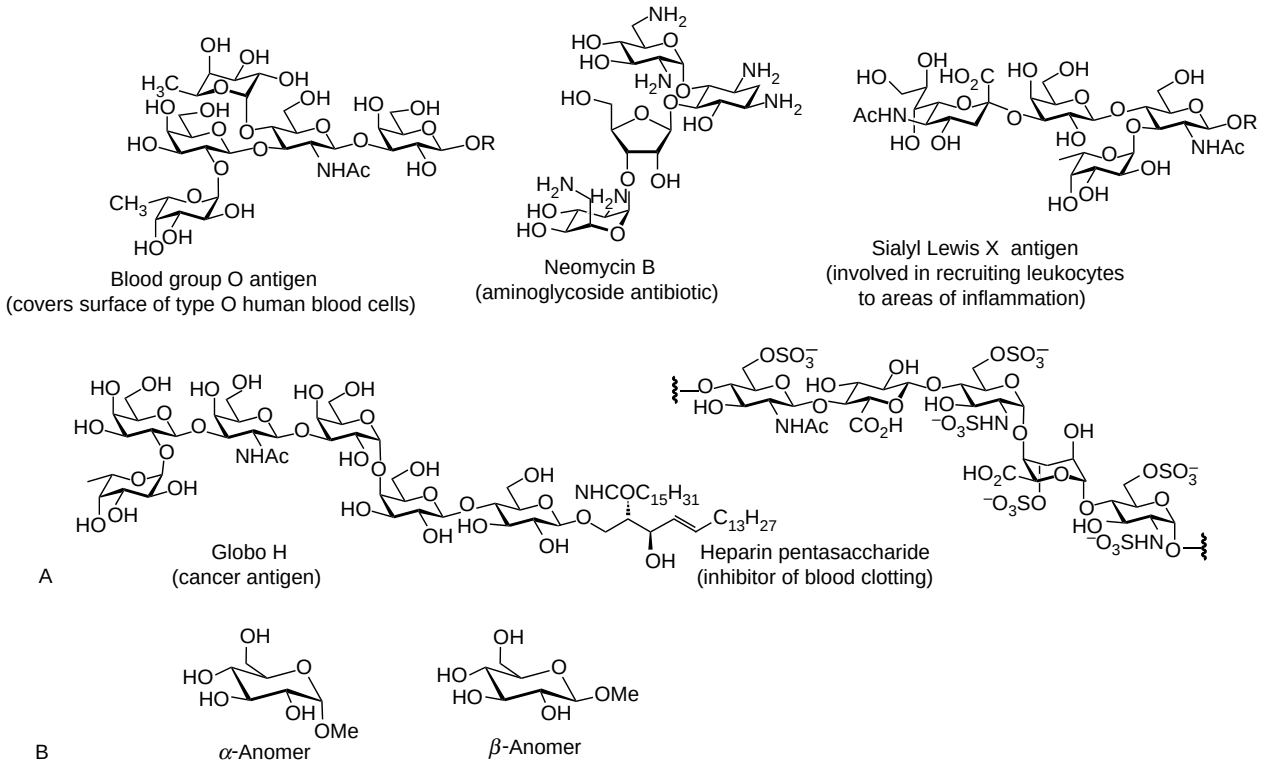

FIGURE 1 Carbohydrate chains: (A) some biologically important oligosaccharides and (B) 1-O-methyl-glucopyranosides, α- and β-anomers.

Carbohydrate Chain Synthesis Utilizing Glycosidases

Glycosidases are enzymes that normally break glycosidic bonds during glycoprocessing or catabolism of oligosaccharides, but by placing glycosidases under certain controlled reaction conditions they can be utilized to form, rather than break, glycosidic bonds. Most often, glycosidases are used to form glycosidic bonds in transglycosylation reactions, where a glycosidic bond is broken in a glycosyl donor glycoside, and a new glycosidic bond is formed with a glycosyl acceptor (Figure 2A). Several approaches can be utilized to favor formation of the desired glycosidic bond, including the use of activated glycosyl donors such as *p*-nitrophenyl glycosides, elevated concentrations of glycosyl donors and acceptors, organic cosolvents, and the use of mutated glycosidases with reduced hydrolysis activity. The use of glycosidases to form glycosidic bonds generally results in low to medium yields ranging from 20% to 40%, although yields as high as 90% have been reported using mutated glycosidases. Glycosidase catalyzed synthesis generally has good stereoselectivity, forming a single α- or β-anomer, but sometimes has low regioselectivity for the different hydroxyls on the acceptor sugar resulting in multiple products being formed. Though glycosidase reactions can suffer from low yield and low regioselectivity, there is a wide range of glycosidases available to catalyze the formation of many different types of glycosidic linkages.

Carbohydrate Chain Synthesis Utilizing Glycotransferases

Glycotransferases are enzymes that catalyze the transfer of activated monosaccharide donors to carbohydrates during the biosynthesis of oligosaccharides. They are very useful in synthesizing oligosaccharides *in vitro* because they exhibit high regioselectivity and stereoselectivity in the formation of glycosidic bonds. Glycotransferases that utilize nucleotide sugars as activated monosaccharide donors have been used most often in the *in vitro* synthesis of carbohydrate chains (Figure 2B). A wide variety of oligosaccharide structures can be produced using the available glycotransferases and activated nucleotide sugars such as UDP-glucose (UDP-Glc), UDP-N-acetylglucosamine (UDP-GlcNAc), UDP-galactose (UDP-Gal), UDP-N-acetylgalactosamine (UDP-GalNAc), UDP-glucuronic acid (UDP-GlcUA), GDP-mannose (GDP-Man), GDP-fucose (GDP-Fuc), and CMP-sialic acid (CMP-NeuAc). Generally, each glycotransferase is selective for a specific

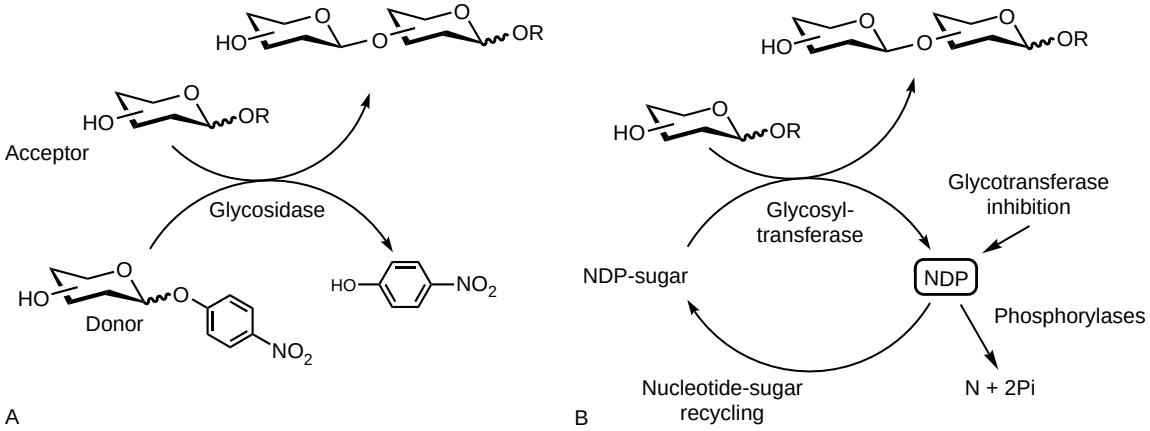

FIGURE 2 Enzymatic synthesis of oligosaccharides using: (A) glycosidases and (B) glycotransferases.

nucleotide-sugar donor, and also has specificity for certain oligosaccharide structures in its substrates. Because of this it is often difficult to make unnatural oligosaccharides using glycotransferases, but in some cases relaxed substrate and nucleotide-sugar specificity has been utilized to make unnatural carbohydrate chains. Formation of oligosaccharides with glycotransferases requires the substrate oligosaccharide, manganese, the nucleotide-sugar donor, and the glycotransferase itself in an appropriate buffer. Glycotransferase-catalyzed synthesis of carbohydrate chains usually results in high yields, approaching 100%, but the enzymatic reaction can suffer from product inhibition that has to be overcome to achieve those high yields. The use of glycotransferases in oligosaccharide synthesis is limited by the high cost of nucleotide sugars and the availability of glycotransferases that form certain oligosaccharide structures. Sugar-nucleotide recycling alleviates some of the former problem while genomic sequencing and research has started to alleviate some of the latter problem.

Product Inhibition in Glycotransferase Reactions

Though glycotransferases can be used to form oligosaccharides in nearly 100% yield, they suffer from product inhibition from the nucleoside diphosphates and nucleoside monophosphates that are produced as the activated nucleotide-sugar donors are transferred to the growing carbohydrate chain. This product inhibition can drastically slow the enzymatic reaction and also reduce the yield of product, and so it is desirable to remove the nucleotide by-products of the glycotransferase reactions. Two approaches can be used to overcome product inhibition in glycotransferase reactions use of phosphorylases and nucleotide-sugar recycling (Figure 2B).

Reduction of Glycotransferase Inhibition with Phosphorylases Nucleoside diphosphates and monophosphates can be converted into nucleosides, which do not inhibit glycotransferases, using phosphorylases. This is a very simple method, which requires only one or two additional enzymes to be added to the glycotransferase reaction. Unfortunately this method requires a stoichiometric amount of nucleotide-sugar donor for formation of the desired oligosaccharide, which can be quite costly on larger scales since nucleotide sugars are generally very expensive.

Reduction of Glycotransferase Inhibition with Nucleotide-Sugar Recycling Another method to remove nucleotide by-products of glycotransferase reactions is to regenerate the nucleotide-sugar donors from the nucleotide by-products using an enzymatic recycling reaction. This method of overcoming product inhibition is somewhat more complicated than using phosphorylases, requiring several additional enzymes for the nucleotide-sugar recycling reaction, but it allows a catalytic amount of nucleotide-sugar donor to be used in the glycotransferase reaction. Since nucleotide-sugars are generally expensive, this method is desirable for larger-scale glycotransferase reactions.

Chemical Synthesis of Oligosaccharides

Chemical synthesis of oligosaccharides is often the method of choice for constructing carbohydrate chains because chemical methods are flexible, can be used to produce both natural and unnatural oligosaccharides, and are also not limited by the availability of specific enzymes. Formation of glycosidic bonds by chemical methods usually relies upon activation of a leaving group on the anomeric carbon of a glycosyl donor with a

Lewis acid, which once activated will react with a free hydroxyl upon a glycosyl acceptor (Figure 3A). A wide variety of glycosyl leaving groups have been utilized for carbohydrate chain synthesis some of which are shown in Figure 3B.

Control of Stereochemistry in Chemical Glycosidic Bond Formation

Control of the stereochemistry of the anomeric linkage in the products of glycosylation reactions can be very complex, and many factors including types of protecting groups on the sugars, solvent, temperature, and leaving groups can be used to influence the α/β ratio of the products formed in glycosylation reactions. In general, the anomeric effect, stabilization of axial orientation over equatorial orientation of electron withdrawing groups attached to the C1 of pyranose sugars, can be utilized to produce α-linked glucosides and galactosides. Participation of protecting groups of the 2-OH, such as acetate, and the use of polar solvents in glycosylation reactions can direct products toward β-linked glucosides and galactosides through dioxocarbenium or solvent intermediates (Figure 3A). Sometimes it is difficult to obtain the desired anomer using chemical synthesis, as in the case of sialic acid glycosides, where the natural sialic acid linkage is exclusively the α-anomer, but the β-anomer is obtained from most chemical glycosylation reactions. Controlling the anomeric outcome of chemical glycosylation reactions can still be a difficult problem, and requires several approaches for different types of glycosidic linkages and sugars.

Protection of Sugar Hydroxyls in Chemical Carbohydrate Synthesis

Chemical oligosaccharide synthesis relies heavily upon sugar protecting groups to both distinguish between sugar hydroxyls with similar chemical reactivity and also to control the stereochemical outcome, either α or β, of glycosylation reactions. Because of this, chemical oligosaccharide synthesis typically requires a large amount of protecting group manipulations. Normally, protecting groups must be placed on hydroxyls that are not going to be used to form glycosidic linkages to prevent them from reacting in glycosylation reactions. In addition, the synthesis of carbohydrate chains longer than two sugars requires sugar subunits that can act both as glycosyl donors and acceptors, and this usually requires selective protection and deprotection of the hydroxyls that are to form glycosidic linkages. Selective protection of sugar subunits for glycosylation reactions often requires many chemical steps to produce each selectively protected subunit for the synthesis of an oligosaccharide, and this is one factor that can contribute to the large number of steps required for chemical oligosaccharide syntheses. Some protecting groups commonly used in chemical carbohydrate chain synthesis include benzyl ethers, *p*-methoxybenzyl ethers, *tert*-butyl-diphenylsilyl ethers, *tert*-butyl-dimethylsilyl ethers, allyl ethers, acetate esters, benzoate esters, levulinoyl esters, and dimethyl acetals.

Solution Phase Chemical Oligosaccharide Synthesis

In conventional solution-phase oligosaccharide synthesis, a donor sugar is activated by a Lewis acid at the anomeric carbon, and then reacted with an acceptor

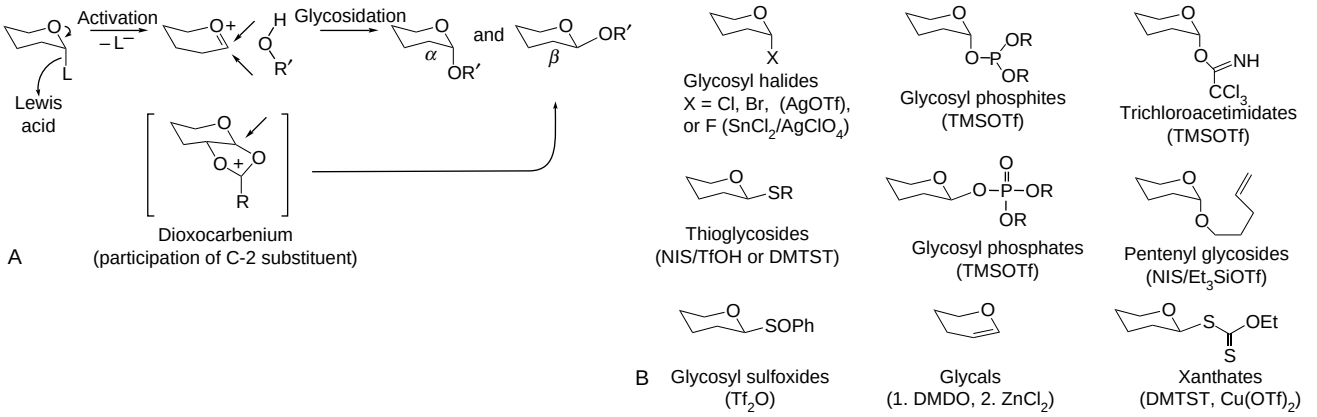

FIGURE 3 Chemical glycosylation reactions. (A) Mechanism of glycosylation. (B) Some commonly used glycosylation leaving groups and the reagents used to activator them (in parentheses). Abbreviations: L, leaving group; R, variable group; TMSOTf, trimethylsilyl triflate; NIS, N-iodosuccinimide; TfOH, triflic acid; Et_3SiOTf, triethylsilyl triflate; Tf_2O, triflic anhydride; DMDO, 3,3-dimethyldioxirane; DMTST, dimethylthiosulfonium triflate.

sugar that contains a free hydroxyl. Once the glycosidic bond has been formed, the product disaccharide must be purified away from other glycosylation reaction reagents and side products, and then selectively deprotected to unmask a single hydroxyl so that it can then act as a glycosyl acceptor in the next glycosylation reaction (Figure 4A). Purification is often necessary after each glycosylation and deprotection step in the preparation of an oligosaccharide by solution phase synthesis. When combined with the number of steps necessary to produce selectively protected sugar subunits, the number of chemical steps and purifications necessary to construct even small oligosaccharides can be very large.

Automated Oligosaccharide Synthesis

Because of the large amount of work necessary to construct even relatively small oligosaccharides by solution-phase synthesis, many approaches toward automating oligosaccharide synthesis have been developed in hopes of minimizing the number of chemical steps and purifications required to synthesize oligosaccharides. Two approaches to automated oligosaccharide synthesis will be discussed below: solid-phase oligosaccharide synthesis and programmable one-pot oligosaccharide synthesis.

Solid-Phase Chemical Oligosaccharide Synthesis

In solid-phase oligosaccharide synthesis, either the glycosyl donor or acceptor of a glycosylation reaction is attached to the solid phase. The advantage of this is that large excesses of the other components of the glycosylation reaction can be used to increase the rate of the reaction and insure that it goes to completion, and then rinsed away by simple filtration. This has the potential of increasing the yield of glycosylation reactions and also eliminates many of the laborious purification steps that are necessary in solution-phase oligosaccharide synthesis (Figure 4B). Unfortunately there are many technical difficulties that must be overcome to successfully apply solid-phase synthesis to the production of oligosaccharides. Solid supports that function well with many solvents must be selected, since a wide variety of solvents are used to affect the outcome of glycosylation reactions. Linkers must be developed that are not sterically hindering for glycosylation reactions, stable to glycosylation conditions, and easily cleaved after the oligosaccharide has been synthesized. Strategies for protecting sugar monomers that allow highly flexible and selective deprotection of sugar hydroxyl groups in the presence of many other protected hydroxyls must be worked out. Since the reaction conditions of glycosidic bond formation can vary widely depending on oligosaccharide structure and the types of glycosidic linkages to be formed, there has been great difficulty in developing broadly applicable general methods for solid-phase oligosaccharide synthesis. Nevertheless, there have been many notable examples of successful solid-phase syntheses including the synthesis of a dodecasaccharide by both the Nicolaou and Seeberger groups.

Programmable One-Pot Oligosaccharide Synthesis

One-pot reaction approaches that involve conducting several sequential glycosylation reactions in one reaction flask have been developed to facilitate automated oligosaccharide synthesis. The one-pot approach relies upon using a reactivity profile of protected sugars to determine what sequence of sugars to add to glycosylation reactions to obtain the desired products. Protected sugars are added to one-pot reactions in the order of most reactive to least reactive, thereby controlling the order of glycosidic bond formation during the synthesis of carbohydrate chains (Figure 4C). Since it has been shown that the types of protecting groups and type of anomeric activating groups used on sugars can greatly alter the speed at which a sugar will react in a glycosylation reaction, a wide range of reactivities can be obtained for a single type of sugar, allowing wide flexibility in oligosaccharide synthesis using this approach. The one-pot approach greatly reduces the number of steps necessary to construct oligosaccharides and eliminates several tedious purifications by combining multiple glycosylation reactions into a single one-pot reaction. The one-pot approach also minimizes protecting group manipulations, eliminating protecting group manipulations after construction of the building blocks. A large number of *p*-methylphenyl thioglycosides have been synthesized and had their reactivities measured to facilitate the use of this strategy. A computer program, OptiMer, has been developed that uses these *p*-methylphenyl thioglycosides as a set of building blocks to choose from to build oligosaccharides. When a carbohydrate chain structure is entered as input, the OptiMer program will calculate the best set of reactants for the construction of that carbohydrate chain. Because the programmable one-pot strategy requires a minimum of protecting group manipulations and has a large library of building blocks, a wide range of oligosaccharide structures can be synthesized rapidly using this method.

Carnitine and β-Oxidation

Janos Kerner and Charles L. Hoppel
Case Western Reserve University School of Medicine, Louis Stokes VA Medical Center, Cleveland, Ohio, USA

Carnitine is derived from the essential amino acids lysine and methionine. It is ubiquitous in nature, found in especially high concentration in muscle tissue of higher organisms. It functions as a transport vehicle for activated fatty acids of different chain length through membranes within the cell. This transport function is best characterized in mitochondrial oxidation of long-chain fatty acids. This latter process, also known as mitochondrial β-oxidation, represents the repetitive oxidative cleavage of long-chain fatty acids into two-carbon units, acetyl-CoA. Acetyl-CoA is then either further oxidized for energy production (all tissues) or used to synthesize ketone bodies (liver) as metabolic fuel for peripheral tissues.

Carnitine Biosynthesis and Homeostasis

The first clue about the physiological function of carnitine (Figure 1) came from studies in the mealworm, *Tenebrio molitor*, that suggested that carnitine plays a vital function in fat catabolism. However, carnitine is not a vitamin for higher animals; the daily need is met by endogenous synthesis and dietary intake, mostly from meat products. For endogenous synthesis, the ultimate precursors are the essential amino acids lysine and methionine. Protein-bound lysine is methylated to trimethyllysine using S-adenosylmethionine; following liberation by proteolysis, the free trimethyllysine is converted (mostly in muscle) by a series of reactions to butyrobetaine, the ultimate carnitine precursor. Although most tissues are capable of synthesizing butyrobetaine, the hydroxylation of butyrobetaine to carnitine is restricted to the liver (and to a lesser extent to the kidney and brain). Following release of carnitine from the liver into the plasma, carnitine is taken up by other tissues in a carrier-mediated transport process (Figure 2).

The body distribution of carnitine is determined by a series of systems that transport carnitine into cells against a concentration gradient, an independent efflux process, and an exchange mechanism in a tissue-specific fashion. Under physiological conditions, plasma carnitine concentration is maintained within a narrow range, predominantly by renal clearance, which is determined by the kinetic properties of carnitine transport system in the brush border.

Functions of Carnitine

In higher animals, the only reaction carnitine undergoes is a reversible transesterification with acyl-CoAs catalyzed by carnitine acyltransferases of differing chain length specificity (carnitine acetyl-, octanoyl-, and palmitoyltransferases) (Figure 3).

All known functions of carnitine are based on the reversible transesterification with acyl-CoA esters. The physiologically most important and therefore best studied metabolic pathway in which carnitine plays a significant role is the mitochondrial oxidation of long-chain fatty acids.

Mitochondrial β-Oxidation

Cellular Uptake and Activation of Long-Chain Fatty Acids

Long-chain fatty acids represent a main energy source for many organs, especially for muscle (heart and skeletal) and liver. Since most tissues contain only small amounts of storage lipids, for energy production they depend on a continuous supply of fatty acids, mostly from adipose tissue. Following mobilization by lipolysis in adipose tissue and transport in the blood bound to albumin, fatty acids are taken up by the tissues in a process mediated by transport proteins present in the plasma membrane. Once within the cell, free fatty acids are bound to fatty acid binding proteins, which are present in the cytosol in large amounts. Depending on the tissue and its metabolic demand, fatty acids are converted to triglycerides and stored, secreted as very-low-density lipoproteins (liver), or oxidized in the mitochondria for energy production. Before being directed into storage or oxidation, fatty acids first are activated to acyl-CoA esters. This reaction is catalyzed by long-chain acyl-CoA synthetase, an enzyme present in abundance both in microsomes and in mitochondria. In mitochondria, long-chain acyl-CoA synthetase is

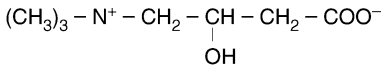

FIGURE 1 Structure of L-carnitine (4-N-trimethylammonio-3-hydroxybutanoate).

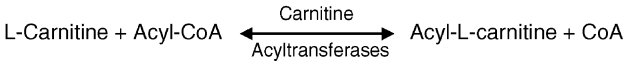

FIGURE 3 Reversible transesterification of carnitine catalyzed by carnitine acyltransferases with different chain-lengths specificity.

associated with the mitochondrial outer membrane and appears to be a transmembrane protein with its active site exposed to the cytosol. This orientation of long-chain acyl-CoA synthetase gives rise to cytosolic production of long-chain acyl-CoAs, which for their further β-oxidation must cross both mitochondrial boundary membranes. Although the impermeability of the inner membrane to metabolites is well known, it is now recognized that the outer membrane is not freely permeable to solutes as previously thought. A potential route for long-chain acyl-CoAs to cross the outer membrane is the voltage-dependent, anion-selective channel (VDAC), also called mitochondrial porin, which occurs at high density in the mitochondrial outer membrane and regulates the permeability of this membrane to ions and metabolites (Figure 4).

Mitochondrial Uptake of Activated Fatty Acids: The Mitochondrial Carnitine System

The mitochondrial carnitine system plays an obligatory role in β-oxidation of long-chain fatty acids by providing a means for their transport into the mitochondrial matrix. This transport system consists of the malonyl-CoA sensitive carnitine palmitoyltransferase-I (CPT-I) localized in the mitochondrial outer membrane, the carnitine:acylcarnitine translocase, an integral inner membrane protein, and carnitine palmitoyltransferase-II (CPT-II) localized on the matrix side of the inner membrane. In the schema depicted in Figure 4, the catalytic site of CPT-I faces the intermembrane space. In an alternative model, the catalytic site of CPT-I faces the cytosol. In this scenario, the carnitine esters must cross both mitochondrial membranes. In either case, transesterification of long-chain acyl-CoA esters to their carnitine esters by CPT-I commits activated fatty acids to oxidation in the mitochondrial matrix.

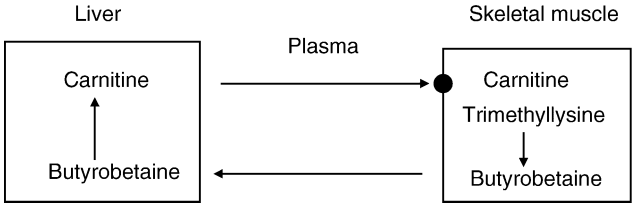

FIGURE 2 Interorgan relationship in carnitine biosynthesis.

CPT-I, by virtue of its inhibition by malonyl-CoA, represents a key regulatory site controlling the flux through β-oxidation. Consistent with its central role in mitochondrial fatty acid oxidation, the enzyme exists in at least two isoforms with significantly different kinetic and regulatory properties. The liver type displays a higher affinity for carnitine and a lower affinity for the physiological inhibitor, malonyl-CoA, as opposed to the muscle isoform. Long-term regulation of both isoforms is accomplished at the transcriptional level. Short-term or acute regulation is achieved via changes in tissue malonyl-CoA concentration, and for the liver isoform also via changes in the enzyme's sensitivity to malonyl-CoA inhibition.

The long-chain acylcarnitines formed by CPT-I in the mitochondrial outer membrane enter the mitochondrial matrix in exchange for free carnitine catalyzed by the carnitine:acylcarnitine translocase, an integral inner membrane protein. The carnitine:acylcarnitine translocase catalyzes a homologous/heterologous carnitine exchange (in addition to the slow unidirectional carnitine transport) and displays increasing affinity for carnitine esters with increasing acyl chain length. Experimental data suggest the existence of a single transporter protein with a substrate specificity ranging

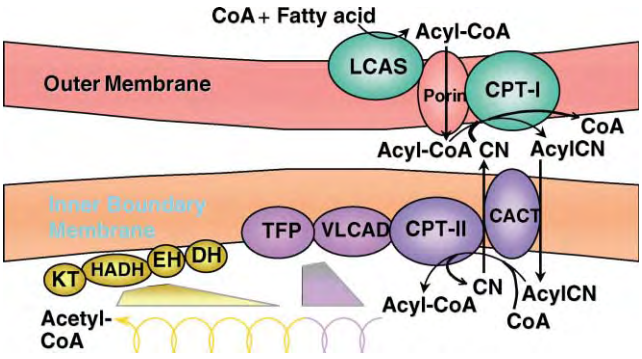

FIGURE 4 Schematic depiction of the carnitine-dependent transport of activated fatty acids into the mitochondrial matrix and of their oxidative chain shortening via the β-oxidation pathway. CACT, carnitine:acylcarnitine translocase; CN, carnitine; CPT-I, malonyl-CoA sensitive carnitine palmitoyltransferase; CPT-II, malonyl-CoA insensitive carnitine palmitoyltransferase; DH, acyl-CoA dehydrogenase; EH, enoyl-CoA hydratase; HADH, 3-hydroxyacyl-CoA dehydrogenase; KT, 3-ketoacyl-CoA thiolase; LCAS, long-chain acyl-CoA synthetase; TFP, trifunctional protein; VLCAD, very-long-chain acyl-CoA dehydrogenase.

from free carnitine to long-chain carnitine esters. This is in contrast to the known substrate specificity of the mitochondrial carnitine acyltransferases (carnitine palmitoyl- and acetyltransferase) and implies that in addition to its role in mitochondrial fatty acid oxidation, the same transporter also is engaged in other functions involving membrane transport of acyl groups.

Following the translocation of long-chain acylcarnitines by carnitine:acylcarnitine translocase into the mitochondrial matrix, the carnitine esters are reconverted to their respective CoA esters by CPT-II, thus completing the carnitine-dependent uptake of activated fatty acids. Within the matrix, CPT-II is anchored to the inner membrane as a peripheral membrane protein. The enzyme has been isolated in catalytically active form from a variety of tissues, and its physical, kinetic, and immunological properties have been determined. CPT-II is the product of a single gene and is expressed as the same protein in all tissues within the body. It is not inhibited by malonyl-CoA, either in its native environment (membrane-bound) or when isolated.

Pathway of Mitochondrial β-Oxidation

In the fatty acid oxidation cycle, the activated long-chain fatty acid undergoes a consecutive oxidative chain shortening. Each cycle of this sequence of four reactions results in the removal of two-carbon atoms from the fatty acyl residue in the form of acetyl-CoA (Figures 4 and 5) and two reducing equivalents (FADH and NADH). Thus, the complete oxidation of palmitoyl-CoA requires seven cycles, yielding eight acetyl-CoAs and seven FADH and NADH. Acetyl-CoA is then further oxidized in the tricarboxylic acid cycle to CO_2 and reducing equivalents, each acetyl-CoA yielding three NADH and one FADH. The reoxidation of these reducing equivalents in the electron transport chain then produces ATP. The complete oxidation of 1 mole palmitic acid thus results in the formation of 131 moles ATP. On a molar basis, this is 3.6 times more ATP generated (on a weight basis, 2.5 times more) compared to an equivalent amount of glucose.

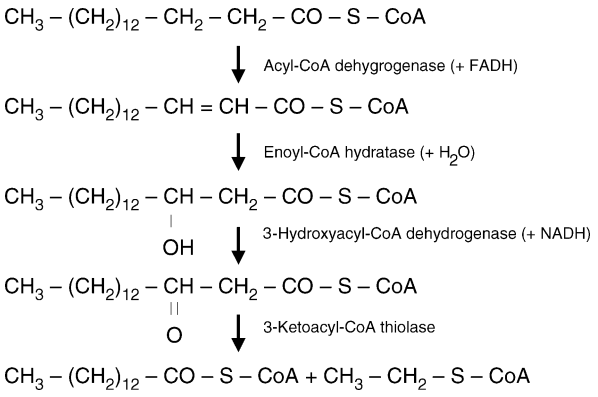

FIGURE 5 Reactions of mitochondrial β-oxidation of saturated long-chain acyl-CoAs.

The first of the four reactions in mitochondrial β-oxidation of activated long-chain fatty acids is catalyzed by the acyl-CoA dehydrogenases, a group of enzymes with differing but somewhat overlapping chain-length specificity (very-long-chain, long-chain, medium-chain, and short-chain), resulting in the formation of 2-*trans*-enoyl-CoA. They are composed of four identical subunits, each of which contains a non-covalently bound flavin adenine dinucleotide (FAD). The enzyme is reoxidized via the electron-transferring flavoprotein and then in the electron transport chain by electron-transferring flavoprotein:ubiquinone oxidoreductase.

The second step of β-oxidation is catalyzed by 2-enoyl-CoA hydratases converting 2-*trans*-enoyl-CoA to 3-hydroxyacyl-CoA. This reaction is catalyzed by the membrane-bound long-chain trifunctional protein TFP, formerly known as the long-chain enoyl-CoA hydratase. The TFP is composed of two nonidentical subunits, the α and β subunits, present in a 1:1 molar ratio. The enzyme comprises the catalytic activities of 2-enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase (α subunit) and 3-ketoacyl-CoA thiolase (β subunit). The soluble short-chain specific form, also known as crotonase, catalyzes the hydration of short-chain 2-enoyl-CoAs.

The third reaction is catalyzed by 3-hydroxyacyl-CoA dehydrogenases. At least two 3-hydroxyacyl-CoA dehydrogenase activities are found in the mitochondria. In addition to the TFP, there also is a short-chain specific form. The latter is composed of two identical subunits. Both activities require NAD as a cofactor. The NADH formed is then reoxidized by complex I of the electron transport chain.

The last reaction of the β-oxidation spiral is the thiolytic cleavage of 3-ketoacyl-CoA catalyzed by 3-ketoacyl-CoA thiolases. The general acyl-CoA thiolase and the long-chain 3-ketoacyl thiolase of the TFP have overlapping substrate specificities. The reaction is greatly in favor of product formation. There also is a third thiolase enzyme present in mitochondria called acetyl-CoA acetyltransferase or acetoacetyl-CoA thiolase. This enzyme is specific for acetoacetyl-CoA and 2-methylacetoacetyl-CoA and probably is involved in branched-chain amino acid metabolism, in ketogenesis, and in ketone body utilization.

The oxidation of (poly)unsaturated fatty acids requires auxiliary enzymes for their complete β-oxidation. Most unsaturated fatty acids have their double bonds in *cis* configuration with the first double bond between carbon atoms 9 and 10. Additional double bonds, if any, occur at three-carbon intervals.

Several cycles of β-oxidation yield a chain-shortened acyl-CoA with a *cis* double bond in 3, 4 position that is not a substrate for enoyl-CoA hydratase. Isomerization catalyzed by 2,3-enoyl-CoA isomerase leads to 2-*trans*-enoyl-CoA, which can undergo further β-oxidation, yielding after two additional cycles *trans*-2, *cis*-4-dienoyl-CoA, which also is a poor substrate for enoyl-CoA hydratase. The *cis*-4 double bond is reduced by the enzyme 2,4-dienoyl-CoA reductase, producing *trans*-3-enoyl-CoA, which is isomerized to *trans*-2-enoyl-CoA by 2,3-enoyl-CoA isomerase.

The rate of β-oxidation is adjusted to physiological needs and is subject to control in which substrate supply is important. The reaction catalyzed by CPT-I committing activated fatty acids toward oxidation in the mitochondria often is considered rate limiting. The regulatory property that imparts such control to this otherwise near-equilibrium reaction is the inhibition of CPT-I by malonyl-CoA. The muscle isoform of CPT-I is extremely sensitive to inhibition by malonyl-CoA, and it is thought that in heart and skeletal muscle, CPT-I is regulated only by changes in tissue malonyl-CoA concentrations. The liver isoform of CPT-I is much less sensitive to malonyl-CoA inhibition, and in liver the entry of activated fatty acids into the mitochondria is controlled by changes in the enzyme's sensitivity to malonyl-CoA as well as by changes in hepatic malonyl-CoA concentrations.

Although the mitochondrial uptake of long-chain activated fatty acids is absolutely carnitine dependent, the efficiency of the system is such that under physiological conditions, tissue carnitine concentrations seemingly have no significant impact on this process.

The control of β-oxidation flux by the redox state of NAD/NADH and FAD/FADH (ETF/$ETFH_2$) as well as by the acetyl-CoA/CoA ratio is important under some conditions.

Regulation of Mitochondrial Acyl-CoA/CoA Ratio

β-oxidation is not the only pathway in which carnitine plays a role as a carrier of activated acyl groups. In conjunction with carnitine acetyltransferase and carnitine:acylcarnitine translocase, carnitine forms an effective shuttle system for acetyl groups out of the mitochondria, thus preventing sequestration of intramitochondrial free CoA. This acetyl-CoA buffer function allows CoA-dependent reactions such as pyruvate oxidation to proceed unimpaired. The CoA buffer function is not restricted to acetyl-CoA. Under normal physiological conditions, long-chain fatty acid movement is directed into the mitochondrial matrix. However, the carnitine:acylcarnitine translocase and CPT-II/carnitine acetyltransferase system can under certain conditions operate in the reverse direction, e.g., removing activated short-, medium-, and long-chain acyl groups from the matrix. This buffering has been demonstrated with isolated mitochondria as well as with cultured fibroblasts and lymphocytes from patients with defects in mitochondrial fatty acid oxidation. The accumulation of cellular acyl-CoAs as a result of an inborn error of fatty acid metabolism leads to a corresponding increase in acylcarnitines in the cell. In contrast to the acyl-CoAs, the acylcarnitines can be transported across the plasma membrane into the blood. The identification of these acylcarnitines in blood thus is a signpost for the metabolic defect.

Gerry Melino
MRC Toxicology Unit, Leicester University, Leicester, UK

Caspases are cysteine proteases involved in cell death. The name "caspase" is derived from *c*ysteinyl aspartate-specific protease, i.e., proteases which cleave after an aspartate. The caspase family is comprised of 13 proteins in humans, seven in *D. melanogaster*, and a single protein in *C. elegans*. All caspases consist of three structural domains: a prodomain, a large subunit, and a small subunit. The prodomain is important for the regulation of the enzymatic activation of caspases; the active enzyme consists of the small and large subunits together. To obtain an enzymatically active enzyme, the three subunits must be proteolytically cleaved, which is effected by other endoproteases, normally also a caspase. This article discusses caspases in the context of cell death.

History and Classification

Caspases were first identified in 1989 by Sleath and Schmidt as a protease required for the activation of interleukin-1β. In 1993, the group of Bob Horvitz discovered that the cell death gene ced-3 is a protease belonging to the same family. In 1999, the first human genetic disease caused by mutation of a caspase (type 10) was identified by Michael Lenardo.

Phylogenetic analyses, and also studies of substrate specificity, indicate that caspases can be subdivided into three different groups. Figure 1 reports the present classification of the human caspases.

Group 1 includes caspases 1, 4, 5, and 12, which are involved in inflammation. The prototype of this group is caspase 1, previously known as interleukin conversion enzyme 1β, or ICE. Its enzymatic activity was identified in 1989, but the enzyme was only purified and cloned in 1992, the same year in which Lois Miller identified the first inhibitor, the viral protein CrmA. Caspase 1, or ICE, controls the maturation of IL-1β, actively participating in the inflammatory response. Site P4 of the substrate is preferentially a hydrophobic residue.

Group 2 includes caspases 2, 3, and 7, shown by a star in Figure 1. The prototype of this group is caspase 3, the homologue of ced-3 in *C. elegans*. Group 2 caspases are directly involved in apoptosis in the terminal effector phases. Group 2 caspases have a very small prodomain, indicating a simple regulation of their enzymatic activation. These caspases are in general activated directly by another caspase, in a cascade of enzymatic amplification. Site P4 of the substrate is preferentially an Asp (D) residue. Site P3 of the substrate is preferentially a Glu (E) residue. Therefore, this subfamily preferentially cleaves substrates with the sequence DExD.

Group 3 consists of caspases 6, 8, 9, and 10. These caspases have a very large prodomain, and therefore a complex mechanism of activation. In fact, these caspases need molecular adaptors to be enzymatically activated, in contrast to group 2 caspases. Caspases 8 and 10 are part of the signal transduction mechanism of apoptosis receptors such as CD95; in this case, the adaptor molecule is FADD. Caspase 9 is activated in the apoptosome, and the necessary adaptor molecule is Apaf-1. Site P4 of the substrate is preferentially an aliphatic residue.

Structure and Active Site

As already mentioned, caspases consist of three structural domains: a prodomain, a large subunit (also named as p20), and a small subunit (called p10).

The enzyme is constituted of the small and large subunits (p20/p10, ~30 kDa). In fact, the active site is mostly in the p20 subunit: it can be further classified into four different subsites, S4 to S1. The S1 subsite, which attacks the carboxyl group of the polypeptide side chain in P1 (the site of cleavage is Asp-D), is composed of p20 as well as p10 subunits. Similarly, the site for recognition and positioning of the substrate (S4–S1) is furnished by both p20 and p10, even though the residues mostly

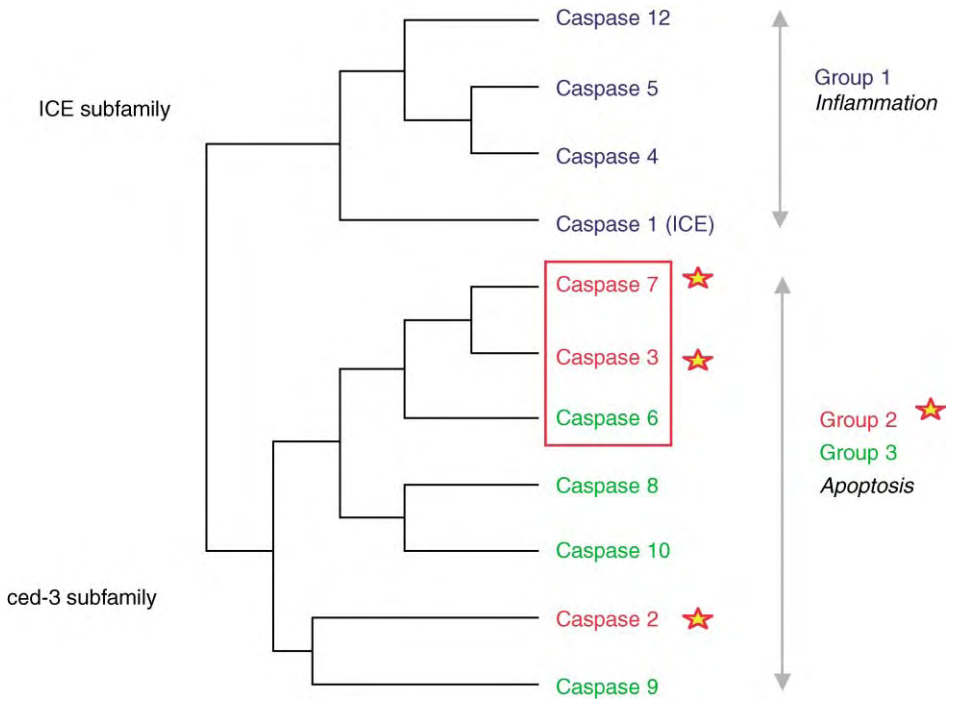

FIGURE 1 The human caspases family. Classification of the human caspases. According to the phylogenic tree, caspases are subdivided in two major subfamilies, ICE and ced-3. The former are involved in inflammation, and the latter in apoptosis. The caspases with a very short prodomains (<30 a.a.) are boxed (types 3, 6, 7); all the other enzymes have long prodromains (>10 kDa) subject to complex regulation. The enzymes can be divided according to their proteolytic specificity into group 1, involved in cytokine maturation, group 2, involved in the final effector phase of apoptosis (indicated by a star), and group 3, involved in the upstream regulation of apoptosis. At least two gene clusters have been identified, consistent with some caspases arising from tandem gene duplication. Caspase 13 is an error of sequencing; caspase 12 is mutated into a nonfunctional enzyme in up to 90% of the human population; caspase 11 is involved in neuronal death; caspase 14 is involved in skin differentiation. Please note that caspases are not indicated in the scheme. Modified from Nicholson, D. W. (2000). From bench to clinic with apoptosis-based therapeutic agents. *Nature* **407**, 810–816.

responsible for specificity (S4) are contained in p10 (Figure 2).

Caspases enzymatically function as dimers of two identical molecules bound to each other. Figure 2 shows a very schematic view of the dimer formation.

Each monomer (p20/p10) is formed by a compact cylinder dominated by six β-sheets and five α-helices distributed on the opposite site of the plane formed by the β-sheets. The dimer (p20/p10)2 contains two (p20/p10) units aligned head to tail, which therefore position their respective active sites on opposite sides of the molecule. While there are two active sites, their cooperation has never been observed. The orientation of the molecule indicates a specific mechanism of activation, well regulated with security systems (a "safety catch").

Substrate Recognition

The substrate recognition site of the caspase is indicated as S4–S1, at which the substrate is bound at residues P4–P1 (Figure 3). This recognition guarantees an absolute specificity. The S4–S1 substrate recognition site varies in each caspase, even if S1 is absolutely constant and highly tight. This is responsible for the absolute specificity to bind Asp (D) as the substrate residue P4. In fact, Asp is physically constrained and held by a hydrogen bond with Arg179, Gln283, and Arg341 (the numbers refer to caspase 3). The dimensions of the S1 subsite are reduced to a minimum and are therefore responsible for the lack of tolerance for P1 (Arg). Bond sites P2 and P3 (subsites S2 and S3) are more tolerant, less specific, and more heterogeneous in the various caspases. Therefore, the substrate (or the inhibitor) positions itself within the S1–S4 site, creating interactions as hydrogen bonds with Ser339 and Arg341 (conserved in practically all of the caspases). The P4 (S4) binding site is the major determinant of specificity.

Mechanism of Action

Caspases are cysteine proteases and, therefore, possess a catalytic triad, which includes a cysteine (active site) in the vicinity of a histidine. The third component of the classical catalytic triad typical of cysteine proteases is

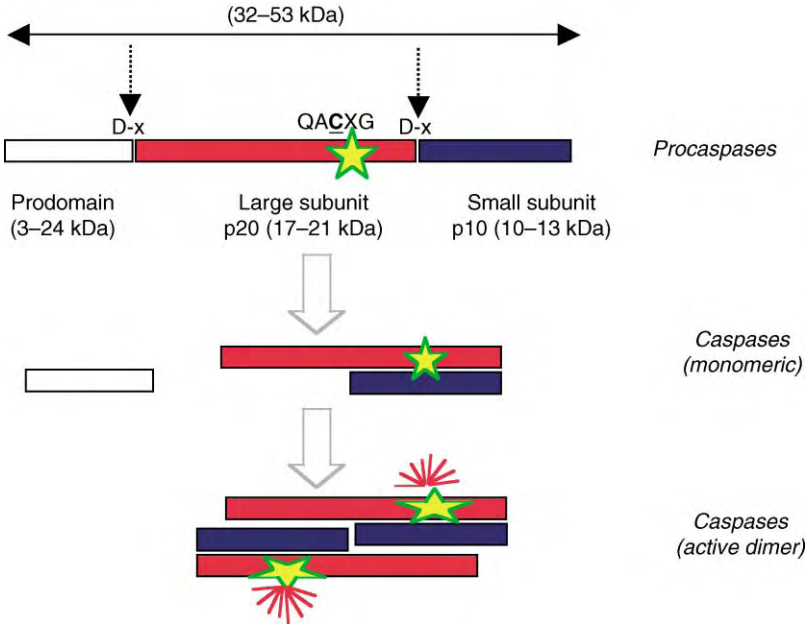

FIGURE 2 Structural organization and activation of caspases. The caspases are produced as proenzymes (32–53 kDa), including a prodomain (3–24 kDa), the large subunit (17–21 kDa) containing the active site, and the small subunit (10–13 kDa). To become enzymatically active, these three components must be proteolytically cleaved (D-x site), a phenomemon that is regulated by the prodomain itself; this allows the assembly of the large and small subunits, with the dimerization into a functional enzyme.

not constant in caspases, and its function can be substituted by different groups in different components of the family. For example, if we consider caspase 3, subsequent to substrate binding, the catalysis can take place with the catalytic diad Cys285 and His237. In fact, the third element of the cysteine protease triad is substituted by an ossianionic bond formed with Gly238 and Cys285 (conserved in all caspases).

Sequence of Action

While the regulatory caspases of the death receptor (types 8 and 10) or of the apoptosome (type 9) participate in signal transmission, the effector caspases (types 3, 6 and 7) determine the death of the cell. Effector caspases are diverse, and are not activated in parallel, but in a sequential manner, resulting in an amplification cascade of proteolytic cleavage (vaguely similar to the cascade of proteolytic activation and amplification of the complement system, or blood coagulation). These cascades have the effect of augmenting the signal.

In the apoptosome, the first caspase to be activated is caspase 9. This in turn activates caspases 3 and 7. Caspase 3 is also able to proteolytically activate caspase 9, therefore creating a reciprocating loop of potentiation.

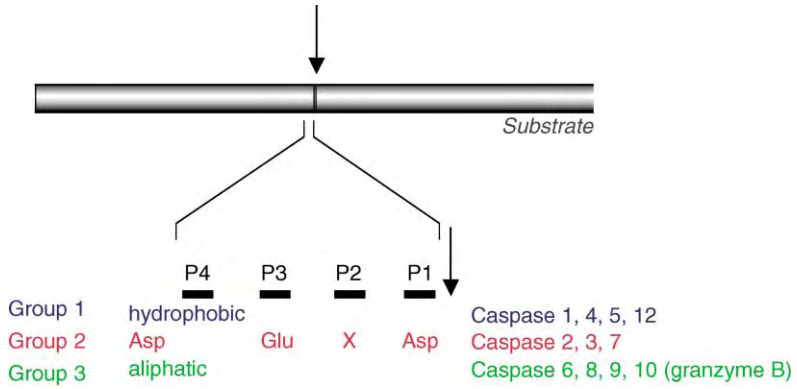

FIGURE 3 Caspase proteolytic specificity. The caspases recognize a tetrapeptide motif corresponding to the four residues P4–P3–P2–P1. While the positions at P3 and P1 seem to be obligatory, the position P4 allows the classification of three subfamilies (Figure 5). This property has facilitated the identification of group-specific inhibitors.

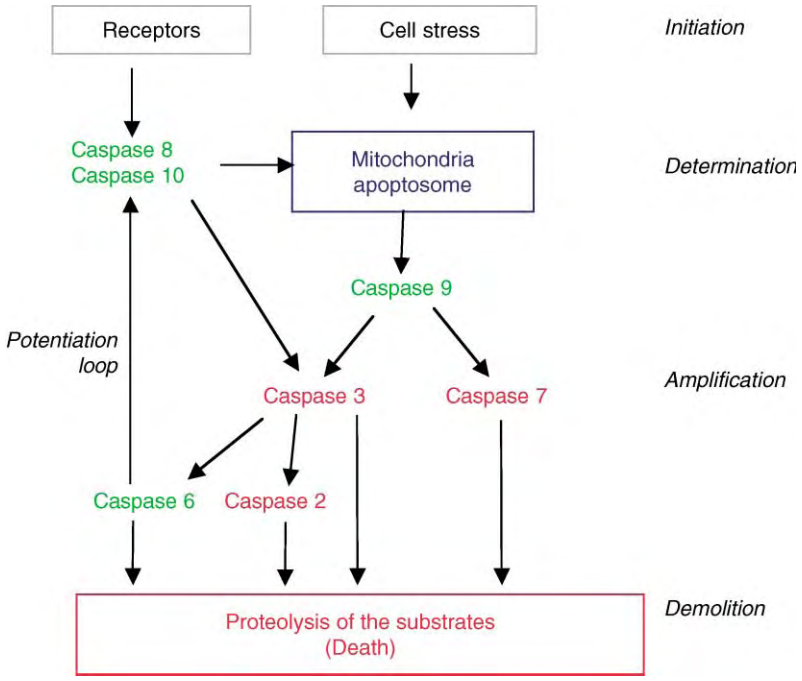

FIGURE 4 Sequential activation of caspases. In general, caspases with a long prodomain are involved in the upstream regulation and activation of the apoptotic pathway; they require a tight regulation and activation; furthermore, they cleave very specific substrates. Caspases with a short prodomain are involved in the amplification of the effector cascade, thus they have a very simple, fast, and direct activation, and they also have many substrates, inactivation of which finally kills the cell. Caspase 6 seems to be able to reactivate the upstream regulatory caspases, creating a feedback forward potentiation loop that strongly enhances the amplification of the death signal. Color code is in keeping with Figure 4. Modified from Slee, E. A., Adrian, C., and Martin, S. J. (1999). Serial killers: Ordering caspase activation events in apoptosis. *Cell Death Diff.* **6**, 1067–1074.

Caspase 3 proteolytically activates caspases 6 and 2. At this point, caspases 3, 7, 6, and 2 are highly activated and work to proteolytically cleave their intracellular substrates and determine cell death itself. A diagram of this order of activation is depicted in Figure 4.

Caspase 6 can also proteolytically activate the apical regulatory caspases 8 and 10, therefore creating a further loop of potentiation, which further enhances the death receptor signals. Figures 5–7 show the caspase activation, the apoptic pathway in humans, and the regulation of the apical regulatory caspases.

Schematically we can redefine the molecular phases of apoptosis in the following manner: (1) "initiation," activation of death receptors (caspases 8 and 10), (2) "determination," activation of the apoptosome (caspase 9), (3) "amplification," increase in the type and number of active caspases (caspases 3, 7, 6, and 2) and apical reactivation loop (caspases 8 and 10), and (4) "demolition," proteolytic cleavage of over 250 different substrates which determine the death of the cell (Figure 4).

Substrates during Apoptosis

Experimental studies indicate that over 700 different polypeptides can be generated during apoptosis. Up to

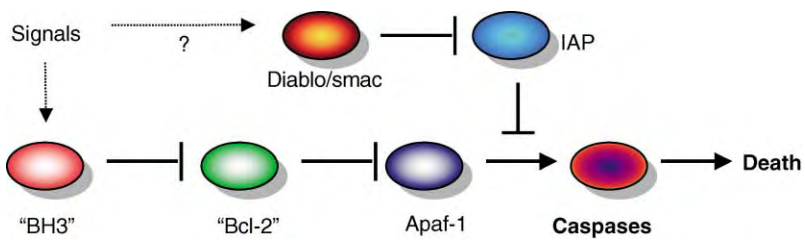

FIGURE 5 Caspases and cell death. Caspases are the proteolytic enzymes responsible for cell death. They are activated by an adaptor molecule (apaf-1), which in turn are controlled by the Bcl-2 family, and in particular by the "BH3-only" subfamily and the Bcl2-subfamily. The final stages of activation of the caspase can be regulated by a different pathway, the IAPs. This simple scheme is conserved in evolution from *C. elegans* and *D. melanogaster.*

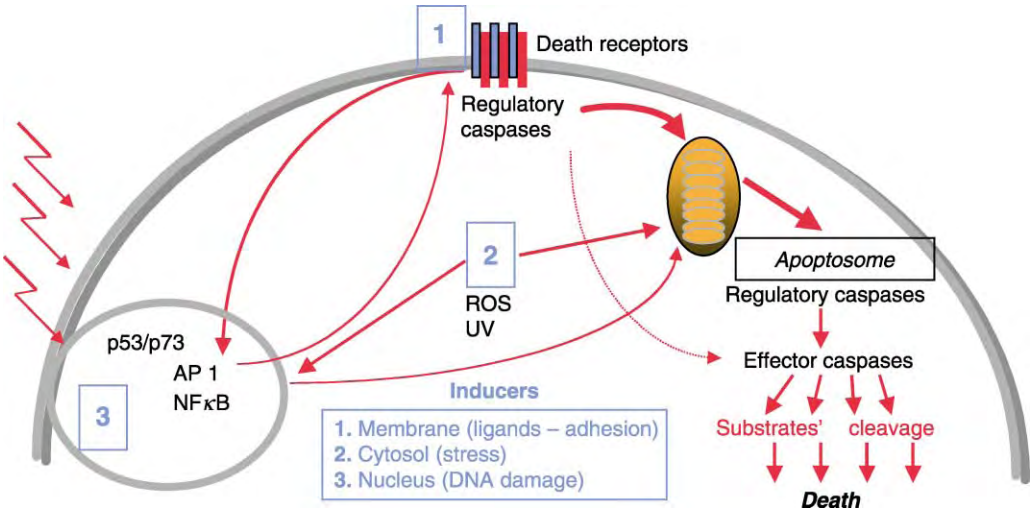

FIGURE 6 The apoptotic pathways in humans. In mammalian cells, apoptosis can de triggered at three different levels, as indicated. The signal converges to the apoptosome were the final effector phase occurs. Caspases are involved both in the upstream regulatory phase, and in the final terminal phase. The regulation at the level of the death receptor, and of the apoptosome is shown in greater detail in Figure 7.

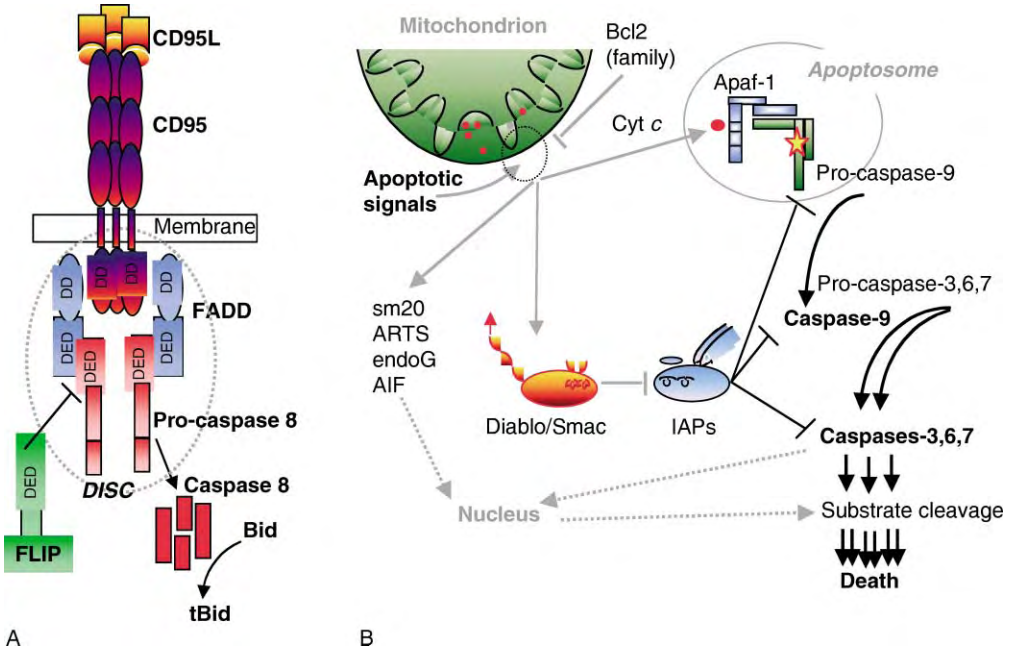

FIGURE 7 Regulation of the apical regulatory caspases. The general scheme is reported as Figure 6. (A) Formation of the death inducing signaling complex (DISC), following the activation of a death receptor such as CD95 (also called Fas or APO-1). Three molecules of ligand (CD95L) bind three molecules of receptor (CD95), allowing the recruitment of the adaptor molecule FADD via their death domain (DD). In turn FADD, via its death effector domain (DED), recruits and activates caspase 8, which cleaves the specific substrate Bid. Truncated Bid (tBid) is in fact the molecular signal that propagates the death signal to the mitochondria and the apoptosome. This mechanism can be inhibited by the molecule FLIP, via its DED. (B) When activated by apoptotic signals (e.g., by tBid), mitochondria release several molecules, as indicated. In particular, cytochrome *c* goes to the apoptosome (formed by cytochrome *c*, Apaf-1, pro-caspase 9, and dATP), and allows the activation of caspase 9. This in turns activates several molecules of downstream effector caspases (types 3, 6, 7), and consequently the cleavage of many cellular substrates results in cell death. Still at its terminal stage, cell death can be inhibited by specific inhibitory proteins (IAPs), but another mitochondria-released protein, Diablo/Smac, can remove the protection by IAPs. The cascade of proteolytic amplification created by caspase 9 (apical regulatory caspase) and caspases 3, 6, and 7 (downstream effector caspases) is extremely powerful.

2003, according to Schultze Ostoff, over 250 proteins have been found to be cleaved by caspases during the execution of apoptosis.

Table I indicates some of the principal substrates. The proteolytic cleavage of these substrates clearly renders the cell incapable of performing its proper functions.

Inhibitors

For practical reasons we distinguish pharmacological (Table II) and natural (Table III) inhibitors of caspases.

TABLE I

Caspase Substrates

DxxD site	*non-DxxD Site*
DNA-PKs	STAT1
PARP	Sp-1
Rad 51	SRP p72
Acinus	NFκB
CAD/DFF45	PITSLRE kinases
DNA-RTC140	PAK-2
Rb	p59 fyn
mdm2/HDM	CaMK-IV

LAP2	Raf 1
Nup153	Akt 1
Rabaptin-5	Cbl e Cbl-b
APC	PKN
Hsp90	Catenin-beta, -gamma
UbqCE NEDD4	Kinectin
Bcl 2	Caplastatin
Presenilin 2	Ataxin-3
Huntigtin	AMPA receptors
SBMA-AR	p27 kip1
Atrofin-1	MCM3

The substrates of caspases can have single cleavage site (e.g., DQTD in Gelsonin), nested multiple sties (e.g., DEVDGVD in PARP), redundant clustered sites (e.g., DSLD-(X13)-DEED-(X16)-DLND-(X32)-DGTD in Huntigtin), or distal multiple sites (e.g., DEPD and DAVD in ICAD).

TABLE II

Peptide Inhibitors of Caspases

	zVAD-fmk	aDEVD-cho	aYVAD-cho
Caspase 1	2	15	1
Caspase 2	2400	1700	>10 000
Caspase 3	40	1	>10 000
Caspase 4	130	130	360
Caspase 5	5	200	160
Caspase 6	100	30	>10 000
Caspase 7	40	2	>10 000
Caspase 8	2	1	350
Caspase 9	4	60	1000
Caspase 10		10	400

Inhibition constant (Ki, nM) shown is t1/2 at 1 μM in seconds.

Modified from Ekert, P. G., Silke, J., and Vaux, D. L. (1999). Caspase inhibitors. *Cell Death Diff.* **6**, 1081–1086.

The understanding of the molecular mechanism of catalysis and of the properties of the sites P4–P1 of the substrate were the basis for designating pharmacological inhibitors, both of polypeptide type and of low molecular weight compounds. The electrophylic groups, which interact irreversibly with the catalytic Cys are aldehydes, nitriles, and ketones, of which the latter are much more stable than the others *in vivo* and therefore are most easily applied to pharmaceutics. Caspase inhibitors are all constituted according to the following schema: [tetrapeptide]-C-CH2-X. Here X signifies a –Cl or –F (fluoro- or chloro-methyl ketone, fmk), -N2 (diazomethylketone), or –OCOR (acyloxymethylketone). The peptide portion (stabilized), determines the specific selectivity of the various caspases. Thus, zVAD-fmk is a nonspecific inhibitor of almost all of the caspases. DEVD-fmk, on the other hand, is specifically selective for effector caspases such as caspases 3, 6, and 7. Table II gives an idea of the specific inhibitors for different caspases.

In 1991, Lois Miller first identified a natural inhibitor of apoptosis, before even the discovery of caspases. The protein p35 produced by baculovirus (*Autographa californica*) is a potent and selective inhibitor of caspases. Subsequently, numerous other viral caspase inhibitors were identified, such as cytokine response modifier A (CrmA). Inhibition of caspases by these specific proteins is one of the important pathways among which viruses regulate apoptosis.

Numerous cellular proteins exist with actions similar to those of these viral caspase inhibitors. They are called IAPs (inhibitors of apoptosis). Table III shows the different viral and human IAPs with their relative inhibitory effects on each caspase.

All of the proteins which inhibit caspases, whether viral or cellular, are characterized by structural domains

TABLE III

Natural Caspase Inhibitors

	Viral			Cellular					
	crmA	p35	OpIAP	XIAP	cIAP1	cIAP2	Survivin	NAIPPI9	GBI
Caspase 1	0.01	9	Inib	NI	NI	NI			NI
Caspase 2	>10 000	Inib	Inib						
Caspase 3	1 600	0.1	NI	0.7	100	35	Inib	NI	
Caspase 4	1								
Caspase 5	0.1								
Caspase 6	110	0.4		NI	NI	NI			
Caspase 7	>10 000	2		0.2	40	30	Inib	NI	
Caspase 8	0.8	0.5		NI	NI	NI	NI		NI
Caspase 9	2			Inib	Inib	Inib			
Caspase 10	17	7							
Granzyme B	NI	NI							Inib

Inhibition constant (Ki, nM) shown is t1/2 at 1 μM in seconds. NI = noninhibitory, Inib = inhibitory.

Modified from Ekert, P. G., Silke, J., and Vaux, D. L. (1999). Caspase inhibitors. *Cell Death Diff.* **6**, 1081–1086.

called BIR (baculovirus IAP repeat), consequently all IAP proteins are also called BIR proteins (BIRp). On the other hand, the contrary does not hold: there are BIR proteins which do not show IAP activity. This fact is due to the prokaryotic origin of BIR proteins, which are multifunctional. Many BIR proteins in humans (e.g., survivin) are passenger proteins in the mitotic spindle and are implicated in cell division.

Caspase Knockouts

The creation of transgenic mice lacking specific caspases has been accomplished for most caspases. Table IV displays the phenotypes for these mice. Because caspases play a determining role in apoptosis, sometimes specifically, sometimes redundantly, the phenotypes are extremely diverse, as indicated by the table.

The role of caspases in the receptor mechanism is indicated by the caspase 8 knockout.

The similarity of the phenotypes of the knockouts of caspases 3, 9, and Apaf-1 indicate the presence of a very important mechanism in the apoptosome by which the amplification of the caspase cascade is initiated and regulated.

TABLE IV

Caspase Knockouts

	Development	Apoptotic phenotype
Caspase 1	Normal	Inflammation (CD95?)
Caspase 2	Normal	Germinal cells (stem cells?)
Caspase 3	Lethal PN	Neural
Caspase 6	Normal	
Caspase 7	Lethal E	
Caspase 8	Lethal E	Death receptors (CD95, TNF, DR3)
Caspase 9	Lethal E	Neural
Caspase 11	Normal	Thymocytes, neural (CD95?)

Often, the severity of the phenotype depends on the genetic background of the animals, as, for example, described in caspase 3.

E = embrionically lethal; PN = perinatally lethal.

Pathological Implications

The execution of apoptosis is dependent on the activation of caspases, and as a result, caspases play a determining role in all pathologies of excessive apoptosis. For example, caspases play a crucial role in the *in vivo* activation of death described in myocardial infarction and in cerebral ischemia, conditions in which cell death occurs both by apoptosis as well as by necrosis.

Caspases can also play an aberrant role in regulatory processes determining the major propensity or vulnerability of cells to lethal insults. Examples are the possible role played by caspases in triplet diseases such as Huntington's and in neurodegeneration like in Alzheimer's disease.

In the case of Huntington's disease, low level of intracellular activation of caspase 3 liberates an amino terminal fragment of the protein Huntington (four DxxD sites in a cluster), containing the Glu expansion, facilitating a pathological aggregation. In turn, this

aggregate sensitizes more caspase 3, forming a vicious cycle of activation and aggregation of poly-Glu. The cell, thus sensitized, facilitates the activation of caspase 8 (from the CD95 receptor, or directly by an effector caspase, or even stimulated indirectly by the poly-Glu aggregate), determining the death of the cell. This sensitization can also occur extremely slowly (years).

In Alzheimer's disease, caspase 3 alters the normal processing of the amyloid β-precursor protein (APP), removing the carboxy terminal. APP, deprived of the intramolecular reinternalization signal, proceeds down a route of degradation that results in the formation of the amyloid beta (Aβ) peptide, which can in turn favor the activation of apoptosis by means not yet clearly understood.

In either case, caspase 3 seems to augment the baseline levels (threshold?) of activation of cell death, rendering the cell more sensitive to death, and participating therefore in the pathogenetic mechanisms of these important illnesses.

Therapeutic Outlook

Selective peptide inhibitors of different caspases (Table II) have been successfully developed, even though they show serious problems penetrating the cell membrane, as well as having electrophyllic promiscuity and stability in solution, which makes them susceptible to attacks by biological nucleophiles, such as catepsin. Because of this, they are not easily adaptable to clinical use; this has allowed scientists to obtain many interesting *in vitro* results. More recently, Merck (like Smith Kline Beecham, BASF, Idun/Novartis, and Vertex) has in advanced stages of development, new classes of low molecular weight nonpeptide inhibitors. These show a much higher potency and specificity, opening new therapeutic perspectives. Nonpeptide inhibitors like "isatins" attain potencies 100–1000 times greater than the class of zVAD-fmk, with substantial improvements *in vivo*. These studies are still in early stages, and we hope that the near future will tell as the best clinical application for this new class of drugs.

Glossary

apoptosis The physiological mechanism of programmed cell death mediated by caspases (cysteine proteases), regulated by the Bcl-2 family of proteins, and triggered from the membrane (death receptors, adhesion), cytosolic stress, or nuclear signals (DNA damage). Excessive or defective apoptosis is involved in diseases such as ischemia, AIDS, neurodegeneration, autoimmunity, and cancer.

apoptosome Multiprotein complex of 700 kDa molecular weight formed by procaspase-9, apaf-1, dATP, and cytochrome *c*. It proteolytically activates caspase-9, leading to the activation of downstream-effector caspases, and subsequently death of the cell.

BIR Baculovirus IAP Repeat. A protein-structural domain, conserved in both mammalian and viral proteins, able to react with the apoptosome or with the active caspases. It characterizes the IAP proteins.

caspase Cysteinyl *asp*artate-specific prote*ase*, cysteine proteases which cleave after an aspartate (D). The family includes 13 enzymes involved either in programmed cell death (apoptosis) or in inflammation.

death receptors Cell membrane receptors (e.g., CD95, TRAIL-R, TNF) belonging to the TNF (tumor necrosis factor) superfamily, able to activate apoptosis via the formation of a DISC when bound by their specific ligands (e.g., CD95L, TRAIL, TNF). Essential in regulating immune responses.

DISC Death initiation signaling complex. Multiprotein complex beneath the cell membrane activated by trimeric death receptors (e.g., CD95, TRAIL-R, TNF). It includes the receptor, adaptor molecules, procaspases (caspases 8 and 10), and their related substrates (e.g., Bid) that signal to the mitochondria-apoptosome to activate the caspases, and therefore kill the cell by apoptosis.

IAP *I*nhibitors of *ap*optosis. Mammalian or viral proteins able to inhibit the activation of the apoptosome or the active caspases. They are characterized by structural domains called BIR; consequently all IAP proteins are also called BIR proteins (BIRp).

Biography

Gerry Melino is Editor in Chief of the journal *Cell Death Differentiation* (www.nature.com/cdd) as well as group leader at the Medical Research Council, Toxicology Unit in Leicester, UK, and Professor at the University of Rome "Tor Vergata." His research is mainly focused on the p53 family and in particular on p73 and p63.

Pierluigi Nicotera is the Director of the Medical Research Council, Toxicology Unit in Leicester, UK, and his research interest is on neurodegeneration and neurotoxicology.

Don W. Nicholson is Vice President of Merck, responsible for the San Diego (California, USA) research site dedicated to neurodegeneration. He is a major contributor to the enzymology of caspases, and to drug development of low molecular weight inhibitors of caspases.

Cell Cycle Controls in G_1 and G_0

Wenge Shi and Steven F. Dowdy
University of California, San Diego School of Medicine, La Jolla, California, USA

The cell cycle is the process by which one cell becomes two. Somatic cell division involves cell growth (increase in cellular components, such as ribosomes, membranes, organelles) throughout the cell cycle, faithful replication of its DNA during the S phase of the cell cycle, and precise distribution of DNA between daughter cells during the mitosis (M) phase. In addition, with the exception of early embryonic cell divisions, two gap phases, Gap 1 (G_1) and Gap 2 (G_2), are separated by S phase. As multicellular eukaryote organisms regulate cell division tightly to maintain tissue homeostasis, the most important regulatory decision is made during exiting of the resting state so called the G_0 phase and G_1 phase of the cell cycle before cells become committed to initiate DNA synthesis and complete the cell cycle.

G_1 and G_0 Phase of the Cell Cycle

The majority of cells in adult metazoans are permanently withdrawn from the cell cycle in a terminally differentiated state. Only small numbers of cells, such as hematopoietic and epithelial early progenitor cells, are actively proliferating. Other cells are reversibly withdrawn from the cell cycle and remain in a quiescent stage or the G_0 phase of the cell cycle. Upon proper stimulation, these cells can re-enter the cell cycle. For example, highly differentiated hepatocytes in adult liver are present in the G_0 resting phase and rarely replicate normally. However, in response to acute liver injury or distress, these G_0 hepatocytes can be stimulated to re-enter the cell cycle and regenerate the liver. Similarly, primary peripheral blood lymphocytes (T and B cells), which are present in the G_0 phase, can re-enter the cell cycle and start clonal expansion when presented with the appropriate antigen. These examples serve to demonstrate that certain cell types may enter and exit the cell cycle pending the appropriate stimulus, whereas the vast majority of cells in a matured metazoan have permanently exited the cell cycle.

The most important decision for cell cycle progression is made during the G_1 phase. In G_0 phase, cells respond to extracellular signals by entering the G_1 phase of the cell cycle. However, prior to transiting into the late G_1 phase, they must traverse the growth factor-dependent restriction point. This is a critical regulatory phase of the cell cycle where a cell becomes committed to enter S phase and finish the remaining cell cycle. In contrast to normal cells, tumor cells are often less growth factor-dependent and fail to respond to growth inhibitory signals. Consequently, tumor cells select for genetic mutations that disrupt the important decisions performed at the restriction point and this is, in fact, one of the hallmarks of cancer.

Regulators of G_0 Exit and G_1–S Progression

One of the key negative regulators of the restriction point and early G_1 to G_0 cell cycle exit is the retinoblastoma tumor suppressor protein (pRb) and two closely related family members, p107 and p130. Murine embryonic fibroblasts (MEF) deficient for all three pocket proteins fail to respond to G_1 phase arrest signals following contact inhibition, serum starvation, or DNA damage. The antiproliferation function of the pocket proteins depends, at least in part, on their interaction with E2F/DP transcriptional factors, which regulate the expression of key genes required for DNA synthesis, DNA repair, DNA-damage checkpoint, apoptosis, and mitosis. Direct interactions of pRb family members with E2F/DP complexes and the recruitment of chromatin-modifying enzyme complexes, such as histone deacetylases (HDAC), polycomb group proteins, the SWI/SNF complex, and histone methyl transferases, to E2F-reponsive genes results in inhibition of target gene expression.

Distinct pRb family member–E2F repressor complexes exist in different cell cycle phases. As an example, during the G_0 phase, p130 and p107 interact with E2F4 and E2F5, whereas pRb remains unbound. E2F4 and E2F5 are expressed constitutively and are involved in E2F-dependent gene repression during cell cycle exit and terminal differentiation. It is also reported that E2F6, the sole E2F family protein that does not interact with the pocket proteins, mediates gene repression with polycomb group proteins in the G_0 phase. Further studies are

needed to resolve the contributions of E2F6 versus E2F4 and E2F5 for maintaining quiescence. In contrast, during early G_1 phase, pRb interacts with E2F1, E2F2, and E2F3, the so-called "activator E2Fs." When the cell passes through the restriction point, pRb becomes inactivated by hyperphosphorylation, releasing E2Fs 1–3 and promoting the activation of E2F-responsive genes for cellular proliferation. Not surprisingly, MEFs deficient for these E2F1, E2F2, and E2F3 exhibit impaired E2F-responsive gene induction in response to serum and significant proliferative defects.

pRb undergoes cell-cycle-specific phosphorylation through the G_1 and S phases of the cell cycle and subsequent dephosphorylation during mitosis. Hypophosphorylated (low level of phosphorylation) pRb is the active, transcriptional repressing form of pRb and can simultaneously bind to both E2F and HDAC. Hypophosphorylated pRb is also selectively bound and inactivated by DNA tumor virus oncogenes, SV40 large T antigen, adenovirus E1A protein, and human papillomavirus (HPV) E7 protein.

pRb is physiologically regulated by a group of serine/threonine-specific protein kinases called cyclin-dependent kinases (Cdks). Specifically, cyclin D:Cdk4/6 and cyclin E:Cdk2 kinases are responsible for phosphorylating pRb during the G_1 phase of the cell cycle. However, cyclin D and cyclin E are regulated differently and play distinct roles in the cell cycle regulation of pRb (Figure 1). D-type cyclins are not expressed in G_0 cells. However, cyclin D levels increase after stimulation of growth factors as a result of increased transcription mediated by Myc and Ras/MEK/MAPK signaling pathway and increased stability mediated by the PI(3)K/Akt signaling. In cycling cells, cyclin D levels and associated kinase activity remain relatively constant. Therefore, the D-type cyclins control cell cycle entrance and exit by linking the mitogenic pathway to the core cell cycle machinery.

Unlike cyclin D, the expression of cyclin E is mitogen-independent and dependent on the action of E2Fs after the hyperphosphorylation and inactivation of pRb at the late G_1 phase of the cell cycle. However, because pRb represses cyclin E expression, questions remain as to how cyclin E gene expression and cyclin–Cdk2 activity is initially turned on. Once cyclin E levels reach a critical threshold, its levels can be further increased as a result of a positive feedback loop. Active cyclin E:Cdk2 increases degradation of $p27^{Kip1}$ by phosphorylation, which leads to more inactive pRb, free E2F for activation of cyclin E transcription and hence, more active cyclin E:Cdk2.

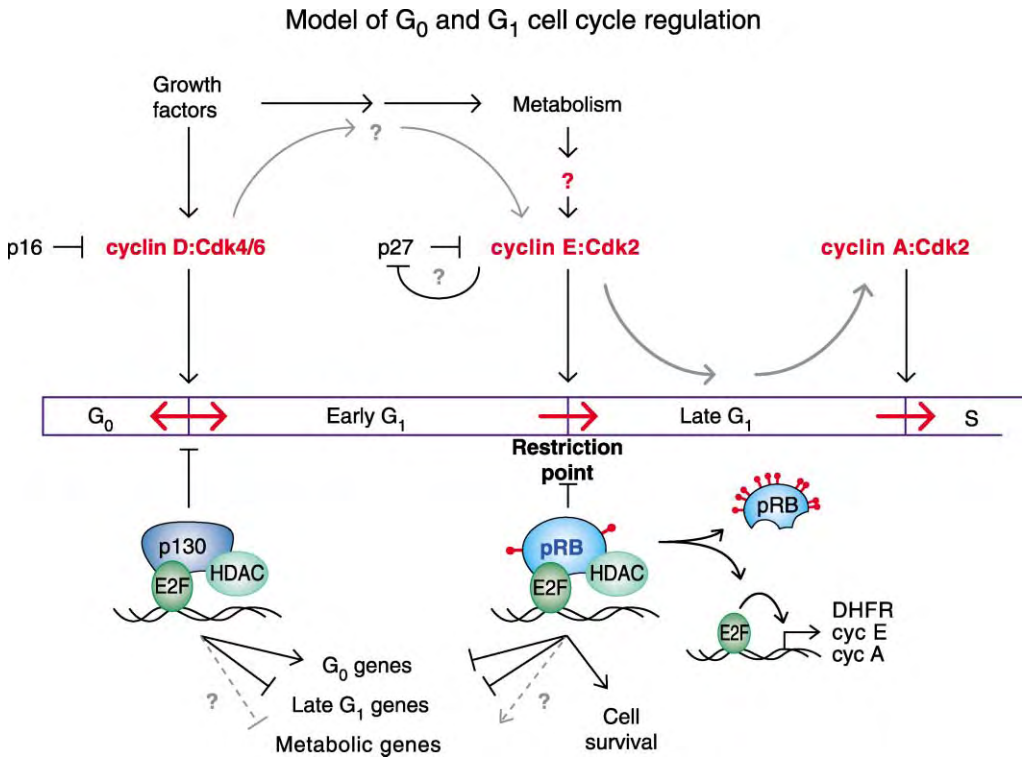

FIGURE 1 Model of G_0 and G_1 cell cycle progression. Activation of cyclin D:Cdk4/6 kinases by growth factor stimulation of G_0 cells results in increased metabolism or growth and switching of p130:E2F complexes to pRb:E2F complexes. By an unknown mechanism increased metabolism and cell mass leads to activation of cyclin E:Cdk2 complexes at the restriction point resulting in hyperphosphorylation (inactivation) of pRb, release of E2Fs, and activation of late-G_1-specific genes involved in DNA synthesis and late G_1 cell cycle regulation. Activation of cyclin A:Cdk2 complexes initiates DNA synthesis.

Several mechanisms may contribute to this process. First, $p27^{Kip1}$ in the cyclin E–Cdk2 complex may be sequestered by increased cyclin D–Cdk4/6 complexes. Second, growth factor-activated PI(3)K/Akt pathway may cause the phosphorylation and relocation of the family of forkhead transcription factors into cytosol, which leads to a decrease in the transcription of $p27^{Kip1}$. Furthermore, $p27^{Kip1}$ can be phosphorylated directly by Akt and relocate into cytosol.

The consequence of cyclin D-dependent and cyclin E-dependent kinase activity on pRb also results in differential regulation. It is apparent that cyclin D-dependent kinases are not sufficient for disrupting the pRb-E2F–HDAC complex. Indeed, this is most dramatically supported by the detection of functional pRb–HDAC–E2F complex in $p16^{INK4a}$-deficient cancer cells with deregulated and active cyclin D-dependent kinases. Furthermore, in T cells entering the cell cycle, E2F4 associates with pRb only after cyclin D kinase activity is turned on. In contrast, cyclin E-dependent kinase activity and hyperphosphorylation of pRb are required for disrupting E2F–pRb and HDAC–pRb interactions. Moreover, in addition to pRb family members, cyclin E-dependent kinase phosphorylates target proteins involved in chromatin remodeling, DNA synthesis, centromere functions, further triggering the cell to traverse across the restriction point into late G_1 and S phase.

Cell Growth Regulation

The other aspect of cell cycle regulation is the increase in cell mass or cell growth. In general, cells must grow to a minimum size to be able to divide and generate two daughter cells equal in size to the starting mother cell. Premature entry into S phase results in smaller daughter cells. Therefore, it has been realized, but not well understood, that generally with the exception of some developmental programs, such as early embryonic cell division and endo-reduplication, cell division and cell growth must be coordinated. Although cell growth is often reflected by an increase in cell size, cell growth needs to be defined as an increase in cell mass, or more precisely, the underlying global RNA and protein synthesis capacity, and additional macromolecule synthesis and storage.

How mitotic cells coordinate cell growth and division remains an open question. Some of the key regulators involved in cell cycle regulation also control cell growth. For example, the Myc transcription factor has long been implicated in cell growth regulation in both *Drosophila* and mammalian cells. Besides the gene products involved in cell cycle regulation, such as cyclin D2, Cdk4, cdc25, cyclin E, and cyclin A, many Myc-target gene products are involved in ribosome biosynthesis, protein synthesis, and specific metabolic pathways. Another example of a key cell cycle regulator is pRb. In addition to regulating E2F-dependent gene transcription, pRb can also repress RNA polymerase I- and III-dependent transcription that are responsible for the synthesis of rRNA, various small RNAs such as 5S rRNA, and tRNA. This regulation is mediated by direct interaction of pRb with the upstream-binding factor (UBF) and with the TF-IIIB coactivator, respectively.

On the other hand, cell growth may influence cell division. Understanding of cell growth regulation comes from studying immune suppressant rapamycin. Treatment of both yeast cells and mammalian cells with rapamycin delays cell growth and proliferation. In budding yeast, signaling of the target of rapamycin (TOR), a protein kinase, coordinates nutrient availability, such as carbon source and nitrogen, with cell growth and proliferation. It turns out that the yeast G_1/S cyclin Cln3 is both translationally and post-translationally regulated in response to nutrient levels. Cell division occurs when cells reach a certain size. In metazoans, the situation is more complex since nutrient levels are maintained by tissue homeostasis. Not only does mammalian TOR (mTOR) signaling coordinate protein synthesis with glucose and amino acid availability (linked to nutrient sensing signaling pathways), but it also mediates hormonal and mitogenic factor responses. mTOR lies downstream of PI(3) kinase/Akt, although it is currently unclear that they belong to a linear signaling cascade.

PI(3)K/Akt may also activate further downstream targets through tumor suppressor tuberous sclerosis (TSC) complexes. It turns out that the mTOR pathway in conjunction with signaling through the PI(3)K pathway regulates the translational initiation and elongation, ribosome biosynthesis, amino acid import and metabolism. One of the important targets in ribosome synthesis regulated by the PI(3)K/Akt/mTOR pathway is S6 kinase, which phosphorylates ribosomal protein S6. In *Drosophila*, S6 is associated with body size and cell growth. S6 phosphorylation is required for the translation of a group of mRNAs with a 5′ terminal oligopyrimidine tract (5′TOP), including ribosomal protein mRNAs and mRNAs encoding for translation machinery. In addition, the Akt/mTOR pathway regulates protein translation by phosphorylating and inactivating the translation initiation factor 4E-binding protein (4E-BP1). As a result, PI(3)K/Akt and mTOR are linked to translation initiation by regulating the eukaryotic translation initiation factor 4E (eIF-4E), which enhances the translation of essential genes for cell cycle regulation, including cyclin D and $p27^{Kip1}$. Future studies will ultimately resolve how cell growth signaling impinges on and is incorporated into the cell cycle regulatory machinery.

Future Perspectives

There has been an increased understanding of signal transduction and cell division. A lot of focus has been on protein post-translational modification and gene expression regulation. However, until recently, the importance of cell growth has not been fully appreciated. Clearly there is cross-talk between cell growth and cell cycle regulation. Future studies should fill in the gaps in our understanding of cell growth, cell cycle progression, and their subsequent contributions to neoplastic transformation.

Cell Cycle: Control of Entry and Progression Through S Phase

Susan L. Forsburg
University of Southern California, Los Angeles, California, USA

The process of DNA synthesis during S phase requires regulation at multiple levels to ensure that DNA replication is coordinated with overall cell-cycle progression. There are numerous mechanisms to ensure that S phase occurs in a timely and regulated fashion. These ensure the onset of replication occurs in response to the appropriate signals, and they also prevent the re-replication of the genome in a single cell cycle. Much of this regulation occurs by controlling the activation of DNA synthesis at individual origins of replication.

The study of S phase and its many levels of control is continuing in many laboratories. This work has benefited from genetic systems such as the yeasts *S. cerevisiae* and *S. pombe*, and the fruit fly *Drosophila*. Biochemical studies primarily in *Xenopus* extracts complement early work that reconstituted the replication apparatus using viral systems and human cells. Given this long and distinguished history, there are inevitably different names for the conserved proteins involved. A listing of the equivalents that are most relevant to this article is provided (Table I).

Initiation and Elongation of DNA Replication Origins

The major control of DNA replication occurs at initiation, by regulating assembly and activation at the origins of replication of the multiple proteins of the prereplication complex (preRC). Following initiation, the enzymes of the DNA synthesis machinery take over and extend replication forks to duplicate the genome.

Origins

DNA synthesis begins at replication origins. Generally, there are many replication origins in each chromosome, to facilitate the timely duplication of the genome. In a few species, the origin is defined by a consensus sequence in the DNA. More commonly, origins are defined by general features of the sequence rather than a linear consensus, and are typically A/T rich and easily unwound. In some cases, origins appear to be distributed not by sequence, but by some sort of spacing mechanism. Not all origins are activated at the same time: while some regions of the genome may undergo initiation early in S phase, others are activated late. Despite these differences, the proteins responsible for replication initiation at individual origins are remarkably similar amongst species.

Assembly of the preRC

The preRC is assembled by sequential binding of conserved proteins (Figure 1). This occurs at the end of M phase in cycling cells. First, the six proteins of the origin recognition complex (ORC) bind DNA near what will become the initiation site in the replication origin. Next, Cdc6 (called Cdc18 in fission yeast) and Cdt1 bind. These are followed by the six-membered mini-chromosome maintenance (MCM) complex (Mcm2–7). Biochemical studies suggest that once the MCM complex is loaded, the other preRC components are no longer essential for origin initiation. The assembled preRC is now poised for initiation of the origin. The triggers that activate initiation will be discussed later.

Initiation

Initiation at each origin requires assembly of another set of proteins. It begins with the binding of a protein called Cdc45, which is required for association of the single-stranded DNA-binding protein RPA. This is the essential first step that leads to assembly of primase and DNA polymerase α, the initiating polymerase.

Studies suggest that the MCM complex is not only an assembly factor, but plays an active role in elongation. A subset of MCM proteins has *in vitro* helicase activity, and there is some evidence that the MCM proteins are associated with the replication fork. The current model suggests that the MCMs provide an unwinding activity required for replication fork elongation. Curiously, MCMs are extremely abundant proteins, far outnumbering the replication origins, and it remains to be determined why the cell requires so many of them.

TABLE I

Names of Replication Proteins in Multiple Systems. The same Protein may have Synonyms even in one Species (Indicated by a Slash)

S. cerevisiae	*S. pombe*	Metazoans	Product
Cdc7	Hsk1	Cdc7	DDK kinase
Cdc28	Cdc2	Cdk2 and Cdk4	S phase CDK
Cdc6	Cdc18	Cdc6	Activator
Mcm2–7	Mcm2–7	Mcm2–7	MCM complex members
Orc1–6	Orp1–6	Orc1–6	ORC
Cdc45	Sna41	Cdc45	Initiation factor
RPA	RPA	RPA	Replication protein A: single-strand DNA-binding protein
Dpb11	Rad4/Cut5	TopBP1/Mus101	Possible assembly factor?
Tah1	Cdt1	Cdt1/Dup	pre-RC factor
No homologue[a]	No homologue[a]	Geminin	Cdt1 inhibitor
Mec1	Rad3	ATR	ATM-related kinase
Chk1	Chk1	Chk1	Damage checkpoint kinase
Rad53	Cds1	Chk2	Replication checkpoint kinase
Drc 1, S1d2	Drc1	No homologue[a]	Dpb11 associated factor
Sld3	Sld3	No homologue[a]	Cdc45 associated factor
RFC	RFC	RFC	Replication factor C: PCNA clamp loader
Cdc17/Pol1	Swi7/Pol1	Polα	DNA pol α
Cdc2/Pol3	Cdc6/Pol3	Pol δ	DNA pol δ
Pol 2	Cdc20/Pol2	Pol ε	DNA pol ε
Cdc44	Pcn1	PCNA	Clamp
Cdc9	Cdc17	Ligase	Ligase
Mcm10	Cdc23	Mcm10	Initiation factor
Sic 1[b]	Rum 1[b]	P27[b]	Non-homologous CKIs

[a] Homologue not (yet) identified.
[b] Not related by sequence.

Elongation

As the leading strand is elongated, a polymerase switch occurs, and the highly processive DNA polymerase δ assumes the job of DNA synthesis. It is locked into place by a clamp called PCNA, which is loaded onto the DNA by a clamp-loader called RFC. Replication proceeds bi-directionally from the origin, with each leading strand generating a replication fork structure. While DNA polymerase δ elongates the leading strand, the opposite lagging strand is synthesized in a series of short fragments by DNA polymerase α. These Okazaki fragments are joined together by a group of processing enzymes including DNA ligase, to create a single continuous strand. Processive DNA replication may be interrupted if the polymerase encounters lesions in the template, or if it runs out of nucleotide precursors. Checkpoint mechanisms that protect the integrity of the replication fork in these conditions will be discussed below.

Little is known about the resolution of two colliding replication forks from adjacent origins, or the termination of replication. However, studies show that the MCM proteins are dislodged from the chromatin as S phase progresses, and by the conclusion of DNA synthesis they are no longer DNA associated.

Regulation of Origin Firing by Kinases

Activation of DNA synthesis at the assembled preRC requires the activity of at least two kinases: a cyclin dependent kinase (CDK), and a related kinase called Cdc7 (DDK). Investigators are still examining the molecular effect of these kinases, but a general model for their function has been determined (Figure 1).

Cdc7 (DDK)

The Cdc7 kinase is essential for initiation of DNA replication. It acts at individual replication origins to initiate DNA synthesis. Its activity requires binding to a regulated subunit, originally identified as Dbf4, which is required for the catalytic Cdc7 subunit to recognize its substrates and targets it to the preRC. Dbf4 is regulated

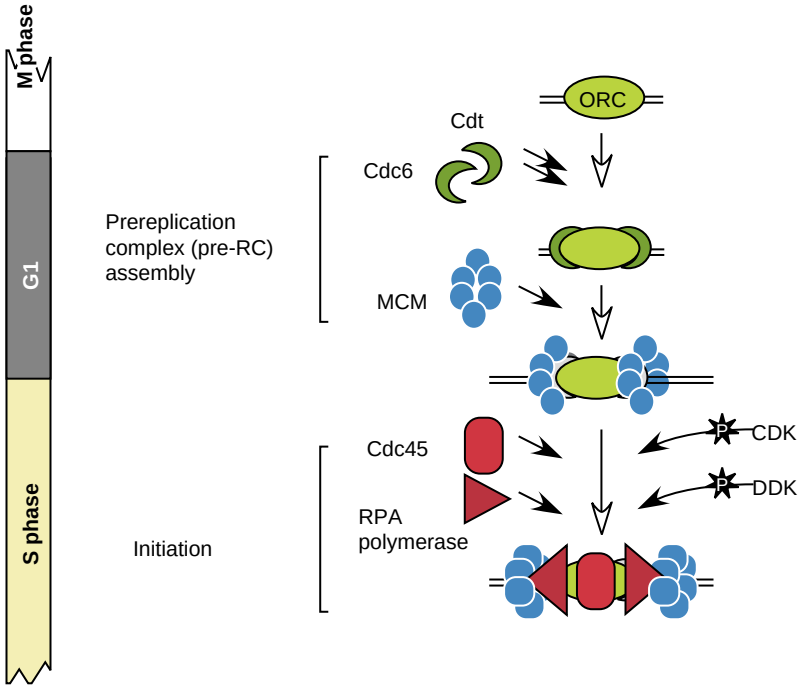

FIGURE 1 Ordered assembly of the prereplication complex (pre-RC) occurs during late M and G1 phase. Initiation at individual replication origins occurs during S phase. Kinase activity is indicated by stars and results in recruitment of DNA synthesis factors. Positive effects, arrow; Negative effects, bars.

both transcriptionally and posttranslationally, and restricts kinase activity to the S phase of the cell cycle. The Cdc7 kinase is sometimes called a DDK, or Dbf4-dependent kinase, in recognition of its similarity to CDKs. *In vitro* data indicate that Cdc7 kinase can phosphorylate components of the preRC and initiation proteins, including MCM proteins, Cdc45, and DNA polymerase α.

A change-of-function mutation in *S. cerevisiae MCM5* was isolated that completely bypasses the requirement for Cdc7 kinase. This led to the suggestion that phosphorylation of the MCM complex by Cdc7 results in a conformational change in the complex that allows Cdc45 to bind to the origin. As described above, Cdc45 binding is a prerequisite for assembly of RPA and primase, and is thought to be limiting for replication. This model has not been confirmed biochemically, but is consistent with genetic data.

Cyclin-Dependent Kinase

CDKs are the engine of the cell cycle, and their oscillation controls multiple events. In yeasts, a single kinase subunit switches cyclin partners during the cell cycle to provide substrate specificity. In metazoans, multiple kinases combine with multiple cyclins to achieve the same specificity. Studies *in vitro* and *in vivo* investigating replication proteins show that CDK phosphorylates ORC, MCMs, RPA, and DNA polymerase α. CDKs play both positive and negative roles in the regulation of DNA replication: while initiation clearly requires CDK activity, the kinase is also required to prevent reinitiation of origins within the same cell cycle (Figure 2).

Recent data from several systems provide an intriguing suggestion that the positive role of CDK in replication initiation operates in a pathway parallel to MCM assembly. In the two yeasts, a conserved protein called Dpb11 (Rad4) interacts with Drc1, which is a known CDK substrate. If Drc1 is not phosphorylated, it cannot bind to Dpb11. Data from *Xenopus* suggest that the Xmus101 protein (related to Dpb11) is required for Cdc45 binding. Together, these studies suggest that two components are required for Cdc45 binding: Cdc7 activation of the preRC, and CDK activation of the Dpb11 pathway. This model is speculative. However, it provides an attractive fail-safe mechanism for the cell to ensure that multiple signals are integrated before it fires a single replication origin, which would significantly reduce the chance of aberrant initiation.

Coupling Replication to the Cell-Cycle Engine

Activation and inhibition of replication from individual origins is controlled at multiple levels that ultimately depend upon the oscillation of CDK activity during the cell cycle. This oscillation reflects the control of

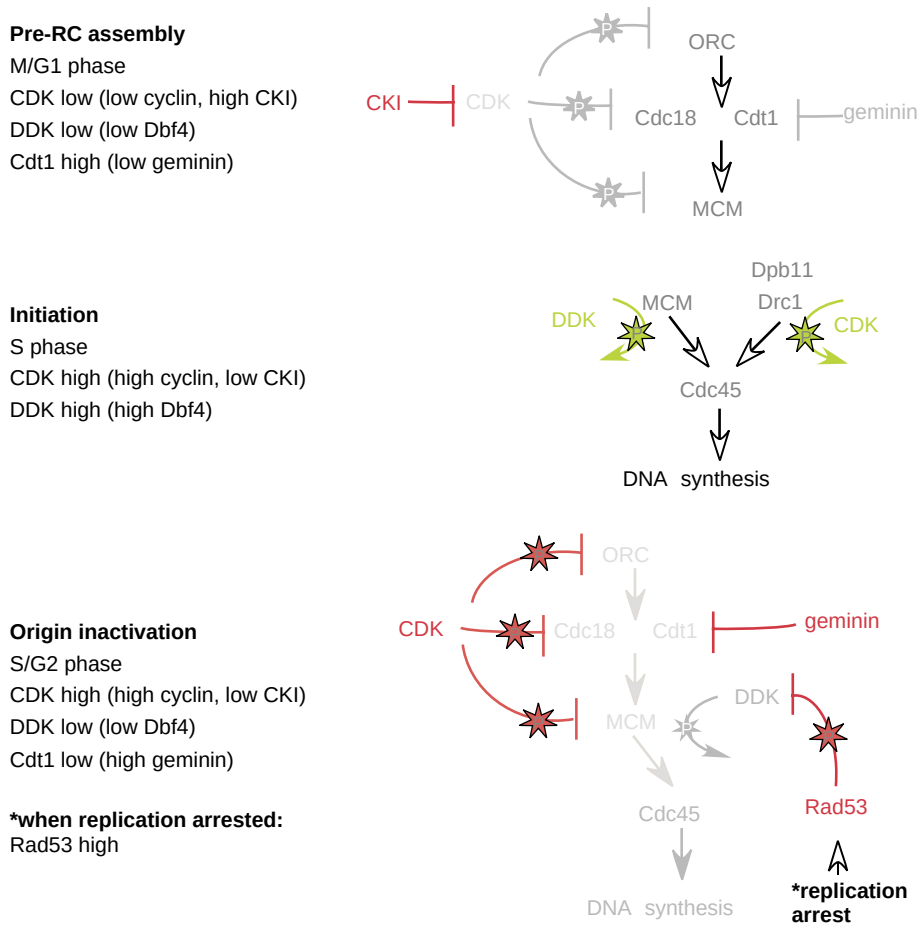

FIGURE 2 Positive and negative regulation of S phase initiation prevents re-replication. The pre-RC is assembled on origins when CDK activity is low, and reassembly is prevented when CDK activity is high. Origins only fire when both CDK and DDK are active on pre-RCs. Fluctuation in the levels or activity of cyclins, cyclin kinase inhibitors (CKI), Dbf4 protein, and geminin contribute to this regulation. Under conditions when defects in replication block synthesis, Rad53 checkpoint kinase is activated to prevent further origin firing and to protect the structure of active replication forks. Gray text/arrows indicates inactivated pathway components.

the individual cyclins. The DDK subunit Dbf4 is also subject to this regulation (Figure 2).

CDK Inhibitors and Proteolysis

CDK activity is regulated at multiple levels including phosphorylation. Most obviously, association of the kinase with transiently produced cyclin proteins provides temporal specificity (Figure 2). The cyclins are targeted for destruction by specific ubiquitination complexes at various points in the cell cycle. The Dbf4 subunit of the DDK in yeasts (and probably in larger cells) also oscillates in the cell cycle. It is regulated transcriptionally, and is also a target for ubiquitination during M phase, which restricts its activity to the S phase of the cell cycle. Thus, destruction of proteins in M phase helps maintain the timing of events in S phase.

Specific inhibitor molecules expressed during G1 also modulate CDK activity prior to S phase. These are usually specific to particular cyclin forms of the CDK. These inhibitors keep kinase activity repressed, which allows assembly of a preRC. As cells proceed towards S phase, the increasing levels of cyclin lead to increasing CDK activity which ultimately overcomes the inhibitor. The accumulating CDK phosphorylates its inhibitor, leading to its ubiquitination by an S-phase specific complex that targets the inhibitor for destruction. Although this same general pattern describes most cell types, surprisingly the individual CDK inhibitor molecules in different species such as *S. cerevisiae* Sic1, *S. pombe* Rum1 and human Kip1 are highly diverged, and show no primary sequence homology.

In mammals, Cyclin D/CDK4 phosphorylates and inactivates the Rb protein. Active Rb inhibits E2F, a component of the S-phase-inducing transcription factor; thus Rb needs to be inactivated before S phase can initiate. Because Rb inhibits entry into S phase and the cell cycle, its loss can lead to dysregulation of cell-cycle progression, so it is not surprising that Rb was originally identified as a tumor suppressor.

Activation of the preRC: Once and Only Once

The negative role of CDKs in preventing reinitiation of DNA replication is dramatically illustrated in fission yeast, in which overproduction of the CDK inhibitor Rum1 results in cells repeating S phase many times, without an intervening mitosis. The CDK is inhibited so it cannot promote mitosis, or prevent reinitiation of replication origins; however, the S-phase-promoting form of the CDK remains active.

The targets of the CDK for this inhibitory activity include several factors at the replication origin. Data suggest that the ORC complex is a CDK target that prevents re-replication. Similarly, Cdc6 protein is tightly regulated so that it is only present in the nucleus at the time of preRC assembly (between mitosis and S phase). It is a CDK substrate, and depending on the system, is either degraded, or exported from the nucleus, in response to phosphorylation. In metazoans, Cdt1 associates with an inhibitor molecule called geminin, which itself is degraded during mitosis to free active Cdt1. Thus, active forms of Cdc6 and Cdt1 are only present at the time of preRC assembly to allow MCM loading. This provides one way to ensure that origins cannot be reactivated in a single cell cycle.

The MCM complex, although present throughout the cell cycle, can only bind at the origin in the presence of Cdc6 and Cdt1. The MCM complex is dislodged during replication, and some subunits are phosphorylated by CDK. In the yeast *S. cerevisiae*, this phosphorylation results in the active export of MCMs from the nucleus as S phase proceeds. The dislodged proteins remain in the nucleus in other species, but are unable to bind the chromatin. The MCMs cannot regain access to the origin (or in *Saccharomyces*, the nucleus) until CDK levels fall at the end of mitosis, and Cdc6 and Cdt1 are active again in the next G1 phase.

This sequential requirement for origin binding allows tight cell-cycle regulation of initiation. Low CDK activity allows pre-RC assembly. High CDK activity allows origin firing, but prevents reassembly of initiation factors. The CDKs thus play a dual role by both promoting initiation and preventing re-replication at individual origins.

Genome Integrity during S Phase

The assembly and elongation of a replication fork involves nicks and unwinding, generating fragile regions in the chromosome that may be prone to breakage. Replication does not proceed all in one piece, but involves pauses and stops along the way. Thus, the cell must have a sensitive quality control mechanism to prevent damage from occurring, and to respond appropriately if it does occur. The response prevents mitosis (by inhibiting the mitotic CDK), and repairs the damage (by activating repair proteins). Components of the replication checkpoint pathways are responsible for processing these signals and generating the correct response. Proteins required for repair via recombination are also likely to be important components for quality control during DNA replication.

Data suggest that the Rad53/Cds1/Chk2 kinase is a crucial component of the response to replication defects in all eukaryotes. In a few species, cells can survive loss of this kinase, but even these survivors show genome instability and sensitivity to damaging agents when it is missing. Some experiments suggest that the Rad53/Cds1/Chk2 kinase regulates the timing of origin activation even in normal cells, by inhibiting DDK activity. But its best-understood function is in response to replication arrest early in S phase. The kinase maintains the structure of the assembled replication fork and promotes repair, by phosphorylation of substrates in the recombination-repair pathway. It also prevents initiation from late origins during replication arrest by inhibiting DDK activity.

Regulating Chromosome Structure during S Phase

The events of S phase are intimately linked to chromosome structure. Although the mechanism is not clear, it is known that cohesion between sister chromatids is established during S phase, as the sister chromatids are generated. Cohesion is essential for proper segregation of the chromosomes during mitosis. It prevents chromosome loss, contributes to centromere structure, and helps orient the chromatids to the opposite spindles. Whether the passing replication fork activates the cohesin proteins, or they are activated by the S-phase kinases, remains to be determined.

Chromatin assembly is also affected during S phase. The cell must assemble its newly duplicated DNA into nucleosomes and higher-order chromatin structures. The mechanisms for this are also not well understood, but are likely to involve conserved protein complexes activated during DNA replication. Chromatin structure may in turn regulate S-phase timing. Recent studies suggest that modification of histones by acetylation may help determine the timing of firing for individual origins.

Conclusions

Events during S phase have profound effects on chromosome biology throughout the cell cycle. The replication fork has an enormous capacity to remodel chromatin.

In addition, activation of specific kinases only during S phase can provide a temporal link between DNA replication and modification of other proteins. Clearly, investigators are only beginning to trace these links. The study of S-phase regulation of multiple chromosome events will expand for years to come.

Cell Cycle: DNA Damage Checkpoints

Jean Y. J. Wang
University of California, San Diego, La Jolla, California, USA

DNA damage activates cell cycle checkpoints to prevent replication and segregation of damaged genome. DNA damage also inhibits cellular differentiation, activates apoptosis, and induces premature senescence. Defects in these checkpoint responses to DNA damage contribute to tumor progression, resistance to radiation/chemotherapy, and the development of degenerative diseases.

Overview

The orderly progression through a cell division cycle is controlled by a series of checkpoints. Two fundamental checkpoints, i.e., replication checkpoint and spindle checkpoint, operate in every round of cell cycle (Table I). The replication checkpoint monitors progress of DNA replication; it prevents entry into mitosis until replication is completed. The spindle checkpoint monitors attachment of chromosomes to the mitotic spindles; it prevents segregation of sister chromatids until they are properly aligned on the metaphase plate. Under normal physiological conditions of abundant energy and nutrients, these checkpoints are experimentally invisible. Perturbation in the cellular environment can prolong the operation of these two checkpoints and/or activate additional checkpoints, leading to an observed inhibition of cell cycle progression.

This article discusses three distinct cell cycle checkpoints activated by DNA damage: the G1/S checkpoint, the intra-S checkpoint and the G2/M checkpoint (Figure 1). The G1/S checkpoint inhibits S-phase entry in G1 cells that have not yet committed to DNA replication. The intra-S checkpoint prevents initiation of DNA replication at origins that have not yet been activated. The G2/M checkpoint inhibits entry into mitosis. DNA damage also delays differentiation, activates programmed cell death, or induces premature senescence (Figure 2). The inhibition of cell cycle progression or differentiation is reversible, allowing resumption of cell proliferation and differentiation after DNA repair. Apoptosis and premature senescence are irreversible, most likely triggered by the accumulation of persistent lesions in the genomic DNA.

Cell Cycle Checkpoints Activated by DNA Damage

G2/M Checkpoint

The G2/M checkpoint is activated by a variety of DNA lesions, including base modification, cross-linking, and strand break. The sister chromatids in G2 cells are advantageous to DNA repair. Thus, G2 arrest serves two important purposes: to promote the repair of DNA lesions and to prevent mitotic catastrophe caused by segregating damaged DNA. The G2/M checkpoint causes G2 arrest by blocking mitosis (Table I).

Inhibition of Mitosis

In all eukaryotic cells, mitosis requires the cyclin-dependent protein complex of Cdc2/M-cyclin (also known as MPF). This MPF complex is formed throughout S and G2, but held in a latent state through phosphorylation of a threonine and a tyrosine in the N-terminal ATP-binding lobe of Cdc2. The G2/M checkpoint prevents dephosphorylation of Cdc2, holding MPF in the inactive state, and thereby prolongs G2 phase of the cell cycle (Figure 1).

DNA damage maintains the inhibitory phosphorylation of Cdc2 by several mechanisms. Dephosphorylation of Cdc2 at the two inhibitory sites requires a dual specificity phosphatase encoded by the highly conserved Cdc25 gene. DNA damage causes an inhibition of Cdc25 phosphatase through the Chk1 kinase, which is also conserved in all eukaryotes. Chk1 phosphorylates Cdc25 to inhibit its activity and its access to MPF. Sequestration of phosphorylated Cdc25 requires the adaptor protein 14-3-3, another function that is conserved through evolution. The Cdc25 phosphatase is further controlled by DNA damage

TABLE I

Summary of Cell Cycle Checkpoints

Checkpoint	Trigger	Target of inhibition
Replication checkpoint	Cell cycle intrinsic	MPF
Spindle checkpoint	Cell cycle intrinsic	Sister chromatin separation
G2/M checkpoint	DNA lesions	MPF (Sister chromatin separation)
Intra-S checkpoint	DNA lesions (stalled replication forks)	Origins of replication
G1/S checkpoint	DNA lesions	SPF

through the inhibition of polo-like kinase 1 (Plk1), which activates Cdc25. DNA damage also maintains the activity of Wee1, the conserved kinase that phosphorylates Cdc2 at the inhibitory tyrosine site. Therefore, DNA damage targets several regulators of MPF to keep it in the latent state and thereby blocking the entry into mitosis.

Replication Block Also Inhibits Mitosis

The cell cycle intrinsic replication checkpoint also controls the activity of MPF (Table I). Experimentally, replication checkpoint function is measured by the inhibition of MPF under conditions when DNA replication is blocked. Hydroxyurea (HU), an inhibitor of nucleotide biosynthesis, is commonly used to reveal the replication checkpoint. In the fission yeast, HU-induced inhibition of MPF requires Cds1 kinase, another checkpoint protein conserved in all eukaryotes. The budding yeast contains two Cds1-related kinases: RAD53 and DUN1. The mammalian homologue of Cds1 is commonly known as the Chk2 kinase. Similar to Chk1, Cds1 (Chk2) kinase also inhibits Cdc25 to keep MPF in the inactive state. DNA damage-induced G2 arrest is therefore triggered by a mechanism that overlaps in part with the cell-cycle-intrinsic replication checkpoint.

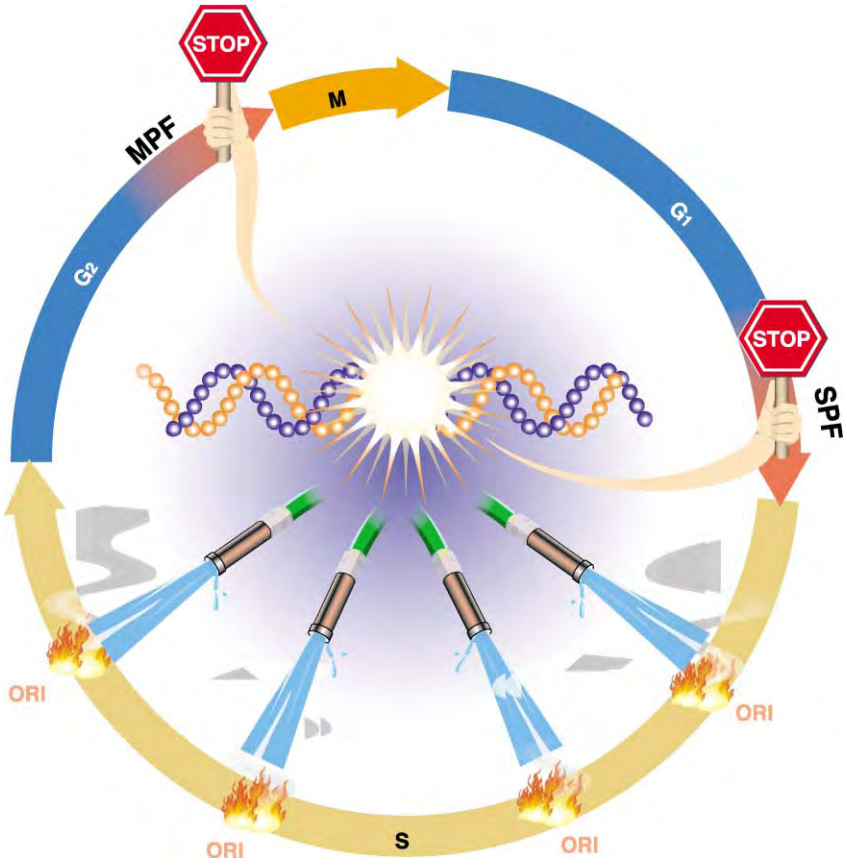

FIGURE 1 DNA damage checkpoints. DNA lesions activate three distinct cell cycle checkpoints. The G1/S checkpoint prevents G1 cells from entering S phase by inhibiting the function of S-phase-promoting factor (SPF). The intra-S checkpoint inhibits the origins of replications (ORI). The G2/M checkpoint prevents G2 cells from entering M phase by maintaining the M-phase-promoting factor (MPF) in its latent, inactive state.

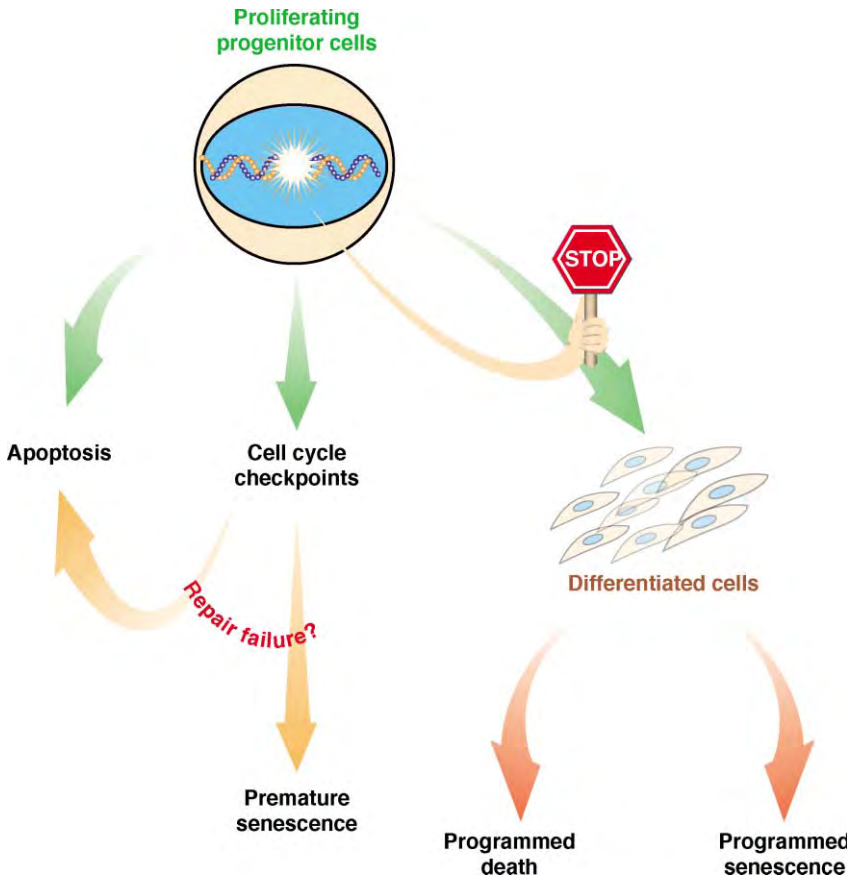

FIGURE 2 DNA damage responses. Cell cycle checkpoints are among several different cellular responses to DNA damage. In some cell types, DNA damage triggers a rapid death response, through the activation of the cellular suicide program (apoptosis). DNA damage also halts differentiation, preventing the global reprogramming of gene expression until lesions are repaired. Death and senescence are preprogrammed for different types of terminally differentiated cells. Interestingly, DNA damage can also cause death or senescence as a delayed response that is likely to be triggered by failure in DNA repair. The choice between apoptosis or premature senescence is not determined by the damage alone, but also dependent on cell type and developmental lineage.

Overlapping Function of Chk1 and Chk2 Kinases in Blocking Mitosis

In fission yeast, Chk1 is required for DNA damage to cause G2 arrest; whereas Cds1 is required to prevent premature mitosis when replication is blocked. In the budding yeast, RAD53 is required for both the replication checkpoint and the damage-induced G2/M checkpoint. Unlike the fission yeast, the budding yeast does not arrest in G2 following DNA damage. Instead, the budding yeast arrests at the metaphase–anaphase transition, unable to separate sister chromatids. Thus, DNA damage activates a G2/M-phase checkpoint that overlaps in part with the spindle checkpoint in the budding yeast. Whether DNA damage also maintains the cohesion of sister chromatids in other eukaryotic cells awaits further investigation. In mammalian cells, current results suggest Chk1 and Chk2 to have redundant and overlapping functions in DNA damage-induced G2 arrest. In mouse embryonic stem (ES) cells, elimination of Chk1 but not Chk2 causes mitotic catastrophe, suggesting Chk1 to have an essential role in preventing premature mitosis in every round of the ES cell cycle.

Intra-S Checkpoint

The intra-S checkpoint is activated by DNA lesions that impede the progress of replication forks. The eukaryotic genomes are divided into replicons, each with an origin of replication. During G1 phase, origins become licensed for replication. Not all of the licensed origins are activated at the onset of S phase. Instead, they are activated in stages; some of them activated early, others late in S phase. When ongoing replication forks are stalled due to DNA lesions, intra-S checkpoint is activated to prevent initiation at licensed origins that have not yet been activated (Table I). Stalled replication, as discussed above, also prevents the activation of MPF; this is known as the replication checkpoint. Therefore, stalled replication forks can cause the inhibition of

replication origins (intra-S checkpoint), or the inhibition of MPF (replication checkpoint) (Table I).

Intra-S Checkpoint Defect in *Ataxia telangiectasia*

In mammalian cells, defect in the intra-S checkpoint was first described decades ago as radiation-resistant DNA synthesis (RDS) in cells isolated from patients suffering from the genetic disease *Ataxia telangiectasia* (AT). Exposure of normal human fibroblasts to ionizing radiation causes a transient inhibition of DNA synthesis due to the inhibition of replication origins. Thus, ionizing radiation (IR), which generates single-stranded and double-stranded breaks, can activate the intra-S checkpoint. Fibroblasts from AT patients continue to synthesize DNA irrespective of IR, i.e., exhibiting the phenotype of RDS. Therefore, RDS results from a defect in the intra-S checkpoint; and *ATM*, the gene mutated in AT, is required for IR to activate the intra-S checkpoint in mammalian cells.

Inhibition of Replication Origins

The target of inhibition by the intra-S checkpoint is the licensed origins of replication. Licensing of replication is a complicated process involving the orderly assembly of a large protein complex called the pre-RC (replication complex) during G1. The pre-RC is then converted to pre-IC (initiation complex) in late G1. Activation of the pre-IC initiates the onset of S phase. The formation and activation of pre-IC requires two types of protein kinase complexes: the Cdk/S-cyclin complex and the Cdc7/Dbf4 kinase complex, both are conserved through evolution. In the budding yeast, inhibition of late origins during S phase requires the RAD53 kinase and involves the inhibition of Cdc7/Dbf4. In mammalian cells, the IR-induced and ATM-dependent intra-S checkpoint requires the Chk2 kinase, which phosphorylates Cdc25A to promote its degradation. Mammalian cells contain three Cdc25 genes: *A*, *B*, and *C*. Cdc25C dephosphorylates and activates the Cdc2/M-cyclin complex (MPF), whereas Cdc25A dephosphorylates and activates the Cdk/S-cyclin complex (S-phase-promoting factor, SPF). Degradation of Cdc25A, therefore, interferes with the formation and activation of pre-IC, leading to the inhibition of replication initiation. Whether the mammalian Cdc7/Dfb4 complex is also a target of the mammalian intra-S checkpoint remains to be determined. The Cdk/S-cyclin and Cdc7/Dbf4 kinases may not be the only targets of the intra-S checkpoint. Ongoing studies in the yeast model system have suggested several intra-S checkpoint pathways. Therefore, molecular mechanisms of intra-S checkpoint have yet to be fully elucidated.

G1/S Checkpoint

The G1/S checkpoint is activated by DNA damage in cells that have not yet initiated replication, and its function is to prevent the onset of S phase. The G1/S checkpoint inhibits Cdk/G1–cyclin to prolong the G1 phase. The G1/S checkpoint also inhibits Cdk/S–cyclin to prevent the onset of S phase, thus arresting cells in G1.

The p53-Dependent G1 Arrest

The most well-known mechanism for DNA damaged-induced G1 arrest is that mediated by the tumor-suppressor protein p53 in mammalian cells. DNA damage stabilizes the p53 protein and activates its transcription function. One of the p53 target genes is p21Cip1, a heat-stable inhibitor of Cdk/cyclin. The p53-dependent up-regulation of p21Cip1 causes inhibition of Cdk2/cyclin-E and Cdk2/cyclin-A to block S-phase entry. This p53-mediated G1 arrest is a slower response, because up-regulation of p21Cip1 requires transcription and new protein synthesis. The p53 gene is conserved in metazoan. However, the *Drosophila* p53 does not stimulate the expression of p21Cip1. Therefore, the p53/p21Cip1 pathway is not a conserved mechanism for DNA damage to cause G1 arrest.

The p53 protein belongs to a family of transcription factors with similar DNA binding specificity. The other two members, p63 and p73, are also activated by DNA damage. Together, this family of transcription factors may induce G1-arrest, premature senescence, or apoptosis in damaged cells (Figure 2). Premature senescence describes the phenotype of long-term arrest in G1, S, or G2. This long-term arrested state requires the RB-family of pocket proteins, which repress the expression of E2F-regulated cell cycle genes. DNA damage-induced apoptosis requires the functions of p53 and its related p63 and p73 proteins. The current model proposes that this family of transcription factors regulates the expression of pro-apoptotic proteins to induce cell death. At present, we do not understand how a damaged cell chooses between premature senescence and apoptosis through p53-family proteins. Choice between these two irreversible cell fates appears to be determined by cell types and developmental lineage.

Inhibition of S-Phase Entry

The up-regulation of p21Cip1 is not the only way to inhibit G1/S transition by DNA damage. In late G1 cells, Cdk2 is in complex with cyclin-E, and Cdk2/cyclin-E is required for the initiation of DNA replication. DNA damage can cause the inhibition of Cdk2/cyclin-E by two mechanisms: the up-regulation of p21Cip1 and the degradation of Cdc25A. As discussed above,

degradation of Cdc25A contributes to the inhibition of pre-IC in S phase cells. The inhibition of pre-IC can also cause G1 arrest if it occurs prior to the onset of S phase. Current evidence suggests that p21Cip1 only prevents the onset of S phase but does not contribute to the intra-S checkpoint. The degradation of Cdc25A, however, can inhibit S-phase entry and origin activation within the S phase.

Delay in G1 Progression

In the budding yeast, a short-lived G1 delay is observed in response to DNA damage. This G1 delay requires RAD53 and involves the inhibition of G1-cyclin (yeast CLN) expression. The mammalian G1-cyclins are the D-type cyclins, which form complex with Cdk4 or Cdk6. Degradation of cyclin D1 has been observed in response to DNA damage. The D-type cyclins promote G1 progression but they are dispensable for DNA replication. Loss of D-type cyclins alone is not likely to block S-phase entry, but may contribute to a delay in G1 progression.

DNA Damage Signal Transduction

The G1/S, intra-S, and G2/M checkpoints are terms to describe the distinctive effects of DNA damage on the cell cycle. These descriptive terms, however, do not imply distinctive molecular mechanisms. As discussed above, these cell-cycle effects can result from a common biochemical mechanism. For example, negative regulation of Cdc25 phosphatase can inhibit the onset of DNA replication in G1, prevent origin firing in S phase, or arrest cells in G2. Indeed, current evidence suggests DNA damage checkpoints are the effects of a common signal transduction network, the core of which is conserved in all eukaryotic cells. The conserved core components of this DNA damage-signaling network are listed in Table II. This list is far from complete, because the workings of this network are still under investigation.

The 9–1–1 Complex

Functioning at the top of the conserved signaling network is a PCNA-like protein complex composed of three proteins forming a heterotrimer that resembles the PCNA homotrimeric DNA-clamp. This PCNA-like complex is conserved from yeast to man. Based on the fission yeast gene names (RAD9, Rad1, Hus1), a unifying term has recently been coined to describe this trimer as the 9–1–1 complex. The 9–1–1 complex is loaded onto DNA by a protein (fission yeast Rad17) that resembles a subunit of the RFC (replication factor C). The normal RFC loads PCNA at the origin of replication. Rad17 is a component of a special RFC that loads the 9–1–1 complex onto damaged DNA. Together, Rad17-RFC and 9–1–1 function as a sensor of DNA damage. The 9–1–1 complex may provide a molecular platform for the assembly of DNA damage signaling complex.

TABLE II

Conserved Core Components in DNA Damage Signal Transduction

Name	Biochemical activity	Role in DNA damage signaling
Rad17-RFC	Loading the 9–1–1 clamp onto damaged DNA	Sensor
9–1–1	Heterotrimeric DNA clamp	Sensor
ATR, ATM, MEC1 (*S.c.*), Rad3 (*S.p.*)	Protein kinase of the PI3-kinase superfamily	Master switch
BRCA1, p53-BP1, MDC1, RAD9 (*S.c.*), Crb2 (*S.p.*)	Varied	Adaptor
Chk1	Protein kinase	Effector
Chk2, RAD53 (*S.c.*), Cds1 (*S.p.*)	Protein kinase with FHA domain	Effector

S.c.: Saccharomyces cerivisiae; *S.p.: Schizosaccharomyces pombe*.

Protein Kinase of the PI3K Family

The master switch in DNA damage signaling is a protein kinase of the PI3-kinase superfamily. In the budding yeast, *mec1* gene encodes this master protein kinase. In the fission yeast, *rad3* encodes a similar master protein kinase. In mammalian cells, ATR is likely to be the functional homologue of the yeast MEC1, Rad3 protein kinase. The MEC1, Rad3, and ATR kinase each associates with an accessory factor, encoded by the budding yeast Ddc2, fission yeast Rad23 and mammalian ATRIP, respectively. The MEC1/Ddc2, Rad3/Rad26 or ATR/ATRIP complex each associates with damaged DNA, in parallel with the Rad17-RFC/9–1–1 sensor. The MEC1, Rad3 and ATR kinase then phosphorylate downstream effectors to propagate the damage signals.

In mammalian cells, the ATM kinase, another member of the PI3K-family, also plays an important role in DNA damage signaling. As discussed above, ATM is required for IR to activate the intra-S checkpoint. *ATM* is not an essential gene. *Atm*-knockout mice are born, and they exhibit many of the phenotypes of AT patients. By contrast, *ATR* is essential for life. *Atr*-knockout causes early embryonic lethality in mice. Conditional knockout of *Atr* causes lethality

within one round of cell cycle, suggesting ATR to control cell cycle intrinsic regulatory processes.

Chk1 and Chk2 Kinases

Downstream of the master switch kinase is a network of substrates with varying degree of evolutionary conservation. The most highly conserved substrates with essential functions in DNA damage signaling are the Chk1 and Chk2 kinases. The fission yeast Chk1 is required for DNA damage to prevent the activation of MPF. This function is conserved for the metazoan Chk1 kinase. The mammalian Chk2 is homologous to the fission yeast Cds1, and the budding yeast RAD53 and Dun1. The Chk2-family of kinases is distinguished by the FHA domain, which is not found in Chk1. The FHA domain preferentially interacts with peptides that contain a phospho-threonine residue. The FHA domain in Chk2 mediates phosphorylation-dependent protein-protein interaction and plays a critical role in the regulation of Chk2 kinase activity. The Chk1 and Chk2 kinases are directly phosphorylated by ATR/ATM kinases in mammalian cells. Phosphorylation is necessary, although not sufficient, for activation of the Chk1 and Chk2 kinase activity.

BRCT-Containing Adaptor Proteins

The master switch kinase also phosphorylates another class of proteins, which have been postulated to function as "adaptors" in DNA damage signal transduction. The founding member of this class of adaptor proteins is the budding yeast RAD9 gene product. The RAD9 protein contains a pair of BRCT domains at its C terminus. RAD9 is phosphorylated by the PI3 kinase; and phosphorylated RAD9 has an essential role in activating RAD53 kinase. In the fission yeast, Crb2 contains a pair of BRCT domains at its C terminus and it is required for DNA damage to activate Chk1 kinase. In mammalian cells, at least three proteins have exhibited structural and functional characteristics similar to RAD9. These are BRCA1 (breast cancer associated 1), p53-BP1, and MDC1 (also known as Kiaa0170). Each of these three proteins are phosphorylated in response to DNA damage and each plays important roles in activating DNA repair or cell cycle checkpoints. Whether these BRCT proteins have specific or redundant functions in DNA damage signal transduction is presently unknown.

Other Transducers

DNA damage signal transduction involves many more proteins than those summarized in Table II. A number of downstream effectors in this signal transduction network are not conserved through evolution and not included in Table II. A good example is the p53 tumor-suppressor protein. As discussed earlier, p53 is conserved in metazoan. The conserved biological effect of p53 is to activate apoptosis in response to DNA damage. In vertebrates, p53 can additionally activate p21Cip1 to cause G1 arrest. The conserved core of the DNA damage signal transduction network, therefore, recruits non-conserved effectors to tailor the biological responses. If so, studies of the conserved core alone may not elucidate all the damage response pathways. Instead, each response to DNA damage may have to be investigated in an appropriate experimental system to identify the specific downstream effectors for that biological response.

Glossary

ATM A large-molecular-weight protein encoded by the gene that is mutated in the human disease AT. AT patients suffer from cerebella degeneration, extreme sensitivity to ionizing radiation, increased cancer risk, and sterility. *Atm*-knockout mice exhibit most of the AT phenotypes, except cerebella degeneration. ATM contains a PI3-kinase homology domain and its function is required for IR to activate the DNA damage checkpoints.

ATR ATM and Rad3 related, a protein with a PI3-kinase homology domain. ATR has an essential function in mammalian cells, and is required for the activation of replication, G2/M, and intra-S checkpoints.

BRCT A modular protein–protein interaction domain conserved through evolution and found in proteins required for checkpoint activation or DNA repair.

Cdk Cyclin-dependent protein kinase. Cdk forms complex with and is activated by cyclin. Cdk1 is also known as Cdc2 kinase.

Chk1 Checkpoint kinase-1, first identified in the fission yeast and conserved through evolution. DNA damage activates Chk1 to maintain MPF in the latent, inactive state. Chk1 is not an essential gene in yeasts, but Chk1-knockout mouse ES cells die from mitotic catastrophe.

Chk2 Checkpoint kinase-2, first identified in the fission yeast as the Cds1 kinase and conserved through evolution. The budding yeast contains two Chk2-like kinases: RAD53 and DUN-1. Germline mutation of the *CHK2* gene is found in a fraction of patients with the Li–Fraumeni cancer syndrome, which can also result from germline mutation of the p53 tumor-suppressor gene.

Cyclins Activators of cyclin-dependent kinases. Cyclins are expressed and degraded periodically through the cell cycle.

FHA A modular protein–protein interaction domain conserved through evolution. FHA domain binds peptides with phosphorylated-threonine. However, binding to unphosphorylated peptide can also occur. FHA domain is found in a variety of proteins with diverse functions, including those involved in DNA damage signal transduction.

MPF M-phase-promoting factor, a protein kinase composed of a catalytic subunit Cdc2 and a regulatory subunit, M-phase cyclin.

premature senescence A prolonged growth arrest induced by DNA damage. The arrest can occur in G1, S, or G2 and is mediated by the repression of cell cycle genes.

SPF S-phase promoting factor. In the context of this article, SPF denotes the function of Cdk2, activated by the mammalian E-type or A-type cyclins.

Biography

Jean Y. J. Wang is a Professor in the Division of Biological Sciences at the University of California, San Diego. Her principal research interest is to understand mammalian cell growth control. Her research has been focused on elucidating the role of retinoblastoma tumor suppressor protein, Abl tyrosine kinase and p73 in regulating differentiation and apoptosis. She holds a Ph.D. in biochemistry from the University of California, Berkeley. She was also a postdoctoral fellow at the Massachusetts Institute of Technology Cancer Center.

Cell Cycle: Mitotic Checkpoint

Tim J. Yen
Fox Chase Cancer Center, Philadelphia, Pennsylvania, USA

The mitotic checkpoint is a fail-safe mechanism that evolved to ensure that cells with even a single unaligned chromosome do not exit mitosis to produce aneuploid cells. The mitotic checkpoint solves a inherent problem that arises because of the stochastic nature by which chromosomes attach to the spindle. At the onset of mitosis, chromosomes are randomly distributed throughout the cell so that not all chromosomes will achieve alignment at the spindle equator at the same time. Chromosomes located in the center of the spindle will rapidly establish bipolar attachments due to their higher frequency of encounters with microtubules. By contrast, chromosomes located near a pole will rapidly attach to that pole but attachment to the opposite pole will take more time given the lower frequency that it will find the rare microtubule that originates from the opposite pole. As the kinetochore is the structure on chromosomes that establishes connections with spindle microtubules, the checkpoint monitors this site to determine if chromosomes are properly attached to the spindle and whether it has achieved alignment.

The goal of this article is to discuss current models that explain how the checkpoint monitors kinetochore functions and how a localized defect that is restricted in space can alter the global biochemical status of a cell.

The Mitotic Checkpoint Monitors Kinetochores

The checkpoint is able to sense the status of chromosome alignment by monitoring microtubule occupancy and tension (or the lack thereof) at kinetochores. Once a defect is detected, the kinetochore generates an inhibitory signal to block the onset of anaphase. Early studies showed that a single unattached kinetochore is sufficient to arrest cells in mitosis. Thus, the mitotic checkpoint functions much like a signal transduction cascade where a defective kinetochore generates a signal that must be amplified throughout the cell to inhibit its targets. The discovery of the molecular components of the mitotic checkpoint has shed considerable light into how the mechanical activities at the kinetochore can regulate mitotic progression.

Molecular Components of the Mitotic Checkpoint

The mitotic checkpoint is specified by six evolutionarily conserved genes, BUB1, BUB3, MAD1, MAD2, MAD3, and MPS1. All of these genes are essential as inactivation of any single gene prevents cells from delaying mitosis in the presence of unaligned chromosomes. BUB1 and MPS1 are protein kinases, while the biochemical activities of the remaining proteins are unknown. It appears that MAD3 in metazoans has evolved into BUBR1, a third protein kinase of the mitotic checkpoint. It is interesting that BUBR1 may have co-evolved with CENP-E, a kinetochore motor whose activity is thought to be monitored by BUBR1 and is also only present in metazoans. With the identification of checkpoint genes, the outstanding question is how their gene products interact at the molecular and biochemical levels to specify the signaling pathway that links a defective kinetochore to inhibition of the anaphase promoting complex (APC).

Monitoring Microtubule Occupancy and Tension at Kinetochores

The discovery that mitotic checkpoint proteins preferentially localize to unattached kinetochores suggested their roles in monitoring kinetochore activities and generating the "wait anaphase" signal. In this regard, the role of the MAD2 checkpoint protein at kinetochores has been extensively characterized. Quantitative studies have shown that the staining intensity of MAD2 at unattached kinetochores can be nearly 100-fold higher than that detected at kinetochores that are fully saturated with microtubules. In contrast, the intensity of BUB1 and BUBR1 staining varies only three- to fivefold between unattached and attached kinetochores. It is now evident that MAD2 localization is sensitive to microtubule attachments rather that kinetochore tension. When microtubule dynamics is suppressed by drugs (taxol or low concentrations of nocodazole or vinblastine) or low temperature, kinetochores are fully attached with microtubules, but no tension develops. As MAD2 is

not detected at these kinetochores, the conclusion was that MAD2 monitors microtubule attachment, but not the tension. These studies therefore reinforced an early notion that kinetochore tension is monitored by the checkpoint.

How tension is monitored by the checkpoint is not fully understood but it clearly involves aurora B/Ipl1, a protein kinase that is situated between sister kinetochores where tension is developed. Recent studies in yeast and mammalian cells showed that aurora B/Ipl1 is required for cells to arrest in mitosis when their kinetochores fail to establish tension despite being saturated with microtubules. Thus, aurora B was found to be essential for cells to arrest in the presence of taxol, a drug that suppresses microtubule dynamics and thus prevents kinetochores from developing tension. Despite this data, aurora-B/Ipl1 does not behave like the other checkpoint proteins, as it is not required for cells to arrest in mitosis in response to the loss of microtubule attachments. Aurora B/Ipl may therefore provide tension-sensing checkpoint functions.

AuroraB/Ipl1 has been proposed to be part of a mechanism that ensures that improperly attached kinetochores are provided the opportunity to establish proper connections to the spindle. The need for a self-correcting mechanism is evident because of the error-prone nature by which kinetochores establish microtubule connections. Merotelic and syntelic attachments are conditions where both kinetochores are connected to the same pole or when one kinetochore is attached to opposite poles, respectively. As kinetochores with merotelic and syntelic attachments are fully saturated with microtubules, a checkpoint that is only sensitive to microtubule occupancy at kinetochores will fail to detect these aberrant connections. AuroraB/Ipl is thought to monitor merotelic and syntelic attachments as these abnormal connections accumulated when this kinase was inactivated. Aurora B/Ipl1 is thought to resolve merotelic and syntelic attachments by stimulating the release of microtubules from these kinetochores and thus promoting new rounds of interactions. Given this scenario, it is possible that kinetochores lacking tension do not directly activate the checkpoint but do so as a result of microtubule detachments that is stimulated by aurora B kinase. This could explain why, in taxol arrested cells, there is on average one kinetochore that exhibits MAD2 staining. It may be possible that this is sufficient to arrest these cells in mitosis.

The mechanism by which aurora B promotes microtubule release from kinetochores has not been clarified but is likely mediated through MCAK, an unconventional kinesin-like protein that colocalizes with aurora B and functions to depolymerize microtubules.

The Mitotic Checkpoint Monitors a Kinetochore Motor

CENP-E is a kinesin-like protein that binds to kinetochores at the onset of mitosis where it plays a critical role in establishing microtubule attachments. The link between CENP-E and the mitotic checkpoint was first established when cells whose kinetochores were depleted of CENP-E were found to arrest in mitosis. Cells defective for CENP-E functions characteristically accumulate a few chromosomes with monopolar attachments while the majority establish bipolar connections. The inability of monopolar chromosomes to establish bipolar connections is thought to reflect the importance of CENP-E in allowing kinetochores to capture the rare microtubules that emanate from the opposite pole. On the other hand, chromosomes that are positioned near the middle of the cell can establish bipolar attachments because the higher-frequency encounters with microtubules from both poles can compensate for the loss of CENP-E. Quantitative EM analysis showed that the bipolar attached kinetochores lack tension despite attaining near normal numbers of microtubule attachments. In contrast, the kinetochores of the monopolar chromosomes established very few microtubule connections. The defects of the monopolar versus the bipolar attached chromosomes are viewed differently by the mitotic checkpoint. Consistent with its role in detecting microtubule attachments, MAD2 accumulated at kinetochores of the monopolar chromosomes, while it was undetectable at kinetochores of the bipolar chromosomes. These findings clearly show that the mitotic delay induced by the loss of CENP-E may be due to loss of microtubule attachments and tension.

The precise role of CENP-E in the mitotic checkpoint has been somewhat controversial. Studies in human cells suggested that it was not essential for the checkpoint as cells were able to arrest in the absence of CENP-E. In contrast, *Xenopus* egg extracts depleted of CENP-E and hepatocytes derived from CENP-E null mice failed to delay mitosis in the presence of unaligned chromosomes. The difference in response however is most likely a function of whether the assembly of checkpoint proteins to kinetochores is dependent on CENP-E. In egg extracts, the localization of a number of checkpoint proteins to kinetochores was absolutely dependent on CENP-E. Thus, the failure of egg extracts to delay mitosis in the absence of CENP-E can be ascribed to the absence of checkpoint proteins at unattached kinetochores. This contrasts with human cells where checkpoint proteins present at kinetochores that were depleted of CENP-E. However, quantitative analysis showed that in mouse and human cells, CENP-E did affect the assembly of checkpoint proteins at kinetochores. In both species, kinetochores depleted of CENP-E had approximately two- to fourfold lower levels of

MAD1, MAD2, and BUBR1 than normal. However, this did not resolve why mouse cells failed to arrest in mitosis in the absence of CENP-E while human cells arrested. The discrepancy could be resolved if we take into account the fact that far fewer monopolar chromosomes accumulated in CENP-E depleted mouse cells than in human cells (two versus eight). Given that the reduction in the amount of checkpoint proteins at these kinetochores likely compromised their ability to generate the "wait anaphase" signal, the combined output from all of the unattached kinetochores in mouse cells may not reach a threshold level that is required to sustain a prolonged arrest. In human cells, this threshold may be achieved as a result of the higher numbers of unattached kinetochores. Indeed, both mouse and human cells depleted of CENP-E were able to arrest in mitosis if the number of unattached kinetochores were increased by using drugs that inhibit spindle formation.

The mechanism by which CENP-E function is monitored by the checkpoint is believed to be mediated by the BUBR1 kinase. This connection was uncovered when hBUBR1 was identified in a yeast two-hybrid screen for proteins that interacted with CENP-E. This interaction was subsequently validated when CENP-E and hBUBR1 were found to form a complex in cells. This finding coupled to the fact that hBUBR1 is an essential checkpoint protein suggested that hBUBR1 might act as a mechanosensor to monitor the activities of CENP-E at kinetochores (Figure 1). Consistent with this, hBUBR1 was found to be required for cells to arrest in mitosis when CENP-E functions were inhibited. The mechanism by which hBUBR1 monitors CENP-E activity remains to be clarified but the working hypothesis is that hBUBR1 kinase activity is sensitive to interactions between CENP-E and microtubules. In the absence of microtubule interactions, CENP-E assumes a conformation that stimulates hBUBR1 to generate the "wait anaphase" signal. When CENP-E is interacting productively with microtubules, hBUBR1 is then silenced. Recent *in vitro* data showed that both *Xenopus* and human CENP-E can directly bind to BUBR1 and this binding stimulated its kinase activity. As microtubules were not present in these reactions, it is possible that the interaction reflected the "checkpoint on" state. Addition of a CENP-E antibody to the CENP-E:BUBR1 complex inhibited kinase activity without disrupting the complex. The interpretation of this finding was that antibody binding altered the conformation of CENP-E so that it was unable to stimulate BUBR1 kinase activity. Thus, kinase activity of BUBR1 may be regulated allosterically by different conformational states of CENP-E. Although this model may indeed apply to the situation *in vivo*, the exact details of the mechanism remain to be clarified. For example, the *in vitro* dependence of BUBR1 kinase activity on CENP-E does not account for how cells that are depleted of CENP-E arrest in mitosis.

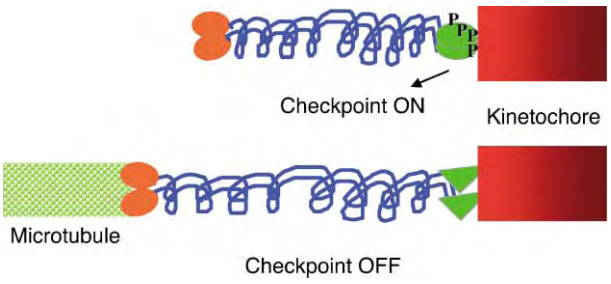

FIGURE 1 BUBR1 kinase acts as a mechanosensor that monitors CENP-E at kinetochores. BUBR1 kinase (green) interacts near the carboxy-terminus of CENP-E where it is postulated to monitor the microtubule binding status of CENP-E. In the absence of microtubule attachments, BUBR1 is phosphorylated and activated (green oval) so that it generates the "wait anaphase" signal. When CENP-E is properly attached to microtubules, it undergoes a conformational change that inhibits BUBR1 kinase (green triangles) and thus extinguishes the "wait anaphase" signal.

Inhibition of Mitotic Exit by the Checkpoint

Checkpoint proteins are functionally complex as they participate in multiple steps along the checkpoint signaling pathway. A confluence of genetic and biochemical studies showed that the target of the checkpoint is the APC, an E3 ubiquitin ligase that promotes the degradation of substrates that inhibit the onset of anaphase.

Sequestration Model

Studies in budding and fission yeast identified checkpoint defective alleles of CDC20/Slp1, a protein that was shown biochemically to activate the APC by recruiting substrates to it. These CDC20 and Slp1 mutants were unable to bind to MAD2 and thus supported *in vitro* data that MAD2 can inhibit the ubiquitin ligase activity of CDC20-dependent APC. These findings coupled with the *in vivo* observation that MAD2 exhibited a rapid rate of turnover at unattached kinetochores led to a model that described how MAD2 might act as the diffusible wait anaphase signal. In this Sequestration Model, unattached kinetochores are thought to catalytically convert MAD2 into an "activated" state which upon release from kinetochores binds to CDC20 and sequesters it from the APC (Figure 2). The existence of an activated MAD2 initially gained support when it was discovered that recombinant MAD2 existed as monomers and oligomers (di- and tetramers), but the oligomeric form was more potent at inhibiting APC than the monomeric form *in vitro*. However, the existence of a

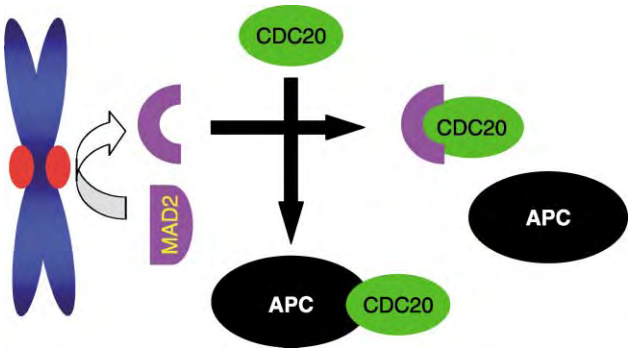

FIGURE 2 Sequestration model. The MAD2 checkpoint protein (purple semicircle) transiently binds to unattached kinetochores (red ovals) where they are converted to a form that upon dissociation will bind to CDC20. CDC20 when associated with MAD2 is incapable of activating the APC. In this model, the pool of MAD2 that is released from kinetochores acts as the "wait anaphase" signal by indirectly preventing the activation of APC.

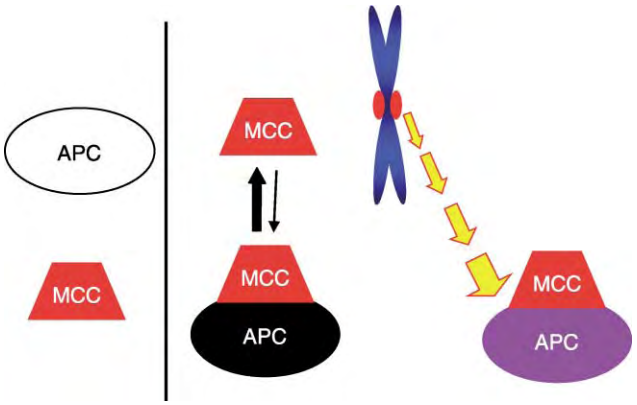

FIGURE 3 Direct inhibition model. BUBR1, Bub3, CDC20, and MAD2 form the MCC that does not depend on kinetochores and exists throughout the cell cycle. The MCC exhibits little affinity for the interphase form of the APC (white oval). Upon entry into mitosis, the APC is rapidly activated by modifications (black oval) that if unchecked will prematurely drive cells out of mitosis. A preformed pool of MCC binds and inhibits the APC. The interaction between MCC and the mitotic APC is by necessity unstable. The role of unattached kinetochores (red ovals) is to generate a signal transduction cascade that targets and sensitizes the APC (purple) to prolonged inhibition by the MCC.

MAD2 oligomer *in vivo* has been elusive. Furthermore, MAD2 mutants that failed to form tetramers *in vitro* were found to be well tolerated in yeast. These data suggest that if an activated MAD2 does exist *in vivo*, it is unlikely to be a tetramer. Regardless, the biochemical fate of the MAD2 that is released from kinetochores is unknown. Thus, it remains open as to whether turnover of MAD2 at kinetochores is functionally significant for the checkpoint.

A similar model has been proposed for how BUBR1 inhibits the APC. As with MAD2, recombinant BUBR1 was found to also bind CDC20 *in vitro*. Not surprisingly, BUBR1 was found to block CDC20-dependent activation of the APC *in vitro*. This result led to the proposal that BUBR1 may act in parallel with MAD2 to inhibit the APC *in vivo*. The caveat of these studies was that the experimental design for the BUBR1 assays employed the interphase form of the APC, which is not the *in vivo* substrate for the mitotic checkpoint. The rationale for this approach was that the activity of the interphase APC was dependent on the addition of exogenous CDC20. This assay was limited in the sense that it was designed to identify factors that inhibited CDC20. The caveat of these studies was further highlighted when recombinant BUBR1 failed to inactivate mitotic APC, which should be the physiologically relevant substrate of the mitotic checkpoint.

Direct Inhibitor Model

The Direct Inhibitor model differs from the sequestration model in that the APC is directly inhibited by checkpoint proteins and posits that unattached kinetochore sensitize the APC to its inhibitor (rather than generating a factor that sequesters an activator of the APC) (Figure 3). This model was proposed as a result of the discovery of the mitotic checkpoint complex (MCC), a factor that was identified in cell extracts that inhibited mitotic APC *in vitro*. The MCC was originally identified in Hela cells, where it was found to consist of near stoichiometric amounts of hBUBR1, hBUB3, CDC20, and MAD2. The interesting finding was that the MAD2 that was present in the MCC represented a very small fraction ($<5\%$) of the total pool of MAD2. Despite the presence of a large pool of monomeric MAD2, this pool was not found to inhibit the mitotic APC. Furthermore, MCC was more than 3000-fold more potent inhibitor of the APC than recombinant MAD2 (which was used in all the previous studies). The large difference in the inhibitory activities suggests that Hela cells do not express sufficient amounts of monomeric MAD2 to inhibit the APC. The mechanism by which MCC inhibited APC activity is not clear but is likely to depend on its ability to bind to the APC. When purified from cells, APC that was associated with MCC was found to be inactive, while APC that lacked MCC was highly active. Based on these findings, the MCC was proposed to be primary checkpoint inhibitor of the APC in mitotically arrested cells.

Although MCC was identified in mitotic Hela cells, it was subsequently found to be present and active throughout the cell cycle. Importantly, only APC that was isolated from mitotic cells was sensitive to inhibition by the MCC. How MCC distinguishes between interphase APC from mitotic APC is not

known but is most likely due to mitosis-specific modifications. Indeed, MCC appeared to preferentially bind to APC whose CDC27 subunit was mitotically phosphorylated. It is currently unknown if MCC directly interacts with CDC27 or through other APC subunits that undergo mitotic modifications. Regardless, the existence of MCC in interphase was unexpected, given that kinetochores, which are the sites thought to generate the inhibitor of the APC, are not fully formed until cells are in mitosis.

The importance of MCC in interphase becomes evident when one considers that the APC is rapidly activated at the onset of mitosis. A pre-formed pool of inhibitor provides the cell with a rapid way to inactivate APC. The inhibition of the APC by the MCC must be reversible so that cells can exit mitosis once the checkpoint is extinguished. Indeed, the interaction between MCC and the APC/C appears to be quite labile as APC activity in lysates prepared from mitotically arrested Hela cells cannot remain suppressed as ubiquitin ligase activity is reproducibly reactivated after a 10–15 min lag. This lag, however, could be extended if the extracts were supplemented with chromosomes (which provide the unattached kinetochores). Further studies using partially purified components showed that chromosomes did not enhance the inhibitory activity of MCC or the stimulating activity of CDC20, the likely target of kinetochores appears to be the APC/C.

The discovery of the MCC has led to a view that is fundamentally different from the predominant view that MAD2 cycles through kinetochores to bind and sequester CDC20 from the APC. In the "Direct Inhibitor model" the MCC acts independently of kinetochores to inhibit the APC. However, the interaction between MCC and APC is not stable unless unattached kinetochores are present. The role of unattached kinetochores is to sensitize the APC to prolonged inhibition by the MCC. The mechanism of APC sensitization is purely speculative. It is envisioned that unattached kinetochores initiate a kinase cascade that phosphorylates critical APC subunits that are required for MCC interactions. One expectation is that the modifications that sensitize APC to MCC inhibition must also be labile so that when the signaling cascade from kinetochores is extinguished, the APC will be de-sensitized. If unattached kinetochores generate a kinase cascade, it may target additional components besides the APC. One potential target is CDC20, as recent studies in *Xenopus* showed that phosphorylated CDC20 was unable to activate the APC.

The existence of the MCC has been confirmed in other species including *Xenopus* and yeast. Interestingly, MCC formation in budding yeast was also found to be independent of kinetochores. In the light of this finding, the molecular basis for the checkpoint-defective CDC20 mutants should be reinterpreted. The original interpretation was that these CDC20 mutants failed to be sequestered from the APC because they were unable to bind MAD2. From the perspective of the MCC, the checkpoint phenotype of these CDC20 mutants may result from their inability to assemble a functional MCC.

Dual Roles for Mitotic Checkpoint Proteins

The discovery that the MCC contains proteins that are also localized at kinetochores suggested that they might play dual roles in the checkpoint. These proteins participate in monitoring kinetochore defects and then generating the "wait anaphase" signal. The same proteins can act independently of the kinetochore by being part of the MCC that directly inhibits the APC.

Checkpoint Proteins can have Dual Functions

Until recently, it was technically not possible to design experiments that directly test if checkpoint proteins can serve dual functions. The solution came when it was discovered that the assembly of MAD2 onto kinetochores depended on hNuf2 and CENP-I. When kinetochores in Hela cells were depleted of hNuf2, they failed to assemble the checkpoint proteins, MPS1, MAD1 and MAD2. Similarly, kinetochores depleted of CENP-I failed to bind MAD1 and MAD2 (MPS1 was not investigated). In both cases, cells defective for hNuf2 or CENP-I functions failed to align chromosomes properly. Despite the lack of detectable MAD2 at kinetochores, the cells were able to delay mitotic exit. More surprisingly, this delay was still dependent on MAD2 as simultaneous depletion of MAD2 and hNuf2 by siRNA prevented accumulation of mitotic cells. Similarly, mitotic cells depleted of CENP-I rapidly exited mitosis when they were injected with MAD2 antibodies, while those injected with nonimmune antibodies remained in mitosis. These results are fully consistent with the idea that there are two functional pools of MAD2. The one that is present at kinetochores is involved in generating the "wait anaphase" signal, while the other pool acts independently of kinetochores. These studies indicate that the kinetochore-bound MAD2 is not essential. The characteristics of the kinetochore-independent pool of MAD2 are highly reminiscent of MCC, which is postulated to directly inhibit APC activity.

Aside from MAD2, there is also evidence to suggest that MPS1 and BUBR1 functions in a kinetochore-dependent and kinetochore-independent manner. MPS1 was one of the checkpoint proteins that was depleted

from kinetochores that lacked hNuf2. While hNuf2-depleted cells were shown to delay mitosis, cells directly lacking MPS1 failed to arrest in mitosis in response to microtubule poisons. The difference in outcomes is best explained if MPS1 possessed two distinct functions. As MPS1 is not associated with the MCC, its kinetochore-independent function remains uncertain.

Early studies of the human BUBR1 kinase showed that its kinase activity was essential for the mitotic checkpoint. Nevertheless, hBUBR1 purified from interphase cells as part of the MCC exhibits no detectable kinase activity, yet is fully capable of inhibiting APC. Likewise, *in vitro* studies showed that inhibition of the CDC20-dependent APC activity by recombinant BUBR1 can also be independent of its kinase activity. The apparent contradictory findings could be resolved by postulating that kinase activity of BUBR1 was required for the kinetochore while kinase activity was not required for its kinetochore-independent role as the MCC. This hypothesis has now been confirmed that were conducted in *Xenopus* egg extracts by BUBR1 depletion and add-back experiments. When extracts depleted of BUBR1 are reprogrammed with a kinase-dead mutant, they are no longer able to activate their checkpoint. Interestingly, if the BUBR1 (wild type or mutant) was supplemented to 20% of the endogenous level, it is sufficient to saturate all the kinetochores to levels seen in normal kinetochores. However, the presence of BUBR1 at kinetochores is still insufficient to activate the checkpoint unless the cytosolic pool of BUBR1 is also restored. This suggests that BUBR1 might provide two separable functions in the checkpoint. Whether the cytosolic BUBR1 acts by sequestering CDC20 or as part of the MCC is not clear. The finding that either wild-type or kinase-dead BUBR1 can restore the checkpoint to kinetochores that had assembled BUBR1 wild-type kinase but not the mutant supports the idea that its kinase activity was essential at kinetochores but not in the cytosol.

"Wait Anaphase" Output Regulated by Checkpoint Proteins

Studies of hNuf2 and CENP-I led to the remarkable finding that MPS1, MAD1, and MAD2 do not appear to play an essential role at the kinetochore. How do kinetochores that lack MPS1, MAD2, and MAD2 maintain the checkpoint? This is most likely achieved in part by BUBR1 and BUB1 whose levels were not noticeably depleted. However, these proteins by themselves do not appear to be sufficient to generate a robust "wait anaphase" signal from unattached kinetochores. Cells defective for CENP-I accumulate a few monopolar chromosomes, while most chromosomes appear aligned (similar to loss of CENP-E). These cells are unable to sustain a prolonged mitotic arrest because the unattached kinetochores cannot generate sufficient amounts of "wait anaphase" signal to sustain a prolonged arrest. Consistent with this explanation, if the total number of unattached kinetochores was increased by disrupting the spindle with microtubule poisons, the collective output from a large number of unattached kinetochores must reach a critical threshold that is required for cells to arrest in mitosis. The caveat of this interpretation is that, after nocodazole treatment, kinetochores depleted of CENP-I exhibited detectable MAD2, although it was 20-fold lower than the level that is present at in-control cells. Nocodazole-treated Hela cells easily contain more than 20 unattached kinetochores (Karyotype > 60 chromosomes) and should therefore be able to generate a threshold level that can normally be achieved by a single unattached kinetochore.

Glossary

anaphase promoting complex (APC) A multisubunit E3 ubiquitin ligase that promotes the proteolytic degradation of substrates such as cyclin B and securin in order for cells to exit mitosis.

kinetochore A macromolecular complex that is assembled at centromeres near the onset of mitosis that is essential for chromosomes to attach to the spindle.

kinetochore tension The force that is developed between sister kinetochores because of opposing poleward forces that attempt to separate them.

monopolar and bipolar States of attachment of chromosomes to either a single pole or to both poles of a spindle.

"wait anaphase" signal An inhibitory signal generated from unattached kinetochores that diffuses throughout the cell to block the onset of anaphase.

Biography

Tim Yen is a senior member at the Fox Chase Cancer Center in Philadelphia, Pennsylvania. His major research interest is to characterize the molecular and biochemical composition of the kinetochore as a means to understand the mechanism of chromosome segregation in mammalian cells. He obtained his Ph.D. at the University of California at Santa Barbara and trained as a Postdoctoral Fellow at the Department of Biological Chemistry at the Johns Hopkins University School of Medicine. He was a Lucille Markey Scholar and a Scholar of the Leukemia and Lymphoma Society.

Cell Death by Apoptosis and Necrosis

Pierluigi Nicotera
MRC Toxicology Unit, Leicester University, Leicester, UK

Various genetically encoded programs involved in the signaling, initiation, and execution of cell death decide cells' fate during development and adult life. These programs can execute physiological cell death during development or tissue turnover, but are also involved in the inappropriate elimination of cells under pathological conditions. Because balanced cell turnover is essential for life, defects in cell elimination can also result in disease, the foremost example being cancer. In many circumstances, both physiological cell death and cell death in pathological settings have similar morphological and biochemical characteristics. Perhaps the best characterized biochemical and morphological changes during a cell death program are those defined as apoptosis. Apoptosis is characterized by condensation and fragmentation of the nucleus with shrinkage of the cytoplasm and exposure of surface molecules that facilitate recognition of the dying cells by phagocytes. However, other types of cell death are present and are strictly regulated *in vivo*, including cell lysis/necrosis or autophagy. Imbalance in cellular calcium regulation has been involved in both apoptotic and non-apoptotic cell death. Calcium can be a signal for cell death or simply a downstream consequence of the activation of the death machinery.

Ca^{2+} as a Signal for Cell Death

A sustained Ca^{2+} overload, such as that resulting from dysfunction of the main routes of Ca^{2+} entry or efflux or from the irreversible loss of intracellular buffering capacity, can be lethal. The idea that Ca^{2+} may be cytotoxic dates back to A. Fleckenstein's suggestion in 1968 that excessive entry of Ca^{2+} into myocytes could be the underlying mechanism of cardiac pathology following ischemia. Subsequent studies showed that agonist stimulation or cytotoxic agents could cause lethal Ca^{2+} entry into cells. Cellular Ca^{2+} overload involves multiple intra- and extracellular routes, most of which are also used for physiological signaling, which implies that not only alterations of the normal Ca^{2+} homeostasis but also changes in Ca^{2+} signaling can have adverse effects. The following have been shown in a large number of experimental paradigms: (1) Direct sustained elevation of $[Ca^{2+}]_i$ (e.g., by exposure of cells to ionophores or to conditions that cause prolonged gating of inward-directed channels) causes cell death. (2) A $[Ca^{2+}]_i$ elevation precedes cell death induced by pathophysiological stimuli. (3) Prevention of $[Ca^{2+}]_i$ elevation during such experiments can inhibit cell death. (4) Alterations of Ca^{2+}-signaling pathways (e.g., potentiation or inhibition of Ca^{2+} currents) can result in cytotoxicity.

Executors of Ca^{2+} Death Signals

Intracellular Ca^{2+} signals can set off cell demise via Ca^{2+}-dependent processes, change the mode of cell death from apoptosis to necrosis, or synergize with elements of the apoptotic death program. In particular, Ca^{2+}-activated proteases (calpains) can synergize with caspases and amplify apoptotic death routines, while modulators of apoptosis such as members of the Bcl-2 protein family can modulate Ca^{2+} compartmentalization. Hydrolytic enzymes, which include calpains, various DNAses, and lipases, are the best-characterized effectors of cell death directly mediated by calcium overload. Calpains are Ca^{2+}-activated cysteine proteases that have been implicated in toxic cell death in the liver and in excitotoxic neuronal death. Calcium-dependent DNAses can be responsible for DNA degradation, although the nature of the Ca^{2+}-dependent enzyme(s) responsible for the typical oligonucleosomal DNA cleavage has remained elusive. Among lipases, the Ca^{2+}-dependent phospholipase A_2 (PLA_2) has been implicated in neurotoxicity. Its activation results in the release of arachidonic acid and related polyunsaturated fatty acids, which are further metabolized by lipoxygenases or cyclooxygenases with concomitant generation of reactive oxygen species (ROS). In addition, PLA_2 activation generates lysophosphatids that alter the membrane structure, which may facilitate Ca^{2+} influx and Ca^{2+} release from internal stores.

Ca^{2+}, Excitotoxicity, and Death During Brain Ischemia

Excitotoxicity is a phenomenon typically encountered in neurons or myocytes following receptor stimulation by excitatory amino acids that exceeds the physiological range with respect to duration or intensity. Typical excitotoxic stimulators are capsaicin, acetylcholine, or – most important in the central nervous system – glutamate. Direct injection of glutamate is selectively neurotoxic *in vivo*. Also, inhibition of excess synaptic activity by inhibitors of glutamate receptor subtypes (mainly N-methyl-D-aspartate, or NMDA) protects neurons from hypoxia. Generally, excitotoxicity is induced by conditions favoring glutamate accumulation in the extracellular space. Typical conditions leading to increased extracellular glutamate concentration are depolarization of neurons, energy depletion due to hypoglycemia or hypoxia, or defects in the glutamate reuptake systems.

Overall, three different lines of evidence suggest the key role of Ca^{2+} in excitotoxicity: (1) There is an obvious increase in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) in both *in vivo* and *in vitro* models of excitotoxic cell death. This has been observed in ischemic brain and in brain slices exposed to NMDA agonists or anoxia. In addition, glutamate-stimulated Ca^{2+} influx in cultured neurons has been shown by the Ca^{45} technique, and increased $[Ca^{2+}]_i$ after NMDA stimulation has been observed repeatedly using fluorescent probes. (2) Prevention of Ca^{2+} entry into the cell by removal of extracellular Ca^{2+} depletion of NMDA or by pharmacological inhibition of glutamate receptors or voltage-dependent Ca^{2+} channels prevents neuronal death in many paradigms of excitotoxicity. (3) Prevention of neurotoxicity by inhibition of downstream effects of Ca^{2+} overload strongly suggests a causal role of Ca^{2+} in excitotoxicity. Intracellular Ca^{2+} chelators can prevent ischemic damage *in vivo* and excitotoxic neuronal damage *in vitro*. Also, inhibition of effectors of Ca^{2+} toxicity such as calmodulin, calcineurin, and bNOS protects neurons from the toxicity of excitatory amino acids. On the other hand, there could potentially be other routes for Ca^{2+} entry under excitotoxic conditions.

Using a model of hypoxia (oxygen/glucose deprivation, or OGD), a new lethal pathway that involves the activation of a cation conductance (I_{OGD}) has recently been unveiled. This leads to neuronal Ca^{2+} overload in the absence of excitotoxic stimulation. I_{OGD} requires the TRMP7 ion channel protein, a member of the TRP (transient receptor potential) cation channel super family. Gating of TRMP7 occurs because of the generation of an excess of reactive oxygen/nitrogen species in anoxic neurons. Because gating TRMP7 allows Ca^{2+} entry into the neuron and Ca^{2+} can stimulate further radical production, a vicious loop leading to sustained Ca^{2+} overload is established in the absence of NMDA-R stimulation by excess glutamate.

In addition to excessive entry of Ca^{2+} trough membrane channels, mitochondrial Ca^{2+} sequestration and subsequent release play a central role in ischemia- or glutamate-mediated cell death. Nevertheless, mitochondrial Ca^{2+} release and increased Ca^{2+} influx into neurons cannot fully account for the irreversible build-up of intracellular Ca^{2+} after excitotoxic stimulation. The bulk increase in cellular Ca^{2+} should be rectified over time, unless cellular Ca^{2+} extrusion is inhibited. Inhibition of cellular Ca^{2+} efflux from cells is sufficient to trigger cell death in non-neuronal cells, and in neurons may be brought about by oxidative damage downstream of mitochondrial dysfunction. Recent work shows that calpains can cleave the plasma membrane Na^+/Ca^{2+} exchanger (NCX) in brain ischemia and in cerebellar granule neurons exposed to glutamate. Calpain-mediated NCX proteolysis is necessary for the delayed excitotoxic Ca^{2+} deregulation leading to neuronal death (for a schematic summary of excitotoxicity, see Figure 1).

Apoptosis, Necrosis, and Other Ca^{2+}-Dependent Forms of Cell Death in Brain Ischemia

Neuronal demise and neurological dysfunction in brain ischemia are clearly due to several components. Apoptosis and necrosis, in their classical definition, are two fundamentally different modes of cell death. Whereas apoptosis is characterized by a preservation of membrane integrity until the cell is phagocytosed, this is not the case in necrosis/lysis of cells. The duration and extent of Ca^{2+} influx may determine if neurons survive, die by apoptosis, or undergo necrotic lysis. Very low $[Ca^{2+}]_i$ or the prolonged inhibition of Ca^{2+} influx may be neurotoxic. A continuous moderate increase in $[Ca^{2+}]_i$, such as that produced by a sustained slow influx, may cause apoptosis, whereas an exceedingly high influx causes rapid cell lysis. For example, stimulation of cortical neurons with high concentrations of NMDA results in necrosis, whereas exposure to low concentrations causes apoptosis. Accordingly, neuronal death in experimental stroke models is predominantly necrotic in the ischemic core, but apoptosis occurs in the less severely compromised penumbra or border regions. The same applies to several other neuropathological conditions in which apoptosis and necrosis have been observed to occur simultaneously. One sensor that switches neurons toward one of the two fates is the ability of cells to generate ATP. A complete de-energization of the cell (e.g., failure of all mitochondria and of glycolysis) does not allow the

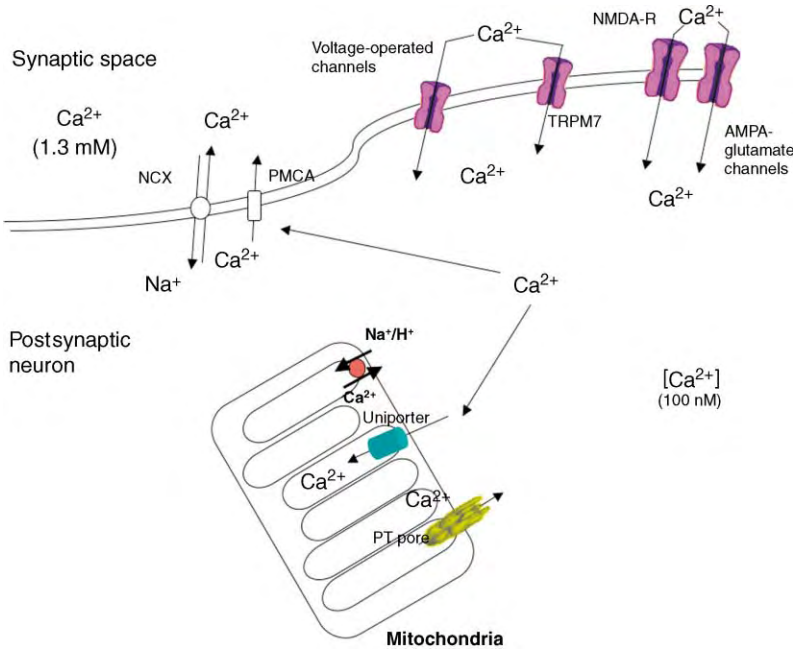

FIGURE 1 The term neuronal excitotoxicity defines as consequences of excessive stimulation of postsynaptic glutamate receptors. Excess glutamate in the synapse causes gating of AMPA and NMDA receptors. The former allows entry of Na^+ and Ca^{2+} into the neuron. Na^+ hyperpolarizes the plasma membrane and removes the Mg^{2+} block from the NMDA receptor (the NMDA receptor is normally "plugged" by Mg^{2+}). The NMDA receptor is then gated to Ca^{2+} that flows into the neuron. Additional routes for Ca^{2+} entry involve the TRPM7 cation channel and voltage-operated Ca^{2+} channels. Ca^{2+} accumulates in mitochondria as amorphous calcium phosphate. When the buffering capacity of mitochondria is overwhelmed, Ca^{2+} is released in a process known as permeability transition (PT). Efflux of Ca^{2+} from the neuron is operated by the NCX and the PMCA. When mitochondria release their Ca^{2+} and the efflux systems are unable to extrude the excess intracellular Ca^{2+}, Ca^{2+} overload becomes irreversible and causes neuronal demise.

ordered sequence of changes required for the apoptotic demise. In such a case, other processes result in rapid, uncontrolled cell lysis/necrosis. Therefore, under conditions of Ca^{2+} overload, apoptosis ensues when sufficient energy production (ATP) is available to execute the death program. The main ATP-requiring step for the execution of apoptosis is the formation of the apoptosome protein complex between cytochrome c released from damaged mitochondria, the cytosolic protein APAF-1, and procaspases. Either ATP or dATP is required to promote the functional activation and assembly of this complex, which then leads to caspase activation and cell breakdown.

Ca^{2+} Signals as Subroutines of the Apoptotic Program

The role of Ca^{2+} in apoptosis signaling was initially suggested by studies in thymocytes and lymphocytes showing that sustained Ca^{2+} increases could trigger the DNA fragmentation typical of apoptosis and all the other features of the apoptotic demise. Ca^{2+} may be central in the unfolding of the apoptotic program at different stages. Ca^{2+}-mediated mitochondrial permeability transition is recognized as one important mechanism for cytochrome c release and caspase activation. In addition, ER-mitochondrial Ca^{2+} fluxes are modulated by the Bcl-2 protein family, and caspase-mediated cleavage of Ca^{2+} transporters then results in further disruption of ER Ca^{2+} handling, with subsequent mitochondrial Ca^{2+} overload and permeability transition. Ample evidence has documented crosstalk among calpains, caspases, and other protease families, which alters the downstream effects of these families on cellular Ca^{2+} fluxes. Finally, Ca^{2+}-regulated processes are also involved in the ultimate fate of dying cells, their clearing by phagocytes due to Ca^{2+}-dependent exposure of surface recognition molecules and secondary lysis. The latter can be brought about by caspase-dependent cleavage of the plasma membrane Ca^{2+} ATPase (PMCA), which results in a secondary Ca^{2+} overload and the activation of Ca^{2+}-dependent mechanisms causing cell lysis.

Biography

Pierluigi Nicotera is Professor of Neuroscience and Professor of Toxicology at the University of Leicester, where he is also the Director of the UK Medical Research Council Toxicology Unit. His main research interest is in the mechanisms of cell injury and death in disease and toxic conditions. His research has contributed to the understanding of the mechanisms in which Ca^{2+} can cause cell dysfunction and death in neurons and non-neuronal cells.

Cell Migration

J. Victor Small and Emmanuel Vignal
Austrian Academy of Sciences, Salzburg, Austria

The morphogenesis of multicellular organisms involves the extensive migration of cells from primordial sites to locations destined for specific tissue development. Among the most dramatic are the movements of cells of the neural crest, which travel from the neural tube to distant sites where they differentiate into diverse cell lineages. The fusion of epithelial layers, such as those which occur during closure of the neural tube, entails coordinated cell migration. In the adult, wound closure and tissue repair depends on the migration of surrounding cells to effect the regeneration process. In defense against foreign organisms, cells of the immune system are mobilized and migrate to the sites of inflammation to engage with the enemy. In another context, cell migration contributes to the dissemination of malignant cells in the spread of cancer. Understanding cell migration has therefore much to do with life and death, which concerns all.

Metazoan cells migrate by a crawling mechanism that entails continuous changes in shape. Crawling, in turn, requires traction and this is provided by the development of transient points of anchorage with the connective tissue scaffold and with other cells. In both processes, shape change and traction, the intracellular polymer framework of the cell, the so-called cytoskeleton, plays a central role. Changes in the cytoskeleton framework are influenced, in turn, by the chemical and mechanical properties of the surrounding matrix, so there is an active crosstalk between the two. Most of what is known about the mechanisms of cell migration comes from studies of cells moving on planar surfaces *in vitro* and from investigations of the test tube properties of cytoskeleton polymers and their associated proteins. However, parallel studies indicate that the basic principles derived from these approaches apply also to cell movement in a tissue environment.

The Cytoskeleton

The cytoskeleton is composed of three distinct, but interlinked networks of polymers, composed of actin, tubulin, and proteins of the intermediate filament family, together with many associated proteins. The term cytoskeleton is a misnomer, because the cytoplasmic filament networks that make it up are in a state of continuous turnover and rearrangement. Cell migration is driven primarily by the programmed turnover of the actin cytoskeleton, but microtubules exert an important influence on polarization and guidance, which is required for directional motility. Intermediate filaments do not appear to play an important role in cell motility, but a subtle modulatory role cannot yet be excluded.

The Actin Cytoskeleton

The actin cytoskeleton is composed of actin filaments organized in networks and bundles: the salient features of the actin cytoskeleton in a fibroblast are illustrated in Figures 1 and 2. The cell periphery is delimited by either bundles of actin filaments, running parallel to the cell edge, or by dense actin meshworks (Figure 2A) that are commonly punctuated by small, radial actin bundles, termed microspikes or filopodia (Figure 2B). The actin meshworks (Figure 2) are the structural component of the sheet-like lamella regions at the cell periphery called lamellipodia (or ruffles, when they fold upwards. Figure 3). The body of the cell is pervaded by a loose network of actin filaments, a proportion of which are organized into prominent bundles, called stress fibers. According to cell type, the ratio of peripheral actin meshworks to stress fibers differs and as a general rule, cells that migrate faster have fewer stress fiber bundles in the body of the cell. The different organizations of actin filaments that make up the subcompartments of the actin cytoskeleton are signaled via pathways involving different members of the Rho family of small GTPases: Rho for stress fibers, Rac for lamellipodia, and Cdc42 for filopodia.

One important feature of the actin cytoskeleton is its linkage to the cell membrane, which explains its pivotal influence on cell form. Major sites of linkage occur at the termini of the stress fiber bundles, which in turn correspond to sites of adhesion of the cell to the extracellular matrix. Because of their focal nature, these sites are called focal adhesions (Figure 2C). They comprise more than 50 structural, adaptor, and signaling proteins that form and regulate the linkage of the actin cytoskeleton, via transmembrane receptors of the integrin family, to the extracellular matrix. The precursors of these anchorage sites are assembled in

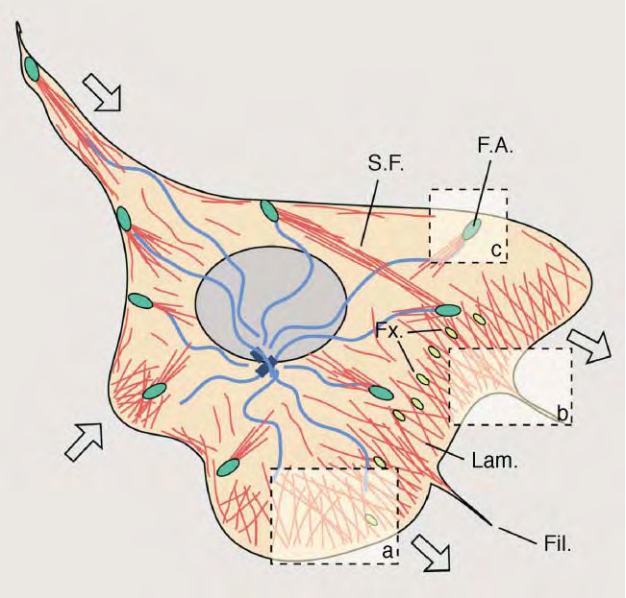

FIGURE 1 General features of the actin cytoskeleton of a migrating cell. Actin filaments are in red. Protrusion of the cell is driven by the formation of sheet-like meshworks (lamellipodia, Lam) and rod-like projections (filopodia, Fil). Early adhesions form beneath protrusions as focal complexes (Fx) and can mature into larger, focal adhesions (FA) at the termini of actin bundles, called stress fibers (SF). The polarization of the cell is reflected in a polarization of the adhesion pattern, with stationary focal complexes and focal adhesions at the front and sliding focal adhesions at the rear. Microtubules (blue) interact with adhesions and influence their turnover. Details of the boxed areas are provided in Figure 2.

association with lamellipodia and filopodia at the cell periphery and are called focal complexes (Figure 1).

Phases of Movement

In general terms, the mode of translocation of a cell can be divided into three phases: (1) protrusion of a cell front; (2) the development of adhesion to the substrate for the purpose of traction; and (3) retraction of the cell rear.

Protrusion

In the first step of movement, the cell protrudes lamellipodia and filopodia: sheet-like and rod-like processes $\sim$0.2 μm thick and several microns in length (Figures 3 and 4). The rate of protrusion varies from $\sim$2–15 μm min^{-1}. Protrusion is based on the unidirectional polymerization of actin, whereby actin monomers are inserted at the tips of actin filaments where they abut the cell membrane at the leading front (Figures 2A and 2B). Complexes of proteins are recruited at these membrane sites that signal and drive actin polymerization, downstream from Rac and Cdc42. Additional proteins are responsible for cross-linking the formed actin filaments into meshworks (lamellipodia) and bundles (filopodia) and for disassembling actin filaments at the base of lamellipodia and filopodia to provide building blocks for further protrusion. Protrusion therefore involves a regulated "treadmilling" of actin monomers from the front to the rear of lamellipodia and filopodia. This produces a "retrograde flow" of actin which is accompanied by a retrograde flow of associated material in protruding zones. The mechanisms underlying the delivery of actin and other components to the front of lamellipodia, to support polymerization and retrograde flow have yet to be clarified, but likely involve the engagement of myosin motor molecules. In their role as protruding organelles, lamellipodia and filopodia are major sites of actin filament generation in a motile cell and contribute filaments also to the cytoskeleton network that spans the cell.

Adhesion

In addition to their role in protrusion, lamellipodia and filopodia initiate adhesion to the extracellular matrix. This involves the recognition of matrix ligands on the outside and the accumulation of integrins and proteins of the adhesion machinery to form specific focal points, the focal complexes (Figure 1). The accumulation of proteins in focal complexes is likely to be linked to the cycling of proteins through lamellipodia and filopodia by retrograde flow.

Focal complexes do not move relative to the substrate and can experience one of two fates. They either exist transitorily for a few minutes and disperse, or they enlarge and differentiate into larger anchorage sites at the ends of stress fiber bundles, the focal adhesions. The transition from focal complexes to focal adhesions is linked to a switch in signaling from Rac/Cdc42 to Rho and to the engagement of muscle-type myosin with actin to form contractile bundles.

The regulation of adhesion formation and turnover is a complex process that involves both enzymatic and mechano-sensory pathways. Both focal complexes and focal adhesions are enriched in tyrosine kinases as well as their substrates and changes in their activities modulate adhesion complex turnover. Focal adhesion formation and maintenance depends also on mechanical stress in the actin cytoskeleton. This is illustrated dramatically by their disappearance when cells are treated with drugs that inhibit the interaction between muscle type myosin and actin. Mechano-sensory mechanisms therefore play a role in regulating adhesion dynamics, most likely through mechanically induced

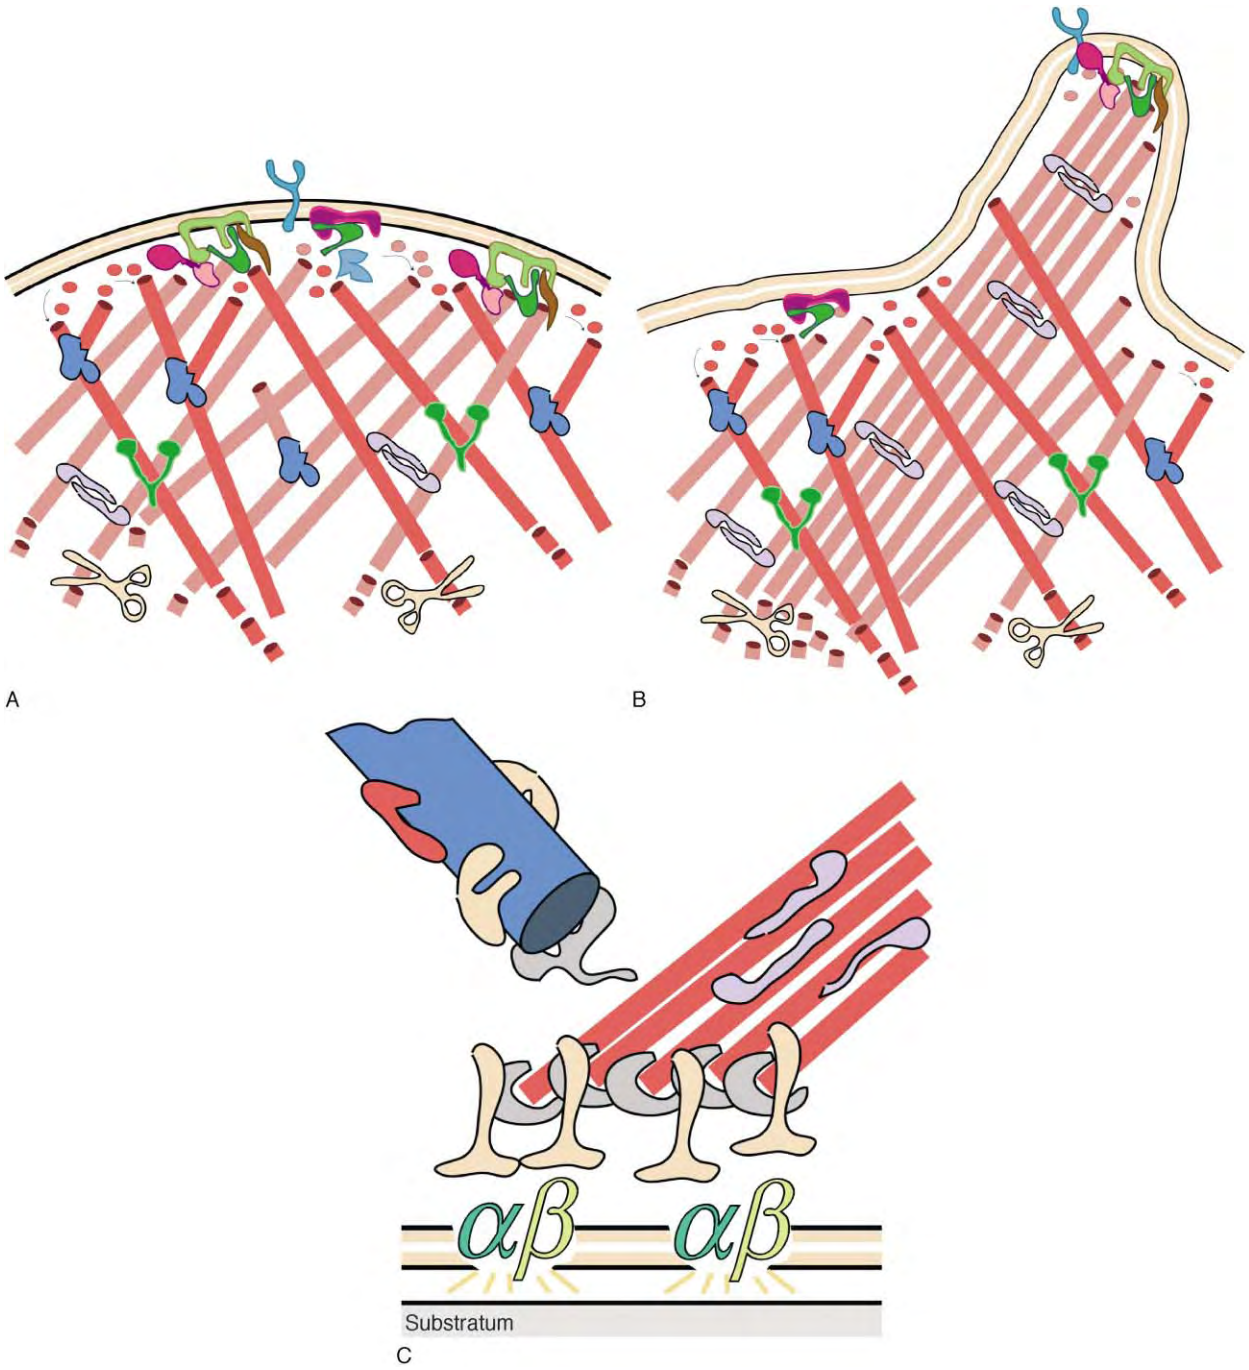

FIGURE 2 Schematic details of the boxed areas in Figure 1. Lamellipodia (A) are formed by the generation of an actin meshwork through the initiation of actin polymerization and the addition of actin monomers (red dots) at the cell membrane. Protein complexes recruited to the membrane control the polymerization process in response to signaling stimuli. Other actin-binding proteins serve to cross-link the actin network. Turnover of the lamellipodium components occurs through the depolymerization of most of the actin filaments towards the base of the lamelipodium by destabilizing and severing factors (scissors). Filopodia (B) are formed by the bundling of lamellipodia filaments, by additional proteins (antiparallel bars), followed by extension via actin polymerization at the tip. Focal adhesions (C) are sites of linkage of actin filament stress fiber bundles to the extracellular matrix via transmembrane matrix receptors called integrins ($\alpha\beta$). A complex of at least 50 structural, adaptor, and signaling proteins are recruited to these sites. The actin filaments are bundled by the cooperation of myosin and actin cross-linking proteins. Microtubules (blue cylinder) polymerize into focal adhesions and impart signals via associated proteins, that promote adhesion turnover.

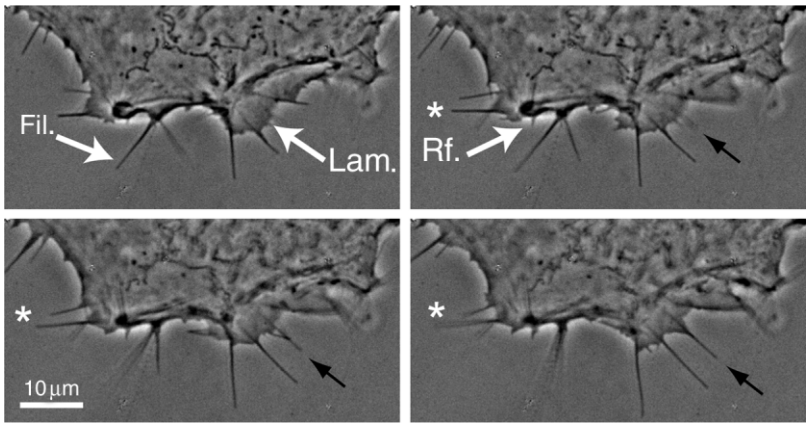

FIGURE 3 Lamellipodia (Lam.) and filopodia (Fil.) in a living fibroblast. Figure shows a sequence of video frames (20 s apart) of the periphery of a living goldfish fibroblast seen in phase contrast optics. These cells show a high incidence of filopodia. The white asterisk indicates a filopodium situated close to the ruffling region that lifted upwards during the sequence. The black arrow indicates the position of a protruding filopodium. These images were kindly supplied by Dr. Irina Kaverina.

conformational changes of specific proteins in adhesion sites.

Adhesion Asymmetry and Polarization

For a cell to move it must develop an advancing front and a retracting tail (Figure 4). This polarization process is reflected in an asymmetry of the pattern of adhesions developed with the extracellular matrix. It is interesting to consider how this asymmetry is established as it is relevant to the question of how polarization is determined.

As long as a cell edge protrudes, focal complexes are created in newly won territory under lamellipodia and filopodia and a proportion differentiates into focal adhesions. In general, however, lamellipodia and filopodia do not protrude in a persistent manner. Instead, forward advancement is the net result of repetitive protrusion and retraction events. Retraction involves the withdrawal of lamellipodia or filopodia, or their backfolding, as ruffles. When this occurs, focal complexes dissolve, or convert into focal adhesions that tether the retracted cell edge.

In the above context, polarization can be considered the result of regional changes in the ratio of protrusion and retraction events at the cell edge. Thus, at the advancing front of a migrating cell the duration of protrusion exceeds that of retraction. Elsewhere, at the rear and flanks, protrusion can occur, but retraction dominates. In the simplest terms, the front edge of a migrating cell is accordingly populated by focal complexes and the rear edge by focal adhesions. In many cases, focal adhesions are also formed behind the front edge and contribute to traction. This asymmetry of adhesion site development is the hallmark of a polarized cell.

Traction and Retraction

An important difference between focal adhesions at the front and rear of migrating cells is that those at the front remain fixed relative to the substrate, whereas those at the retracting rear and flanks can slide. Studies of fibroblasts moving on flexible substrates show that the anterior focal adhesions exert more stress per unit area on the substrate than those at the rear. The anterior adhesions therefore provide anchorage points for the actin cytoskeleton that support the retraction of the trailing cell body. Retraction itself is driven by the interaction of myosin with the actin filaments of the cytoplasmic network.

Microtubules and Cell Guidance

When fibroblasts are treated with drugs that dissassemble microtubules they become depolarized and extend protrusions in all directions. At the same time, tension in the actin cytoskeleton increases and focal adhesions grow in size. These changes are linked to an increase in the activity of Rho. Microtubules are therefore required for polarization and they exert their influence on polarity via a cross-talk with the actin cytoskeleton. The cross-talk takes place between the tips of microtubules and the focal adhesion sites at the ends of actin bundles (Figures 1 and 2C).

Microtubules grow from the centrosome towards the cell periphery, but not in a continuous manner. Instead, they exhibit alternating periods of polymerization and depolymerization in a mode referred to as

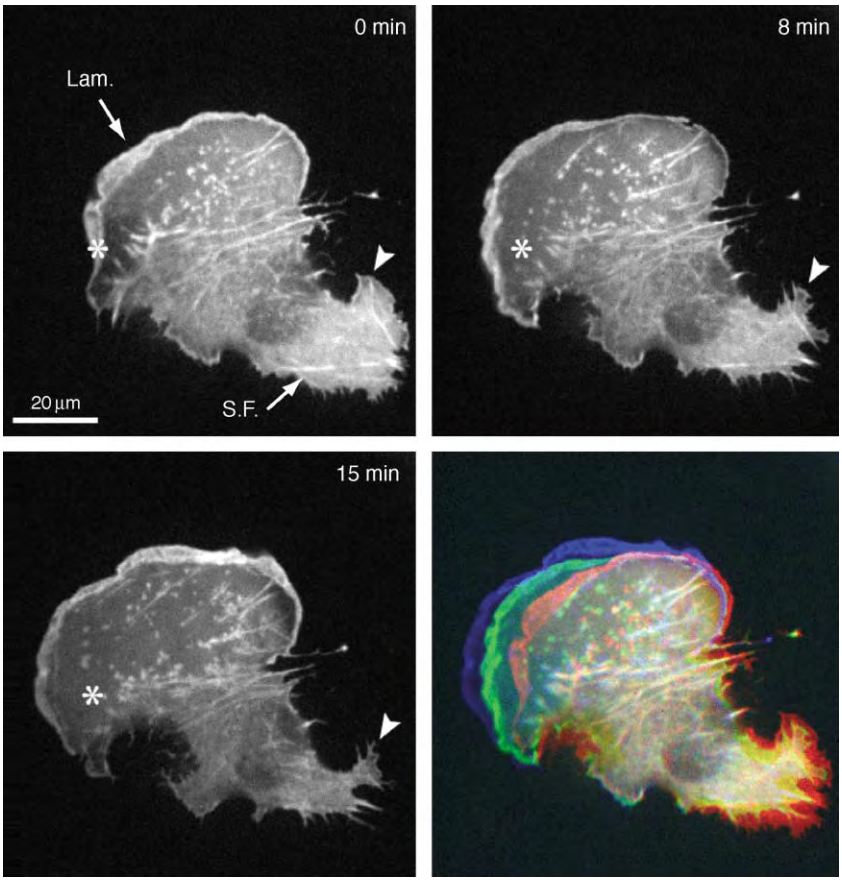

FIGURE 4 A motile melanoma cell, showing a protruding front and a retracting rear. The cell was transfected with GFP-actin and images were recorded by fluorescence optics. The protruding front is marked by a prominent lamellipodium (Lam.). When moving on laminin these cells show few filopodia. The extent of protrusion and retraction during the video sequence is indicated by reference to the fixed points marked by an asterisk and the arrowhead as well as by the color overlay of the frames. Retraction is mediated by the shortening of actin stress fiber bundles that connect to the cell rear (e.g., S.F.).

"dynamic instability." When they reach the cell periphery, microtubules target focal adhesions and this targeting can occur in a repetitive manner. Targeting is more frequent at retracting cell edges and is correlated with the dispersal of focal adhesions or with their release from the substrate. Microtubules bind various molecules including Rho family exchange factors that have an influence on the turnover of the actin cytoskeleton. Some of these associate with proteins concentrated at the growing tips of microtubules. Microtubules then serve as transmission elements to target potential regulators of actin cytoskeleton turnover to focal adhesions. Transmission most likely involves the engagement of microtubule motors to deliver the regulators to the microtubule tip.

Microtubules and Contractility

The global effect of microtubules is to reduce cell contractility. At the level of focal adhesions, microtubules appear to mediate the localized relaxation of actomyosin interactions at the ends of stress fibers, to promote focal adhesion disassembly. This occurs in a feedback mode, whereby an increase in mechanical stress at adhesion sites signals the polymerization of microtubules into them. The influence of microtubules on cell polarity can be explained by their modulation of focal adhesion turnover, in a spatially defined manner involving a mechano-sensory feedback on microtubule dynamics.

The dependence of a cell on microtubules to maintain polarity is linked to the extent of formation of focal adhesions. Very motile cells, such as neutrophils do not form stress fibers and typical focal adhesions and are less dependent on microtubules for directional locomotion. Likewise, fish epidermal keratocytes exhibit focal complexes, but lack focal adhesions and can also migrate without microtubules. Some cells appear to have the inherent ability to segregate protruding and contractile domains. But most cells are unable to maintain this segregation without the modulatory input of microtubules.

Migration *in vivo*

Cells migrating in tissues exhibit both filopodia and lamellipodia. These thin protrusive extensions are ideal for exploring and penetrating tissue spaces. They are also well suited for intercalating between cells, such as during the migration of leukocytes across endothelial layers. Stress fibers, as seen in cultured cells, are not obvious features of cells moving in a three-dimensional environment. However, inhibition of the Rho pathway – which signals contractility – inhibits the migration of primordial cells during embryogenesis and prevents tail retraction during the transendothelial migration of monocytes. Migration *in vivo* therefore involves protrusion of lamellipodia and filopodia signaled by Rac and Cdc42 as well as retraction signaled by Rho. The closure of epithelial layers during embryogenesis is likewise dependent on protrusion and retraction events, whereby the contractility of actin bundles parallel to the epithelial boundary contributes to closure in a zipper-like mode.

Further factors important for cell migration have not been discussed here. These include the cues initiating migration at an appropriate timepoint and the gradients of chemotactic factors that define the destinations of migrating cells. Needless to say, these must impinge on the network of pathways that signal to the locomotion machinery.

Glossary

actin filament A filament of ~8 nm in diameter, made up from two helical strands of actin monomers.

filopodia Bundles of unipolar actin filaments, ~0.2 μm in diameter, that protrude from the cell edge, normally in association with lamellipodia and ruffles. Filopodia and lamellipodia are interconvertible assemblies of actin filaments.

focal adhesions Longer-lived adhesion foci that link to contractile actin bundles (stress fibers) in the actin cytoskeleton. Both focal complexes and focal adhesions harbor more than 50 proteins, involved in structural and signaling activities.

focal complex A site of early adhesion to the extracellular matrix, formed beneath a lamellipodium or a filopodium. Focal complexes can either form and dissolve, within 1–2 mins, or they can mature into focal adhesions.

integrins A family of transmembrane receptor molecules that cluster at adhesion foci to link the matrix on the outside to the actin cytoskeleton on the inside.

lamellipodia Thin, membrane-bound leaflets of cytoplasm, 0.2–0.3 μm thick and up to several microns wide that are protruded at the cell edge, close to and parallel to the substrate. They are composed of unipolar networks of actin filaments.

Rho (Ras homology) proteins A subfamily of small GTPases whose roles include signaling to the actin cytoskeleton.

ruffles Manifestations of lamellipodia, protruding upward from the dorsal cell surface, and migrating generally rearwards over it. Lamellipodia can also fold upwards and rearwards to form ruffles.

Biography

Victor Small graduated from King's College in London in 1969 with a Ph.D. in Biophysics. From 1970 to 1977 he held a lectureship position in Aarhus University, Denmark where he began work on contractile systems and the cytoskeleton. Since 1977, he has headed the Department of Cell Biology of the Institute of Molecular Biology of the Austrian Academy of Sciences in Salzburg. His laboratory explores live cell microscopy in studies of the cytoskeleton and the mechanisms underlying cell motility.

Emmanuel Vignal is a postdoctoral Fellow at the Institute of Molecular Biology in Salzburg. He graduated in 2001 with a Ph.D. in Cell Biology from the University of Montpellier in France. His current work focuses on the molecular mechanisms of lamellipodia protrusion.

Cell–Matrix Interactions

Janet A. Askari and Martin J. Humphries
The Wellcome Trust Centre for Cell–Matrix Research, School of Biological Sciences, University of Manchester, Manchester, UK

The extracellular matrix (ECM) is a network of macromolecules that underlies all epithelia and endothelia and that surrounds all connective tissue cells. The ECM provides mechanical support and also profoundly influences the behavior and differentiation state of cells in contact with it. The main receptors mediating the interaction of cells with ECM proteins are known as integrins, referring to their function of integrating the cell's exterior with its interior. Following ligand binding, the cytoplasmic domains of integrins connect to the cytoskeleton and trigger the assembly of signaling complexes. Conversely, the binding of intracellular cytoplasmic components influences cell adhesiveness by altering integrin conformation. Thus, a large variety of complex signaling events can be transduced by integrins in a bidirectional manner across the cell membrane. These events serve to modulate and coordinate many aspects of cell behavior, such as proliferation, survival, shape, polarity, motility, gene expression, and differentiation, that are required for such fundamental processes as development, tissue morphogenesis, and wound healing within multicellular organisms. Integrins are also implicated in several disease processes such as inflammation, thrombosis, and cancer metastasis, whereas mutations in integrin genes lead to deficiencies in leucocyte adhesion, myopathy, and blistering skin diseases.

The Extracellular Matrix

Main Components

The extracellular matrix (ECM) components are diverse in composition, but they generally comprise a mixture of fibrillar proteins, polysaccharides, and glycoproteins synthesized, secreted, and organized by neighboring cells. Collagens, fibronectin, and laminins are the principal components involved in cell–matrix interactions; other components, such as vitronectin, thrombospondin, and osteopontin, although less abundant, are also important adhesive molecules.

Over 20 different collagens exist in mammals, but the most abundant exist as helical molecules that assemble into fibrils and provide tensile strength for many tissues. The ECM also contains a large number of glycoproteins, the best studied of which is fibronectin, a dimeric molecule that also forms insoluble fibrils. The laminins are heterotrimeric glycoproteins that fold into cruciform-shaped molecules and are important components of basement membranes. Fibrinogen and von Willebrand factor are also considered to be matrix proteins because they function as major adhesive molecules in blood, but they can also pass into extravascular fluid and influence cell function.

Adhesive Motifs

Although matrix proteins are large molecules, their major integrin recognition sites are very short peptide motifs of only three to six amino acids. The best known and most widespread of these adhesive motifs is arginine–glycine–aspartic acid (RGD, using the single-letter amino acid nomenclature). This motif was first discovered in 1984 by Pierschbacher and Ruoslahti in the center of fibronectin (FN), but it is also present and functional in vitronectin, von Willebrand factor, and thrombospondin. The crystal structure of the area of FN containing this motif has been solved and shows the tripeptide extending out as a loop from the surface of the protein. Similar short peptide motifs are present in other matrix proteins (see Table I). A constant feature of the motifs is the presence of an acidic residue, either aspartic or glutamic acid, which is an absolute requirement for the adhesive activity of the proteins in which they reside. As yet, no corresponding motif has been determined in laminin; however, integrin binding has been localized to distinct regions within the molecule.

In FN, a second region of the molecule, termed the synergy site, has been shown to work in concert with the RGD motif and to enhance integrin-binding affinity. Part of the synergy site is a pentapeptide proline–histidine–serine–arginine–asparagine (PHSRN). Although they probably exist, no synergy sequences have as yet been defined for other matrix proteins.

TABLE I

Adhesive Sequences in Matrix Proteins and their Integrin Receptors[a]

Matrix protein	Adhesive sequence	Integrin receptor
Collagens	GFOGER	$\alpha1\beta1$, $\alpha2\beta1$, $\alpha10\beta1$, $\alpha11\beta1$
Fibronectin	RGD	$\alpha5\beta1$, $\alpha V\beta3$, $\alpha8\beta1$, $\alpha V\beta1$, $\alpha V\beta6$, $\alpha IIb\beta3$
	LDV	$\alpha4\beta1$, $\alpha4\beta7$
	REDV	$\alpha4\beta1$
Laminins	E1′ fragment	$\alpha1\beta1$, $\alpha2\beta1$, $\alpha10\beta1$
	E8 fragment	$\alpha3\beta1$, $\alpha6\beta1$, $\alpha7\beta1$, $\alpha6\beta4$
Vitronectin	RGD	$\alpha V\beta3$, $\alpha IIb\beta3$, $\alpha V\beta5$, $\alpha V\beta1$ $\alpha V\beta8$
Fibrinogen	RGD	$\alpha V\beta3$
	KQAGDV	$\alpha IIb\beta3$
von Willebrand factor	RGD	$\alpha IIb\beta3$, $\alpha V\beta3$

Integrins

Structure

Integrins are noncovalently linked dimers consisting of an α- and a β-subunit, and the 18 α- and 8 β-subunits that have been identified in humans combine to form 24 different receptors. Integrin homologues are present in organisms ranging from sponges to humans, indicating their central role in metazoan evolution. Integrins possess large extracellular domains, approximately 1200 amino acids in α-subunits and 800 in β-subunits, a transmembrane domain, and short cytoplasmic regions of 50 residues or less. The exception to this rule is the $\beta4$-subunit, which has a cytoplasmic domain of over 1000 amino acid residues. In addition, half of all α-subunits contain an extra 200 residue module toward their N terminus (see Table II), which has homology with the von Willebrand factor A-domain and is referred to as the α A- or I- (for inserted) domain. Several α A-domains have been crystallized and all adopt a Rossmann fold characterized by central β-sheets surrounded by α-helices. A conserved motif, the metal-ion-dependent adhesion site (MIDAS), which includes the sequence aspartic acid–any residue–serine–any residue–serine (DxSxS), coordinates a divalent metal cation at the top of the domain. The N terminus of the β-subunit also contains an A-domain with a MIDAS motif. Electron micrographs show the integrin dimer to have a globular head 8–12 nm in diameter that constitutes the ligand-binding domain from which two stalks 2 nm thick and 14–20 nm in length project; the distal regions of these contain hydrophobic sequences representing the transmembrane domains.

TABLE II

Properties of Integrins[a]

Integrin	Alternative names	Matrix ligands
With an A-domain		
$\alpha1\beta1$	VLA 1, CD49a/CD29	CO, LM
$\alpha2\beta1$	VLA 2, GPIaIIa, CD49b/CD29	CO, LM
$\alpha10\beta1$		CO, LM
$\alpha11\beta1$		CO
$\alpha D\beta2$	CD11d/CD18	[b]
$\alpha L\beta2$	LFA-1, CD11a/CD18	[b]
$\alpha M\beta2$	Mac1, CD11b/CD18	FG
$\alpha X\beta2$	p150,95, CD11c/CD18	FG
$\alpha E\beta7$	$\alpha_{IEL}\beta7$, HML-1 antigen, CD103(αE)	[b]
Without an A-domain		
$\alpha3\beta1$	VLA 3, CD49c/CD29	LM
$\alpha4\beta1$	VLA 4, CD49d/CD29	FN, OP
$\alpha5\beta1$	VLA 5, FNR, CD49e/CD29	FN, OP
$\alpha6\beta1$	VLA 6, CD49f/CD29	LM
$\alpha7\beta1$		LM
$\alpha8\beta1$		FN, TN, NN
$\alpha9\beta1$		TN, OP
$\alpha V\beta1$	CD51/CD29	FN, VN
$\alpha IIb\beta3$	GPIIbIIIa, CD41/CD61	FN, FG, VN, vWF, Tsp
$\alpha V\beta3$	VNR, CD51/CD61	VN, FG, FN, vWF, Tsp
$\alpha V\beta5$		VN
$\alpha V\beta6$		FN
$\alpha V\beta8$		VN
$\alpha6\beta4$	CD49f/CD104	LM
$\alpha4\beta7$	LPAM-1	FN

[a] CO, collagen; FG, fibrinogen; FN, fibronectin; LM, laminin; NN, nephronectin; OP, osteopontin; TN, tenascin; Tsp, thrombospondin; VN, vitronectin; vWF, von Willebrand factor.
[b] Involved in cell–cell interactions only.

Those α-subunits that do not contain A-domains undergo posttranslational cleavage into a light and heavy chain held together by a disulfide bond, the exception being $\alpha4$, which is cleaved at a more central position to yield fragments of 70 and 80 kDa. In addition, several integrin subunits, $\alpha3$, $\alpha6$, $\alpha7$, $\beta1$, $\beta3$, $\beta4$, and $\beta5$, are subject to alternative splicing mainly in their cytoplasmic domains, yielding isoforms that are differentially expressed in specific patterns. This splicing serves to increase the cell–matrix interaction repertoire and hone the temporal and spatial adhesive responses of cells.

The field of integrin research was advanced enormously by the publication of the crystal structure of the extracellular domain of $\alpha V\beta3$ in 2001 by a group led by Arnaout. This structure shows that the globular head of

the integrin is made up of a seven-bladed β-propeller contributed by the α-subunit and the A-domain from the β-subunit together with an immunoglobulin fold, termed the hybrid domain, made up of polypeptide sequences from either side of the β A-domain. The integrin stalks are folded into three β-sandwich domains in the α and four epidermal growth factor (EGF)-like repeats in the β-subunit. The β-subunit also has an N-terminal plexin–semaphorin–integrin (PSI) domain and a novel cystatin-like fold just before the transmembrane region. An arginine residue, R261, in the β3-subunit A-domain extends into the core of the α-subunit propeller, where it is held in place by aromatic residues and is the main area of subunit association.

Ligand Binding

All interactions between integrins and matrix proteins are dependent on divalent cations, whereas the ligand-binding specificity of integrin molecules is determined by the particular α–β combination. Some matrix proteins (e.g., FN) can bind to several integrins, or, conversely, one integrin can recognize ligands of diverse structure; for example, $\alpha2\beta1$ binds to both laminin and collagen. In general, each integrin has a specific nonredundant function, which is emphasized by the distinct phenotypes of knockout mice.

The integrin dimers can be broadly divided into three families consisting of the $\beta1$, $\beta2/\beta7$, and $\beta3/\alpha$V integrins. $\beta1$ associates with 12 α-subunits and can be further divided into RGD-, collagen-, or laminin-binding and the related $\alpha4/\alpha9$ integrins that recognise both matrix and vascular ligands. $\beta2/\beta7$ integrins are restricted to leukocytes and mediate cell–cell rather than cell–matrix interactions, although some recognize fibrinogen. The $\beta3/\alpha$V family members are all RGD receptors and comprise αIIb$\beta3$, an important receptor on platelets, and the remaining β-subunits, which all associate with αV. It is the collagen receptors and leukocyte-specific integrins that contain α A-domains.

In non-α A-domain-containing integrins, both the α- and β-subunits are required for ligand binding. An integrin–ligand complex crystal structure showed that RGD peptide binds at the α–β interface, with its arginine residue contacting the α-subunit propeller and its aspartate helping to coordinate the divalent cation at the MIDAS site via a carboxyl linkage, which in the presence of ligand is occupied. Two further cations are present in the ligand-bound structure, one at a site adjacent to the MIDAS (termed ADMIDAS) and the other at a site in close proximity, termed the ligand-induced metal-binding site (LIMBS). Isolated recombinant α A-domains are able to bind peptide and macromolecular ligands with the same affinity as intact dimer. A crystal structure of the A-domain of $\alpha2$ in complex with a triple-helical collagenous peptide containing the glycine–phenylalanine–hydroxyproline–glycine–glutamic acid–arginine (GFOGER) motif also shows the carboxyl from an acidic residue, in this case glutamate, from the ligand directly completing the coordination sphere of the metal ion in the MIDAS. This explains the absolute requirement for either aspartic or glutamic acid in matrix adhesive proteins and the dependence on divalent cations for integrin–ligand interactions.

Cation Modulation

The binding of ligand to integrin cannot take place without a divalent cation, which directly contacts a carboxyl group from the ligand. However, cations also play an important role in the regulation of integrin affinity. Integrin αV$\beta3$ contains six cation-binding sites in the unliganded crystal structure and eight in the presence of cyclic RGD peptide, at least three of which are affected by ligand binding. In general, integrin–ligand binding is stimulated by magnesium and manganese ions and inhibited by calcium ions. However, this situation is complicated by the fact that the binding of one cation can affect the binding of another at a different site. In addition, several cation-binding sites within an individual integrin can influence ligand binding. The physiological relevance of cation modulation of integrin affinity has yet to be resolved.

Activation and Signaling

Focal Adhesions

When cells attach and spread on a matrix ligand, there is an initial clustering of integrins in the membrane, followed by an accumulation of cytoskeletal and signaling molecules into dynamic structures known as focal adhesions or focal contacts. These structures represent the anchor points of the cell where integrins link the cell to both the underlying matrix and the intracellular actin filaments of the cytoskeleton. The contacts appear as dense plaques, often located near the cell periphery, and provide both a scaffold and a means whereby cells can generate traction during migration. More important, focal adhesions also serve as nucleation points for the recruitment of not only structural proteins such as vinculin, talin, and paxillin, but also many signaling and adaptor molecules able to trigger a cascade of phosphorylation events that can activate numerous downstream targets.

Conformational Changes

Many integrins are not constitutively active, and adhesion of cells to matrix proteins needs to be strictly

controlled and regulated in response to environmental changes. Integrins exist in at least three states, inactive, active, and ligand-bound; the switching of integrins from an inactive to an active state involves conformational changes not only in the ligand-binding pocket, but also across the whole of the extracellular domain and in the cytoplasmic face. Thus, the activation of the ligand-binding domain in the head and the binding of ligand are coupled via long-range conformational changes to signaling events in the cytoplasm. Conversely, intracellular events effect changes in the cytoplasmic domains that are translated in the opposite direction to the integrin head, allowing activation and ligand binding. This bidirectional communication is termed outside-in and inside-out signaling.

Cytoplasmic Domains

The short cytoplasmic domains of integrins play a vital role in integrin function because they control the activation states of integrins and are required to maintain integrins in an inactive state. They are also the sites of interaction with, and linkage to, both cytoskeletal and signaling molecules when clustered in focal adhesions. Interactions between the α and β tails occur by a salt bridge and hydrophobic and electrostatic contacts in the α-helical, membrane-proximal region of both domains, and it is likely that this association is lost on integrin activation, allowing the tails to separate and effector molecules to bind. The β-subunit tail is the principal site for binding of cytoplasmic molecules, whereas the α-subunit plays a more regulatory role in controlling activation.

Many proteins are intimately associated with integrins in focal adhesions, but direct interaction has only been proven for the binding of the structural protein talin to the $\beta 3$ cytoplasmic domain. The site of interaction is a conserved asparagine–proline–any residue–tyrosine (NPxY) motif in the $\beta 3$ tail with a phosphotyrosine-binding-like (PTB) subdomain of talin. This interaction may be the prototype for protein interactions with integrin β tails through PTB domains.

Signaling by Integrins

Integrin-mediated signaling can be broadly divided into two categories, direct and collaborative. In the first, ligation and clustering of integrins are the only stimuli and adhesion to ECM proteins activates cytoplasmic tyrosine kinases, for example, focal adhesion kinase (FAK) and serine/threonine kinases such as those in the mitogen-activated protein kinase (MAPK) cascade. Direct signaling also induces ionic transients (e.g. Ca^{2+}, Na^{+}/H^{+}) and stimulates lipid metabolism. In collaborative signaling, integrin–ECM adhesion modulates signaling initiated by other types of receptors, such as receptor tyrosine kinases (RTK) and G protein-coupled receptors, allowing cells to integrate positional information concerning matrix contacts with information about the availability of soluble growth or differentiation factors that are also located in the ECM. Cells that are deprived of anchorage to the ECM eventually die by a specialized form of programmed cell death (apoptosis) known as anoikis. Cell–matrix interactions via integrins are thus essential for cell survival. Integrins also directly affect the organization of the cytoskeleton, and consequently cell motility, by activating the Rho GTPases, a branch of the Ras GTPase superfamily, particularly CDC42, Rac1, and RhoA. Rho promotes the formation and maintenance of actin stress fibers, whereas Rac and CDC42 regulate structures such as lamellipodia and filopodia, respectively.

It is worth remembering that each signaling pathway mentioned influences others at some point, so signaling within a cell is better considered as a series of networks rather than a direct path. Thus, integrins are able to modulate, either directly or indirectly, every signaling pathway within the cell, a fact that emphasizes the importance of cell–matrix interactions on all aspects of cell behavior.

Martin Humphries is Professor of Biochemistry, a Wellcome Trust Principal Research Fellow, and Director of the Wellcome Trust Centre for Cell–Matrix Research at the University of Manchester, U.K. His interests center on integrin structure, mechanisms of integrin priming and activation, and coordination of adhesion-dependent signaling. He received a B.Sc. (Hons) Biochemistry from the University of Manchester in 1980 and a Ph.D. in Biochemistry from the University of Manchester in 1983.

Centromeres

Beth A. Sullivan
Boston University School of Medicine, Boston, Massachusetts, USA

The centromere is a specialized mixture of DNA and proteins, and ensures chromosome inheritance and genome stability. As a chromosomal locus, the centromere is the minimal DNA or chromatin element that promotes formation of the proteinaceous kinetochore complex and coordinates chromosome movement in mitosis and meiosis. The centromere also synchronizes aspects of chromosome structure, such as heterochromatin formation, sister chromatid cohesion, and chromosome condensation. It is a multidomain locus, recruiting a variety of proteins with distinct functions.

Organization of the Centromere Region

Cytologically, centromeres have been defined by the visible primary constriction on metaphase chromosomes. This chromosomal locus is structurally complex, and contributes to various processes that ensure chromosome stability. The centromere region can be broadly classified into two major domains that encode kinetochore and heterochromatin functions. The kinetochore and heterochromatin are assembled independently, but each is equally important for complete centromere function and for ensuring chromosome and genome stability. The centromere/kinetochore domain comprises both DNA and proteins involved in chromatin assembly and structural aspects of the kinetochore. The heterochromatin domain is located adjacent to, or flanks, centromeric chromatin. Studies in various organisms have shown that heterochromatin is equally important for centromere function and chromosome inheritance as the kinetochore domain.

Kinetochore Domain

At metaphase, the kinetochore, a proteinaceous multidomain structure, is assembled on the outer surface of the centromere, promoting attachment of the chromosome to spindle microtubules and movement during anaphase.

The Inner Kinetochore

The inner kinetochore is the region most intimately associated with centromeric DNA and/or chromatin. Many structural proteins that bind centromeric DNA or contribute to specialized chromatin structure are located here (Table I). The inner kinetochore contains constitutive proteins that serve as the foundation for the kinetochore, often termed the prekinetochore. CENP-A, a centromere-specific histone H3 variant that replaces H3 in centromeric nucleosomes, is located here and serves as an initiatory signal for kinetochore assembly by recruiting other inner and outer kinetochore proteins.

The Outer Kinetochore

The outer kinetochore region contains primarily microtubule-associated and chromosomal motor proteins that are involved in chromosome congression to the midzone at metaphase or engage spindle microtubules and move chromosomes to spindle poles in anaphase. In addition, the outer kinetochore contains surveillance or checkpoint proteins that monitor kinetochore attachments to the spindle and regulate the transition from metaphase to anaphase.

The Central Domain

The centromeric region that spans the interior of the centromere and connects sister kinetochores comprise the interior central domain. Centromeric DNA-binding proteins are concentrated here, as well as cohesion and condensation proteins and transiently associated proteins (chromosomal passengers) that co-ordinate chromosome segregation and cytokinesis.

Heterochromatin Domain

Heterochromatin is cytologically dense material that is typically found at centromeres and telomeres. It mostly consists of repetitive DNA sequences and is relatively "gene poor." Its most notable property is its ability to silence euchromatic gene expression. Centromeres in yeast, fruit flies, and mammals are flanked by heterochromatin, indicating that its repetitive composition

or dense chromatin structure may represent an important, conserved function in centromere structure and function. Heterochromatin assembly is linked to chromatin regulation, occurring in a pathway that initiates with methylation of histone H3 at amino acid residue lysine 9 in order to recruit heterochromatin proteins (HPs), such as HP1 (heterochromatin protein 1). Once heterochromatin is established, cohesion and condensation proteins accumulate between sister kinetochores and chromatids. Mutations in HPs or certain histone modifying enzymes lead to chromosome mis-segregation and mitotic defects, indicating that heterochromatin contributes significantly to chromosome stability and segregation.

Specification of Centromere Identity and Function

The Centromere as DNA

How are the distinct kinetochore and heterochromatin domains assembled at centromeric regions? A well-debated question in centromere biology has been the role of primary DNA sequence in centromere identity and assembly. In a few organisms specific DNA sequences are required for centromeric protein binding, while in other organisms, centromere-specific DNA sequences have not been found. In addition, epigenetic mechanisms often determine centromere identity. In short, a centromere is established, and it is consistently maintained at a genomic region, but the site of formation is not determined by the underlying sequence itself. Recent studies indicate that RNA as well participates in centromere assembly.

Point Centromeres

Centromeres in the budding yeast *Saccharomyces cerevisiae* are the best studied and understood. *S. cerevisiae* centromeres are encoded by three distinct DNA elements (CDE I, II, and III) within a 125 bp region (Figure 1). Two elements (CDE I and III) are absolutely conserved and required to recruit centromere and kinetochore proteins. The centromeric histone CENP-A (Cse4p) is recruited to CDE II, the centromeric element that varies in sequence, but not size, from chromosome to chromosome. The small size of budding yeast centromeres, as well as the strict reliance on DNA–protein interactions for assembly, have resulted in detailed molecular maps and models of centromere assembly that are lacking in larger eukaryotes.

Regional Centromeres

Centromeres in fission yeast, *Schizosaccharomyces pombe*, and in flies, worms, mammals, and plants are monocentric, forming on a limited, specific region of the chromosome (Figure 1). These centromeres are comprised of multiple subunits encoding kilobase or megabase-sized genomic regions. Unlike in budding yeast, centromeric DNA sequences are not obviously conserved, and centromere identity and assembly depend largely on epigenetic factors.

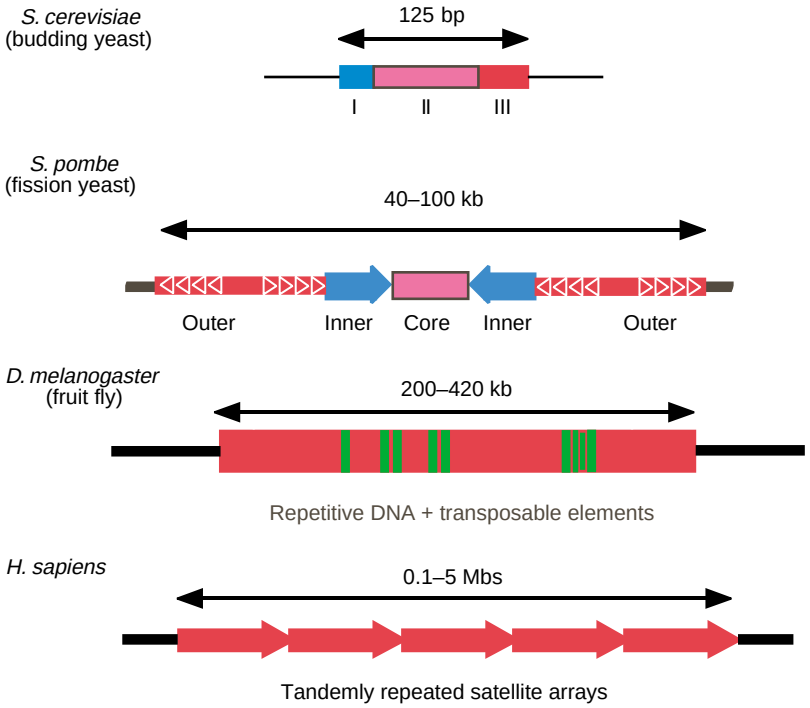

FIGURE 1 Centromeric structure in various eukaryotes. Schematic diagram of eukaryotic centromeres. The DNA sequence of centromeres differs between species, but the organization of the centromere and the presence of centromere proteins is conserved. Budding yeast (*S. cerevisiae*) centromeres are 125 bp and are composed of three distinct elements, two of which are conserved (I and III). *S. pombe* (fission yeast) centromeres contain a unique central core flanked by inverted inner and outer repeats. *Drosophila* centromeres extend for 200–420 kb and contain repetitive DNA (red boxes) that is interspersed with transposable elements (green lines). Human centromeres consist of tandemly repeated alpha-satellite DNA arranged into higher order repeats that extend over several megabases.

Schizosaccharomyces pombe The three centromeres in fission yeast consist of unconserved central core sequences flanked by inverted arrays of inner and outer repeats. Both the central core and portions of the inner repeats are required for establishment and maintenance of centromere function and for recruitment of CENP-A (Cnp1) and other centromeric proteins. The outer repeats are essential for assembly of centric heterochromatin through histone modifications and noncoding RNAs.

Multisubunit Centromeres: Flies, Humans, and Plants Metazoan and plant centromeres are large, often ranging in size from a few hundred kb to 5 Mb. They primarily consist of thousands of copies of satellite DNA, often arranged in tandem (mammals and plants). In flies and plants, these repeats are often interspersed with transposable elements. In humans, *de novo* centromere assembly via artificial chromosomes has been most efficiently achieved when centromeric satellites (alpha-satellite DNA) are introduced into cells. However, not all human alpha-satellite DNAs form centromere *de novo*, indicating that other sequences or factors are required to assemble and maintain human centromeres.

Holocentric Chromosomes In the nematode *Caenorhabditis elegans*, crayfish, and some insects, the holocentric chromosomes assemble centromeres along their lengths. *C. elegans* centromeres are the best-studied holocentrics. Most of the known eukaryotic centromere and kinetochore proteins have been identified in worms and the order of assembly, with CENP-A (CeCenp-A or HCP-3) at the top of the assembly pathway, are conserved. Proteins are recruited into distinct foci at prophase, but by metaphase, these foci spread evenly into "ribbons" along the poleward face of the chromosome arms. The distribution of centromere and kinetochore proteins into inner and outer kinetochore regions is conserved in *C. elegans*.

The Centromere as Chromatin

Chromatin is an important regulator of gene expression and compartmentalization of the genome in interphase. Establishment of distinct chromatin domains (kinetochore, heterochromatin) is necessary for complete centromere function, thus chromatin may be a more important determinant of centromere function than DNA sequence.

Epigenetic Centromeres

The simple presence of centromeric DNA in a cell or a chromosome does not necessarily correlate with centromere function. Besides the obvious lack of sequence conservation at eukaryotic centromeres, additional evidence exists to argue the role of underlying DNA sequence in centromere assembly. First at normal mammalian centromeres, only a fraction of the arrays actually participate in centromere assembly. In humans, the kinetochore domain typically comprises one-half to two-thirds of the satellite DNA found at eukaryotic centromeres. The remainder of the satellite DNA is involved in forming heterochromatin and cohesion. Secondly, naturally occurring or engineered dicentric chromosomes that contain two regions of centromeric DNA are stably transmitted in flies and humans only after inactivation of one centromere. Finally, neocentromeres are formed in flies and humans on stable marker chromosomes that completely lack centromeric sequences. None of the neocentromeres share sequence homology and even those that are derived from similar genomic regions assemble centromere, kinetochore, and heterochromatin proteins on different sequences.

Specification by CENP-A

All centromeres are associated with the centromere-specific histone CENP-A. CENP-A is required to recruit all other centromere and kinetochore proteins, with the exception of HP1, making it is a strong candidate for a protein that specifies and maintains the site of kinetochore assembly. Unlike replication-dependent histones, CENP-A is dispersed in a semiconservative manner, thus providing the scaffold on which new CENP-A can be loaded and the centromere can be maintained irrespective of underlying DNA sequence. The organization of

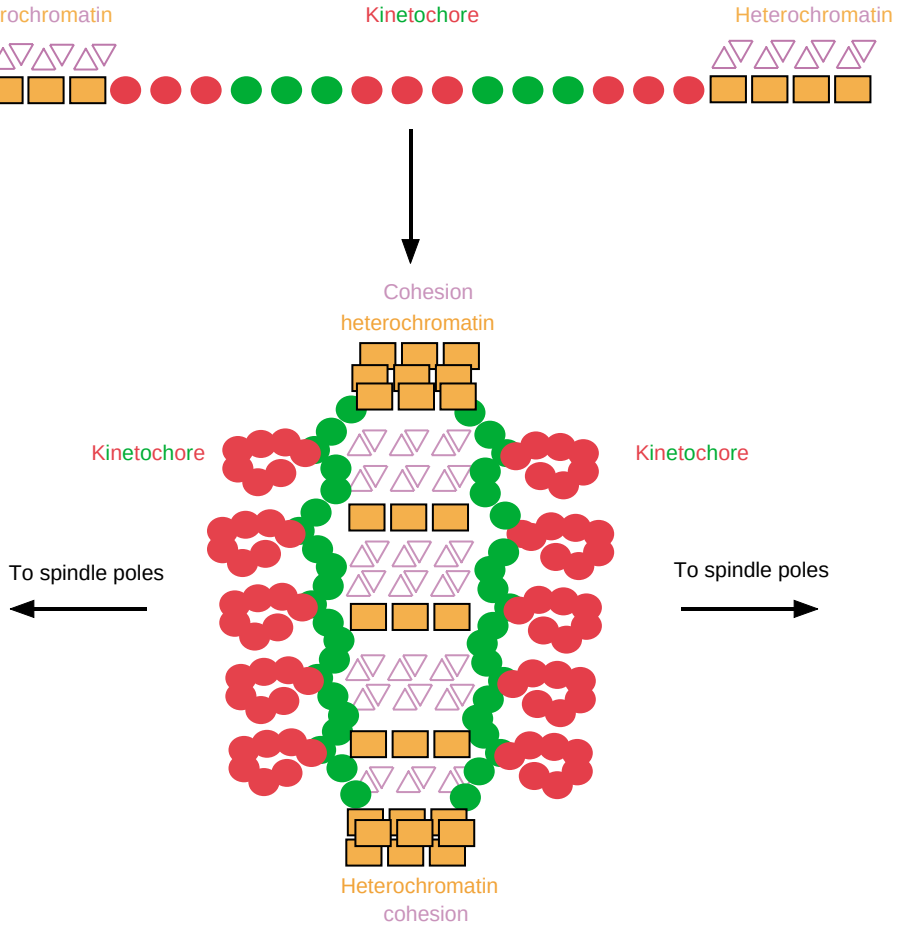

FIGURE 2 Unique organization of centromeric chromatin creates proper structure of the centromere region. In 2D, CENP-A (red circles) and H3 (green circles) nucleosomes within centromeric chromatin are interspersed, forming the foundation of the kinetochore domain, which is flanked by heterochromatic proteins (squares) and cohesion proteins (triangles). In metaphase (3D), the blocks of CENP-A and H3 nucleosomes may be arranged in a spiral, orienting CENP-A nucleosomes to the poleward face of the chromosome, presumably to bi-orient the chromosome and facilitate recruitment and interactions with other kinetochore proteins. H3 nucleosomes are sequestered to the region between sister kinetochores, where heterochromatin and cohesion proteins are recruited. Flanking heterochromatin that is assembled between sister kinetochores may be as important as CENP-A:H3 interspersion for ensuring that CENP-A opposes spindle poles.

centromeric chromatin may further facilitate its maintenance and/or function. In two dimensions (2D), centromeric chromatin in flies and humans contains interspersed subunits of CENP-A and H3 nucleosomes (Figure 2). CENP-A subunits coalesce to form a three-dimensional (3D) interface that promotes recruitment of additional kinetochore proteins, biorientation of chromatids to opposite spindle poles, and attachments to microtubules. Conversely, the H3 subdomains are oriented toward the interior of the chromosome to establish a platform for recruiting cohesion and condensation proteins. The unique interspersion of CENP-A and H3 nucleosomes is important for centromere function, since depletion of CENP-A by RNA interference (RNAi) or in CENP-A mutants alters the ratio of CENP-A:H3 and leads to chromosome segregation defects and mitotic arrest.

The Centromere as RNA

One of the most exciting discoveries in the past few years has been the involvement of double-stranded RNA (dsRNA) in specifying chromosomal, and particularly centromere, function. Although originally considered "junk DNA," the arrays of repeats that surround active centromeres have been shown to be functionally significant. In particular, noncoding, antiparallel RNAs are transcribed from the outer centromeric repeats in *S. pombe*. These transcripts are typically unstable and are normally processed by RNAi machinery that mediates the formation of heterochromatin. Full-length double-stranded transcripts from the repeats are reduced into small interfering RNAs (siRNAs) by the protein Dicer, a member of the RNA-induced silencing complex (RISC). The siRNAs then initiate methylation of histone H3 at lysine 9 that subsequently recruits heterochromatin proteins. The siRNAs are only required for establishment, but not maintenance of heterochromatin, and although noncoding RNAs from regions that contain CENP-A have not been identified, it is tempting to speculate that kinetochore-specific transcripts might initiate *de novo* centromere assembly that is then maintained by retention of CENP-A and/or other proteins through many rounds of replication and division.

Glossary

epigenetic Referring to or describing any heritable influence on chromosome or gene function that is not correlated with, or dependent on, a change in DNA sequence.

heterochromatin Cytologically defined regions of the genome that contain repetitive DNA (satellite DNA, transposable elements). A defining feature of heterochromatin is the ability to silence gene expression.

kinetochore The proteinaceous structure on each chromosome that is responsible for chromosomal attachment to and movement along spindle microtubules.

RNA interference A cellular defense mechanism for specific gene silencing that is induced by double-stranded RNAs that are processed into 21–23 nucleotide small interfering RNAs (siRNAs), causing degradation of homologous endogenous mRNA.

Biography

Dr. Beth Sullivan is an Assistant Professor in the Department of Genetics and Genomics at Boston University School of Medicine. Her research interests are in eukaryotic centromere structure and function, including organization and regulation of centromeric chromatin. She holds a Ph.D. from the University of Maryland, Baltimore and received postdoctoral training at Case Western Reserve University (Cleveland) and The Salk Institute (La Jolla). Her laboratory focuses on developing new cytological and cell biology techniques to facilitate comparative studies of centromere organization in mammals and *Drosophila*.

Centrosomes and Microtubule Nucleation

Reiko Nakajima, Ming-Ying Tsai and Yixian Zheng
Carnegie Institution of Washington and Howard Hughes Medical Institute, Baltimore, Maryland, USA

In animal cells, the microtubule network consisting of the centrosome and the filamentous microtubule array is required for intracellular trafficking, intracellular organization, and cell division. The timely assembly and organization of different microtubule arrays is critical for executing all functions of microtubules. Centrosome-mediated microtubule nucleation plays an important role in the formation of a functional microtubule network.

Microtubules

Structure of Microtubules

Microtubules are assembled from dimers of α- and β-tubulins that share significant ($\sim$50%) amino acid identity. Each tubulin has a molecular mass of $\sim$50 000 Da and binds to one molecule of GTP. Since the GTP-binding pocket of α-tubulin is covered by β-tubulin in a tubulin dimer, only the GTP in β-tubulin can be exchanged and hydrolyzed. The tubulin dimers, often referred to as tubulin(s), polymerize in a head-to-tail fashion to form protofilaments that associate laterally into hollow cylindrical microtubules with diameters of $\sim$25 nm (Figure 1). The microtubule polymer exhibits a distinct polarity with a fast-growing plus end and a slow-growing minus end. Studies have shown that the plus and minus ends of microtubules terminate with β-tubulins and α-tubulins, respectively.

Microtubule Polymerization

Microtubule polymerization begins with a slow nucleation step where several tubulins come together to form a microtubule "seed" or "nucleus." The rate of microtubule nucleation is proportional to the nth power of tubulin concentration, where n is the number of tubulins in a microtubule seed. Following nucleation, microtubule elongation by adding tubulins to the seeds occurs at a rate that is proportional to tubulin concentration. Therefore, microtubule nucleation is kinetically less favored than microtubule elongation. Once formed, the microtubule polymer exhibits a stochastic growth and shrinkage behavior termed "dynamic instability," which is defined by the rates of elongation and shrinkage as well as by the frequencies of transition from growth to shrinkage and from shrinkage to growth. Therefore, microtubule formation is governed by both the microtubule nucleation rate and by the various parameters of microtubule dynamic instability. These intrinsic features of microtubule polymers are exploited in living cells to achieve proper microtubule organization in response to various cellular signals.

Centrosomes

Structure of the Centrosome

The centrosome provides a major microtubule-nucleating and -organizing site in animal cells. Electron micrographs reveal that a centrosome consists of a pair of centrioles and an electron-dense pericentriolar material (PCM). Each centriole is barrel-shaped with nine triplet microtubules making up the barrel wall (Figure 2). Studies have shown that the two centrioles in a centrosome are linked by filamentous structures. An interesting feature of the centriole pair is that they are arranged in angles of varying degrees with respect to each other. The bottom of one centriole always faces the wall at one end of the second centriole that has additional appendages at the other end of the wall (Figure 2). Compared to the structure of centrioles, the structure of the PCM is less defined. With low-resolution electron microscopy, the PCM appears unstructured. Recent high-resolution electron tomography studies suggest that the PCM is made of filamentous matrices. Although the detailed organization of the centrosome matrix remains largely unknown, a number of centrosome proteins that have the potential to form a filamentous-matrix structure have been identified.

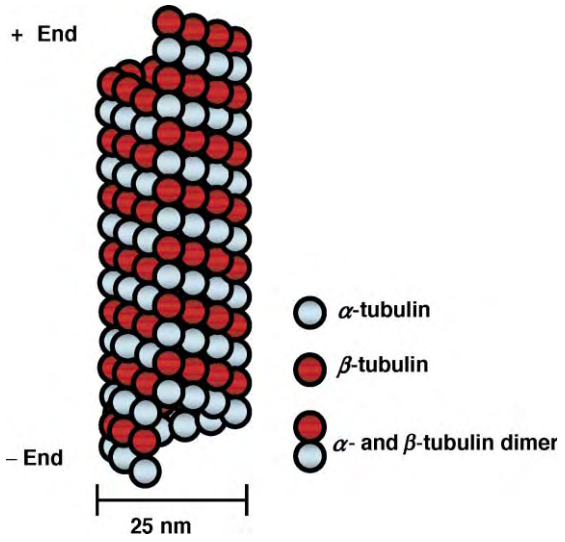

FIGURE 1 Microtubules are assembled from α- and β-tubulin heterodimers. The dimers interact with each other in a head-to-tail fashion to form linear protofilaments that associate with each other laterally to form a hollow cylindrical microtubule with a diameter of 25 nm. The plus and minus ends of the microtubule are indicated.

Centrosome Duplication

Unlike many other cellular organelles, a cell contains either one or two centrosomes depending on the cell-cycle stage. In G1 phase, there is only one centrosome per cell, which duplicates itself in S phase when the nuclear DNA is replicated. Centrosome duplication is characterized by the growth of a new centriole from the side of each of the existing centrioles, which results in two pairs of centrioles. Following centriole duplication, the PCM is partitioned between the two centriole pairs, giving rise to two centrosomes in G2 phase. As the cell cycle progresses into mitosis, the two centrosomes are further separated from each other and each centrosome participates in the organization of the bipolar mitotic spindle. At the end of a cell cycle, cell division results in two new cells each consisting of a single centrosome. Since bipolar spindle assembly is essential for equal chromosome segregation, the single duplication of the centrosome in each cell cycle is important for proper cell division. Recent studies show that the cyclin-dependent protein kinase, CDK2, drives centrosome duplication in S phase. However, the duplication process and the mechanism that ensures only one round of centrosome duplication per cell cycle are not well understood.

The PCM Harbors Microtubule Nucleating and Organizing Activity

The centrosome was first recognized as a microtubule-nucleating and -organizing center over 100 years ago. Studies in the 1990s have now established that a protein complex called the γ-tubulin ring complex (γTuRC), which resides in the PCM, is responsible for microtubule nucleation. Hundreds of γTuRCs at the PCM nucleate the growth of plus ends of microtubules. The minus ends of these microtubules often associate with the PCM through interactions with γTuRC and/or with other PCM proteins (Figure 2), though the detailed mechanism of this association is not clear. The ability of the centrosome to associate with numerous nucleated microtubules gives rise to an organized microtubule array, which is essential for many aspects of microtubule functions.

Microtubule Nucleation

γTuRC

In addition to α- and β-tubulins, eukaryotic cells possess a third tubulin called γ-tubulin. Unlike α- and β-tubulins, γ-tubulin associates with nontubulin proteins to form protein complexes that can nucleate microtubule assembly. γ-Tubulin is a major component of the γTuRC that has been purified and studied in *Xenopus* eggs, *Drosophila* embryos, and human tissue culture cells. In all cases, γTuRC appears as an open-ring structure with a diameter of ~25 nm consisting of approximately seven proteins. The best-characterized *Drosophila* γTuRC consists of at least seven proteins: γ-tubulin, Dgp71WD, Dgrips75, 84, 91, 128, and 163. Dgrip84, Dgrip91, and γ-tubulin, which are the most abundant proteins in *Drosophila* γTuRC, have homologues in all organisms examined to date. Some of the remaining less abundant components of *Drosophila* γTuRC also have homologues in other animal cells. Therefore, the structure and organization of *Drosophila* γTuRC are likely to represent general features of γTuRC in animal cells.

In *Drosophila* γTuRC, γ-tubulin interacts directly with Dgrip84 and Dgrip91 to form a γ-tubulin small complex (γTuSC) consisting of two molecules of γ-tubulin and one molecule each of Dgrip84 and Dgrip91. Multiple γTuSCs are assembled into one γTuRC. Although a detailed structural model of γTuRC is not available, a number of studies strongly suggest that γTuRC consists of a ring and a cap that covers one face of the ring (Figure 3). The ring is primarily made of γTuSCs, whereas some or all of the less abundant γTuRC components (Dgp71WD, Dgrips75, 128, and 163) makes up the cap. The uncapped side of the γTuRC ends with a ring of γ-tubulins that directly interacts with tubulin to mediate microtubule nucleation (Figure 4).

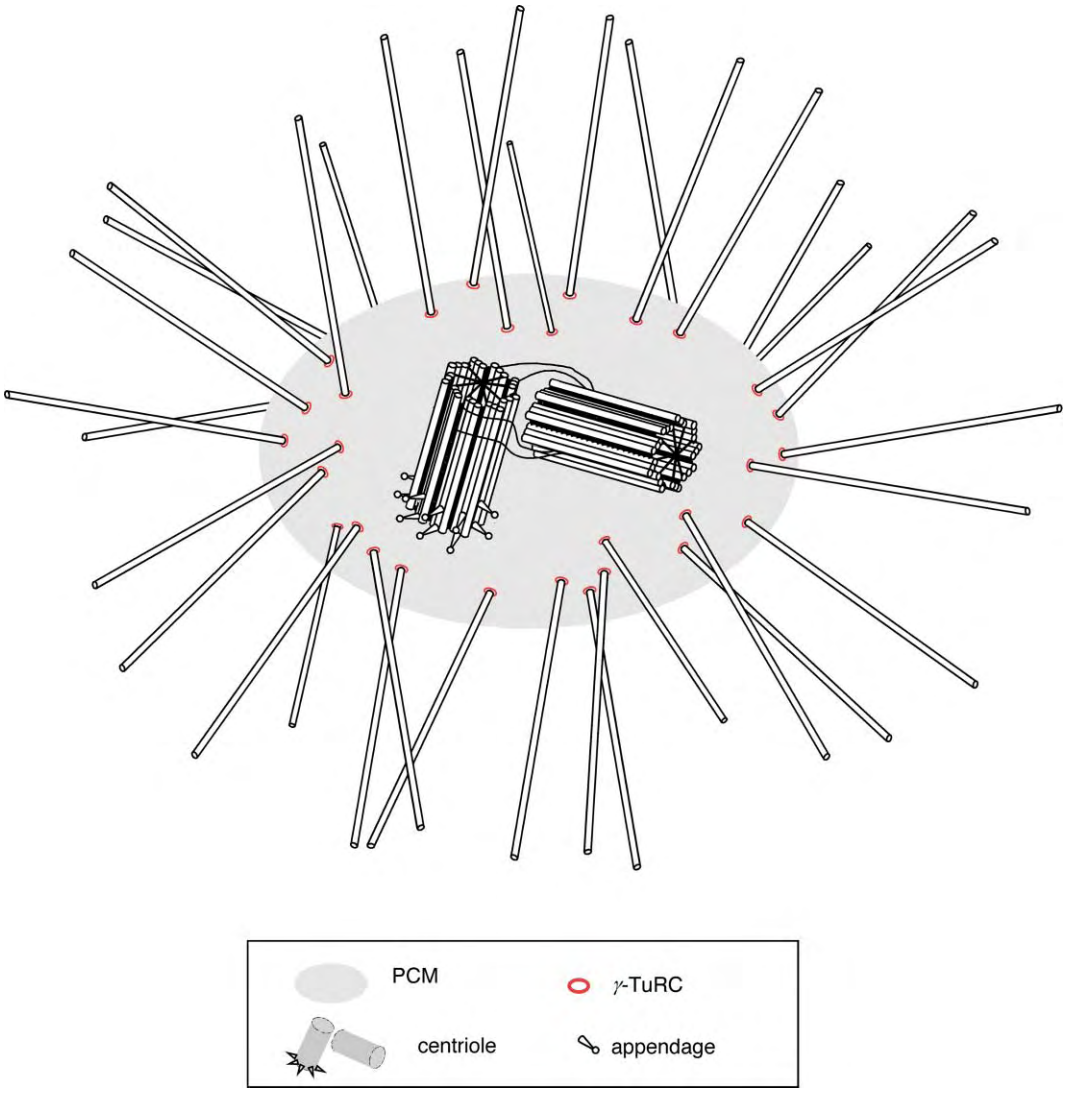

FIGURE 2 The centrosome contains a pair of centrioles and a PCM. The centrioles are connected to each other and one of them has appendages. Microtubules are nucleated from γTuRCs that are associated with the PCM.

Models of γTuRC-Mediated Microtubule Nucleation

The purified γTuRC can stimulate microtubule nucleation from purified tubulin *in vitro*. Although the detailed mechanism of γTuRC-mediated microtubule nucleation remains to be elucidated, two models have been proposed. Both models suggest that the presence of multiple γ-tubulins in the γTuRC allow simultaneous interactions with multiple tubulins during microtubule nucleation, thereby lowering the kinetic barrier of microtubule nucleation. However, the two models are completely different in terms of how the γTuRC may interact with its nucleated microtubules.

The so-called template nucleation model suggests that the γ-tubulin ring of the γTuRC acts as a template during microtubule nucleation (Figure 4). The newly formed microtubule is capped by the γTuRC at its minus end. Consistent with this model, a number of studies suggest that γTuRC-nucleated microtubules are capped at their minus ends. The other drastically different model—the protofilament model—suggests that the γTuRC ring opens up during microtubule nucleation with the multiple γ-tubulins acting as a protofilament to stimulate or stabilize the formation of microtubule seeds (Figure 4). Further high-resolution studies focusing on the interaction between the γTuRC and the microtubule minus ends are required to unequivocally discriminate between the two models of γTuRC-mediated microtubule nucleation.

γTuRC-Mediated Microtubule Nucleation *in vivo*

In living cells, about half of the γTuRC is recruited to the centrosome where it mediates centrosome

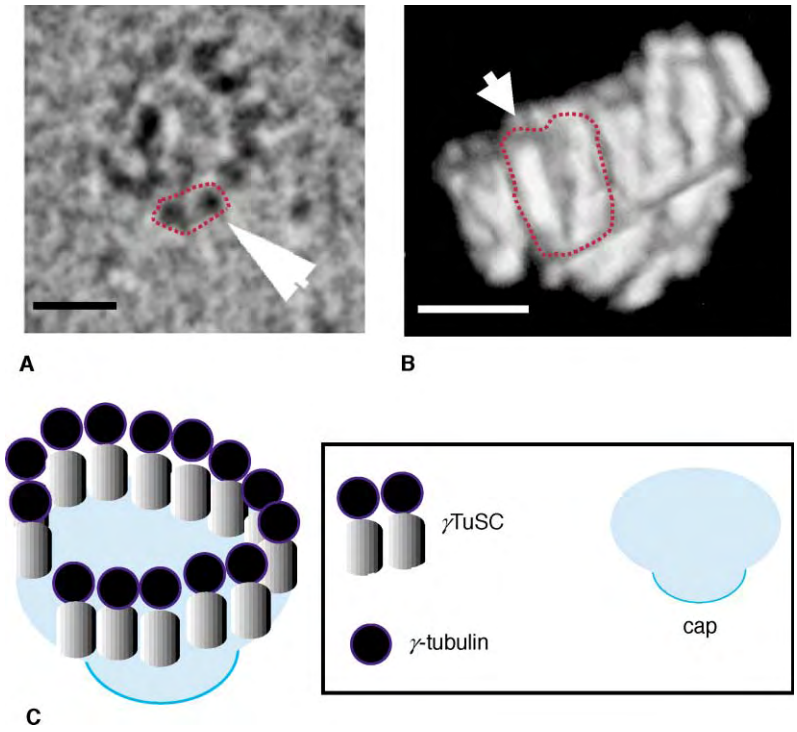

FIGURE 3 The structure of the γTuRC. (A) Cryo-electron micrograph of a γTuRC in cross section. Approximately 13 subunits make up the ring. Arrow points to two subunits that may correspond to one γTuSC. The apparent internal structure may correspond to the cap. Reproduced from *J. Cell Biol.* **144**, 721–733, with permission. microtubule nucleation. Since centrosomes provide the major microtubule nucleating activity in dividing cells, it is not clear whether the other half of the γTuRC in the cytoplasm also participates in microtubule nucleation. One possibility is that the cytoplasmic γTuRC does not nucleate microtubules because it is associated with an inhibitor. Alternatively, centrosomal recruitment of γTuRC may greatly enhance its microtubule-nucleating activity. In this case, even though the cytoplasmic pool of γTuRC can nucleate microtubules, the centrosomal γTuRC provides the major source of microtubule-nucleating activity.

The cytoplasmic pool of γTuRC serves as a reserve for additional centrosome recruitment of γTuRC that occurs at the onset of mitosis. This recruitment of additional γTuRC contributes toward the enhanced microtubule-nucleating activity of the centrosome, which is important for efficient spindle assembly in mitosis. Interestingly, a fraction of the γTuRC also associates with the mitotic spindle in mitosis. It is possible that this pool of γTuRC plays a role in spindle assembly and function.

Other Microtubule Nucleators

By definition, any proteins that facilitate the formation of microtubule seeds during microtubule nucleation can function as microtubule nucleators. Before the discovery of γ-tubulin and γTuRC, microtubule-associated proteins (MAPs) were considered as prime candidates for microtubule nucleators. MAPs may nucleate microtubules by binding and stabilizing tubulin oligomers formed during microtubule seed formation. Interestingly, some MAPs, such as XMAP215, are found at the centrosome in animal cells. Further study is required to determine whether or how the centrosomally localized MAPs mediate microtubule nucleation *in vivo*.

Centrosome Abnormalities in Cancer

A number of studies have shown that abnormalities in centrosome shape, nucleating capacity, and number exist in cells derived from many tumor tissues. These centrosome anomalies can disrupt bipolar spindle assembly in mitosis, resulting in the formation of either monopolar or multipolar spindles and chromosome mis-segregation. Since aneuploidy – the gain or loss of chromosomes due to chromosome mis-segregation – is linked to genomic instability in human cancers, centrosome abnormalities have been implicated in causing aneuploidy and tumorigenesis.

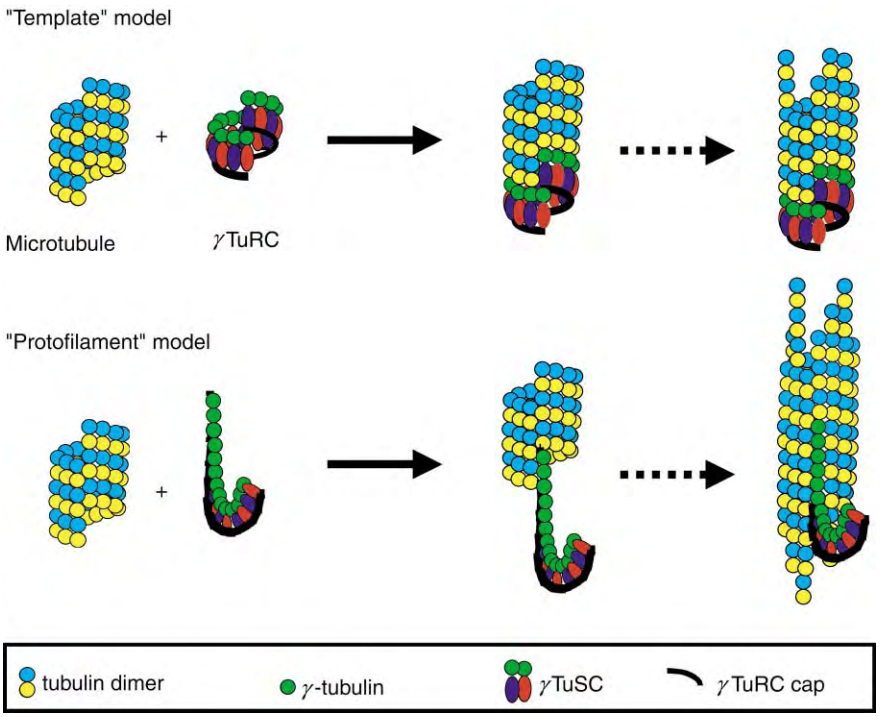

FIGURE 4 Microtubule nucleation by the γTuRC. In the "template model" of microtubule nucleation, the γTuRC caps the minus ends of microtubules after nucleation. In the "protofilament model" of microtubule nucleation, the γTuRC undergoes a large structural change, resulting in the formation of protofilament-like γ-tubulins that nucleate microtubules. For simplicity, the cap of the γTuRC is represented as a line in the γTuRC drawings. (Reproduced from Wiese, C., and Zheng, Y. (2000). A new function for the γ-tubulin ring complex as a microtubule minus-end cap. *Nat. Cell Biol.* **2**, 358–364 with permission of Nature Publishing Group.)

Biography

Yixian Zheng is a staff member and assistant investigator of the Carnegie Institution of Washington and the Howard Hughes Medical Institute, respectively. She holds a B. S. from Sichuan University (P. R. China) and a D.Phil. from the Ohio State University. Her research includes microtubule nucleation and mitotic spindle morphogenesis.

Reiko Nakajima holds a B.S. from Tokyo University and a D.Phil. from Osaka University, while Ming-Ying Tsai holds a B.S. from National Yang Ming Medical School and a D.Phil. from University of Southwestern Medical Center. Both are currently postdoctoral fellows in Yixian Zheng's group studying different aspects of spindle morphogenesis.

c-*fes* Proto-Oncogene

Thomas E. Smithgall
University of Pittsburgh, Pittsburgh, Pennsylvania, USA

Robert I. Glazer
Georgetown University, Washington, DC, USA

The human c-*fes* proto-oncogene (Fes) encodes a protein-tyrosine kinase distinct from c-Src, c-Abl, and other non-receptor tyrosine kinases. Originally identified as the cellular homologue of avian (v-Fps) and feline (v-Fes) transforming retroviral oncoproteins, Fes is strongly expressed in myeloid hematopoietic cells where it may play a direct role in myeloid differentiation. The Fes promoter exhibits strong myeloid lineage specificity for directing transgene expression in animals. Fes is also expressed in endothelial and epithelial cells where it is involved in migration and cell survival, respectively. Structurally, Fes consists of a unique N-terminal region, a central SH2 domain, and a C-terminal kinase domain. Within the unique region are two coiled-coil oligomerization domains that regulate kinase activity. Fes is linked to growth, differentiation, and survival signaling through Ras and other small G proteins, STAT transcription factors, and phosphatidylinositol 3-kinase. Fes phosphorylates cell adhesion-related substrates in macrophages and promotes myelomonocytic differentiation. Fes is also involved in endothelial cell migration in response to angiogenic factors, neuron differentiation, and is up-regulated in the mammary gland during pregnancy. Although Fes had not been directly implicated in human disease, it can suppress the transforming activity of Bcr-Abl, the transforming oncoprotein associated with chronic myelogenous leukemia (CML).

Structure and Regulation

Human c-*fes* is located on chromosome 15 at position 15q26.1 and is comprised of 19 exons, the first of which is noncoding. The product of the *fes* gene is a 93 kDa protein-tyrosine kinase with three distinct structural regions (Figure 1). These include a long N-terminal unique region, a central Src homology 2 (SH2) domain, and a C-terminal kinase domain. Absent are an SH3 domain and signal sequences for lipid modification, such as an N-terminal myristoylation site associated with Src, Abl, and other nonreceptor tyrosine kinase families. Fes tyrosine kinase activity can be readily demonstrated *in vitro*, however, unlike its transforming viral counterparts, Fes kinase activity is tightly regulated in cells. As described, recent evidence suggests that the unique N-terminal region plays an important role in negative regulation.

N-Terminal Region

One unusual feature of Fes is that its active form exists as a large oligomeric complex. Oligomerization requires the N-terminal region and promotes Fes autophosphorylation by a *trans* mechanism, a key step in the activation of the kinase domain. Analysis of the unique region using COILS, a computer algorithm that searches for the heptad repeat pattern associated with coiled-coil domains, reveals the presence of at least two regions with a high probability of forming coiled-coil structures. The presence of two N-terminal coiled-coil-forming sequences suggests several mechanisms for the regulation of Fes tyrosine kinase activity. One possibility is that a cellular protein binds to the coiled-coil regions and suppresses oligomerization. Alternatively, the two coiled coils may interact in an intramolecular fashion, thus preventing the formation of the active oligomer. A recent study has shown that Fes activity is repressed following ectopic expression in yeast, suggesting that the kinase naturally adopts the inactive conformation without the need for mammalian host cell factors. Deletion or mutagenesis of the more N-terminal coiled-coil domain releases the tyrosine kinase and biological activities of Fes in living cells, consistent with a critical role for this domain in negative regulation. In contrast, deletion of the more C-terminal coiled-coil domain impairs the kinase activity and biological function of active Fes mutants, suggesting a more dominant role in maintenance of the active state or recruitment of signaling partners.

In addition to its role in the regulation of kinase activity, the unique N-terminal region of Fes also contributes to the recruitment of signaling partners. One example is the breakpoint-cluster region protein (Bcr), which was originally discovered in the context of the Bcr-Abl oncoprotein associated with chronic

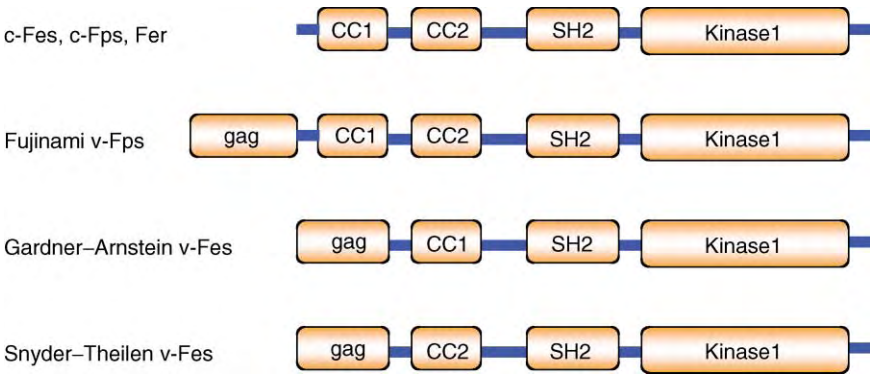

FIGURE 1 Primary structure of the c-Fes protein-tyrosine kinase. Fes consists of a unique N-terminal region, a central SH2 domain, and a C-terminal kinase domain. Two coiled-coil oligomerization motifs (CC1 and CC2) are located in the unique region.

myelogenous leukemia (CML). Bcr is a multidomain signaling protein with an N-terminal Ser/Thr kinase domain, a central region with homology to the Dbl family of guanine nucleotide exchange factors, and a C-terminal GTPase-activating domain for Rho-related small GTPases. Bcr-Fes interaction involves the unique N-terminal region and SH2 domain of Fes and the N-terminal kinase domain of Bcr. Bcr is strongly phosphorylated by Fes both *in vitro* and *in vivo* on a cluster of sites localized to the N-terminal domain. Expression of this Bcr region suppresses Fes-induced neurite outgrowth in rat PC12 cells, suggesting that Bcr may couple Fes to Rho family small GTPases in neuronal cells (C. Laurent and T. Smithgall, unpublished data). Fes also interacts with Bcr-Abl through the Bcr-derived portion of the protein. This interaction may contribute to Fes-induced suppression of transformation signaling by Bcr-Abl.

SH2 Domain

SH2 domains are signaling modules that mediate protein–protein interactions during tyrosine kinase signal transduction. By binding with high affinity and specificity to short, tyrosine-phosphorylated target sequences, SH2 domains mediate the assembly of multiprotein complexes in response to tyrosine kinase activation. Although the role of SH2 domains in the recruitment of effector proteins to autophosphorylated growth factor receptors is well known, SH2 domains were first identified within the sequences of nonreceptor tyrosine kinases. In fact, the SH2 domain of the Fes-related oncoprotein v-Fps was among the first to be described, and was shown to be required for full catalytic activity and to influence host range. Later work established a function for the SH2 domain in v-Fps-induced phosphorylation of transformation-related substrates. More recent studies reveal a similar dual role for the human Fes SH2 domain in the regulation of kinase activity and biological function. Deletion of the SH2 domain greatly reduces Fes kinase activity both in terms of substrate phosphorylation as well as autophosphorylation *in vitro*. The SH2 region also contributes to substrate recognition in macrophages.

Kinase Domain

The Fes catalytic domain is localized to the C-terminal region of the protein and exhibits structural features typical of tyrosine kinases. These include a conserved lysine in the ATP-binding pocket (Lys 590) and a major site of tyrosine autophosphorylation (Tyr 713). Mutagenesis of Tyr 713 to Phe greatly reduces catalytic activity both *in vitro* and *in vivo*, suggesting that autophosphorylation is required for kinase activation. Substitution of Lys 590 with Glu or Arg completely abolishes kinase activity. *Trans* or autophosphorylation of Tyr 811 is likely associated with recruitment of other SH2 proteins but not with kinase regulation.

Biological Functions

Myeloid Differentiation

Early studies describing Fes expression patterns noted a striking correlation with terminal differentiation of myeloid hematopoietic cells. Fes expression is absent in myeloid leukemia cell lines resistant to myeloid differentiation inducers or selected for differentiation resistance, while expression increases following induction of differentiation with a variety of agents. Other work demonstrates a strong connection between Fes and the induction of myeloid differentiation. Chicken bone marrow cells infected with Fujinami sarcoma virus, which carries the fes-related oncogene, v-fps, undergo macrophage differentiation in the absence of macrophage colony-stimulating factor. Recent studies show

that expression of activated c-Fes mutants is sufficient to induce differentiation of myeloid leukemia cells along the macrophage lineage. Consistent with these observations, Fes activation is linked to a number of hematopoietic cytokines. Fes associates with the IL-4, IL-3, GM-CSF, and erythropoietin receptors. Kinase-inactive Fes blocks IL-4-induced phosphorylation of the insulin receptor substrate-2 and recruitment of phosphatidylinositol 3-kinase (PI3-K) in hematopoietic cells.

Evidence supporting a requirement for Fes in myeloid differentiation also comes from antisense experiments. Suppression of Fes expression in HL-60 promyelocytic leukemia cells using antisense oligonucleotides blocks the myeloid differentiation response to phorbol esters and other chemical inducers. However, targeted disruption of Fes in mice has yielded contradictory findings with respect to its role in hematopoiesis. Replacement of the *fes* alleles with a kinase-defective K588R mutant Fes did not show any remarkable effect on hematopoiesis, although STAT3 and STAT5A phosphorylation in response to GM-CSF was markedly reduced. In contrast to these findings, homozygous deletion of Fes led to a runted appearance, abnormal myeloid proliferation, but increased STAT3 activation in response to GM-CSF and IL-6. These apparently contradictory results can be explained by the competition of kinase-dead Fes with Jak2 for STAT3 resulting in a lower degree of STAT3 activation, whereas the complete absence of Fes produces less competition with Jak2 for STAT3 resulting in STAT3 hyperactivation.

Is Fes a Tumor Suppressor?

Other work shows that Fes-induced differentiation may overcome signals for transformation in certain forms of leukemia. The first demonstration of this phenomenon involved transfer of the c-*fes* gene into the human cell line K-562, resulting in growth suppression and differentiation to macrophage-like cells. K-562 cells were established from the blast crisis phase of CML and exhibit no detectable Fes expression. Because they are CML derived, K-562 cells exhibit the Philadelphia chromosome translocation and express p210 Bcr-Abl, the oncogenic tyrosine kinase, that initiates the disease process. Thus, the Fes signal for differentiation is dominant to the Bcr-Abl signal for growth and survival. Fes can also suppress Bcr-Abl-induced transformation of murine myeloid leukemia cells to cytokine independence, providing further support for the idea that Fes may delay the progression of CML.

Angiogenesis

In addition to its role in hematopoiesis, Fes may contribute directly to differentiation and development of the vascular endothelium. Expression of constitutively active Myr-Fes in transgenic mice under the control of the general SV40 promoter induced hypervascularity, which progressed to multifocal hemangiomas. This study also demonstrated expression of endogenous Fes in primary human vascular endothelial cells at levels comparable to those detected in myeloid cells. Consistent with these findings are the observations that Fes is activated by the angiogenic growth factors FGF-2 and angiopoietin-2 in capillary endothelial cells, and that overexpression of Fes is sufficient to induce formation of tube-like structures and chemotaxis in this cell type.

Downstream Signaling Pathways

Major signaling pathways linked to Fes are briefly summarized here (Figure 2).

Small G Proteins

Ras and other small *GTPases* are critical intermediates in most tyrosine kinase signal transduction pathways, and Fes is no exception. Activation of Ras and the related small GTPases Rac and Cdc42 are required for fibroblast transformation by Fes oncogenes. Dominant-negative mutants of all three small G proteins inhibit fibroblast colony-forming activity by Myr-Fes and v-Fps, and transformation correlates with constitutive activation of both the Erk and Jnk serine/threonine kinase pathways downstream. Sustained Erk activation is sufficient to induce myeloid differentiation of K-562 cells, suggesting that Fes-induced differentiation in these cells may be due in part to activation of the Ras/Erk pathway.

The activation and termination of small GTPase signaling are regulated by protein factors (guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs), respectively) that link small GTPases with upstream tyrosine kinases, including Fes and its transforming viral homologues. Transformation of fibroblasts by v-Fps has been shown to induce tyrosine phosphorylation of p120 Ras GAP, and similar results have been observed *in vitro* with purified Fes and GAP proteins. Fibroblast transformation by v-Fps also correlates with tyrosine phosphorylation of Shc, an adaptor protein that serves as an intermediate between tyrosine kinases and the Ras GEF complex, Grb-2/Sos. As mentioned above, endogenous Bcr is also strongly tyrosine-phosphorylated in fibroblasts transformed by v-Fps. Tyrosine phosphorylation of Bcr in v-*fps*-transformed cells induces its association with Grb-2/Sos via the Grb-2 SH2 domain. Like Shc, Bcr may serve as an intermediate between Fes and the activation of Ras downstream. In addition, tyrosine phosphorylation of

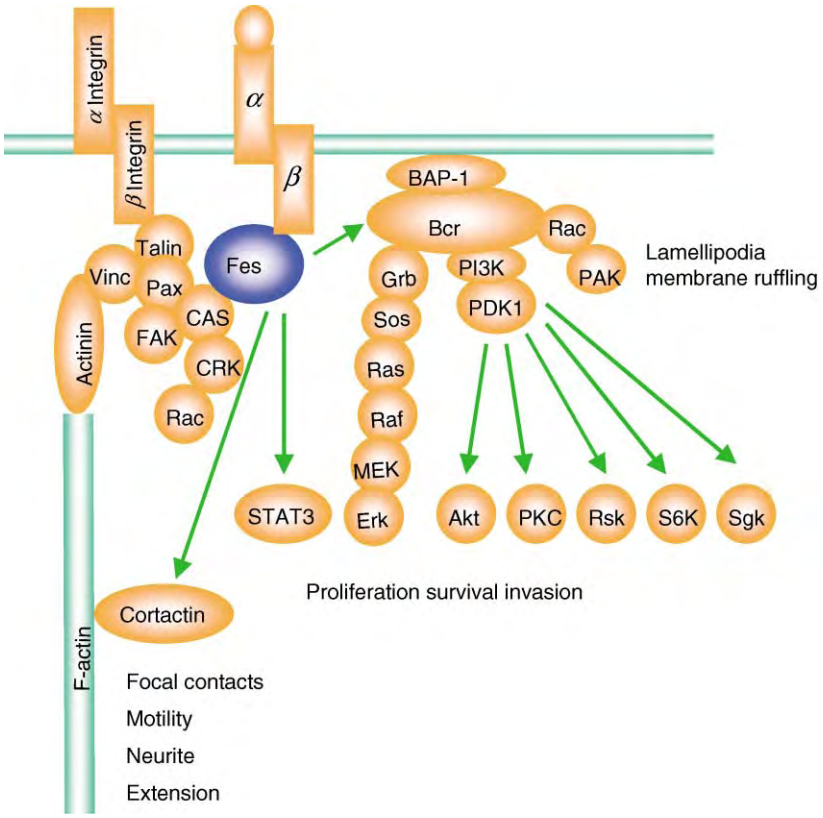

FIGURE 2 Fes signaling pathways involved in cell motility, proliferation, survival, and differentiation.

Bcr may modulate either its GEF or GAP activities toward Rac and other GTPases.

STAT Signaling

STATs are transcription factors with SH2 domains that are activated by tyrosine phosphorylation, often in response to cytokine stimulation. Although kinases of the Jak family are most often associated with STAT activation, a growing body of evidence indicates that Fes and other tyrosine kinases can induce STAT activation as well. For example, STAT3 DNA-binding activity is strongly activated following co-expression with Fes in Sf-9 insect cells, which lack endogenous Jak kinases. In addition, macrophages from homozygous knockout mice in which both *fes* alleles have been deleted hyperactivates STAT3 in response to GM-CSF. STAT3 has been strongly implicated in myeloid differentiation, making it tempting to speculate that Fes may signal to differentiation-related genes through a STAT3-dependent pathway.

PI3-K Pathway

PI3-K phosphorylates phosphoinositol lipids at the 3′ position, leading to the generation of second messengers such as phosphatidylinositol-3,4,5-trisphosphate (PIP_3). PI3-K is a heterodimer consisting of 85 kDa regulatory (p85) and 110 kDa catalytic (p110) subunits, and interacts with tyrosine phosphorylated target proteins through SH2 domains found in the p85 subunit. Several reports have linked Fes to the activation of PI3-K signaling. Early work demonstrated elevated PI3-K activity in chicken embryo fibroblasts transformed by v-Fps as well as other transforming tyrosine kinases. More recently, IL-4 was shown to induce the association of endogenous Fes with PI3-K in IL-2-dependent T-cell lines. The SH2 domain of p85 forms a stable complex with Fes, suggesting a possible mechanism for factor-induced complex formation. The PI3-K pathway is often associated with survival signaling, and activation of this pathway by Fes may contribute to macrophage survival, perhaps through association with the Crk substrate, CAS (Figure 2). Interestingly, the protein-serine kinase immediately downstream to PI3-K, 3-phosphoinositide-dependent protein kinase-1 (PDK1) (Figure 2), coimmunoprecipitates with Fes, and is phosphorylated on tyrosine (Zeng and Glazer, unpublished data). This suggests a mechanism by which Fes can mediate the activation of other downstream signaling pathways such as $p70^{S6K}$. Activation of PI3-K is also essential to Fes-induced neurite extension in PC12 cells, where it may serve to couple Fes to Rac activation in this system.

Other Substrates

Most of the substrates reported for Fes have been identified using fibroblast transformation as a model system. However, overexpression of Fes in a macrophage cell line, which represents a physiological context, led to the phosphorylation of proteins related to integrin-mediated responses including adhesion and cell-cell contact. Interestingly, phosphorylation of Shc and other proteins associated with mitogenic responses have not been observed. A role for Fes in cell adhesion is further suggested by the interaction of the Fps SH2 domain with cortactin (Figure 2), which is also phosphorylated by Fes. These results suggest a mechanism for the localization of Fes with focal adhesions.

Transcriptional Regulation of Fes

Transgene expression directed by the 13 kb genomic Fes locus reproduced the myeloid-specific expression pattern of the endogenous gene. The Fes promoter sequence spanning + 28 to +2523 (within exon 1 to intron 3) directed myeloid-specific expression of a heterologous gene in transgenic mice. Myeloid-specific expression has been attributed to a tissue-specific repressor at + 441 to +454, a Fes-specific transcription factor (FEF) binding to a *cis*-acting element at − 9 to − 4 and to transcription factors Sp1, PU.1, and Spi-1 binding to elements within the − 425 to +75 promoter sequence. Although these studies account for the myeloid-selective expression of Fes, they do not address Fes expression in other tissues, such as endothelial and epithelial cells, and its transient expression in embryonic tissues, such as the brain. Fes up-regulation occurs during neuronal differentiation and accelerates neurite outgrowth in PC12 cells. Fes also associates with and activates semaphorin3A that is associated with axonal guidance and neuronal outgrowth, further suggesting a role for Fes in brain development and differentiation.

Conclusions

The c-*fes* proto-oncogene encodes a unique cytoplasmic tyrosine kinase involved in myelopoiesis, angiogenesis, CML progression and likely survival in mammary epithelial cells. Although the SH2 and kinase domains found in Fes share homology with other tyrosine kinase families, the N-terminal region is structurally distinct. The presence of coiled-coil oligomerization domains within the N-terminal region suggests a mode of kinase regulation and substrate recruitment that is unique to this tyrosine kinase family. Fes is associated with terminal differentiation in myeloid cells, as opposed to other tyrosine kinases that serve a predominant role in proliferation and survival. Work implicating Fes in the regulation of vascular endothelial cell migration suggests a role in tumor angiogenesis, and Fes may also serve a role in regulating cell survival and apoptosis during mammary gland differentiation, as well as neuronal differentiation.

Chaperones for Metalloproteins

Valeria C. Culotta and Edward Luk
Johns Hopkins University Bloomberg School of Public Health, Baltimore, Maryland, USA

Metal ions are not only essential co-factors for enzymes, but are also potentially toxic to cells. Therefore, the passage of metals inside a cell must be tightly regulated. A family of proteins has been identified that functions in the intracellular trafficking of copper ions to enzymes that require the metal for activity. These copper carriers are known as copper chaperones or metallochaperones. This article will highlight recent findings regarding the mechanism of copper chaperones.

Historical Background

Chaperones for metalloproteins are a small family of molecules that have evolved specifically to insert metal ion cofactors into enzymes or other proteins that rely on metals for function. All living cells, from bacteria to humans, harbor numerous metalloproteins that require metal ions such as zinc, copper, manganese, or iron to function. These metals either can serve in a structural role to help maintain the proper conformation of a protein or can actually carry out the chemistry that represents the protein or enzyme's catalytic function. Generally, each metalloprotein is only active with one particular metal ion type and, if fortuitously loaded with the wrong metal, the function of the protein is inhibited. Therefore, it is paramount that the right metal be delivered to the right metalloprotein and also that it be delivered at the right time. How this occurs in a regulated fashion eluded biochemists until the late 1990s, when a new paradigm for metal ion homeostasis emerged. It was discovered that many metalloproteins actually coexist with accessory molecules that ensure the acquisition of the proper metal ion. These accessory proteins have been termed metallochaperones or chaperones for metalloproteins. The term chaperone, first coined by Tom O'Halloran in 1997, was derived from Webster's definition of chaperone, "one delegated to ensure proper behavior." In this case, the one delegated is the metallochaperone, which ensures the proper behavior of the potentially promiscuous metal ion.

The Concept of Metal Trafficking

There are a number of barriers that a metal ion must cross before it reaches its metalloprotein target inside the cell. First, the metal existing in the extracellular environment must traverse the plasma membrane. Metals by themselves cannot penetrate lipid bilayers and therefore rely on metal-transporter molecules to direct their movement across membranes. A variety of membrane transporters exist at the cell surface that act in the specific uptake of metals such as copper, zinc, iron, and manganese. Once inside the cell, some metal ions are delivered directly to proteins in soluble compartments (i.e., the cytosol); however, many metalloproteins reside in membranous organelles such as the mitochondria or secretory pathway, and as such the metal needs to cross a second membrane barrier. This again is accomplished by metal transporters that help translocate the ion across the lipid bilayer. Finally, at a site proximal to the metalloprotein target, the metal cargo is carried by a highly specific metal chaperone that helps insert the metal into the proper site of the metalloprotein. In essence, a metal ion does not freely move about the cell but rather is carried through a well-defined pathway involving the combined action of metal transporters and metal chaperones. This process of moving metals through defined pathways is commonly referred to as metal trafficking, and there are many such highways for the trafficking of metals to metalloproteins.

Why the Need for Metal Trafficking?

The cell devotes a great deal of effort to ensure a highly regimented fate of a metal ion. Why not instead have the metal freely diffusible in the cell? Metalloproteins typically exhibit a very high affinity for their cofactor and are inherently able to self-activate with metals in a test-tube setting. However, the availability of metals inside cells is very limited. Although metals are essential for life, metals are also notoriously toxic and can cause much cellular damage. Therefore, all organisms have

evolved with a series of metal detoxification pathways that act to sequester metals and prevent them from reacting at biological sites. A classic example is the metal-binding metallothionein protein that acts as a sponge for these ions and precludes metals from accumulating in their free ionic form. In measurements that have been made in yeast and bacteria, not a single atom of copper or zinc is freely available in the cytoplasm of the cell, in spite of the micromolar quantities of metal that are accumulated. Intracellular metalloproteins therefore have the challenge of acquiring their cognate metal cofactor in an environment that is essentially a vacuum for metals. To overcome this dilemma, the metal ion chaperones spare a few ions from the metal detoxification pathways and ensure the safe delivery of metals to the active site of metalloproteins. Whereas proteins such as metallothioneins act to protect the *cell from the metal*, the metal chaperones act to protect the *metal from the cell*.

Copper Metalloproteins as Models for Metal Trafficking

Much of what is currently known about metal chaperones and metal trafficking pathways stems from studies on copper. Because copper is a redox-active metal ion that can readily donate or accept electrons, it serves as an excellent catalytic cofactor for enzymes involved in oxygen chemistry. Compared to metalloproteins that bind iron or zinc, copper-containing enzymes are relatively few in number. However, an abundance of information is available on the metal-trafficking pathways relevant to this small subset of metalloenzymes.

In eukaryotes, copper is generally taken up into cells via a cell surface transporter, CTR1. This transporter was originally discovered in 1994 by Andrew Dancis through elegant genetic studies in yeast, and the human homologue was subsequently isolated by J. Gitschier in 1997. Following entry into the cell via CTR1, the copper ion can be shuttled through one of many distinct trafficking pathways, depending on its destination or fate. The copper is either subject to detoxification (a dead-end fate) or is selected for use by copper-containing enzymes. Three such utilization pathways for copper have been identified, and these specifically supply the metal to copper proteins in the Golgi, the cytosol, and the mitochondria (Figure 1).

There are a variety of enzymes that acquire copper in the Golgi compartment, and these are copper proteins destined for the cell surface or for export outside the cell. Examples include multicopper oxidases needed for iron transport (i.e., human ceruloplasmin), extracellular superoxide dismutases for anti-oxidant defense

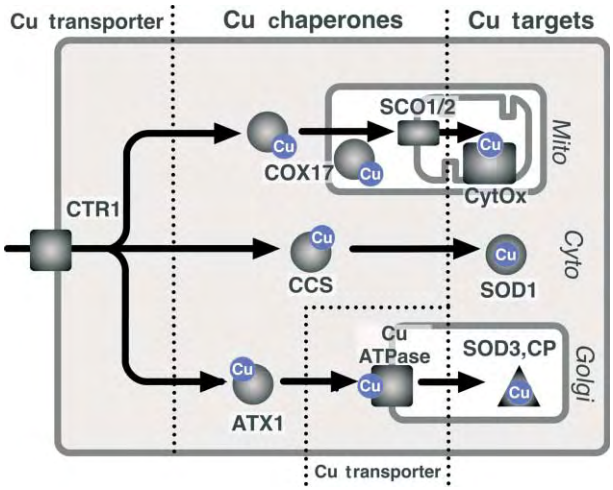

FIGURE 1 Three metal-trafficking pathways involving copper in a typical eukaryotic cell. Copper is first taken up by the cell surface CTR1 copper transporter. The metal can then be delivered in one pathway involving cytosolic ATX1, which carries the copper to the P type copper-transporting ATPase. This transporter in turn pumps copper into the lumen of the Golgi for the activation of a variety of copper enzymes in the secretory pathway, such as extacellular superoxide dismutase (SOD3) and ceruloplasm (CP). A second pathway involves copper carried by CCS to the copper-zinc superoxide dimustase (SOD1) in the cytosol (Cyto). The third pathway involves a relay system of copper delivery to cytochrome oxidase (CytOx) in the mitochondria involving COX17 (both cytosolic and mitochondrial) and mitochondrial SCO1 and SCO2 proteins. Grouped within dotted lines are molecules designated as cell surface and intracellular copper transporters, copper chaperones, and targets for copper delivery.

(SOD3), enzymes for connective-tissue formation (lysyl oxidase), enzymes for pigment formation (tyrosinase), and enzymes for neuronal function (peptidly amidating enzyme and dopamine β-hydroxylase). Prior to reaching their location at the cell surface or extracellular milieu, all these enzymes pass through a specific compartment of the Golgi, where they are activated with copper.

A second copper-trafficking pathway in the cell delivers copper to the cytoplasm, where the ion activates a single enzyme, a cytosolic copper- and zinc-containing superoxide dismutase (SOD1). SOD1 functions to protect the cell against oxidative damage. The third copper-trafficking pathway delivers the metal to the mitochondria. Here a copper-containing oxidase (cytochrome oxidase) resides that functions as the terminal electron acceptor during cellular respiration.

These three pathways involve separate factors for transmembrane metal transport and metal ion chaperoning, and they are discussed independently next.

Delivering Copper to the Golgi: Pathways Involving the ATX1 Copper Chaperone

In order for copper to gain access to enzymes that pass through the Golgi, the metal must traverse the

Golgi membrane. This is accomplished through the action of a specialized copper transporter, called P type ATPase, that uses the energy of ATP hydrolysis to drive the transmembrane translocation of copper from the cytoplasma into the lumen of the Golgi. Humans express two such copper transporters, known as the Wilson or Menkes disease proteins. As the names imply, these molecules have been associated with inherited diseases of copper transport. Copper-transporting ATPase molecules are found in virtually every eukaryotic cell, and they all contain a series of two to six short copper-binding protein domains that capture copper in the cytosol for translocation into the Golgi. How does the metal find these domains if there is no free copper in the cytosol? This is achieved through the action of a small copper-binding copper chaperone known as ATX1 (also called ATOX1).

ATX1 was originally identified in 1995 by V. Culotta as a potential anti-oxidant protein in yeast that guards against oxidative damage, hence the name ATX1. However, subsequent studies revealed that the major function of this molecule was to carry copper from the cytosol to the copper-transporting ATPase in the Golgi. Interesting, the polypeptide sequence of ATX1 is very similar to its recipient of copper delivery, the copper-binding domains of the Cu ATPase in the Golgi. ATX1 and these domains of the transporter bind copper via a single copper-binding site CXXC (where C = cysteine, a sulfur-containing amino acid, and X = any amino acid). With the same copper site present in the donor (ATX1) and recipient (Cu ATPase) molecules for copper transfer, copper is able to move from one site to the other by a facile exchange of sulfur ligands. This mechanism, originally proposed by O'Halloran, Culotta, and Penner-Hahn in 1997, was the first description of a copper-transfer reaction involving a copper chaperone.

The Copper-Trafficking Pathway Involving the CCS Copper Chaperone for SOD1

The SOD1 enzyme is a copper- and zinc-containing superoxide dismutase that protects cells against oxidative damage by scavenging toxic superoxide anion radicals. This is a highly abundant copper enzyme that is ubiquitously expressed among eukaryotes, and in some cells SOD1 represents as much as 1% of the total cellular protein. It is the copper at the active site that carries out enzyme catalysis, whereas the zinc serves more of a structural role.

Although SOD1 has been found in numerous cellular compartments, the bulk ($\geq$95%) of the enzyme is cytosolic, and so there is no intracellular membrane barrier for copper delivery to SOD1. However, due to the absence of free cytsolic copper, SOD1 is highly dependent on its metal chaperone for acquiring its copper.

The copper chaperone for SOD1 (CCS) was first identified by Culotta and Gitlin in 1997. As is the case with ATX1, CCS was discovered by genetic studies in the baker's yeast *Saccharomyces cerevisiae*, but this protein is well conserved throughout eukaryotes. Unlike ATX1, which is a simple one-domain protein, CCS is a complex molecule consisting of three domains that serve separable functions in the copper-transfer process. At the extreme amino terminus, CCS has a short domain that exhibits extensive homology to ATX1, including the CXXC copper site. However, this site is not needed for copper transfer to SOD1 but rather appears to be involved in capturing copper under conditions of copper starvation. A large middle portion of CCS exhibits strong homology to SOD1, but is missing the SOD1 copper site. This homology allows CCS to dock with SOD1 by the formation of a transient heterodimer. SOD1 is normally a homodimer consisting of two identical molecules, and the formation of a heterodimer with CCS is the prerequisite to copper transfer. Finally, at the extreme carboxyl terminus of CCS lies a very short copper-binding domain containing a CXC copper site essential for mediating copper insertion into SOD1.

The mechanism of copper transfer from CCS to SOD1 is far more complicated than that described for ATX1. With ATX1, the donor and recipient for copper transfer bind the metal in the same manner. However, copper transfer by CCS is accompanied by a large change in metal coordination chemistry. Copper binds to CCS in the reduced Cu(I) form via sulfhydral ligands from cysteines in domain III and possibly in domain I as well. Yet in SOD1, copper is oxidized to the cupric Cu(II) state and is coordinated in an all-nitrogen environment. The mechanism by which transfer occurs with this drastic change in metal coordination is just now being elucidated. Oxidation of the copper ion is certainly involved, and oxygen or superoxide itself could be the driving force, as recently proposed by O'Halloran and colleagues.

Delivery of Copper to Mitochondrial Cytochrome Oxidase

Cytochrome oxidase is a very large multisubunit enzyme that represents the terminal electron acceptor in the respiratory chain of the mitochondria. Two subunits of the enzyme contain harbor copper sites that are employed for electron-transfer reactions:

The Cu_A site in subunit 2 of cytochrome oxidase contains two copper ions, whereas subunit 1 of the

enzyme harbors a single copper atom. The Cu_A site acquires its metal via two sets of accessory proteins in the mitochondria: COX17 and SCOI/SCOII. Less is known regarding the assembly of the copper site in subunit 2, but it appears to require separate accessory factors. For the purposes of this review, we focus on assembly of the Cu_A site.

As with ATX1 and CCS, all the accessory proteins for metal insertion into the Cu_A site of cytochrome oxidase were originally discovered by genetic studies in the baker's yeast. Much of this work was pioneered by Moira Glerum and Alexander Tzagaloff in 1996.

COX17 is a cysteine-rich soluble copper-binding protein. Because COX17 exists in both the cytoplasm and the mitochondrial intermembrane space, it was proposed as the shuttle for copper ions between these cellular compartments. However, this function has not been confirmed and it is possible that COX17 only operates in the mitochondria to bring copper to the second set of accessory proteins for the Cu_A site of cytochrome oxidase: SCO1 and SCO2.

The SCO proteins are two very homologous molecules that lie in the inner membrane of the mitochondria. These proteins are believed to capture copper from COX17 and then transfer the metal to the Cu_A site of cytochrome oxidase. The SCO proteins clearly play an essential role in the assembly of cytochrome oxidase and in cellular respiration. A deletion of *SCO1* and also *COX17* in yeast results in a cell that is respiratory deficient. And in humans, mutations in *SCO2* have been associated with a fatal disease in infants, hypertrophic cardioencephalomyopathy.

Perspectives

Virtually all that is known regarding specific metal-trafficking pathways and metal ion chaperones has stemmed from studies in copper. However, it is highly likely that analogous pathways will exist for other metals as well. Metal ions such as iron, manganese, and even zinc are known to be toxic but essential nutrients. Therefore, it is critical that cells maintain these ions under strict guidance and regulation to ensure their proper incorporation into cognate metalloproteins while minimizing deleterious reactivity with other biological sites in the cell.

Glossary

ATX1 A copper chaperone for the copper-transporting P type ATPase in the Golgi.

CCS A copper chaperone for the largely cytosolic copper-zinc superoxide dismutase.

copper COX17 A copper-carrying molecule for the mitochondria.

metal chaperone A molecule that binds a specific metal and helps insert this ion into the metal-binding site of a metalloprotein.

metalloprotein A protein that binds a specific metal ion and requires that metal ion for proper function.

metal transporter A transmembrane protein responsible for the translocation of metal ions across a lipid bilayer.

SCO A copper-carrying molecule, possibly the copper chaperone or copper insertion factor for cytochrome oxidase.

transporting P type ATPase A membrane transporter for copper that uses energy derived from ATP hydrolysis to drive copper transport.

Biography

Valeria Culotta is a professor of environmental health sciences at the Johns Hopkins University Bloomberg School of Public Health in Baltimore, MD. She received her Ph.D. from the Johns Hopkins University Medical School and conducted her postdoctoral training at the National Institutes of Health. Her laboratory focuses on metal ion homeostasis and metal chaperones using baker's yeast as a genetic model system.

Edward Luk is a Ph.D. student in the Department of Biochemistry and Molecular Biology, Johns Hopkins University. His research interests are yeast genetics and metal ion biology.

Chaperones, Molecular

Sue Wickner and Joel R. Hoskins
National Cancer Institute, National Institutes of Health, Bethesda, Maryland, USA

A new concept in molecular biology that has evolved over the past 15 years is that proteins fold with assistance from other proteins, collectively referred to as molecular chaperones. All organisms, from bacteria to humans, possess several classes of molecular chaperones that are highly conserved throughout evolution. In general, molecular chaperones are proteins that bind to unfolded or misfolded proteins and facilitate protein remodeling without being part of the final complex themselves. Typically, they catalyze protein folding or unfolding in energy-dependent reactions. Chaperones participate in many cellular processes, including DNA replication, regulation of gene expression, protein synthesis, cell division, protection and recovery from stress conditions, membrane translocation, and protein degradation. There are four major classes of energy-dependent molecular chaperones: (1) GroEL or Hsp60, (2) DnaK or Hsp70, (3) Hsp90, and (4) Clp or Hsp100. All of these chaperones act in some situations in conjunction with cochaperones or accessory proteins. For example, DnaK acts with DnaJ/Hsp40 and GrpE, GroEL acts with GroES/Hsp10, Hsp90 associates with numerous partner proteins, and Clp proteins associate with proteases and other specificity factors to regulate protein degradation. This entry focuses on the role of Clp/Hsp100, Hsp90, and DnaK/Hsp70 chaperones in protein quality control. Another article in this encyclopedia will cover GroEL/Hsp60.

Protein Quality Control in the Cell

Molecular chaperones play a critical role in protein quality control during the course of cell growth as well as during stress conditions (Figure 1). Normal protein synthesis produces nascent unfolded proteins. Although some nascent polypeptides are able to fold spontaneously into their native conformation as they emerge from the ribosome (1 in Figure 1), others require the action of molecular chaperones, including members of the DnaK/Hsp70 and GroEL/Hsp60 families, to facilitate folding (2 in Figure 1). Unfolded and misfolded proteins also arise in cells as a result of environmental stresses, such as heat shock, or pathologic conditions, such as inflammation, tissue damage, infection, and genetic diseases involving mutant proteins. Molecular chaperones are able to refold and reactivate some misfolded proteins (2 in Figure 1). Other irreversibly misfolded proteins are recognized by proteases, such as Lon and Clp proteases in prokaryotes and the proteasome in eukaryotes. These multicomponent proteases use associated chaperones to unfold and deliver damaged proteins to the protease for degradation (3 in Figure 1). Finally, proteins that are neither refolded nor degraded form insoluble aggregates in the cell (4 in Figure 1). Aggregates are not always an end product, but can be dissolved by molecular chaperones. For example, the combined action of Clp/Hsp100 chaperones and DnaK/Hsp70 chaperones and cochaperones can carry out this function. Thus, chaperones play a critical role in protein quality control during both normal growth and cell stress by assisting proteins with functional potential to become properly folded and by ensuring that irreversibly damaged proteins are degraded.

Clp/Hsp100 Chaperones

Clp ATPases, like the other chaperone families, are highly conserved and have been identified in many diverse organisms, including bacteria, archaea, yeast, plants, insects, and humans. They were first identified as molecular chaperones by S. Lindquist and colleagues and by S. Wickner and colleagues. Many organisms have multiple family members. For example, *Escherichia coli* has four Clp ATPases: ClpA, ClpB, ClpX, and HslU.

The Clp ATPase family is broadly divided into two classes. Class I Clp ATPases contain two nucleotide-binding domains, such as ClpA and ClpB in *E. coli*, Hsp104 in *Saccharomyces cerevisiae,*ClpC in plants, and ClpE in *Bacillus subtilis*. Class II Clp proteins contain one nucleotide-binding domain, such as ClpX in *E. coli*, yeast, plants, mice, and humans. Although the two ATP-binding domains of Class I differ from one another, they are highly conserved in all members of the class. The single ATP-binding domain of Class II Clp ATPases shares significant homology to the second ATP-binding domain of Class I. The Clp ATPases are members of the AAA^+ superfamily of ATPases (*A*TPases *a*ssociated with a variety of cellular *a*ctivities). The key feature of the superfamily is a

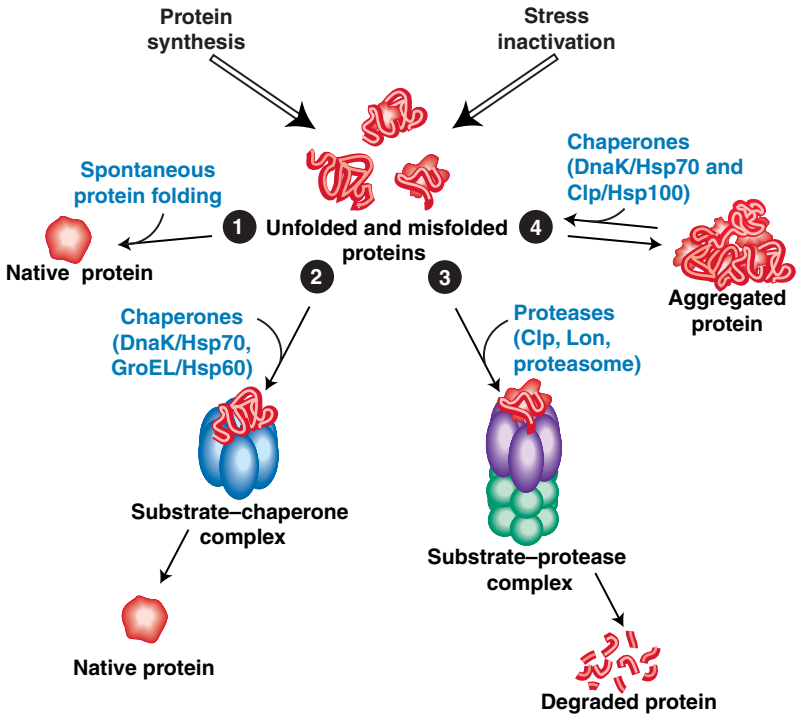

FIGURE 1 Interplay of molecular chaperones and proteases in the cell. See text for description. Substrate proteins are shown in red; an ATP-dependent chaperone, such as GroEL, is shown in blue; a Clp chaperone is purple and is associated with a compartmentalized protease shown in green.

highly conserved ATP-binding module. Another feature is a protein recognition domain located C-terminally to the ATPase domain, referred to as the sensor-2 domain. Many AAA^+ ATPases, including many Clp ATPases, are components of molecular machines that function in a large number of diverse cellular processes.

Clp ATPases act as classical ATP-dependent chaperones. For example, ClpA performs ATP-dependent chaperone functions *in vitro* that mimic those of the DnaK/Hsp70 chaperone system. It catalyzes the remodeling of dimers of the plasmid P1 replication initiator protein into monomers. In an analogous reaction, ClpX dissociates the dimeric initiator protein of plasmid RK2 into monomers *in vitro*. ClpX participates in DNA transposition and replication of bacteriophage Mu by mediating the disassembly of MuA transposase tetramers from Mu DNA after recombination. Similar to other chaperones, both ClpA and ClpX prevent heat inactivation of proteins *in vitro*. Many of the Clp ATPases, such as ClpB, Hsp104, ClpX, and HslU, are induced by heat shock, suggesting that one of their *in vivo* roles is to prevent heat denaturation and to promote reactivation of heat-damaged proteins. Mutants in Hsp104 and ClpB are unable to grow at high temperatures, and *in vitro* Hsp104 and ClpB act in conjunction with their respective Hsp70 chaperone and cochaperones to resolubilize aggregates formed during exposure to high temperature or denaturants.

Some Clp chaperones associate with proteolytic partners, forming ATP-dependent proteases. The founding member of the Clp ATPase family, ClpA, was first identified as the ATPase component of a two-component ATP-dependent protease (referred to as ClpAP or protease Ti). ClpP, the proteolytic component, is unrelated to the Clp ATPases but is a member of a large family of serine proteases. By itself ClpP can degrade only short peptides, but when present as a complex with ClpA or ClpX it can degrade large proteins. Similarly, *E. coli* HslU associates with HslV, a proteolytic component, forming HslUV protease, and *B. subtilis* ClpE associates with ClpP of *B. subtilis*, forming ClpEP protease.

In view of the fact that Clp chaperones and proteases are generally not essential for growth, there is very likely an overlap in the functions carried out by the various cellular chaperones and proteases.

Structure of Clp ATPases and Their Associated Proteases

The structures of the Clp ATPases that have been determined, including ClpA, ClpB, ClpX, and HslU, are very similar. Both electron microscopic and X-ray crystallographic studies show that Clp ATPases

self-assemble into oligomeric rings in the presence of ATP. The Clp ATPases that are known to be components of degradation machinery form stable complexes with their corresponding proteolytic component. The structure of one Clp ATPase, *Haemophilus influenzae* HslU, has been solved alone and in a complex with its proteolytic component, HslV, by McKay and colleagues (Figure 2). The HslUV structure shows that a hexameric ring of HslU ATPase binds to each axial end of the HslV proteolytic core. The proteolytic core is made up of two stacked rings of six identical subunits. The junction of the two stacked rings forms a chamber with the proteolytic active sites lining the interior chamber. With this molecular architecture, the active sites of the protease are sequestered from the cytoplasm. The structure of HslV is similar to other compartmentalized proteases, including the 20S proteolytic core of the proteasome and ClpP. The cavities formed by HslV, and also by ClpP, can accommodate unfolded proteins of roughly 30–40 kDa. Access to the proteolytic chamber appears to be through narrow pores at either end of the stacked rings; these small pores are only large enough to allow short polypeptides or unfolded proteins entry into the proteolytic chamber without major conformational changes. The pores of HslV are covered at one or both ends by the HslU ATPase rings, indicating the role of the Clp chaperone in regulating entry to the protease cavity. ClpAP and ClpXP have similar structures. The archaebacterial and eukaryotic 26S proteasomes are also similar to Clp proteases, in that regulatory ATPase components cover the pores of the 20S proteolytic core, indicating a common mechanism of action despite little sequence similarity between the analogous components.

HslU is represented in yellow, with one subunit per hexamer shown in white and ADP shown in red. HslV is represented in blue, with one subunit per hexamer shown in green and serine active sites shown in magenta. The crystal structure was solved by Sousa, M. C., Trame, C. B., Tsuruta, H., Wilbanks, S. M., Reddy, V. S., and McKay, D. B. (2000). Crystal and solution structures of an HslUV protease-chaperone complex. *Cell* **103**, 633–643.

Mechanism of Action of Clp Chaperones and Proteases

The mechanism of action of Clp chaperones and Clp proteases is emerging from structural and biochemical data. Clp ATPases bind substrates that have Clp-specific recognition signals (1 in Figure 3). The recognition signals are approximately 10 amino acids and are typically found very near the N or C terminus of the protein. The various Clp ATPases recognize different motifs and thus act on separate but sometimes overlapping sets of substrates. As first shown by A. L. Horwich and colleagues, Clp ATPases catalyze ATP-dependent unfolding of bound substrates (2 in Figure 3). When Clp ATPases function as chaperones, they bind and unfold the substrate and then release the unfolded protein (3 in Figure 3). The released protein either refolds spontaneously (4 in Figure 3) or is rebound by Clp or another chaperone to undergo another cycle of unfolding. Multimeric complexes and aggregates can also be substrates for Clp chaperones. In these cases, the process of unfolding and release by the combined action of a Clp chaperone and the DnaK/Hsp70 chaperone system results in disassociation of the complex or aggregate.

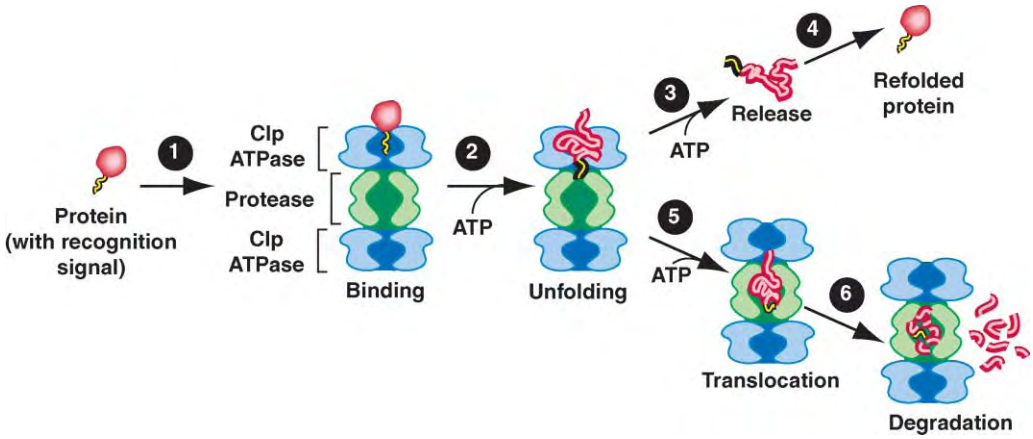

FIGURE 3 Model of the mechanism of protein unfolding by Clp chaperones and degradation by Clp proteases. See text for description. A lateral cross section of a Clp chaperone is shown in blue, associated with a proteolytic core shown in green. A substrate protein is shown in red, with a recognition signal shown in yellow.

When Clp ATPases function as regulatory components of proteases, they specifically bind and unfold substrates (1 and 2 in Figure 3), but rather than releasing the unfolded substrate, the unfolded protein is translocated to the cavity of the protease in an ATP-dependent reaction (5 in Figure 3). The unfolded protein is threaded processively into the proteolytic cavity starting with the end containing the recognition signal. Degradation occurs in the proteolytic cavity (6 in Figure 3).

Clp Specificity Factors or Cofactors

The activity of Clp ATPases is modulated in some situations by proteins that act as specificity factors. Specificity factors interact simultaneously with a substrate and a Clp ATPase. In this way they deliver otherwise unrecognizable substrates to a protease for degradation. There are examples of specificity factors that interact with ClpA, ClpX, and eukaryotic Clp homologues.

DnaK/Hsp70

The most extensively studied DnaK/Hsp70 family member is the *E. coli* homologue DnaK. DnaK and its homologues consist of two domains, an amino-terminal ATPase domain and a carboxy-terminal peptide-binding domain. The structures of the ATPase domain and the peptide-binding domain have been solved separately (Figure 4). Because the structure of full-length DnaK has not yet been determined, it is still unknown how the two domains interact at the molecular level. Unlike GroEL and Clp chaperones, DnaK does not assemble into a multisubunit structure with a central cavity to accommodate substrates undergoing remodeling.

DnaK/Hsp70 chaperones act in conjunction with cochaperones. One cochaperone that is essential for DnaK/Hsp70 activity is DnaJ/Hsp40. DnaJ binds hydrophobic regions in substrate polypeptides and in addition interacts with DnaK. Another cochaperone is GrpE, a protein that stimulates nucleotide exchange by DnaK.

The current model for the mechanism of reactivation of heat-inactivated proteins by the DnaK chaperone system is that ATP-bound DnaK binds and releases heat-denatured polypeptides rapidly, through interactions with exposed hydrophobic region. DnaJ stimulates hydrolysis of ATP bound to DnaK, forming the ADP-bound state of DnaK, which stabilizes the DnaK–substrate interaction. GrpE binds to the ATPase domain of DnaK and induces nucleotide exchange. Conformational changes in DnaK accompanying ADP/ATP exchange force the release of the substrate and DnaJ. When released from DnaK, the substrate is likely in a partially unfolded conformation and either refolds spontaneously or is rebound by other chaperones or proteases.

Hsp90 Chaperones

Hsp90 has been most extensively studied in eukaryotes, although there is a bacterial homologue, HtpG. The Hsp90 chaperone system is the most complex of the molecular chaperones in that it includes the Hsp70 chaperone system and a large number of cofactors. Hsp90 has an amino-terminal ATPase domain and a carboxy-terminal dimerization domain. The amino-terminal domain has been crystallized with

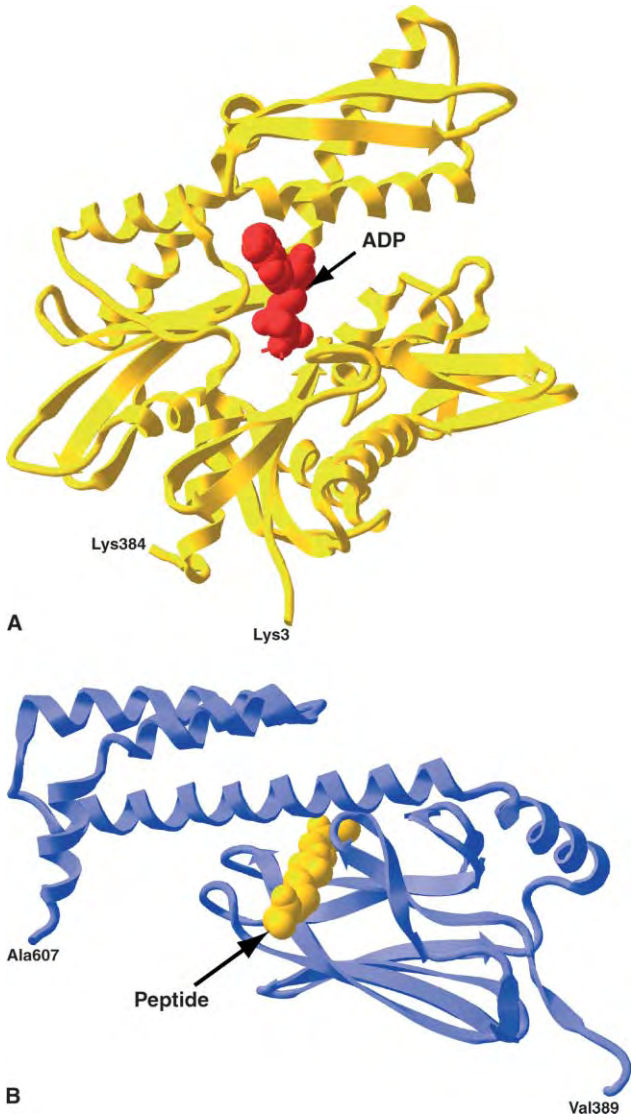

FIGURE 4 Model of the crystal structure of a DnaK/Hsp70 chaperone. (A) Structure of the nucleotide-binding domain of a DnaK homologue, Hsc70, with bound ADP (shown in red). The structure was solved by Flaherty, K. M., Deluca-Flaherty, C., and McKay, D. B. (1990) *Nature* **346**, 623–628. (B) Structure of the peptide-binding domain of DnaK with a bound peptide (shown in yellow). The structure was solved by Zhu, X., Zhao, X., Burkholder, W. F., Gragerov, A., Ogata, C. M., Gottesman, M. E., and Hendrickson, W. A. (1996). Structural analysis of substrate binding by the molecular chaperone DnaK. *Science* **272**, 1606–1614.

bound ATP (Figure 5). The mechanism of action of the Hsp90 system is less well characterized, but very likely it functions in a fashion similar to the other energy-dependent chaperones by remodeling substrate proteins through ATP-induced conformational changes. Hsp90 appears to be important for the folding of some proteins that are involved in key regulatory processes. It does not appear to play a major role in the de novo folding of proteins.

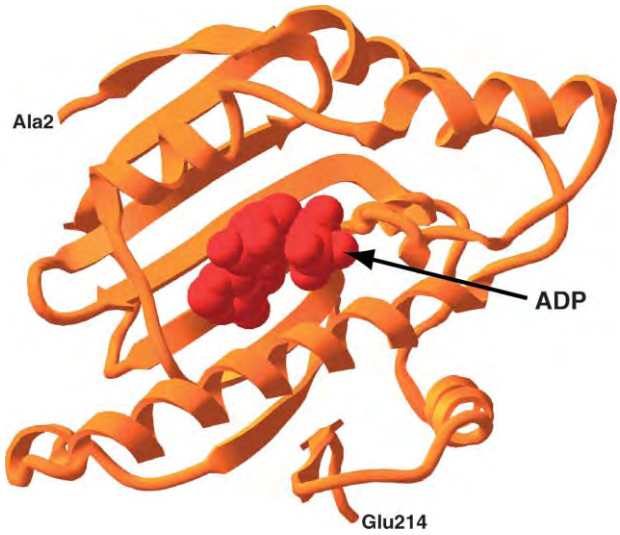

FIGURE 5 Model of the crystal structure of the ATPase domain of Hsp90 with bound ADP (shown in red). The structure was solved by Prodromou, C., Roe, S. M., O'Brien, R., Ladbury, J. E., Piper, P. W., and Pearl, L. H. (1997) Identification and structural characterization of the ATP/ADP-binding site in the Hsp90 molecular chaperone. *Cell* **90**, 65–75.

Summary

In summary, chaperones and proteases function together to determine the fate of proteins by facilitating the kinetic partitioning of substrates between pathways leading to reactivation, degradation, or, when quality control fails, aggregation.

Biography

Sue Wickner is a Scientist in the Laboratory of Molecular Biology at the National Cancer Institute in Maryland. She received her Ph.D. from Albert Einstein College of Medicine and her postdoctoral training at the National Institutes of Health. Her principal research interests are in molecular chaperones and their role in proteolysis. Her more recent work helped to demonstrate that Clp ATPases are a class of ATP-dependent molecular chaperones and demonstrated that molecular chaperones act directly in protein degradation. She is a member of the National Academy of Sciences and the American Academy of Arts and Sciences and is a fellow of the American Association for the Advancement of Sciences.

Joel Hoskins received his B.S. from Catholic University and his M.S. from Johns Hopkins University. He is currently a Senior Research-Associate in the Laboratory of Molecular Biology in the NCI and has collaborated with Dr. Wickner on studies of molecular chaperones for 15 years.

Chaperonins

Arthur L. Horwich, Wayne A. Fenton and George W. Farr
Howard Hughes Medical Institute and Yale School of Medicine, New Haven, Connecticut, USA

Chaperonins are large ring assemblies that provide essential assistance in folding to the native state of a large variety of proteins through an ATP-driven mechanism. Substrate proteins acted on by these machines include many newly translated proteins in the cytosol of eubacteria, archaebacteria, and eukaryotes, and newly imported proteins inside eukaryotic mitochondria and chloroplasts. Chaperonins in many of these compartments are heat-shock proteins that help to restore native conformation under stress conditions. For example, in archaebacteria and eubacteria, a high basal abundance of ~1% of soluble protein can be increased by heat shock to more than 10%.

Two Classes of Chaperonin

Two classes of chaperonin have been distinguished, based on evolutionary and structural considerations (Table I). One class, termed type I, includes GroEL, Hsp60, and ribulose bis-phosphate carboxylase/oxygenase (rubisco)-binding protein. These reside in the bacterial cytoplasm and endosymbiotically related mitochondria and chloroplasts, respectively. Type I chaperonins function through cooperation with distinct co-chaperonins, e.g., GroES, Hsp10, and Cpn10 respectively. Co-chaperonins also form ring structures and dynamically associate coaxially with chaperonin rings, functioning as "lid" structures that encapsulate a protein substrate during folding in the central cavity. The other class of chaperonins, termed type II, includes TF55 (thermophilic factor 55) and the thermosome in archaebacteria and the eukaryotic cytosolic chaperonin, known as chaperonin containing TCP1 (CCT). This class differs architecturally from type I in containing a built-in lid structure.

Overall Mechanism

Both classes of chaperonin function by the same general mechanism, a sequence of steps involving substrate protein binding, substrate folding in an encapsulated cavity, and release into the bulk solution (Figure 1). An open ring binds non-native protein in its central cavity through interactions between the cavity lining and exposed surfaces of the substrate protein, preventing misfolding and aggregation. In the case of type I chaperonins, this interaction occurs between the hydrophobic cavity lining of the chaperonin (Figure 2C) and exposed hydrophobic surfaces of the non-native protein, surfaces that will become buried to the interior of the substrate protein in the native state. Upon binding ATP and co-chaperonin in the case of type I, or ATP alone in the case of type II, large rigid body changes occur in the subunits of the ring, which dislocate its binding surface away from the central cavity, ejecting polypeptide into the cavity where it commences folding (Figure 1). Associated with the same movements, the cavity becomes encapsulated, in the case of type I chaperonins by binding co-chaperonin (Figure 2A) and in the case of type II chaperonins by the movement of protrusions comprising the built-in lid structure over the mouth of the cavity. Such encapsulation produces an environment in which polypeptide folds in isolation, prevented from forming any multimolecular interactions that could lead to aggregation. The enclosed chamber may also contribute to productive folding via a change in its wall character. In the case of type I chaperonins, there is a switch from the hydrophobic character of an open polypeptide-accepting ring to the hydrophilic character of the folding-active ring (Figure 2C). This switch presumably favors exposure in the folding polypeptide of hydrophilic surfaces and burial of hydrophobic ones, properties of the native state. Additionally, encapsulation in a confined space may also contribute to efficient folding, preventing population of a variety of extended off-pathway conformations.

Subsequent to the step of folding in an encapsulated space, shown to be the longest phase of the chaperonin reaction, hydrolysis of ATP permits release of the substrate protein from the central cavity into the bulk solution (Figure 1). For many substrate proteins, multiple rounds of binding to an open ring and folding inside the encapsulated cavity, followed by release into the bulk solution, are required to achieve the native state, with each round likely comprising an "all-or-none" trial at reaching the native state.

TABLE I

Characteristics of Chaperonins

Chaperonin	Cellular compartment	Co-chaperonin	Subunits/ring	Subunit composition	Substrate proteins
Type I					
Hsp60	Mitochondrial matrix	Hsp10	7	Homo-oligomer	Many imported proteins
Rubisco binding protein	Chloroplast stroma	Cpn10	8	α, β	Rubisco small subunit, other imported proteins
GroEL	Eubacterial cytoplasm	GroES	7	Homo-oligomer	Many cytoplasmic proteins, including λ phage components
Type II					
TF55	Archaebacterial cytoplasm	None	9	α, β	Unknown
Thermosome	Archaebacterial cytoplasm	None	8	α, β	Unknown
CCT (TRiC)	Eukaryotic cytosol	None	8	α, ε, ζ, β, γ, θ, δ, η	Actin, tubulin, cyclin E, G_α-transducin, VHL

Those molecules failing, at the point of release into the bulk solution, to reach native form or a state that is committed to reaching native form in the bulk solution, are subject to an unfolding action upon rebinding to a chaperonin ring that likely returns them to the original non-native ensemble of states, enabling a fresh trial at folding.

The sum of these actions is the provision of kinetic assistance to the process of protein folding, effectively smoothing an energy landscape. That is, while the primary amino acid sequence of the substrate polypeptide provides all the information necessary to specifying a characteristic native conformation that typically lies at the energetic minimum, as articulated by Anfinsen and co-workers, during folding under physiologic conditions, there can be production of conformations that are kinetically trapped, preventing a protein from reaching the native state on a physiologic timescale. Chaperonins function in this context as biological catalysts that prevent or reverse formation of such misfolded species, thus enhancing the rate of folding *in vivo*.

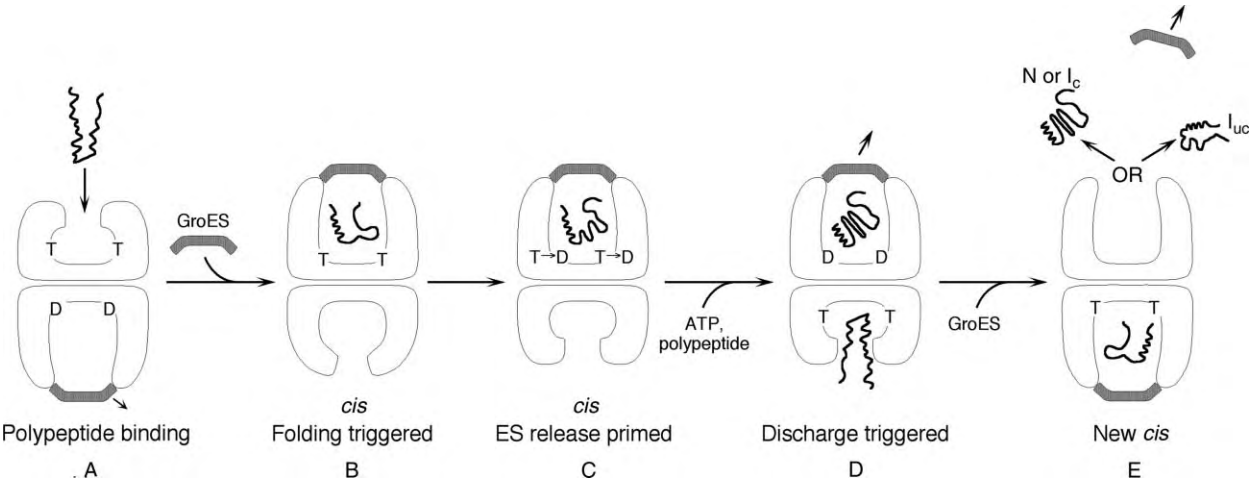

FIGURE 1 The ATP-driven folding cycle of GroEL–GroES. Asymmetric GroEL–GroES–ADP complexes (A) are the most likely polypeptide-acceptor state *in vivo*. In the presence of ATP, GroES binds to the open ring, simultaneously discharging the substrate polypeptide from its binding sites and encapsulating it in the folding chamber (B). Folding proceeds in this sequestered environment, the longest step of the reaction cycle (~10 s), until ATP hydrolysis occurs (C). This weakens the GroES association and permits ATP and polypeptide to bind to the opposite ring (D). This discharges the ligands from the folding chamber and simultaneously establishes a new folding chamber in the opposite ring (E). Thus, the two rings of GroEL alternate asymmetrically between binding-active and folding-active states. The discharged polypeptides in (E) are in several possible states: N (native) or I_c, a state committed to becoming native without further chaperonin action; or I_{uc}, a non-native intermediate state that must rebind to chaperonin for another trial at folding. For many GroEL substrates, any given round of folding only produces a few percent of N or I_c states; most of the population must be rebound for another attempt. In a cellular context, I_{uc} states can also partition to other chaperone pathways or to degradative pathways. This latter option is vital for removing potential chaperonin substrates that are damaged or mutated such that they cannot fold.

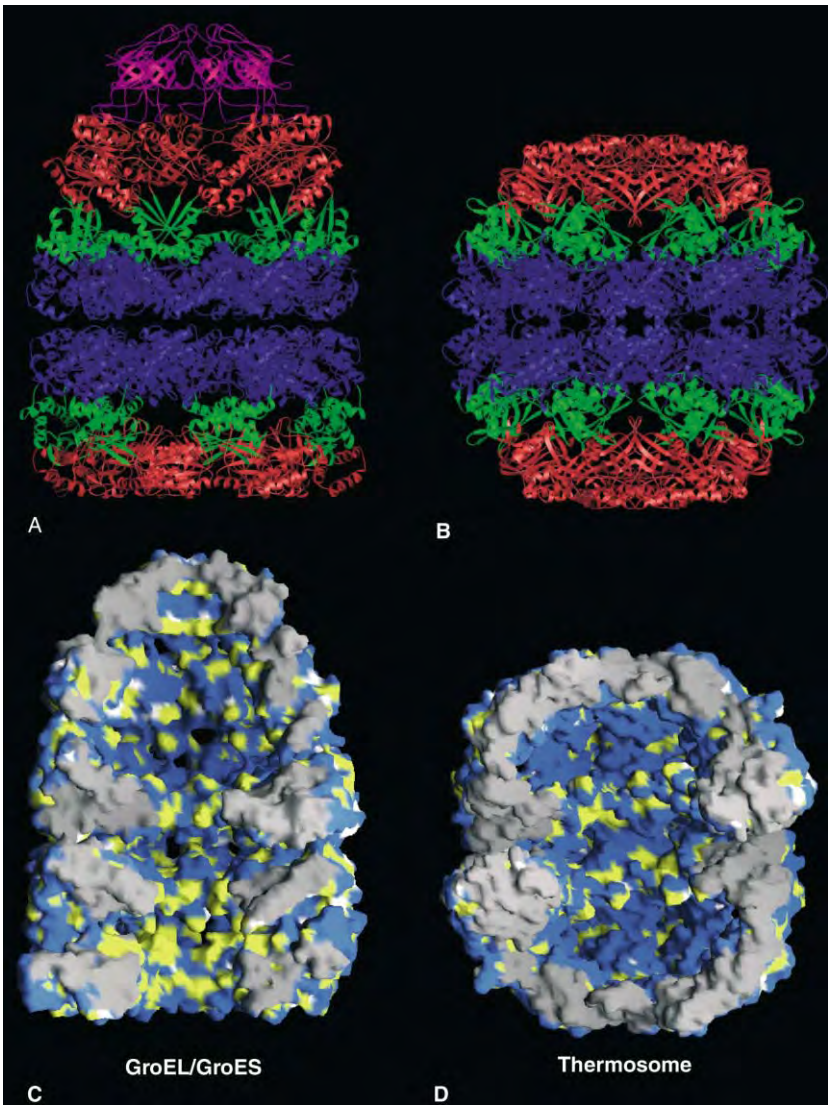

FIGURE 2 Architecture of chaperonins. Structural models of a type I chaperonin, GroEL from *E. coli*, complexed with its co-chaperonin GroES (A, C) and structural models of a type II chaperonin, the thermosome from *T. acidophilum* (B, D). (A, B) Ribbon diagrams showing the domains of each chaperonin: equatorial, blue; intermediate, green; apical, red. In (A), GroES is colored magenta. (C, D) Space-filling models presented as cutaway views to show the interior cavities of the chaperonins, with surfaces colored according to hydrophobicity of the amino acid side chains: yellow, hydrophobic; blue, hydrophilic. Gray represents cutaway interface between subunits. Note the relative hydrophobicity of the lower (trans) ring of the GroEL/GroES, its polypeptide binding surface, as compared to the upper, GroES bound ring, relatively hydrophilic in character. Note also the absence of exposed hydrophobic surface in the type II complex.

Architecture

Chaperonins are generally composed of two rings, stacked back-to-back, that function out of phase with respect to each other during the reaction cycle, such that only one ring is folding-active at a time. Each ring is composed of radially arranged identical or nearly identical subunits, each folded into three domains (Figure 2A, B). The "equatorial" domains, at the waistline of the cylinder, each contain an ATP-binding pocket. The collective of these domains comprises the stable base of the assembly, with the domains forming tight contacts with each other both side-by-side within a ring and across the ring–ring interface. The "apical" domains, at the end portion of the cylinder, are mobile, hinged at their bottom aspect, and contain the polypeptide-binding site at the inside surface. For type I chaperonins, this same binding surface, hydrophobic in character, is the one that associates with the co-chaperonin following rigid body elevation and twisting of the domains directed by ATP binding to the ring. These apical movements, captured by cryoEM and X-ray analyses of *E. coli* GroEL–GroES, amount to elevation by 60° and clockwise twist of 90°. They serve to dislocate the hydrophobic polypeptide-binding surface away from the central cavity, driving

polypeptide release into the cavity. Simultaneously, they enable GroES binding via interaction through its mobile loop segments, which extend down from each of the seven GroES subunits to contact the hydrophobic surface of each of the dislocated apical domains. This interaction is itself hydrophobic in character, mediated by an isoleucine-valine-leucine edge of the β-hairpin loop extended from GroES, which interacts with a portion of the hydrophobic binding surface of GroEL. This association of GroES with GroEL, and of other chaperonin–co-chaperonin pairs, results in encapsulation of the central cavity. For type II chaperonins, the apical domains each contain an insertion of residues, relative to type I, that comprises a protrusion, the collective of which function as a lid. The protrusions are marginated to the cavity wall of an open ring, but then are pointed centrally to collectively form a lid upon ATP binding. For both classes of chaperonin, the apical domains are covalently connected to the corresponding stable equatorial domains via a slender "intermediate" domain, which is hinged at both its top (apical) and bottom (equatorial) aspects (Figure 2A, B). This domain almost certainly contributes to transmitting the signal of ATP binding into the rigid body movements of the apical domains, and it also supplies a highly conserved aspartate residue that functions as a base in the mechanism of ATP hydrolysis: upon downward rotation of the intermediate domain attendant to ATP binding, the aspartate swings into the equatorial nucleotide pocket and activates water to attack the gamma phosphate of ATP.

The variations within different kingdoms on the basic theme of chaperonin architecture are interesting to contemplate and not fully understood (Table I). For example, an exception to the double-ring architecture is the mammalian mitochondrial chaperonin, which can be isolated as a single ring. Evidence has suggested that it may remain as a single ring throughout the nucleotide cycle, implying that it does not use the same allosteric ejection mechanism as the other chaperonins, which employ ATP binding on the opposite ring as a signal for release. The number of subunits per chaperonin ring also varies, with the bacterial and mitochondrial (type I) chaperonins containing seven subunits per ring, the chloroplast chaperonin containing eight subunits per ring, archaebacterial (type II) chaperonins containing eight or nine subunits per ring, and the eukaryotic cytosolic chaperonin (CCT) containing eight subunits per ring. Clearly, the volume of the central cavity, as well as the angle of adjacent subunits with respect to each other, is affected by the number of subunits per ring. Notably, because substrate proteins likely co-evolved with the machines that assist their folding, there could be stringency with respect to subunit number and ring size.

The hetero-oligomeric nature of some of the chaperonins also remains to be fully understood. For example, while GroEL and Hsp60 (type I) are homo-oligomers, the thermosome in archaebacteria (type II) contains eight-membered rings that are composed of α–β heterodimers in which the two subunits differ in amino acid sequence, principally in their apical domains. Most extreme is the eukaryotic cytosolic CCT chaperonin (type II), which contains eight different subunits per ring, arranged in a characteristic order. Here also, apical domain sequences are the most varied among the subunits (but any given subunit is well conserved across species lines, for example, from yeast to man). Studies of two major substrate proteins assisted by CCT, actin and tubulin, suggest that specific apical domains that are positioned at opposite aspects of the ring are involved in binding these proteins. Thus, it would seem that binding affinity for particular substrate proteins can comprise an evolutionary force directing apical domain evolution and hetero-oligomeric composition. Indeed, the overall character of the cavity wall of type I and II chaperonins seems to differ (Figure 2C, D). Rings of type I chaperonins present a hydrophobic cavity surface in the open state, with highly conserved hydrophobic residues positioned on a tier of three structures, two horizontally configured α-helices and an underlying extended segment, that form the cavity-facing aspect of the apical domains (Figure 2C, bottom ring). By contrast, type II chaperonins present a surface, corresponding to these same secondary structures, that is not obviously hydrophobic – in fact, some of the residues that are hydrophobic and conserved in type I chaperonins are instead hydrophilic in type II (Figure 2D). Yet type II chaperonins harbor hydrophobic residues on their protrusions, and the potential role of these residues, as well as those lining the cavity wall, in substrate binding remains to be addressed.

Polypeptide Binding by Type I Chaperonins

As mentioned, the step of polypeptide binding appears to be associated with capturing non-native states before they can irreversibly misfold and aggregate, and the step of binding, via exposed hydrophobic surfaces at least in the case of GroEL, appears to be associated with an action of unfolding. Such an action may be either a passive one, in which less folded states are preferred, with mass action shifting an ensemble of states in equilibrium with each other toward the less-folded ones, or unfolding may be catalyzed, where the polypeptide, bound by multiple apical domains simultaneously, is effectively unfolded. Either or both mechanisms could

be operative, but the net result for many canonical GroEL substrate proteins is a stably bound state that is weakly structured, e.g., very susceptible to exogenously added proteases and highly exchangeable in hydrogen/deuterium isotope exchange experiments. In the case of GroEL, crystallographic studies of peptides associated with the chaperonin apical domain have captured the peptides bound horizontally in the groove between the two α-helices of the apical domain, forming hydrophobic contacts with those residues projected from the helices. Additional NMR studies reveal that other peptides are capable of forming α-helices when they become associated with GroEL. Thus, it appears that at least some secondary structural elements can be preserved through the step of binding by chaperonin, but tertiary structure is unstable.

The Nucleotide Cycle

The progression through the chaperonin reaction is driven by ATP binding and hydrolysis. This has been best studied in the case of the GroEL–GroES reaction (Figure 1). Here, ATP binds cooperatively to the seven equatorial sites within a ring but anti-cooperatively with respect to the opposite ring. Because GroES binding requires initial ATP occupancy of a ring, the GroEL–GroES complexes formed are asymmetric in character. The normal acceptor state for non-native polypeptide is an open ring of an asymmetric GroEL–GroES–ADP complex (Figure 1A). Once bound with polypeptide, a GroEL ring is converted to its folding-active state by the binding of ATP and GroES (Figure 1B). These produce the large rigid body domain movements associated with ejection of polypeptide into the central cavity and attendant folding. These steps can occur in the setting of a GroEL mutant unable to hydrolyze ATP and also in the presence of ADP–metal complexes such as ADP–beryllium fluoride (an ATP ground-state analogue) or ADP–aluminum fluoride (a transition-state analogue). In all of these cases, polypeptide proceeds to the native state inside a very stable GroES-encapsulated cavity. That is, the energy of ATP/GroES binding is sufficient to trigger the rigid body conformational changes that lead to ejection into the central cavity and productive folding. Thus, it is ATP binding, not hydrolysis, that is crucial for triggering folding.

The folding-active complex has a long half-life ($\sim$10 s for GroEL–GroES–ATP), after which ATP hydrolysis occurs (Figure 1C). This event does not interfere with folding but serves rather to weaken the stability of the GroEL–GroES complex. This "primes" the complex for discharge of its ligands, GroES, polypeptide, and ADP, effected by ATP binding to the opposite ring (Figure 1D). In sum, then, the GroEL–GroES machine functions asymmetrically, with only one ring folding-active at a time (and the other, opposite an ATP–GroES-occupied ring, empty of polypeptide and nucleotide until ATP hydrolysis occurs). The machine oscillates back and forth using one round of binding seven ATPs to simultaneously nucleate one folding-active ring and discharge the opposite ring that has completed its folding cycle (Figure 1E). It seems likely, given recent studies of CCT and archaebacterial chaperonins, that the same asymmetric cycle pertains there as well, with the apical protrusions mimicking the behavior of GroES with respect to the open or encapsulated state of a ring.

Substrate Proteins

In general, small proteins (fewer than 100–150 amino acids) fold very rapidly and thus do not appear to require chaperonin assistance *in vivo*. Many larger proteins fold slowly, however, and are potential substrates for chaperonin-assisted folding. The actual *in vivo* substrates of chaperonins vary widely depending on chaperonin-type and subcellular compartment (Table I). GroEL in the bacterial cytoplasm is estimated to fold 10–30% of newly synthesized proteins, with particular preference for those between 20 and 60 kDa in size. Mitochondrial Hsp60 and the chloroplast rubisco-binding protein appear to be required for folding a potentially larger percentage of proteins newly translocated into these organelles. In the case of mitochondria, several large proteins, too large to be encapsulated inside the Hsp60 cavity, have been identified that require both Hsp60 and Hsp10. In the case of the yeast mitochondrial Krebs cycle enzyme, aconitase, studies with GroEL–GroES have resolved a *trans*-acting mechanism in which the polypeptide, unable to be encapsulated by GroES in *cis*, is productively released from the open ring by binding of ATP and GroES in *trans*.

The natural substrate specificity of archaebacterial (type II) chaperonins has not been defined, in part because these species have not been amenable to genetic manipulation. On the other hand, CCT, the type II chaperonin of the eukaryotic cytosol, may have a narrower substrate specificity than the other cytosolic chaperonins. Actin and tubulin are major substrates, yet additional cytosolic polypeptides have been shown to require CCT for efficient folding, including G_α transducin, cyclin E, and the von Hippel–Lindau tumor suppressor protein. For several of these substrates, evidence has emerged to suggest that they may be recognized in non-native form via exposed hydrophobic surfaces, as with type I chaperonins, yet the sites of binding on CCT itself remain to be identified.

Glossary

ATP Adenosine triphosphate, the major energy metabolite in cells.

cryoEM An electron microscopy (EM) technique that involves rapid freezing of droplets of a protein solution to form a glass, which is then analyzed without further fixation or staining; as a result, the images closely represent the structural state of the protein in solution.

energy landscape The representation of the energetics of protein folding as a three-dimensional surface with hills and valleys (local energetic maxima and minima) to reflect the complexity of multiple interconnected pathways to the native state for the ensemble of non-native and intermediate folding states; this is in contrast to a two-dimensional reaction coordinate diagram used for simpler reactions.

hydrophilic/hydrophobic A description of the relative polarity of amino acid side chains in terms of their affinity for an aqueous environment. Hydrophilic side chains are polar, including ones with charged groups (e.g., lysine and aspartic acid) and ones with hydroxyl or amide groups (e.g., serine and asparagine). Hydrophobic side chains are non-polar, including aliphatic and aromatic groups (e.g., leucine and phenylalanine).

rubisco Ribulose bis-phosphate carboxylase/oxygenase, a major protein in the photosynthetic pathway.

Biography

Arthur Horwich is Professor of Genetics at Yale School of Medicine and an Investigator in the Howard Hughes Medical Institute. His research interests are in the general areas of cellular protein folding, unfolding, and misfolding. He holds an M.D. from Brown University and carried out postdoctoral research at the Salk Institute and Yale University. He is a member of the National Academy of Sciences.

Wayne Fenton is a Research Scientist in Genetics at Yale University School of Medicine. His general interests are in the mechanisms of protein folding and unfolding. He received a Ph.D. from Brandeis University and carried out postdoctoral work at Yale University.

George Farr is an Associate Research Scientist in the Howard Hughes Medical Institute. His research interest is in chaperonin-assisted protein folding. He received a Ph.D. from Case Western Reserve University and carried out postdoctoral work at Case Western and Yale University.

Chemiluminescence and Bioluminescence

Thomas O. Baldwin
University of Arizona, Tucson, Arizona, USA

Chemiluminescence and bioluminescence are terms that refer to the same physical process of light emission without heat. Bioluminescence is the process by which a living system or components isolated from a living system, such as a firefly tail, carries out a series of reactions that result in emission of light. Chemiluminescence is the same kind of process, but involving molecules that are not of biological origin. Chemiluminescence should be distinguished from incandescence, which occurs at high temperatures. Both bioluminescence and chemiluminescence are well known to the public, and both hold great fascination for all observers. Light without heat has intrigued people since the beginning of recorded history, and surely before.

Fluorescence: The Underlying Property

Fluorescence is a characteristic common to molecules formed as a result of chemiluminescent and bioluminescent reactions. At normal ambient temperatures, the vast majority of molecules exist in what is known as the ground state. However, under certain conditions, such as absorption of light energy, a molecule may be converted into an excited state. For fluorescent molecules, the excited state can return to the ground state by emitting energy as light. Virtually all molecules are fluorescent to some extent, but most emit such a small amount of light that sensitive instruments are required to detect it. A graphic description of fluorescence is shown in Figure 1.

In the case of fluorescence, the energy input is the absorption of light. The chemical characteristics of a molecule will determine which wavelengths (color) of light it will absorb. As in the ground state, the excited state will have multiple vibrational modes at discrete energy levels. At normal ambient temperatures, most of the molecules will be in the lowest vibrational energy level, so following absorption of the input energy, the molecules will relax to the lowest vibrational level of that excited state. Excited states tend to be very unstable, with lifetimes in the nanosecond to picosecond range. There are many ways for a molecule to return to the ground state. In solution, the excited molecules may collide with other molecules in solution and impart energy through the collisions, thereby increasing the vibrational and translational energies of the other molecules while itself returning to the ground state. Alternatively, some molecules, referred to as fluorescent molecules, have the ability to return to ground state by emission of light. Note that the emitted light will be of a lower energy (red-shifted in the spectrum) relative to that of the input energy due to the relaxation of the excited state. This effect is known as the Stokes shift.

Chemiluminescence: Fluorescence from a Chemical Reaction

In the case of chemiluminescence, the input energy is derived from the making and breaking of bonds that occur during a chemical reaction. Other than that important detail, fluorescence and chemiluminescence result from the same fundamental characteristics of the molecules involved. For a reaction to be chemiluminescent, one of the products must be fluorescent, and the chemical step that results in generation of the fluorescent product must be of sufficiently high energy to result in formation of the excited state. Therefore, the efficiency of light emission from a chemiluminescent reaction is the product of the efficiencies of each step. That is, the chemiluminescent quantum yield, Φ_{CL}, or the yield of photons per molecule of reactant consumed in the reaction, is given by the equation

$$\Phi_{CL} = \Phi_R \cdot \Phi_{CE} \cdot \Phi_F$$

All of these efficiencies have values between 0 and 1. The reaction yield, Φ_R, is the chemical yield of the correct products, rather than the products of side reactions, which may not be fluorescent, and is typically near 1. The chemical excitation yield, Φ_{CE}, is the fraction of the fluorescent product molecules that are produced in the excited state, rather than the ground state.

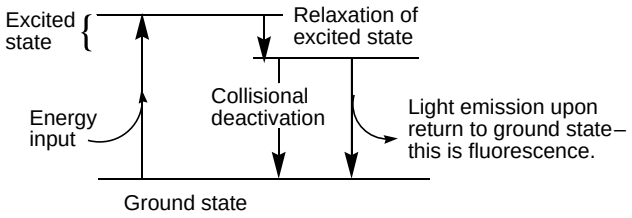

FIGURE 1 Diagram showing the processes of generation of the excited state and return of the excited state to the ground state.

To be considered a chemiluminescent reaction, this value should be 10^{-3} or greater. Finally, the fluorescence quantum yield, Φ_F, is the proportion of those molecules that are produced in the excited state that return to the ground state by emission of light rather than by collisional quenching or some other process, as depicted in Figure 1. The fluorescence quantum yield is typically 0.1 or greater. Conditions that impact any of these three factors will impact the overall yield of light from the reaction.

In some cases, product molecules are produced with exceptionally high chemical yield in the excited state, but the product is itself nonfluorescent (very low Φ_F). In these cases, the yield of luminescence can be increased dramatically by addition of a highly fluorescent molecule to the reaction, which can, by a process called energy transfer, accept the energy from the excited product to become excited itself. The overall chemiluminescence quantum yield in such cases becomes

$$\Phi_{CL} = \Phi_R \cdot \Phi_{CE} \cdot \Phi_F \cdot \Phi_{ET},$$

where Φ_{ET} is the efficiency of energy transfer from the primary excited state produced in the chemical reaction to the acceptor, which then emits with the efficiency given by Φ_F. The chemiluminescence quantum yields in some sensitized chemiluminescent reactions can be very high indeed, approaching 1.

Much research has been reported on the chemiluminescence properties of a wide array of peroxides, especially the cyclic peroxides such as the dioxetanes. Tetramethyldioxetane will decompose to yield 2 molecules of acetone, one in the singlet excited state and the other in the triplet (Figure 2). Of course, acetone is nonfluorescent, so the decomposition reaction is essentially dark. However, if 9,10-dibromoanthracene or 9,10-diphenylanthracene is added to the reaction, intense light emission is detected as a result of the energy transfer from the excited state acetone product to the fluorescent dye, DBA or DPA.

These and related technologies have found wide use in the form of chemiluminescence-based diagnostics and other applications. Perhaps one of the best known applications is the "light-stick" technology used by campers and hikers, and for fun and safety during Halloween. The light stick consists of a sealed, flexible plastic tube containing a solution of oxalic phthalate ester and a sealed glass vial containing a solution of hydrogen peroxide. Bending of the plastic tube will cause the glass vial to break, mixing the two solutions. The hydrogen peroxide will oxidize the ester, yielding 2 molecules of phenol and 1 molecule of 1,2-dioxetane-3,4-dione. The dioxetane will decompose to yield 2 molecules of carbon dioxide in the excited state. By including a dye sensitizer in the solution, the energy of the excited state carbon dioxide will result in light emission (see Figure 3). The color of the light emitted is determined by the fluorescence properties of the dye used in the light stick and can range from blue to red. Examples of dyes used are shown in Figure 3. One characteristic common to most fluorescent compounds and demonstrated in these examples is a system of conjugated double bonds.

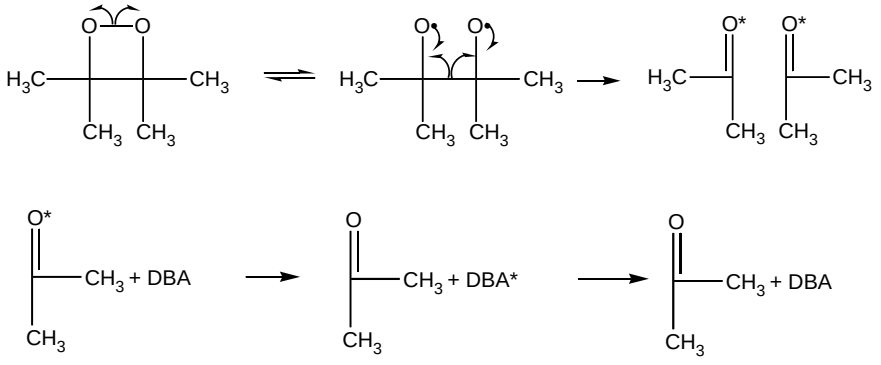

FIGURE 2 Chemiluminescent decomposition of tetramethyldioxetane. The first step of the reaction is the hemolytic cleavage of the oxygen–oxygen bond, followed by hemolytic cleavage of the carbon–carbon bond to yield the diradical, which recombines to form acetone in the excited state. In the absence of the dye 9,10-dibromoanthracene, the reaction is dark. However, the dye can accept the energy from the excited state carbonyl to yield the excited state of the dye, which returns to ground state with the emission of light.

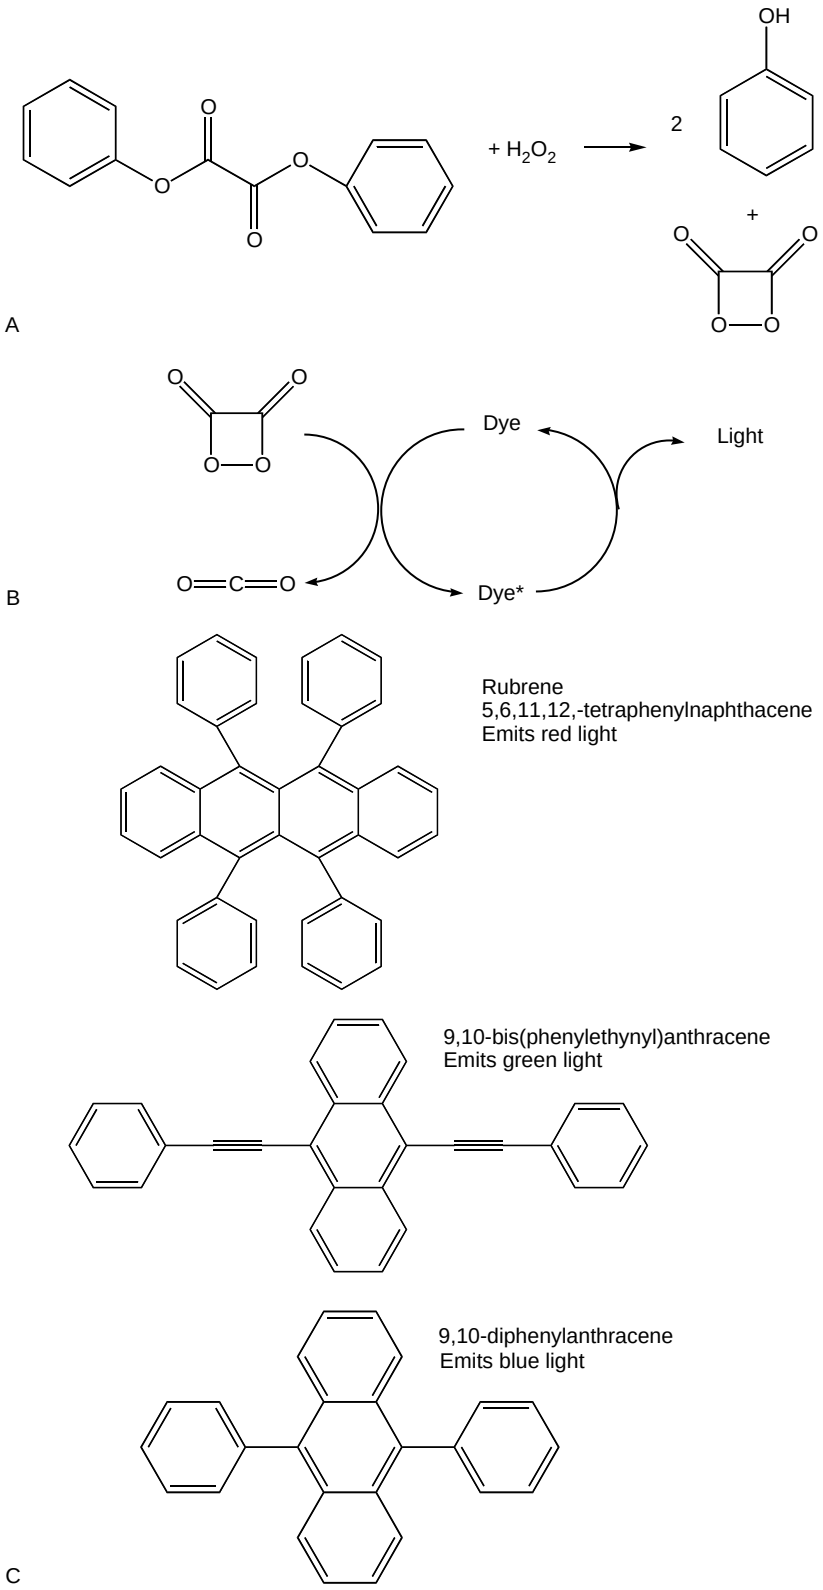

FIGURE 3 The chemistry of the light stick. The reaction that occurs in a light stick upon breaking the glass ampule and allowing the two solutions to mix is shown in panel A. The oxalic phthalate ester is oxidized to yield 2 molecules of phenol and 1 molecule of the dioxetane. In panel B, the dioxetane decomposes by the same mechanism shown in Figure 2 to yield 2 molecules of carbon dioxide. The excited state carbon dioxide transfers energy to the dye to yield the excited state of the dye, which in turn emits light. The color of the light is determined by the chemistry of the dye. Three examples are shown in panel C, spanning the spectrum from red to blue.

Bioluminescence: Chemiluminescence from a Biological Source

Bioluminescence reactions, unlike chemiluminescence, require an enzymatic catalyst for the reaction to occur. These enzymes are generically referred to as luciferases. Even though they have the same name, they catalyze vastly different reactions. For comparison, other groups of enzymes that have a common name, such as proteases, all catalyze the same kind of reactions. Proteases all hydrolyze peptide bonds, but luciferases catalyze reactions on completely different substrates, and they have no evolutionary relationship. Firefly luciferase, bacterial luciferase, and Renilla luciferase catalyze different reactions, having in common only the fact that light is emitted from a product of the reaction. It is therefore very important when discussing bioluminescence to stipulate the biological source of the enzyme.

There are many examples of bioluminescence that resemble the nonbiological chemiluminescence reactions described previously. For example, the reaction that occurs in the tail of the firefly is very similar to that of the light stick, but unlike the light stick, the firefly reaction requires the participation of an enzyme, firefly luciferase. As with chemiluminescent reactions, the firefly luciferase-catalyzed reaction has found numerous practical applications, primarily due to the involvement of ATP in the reaction (Figure 4). Many of these applications involve accurate and sensitive analysis of ATP levels within samples. The role of the ATP is to activate the carboxyl group of the firefly luciferin, the substrate for the luciferase-catalyzed reaction. As a result of this adenylation reaction, the luciferyl adenylate is now poised to react with molecular oxygen, eliminating AMP and forming the dioxetanone intermediate (Figure 5). The dioxetanone ring then decomposes by a mechanism similar to that shown in Figure 2, ultimately yielding CO_2 and the excited state of the product oxyluciferin, which emits light as it returns to ground state.

Different species of firefly emit light of different colors, but they all appear to use the same substrate luciferin, and there appear to be no energy transfer systems involved. At present, the detailed mechanism by which the insects emit light of different color is unknown, but it surely has to do with the details of the interactions of the excited state with the luciferase enzyme, since the enzymes are slightly different between the species. The color of the light emitted ranges from green to red, and the quantum yield of these reactions approaches 1.

Unlike firefly luciferase, which is a single polypeptide and employs ATP and a special substrate firefly luciferase, bacterial luciferase is a heterodimer ($\alpha\beta$) consisting of two similar but nonidentical polypeptides. In bacterial luciferase there is a single active center on the α subunit, but both subunits are required for the high quantum yield reaction. The substrates for the bacterial luciferase reaction are reduced flavin mononucleotide, molecular oxygen, and a long-chain saturated aldehyde. The enzyme formally is a flavin monooxygenase, catalyzing the cleavage of molecular oxygen and inserting 1 atom of oxygen into a substrate and the other into water. The mechanism of light emission in the bacterial luciferase-catalyzed reaction is still under debate, but there is general agreement regarding most of the reaction. In the first step of the reaction, reduced flavin mononucleotide ($FMNH_2$) reacts with O_2 to yield a reduced flavin peroxide (step 1, Figure 6). In the second step, the peroxide reacts with the aldehyde substrate to form the tetrahedral intermediate shown in Figure 6, step 2. There is general agreement in the field that this tetrahedral intermediate forms in the reaction, but how the intermediate decomposes to yield the excited state is under debate. One possible mechanism is shown in step 3 of Figure 6.

The identity of the emitter in the bacterial bioluminescence has been difficult to identify unambiguously because the product of the reaction, oxidized flavin mononucleotide, although fluorescent in solution, is nonfluorescent when bound to the luciferase. Various lines of evidence suggest that the emitter in the reaction is the flavin pseudobase shown in step 3 of Figure 6. The primary excited state, however, must be some other molecule, possibly the excited carbonyl shown in step 4 of Figure 6. In some species of bioluminescent bacteria, light emission from the living bacteria is significantly blue-shifted from that from the purified luciferase enzyme. It has been shown that the blue light comes from another protein, the lumazine protein, which becomes excited through some form of interaction with the luciferase during the reaction. This is an example of an energy transfer process in a bioluminescence

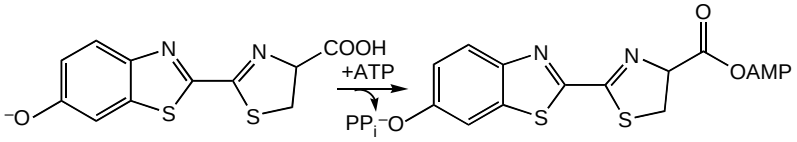

FIGURE 4 Proposed mechanism of the firefly luciferase reaction. The luciferin reacts with ATP to form the luciferyl adenylate, thus preparing the molecule for reaction with oxygen.

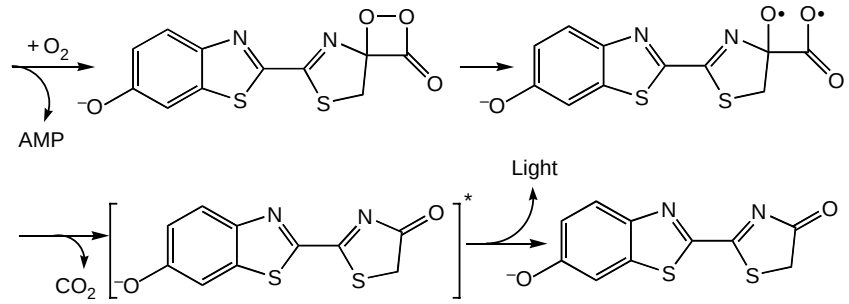

FIGURE 5 Proposed mechanism of the firefly luciferase-catalyzed reaction. The luciferyl adenylate (Figure 4) reacts with molecular oxygen, eliminating the AMP and forming the cyclic peroxide dioxetanone structure. The dioxetanone then decomposes by homolytic cleavage of the O–O and C–C bonds, liberating CO_2 and yielding the excited state of the oxyluciferin. Light emission occurs as the excited state returns to ground state.

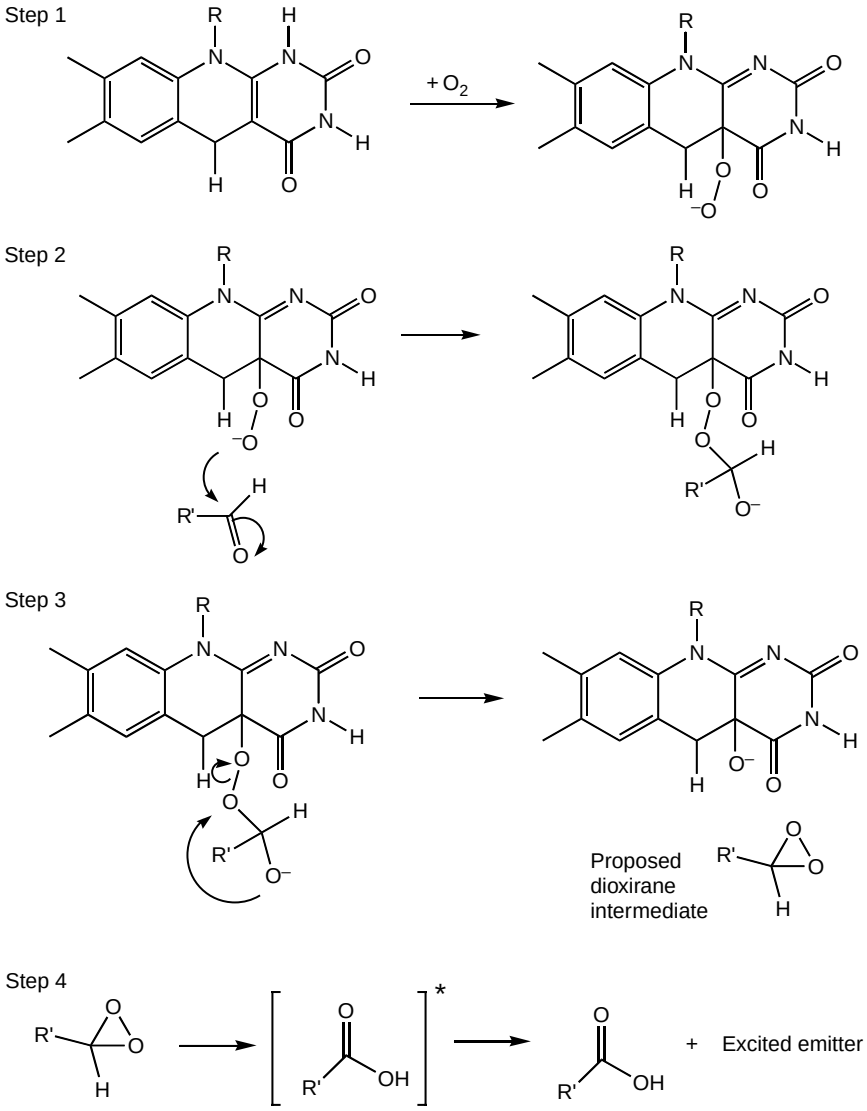

FIGURE 6 Proposed mechanism of the bacterial luciferase-catalyzed reaction, as described in the text.

system, similar to the chemiluminescent examples described in Figure 3. But for the energy transfer to be efficient, it must occur in an energetically downhill direction. That is, the primary excited state must have an energy level higher than the excited flavin, which emits at a longer wavelength (lower energy) than does the lumazine protein. It is this fact, among others, that leads to the belief that the primary excited state in this reaction is likely to be an excited carbonyl, rather than the excited flavin. In the absence of the lumazine protein, energy transfer can occur to the flavin with emission from the excited flavin.

Another example of energy transfer in the bacterial bioluminescence system is from a yellow-emitting strain of *Vibrio fischeri*. These bacteria have a luciferase that emits blue-green light, similar to other bacterial luciferases, but *in vivo* and at temperatures of 20°C or lower, the color of the light emitted is bright yellow. This color shift is the result of a yellow fluorescence protein that has a highly fluorescent oxidized flavin mononucleotide chromophore. It is interesting that the lumazine protein, which causes a blue shift, and the yellow fluorescence protein appear to be homologous and carry out similar functions of energy transfer but do so with different chromophores.

There are many other examples of bioluminescent and chemiluminescent reactions, many of which have found important and valuable uses. The green fluorescent protein that was isolated from jellyfish is a very important tool in the study of protein trafficking and other molecular imaging applications. In immunoassays, chemiluminescent and bioluminescent reactions offer sensitivity, but without the hazards of radioactive labels. In recent years, work in the field has become primarily focused on applications of the technology; by comparison, very little effort is being directed at a basic understanding of the mechanisms of the processes involved. As should be apparent from this brief overview, much remains to be learned.

Flavins

Glossary

bioluminescence The light that results from a chemiluminescent reaction in a living organism or from components of a living system, such as firefly tails.

chemiluminescence The light that is emitted from certain chemical reactions without the production of significant heat.

flavin mononucleotide Riboflavin-5′-phosphate, the 5′-phosphate derivative of vitamin B_2.

flavin monooxygenase An enzyme that employs a flavin coenzyme to split the two atoms of molecular oxygen apart, depositing one in an organic substrate as a hydroxyl group and the other in water.

fluorescence The phenomenon of light emission that occurs from certain molecules as they return to the ground state from the lowest excited singlet excited state. Population of the singlet excited state is the result of absorption of energy from incident light.

luciferase An enzyme that catalyzes a reaction that emits visible light with high efficiency. Luciferases are exceptionally diverse, many with no evolutionary relationship to the others.

Biography

Thomas O. Baldwin received his graduate education at the University of Texas at Austin in the laboratory of Professor Austen Riggs. He then did postdoctoral studies at Harvard University, where he began his studies of the structure and function of bacterial luciferase. He has been on the faculty of biochemistry at the University of Illinois and Texas A&M University. In 1999, he moved to the University of Arizona, where he is professor and head of biochemistry and molecular biophysics and Founding Director of the Institute for Biomedical Science and Biotechnology.

Chemiosmotic Theory

Keith D. Garlid
Portland State University, Portland, Oregon, USA

Mitochondria transform the chemical energy derived from food and body stores into ATP by a process called oxidative phosphorylation. The chemiosmotic theory begins by describing the mechanism of coupling between substrate oxidation and phosphorylation. It goes on to describe the membrane properties that are required in order for mitochondria to provide ATP to the cell and, indeed, to survive within the cell. The chemiosmotic theory was presented as a hypothesis far in advance of experimental evidence, and it stands as a monument to the scientific method. For this extraordinary achievement, Peter Mitchell was awarded the Nobel prize in chemistry in 1978.

Basic Chemiosmotic Theory

Mitochondrial Structure

Mitochondria are small, vesicular organelles. The internal aqueous compartment is called the *matrix*, which contains the enzymes of the Krebs tricarboxylic acid cycle. The matrix is enclosed by a highly folded, insulating membrane called the inner membrane, which contains the enzymic machinery of oxidative phosphorylation. The inner membrane is separated from the cytosol by a more permeable outer membrane, and the aqueous compartment between the inner and outer membranes is called the intermembrane space.

The Four Postulates

Peter Mitchell proposed that nature uses protonic batteries to drive ATP synthesis and that biological energy conservation is essentially a problem in membrane transport, as diagrammed in Figure 1. The chemiosmotic theory consists of four postulates.

1. The inner membrane contains electron transport enzymes which are vectorially oriented so that the energy of electron transport drives ejection of protons outward across the membrane. The energy of substrate oxidation is thereby converted to and stored as a proton electrochemical potential gradient, called the protonmotive force.

2. The inner membrane contains a reversible, proton-translocating ATPase, which is also vectorially oriented so that the energy of ATP hydrolysis will drive protons outward across the inner membrane. The ATPase is reversible, so that protons driven inward through the enzyme by the redox-generated protonmotive force will cause ATP synthesis.

3. The inner membrane must have a low diffusive permeability to ions in general and to protons in particular. Otherwise, ion leaks would short-circuit the protonmotive batteries, and ATP would not be synthesized.

4. The inner membrane was postulated to contain exchange carriers in which anion entry is effectively coupled to proton entry. This provides a thermodynamically favorable pathway for substrate anions to reach enzymes within the electronegative matrix. The membrane was also postulated to contain exchange carriers in which cation exit is coupled to proton entry. This provides a thermodynamically favorable pathway for removal of cations that entered the matrix by diffusion down the very large electrical gradient caused by outward proton pumping.

First Postulate – Respiration and the Electron Transport System

Electron Transport

NADH and succinate arising from the tricarboxylic acid cycle are oxidized by the electron transport chain as diagrammed in Figure 2. The structure–function of the electron transport enzymes is discussed in other articles.

Protonmotive Force

Electron transport through complexes I, III, and IV is coupled to electrogenic proton ejection across the inner membrane. The protonmotive force (Δp) is the free energy per mol required to move protons outward across the membrane. It is simply the sum of the work done against the electrical force and the work done against the

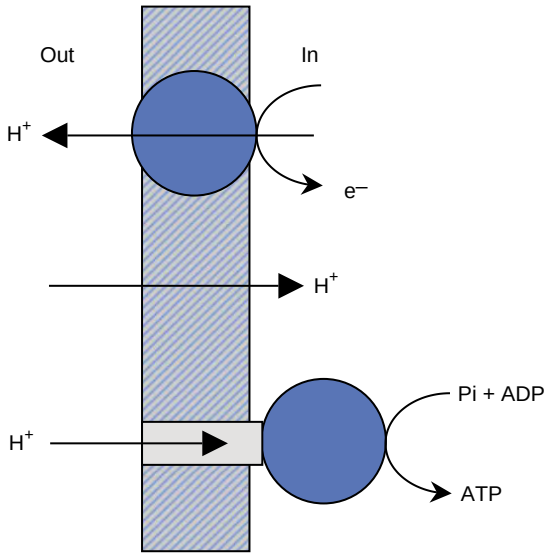

FIGURE 1 Coupling of electron transport with ATP synthesis. The chemiosmotic theory states that vectorial enzymes of electron transport and ATP synthesis are coupled "indirectly" via the protonmotive force across the inner membrane of mitochondria. In order for oxidative phosphorylation to be coupled by this mechanism, the membrane must have a low permeability to protons (postulate 4).

proton concentration difference. Δp is defined as the electrochemical proton gradient divided by the Faraday constant ($\Delta\mu_{H+}/F$); therefore

$$\Delta p = Z\Delta\text{pH} - \Delta\psi \qquad (1)$$

where $Z \equiv (RT\ \ln 10)/F = 59$ mV at 25 °C, and $\Delta\psi$ is the membrane potential (inside minus outside). $\Delta\psi$ and ΔpH can be estimated from equilibrium distributions of cationic dyes and weak acids, respectively. It is customary in bioenergetics to drop the negative signs of $\Delta\psi$ and Δp. Commonly observed values in isolated, nonphosphorylating mitochondria are 190 mV for $\Delta\psi$, 0.3 units for ΔpH, resulting in a Δp of ~208 mV.

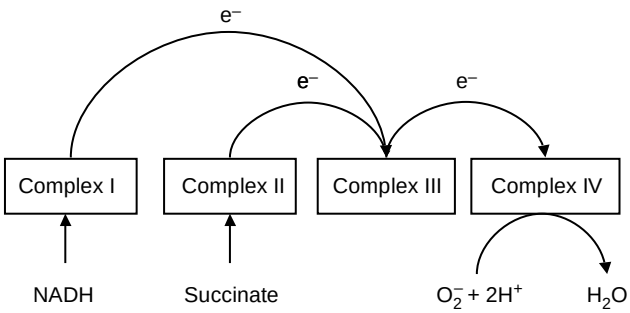

FIGURE 2 Electron transport chain in mitochondria. Complex I (NADH-coenzyme Q reductase) and complex II (succinate coenzyme Q reductase) feed electrons into coenzyme Q at complex III (coenzyme Q cytochrome c reductase), then onto cytochrome c, which delivers them to complex IV (cytochrome *c* oxidase). At complex IV, molecular oxygen is reduced by the electrons to water. Electrogenic proton ejection occurs via complexes I, III, and IV.

Stoichiometries

In the final step of electron transport, the dioxygen molecule (O_2) is reduced to water by four electrons ($e^-/O = 2$). When a pair of electrons moves from NADH to oxygen, it is estimated that ten protons are ejected across the inner membrane ($H^+/O = 10$).

Respiratory Control

Respiration can readily be measured as oxygen uptake by isolated mitochondria. The typical traces in Figure 3 illustrate the principle of respiratory control, which is that respiration increases if the proton back-flux across the inner membrane is facilitated, either through the ATP synthase or by proton-translocating drugs or proteins.

The Protonmotive Circuit

The chemiosmotic theory identifies the electron transport system (ETS) as a protonmotive cell, the behavior of which is identical to the well-known behavior of electromotive circuits, such as is shown in Figure 4. We note four salient aspects of this circuit: (1) The electron current is measured as respiration, as shown in Figure 3. (2) The current is determined entirely by the external resistances, and the battery will deliver increased current only when R_e or R_{ATP} are decreased.

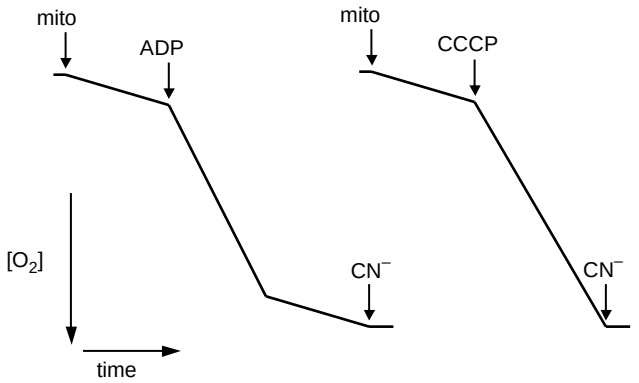

FIGURE 3 Respiratory control in mitochondria. Mitochondria are added to a closed vessel containing an oxygen electrode and a medium containing phosphate and substrates to support respiration. A slow rate of oxygen consumption is observed, which is due primarily to proton leak across the inner membrane. When ADP is added, respiration accelerates until most of the ADP is consumed, after which it returns to the control rate. The protonophore CCCP accelerates respiration by catalyzing proton back-flux across the inner membrane. Respiration is stopped by addition of cyanide, which inhibits cytochrome *c* oxidase.

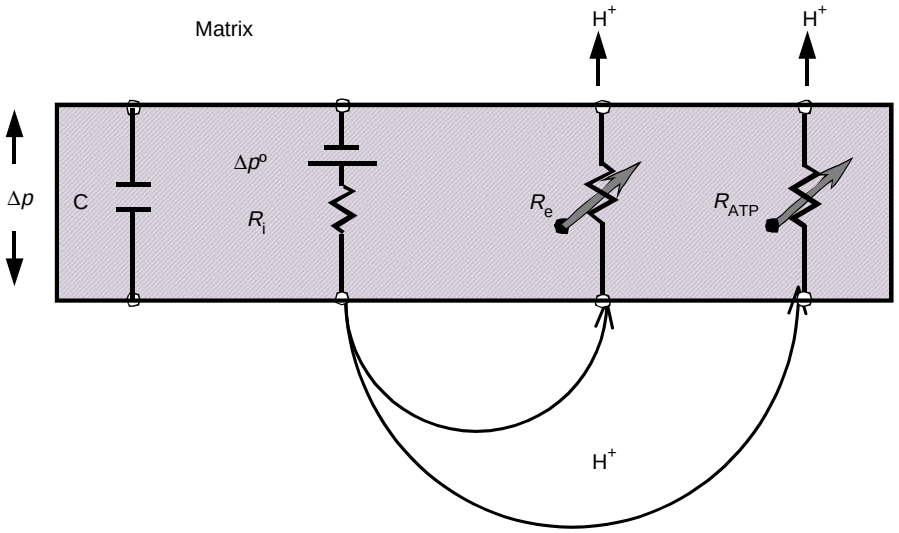

FIGURE 4 Circuit diagram of the mitochondrial electron transport sytem (ETS). In the diagram, the battery symbol corresponds to the ETS, connected across the membrane through an internal resistance, R_i. C is the capacitance of the membrane. Δp^o corresponds to the free energy drop when two electrons pass from the input redox couple to oxygen. R_e is the sum of cation and proton leak resistances and those of the futile cation cycles necessary to regulate mitochondrial physiology. Proton back-flux through the ATP synthase is designated by the element containing R_{ATP}. If conductance through both of these back-flux pathways were zero, there would be no respiration, no proton pumping, and Δp would equal Δp^o, the open-circuit voltage.

(3) The battery will respond the same whether current is drawn through R_e or R_{ATP}. (4) As increasing current is drawn from the battery, the voltage will decrease, due to the internal resistance, R_i. Thus, respiration is "driven" by the free energy contained in the redox drop, and it is "controlled" by the proton back-flux through leak pathways and the ATP synthase.

Behavior of the Protonmotive Circuit

The experiment in Figure 5 shows how Δp varies when electron current is progressively increased by adding a protonophore that decreases external resistance (R_e) to H^+ ions. The resulting increase in respiration causes Δp to fall gradually until the V_{max} of the ETS is reached. What is being measured in such experiments is evident from the circuit diagram of Figure 4:

$$\Delta p = \Delta p^o - R_i \times V_O \qquad (2)$$

where V_O is the respiration rate. The slope, R_i, is the internal resistance of the ETS, representing the weighted sum of frictional coefficients of the reactions leading to proton ejection. The intercept is Δp^o, the theoretical open-circuit voltage of the system, whose value is given by

$$\Delta p^o = (2/n_H)\Delta E \qquad (3)$$

where n_H is the H^+/O stoichiometry, and ΔE is the redox span being studied. The total redox potential, ΔE, for a pair of electrons moving from NADH/NAD^+ to oxygen is ~1.16 V. Therefore, if n_H is 10, $\Delta p^o = 232$ mV. Decreasing R_e to increase proton back-flux may be achieved by ionophores, by uncoupling protein, or by futile Ca^{2+} or K^+ cycling. Decreasing R_{ATP} to increase proton back-flux may be achieved by adding ADP and

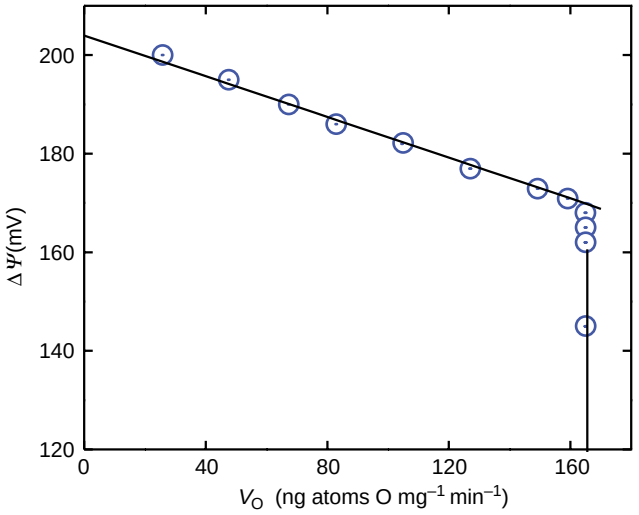

FIGURE 5 Dependence of protonmotive force on electron transport rate. Membrane potential ($\Delta\psi$) of rat liver mitochondria is plotted versus respiration rate (V_o), which was varied by adding the protonophoretic uncoupler, CCCP. Respiration was measured using a standard Clark electrode. $\Delta\psi$ was determined from the distribution of tetraphenylphosphonium cation. The slope of the curve, R_i, is 0.35, the intercept is 210 mV, and V_{max} is ~160 ng atom O min^{-1} mg^{-1}. These are typical values for rat liver mitochondria respiring on succinate. The pH gradient was 0.3 and assumed to be invariant with increased respiration. Therefore, Δp^o is ~228 mV.

phosphate so that current is drawn via the ATP synthase. Careful measurements show that all methods of increasing respiration yield points that fall on the same battery curve as illustrated in Figure 5.

Second Postulate – The ATP Synthase

Δp formed by the ETS is used to drive ATP synthesis via a remarkable series of steps. First, a proton binds to one of the 10–14 C subunits of the F_0 complex. This induces a conformational change that causes the C ring to rotate, after which the bound proton is released into a channel that carries it into the matrix. In this fashion, Δp is transduced into a rotary mechanical force. The rotation of the C ring, in turn, drives the rotation of the attached γ-subunit, and rotation of γ induces conformational changes in the catalytic sites of the three β-subunits of the F_1 head group of the ATP synthase. These catalytic sites exist in three different conformations, corresponding to the three faces presented by the end of the γ subunit. If one proton is associated with each step of the cycle as it occurs on F_1, then the H^+/ATP stoichiometry would be 3 for ATP synthesis. On the other hand, if a complete revolution of the C ring is required for ATP synthesis, and if there are 12 C subunits in F_0, then the stoichiometry would be 4.

Third Postulate – Ion Leaks and the Permeability Barrier

Notwithstanding the low diffusive permeability of the inner membrane, cation, and proton leaks occur at significant rates, and they are physiologically important. Inward K^+ leak causes matrix swelling, and inward proton leak contributes to the basal metabolic rate. Moreover, nature has engineered the uncoupling proteins to increase proton leak under certain physiological circumstances.

Ion Leaks in Mitochondria

Diffusive transport of ions obeys the same laws that govern transport of nonelectrolytes across thin membranes. The rate is proportional to the concentration difference, and the proportionality constant (the permeability coefficient) is a function of the energy barrier that must be crossed during transport. The ionic charge adds a new complexity that derives from the long-range effects of the electric field on the local free energy of the diffusing ions. An ion diffusing across the inner membrane of mitochondria must cross an energy barrier whose maximum is located at the center of the membrane, and only those ions having sufficient energy to reach this peak will cross to the energy well on the opposite side. Net flux will therefore be proportional to the differential probability of getting to this peak from either side. This probability is given by the Boltzmann function, $\exp(-\Delta\mu_p/RT)$, where $\Delta\mu_p \equiv \mu_p - \mu_{aq}$ is the Gibbs energy of the ion at the peak (p) relative to its value in the aqueous energy well at the surface of the membrane (aq). These considerations lead to the following expression for diffusive flux of cations across thin biomembranes:

$$J = fxP(C_1 e^{u/2} - C_2 e^{-u/2}) \tag{4}$$

where u is the reduced voltage ($zF\Delta\psi/RT$), C_1 and C_2 are bulk aqueous concentrations, f is the surface partition coefficient (energy well/bulk), and P is the permeability constant, given by

$$P \equiv k e^{-\Delta\mu_p^{\circ}RT} \tag{5}$$

The factor 1/2 in the exponents of eqn. (4) arises from the fact that the maximum energy barrier is found at the midpoint of the membrane.

The second term in eqn. (4) represents back-flux of cations from the matrix and becomes negligible at the high values of $\Delta\psi$ maintained by mitochondria under physiological conditions. Thus, eqn. (4) reduces to a simple exponential function of $\Delta\psi$:

$$J = fPC_1 e^{u/2} \tag{6}$$

Eqn. (6) emphasizes the point that ion flux at high potentials is not affected by the concentration gradient across the membrane. Figure 6A contains data showing that proton leak is in good agreement with eqn. (6), and the flux–voltage plots in Figure 6B show that diffusion of TEA^+ (tetraethylammonium ion) and H^+ (hydronium ion) across the inner membrane behave identically with respect to their voltage-dependence.

Uncoupling Proteins

Uncoupling proteins (UCPs) are the exception that proves the rule of the inner membrane permeability barrier. Nature devised the UCPs to intentionally short-circuit the inner membrane in order to dissipate energy and generate heat instead of ATP. UCP1 is expressed solely in brown adipose tissue, where it plays a major role in providing heat to hibernating animals and mammalian newborns. The human genome contains at least three additional UCPs, designated UCP2–4. UCP2 is ubiquitously expressed in mammalian tissues; UCP3 is expressed primarily in glycolytic skeletal muscle in humans; and UCP4 is expressed in brain. The roles of UCP in non-thermogenic tissue are uncertain but may involve reduction of mitochondrial production of reactive oxygen species.

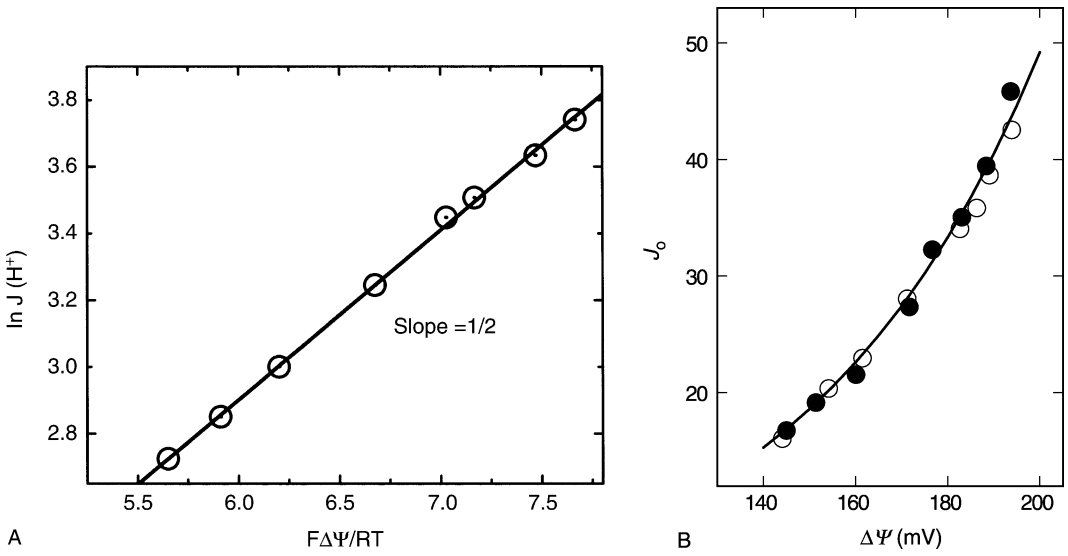

FIGURE 6 Proton and cation diffusion across the inner membrane. (A) Proton flux. The semilogarithmic plot shows that H^+ leak is exponential with voltage, and the slope of ln J_H vs. $F\Delta\psi/RT$ is 1/2, in agreement with eqn. (6). The intercept of such plots gives $J_o \equiv fP[C]_o$, where $[C]_o$ is the aqueous concentration, and f and P are defined in the text. (B) Tetraethylammonium (TEA^+) and H^+ flux. Fluxes were normalized to their respective values of J_o and plotted vs. $\Delta\psi$. Note that the rate-limiting step of crossing the energy barrier is identical for TEA^+ and H^+ (H^+ probably crosses as hydronium ion).

The transport functions and regulation of UCP1–3 have been characterized using recombinant proteins expressed in *E. coli* and reconstituted into liposomes for flux measurements. The purified UCP proteins are qualitatively identical with respect to transport function and regulation. They catalyze electrophoretic flux of protons and alkylsulfonates, and proton flux exhibits an obligatory requirement for fatty acids. Fatty acid-dependent proton transport by UCP1–3 is inhibited by purine nucleotides, including ATP. The mechanism by which UCPs catalyze proton back-flux is somewhat controversial. It is thought that they act as fatty acid anion flipases, causing the outward movement of the fatty acid anion head group across the inner membrane. Once on the outer surface, the fatty acid picks up a proton and then flip-flops rapidly back into the matrix. Thus, UCP does not conduct protons, per se; rather, it enables fatty acids to behave as cycling protonophores, as shown in Figure 7.

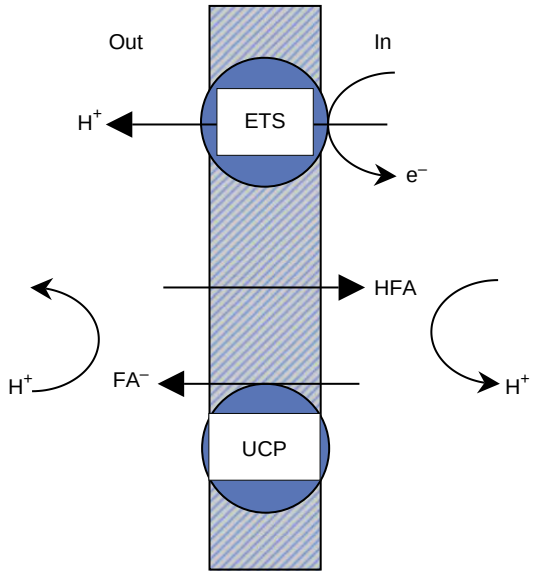

FIGURE 7 Mitochondrial uncoupling protein (UCP). UCP contains a weak binding site for anions near the center of the membrane. This constitutes an energy well for anions and provides a low-resistance pathway for normally impermeant anions to cross the membrane. The physiological substrates of UCP are anions of free fatty acids (FA). The FA head groups are located at the acylglycerol linkages of the phospholipid bilayer. When the FA is at the surface of UCP, the negative membrane potential drives the head group to the energy well at the center of the membrane. The FA then "flip-flops" and the head group is driven to the opposite surface. Here, it diffuses away from the protein and picks up a proton. The protonated FA (HFA) head group freely diffuses across the membrane, during which the FA flip-flops again, and delivers a proton to the other side. Thus, UCP is a FA anion flipase, and its role is to enable FA to behave as cycling protonophores.

Fourth Postulate – Ion Carriers and Channels

With astute physiological insight, Mitchell recognized that solving the problem of energy transduction gave rise to another. The high transmembrane electrical potential required for ATP synthesis would prevent anions, including the substrates of the tricarboxylic acid cycle, from entering the matrix. It would also promote cation uptake, with consequent osmotic swelling and

lysis. Thus, the fourth postulate was born out of physiological necessity.

Anion Exchange Carriers

Because ATP is synthesized in the matrix, ADP and phosphate must be imported and ATP must be exported across the inner membrane. As shown in Figure 8, nucleotides are exchanged on the ATP/ADP translocase (ANT) in a process involving outward movement of one negative charge. The phosphate carrier catalyzes electroneutral P_i/H^+ symport or P_i/OH^- antiport, with the net result that it transports phosphoric acid.

The inner membrane also contains a variety of anion exchange carriers, which are designed to deliver substrates to the tricarboxylic acid cycle. The anion exchange carriers catalyze 1:1 electroneutral exchange of anions, and they are arranged in a cascade in which phosphate and malate are key intermediates. In liver mitochondria, the dicarboxylic acid exchanger catalyzes malate/phosphate exchange, and the tricarboxylic acid exchanger catalyzes malate/citrate exchange. In this way, both di- and tricarboxylic acids are linked to the phosphate carrier. Since the phosphate carrier effectively transports fully protonated phosphate, the net result is that di- and tricarboxylic acids also behave as if they were fully protonated, and they are distributed across the membrane as if they were transported as fully protonated acids:

$$(A-)_{in}/(A-)_{out} = 10^{z\,\Delta pH} \qquad (7)$$

where z is the valence of the acid.

The Sodium–Calcium Cycle

The mitochondrial Ca^{2+} cycle consists of three separate transporters and is diagrammed in Figure 9. Ca^{2+} is taken up by the Ca^{2+} channel at the expense of two ejected protons. In spite of the enormous gradient for electrophoretic Ca^{2+} uptake, free mitochondrial [Ca^{2+}] is comparable to cytosolic [Ca^{2+}] *in vivo*. This disequilibrium is maintained in heart mitochondria by an electrophoretic Na^+/Ca^{2+} antiporter, which exchanges 3 Na^+ per Ca^{2+}. The three Na^+ ions taken up are then ejected by the electroneutral Na^+/H^+ antiporter, which holds Na^+ close to equilibrium with the pH gradient.

The physiological role of the mitochondrial Ca^{2+} cycle is to regulate matrix Ca^{2+} activity in response to signals from the cytosol. As a second messenger, Ca^{2+} signals need to increase cellular work. Because increased work requires a higher rate of ATP production, this

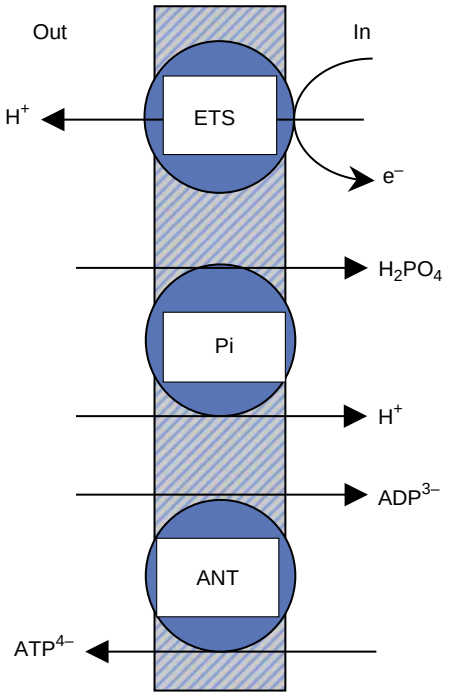

FIGURE 8 Mitochondrial transport of inorganic phosphate, ADP, and ATP. The phosphate carrier (Pi) catalyzes electroneutral transport, and the adenine nucleotide translocase (ANT) catalyzes electrophoretic exchange of ADP and ATP. Uptake of Pi and ADP and expulsion of ATP use one electrogenically ejected proton.

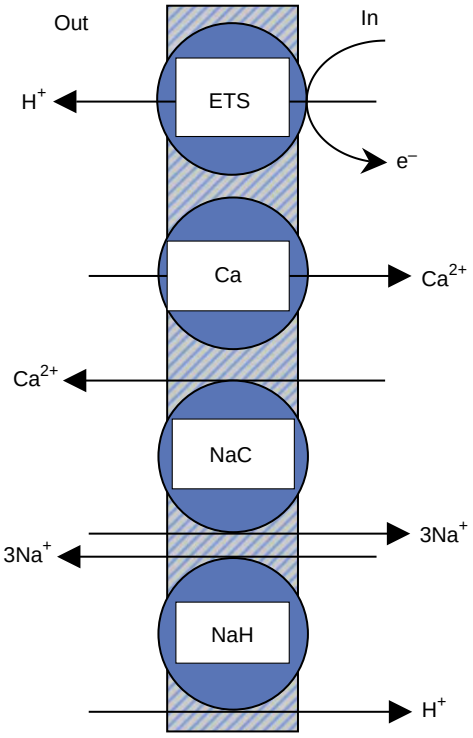

FIGURE 9 The mitochondrial Ca^{2+} cycle. Ca^{2+} enters the matrix via the electrophoretic Ca^{2+} channel and is ejected by the electrophoretic Na^+/Ca^{2+} antiporter (NaC), utilizing three ejected protons per Ca^{2+} taken up. The Na^+ is then expelled by the electroneutral Na^+/H^+ antiporter (NaH).

message must be relayed to the mitochondrial matrix. Intramitochondrial Ca^{2+} is required to activate the phosphorylase that converts pyruvate dehydrogenase to its active form, and α-ketoglutarate dehydrogenase is allosterically activated by matrix Ca^{2+} in the physiological range.

The Potassium Cycle

The mitochondrial K^+ cycle consists of electrophoretic K^+ influx and electroneutral K^+ efflux across the inner membrane, as diagrammed in Figure 10. Mitochondria must regulate net K^+ flux to zero in the steady state; otherwise, inward K^+ diffusion would cause the matrix to swell and eventually lyse. This regulation is provided by the K^+/H^+ antiporter, which ejects exactly the amount of K^+ that is taken in. Regulation of the K^+/H^+ antiporter is mediated by reversible binding of Mg^{2+} and H^+ to the K^+/H^+ antiporter on its matrix side. The activity of these ions decreases with uptake of K^+ salts, causing a graded, compensatory activation of K^+ efflux in response to increases in matrix volume.

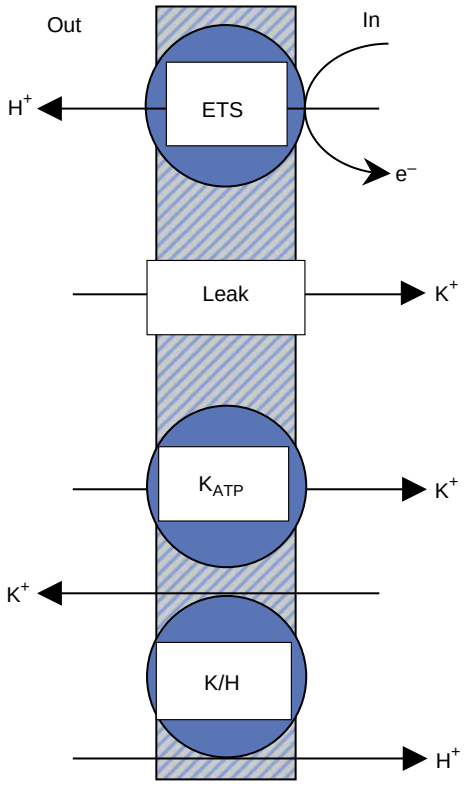

FIGURE 10 The mitochondrial K^+ cycle. Electrogenic proton ejection drives K^+ uptake by diffusive leak. In addition, the inner membrane contains a KATP channel, which is highly regulated by nucleotides, CoA esters, and pharmacological agents. Net K^+ flux is regulated to zero in the steady state. Compensatory K^+ efflux is provided by the electroneutral K^+/H^+ antiporter, which is regulated by matrix Mg^{2+} and H^+ and is exquisitely sensitive to changes in matrix volume.

The primary role of the K^+/H^+ antiporter is to provide "volume homeostasis" to mitochondria in order to maintain the vesicular integrity necessary for oxidative phosphorylation.

The mitochondrial K_{ATP} channel (mitoK_{ATP}) also plays an important role in volume homeostasis. When mitoK_{ATP} is open, the added K^+ conductance is thought to compensate for the lower driving force for K^+ influx (lower $\Delta\psi$) in ischemia and in high ATP-consuming states of the cell. MitoK_{ATP} is regulated by a rich variety of metabolic and pharmacological ligands. It is inhibited with high affinity by ATP, long-chain acyl-CoA esters, the antidiabetic sulfonylurea, glyburide, and 5-hydroxydecanoate. The ATP-inhibited channel is opened with high affinity by guanine nucleotides and K^+ channel openers such as cromakalim and diazoxide. There is indirect evidence that mitoK_{ATP} is opened *in vivo* by phosphorylation. MitoK_{ATP} has been found to play a pivotal role in protecting heart and brain from ischemic stress. Thus, opening mitoK_{ATP}, either with K_{ATP} channel openers or with endogenous signals, confers significant protection against ischemia–reperfusion injury.

Glossary

electrogenic transport Ion transport (and net charge movement) that requires chemical energy to move an ion across the membrane against its electrochemical potential gradient. Electrogenic transport in mitochondria is limited to proton transport by the electron transport system and by the ATP synthase, when ATP is being hydrolyzed.

electrophoretic transport Ion transport (and net charge movement) driven by the ion electrochemical potential gradient. In mitochondria, this includes diffusion and transport by ion channels and ionophores such as valinomycin.

ionophore A chemical compound that conducts ions across membranes. Examples include valinomycin, CCCP, and nigericin.

protonophore An ionophore that conducts protons (H^+ ions) across membranes. Examples include dinitrophenol and CCCP (carbonyl cyanide *m*-chlorophenylhydrazone).

BIOGRAPHY

Keith D. Garlid is a Professor of Biology at Portland State University, in Portland, Oregon. He holds an M.D. from Johns Hopkins University, and a Doctor tecnicae degree from the Norwegian Institute of Technology. His principal research interests are in mitochondrial physiology and bioenergetics. He has published extensively on the mitochondrial uncoupling proteins and on the mitochondrial potassium cycle. His paper showing that the mitochondrial ATP-sensitive K^+ channel is the receptor for drugs that protect the heart from ischemia–reperfusion injury has had a major impact on ischemia research.

Chemokine Receptors

Ann Richmond and Guo-Huang Fan
Department of Veterans Affairs, VA Medical Center, Nashville, Tennessee, USA and Vanderbilt University School of Medicine, Nashville, Tennessee, USA

Chemokine receptors are seven-transmembrane proteins expressed on neutrophils, lymphocytes, dendritic cells, and many other cell types. They function to mediate migration of leukocytes to the sites of injury and infection in response to a gradient concentration of chemokines, a group of small proteins that specifically bind the chemokine receptors. Chemokine receptors belong to the G protein-coupled seven-transmembrane receptor superfamily, which has more than 600 members that use the heterotrimeric G proteins to initiate signals. Eighteen chemokine receptors have been identified and cloned so far, and these receptors have been classified into four subfamilies (CXC, CC, CX3C, and C) based on the chemokine subclass specificity. In addition to the mediation of migration of leukocytes to the inflammatory sites (chemotaxis), chemokine receptors play a role in leukocyte homing, HIV entry, angiogenesis, tumor growth and metastasis, development, and inflammation of the central nervous system.

Ligands

The ligands that bind and activate chemokine receptors are chemokines or chemoattractant cytokines. Approximately 50 chemokines have been identified so far, and these chemokines are classified into four (CXC, CC, C, and CX3C) subfamilies based on their primary amino acid sequences (Table I). The CXC subfamily has six members, which have one amino acid (X) interrupting the first two of their four conserved cysteine residues. The CC subfamily has 10 members, which have no intervening amino acid between the first two of their four cysteine residues. In both the CXC and CC subfamilies, disulfide bonds are formed between the first and third cysteines and between the second and fourth cysteines to establish a stable tertiary structure with the molecular mass of 7–9 kDa. The C subfamily has two members, which are 16 kDa in molecular size. The CX3C subfamily has only one member (CX3L1), which has three intervening amino acids between the N-terminal cysteines, with a molecular mass of 38 kDa, larger than any other known chemokine. Chemokines have two main sites of interaction with their receptors, the flexible N-terminal region and the conformationally rigid loop that follows the second cysteine. Chemokines dock onto receptors by means of the loop region, and this contact is necessary to facilitate the binding of the N-terminal region to the receptor that results in receptor activation. Chemokines possess heparin-binding capacity at their C-terminal end, which enables them to bind to glycosaminoglycans and other negatively charged sugar moieties on cell surfaces and matrix glycoproteins. This property may result in the adsorption of chemokines onto the endothelial cell lining of the blood vessels, connective tissues, and cell matrices. Thus, chemokines immobilized on tissue or matrix surfaces may induce haptotactic migration of target cells.

Structure

The chemokine receptors generally are composed of 340–370 amino acid residues and have 25–80% identity. These receptors share a common putative structural topology composed of seven hydrophobic transmembrane domains, an N terminus outside the cell surface, three extracellular and three intracellular loops, and a C terminus in the cytoplasmic compartment. The poorly conserved N-terminal domains together with a second binding site in the extracellular loops determine the specificity for ligand binding. The sequence DRYLAIVHA, or a variation of it, in the second intracellular loop and the third intracellular loop is required for G protein coupling. A cysteine residue in each of the four extracellular domains is required for the disulfide-bond formation that is critical for cell surface expression. The C terminus of the receptors contains a number of serine and threonine residues that, upon phosphorylation, are involved in signaling and receptor desensitization. A leucine–leucine or isoleucine–leucine motif in the C terminus is required for the receptor internalization (Figure 1). Some chemokine receptors such as CCR2, CCR5, and CXCR4 form homodimers, which may be needed for signal transduction.

TABLE I

Chemokine Receptor Family[a]

Name	Main agonists	Main functions
CXCR1	CXCL8	Neutrophil migration; innate immunity; acute inflammation
CXCR2	CXCL1–3, CXCL5–8	Neutrophil migration; innate immunity; acute inflammation; angiogenesis
CXCR3	CXCL9–11	T-cell migration; adaptive immunity; Th1 inflammation
CXCR4	CXCL12	B-cell lymphopoiesis; bone marrow myelopoiesis; central nervous system and vascular development; HIV infection
CXCR5	CXCL13	B-cell trafficking; lymphoid development
CXCR6	CXCL16	T-cell migration
CCR1	CCL3, CCL5, CCL7, CCL8, CCL13–16, CCL23	T-cell and monocyte migration; innate and adaptive immunity; inflammation
CCR2	CCL2, CCL7, CCL8, CCL13	T-cell and monocyte migration; innate and adaptive immunity; Th1 inflammation
CCR3	CCL5, CCL7, CCL8, CCL11, CCL13, CCL15, CCL24, CCL26	Eosinophil, basophil, and T-cell migration; allergic inflammation
CCR4	CCL17, CCL22	T-cell and monocyte migration; allergic inflammation
CCR5	CCL3, CCL4, CCL5, CCL8, CCL14	T-cell and monocyte migration; innate and adaptive immunity; HIV infection
CCR6	CCL20	Dendritic cell migration
CCR7	CCL19, CCL21	T-cell and dendritic cell migration; lymphoid development; primary immune response
CCR8	CCL1, CCL4, CCL17	T-cell trafficking
CCR9	CCL25	T-cell homing to gut
CCR10	CCL26–28	T-cell homing to skin
CX3CR1	CX3CL1	T-cell and NK cell trafficking and adhesion; innate and adaptive immunity; Th1 inflammation
XCR1	XCL1–2	T-cell trafficking

International Union of Pharmacology, XXII. Nomenclature for chemokine receptors. *Pharmacol. Rev.* **52**, 145–176, National Institutes of Health.

Consequence of Receptor–Ligand Interaction

Signal Transduction

Ligand binding to chemokine receptors initiates a cascade of intracellular events (Figure 2). The first step is the conformational change of the chemokine receptors, inducing the exchange in the α-subunit of the G proteins from the GDP to GTP bound state dissociating the α from the β and γ G protein subunits. The G$\beta\gamma$ subunits activate phospholipase C β2 (PLCβ2), which hydrolyzes phosphatidylinositol 4,5-bisphosphate [(4,5)P2] to produce inositol trisphosphate (IP3) and diacylglycerol (DAG). IP3 mediates Ca^{2+} release from the intracellular stores. DAG activates protein kinase C (PKC), which phosphorylates a number of effector molecules. The activation of isotypes of PLC and hydrolysis of PIP2 vary among chemokine receptors and from cell type to cell type, which may account for the divergent cellular responses to a given chemokine. Another important signaling pathway of chemokine receptors is the activation of phosphoinositide 3-kinases (PI3K), which convert the plasma membrane lipid PI (4,5)P2 to phosphatidylinositol-3,4,5-trisphosphate [PI(3,4,5)P3], resulting in the phosphorylation and activation of the serine-threonine kinase Akt (PKB). An additional part of the signals that evoke the motility response involves activation of the rho GTPase family including rho, rac, and cdc42, which can feed into the activation of P^{21} activated Kinase (PAK), Wiskott-Aldrich syndrome protein (WASP), and Arp2/3 to mediate actin cytoskeletal changes. Chemokines also induce tyrosine phosphorylation of p130 Cas, focal adhesion Kinase (FAK), and members of the src family in several cell types. Through activation of the ras, raf, MAPK cascade and through activation of the NF-κB cascade, transcription factors are activated and gene expression is affected. The signaling pathways of chemokine receptors play a role in cell growth, cell migration, cell survival, and superoxide production.

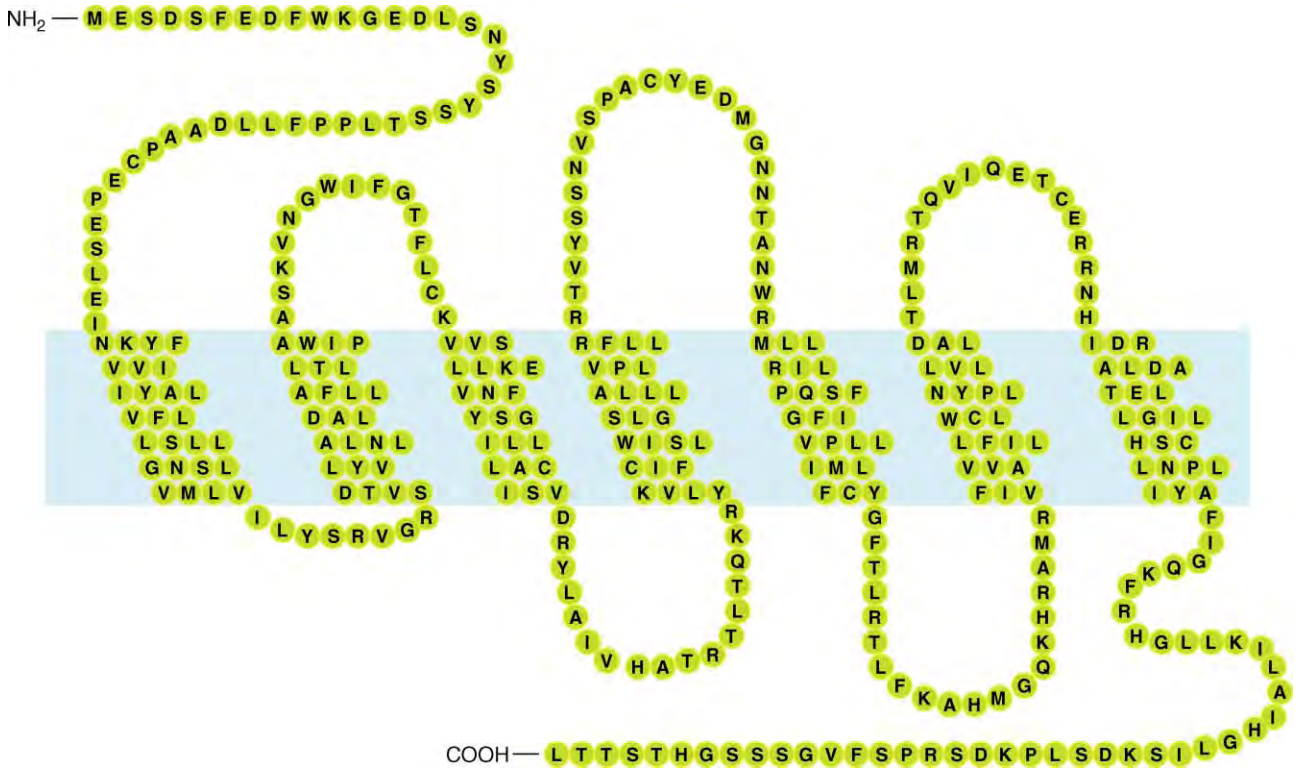

FIGURE 1 Proposed conformation of the chemokine receptor CXCR2. This receptor is a seven-transmembrane G protein-coupled receptor. The free amino terminus provides ligand binding specificity. The third extracellular loop participates in ligand binding, whereas the third intracellular loop is thought to be the site of G protein coupling. The serine residues in the carboxyl terminus are phosphorylation sites.

Desensitization

The ligand-induced activation of chemokine receptors is transient. The functional response of chemokine receptors is rapidly reduced following repeated stimulation by chemokines. This process is called desensitization. Agonist-dependent (homologous) desensitization occurs when a receptor binds chemokine and is phosphorylated by a G protein receptor-coupled receptor kinase (GRK). The phosphorylated receptor recruits β-arrestin, an adaptor protein that uncouples the receptor with G proteins, thus retaining the receptor in a desensitized state, resulting in attenuation in the cell excitability (Figure 3). This mechanism plays a major role in determining the duration of leukocyte trafficking, migration, or sequestration in certain situations (see later discussion). Chemokine receptors can also be phosphorylated by a kinase, such as PKC, activated by a different signaling cascade. This is called heterologous desensitization. For example, the chemokine receptor CXCR1 or CXCR2 can be phosphorylated and desensitized through the activation of formyl peptide receptors by the tripeptide formyl-methionyl-leucyl-phenylalanine (fMLP). The importance of this phenomenon in inflammation and leukocyte trafficking is not completely clear, but the capacity for heterologous desensitization appears to be different among chemokine receptors, suggesting a hierarchy of chemokines.

Internalization

After agonist occupancy, chemokine receptors are rapidly translocated from the cell membrane to the cytoplasm. This process is called receptor internalization. Chemokine receptors generally undergo internalization through clathrin-coated pits, a complex process that involves clathrin and adaptor proteins such as β-arrestins and adaptin-2. After pinching off from the cell membrane through a dynamin-dependent process, the clathrin-coated vesicles containing the internalized receptors fuse with early endosomal compartments. When there is a low pH value in the early endosomes, the receptors become dephosphorylated by a specific serine/threonine protein phosphatase such as protein phosphatase 2A. The dephosphorylated receptors are either transported to recycling endosomes and subsequently reexpressed on the cell surface after removal of the extracellular ligand or delivered to late endosomes and lysosomes for degradation in the continued presence of a high concentration of ligands. The intracellular trafficking processes are regulated by a number of molecules including the Ras-like GTPases (Rabs) (Figure 3). Such trafficking may be important for

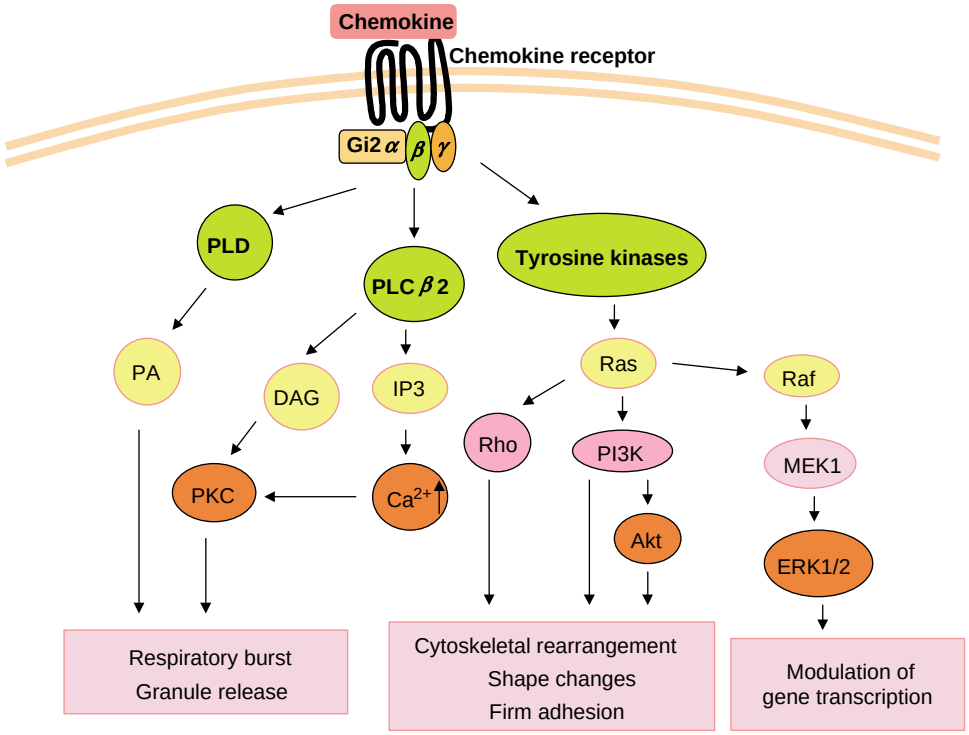

FIGURE 2 The major intracellular signaling events induced by a chemokine binding to its receptor and activating responses in a neutrophil. Stimulation of a chemokine receptor by its ligand results in a conformational change of the receptor and activation of the coupled G proteins. The Gα (proteins coupled with chemokine receptors are generally the inhibitory Gα proteins (Gαi). The β- and γ-subunits of the G protein activate phospholipase C (PLCβ2), which cleave PIP3 to produce diacylglycerol (DAG) and inositol triphosphate (IP3). IP3 initiates mobilization of the intracellular free Ca^{2+} and DAG activates PKC, which is required for the respiratory burst and granule release. Stimulation of chemokine receptors also results in activation of tyrosine kinases, which trigger several signaling pathways, including mitogen-activated protein kinase (MAPK) pathway, phosphotidylinositol 3-kinase (PI3K)/protein kinase B (Akt) pathway, as well as Rho signaling pathway. These pathways are required for cell movement and gene transcription. In addition, stimulation of chemokine receptors results in activation of phospholipase D (PLD), which produces phosphatidic acid (PA), which plays a role in respiratory burst and granule release. ERK1/2, extracellular signal-regulated kinases 1 and 2; MEK, mitogen-activated protein kinase kinase; Ras and Rho, small G proteins.

both transmission and termination of the receptor signals and may play an important role in mediating cell chemotaxis (see later discussion).

Multiple Roles

Chemotaxis

Neutrophils, lymphocytes, and other immune cells migrate to the sites of injury and infection. This process, which is called chemotaxis, occurs through the dynamic response of chemokine receptors expressed on these cells to the gradient concentrations of chemokines produced in the inflammatory sites. Chemokine receptor signaling leading to the establishment of cell polarity, cytoskeletal rearrangement, and interaction with the extracellular matrix plays an essential role in this complex process. In addition, the desensitization and internalization of chemokine receptors play a regulatory role. For example, human immature dendritic cells derived from monocytes express the inflammatory chemokine receptors CXCR1, CCR1, CCR2, CCR5, and CCR7, which allow these cells to follow chemotactic gradients to inflammatory sites. Once there, dendritic cells process antigen and become exposed to the maturation-stimulating cytokines. Maturing dendritic cells express large amounts of chemokines such as CCL3, CCL4, CCL5, CCL8, and CCL10. One consequence of this increased chemokine expression is the down-regulation of chemokine receptors on maturing dendritic cells, particularly CCR1 and CCR5, by receptor desensitization and internalization. The second consequence of this up-regulation of chemokines is that it strengthens the original chemotactic gradient, further boosting recruitment of immature dendritic cells, monocytes, and lymphocytes.

HIV Entry

Human immunodeficiency virus (HIV) is the causative agent of acquired immune deficiency syndrome (AIDS). Type 1 HIV (HIV-1) uses chemokine receptor as a coreceptor together with CD4 to enter the CD4-positive (CD4+) target cells. The main cells targeted by HIV-1 are

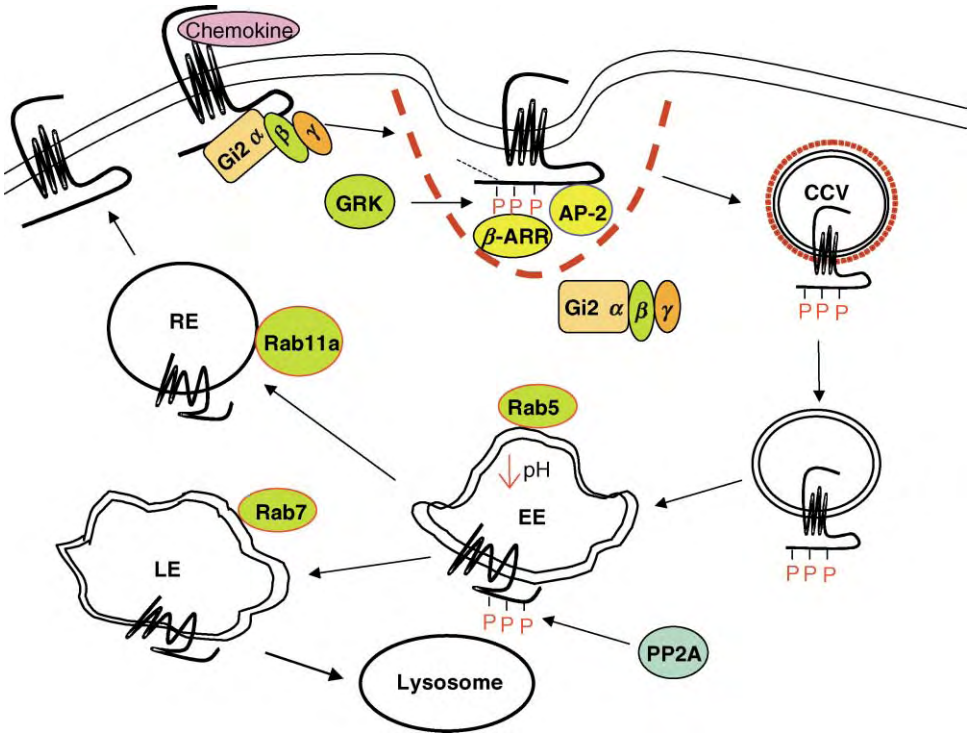

FIGURE 3 Homologous desensitization and intracellular trafficking of chemokine receptors. In response to chemokine stimulation, the receptor undergoes homologous desensitization, in which phosphorylation by a G protein-coupled receptor kinase leads to uncoupling of G proteins, binding of β-arrestins, and subsequent internalization of the receptor through clathrin-coated pits. After pinching off from the membrane, the clathrin-coated vesicles fuse to early endosomes, where the chemokine receptors are dephosphorylated by protein phosphatase 2A, and the receptors are transported to late endosomes and lysosomes for degradation. However, after removal of the extracellular ligands, the receptors are transported from early endosomes to recycling endosomes so as to re-express on the cell surface. β-ARR, β-arrestin; AP2, adaptin 2; CCV, clathrin-coated vesicle; EE, early endosome; GRK, G protein-coupled receptor kinase; LE, late endosome; P, phosphate; PP2A, protein phosphatase 2A; Rab5, Rab11a, Rab7, small GTPases that regulate receptor trafficking; RE, recycling endosome.

T lymphocytes (T cells), macrophages, and probably dendritic cells. The chemokine receptors CXCR4 and CCR5 are the major coreceptors for T-cell line-tropic and macrophage-tropic HIV-1 strains, respectively, although many other chemokine and orphan receptors have also been identified as potential coreceptors for HIV-1. The fusion of the viral envelope and the lymphocyte is as follows. The envelope glycoprotein on the surface of virus particles comprising a trimer of three gp120 and three transmembrane gp41 molecules binds to CD4 and triggers a structural change, which exposes a binding site for a coreceptor. Further structural rearrangements are initiated when the coreceptor is bound. These changes occur predominantly in gp41 and are sufficient to trigger fusion of viral and cellular membranes and entry of the virion core into the cytoplasm.

Angiogenesis

Angiogenesis is the formation of new blood vessels from pre-existing microvasculature. It is a biological process that is critical to both physiological and pathological processes such as wound healing and tumor growth. Angiogenesis is regulated by an opposing balance of angiogenic and angiostatic factors. The CXC chemokines are a family of cytokines unique in their ability to behave in a disparate manner in the regulation of angiogenesis. The N terminus of the majority of the CXC chemokines contains three amino acid residues (Glu-Leu-Arg; the ELR motif). This motif, in general, determines whether these chemokines promote angiogenesis. Members that contain the ELR motif (ELR+), such as CXCL1 and CXCL8, are potent promoters of angiogenesis. In contrast, members that are inducible by interferons and lack the ELR motif (ELR−), such as CXCL10, are potent inhibitors of angiogenesis. ELR-CXC chemokines bind to CXCR2 and a few to CXCR1, whereas non-ELR-CXC chemokines bind to CXCR3, CXCR4, CXCR5, and CXCR6. The mechanisms for the differential regulation of angiogenesis by chemokines and chemokine receptors are under investigation.

Tumor Growth and Metastasis

Many cancer cells such as melanomas express a number of chemokines, including CXCL8, CXCL1-3, CCL5,

and CCL2, which have been implicated in tumor growth and progression. Recent studies have demonstrated organ-specific patterns of melanoma metastasis that correlate with their expression of specific chemokine receptors, including CXCR4, CCR7, and CCR10. The chemokine receptors CXCR4 and CCR7 are also found on breast cancer cells and their ligands are highly expressed at sites associated with breast cancer metastases. Other models in which CXCR4 has been suggested to play a role in metastasis are ovarian, prostate, and lung cancers. It is thus postulated that chemokine receptors and their ligand pairs may play a role in the migration of tumor cells from their primary site via the circulation to the preferential sites of metastases.

Central Nervous System

In addition to their well-established role in the immune system, chemokine receptors also play a role in the development and inflammation of the central nervous system (CNS). Certain chemokine receptors such as CXCR2, CXCR4, CCR1, and CCR5 are constitutively expressed in both developing and adult brains, and the role played by these proteins in the normal brain is the object of intense study. Chemokines are involved in brain development and in the maintenance of normal brain homeostasis; these proteins play a role in the migration, differentiation, and proliferation of glial and neuronal cells. For example, the chemokine receptor CXCR4 is essential for life during development, and this receptor has a fundamental role in neuron migration during cerebellar formation. In the CNS, chemokines play an essential role in neuroinflammation as mediators of leukocyte infiltration and glial cell activation. Their overexpression has been implicated in several neurological disorders, such as multiple sclerosis, trauma, stroke, Alzheimer's disease, tumor progression, and AIDS-associated dementia.

Biography

Ann Richmond is a Professor in the Department of Cancer Biology at Vanderbilt University School of Medicine and a Senior Career Scientist in the Department of Veterans Affairs at Nashville Campus. Her research interests include chemokine receptor signal transduction, desensitization, and trafficking; transcriptional regulation of chemokines; and biological roles of chemokines in tumorigenesis, angiogenesis, and wound healing. She received her Ph.D. from Emory University and her postdoctoral training in the Division of Endocrinology at Emory University. During that time, she and her colleagues characterized one of the first chemokines, which is now known as CXCL1.

Guo-Huang Fan is a Research Assistant Professor in the Department of Cancer Biology at Vanderbilt University and an Assistant Professor in the Department of Pharmacology at Meharry Medical College. His research interests are signaling and trafficking of chemokine receptors. He received his Ph.D. from Shanghai Second Medical University and his postdoctoral training at the Chinese Academy of Sciences, University of Wuerzburg, and Vanderbilt University.

Chemolithotrophy

Alan B. Hooper
University of Minnesota, St. Paul, Minnesota, USA

The chemolithotrophic bacteria are defined by their ability to utilize inorganic or one-carbon molecules as a growth-supporting reductant. Oxidation of the growth-supporting reductant initiates a chain of redox electron-transfer reactions ending with reduction of a terminal electron acceptor such as oxygen and resulting in the generation of ATP. Alternatively, the reducing equivalents from the growth-supporting substrate are used in biosynthetic reductive reactions leading to cellular components.

Bioenergetics

Oxidation of the Growth-Supporting Substrate Drives Synthesis of Adenosine Triphosphate (ATP)

In all organisms a source of energy is required to drive biosynthesis, mechanical work, and pumping of molecules across a membrane against a gradient. Within cells this "energy" is commonly manifest as ATP since the hydrolysis of its terminal phosphoric anhydride bond can drive an otherwise thermodynamically unfavorable reaction when the two reactions are functionally coupled by an enzyme. The rephosphorylation of the resulting adenosine diphosphate (ADP) is most often catalyzed by a remarkable ATP synthase, an enzyme that is able to use the potential energy of a steady-state transmembrane gradient of protons. As the protons are relayed through the protein and across the membrane, the process is coupled to the synthesis of ATP. In turn, maintenance of the proton gradient requires the continuous turnover of a "low potential" half reaction (the oxidation of the growth-supporting reducing substrate). The continuation of the latter oxidative reaction is dependent on a "high potential" half reaction by which a growth-supporting *oxidant* substrate (a terminal electron acceptor) is reduced by electrons originating from the growth supporting reductant. A series of enzymes and electron transfer proteins are arranged in the membrane so that the process results in the net transfer of protons to the external side against a proton gradient.

The Variety of Terminal Electron Acceptors Used by Bacteria

Many bacteria are able to use one or more of the half-reactions shown in Table I as an electron sink supporting the continuity of the energy-generating reactions (i.e., the substrate molecules of Table I are terminal electron acceptors). The name of the enzyme is given for half-reactions: (1a–1g) are half-reactions; (1h–1k) are identified as processes. Because of its high redox potential, half-reaction 1a is preferred by bacteria. The other terminal electron acceptors are used when oxygen is absent (i.e., in anoxic or anaerobic rather than oxic or aerobic environments). Note that the reduction of protons in half-reaction 1f requires a low-potential reductant. Half-reactions 1f and 1g are employed in anaerobic fermentation by organotrophs. Line 1h is a multistep process carried out by the methane-generating bacteria. In line 1i, each step involves two electrons. The sulfur-reducing bacteria vary in the steps they are able to use. The reactions in this table are steps in the cycling of carbon, hydrogen, nitrogen, sulfur, and metals in nature.

Reductant for Biosynthesis

Biosynthetic reactions often require an electron or hydrogen donor molecule with a low enough potential to drive reductive reactions. This is often the reduced form of nicotinamide adenine dinucleotide (NADH). Hence, a second role of the growth-supporting reductant is the reduction of NAD^+; $NAD^+ + 2e^- + H^+ \rightarrow$ NADH.

Lithotrophy

Categories of Growth Based on the Nature of the Growth-Supporting Reductant

Organisms for which the growth-supporting reductant is a reduced carbon molecule such as glucose are called *chemoorganotrophs*. The sum of many reactions, including dehydrogenations, in the pathway of aerobic

TABLE I

Reductive Reactions Employed by Bacteria[a]

Half reaction	Name of enzyme or process
Aerobic conditions	
a. $O_2 + 4e^- + 4H^+ \rightarrow 2H_2O$	cytochrome oxidase
Anaerobic conditions	
b. $NO_3^- + 2e^- + 2H^+ \rightarrow NO_2^- + H_2O$	nitrate reductase
c. $NO_2^- + 2e^- + 2H^+ \rightarrow NO + H_2O$	nitrite reductase
d. $2NO + 2e^- + 2H^+ \rightarrow N_2O + H_2O$	nitric oxide reductase
e. $N_2O + 2e^- + 2H^+ \rightarrow N_2 + H_2O$	nitrous oxide reductase
f. $2H^+ + 2e^- \rightarrow H_2$	hydrogenase
g. $CH_3CHO^- + 4e^- + 4H^+ \rightarrow CH_3CH_2OH + H_2O$	aldehyde dehydrogenase
h. $CO_2 + 8e^- + 8H^+ \rightarrow CH_4 + 2H_2O$	methanogenesis
i. $SO_4^{2-} \rightarrow SO_3^{2-} \rightarrow S_4O_6^{2-} \rightarrow S_2O_3^{2-} \rightarrow S^0 \rightarrow S^{2-}$	reduction of sulfate
j. $Fe^{3+} + e^- \rightarrow Fe^{2+}$	
k. $Mn^{4+} + 2e^- \rightarrow Mn^{2+}$	

[a] The substrates of these reactions are terminal electron acceptors.

glucose oxidation is $C_6H_{12}O_6 + 6H_2O \rightarrow 6CO_2 + 24H^+ + 24e^-$.

Organisms defined as *phototrophs* are able to photochemically activate an internal substituent of a membrane protein thus converting it to a lower potential reductant. Reoxidation of the latter drives the creation of the proton gradient. Electrons are then recycled back to the center of photochemical reduction. Phototrophs require an external source of reductant (e.g., H_2O) only for reduction of NAD for use in biosynthetic reactions.

Bacteria that are specialized to use inorganic or one-carbon compounds as their growth-supporting reductant are called *chemolithotrophs*. Bacteria that are only able to grow in this manner are *obligate* chemolithotrophs; *facultative* chemolithotrophs have the activities necessary for chemoorganotrophic or chemolithotrophic growth.

The reducing half-reactions of the major chemolithotrophic growth-supporting substrates are listed in Tables II–V. In the majority of chemolithotrophic bacteria the oxidation of the growth-supporting reductant is coupled to reduction of oxygen (Table I, line a). The overall reactions supporting ATP synthesis for aerobic bacteria which oxidize ammonia, methane, sulfur, hydrogen, or ferric ion, respectively, are as follows:

$$NH_3 + 1.5O_2 \rightarrow NO_2^- + H_2O + H^+$$

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$$

$$S^0 + 3O_2 \rightarrow SO_4^{2-} + 2H^+ + 2H_2O$$

$$2H_2 + O_2 \rightarrow 2H_2O$$

$$4Fe^{2+} + 4H^+ + O_2 \rightarrow 4Fe^{3+} + 2H_2O$$

Bacteria that use a substrate half-reaction with a sufficiently low redox potential can grow anaerobically using terminal electron acceptors other than oxygen:

$$4H_2 + HCO_3^- + H^+ \rightarrow CH_4 + 3H_2O$$

$$4H_2 + SO_4^{2-} + 2H^+ \rightarrow H_2S + 4H_2O$$

$$5S_2O_3^{2-} + 8NO_3^- + H_2O \rightarrow 10SO_4^{2-} + 4N_2 + 2H^+$$

Examples of Half-Reactions of the Growth-Supporting Reductant in the Chemolithotrophic Bacteria

Nitrifying Bacteria

The half-reactions of the nitrifying bacteria represent the oxidative arm of the nitrogen cycle. Two enzymes are involved in the ammonia-oxidizers and one enzyme is involved in the nitrite oxidizers, respectively (see Table II). A recently discovered anaerobic chemolithotroph generates energy in a series of ANAMMOX

TABLE II

Oxidation of the Growth-Supporting Reductant in the Nitrifying Bacteria

Half reaction	Name of enzyme

reactions involving ammonia and nitrite with hydrazine as an intermediate and dinitrogen as the end product.

Hydrogen-, Methane-, and Carbon Monoxide-Oxidizing Bacteria

Hydrogenase (Table I, line f) of hydrogen-oxidizing bacteria oxidizes hydrogen to protons. The aerobic oxidation of methane by the methanotrophic bacteria (Table III, line b) involves an electron consuming monooxygenase (line c) and successive methanol-, formaldehyde-, and formate- dehydrogenases (lines d–f). The conversion of carbonic acid to CO_2 can be spontaneous or enzyme-catalyzed (line g). In the carboxydobacteria, carbon monoxide reductase catalyzes the net extraction of two electrons and two protons to produce carbon dioxide from carbon monoxide and water.

b. $Mn^{II} \rightarrow Mn^{III} + e^-$
c. $Cu^{I} \rightarrow Cu^{II} + e^-$
d. $Sn^{II} \rightarrow Sn^{III} + e^-$
e. $Fe^0 \rightarrow Fe^{II} + 2e^-$

Sulfur Oxidizing Bacteria

Depending on the specific bacterium, oxidation of a variety of reduced sulfur compounds are used to support growth. Some examples of the half-reactions are shown in Table IV, lines a–d. The enzymatic steps used within the respective pathways are listed in Table IV, lines e–i. Some bacteria utilize the adenosine phosphosulfate (APS) pathway for synthesis of ATP coupled to the oxidation of sulfite.

Metal-Oxidizing Bacteria

The half reactions shown in Table V, lines a–d are carried out by *Thiobacillus ferrooxidans*. A metalloenzyme catalyzes the oxidation of ferrous iron to ferric ion which hydrolyzes to form an orange precipitate: $Fe^{3+} + 3H_2O \rightarrow Fe(OH)_3 + 3H^+$. Metallic Fe^0 can be oxidized by methanogenic bacteria coupled to the reduction of CO_2 to methane (Table I, line h).

Basic Mechanisms of Energy-Transduction and ATP Synthesis in Chemolithotrophs

Generation of the Electrochemical Gradient and ATP Synthesis

Some generalizations regarding location of the enzymes catalyzing the oxidation of substrate, generation of a proton gradient and synthesis of ATP are illustrated in

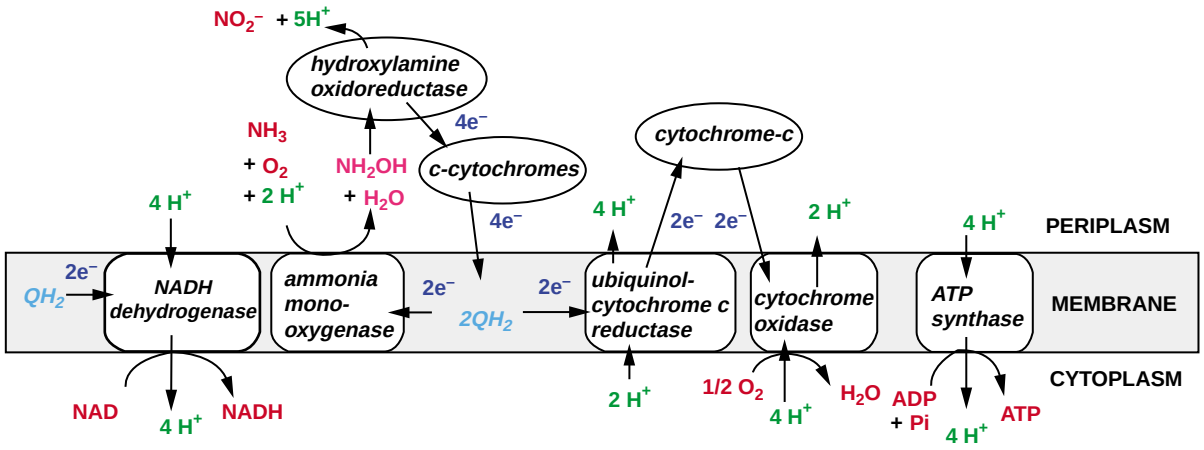

FIGURE 1 Catalysis of the oxidation of ammonia to nitrite coupled to generation of ATP and NADH in the chemolithotrophic bacterium, *Nitrosomonas europaea*. The four enzymes in the center of the figure create a proton gradient that is employed by the enzymes on the left and right to make NADH and ATP, respectively. Electrons from hydroxylamine oxidoreductase are relayed by heme-containing electron-transferring proteins, "cytochromes" in which Fe cycles between Fe^{2+} and Fe^{3+}, to reduce a quinone to a quinol (QH_2). The quinol is reoxidized either by ammonia monooxygenase or by an electron-transfer chain including a proton-pumping ubiquinol–cytochrome c reductase, a cytochrome- c and a proton-pumping cytochrome oxidase. The proton-pumping NADH-dehydrogenase functions in reverse to form NADH as shown in the figure. ATP synthase catalyzes the proton-gradient-driven phosphorylation of ADP. The periplasm is the region outside the cell membrane; the cytoplasm is inside the cell membrane. The membrane itself is impermeable to protons. Substrates and final products are shown in red (the intermediate hydroxylamine is pink). Protons are shown in green. Electrons are shown in blue and quinone is in light blue. Enzymes and cytochromes are italicized and circled.

the oxidation of ammonia to nitrite by the nitrifying bacterium *Nitrosomonas*, an obligate chemolithoautotroph (Figure 1). Although ammonia is the substrate required for growth, it is the oxidation of hydroxylamine that generates low-potential electrons for energy conversion and reductive biosynthetic reactions. Four electrons are transferred from hydroxylamine oxidoreductase (Table II, line c) to an electron-transfer chain made up of two heme-containing proteins (cytochromes) to two quinone molecules in the membrane. Two electrons from the reoxidation of one quinol are utilized by ammonia monooxygenase to regenerate a molecule of hydroxylamine, i.e., to "re-prime the pump." The two electrons (per hydroxylamine oxidized) from the second quinol may reduce dioxygen in a pathway that involves the two membrane enzymes ubiquinol cytochrome c reductase and cytochrome c oxidase, each of which couple the reaction to the transport of protons against a gradient to the outside (the "periplasm" of the bacterial cell). In this way a steady-state electrochemical potential (outside positive) is maintained across the membrane and "drives" ATP synthesis.

Substrate-Level Phosphorylation of ADP

In one chemolithotroph, a sulfite oxidizing bacterium, the net phosphorylation of ADP occurs by a substrate-level process that is independent of the membrane electrochemical gradient. The key reaction involves the simultaneous dehydrogenation of sulfite and reaction with adenosine monophosphate (AMP) to form the anhydride of phosphoric and sulfuric groups in the product, adenosine phosphosulfate (APS).

$$SO_3^{2-} + AMP \rightarrow APS + 2e^-$$

Phosphate can then displace sulfate to form ADP and the subsequent dismutation of two molecules of ADP provides an ATP.

$$APS + P_i \rightarrow ADP + SO_4^{2-}$$

$$2ADP \rightarrow ATP + AMP$$

Release and Uptake of Protons in Chemolithotrophic Reactions

In the reducing half-reactions of the major chemolithotrophic growth-supporting reductants (Tables II–V) the energetically fruitful reactions are, in effect, dehydrogenases where the products are free protons and electrons transferred to a metal redox center. The protons originate from the substrate (in the oxidation of ethanol, formaldehyde, H_2, N_2H_2, H_2S), H_2O (in the oxidation of CO, nitrite, S^0, SO_3^{2-}) or both (in the oxidation of NH_2OH). In all cases where location of the enzyme has been determined, the proton-yielding reactions are found in the periplasm and thus contribute to maintenance of the positive charge on the outer side of the membrane. Correspondingly, almost all terminal electron acceptor reactions (Table I) consume protons and are located on the internal side of

the membrane thus contributing to the maintenance of the negative charge on that side. This is illustrated in the location of hydroxylamine dehydrogenation and oxygen reduction in *Nitrosomonas* (Figure 1).

Production of NADH by Chemolithotrophic Bacteria

With many chemolithotrophs, the potential of the half reaction that drives metabolism (in the case of *Nitrosomonas*, the dehydrogenation of hydroxylamine) is not low enough to reduce NAD^+ directly. The reduction of NAD^+ is catalyzed by an enzyme which, in chemoorganotrophs, dehydrogenates NADH, reduces quinone, and pumps protons to the outside of the cell. However, in the case of *Nitrosomonas* (Figure 1) and other chemolithotrophs, the reaction runs in the reverse direction; thermodynamically, the steady-state gradient of protons drives the reduction of NAD^+ by quinol. This process is not needed in bacteria such as the hydrogen oxidizers in which the growth-supporting reductive half reaction ($H_2 \rightarrow 2H^+ + 2e^-$) has a low enough potential to reduce NAD^+ directly.

Carbon Source for Chemolithotrophic Bacteria

The carbon source for most chemolithotrophic bacteria is CO_2. This mode of growth is called *autotrophic*, i.e., the organisms are chemolithoautotrophs. Most chemolithotrophs are *obligate* autotrophs, meaning that they can only grow having synthesized all or most of their reduced carbon compounds from CO_2. This contrasts with heterotrophic organisms, which can fulfill all their need for carbon compounds with previously fixed carbons such as sugars. *Facultative* autotrophs are able to alter their content of biosynthetic enzymes to catalyze either the autotrophic or heterotrophic mode of life. The most common pathway of carbon dioxide fixation in the chemolithoautotrophs is the Calvin Cycle starting with the reaction of ribulose bis phosphate carboxylase:

$$\text{ribulose 1,5 bis phosphate} + CO_2 \rightarrow 2,3\text{-phosphoglycerate}$$

Considering the reduction of 3-phosphoglycerate and the regeneration of ribulose 1,5 bis phosphate in the Calvin cycle, approximately 12 molecules of NADH and 18 of ATP are required per hexose synthesized from CO_2. Remarkably, the obligate chemolithoautotrophs contain the enzymes for biosynthesis of all cellular constituents. Furthermore, they have genes for enzymes for the uptake, metabolism, and incorporation of carbon from extremely few carbon compounds other than CO_2. This is illustrated nicely by analysis of the genes present and absent in the genome of *Nitrosomonas*.

Growth Yields of Chemolithoautotrophs

Given the required expenditure of energy (in effect, low potential electrons from the substrate) to drive the synthesis of ATP and the reduction of NAD, which are then used in biosynthetic reactions, the yield of biomass per mole of substrate oxidized is usually much lower in the chemolithoautotrophs than with heterotrophic organotrophs. Profiting from their unique catalytic capabilities, chemolithotrophs grow slowly and live frugally with a highly selective diet of a thin soup of inorganic compounds or small carbon molecules.

Ecology

The chemolithotrophs represent the oxidative segment of the biological cycles of inorganic compounds such as hydrogen, nitrogen, sulfur, and metal ions. The vast majority of these steps occur aerobically. Most of the reduced substrates for chemolithotrophs are generated by the terminal electron accepting reactions of anaerobic organisms (Table I). For example, hydrogen from reduction of protons by organotrophic bacteria in cattle rumen (Table I, line f) is oxidized by chemolithotrophic hydrogen-oxidizing bacteria using the conversion of carbon dioxide to methane as the terminal electron acceptor half-reaction (line h). Methane released from ruminants finds its way to an oxic (aerobic) environment, where it is oxidized by the methanotrophic bacteria (Table III, line b). The chemolithotrophs and the anaerobes are sometimes found at oxic/anoxic (aerobic/anaerobic) interfaces, where the respective oxidative and reductive reactions provide a cycle to the advantage of both types of organism.

There are many examples of economically significant effects of chemolithotrophic activity. The production of sulfuric acid by the sulfur-oxidizing bacteria facilitates corrosion of metals and the acidification of mine drainage is attributed to the iron oxidizing bacteria.

Other major natural sources of the reduced compounds include volcanic activity and atmospheric activity such as lightning. Anthropogenic sources of reduced compounds include agricultural waste and residential waste water, combustion of fossil fuels, industrial processes, and mining operations. Significantly, the annual production of ammonia from dinitrogen by industry now exceeds the flux from all other biological and nonbiological sources.

Respiratory Processes in Anoxygenic and Oxygenic Phototrophs

Glossary

autotrophy A mode of bacterial growth in which carbon dioxide is the source of all or most of the carbon for biosynthesis. These bacteria are *autotrophic*. Autotrophy contrasts with heterotrophy, a mode of growth where organic carbon compounds can provide all carbon for biosynthesis.

chemolithotrophy A mode of bacterial growth in which the reductive substrate for energy generation and for biosynthesis is an inorganic or a single carbon compound. These bacteria are *chemolithotrophic*. Chemolithotrophy contrasts with organotrophy or phototrophy in which the energy generation occurs by the oxidation of organic molecule or absorption of light, respectively.

growth-supporting reductant A compound whose oxidation can be coupled biologically to the conservation of energy in forms of general use to cellular activities: as an electrochemical gradient, as a phosphate anhydride bond in ATP, or as the low-potential reductant, reduced nicotinamide adenine dinucleotide.

oxic environment An environment containing dioxygen (O_2). The word *aerobic* is also used. Oxic contrasts with anoxic (or anaerobic), which applies to environments in which oxygen is absent.

terminal electron acceptor A compound whose reduction can be coupled to the stoichiometric oxidation of the growth-supporting reductant and conservation of energy in cells.

Biography

Alan Bacon Hooper is a Professor in the Department of Biochemistry, Molecular Biology and Biophysics at the University of Minnesota. His research interest is in the biochemistry of the ammonia oxidizing chemolithotrophic bacteria. He earned his B.A. from Oberlin College and his Ph.D. from Johns Hopkins University. He joined the University of Minnesota faculty in 1963. He currently teaches biochemistry and a course on Biology, Ethics, and Public Policy.

Chemotactic Peptide/Complement Receptors

Eric R. Prossnitz and Larry A. Sklar
University of New Mexico, Albuquerque, New Mexico, USA

A critical aspect in the normal function of many cell types is their ability to migrate in response to soluble ligands or chemoattractants. Directional migration, where the cell seeks out the highest concentration of chemoattractant, is referred to as chemotaxis. This is of paramount importance in the immune system where a large collection of G protein-coupled receptors (GPCRs) exists to coordinate the complex interactions of immune cells. These receptors can be divided into two families, the chemotactic or chemoattractant GPCRs that respond to a wide variety of endogenous as well as exogenous ligands and the chemokine GPCRs that respond to the structurally conserved family of endogenous peptide chemokines. The chemotactic GPCRs respond to ligands as varied as oligopeptides, such as bacterially derived N-formylated peptides; proteins, such as complement components; and lipids, such as leukotrienes and platelet-activating factor.

Leukocytes and the Immune System

The immune system is responsible for numerous activities in the body including defense against pathogens (bacterial, viral, and parasitic), removal of dead and cancerous cells as well as the rejection of foreign cells. Leukocytes, or white blood cells, which represent the principal cells of the immune system, are produced as progenitor cells in the bone marrow and mature in various sites throughout the body, including the spleen, thymus, and lymph nodes. Leukocytes can be divided into five broad categories: neutrophils (highly mobile phagocytic cells), basophils (allergy mediators through histamine release), eosinophils (parasitic killing and allergy), lymphocytes (B cells, which produce antibodies and T cells, which effect cell-mediated immunity), and monocytes/macrophages (tissue-specific phagocytic cells). These cells differentially participate in two types of immune responses: innate immunity, an inherent and rapid response of neutrophils, macrophages, and natural killer lymphocytes to foreign materials; and acquired immunity, a selective "trained" response involving lymphocytes requiring prior exposure to the agent. An additional noncellular defensive mechanism, the complement system consisting of at least 20–30 distinct serum proteins, destroys foreign cells through membrane lysis of antibody-targeted cells. Two of the smaller bioactive fragments released by proteolysis from the C3 and C5 components, C3a and C5a, are known as anaphylatoxins and play a major role in inflammation. Immune cells for the most part circulate in the vascular and lymphatic systems, although tissue resident cells such as macrophages are essential to proper immune function. In almost any immune response, however, leukocytes must migrate to the site of damage/infection from the blood. This is a complex multistep process involving inflammatory mediators (such as histamine) that induce vasodilation and increased vascular permeability, activation of adhesion molecules on capillary lining endothelial cells to slow leukocytes and release of chemoattractants to activate leukocytes resulting in firm adhesion to endothelial cells. The concentration gradients of chemoattractants induce the leukocyte to transverse the endothelium and migrate through the tissue to the peak concentration of chemoattractant at the site of inflammation or infection. Having arrived at this site, neutrophils, for example, phagocytose bacteria, generate superoxide radicals and release granules containing degradative proteases. Most of these responses are initiated and regulated by a family of cell surface receptors that bind inflammatory mediators.

Receptors

The largest family of proteins in the human genome is the GPCR superfamily consisting of at least 600 members. GPCRs exhibit a highly conserved structure, consisting of seven transmembrane segments with the amino terminus on the cell exterior and the carboxy terminus in the cytoplasm. The chemoattractant family of receptors consists of proteins with ~350 amino acids. The transmembrane regions consist primarily of α-helices arranged in a bundle. Despite this conserved

structure, there is substantial sequence diversity between members of this receptor family. Binding of small ligands, such as chemotactic peptides, occurs deep within the receptor in the plane of the membrane. Ligand binding and receptor activation result in a conformational change that activates heterotrimeric G proteins, which further stimulate a wide variety of effector proteins. Following activation, GPCRs undergo phosphorylation, resulting in desensitization and internalization, which in turn can lead to receptor degradation or recycling back to the cell surface.

Chemotactic Peptide Receptors

Though identified as a neutrophil receptor for formyl peptides in the 1970s, it was not until 1990 that the FPR gene was isolated, representing the first chemoattractant or chemokine receptor to be cloned. Two human homologues were subsequently identified and designated FPRL1 and FPRL2. Of these, only the former responds, though poorly, to formyl peptides. Although the FPR is expressed predominantly in neutrophils, it also appears to be expressed in monocytes, dendritic cells, hepatocytes, endothelial cells, and the nervous system. FPRL1 and FPRL2 are expressed in some of the same cell types as well as unique sites. Although the human FPR gene family consists of only three members, the number varies considerably in other species, with six members in the murine gene family for example. Thus, distinct evolutionary pressures seem to dictate the repertoire of formyl peptide receptors in a given organism.

The role of the FPR in antimicrobial defense has recently been directly demonstrated in knockout mice lacking mFPR1, the homologue of the human FPR. Although such mice appear normal under unstressed conditions, they demonstrate a lack of neutrophil responses to fMLF challenge as well as an increased susceptibility to infection with *Listeria monocytogenes*. Furthermore, in humans, two variant alleles of the FPR representing single point mutations that disrupt normal function are associated with localized juvenile periodontitis, a result of periodontal bacterial infection. It is perhaps surprising that such defects do not lead to more serious conditions.

Complement Receptors

C5a Receptor

At the same time that formylated peptides were being characterized as chemoattractants, proinflammatory peptides derived from the complement system were similarly being studied. Two receptors have been identified that respond to the cleavage products of the complement components C3 and C5. The C5a receptor is similar in size to the FPR and closely related phylogenetically. Interestingly, there exists little interspecies homology in the extracellular regions of the C5a receptor, despite apparent contact sites with C5a and interspecies activation (C5a from one species activating the receptor from another species). Antibodies against peptides representing the amino terminus of the receptor and amino-terminal truncations of the receptor block C5a binding. As the antibodies do not block activation of the receptor by synthetic C5a carboxy terminal peptides, the amino terminus of the receptor may represent a secondary noneffector binding site and not the primary effector site. Mutagenesis studies suggest a critical role for a number of aspartic acid residues in the amino terminus. Recent evidence is consistent with C5a receptor dimerization, a phenomenon now demonstrated for many GPCRs with unclear functional consequences. Studies of genetically engineered mice lacking the C5a receptor demonstrated that this receptor plays a critical role in clearing pulmonary pseudomonas infections, with mice succumbing to pneumonia despite a marked neutrophil influx.

C3a Receptor

The C3a receptor is unusual in that it possesses a second extracellular loop of some 175 amino acids compared to about 30 amino acids for most GPCRs including the C5a and FPRs. Deletion analysis of this loop suggests that it plays a role in C3a binding and receptor activation, although as much as two-thirds of the loop can be deleted without affecting activity. It is thought that the second extracellular loop may replace the function of the amino terminus of the C5a receptor in providing a secondary noneffector binding site. Recent studies with C3a receptor knockout mice suggest a role for the receptor in allergic airway diseases such as asthma.

Ligands

Chemotactic Peptide Receptors

The first leukocyte chemotactic factors to be defined structurally were the N-formyl peptides. These consist of short oligopeptides consisting of 3–6 hydrophobic amino acids with the amino terminal residue being formylated. Such peptides are not synthesized by eukaryotic cells *per se*. There are only two sources of N-formylated peptides in nature: one endogenous to eukaryotic cells, mitochondria, and the other exogenous, bacteria. Each of these sources initiates protein synthesis with an N-formyl methionine tRNA. This suggests an ideal targeting mechanism for leukocytes to sense bacterial infection or cell damage through the release of peptides containing N-formyl-methionyl peptides.

The first chemoattractant peptide was isolated from bacterial lysates and was identified in 1976 as N-formyl-methionyl-leucyl-phenylalanine (fMLP or fMLF). This agonist is capable of eliciting the full complement of leukocyte functions from chemotaxis to degranulation to superoxide production at concentrations ranging from pM to nM. The FPR is the primary receptor responsible for cellular stimulation in these concentration ranges, whereas FPRL1 responds to fMLF at μM concentrations. Both the FPR and FPRL1 have recently been shown to be activated by a diverse collection of endogenous as well as exogenous peptides. These include non-formylated peptides from exogenous sources such as Helicobacter pylori and HIV-1 envelope proteins as well as endogenous host-derived proteins such as serum amyloid A and peptides from annexin I, amyloid precursor protein and prion protein among others. Lipoxin A4, a lipid metabolite, has also been reported to activate FPRL1. The biological relevance of these agonists remains to be determined. Finally, a number of non-formylated high-affinity peptide agonists for the FPR and FPRL1 have been isolated from peptide libraries. A number of antagonists have also been identified including Boc-FLFLF, cyclosporine H (a fungal metabolite), and deoxycholic acid (a bile acid).

Complement Receptors

C5a

The anaphylatoxin C5a, the most potent plasma-derived chemotactic factor, is a 74 amino acid peptide/protein released from the α-chain of C5 by either the classical or alternative pathway C5 convertases. Structurally, the protein consists of four antiparallel α-helices held together by disulfide bonds and an 11-amino acid carboxy terminal tail. Unlike the small formyl peptides, C5a appears to interact with its receptor at two sites. The α-helical bundle interacts with the receptor's amino-terminal domain whereas the tail appears to insert itself into the transmembrane bundle of the receptor, thereby activating the receptor. Synthetic peptides representing the carboxy-terminal 10-amino acids are full agonists, though with potencies 1000–10 000 lower than C5a itself. The sequence Gln–Leu–Gly–Arg is a highly conserved effector sequence in C5a from numerous species. Substitution of residues within this region can greatly augment potency. Removal of the final arginine residue in C5a results in greatly decreased potency, ranging from 1000-fold decrease for spasmogenic activity to tenfold for chemotactic activity.

C3a

Less is known regarding the interactions between C3a and its receptor. C3a is a 77-amino acid protein released from the α-chain of C3 by either the classical or alternative pathway C3 convertases. C3a and C5a, despite having common genetic ancestry, have markedly different sequences. Only 13-amino acid positions have been totally conserved between C3a, C5a, and the related C4a molecules from numerous species analyzed. Six of these residues represent immutable cysteine residues that direct folding of the protein. Again, the carboxy-terminal sequence seems to define molecular action as the terminal sequence Leu–Gly–Leu–Ala–Arg is conserved in all known C3a molecules. C3a appears to interact both with portions of the large second extracellular loop of the receptor as well as charged residues at the transmembrane boundaries of this loop. For both the C5a and C3a receptors, insertion of the carboxy terminus of the anaphylatoxin into a binding pocket formed by the transmembrane helices of the receptor appears essential to receptor activation.

G Proteins

Following ligand binding and the commensurate activation of the receptor, GPCRs interact with G proteins initiating a vast array of intracellular signaling (Figure 1). Of the four major G protein subfamilies (G_s, G_i, G_q, and $G_{12/13}$), chemoattractant/complement receptors activate primarily the G_i family of G proteins. This is demonstrated by the inhibition of virtually all chemoattractant receptor-mediated cell activation by pertussis toxin, a bacterial toxin that inactivates G_i (and closely related G_o) α-subunits of G proteins. G proteins consist of three subunits: the guanine nucleotide-binding α-subunit, and the nondissociable membrane-associated $\beta\gamma$-subunit dimer. Receptor activation catalyzes the exchange of GDP for GTP on the α-subunit followed by activation of the α- and $\beta\gamma$-subunits. Hydrolysis of the bound GTP by the intrinsic activity of the G_α protein, accelerated by a family of regulators of G protein signaling (RGS) proteins, inactivates the protein and allows reassembly of the inactive $\alpha\beta\gamma$ heterotrimer.

Effector Proteins

Chemoattractant-mediated G protein activation leads to a plethora of downstream signaling events. Although G_i proteins are generally considered to inhibit adenylyl cyclase activity, in the case of most chemoattractant and chemokine receptors, G_i activation leads to $G_{\beta\gamma}$-mediated activation of phospholipase Cβ2, resulting in the production of inositol trisphosphate (IP3) and diacyl glycerol (DAG). IP3 generation results in the release of calcium from intracellular endoplasmic reticulum stores, often followed by the influx of

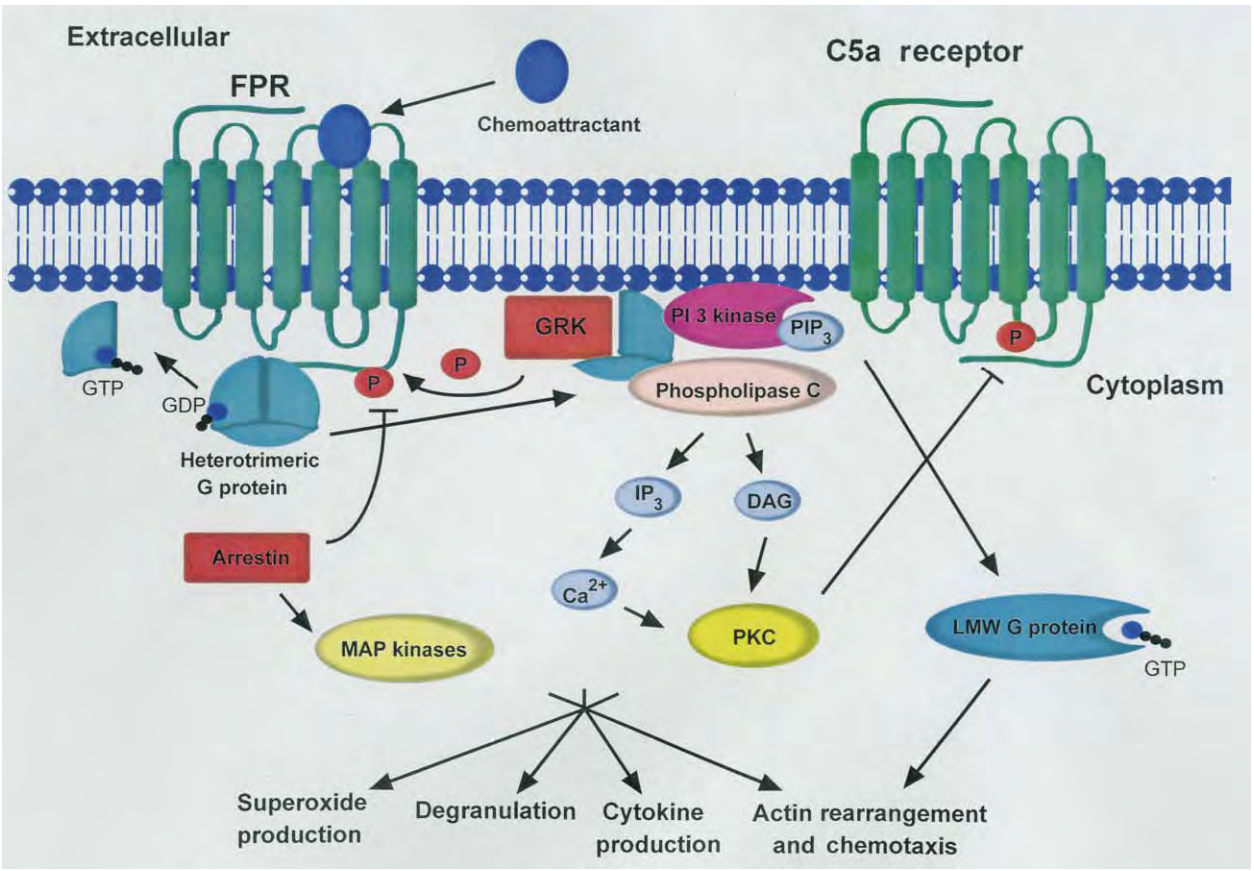

FIGURE 1 Signaling and regulation of chemoattractant/complement receptors in leukocytes. Binding of a chemoattractant (agonist) results in a conformational change in the FPR, which activates G proteins. Dissociation of GDP from the α-subunit is followed by GTP binding and dissociation of the α-subunit from the $\beta\gamma$-subunits, both of which can stimulate downstream effectors. The $\beta\gamma$-subunits provide a docking site for G protein-coupled receptor kinases (GRKs), which phosphorylate (P) the ligand-bound, activated receptor. $\beta\gamma$-subunits also activate phospholipases, which generate diacyl glycerol (DAG) and inositol trisphosphate (IP_3) and phosphatidylinositol-3 kinase (PI_3 kinase), which generates phosphatidyl inositol trisphosphate (PIP_3). PIP_3 is an activator of numerous pathways including those culminating in low molecular weight (LMW) monomeric G proteins of the Ras superfamily that regulate actin assembly and ultimately chemotaxis. IP_3 production results in the release of Ca^{2+} from intracellular stores, and together with DAG activates protein kinase C (PKC). PKC is capable of phosphorylating many proteins including complement receptors, such as the C5a receptor, resulting in their heterologous desenstization. Desensitization of the FPR occurs through the binding of arrestin to GRK-phosphorylated receptors. In addition to preventing further signaling through heterotrimeric G proteins, arrestins serve as scaffolds for multiple MAP kinases, resulting in their localized activation. Together, these and many additional pathways produce cellular responses including superoxide generation, degranulation, chemotactic cell movement and transcriptional activation resulting in cytokine production.

calcium from the extracellular environment through ion channels. The calcium and DAG in turn activate protein kinase C (PKC). Receptor-mediated phospholipase A_2 activation results in the generation of arachidonic acid and subsequently prostaglandins and leukotrienes. Phosphatidylinositol 3-kinase (PI3K) also plays a critical role in leukocyte activation and chemotaxis in particular. MAP kinase family members ERK, p38, and Jnk have all been shown to be essential to cellular activation events. The low-molecular-weight monomeric G proteins Rac and Rap, as well as their associated regulatory proteins and downstream effectors, are important mediators of actin assembly/chemotaxis and superoxide production.

Receptor Regulation

The dysregulated activation of leukocytes is a serious contributing factor to numerous chronic inflammatory diseases such as arthritis and reperfusion injury in ischaemic tissues following myocardial thrombosis and stroke. Activated chemoattractant/complement receptors are rapidly phosphorylated following ligand binding and receptor activation. This can be mediated either by G protein-coupled receptor kinases (GRKs) that are specific for the active state of GPCRs or by second messenger kinases such as protein kinase A and protein kinase C that phosphorylate active and inactive receptors. The latter provides a mechanism

(termed heterologous desensitization) by which GPCRs such as the FPR, which has no PKC phosphorylation sites, can desensitize the C5a receptor, which is phosphorylated by PKC, leading to decreased G protein coupling (see Figure 1). Since any inflammatory process is likely to lead to the generation of multiple simultaneous chemoattractant signals, these regulatory mechanisms create a hierarchy of chemotactic responsiveness to different ligands. GRK phosphorylation of chemoattractant receptors, which occurs within the carboxy terminus of the receptor at sites distinct from PKC sites, leads to binding of arrestins and receptor internalization. Arrestin binding further uncouples receptors from G proteins by physically preventing access of G proteins to the receptor (termed homologous desensitization). For many GPCRs, arrestin binding also mediates interactions with clathrin and adapter proteins such as AP-2 initiating receptor translocation to clathrin-coated pits and subsequent internalization. Contrary to this paradigm, the FPR has recently been shown to internalize in an arrestin-independent manner. However, arrestin is required for recycling of the FPR. Arrestins have also been shown to play an important role in the scaffolding of numerous intracellular signaling cascades including Src and MAP kinases. This mechanism is believed to provide both spatial and temporal regulation of the downstream effectors.

Drug Discovery and Receptor Technology

GPCRs represent ~50% of the targets of drugs on the market today. In particular, the family of chemokine/chemoattractant receptors is a highly sought after target as the receptors are involved in immune disorders such as chronic inflammation and asthma, cancer, and many more disease states. The formyl peptide receptor, in particular, has served as an important model for the real-time analysis of ligand-receptor interactions based on the detection of fluorescent peptide ligands by solution fluorescence, flow cytometry, and microscopy. These ligands and receptors have provided the basis for developing subsecond kinetic resolution of molecular assemblies and disassemblies by flow cytometry as well as small volume, high throughput flow cytometric platforms for screening. These approaches are now being extended to other molecular classes.

Glossary

chemokine A family of structurally related 70–90 aminoacid-long glycoproteins that exhibit potent chemotactic and stimulatory properties on leukocytes.

complement system A series of ~30 components that include proteolytic pro-enzymes, non-enzymatic components that form functional complexes, regulators, and receptors. The proteolytic pro-enzymes become sequentially activated. C5a and C3a are terminal non-enzymatic cleavage products.

G protein A protein that binds and is regulated by guanine nucleotides. Heterotrimeric members of this family couple to GPCRs. Low-molecular-weight monomeric members of the family are activated downstream of heterotrimeric G proteins.

G protein-coupled receptor (GPCR) Transmembrane receptor containing seven membrane-spanning helices that activates cells through coupling to heterotrimeric G proteins.

Biography

Dr. Eric R. Prossnitz is Associate Professor of Cell Biology and Physiology at the University of New Mexico Health Sciences Center. His principal research interest is in the broad field of G protein-coupled receptor activation and regulation, utilizing the N-formyl peptide receptor of leukocytes as a model system. He holds a Ph.D. from the University of California at Berkeley and received his postdoctoral training at the Scripps Research Institute.

Dr. Larry A. Sklar is Regents' Professor of Pathology at the University of New Mexico Health Sciences Center. His principal interests are in signal transduction and cell adhesion molecular assemblies. He holds a Ph.D. from Stanford University and received postdoctoral training at the Baylor College of Medicine.

Chlorophylls and Carotenoids

Hugo Scheer
Universität München, Munich, Germany

The green (Greek "chloros") of leaves (Greek "phyllos") is a mixture of two water-insoluble pigment classes: chlorophylls, mainly the blue chlorophyll (Chl) *a*, and carotenoids, mainly *β*-carotene. Both pigment classes cooperate in photosynthesis to safely capture light provided by the Sun, as the primary energy source for life on Earth. Chlorophylls are responsible for light harvesting and its transduction to an electrochemical potential across the photosynthetic membrane which ultimately serves to reduce atmospheric carbon dioxide to carbohydrates. Thus, the energy of the fleeting photons is stored in increasingly longer-lived products: first Chl excited states are generated with lifetimes in the order of several nanoseconds (10^{-9} s), then a membrane potential which is stable for seconds, then high-energy products such as ATP and NADH that live for minutes or even hours, and eventually storage products like starch.

The carotenoids can act, too, as light-harvesting pigments, in regions where Chl has only little absorption. Their major and indispensable function is, however, to safely drain excess excitation energy from the chlorophylls and convert it into heat. Photons are by biological standards a high-energy source which is potentially highly toxic (sunburn). The combination of chlorophylls with carotenoids allows photosynthetic organisms a careful balance between tapping and competing for this source, and being killed by an overdose. Photosynthesis based on these two pigments has therefore conquered nearly all habitats on earth where light is available. It has produced the atmospheric oxygen we breathe, and fixes $\sim 10^{11}$ ton of carbon annually. The greening and degreening of the vegetation is probably the most obvious life-process on Earth, visible clearly from outer space. The widespread occurrence of photosynthesis is paralleled by considerable variations of the photosynthetic apparatus, including the pigments. It is this variety, but also the basic similarities among the different chlorophylls and carotenoids, respectively, which will be dealt with in this article.

Chlorophylls

Structures

The basic structure of chlorophylls is the porphyrin macrocycle. It is comprised of four pyrrole rings containing each four carbons and one nitrogen, which are joined via one-carbon bridges to an aromatic macrocycle (Figure 1). The four nitrogens face inward, creating a hole which is ideal for binding metal ions. In the chlorophylls, this central metal is almost always magnesium (Mg). While many of the peripheral substituents vary among the different structures, all chlorophylls contain an additional five-membered ring E and, with the exception of some Chl *c*, the C-17 propionic acid side chain is esterified by a long-chain alcohol, usually the C_{20} terpenoid alcohol, phytol. The chlorophylls can further be classified by the degree of unsaturation of the macrocylus, into the fully unsaturated true porphyrins, the chlorins with an unsaturated ring D and the bacteriochlorins in which ring B is unsaturated, too.

Spectroscopy

The spectral properties of chlorophylls are described by the four-orbital model: chlorophylls have four major absorptions termed Q_Y, Q_X, B_Y, and B_X, in the near ultraviolet (NUV), visible (Vis), and near infrared (NIR) spectral regions. The type of spectrum is mainly determined by the degree of unsaturation of the tetrapyrrole macrocycle (Figure 2): in the fully unsaturated Chl *c* containing a porphyrin macrocyclic system, the B-bands around 400 nm overlap, the Q_Y-band around 620 nm is weak, and Q_X-band is visible only with special techniques. In chlorin-type chlorophylls (Chl *a, b, d,* BChl *c, d, e*), the B-bands are reduced in intensity, the Q_X-band increased to near equal intensity and redshifted to $\sim$660 nm. In the bacteriochlorin-type chlorophylls (BChl *a, b, g*), the B-bands are blueshifted to $<$400 nm and well separated, the Q_y-band is even more increased in intensity and redshifted to $\sim$780 nm, and in these pigments the Q_y-band also has gained in intensity and becomes visible around 570 nm. By these characteristics, the chlorophyll type can be readily determined from the spectra, and often also other details like substitution pattern, ligation to the central metal (e.g., by the protein), or aggregation.

Chlorophylls dissolved in organic solvents have long-lived excited states (10^{-8} s). They are therefore highly fluorescent, and there is significant intersystem

FIGURE 1 Structures of common chlorophylls. In particular, reaction centers contain a series of specialized chlorophylls which are being dealt with in a recent survey by M. Kobayashi and co-workers in 1999.

crossing to the triplet state, giving rise to phosphorescence and, more significantly, under aerobic conditions to the generation of highly reactive oxygen species (ROS) like singlet oxygen. Chlorophyll solutions therefore bleach rapidly by attack of the pigment by these ROS, and chlorophylls injected into animals lead to severe "sunburn" and destruction of tissue. This effect is used in photodynamic therapy (PDT) of cancer.

In chlorophyll aggregates, there is generally a pronounced redshift of the Q_Y-band, and the excited state lifetimes (and thereby fluorescence and phosphorescence) are drastically reduced due to rapid conversion of the excitation energy into heat by internal conversion (IC). These effects are summarized under the term "concentration quenching" and probably due to the presence of "traps" in the large aggregates in which the excitation is highly delocalized over many pigment molecules.

Aggregation is also observed in photosynthetic pigment–protein complexes, where it is considered a major organizing force. In addition, there is a general redshift of all bands brought about by the protein environment. There is, however, a very distinct difference to aggregates: while excitation energy is mainly transformed to heat in the latter, this loss is avoided in the pigment protein complexes. Isolated light harvesting complexes (LHC), which contain the vast majority ($\geq 99\%$) of chlorophylls, therefore show, under moderate light intensities, high fluorescence. The avoidance of concentration quenching in these aggregates is in fact one of the major, mechanistically still unresolved tricks of efficient photosynthesis. In the reaction centers

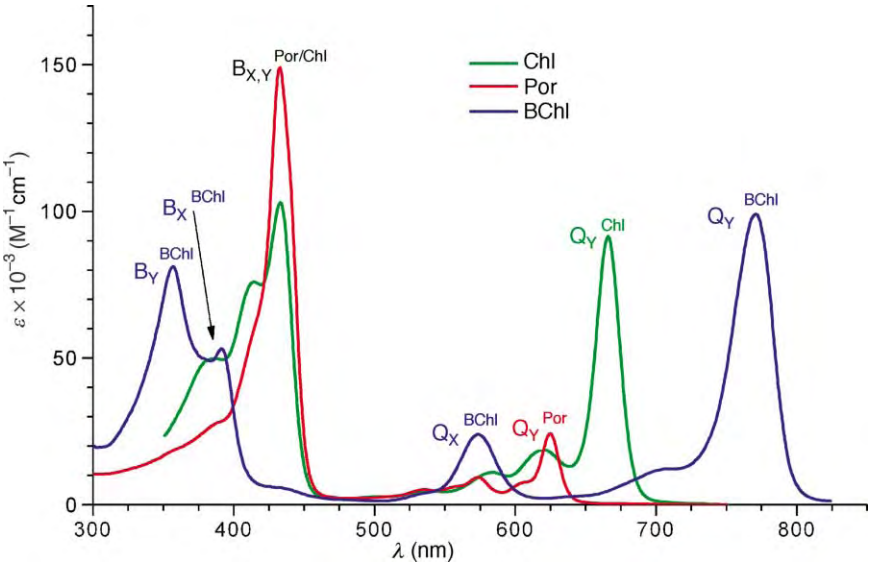

FIGURE 2 Type spectra of the three chlorophyll classes: porphyrins (Por), chlorins (Chl), and bacteriochlorins (BChl).

(RCs), the lifetime is short, but here the excitation energy is used to create, with quantum efficiencies near 100%, a charge separation across the photosynthetic membrane which is otherwise an insulator, thus creating a long-lived membrane potential. This energy transduction process is at the heart of photosynthesis, and the high-resolution crystal structures of RC together with extensive spectroscopy at high time-resolution have provided a general picture on how this process is working. In the photosynthetic apparatus, LHC containing >99% of the chlorophylls are coupled to RC, such that now the excitation energy of the former is efficiently transferred to the latter. By this means, the absorption is increased by orders of magnitude, and different numbers and types of LHC can be combined to adapt to the prevailing light conditions. Since the amount of protein is much less in LHC than in RC, the biosynthetic expenses for such a coupled system are at the same time strongly reduced.

Occurrence and Functions

The majority of chlorophylls, both in terms of structure diversity and quantity, serve as light-harvesting pigments. Taken together, they absorb light across most of the spectral range from 350 to 1020 nm, with a gap only in the region from 500 to 600 nm where carotenoids and biliproteins add to light harvesting. No organism contains all types of chlorophylls, however, so different organisms occupy different spectral niches, and the pigmentation is an important taxonomic criterion. Due to the more demanding energetics, oxygenic organisms (plants, algae, cyanobacteria) can only use light <730 nm, while the anoxygenic photosynthetic bacteria have specialized in the NIR with extremes like the purple bacterium, *Blastochloris viridis*; reaching 1020 nm. RCs contain chlorophylls, too, including besides the bulk pigments some specialized derivatives. They form a chain of pigments across the membrane, over which in a stepwise fashion electrons are transferred from the primary donor, a pair of chlorophylls located on the periplasmic side of the membrane, to the acceptors on the cytoplasmic side. It should be mentioned that some chlorophyll-like pigments perform other functions in nature: certain deep-sea fish use chlorophylls as visual pigments, and in the marine worm, *Bonella viridis*, a chlorophyll-derivative acts as a sex determinant.

Chemical Properties

Chlorophylls are large, aromatic molecules with a central hole fit to complex many metals. They are basically planar, but not rigid, and deviations from planarity are observed in most structures of chlorophyll proteins. While the macrocyclic system is quite stable, the functional groups and the central Mg render the chlorophylls quite labile. Under acidic conditions, the central Mg is lost rapidly, and the long-chain alcohol residue hydrolyzed. The central Mg is also readily replaced by other, more stable metals like Zn, Ni, Ag, Cu. Under alkaline conditions, the isocyclic ring is modified extensively. The macrocycle can be opened at the methine bridges, both (photo)chemically and enzymatically.

After binding to the tetrapyrrole, the central Mg still has free valences, which are important for aggregation, and in particular for interactions with the natural protein environment. By interactions with suitable amino acids (e.g., histidin, methionin, glutamate) they can be positioned properly for efficient energy or electron transfer. In the LHC of green bacteria, the chlorosomes, the coordinating properties of the central Mg and the ligation of special peripheral substituents

combine to form large aggregates of bacteriochlorophylls *c*, *d*, and *e* nearly devoid of protein.

Metabolism

The formation of chlorophylls can be separated in stages. The first is the synthesis of 5-aminolevulinic acid (ALA), the basic building block of all tetrapyrroles. In most organisms it is formed from glutamic acid, involving an intermediate (Glu-tRNA^{glu}) which is otherwise only involved in protein synthesis. Some photosynthetic bacteria (purple bacteria) use, like man, the alternative C_{4+1}-pathway in which succinyl coenzyme A is condensed with glycin. The second stage is ubiquitous in all organisms and for all natural tetrapyrroles. The two ALA first react to yield a pyrrol (porphobilinogen), a five membered ring containing one nitrogen atom. Four such pyrroles then condense to a linear tetrapyrrole, and then cyclize in a remarkable reaction in which one of the pyrroles is flipped. The resulting cyclic tetrapyrrole is transformed by a series of decarboxylation and oxidation reactions to protoporphyrin. It is noteworthy that the latter is the first colored product in the synthesis, and highly phototoxic like most porphyrins. The organisms therefore avoid, over large stretches of biosynthesis, the formation of such potentially harmful precursors. They also regulate precisely the amount of ALA in order to avoid any overproduction of protoporphyrin, and any deregulation of this process, as any alteration of the biosynthesis can result in severe damage and often death. The last stage of the pathway is the insertion of Mg, which is thermodynamically unfavorable and energy requiring, and the formation of the isocyclic ring from the propionic acid side chain at C-13. While the synthesis of Chl *c* is practically complete at this stage, all other chlorophylls require further modifications, viz., the reduction of ring D (chlorins) and B (bacteriochlorins), modifications at the periphery, and the condensation of the C-17 propionic acid with the long-chain alcohol derived from the isoprenoid pathway.

Chlorophyll degradation has been studied in some detail for Chl *a* and *b*, it involves the (light independent) ring-opening to the much less phototoxic open-chain tetrapyrroles (bilins). Very little is known on the degradation of the other pigments.

Applications

Unmodified chlorophylls are too labile for most practical use, but some derivatives are used as dyes for cosmetics and food (Cu-chlorophyllin), and in photodynamic tumor therapy (chlorins, bacteriochlorins). The "chlorophyll" used, e.g., in certain health care is a complex mixture of degradation products. The best source for Chl *a* is the cyanobacterium *Spirulina platensis*, which is available commercially. Chl *a*/*b* mixtures can be obtained from all green plants. All other chlorophylls are less readily accessible, thereby limiting their applications.

Carotenoids

Structures

Carotenoids much more widespread and not confined to photosynthetic organisms, and structurally and functionally more diverse than chlorophylls. There are currently more than 800 natural carotenoids known, each of which can form several *cis–trans* isomers and be further modified. Chemically, most carotenoids are tetraterpenes: two C_{20}-units (originally geranyl-geraniol) are joined tail-to-tail to a chain of 32 carbon atoms bearing eight methyl side chains. Often, this basic carbon C_{40}-skeleton is either retained, or only slightly modified, e.g., by cyclization at one or both ends (Figure 3). However, much more extensive modifications are possible, including isomerization and rearrangement of the double bonds, the introduction of oxygen-containing functional groups, and their glycosylation or acylation. This modification seems to be particularly far-reaching in carotenoids dedicated to light harvesting, as exemplified by peridinin; a highly modified C_{37} pigment from algae.

Spectroscopy

The rod-shaped carotenoids show the typical absorption spectra of linear polyenes, which are characterized by some unusual features. (1) The lowest energy $S_0 > S_1$ transition located in the red to NIR spectral range, is extremely weak (optically forbidden) in most carotenoids, and has been accurately determined only in few pigments by special techniques. (2) The most intense absorption, responsible for the yellow-orange color of most carotenoids, is a series of closely spaced, sometimes overlapping bands in the 400–550 nm range. With an increasing number of conjugated double bonds, this absorption is shifted, in an asymptotic fashion, to the red. The sub-bands are generally well resolved, but can be broadened to a degree that they appear only as a single, somewhat structured band. (2) There is at least one other transition between these two bands, which again is forbidden and therefore very weak. (4) *cis*-Carotenoids show an additional, typical band 100–150 nm to the blue of the main absorption (see Figure 4 for type spectra). Although the "forbidden" bands do not contribute to absorption, they are fundamentally important for the biological functions of carotenoids. The states responsible for them can be reached indirectly, e.g., after absorption into the energy-rich major absorption band and IC, or by energy transfer from neighboring pigments like chlorophylls,

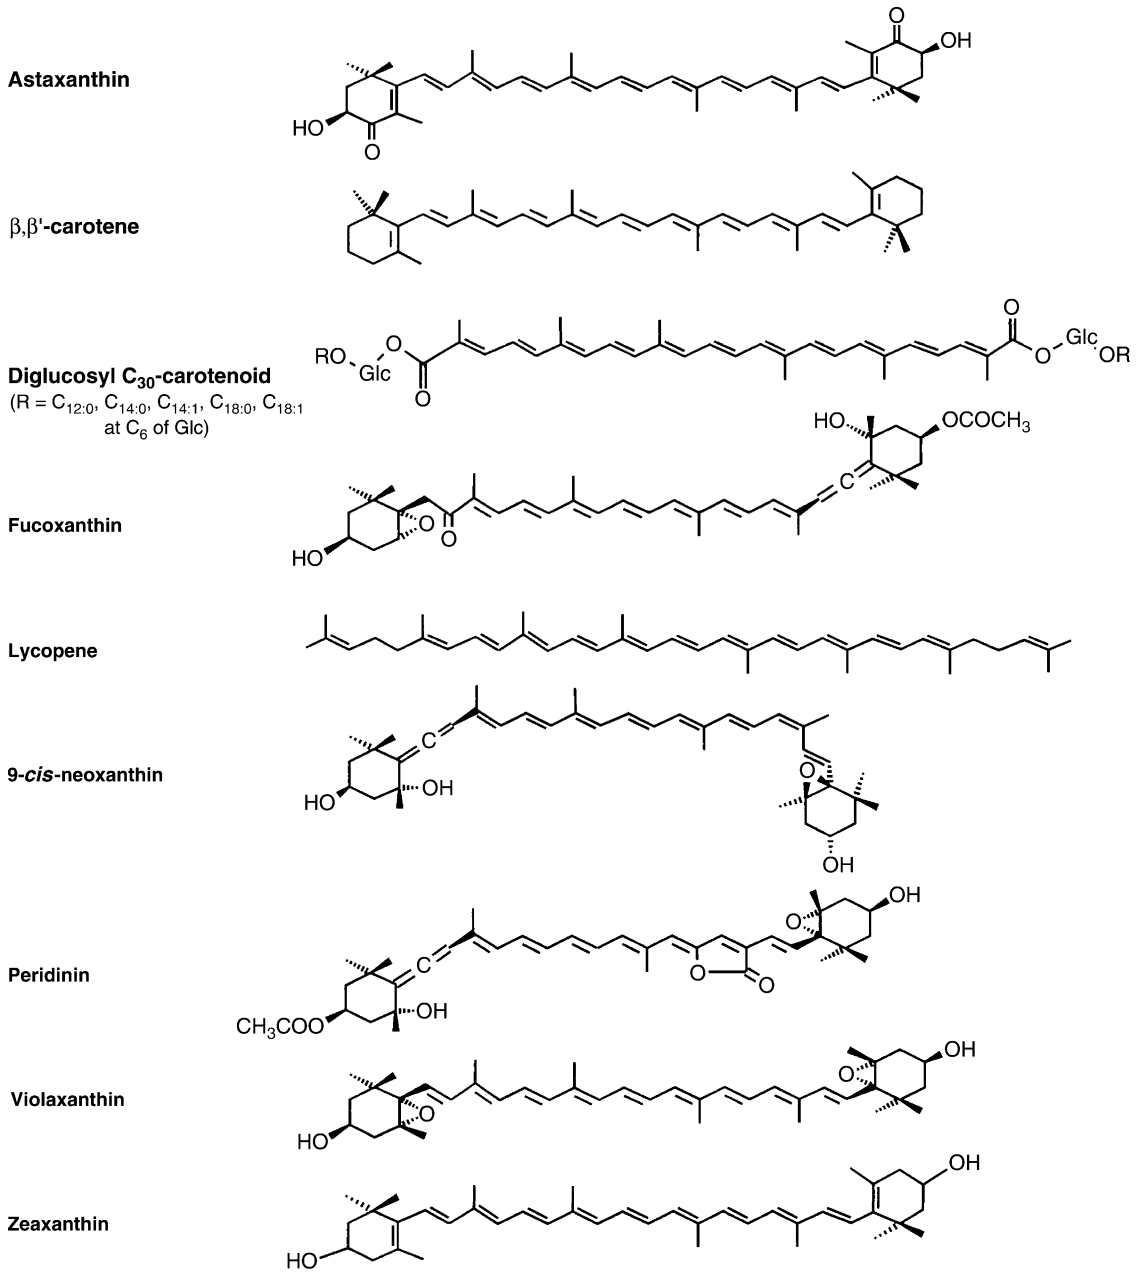

FIGURE 3 Example of carotenoid structures.

and they thereby contribute to energy transfer and dissipation.

Most carotenoids show extremely rapid IC from all excited states, and therefore negligible fluorescence, with lifetimes in the range of only a few picoseconds. Carotenoids have unusually low-lying triplet states, many of them even below the energy of singlet oxygen (1250 nm). Again, they can be reached only indirectly, mainly via energy transfer from triplets (e.g., of chlorophylls) or from singlet oxygen. Since the latter are highly cytotoxic, this property is functionally very important, too, because it is the basis for the protective effects of carotenoids.

The spectral properties of carotenoids can be modified considerably by interactions with the protein. A spectacular case is the color change of astaxanthin from orange to green when it is bound in the crustacean protein, α-crustaxanthin, and its reversion when the protein is denatured by boiling.

Occurrence and Functions

Carotenoids are almost ubiquitous in living organisms, even though animals including man can not synthesize them but have to rely on dietary supplies.

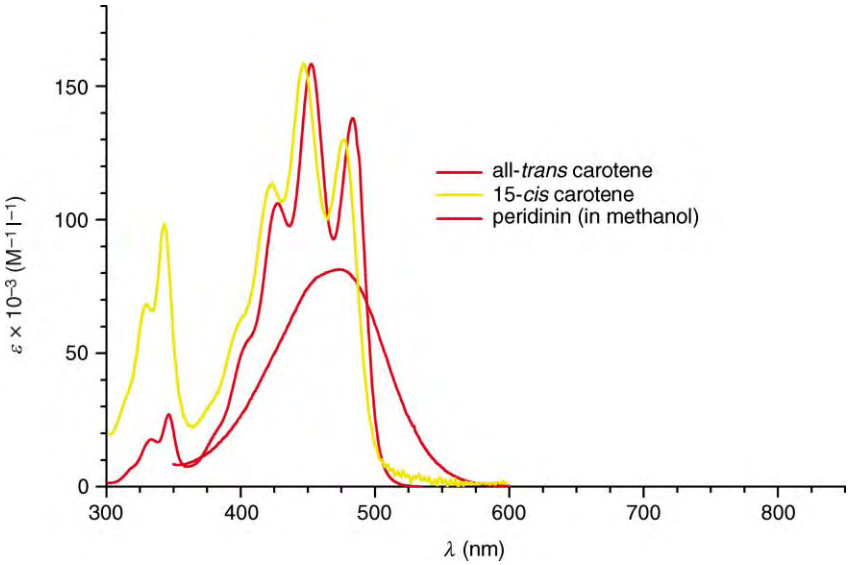

FIGURE 4 Type spectra of carotenoids.

Their functions are as diverse as their structures. In photosynthesis, their essential function is the protection of the photosynthetic apparatus under conditions of light overload. Whenever the RC cannot follow the energy input from the LHC, the long-lived excited states of the chlorophylls pose a deadly danger to these organisms due the formation of ROS. This is prevented by carotenoids at several levels. They can accept excess energy via their low-lying "forbidden" states, they can quench chlorophyll triplets by triplet energy transfer to the low-lying carotenoid triplets, and they can quench ROS by energy transfer, e.g., from singlet oxygen, or addition of ROS to the double bond system. All these processes require very close distances between donor and acceptor, which is nicely corroborated by X-ray structures of photosynthetic complexes. Specialized carotenoids are found in contact to chlorophylls in the RC and in all chlorophyll-containing LHC. In the latter, they seem to be positioned strategically at critical sites where the energy is funneled to the RC.

Since ROS are also important in the attack of infectious agents by the immune system, bacteria synthesize carotenoids for their protection, and many of the more virulent forms are deeply colored by carotenoids.

Carotenoids also protect from light, simply by their function as light filters, removing NUV and blue light by virtue of their high absorption in these spectral regions, and their capacity to rapidly degrade the excitation energy to heat by IC. Certain algae tolerant to extreme light stress contain droplets of pure carotenoids. And many non-photosynthetic organisms synthesize carotenoids when subjected to increasing light intensities. As nonphototoxic pigments, carotenoids often function as "safe" dyes in nature. Examples are the colors of flowers used for attracting insects, or of crustaceans to blend into the marine background.

In spite of their general protective function, carotenoids have also been adapted by photosynthetic organisms for light harvesting in the "green gap" (470–600 nm) where chlorophylls absorb only poorly, in particular in microalgae and phototrophic bacteria which cannot outgrow their competitors. Two factors are important to this function. One is the development of carotenoids in which the excited state lifetime is somewhat increased, and therefore IC reduced. The two most abundant carotenoids, fucoxanthin and peridinin, show this very nicely with lifetimes reaching more than 100 ps. The second factor is to position the carotenoids in contact with chlorophylls, thereby speeding up energy transfer sufficiently to be effective within the short excited state lifetimes (electron exchange mechanism). Since the direction of energy transfer depends on the relative energies of the excited states, they have to be properly ordered: for light harvesting, the carotenoid excited state needs to be above that of the neighboring chlorophyll; for protection it needs to be below. There is evidence that plants and some algae use, in the so-called violaxanthin cycle, subtle structural modifications in order to manipulate the excited state energies of carotenoids, thereby converting a light harvesting into a protecting pigment, and vice versa, in response to the light supply.

Last but not least are carotenoids precursors for certain important metabolites. Only two examples are stated. (1) Retinal, the chromophore of the visual pigment rhodopsin, is derived from carotene. Since the latter cannot be synthesized by animals, they need it supplied as provitamin A. Retinal derivatives are also required for other regulatory functions.

(2) Certain fragrances of roses have also been shown not to be synthesized directly, but rather to be breakdown products of the flowers' carotenoids.

Chemical Properties

Due to their hydrocarbon skeleton, almost all are insoluble in water and well soluble in nonpolar solvents. The conjugated double-bond system is chemically moderately stable. It is subject to rearrangements, in particular in the light, and to additions, for example, of oxygen. The chemical properties of the more highly modified carotenoids are determined by their particular functional groups.

Metabolism

Carotenoids, like all terpenoids, are products of the isopentenyl-pyrophosphate metabolism. This intermediate can be synthesized either by the mevalonate pathway from acetyl-coenzyme A, or via the more recently discovered deoxyxylulose pathway. While still under study, the latter seems to be the pathway leading to carotenoids in most photosynthetic organisms. One of the resulting C_5-units (dimethylallyl-pyrophosphate) is condensed sequentially by prenyl transferases in a head-to-tail fashion with three isomeric C_5-units (isopentenyl-pyrophosphate) to yield geranylgeranyl-pyrophosphate (GGPP), an important branching point in terpenoid metabolism. GGPP is, for example, directly or indirectly, the substrate for esterifying the C-17 propionic acid side chain of most chlorophylls, thereby linking the tetrapyrrole- and terpenoid pathways. The biosynthesis directed to carotenoids begins with a tail-to-tail condensation of two molecules of GGPP by the dedicated enzyme phytoene synthase. Having only three conjugated double bonds, the resulting phytoene is still uncolored. Dehydrogenation by desaturases via phytofluene to lycopene is common to most carotenoids currently known. C_{30} carotenoids are derived from condensation of two C_{15}-units (farnesol-pyrphosphate) in an otherwise very similar reaction sequence. A wide variety of enzymes, many of them still poorly characterized, is responsible for further structural modifications. They include cyclases to form the end rings characteristic of many carotenoids, oxygenases to introduce OH groups, isomerases and (de)hydrogenases to modify the double-bond system, and many more follow-up enzymes allowing for the structural variety of carotenoids.

Applications

The most frequent applications of carotenoids, which are of considerable economic importance, are as food colorants, as dietary supplies, and as sun screens in cosmetics. Food is frequently colored indirectly, e.g., by supplying carotenoids or carotenoid-rich algae in the feedings of fish (salmon) or poultry (chicken eggs). Provitamin A (β-carotene) is supplied directly but also indirectly, e.g., as milk supplement. Industry scale synthetic methods have been developed, natural sources are algae such as *Hematococcus*, plants such as carrots, and genetically manipulated bacteria.

Glossary

absorption The process of interaction of a molecule with a photon to produce an excited state.

excited states More precisely, electronically excited states; there are usually generated by light absorption in molecules containing a large number of conjugated double bonds. Singlet and triplet states are distinguished by their lifetimes. If the ground state is a singlet, as in practically all dyes, excited singlet states are short lived (10^{-12}–10^{-8} s), and the lowest triplet states are long-lived (up to milliseconds). If the ground state is a triplet, one of the rare cases being molecular oxygen, the lowest excited singlet state is long lived.

fluorescence It is the spontaneous decay of an excited state to the ground state with the concomitant emission of the energy in the form of a photon. Together with phosphorescence, which is distinguished from fluorescence mainly by its longer timescale ($>10^{-6}$ versus $<10^{-8}$ s), they are often summarized as luminescence.

internal conversion The spontaneous decay of an excited state to the ground state with the concomitant release of the energy in small packages as heat. It is a so-called loss channel, because the heat is (generally) of no use in biology, but is, by the same token, important in light protection, e.g., by preventing photosensitized generation of reactive oxygen species.

isoprenoids These are compounds derived from the branched C_5-unit, isoprene. Besides carotenoids, important natural isoprenoids are the steroids, gibberellins (plant hormones), mono-, sesqui-, and diterpenes (fragrances and flavors), and polymers like rubber.

photodynamic therapy (PDT) This is the diagnostic and therapeutic application, for example in treatment of cancer, which relies on photosensitizing dyes, light, and oxygen to selectively attack cells, virus, tissue, or organs.

photosensitization The process of indirectly generating reactive oxygen species by triplet energy transfer. A sensitizing dye is excited by light to the singlet state. This reacts spontaneously to a long-lived triplet state, capable of generating reactive oxygen species by several mechanisms.

photosynthesis The natural process of plants, algae and certain bacteria by which (sun)light is converted to biochemical energy (carbohydrates), which is eventually the primary source for life on Earth.

reactive oxygen species (ROS) These species comprise several highly aggressive and cytotoxic chemicals derived from oxygen and often produced by action of light, including singlet oxygen, superoxide, peroxide, and hydroxyl radicals.

tertrapyrroles These are compounds comprised of four pyrrole rings. In natural tetrapyrroles, they are linked either directly or by single carbon bridges, and they can by linked in a linear (bile pigments) or a cyclic fashion (hemes, chlorophylls, vitamin B_{12}).

Biography

Hugo Scheer studied chemistry in Braunschweig, Germany. After graduation he spent 3 years with J. J. Katz and J. R. Norris at Argonne National Laboratory, USA, and then went in 1975 to the Universität München, Germany, where he became Professor of Plant Biochemistry. His research interest is in chlorophylls and plant biliproteins, with a focus on their functions, on pigment–protein interactions, and on their use as probes in protein dynamics and in photodynamic therapy of cancer.

Chloroplast Redox Poise and Signaling

John F. Allen
Lund University, Lund, Sweden

Chloroplasts are membrane-bound compartments (organelles) in plant and algal cells. Chloroplasts perform all of the component reactions of photosynthesis, including absorption of light energy by chlorophyll; conversion of that energy into chemical potential; electron transfer; synthesis of ATP; and assimilation of carbon dioxide to give carbohydrates. Primary steps in photosynthesis are light-driven redox (reduction–oxidation) reactions; transfer of electrons or hydrogen atoms. These redox reactions function safely and efficiently only within a narrow range of degrees of reduction of their reactants and products. In electron transport pathways, each intermediate must be capable of acting as both an acceptor and a donor, and must therefore be present in both its oxidized and its reduced form. An optimal state of redox poise is achieved by a variety of regulatory mechanisms, operating on different stages of gene expression. Redox signaling occurs when a signal of redox imbalance initiates a change that corrects that imbalance, restoring poise. The response may be within or between cells, and may concern chloroplast or nuclear gene expression. Chloroplast redox signaling utilizes the chloroplast genome and apparatus of gene expression. Redox signaling may require, and be the reason for, both chloroplast and mitochondrial genomes.

The Redox Chemistry of Photosynthesis

Redox Reactions and Photosynthesis

A redox reaction involves an electron or hydrogen atom donor, and an electron or hydrogen atom acceptor. During the course of the redox reaction, as the electron or hydrogen atom is transferred, the donor reduces the acceptor, and the acceptor oxidizes the donor. Thus, an electron (or hydrogen) donor is a chemical reductant, and an electron (or hydrogen) acceptor is a chemical oxidant. The direction of electron (or hydrogen) transfer between two chemical species is determined by their relative activities and also by their relative electrochemical potentials, or redox potentials, as given by the Nernst equation. A species with a lower redox potential will tend to act as a reductant, or donor, when coupled in a redox reaction with a species with a higher redox potential, acting as the oxidant, or acceptor.

In photosynthesis, light-driven electron transport may be cyclic, or linear (also known as "noncyclic"). Linear electron transport requires an electron donor and an electron acceptor. In many bacteria the donor is an organic compound, or an inorganic reductant such as H_2S or H_2. In cyanobacteria and chloroplasts, the donor is water, and oxygen is released as a by-product. The electron acceptor is $NADP^+$. Together with ATP produced by photosynthetic phosphorylation, NADPH represents stored energy, which may be used to drive carbon dioxide assimilation and processes including synthesis (e.g., protein synthesis) and transport.

van Niel and Bacteria

Photosynthesis occurs in bacteria, and in most plants and algae. Even in eukaryotes, photosynthesis is localized in chloroplasts, which are bacterial in origin. The microbiologist Cornelius van Niel, working in Stanford, California, showed that photosynthetic bacteria use light as a source of energy to cause hydrogen atom transfer to carbon dioxide, from any one of a range of weak reducing agents, collectively designated "H_2A" in a reaction described by the van Niel equation:

$$2H_2A + CO_2 \xrightarrow{\text{light}} CH_2O + 2A + H_2O$$

In the special case of oxygenic photosynthesis in plant and algal chloroplasts and in cyanobacteria, the weak reducing agent (H_2A) is water (H_2O), and the van Niel equation then becomes:

$$2H_2O + CO_2 \xrightarrow{\text{light}} CH_2O + O_2 + H_2O$$

The Hill Reaction

Independently, Robert (Robin) Hill, in Cambridge, showed that chloroplasts isolated from leaves

produce oxygen in the light, provided a suitable electron acceptor, or "Hill oxidant" is available ("A," below):

$$2H_2O + 2A \xrightarrow{\text{light, chloroplasts}} 2AH_2 + O_2$$

Assimilation of CO_2 by reoxidation of AH_2 will give "complete" photosynthesis, and its overall formulation is identical to a simplified version of the oxygenic version of the van Niel equation:

$$H_2O + CO_2 \xrightarrow{\text{light, chloroplasts}} CH_2O + O_2$$

Reaction Centers

How does light drive electron or hydrogen atom transfer? Louis Duysens, in Leiden, and others demonstrated light-induced oxidation of chlorophyll (Chl) at photosynthetic reaction centers, and it became clear that some chlorophyll molecules themselves undergo photo-oxidation after absorbing a quantum of light and reaching an excited state (Chl^*). Photosynthetic electron transport is initiated when the chlorophyll excited state decays to a ground state by passing an electron on to an acceptor (A), and by taking one from a donor (D):

$$DChlA \xrightarrow{\text{light}} DChl^*A \rightarrow DChl^+A^- \rightarrow D^+ChlA^-$$

The Z-Scheme and Two Photosystems

In 1960, Robert Hill and Fay Bendall proposed a "Z-scheme" for photosynthetic electron transport, in which two separate photosystems, termed I and II, each with a core reaction center, act as intermediates in the chloroplast electron transport chain. The two photosystems are connected, in series, by electron carriers (Figure 1).

Chloroplast Function

Intrinsic to internal membranes called thylakoids, chloroplasts contain chlorophyll and other pigments (such as carotenoids) that harvest and convert light energy, an electron transport chain that intersects with light-harvesting pigments at photosynthetic reaction centers, and an ATPase that couples electron transport with synthesis of ATP. The soluble phase of the chloroplast usually contains the enzymes and intermediates of the Benson–Calvin cycle of assimilation of carbon dioxide. In development, chloroplasts originate from plastids in parallel with nonphotosynthetic plastids with other specific functions in metabolism. Although most plastid proteins are imported from the cytosol, as precursors, all plastids also contain DNA, RNA, ribosomes, and a genetic system, which is responsible for synthesis of some of their components.

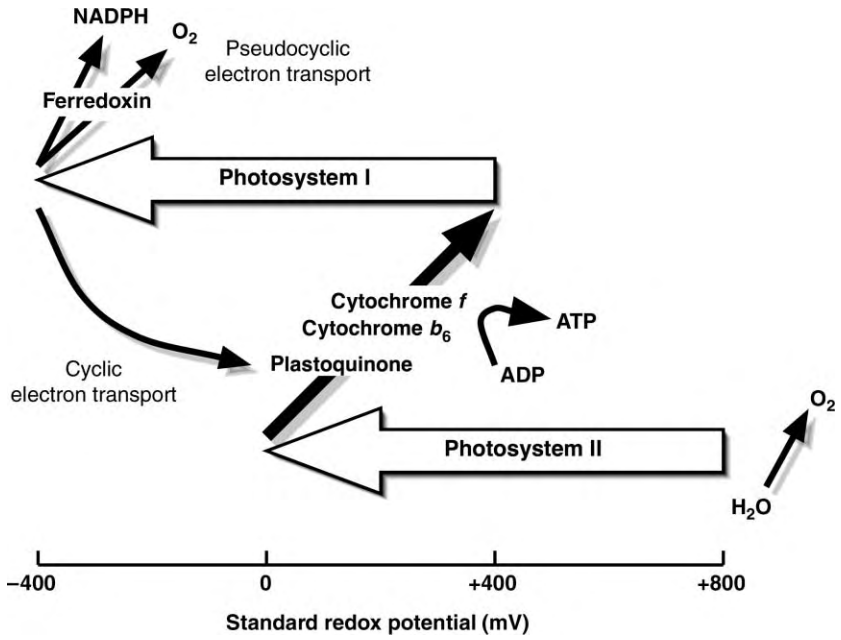

FIGURE 1 The two-light reaction model, or "Z-scheme," for photosynthetic, noncyclic electron transport and photophosphorylation (ATP synthesis) in chloroplasts. Noncyclic electron transport involves photosystems I and II, which are connected in series. The cyclic and pseudocyclic pathways are superimposed on the noncyclic pathway.

Chloroplasts, in particular, still bear a striking resemblance to prokaryotic cyanobacteria, from which all plastids evolved.

Photophosphorylation

In 1954, F. R. (Bob) Whatley, Mary Belle Allen, and Daniel I. Arnon, in Berkeley, California showed that isolated chloroplasts carry out ATP synthesis in the light, a process also demonstrated for isolated bacterial membranes by Albert Frenkel:

$$ADP + P_i \xrightarrow{\text{light, chloroplasts}} ATP + H_2O$$

Cyclic

The original chloroplast photophosphorylation of Whatley, Allen, and Arnon was not accompanied by net redox changes, and is coupled to cyclic electron transport. In the Z-scheme, this cyclic electron transport drives cyclic photophosphorylation, and requires photosystem I alone (Figure 1), although photosystem II activity and other factors greatly affect its onset.

Noncyclic

The Arnon group later showed that ATP synthesis is also coupled to the Hill reaction, and the yield of ATP occurs in a fixed stoichiometry with reduction of a Hill oxidant. There is thus a distinction between cyclic and noncyclic photophosphorylation. After 1960 it was realized that noncyclic photophosphorylation normally requires both photosystems I and II (Figure 1).

Pseudocyclic

In 1952, Alan Mehler discovered that molecular oxygen will act as a Hill oxidant. Noncyclic electron transport (Figure 1) with oxygen as the terminal acceptor is coupled to ATP synthesis, and requires photosystems I and II. However, oxygen is both consumed and produced in this reaction, no net oxidation–reduction is observed, and so the ATP synthesis resembles cyclic one, and is known as pseudocyclic phosphorylation.

Kinetics and Maintenance of Redox Poise

The interplay between noncyclic, pseudocyclic and true cyclic photosphosphorylation first gave rise to the concept of "redox poise" in chloroplast photosynthesis. If the photosystem I of the Z-scheme (Figure 1) is the same for all three forms of phosphorylation, then there is competition between paths of electron transport.

An optimal state for cyclic electron tranport is one of maximal "redox poise," when the total pool of each component gives a redox state that is 50% oxidized and 50% reduced. The rapid, primary photochemical reactions at photosynthetic reaction centers use light energy to move electrons in the direction opposite to that predicted by their redox potentials: the donor has a much higher redox potential than the acceptor, and light is therefore used to generate a redox couple that is far from redox equilibrium. Secondary electron transport nevertheless moves the electrons in the predicted direction, towards equilibrium. "Redox poise" can then still be applied to linear or noncyclic electron transport, and especially to any of its components. When applied to noncyclic electron transport, "redox poise" indicates a position of optimal redox state where the activities of components are such that their effective redox potentials favor physiologically useful electron transfer. Two extreme departures from redox poise exist in the form of states of over-reduction and over-oxidation (Figure 1). A cyclic chain is said to be over-reduced when all components are in their reduced forms; there are no electron acceptors. The same chain is said to be overoxidized when all components are in their oxidized forms; there are no electrons to cycle. When applied to noncyclic electron transport, "over-reduced" and "overoxidized" can be applied to indicate the preponderence of one or other redox state, giving the tendency of a component to engage in redox chemistry with donors or acceptors that are presumed to be nonphysiological, especially where reactive and toxic chemical species are produced in consequence. Oxygen, for example, readily accepts electrons from most components of the photosynthetic chain, a product is the superoxide anion radical, and redox poise may ensure that the "correct" electron transfer competes kinetically with reduction of oxygen.

Cyclic Electron Transport and Photophosphorylation

As first identified by Whatley and Bruce Grant, the onset of cyclic photophosphorylation is delayed, sometimes indefinitely, under anaerobic conditions. The delay can be avoided by addition of an inhibitor of electron transport in photosystem II, or by choice of a wavelength of illumination that is selective for photosystem I. It was concluded that the cyclic chain can become over-reduced when photosystem II is active, and no electron acceptor is available. Over-reduction could also be reversed, and redox poise restored, if a pulse of an oxidant, such as potassium ferricyanide or oxygen, is added to remove excess electrons from the cyclic chain.

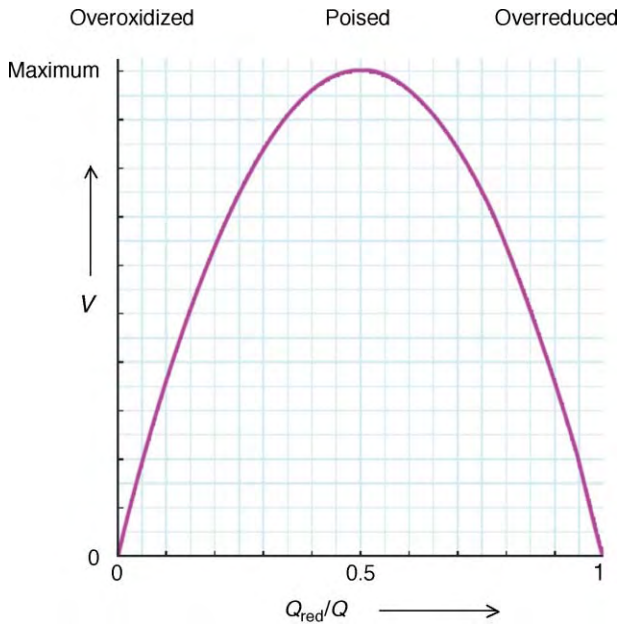

FIGURE 2 The ideal rate, v, of cyclic electron transport as a function of the redox ratio of one of its components, Q. Q must be present in both its oxidized and reduced forms: in cyclic electron flow, Q must be both a donor and acceptor of electrons.

In contrast, under aerobic conditions, Grant and Whatley found that the photosystem II inhibitor, just like a choice of wavelength specific to photosystem I, actually inhibits photosystem I-cyclic photophosphorylation. This is explained by the ability of oxygen to accept electrons from photosystem I, so that, in the absence of photosystem II activity, the cyclic chain becomes drained of electrons, or overoxidized (see Figure 2).

Photosystem 1 Cyclic Electron Flow

The contribution of cyclic photophosphorylation to photosynthesis (Figure 1) depends on maintaining redox poise, and avoiding over-reduction and overoxidation (Figure 2). There is evidence that oxygen acts as a poising oxidant under physiological conditions. Ulrich Heber and colleagues in Wurzburg showed that intact, functional chloroplasts are held in an indefinite lag phase under anaerobic conditions. However, if a pulse of oxygen is given at any time, sufficient ATP is produced to start the Benson–Calvin pathway, and regeneration of the electron acceptor $NADP^+$ then allows whole-chain electron transport to generate oxygen, maintaining a poised cyclic chain, ATP synthesis, and complete photosynthesis. *In vivo*, down-regulation of photosystem II may also counteract over-reduction, and chloroplast NAD(P)H dehydrogenase activity may counteract overoxidation.

The Q-Cycle

In the electron transport chain between photosystems I and II, the cytochrome b_6f complex catalyzes a cycle of electrons through two cytochromes b, involving intermediate states of the two-electron carrier plastoquinone. Redox poise is likely to be essential in the Q-cycle, where the plastosemiquinone participates in one-electron transfer with cytochrome b, despite its tendency to transfer its single electron to oxygen, generating superoxide.

Noncyclic Electron Transport

In intact chloroplasts, continued operation of noncyclic electron transport seems to depend on production of some additional ATP by cyclic electron transport. The ATP is required to drive the Benson–Calvin cycle, and therefore for regeneration of the physiological electron acceptor, $NADP^+$. Insufficient ATP therefore "stalls" photosynthesis by causing over-reduction of the cyclic chain.

Oxygen and Poise

Oxygen is an effective electron acceptor for noncyclic electron transport, and also acts as a poising oxidant for cyclic electron transport. However, the products of oxygen reduction are superoxide and hydrogen peroxide. Reduction of oxygen by the iron–sulfur protein and electron transport intermediate, ferredoxin, may proceed by a physiologically safe route of two one-electron transfers, and also lead to creation of "antioxidant" defenses against the toxicity of reactive oxygen species.

Posttranslational Modification of Pre-Existing Proteins

Regulatory devices that maintain redox poise also extend to gene expression at different levels. Feedback control loops involving components of electron transfer chains and stages in gene expression are seen in all bioenergetic systems. Close association between bioenergetic coupling membranes and genes for their protein components is conspicuous in chloroplasts and mitochondria. The need for direct redox signaling has been proposed as the primary reason for the persistence, in evolution, of chloroplast and mitochondrial genomes.

State Transitions

Control of gene expression by posttranslational modification underpins a well-known process, namely, state transitions. Photosystems I and II have different

light-harvesting pigment systems, and different absorption and action spectra. Thus, any randomly chosen wavelength of light is likely to favor either photosystem I or photosytem II. Yet their connection in series requires a fixed ratio of rates of electron transport through their reaction centers, 1:1 for noncyclic electron transport alone, but incrementally more (estimated at 20%) to photosystem I to account for additional, cyclic electron transport. Cecilia Bonaventura and Jack Myers in Austin, Texas, and Norio Murata in Tokyo independently showed that different unicellular algae redistribute absorbed excitation energy between photosystems I and II, as if to achieve balanced delivery of energy to the two reaction centers. Light delivered to one reaction center whose rate is limited by another will be wasted as heat or fluorescence. Redistribution therefore achieves maximal efficiency despite changing wavelengths of light that otherwise favor one photosystem or the other. Photosystem II works effectively at wavelengths up to ~660–670 nm; photosystem I can utilize light beyond this "red drop" in photosynthetic yield. A beam of light with a spectrum centered at, say, 700 nm, will be selective for photosystem I, and is termed "light 1." A beam centered below 660 nm will drive both photosystems, but is required for photosystem II, and is termed "light 2." Switching beams from light 2 to light 1, or superimposing light 1 onto light 2, induces a change in the light-harvesting apparatus, redistributing energy to photosystem II at the expense of photosystem I. The state arrived at is called the "light 1 state" or "state 1." Conversely, switching from light 1 to light 2 induces a "light 2 state," or "state 2."

Chloroplast Protein Phosphorylation

John Bennett at Warwick University discovered chloroplast protein phosphorylation and showed that one conspicuous phosphoprotein was a light-harvesting chlorophyll *a*/*b*-binding protein forming part of chloroplast light-harvesting complex II (LHC II). LHC II is an intrinsic membrane protein which becomes phosphorylated on a threonine residue by the action of a membrane-associated LHC II kinase.

Plastoquinone Redox Control of the LHC II Kinase

The LHC II kinase was originally thought to be activated by light. However, in Urbana, Illinois, in a collaboration with Bennett, John F. Allen and Charles J. Arntzen showed that LHC II becomes phosphorylated in darkness, provided the electron carrier plastoquinone is chemically reduced. The apparent light activation is sufficiently explained as redox-activation, with electrons being supplied to plastoquinone from photosystem II. In addition, LHC II phosphorylation is accompanied by changes in chlorophyll fluorescence and in electron transport, demonstrating that absorbed light energy simultaneously became redistributed to photosystem I at the expense of photosystem II.

Distribution of Absorbed Excitation Energy

The state-2 transition, an apparently purposeful response increasing efficiency of energy conversion, is the result of activation of the LHC II kinase by reduced plastoquinone. In light 1, the state-1 transition results from oxidation of plastoquinone by photosystem I: the LHC II kinase becomes inactivated, a light- and redox-dependent phospho-LHC II phosphatase catalyzes dephosphorylation of phospho-LHC II, and light energy absorbed by chlorophyll molecules of LHC II is returned to photosystem II, at the expense of photosystem I (Figure 3). Phosphorylation affects the three-dimensional structure of LHC II, and the movement of LHC II between photosystems I and II proceeds because its two structural forms differ in their capacity to bind and interact functionally with the two photosystems – a change in molecular recognition. An LHC II kinase has been identified by Jean–David Rochaix and co-workers in Geneva.

Thioredoxin

A number of enzymes of the Benson–Calvin cycle, and the coupling ATPase of chloroplast membranes, are activated by the reduced form of a soluble iron–sulfur protein, thioredoxin. This example of chloroplast redox signaling was discovered by Robert (Bob) Buchanan and co-workers in Berkeley, California. Thioredoxin accepts electron from ferredoxin, an electron carrier on the acceptor side of photosystem I, and light activation therefore depends on the activity of both photosystems. The function of thioredoxin redox signaling seems to be to ensure that CO_2 assimilation and ATP synthesis are inactivated in darkness, so that energy stored in photosynthesis is not subsequently dissipated.

Posttranscriptional Control

Within chloroplasts, reduced thioredoxin also activates ribosomal translation and processing of RNA, and has been studied for the *psbA* gene product (the D1 reaction center apoprotein of photosystem II) by Steven Mayfield at the Scripps Institute in San Diego, California.

Transcriptional Control

Redox and other signal transduction pathways in bacteria often exert parallel effects at posttranslational

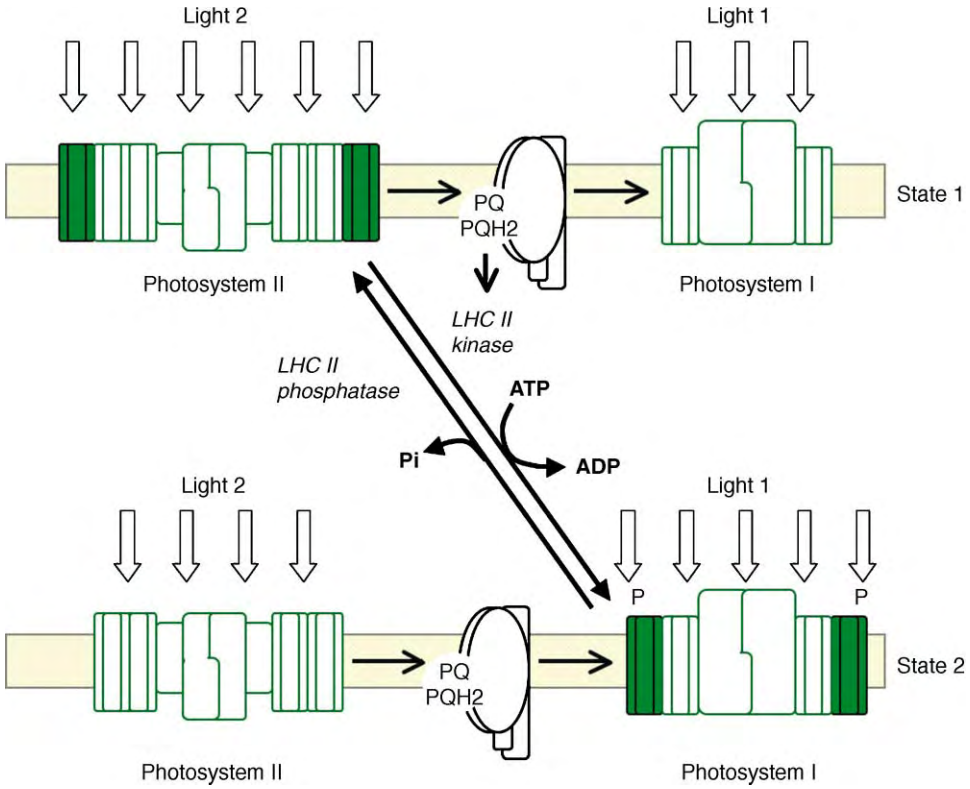

FIGURE 3 Plastoquinone redox control of LHC II kinase activity and its role in balancing distribution of excitation energy between photosystems I and II.

and transcriptional levels of gene expression. Chloroplasts are no exception.

Chloroplast Genes

Thomas Pfannschmidt and John F. Allen, working at Lund University, showed that transcription of chloroplast genes for reaction center apoproteins is regulated by the redox state of plastoquinone. As with phosphorylation of LHC II, the direction of control is functionally intelligible. Reduced plastoquinone is a signal that photosystem I is rate-limiting and photosystem II activity is in excess. Reduction of plastoquinone turns off transcription of photosystem II reaction center genes, and turns on transcription of photosystem I reaction center genes. Conversely, oxidized plastoquinone is a signal of imbalance with photosystem II rate-limiting, and photosystem I in excess: oxidized plastoquinone turns off photosystem I transcription, and turns on photosystem II transcription. Thus, the stoichiometry of photosystems I and II will tend to adjust itself to match changes in the prevailing light regime, as well as changes in metabolic demand for ATP relative to NADPH. Plastoquinone redox control of reaction center gene transcription maintains redox poise of plastoquinone (Figure 4) and of other components linked to it, including components of the cyclic electron transport pathway of photosystem I (Figure 1).

Nuclear Genes

Redox signals from the chloroplast also affect transcription of nuclear genes. In the case of light 1–light 2 effects and redox control at the level of plastoquinone, nuclear genes for photosystems I and II are regulated in the same functionally intelligible way, suggesting a backup which serves the same goal of maintaining redox poise within the chloroplast.

Mechanisms and Evolutionary Implications

Mechanisms and components in chloroplast redox signaling are not fully resolved, especially as regards transcription and translation. Based on bacterial redox signaling, candidate pathways are proposed as follows, and preliminary evidence is consistent with these.

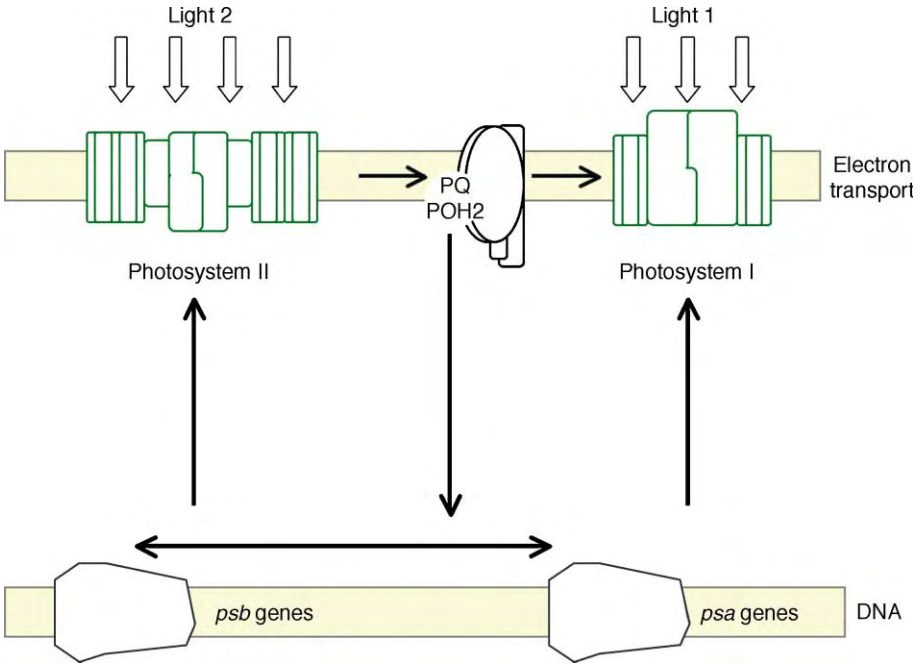

FIGURE 4 Plastoquinone redox control of chloroplast photosynthetic reaction center gene transcription and its role in adjusting the stoichiometry of photosystem I to photosystem II.

Two-Component Systems

A bacterial two-component redox regulatory pathway utilizes a membrane-intrinsic histidine sensor kinase which becomes phosphorylated when ubiquinone in the respiratory chain is reduced. The phosphate from the sensor is then transferred to an aspartate of a soluble response regulator. The response regulator is a sequence-specific DNA-binding protein, and the effect is to switch on transcription of genes for proteins required for anaerobic respiration. This aerobic respiratory control (Arc) system senses redox state. Photosynthetic bacteria, including cyanobacteria, possess cognate systems. Chloroplast genomes of some eukaryotic, red and brown algae have genes for similar components (sensors and response regulators), and green algae and plants have nuclear genes for these components, including transit sequences required for chloroplast import.

FNR and Redox Activators

At the level of thioredoxin, accepting electrons from ferredoxins, bacteria have DNA-binding iron–sulfur proteins. The best-studied example is "fumarate and nitrate reductase" of *Escherichia coli* (FNR: by coincidence, the abbreviation also for ferredoxin–NADP reductase of photosystem I). Since reduced ferredoxin sends redox signals to gene expression, it is likely that a cognate redox activator system is involved.

Redox Signaling and the Function of Cytoplasmic Genomes

Redox signaling is unique neither to chloroplasts nor to photosynthesis. Close coupling between primary redox chemistry and gene expression is seen in bacteria and chloroplasts, with some preliminary evidence also in mitochondria. Inspection of the genes contained in chloroplast and mitochondrial DNA reveals no clear correlation with the hydrophobicity of the gene product, as sometimes supposed. Rather, the core, membrane-intrinsic proteins of primary electron transfer are always encoded in chloroplasts and mitochondria, and synthesized on organelle ribosomes. This rule is especially clear for chloroplast reaction center genes, whose transcription is known to be controlled by the redox state of the plastoquinone pool. It has been proposed that retention, in evolution, of chloroplast and mitochondrial genetic systems gives a co-location of gene with gene product, and that this co-location is essential for redox regulation. Chloroplast redox poise and signaling therefore have important implications for cell evolution, and may account for the distribution of genes between nucleus and cytoplasm in eukaryotic cells.

Glossary

chloroplast (from Greek for "green box") A subcellular organelle of plants and algae. Chloroplasts are the location for the process of photosynthesis in eukaryotes.

photosynthesis The capture of light energy and its utilization to produce reduced carbon compounds whose subsequent oxidation in respiration releases the free energy originally obtained from light.

poise A state of balance. "Redox poise" in electron transport occurs when each electron-carrying intermediate is present in both its oxidized state and its reduced state, in order for that component both to accept and to donate electrons or hydrogen atoms.

redox An adjective derived from "reduction–oxidation," and describing a class of chemical reactions that involve transfer of electrons or hydrogen atoms.

redox signaling Coupling between biological electron transfer and gene expression. Regulatory control is exerted in both directions.

Biography

John F. Allen is Professor of Plant Cell Biology in Lund University, Sweden. He was educated in Newport, Monmouthshire, UK, and then at King's College in London University, obtaining his Ph.D. with David O. Hall. Dr. Allen carried out postdoctoral work in Oxford and Warwick Universities and in the University of Illinois at Urbana, subsequently working in Leeds University, and, on sabbatical, in University of California, Berkeley. He was Professor of Plant Physiology in Oslo for two years before moving to his present position in 1992. Allen demonstrated superoxide production by isolated chloroplasts and, later, plastoquinone redox control of chloroplast protein phosphorylation. His work on redox regulation of photosynthesis contributed to his theory that chloroplast and mitochondrial genomes allow genetic control of redox poise.

Chloroplasts

Nicoletta Rascio
University of Padova, Padova, Italy

Chloroplasts are the organelles specialized in carrying out the photosynthetic process, which uses light energy to synthesize organic compounds: for this reason they are common to all photoautotrophic eukaryotes.

Besides the biosynthetic pathways directly related to photosynthesis, such as synthesis of pigments (chlorophylls and carotenoids), conversion of CO_2 to carbohydrates and reduction and organization of sulfur and nitrogen, several other metabolic pathways occur in chloroplasts. These organelles produce or participate in the production of a series of essential compounds required by other cell compartments. For instance, they are the primary site of biosynthesis of fatty acids, isoprenoids, tetrapyrroles, and aminoacids, as well as of purines, pirimidines, and pentoses necessary for nucleic acid build-up. Thus, chloroplasts, in addition to photosynthesis, play other essential roles in sustaining the metabolism of the cell and the whole plant. The complexity and variety of chloroplast activities can arise from the fact that this, which is now a cell organelle, was originally an organism.

Chloroplast Origin

The chloroplast originated from a cyanobacterium-like prokaryotic ancestor with oxygenic photosynthesis, which was engulfed by a heterotroph proeukaryote. This endosymbiotic event, which took place about 1 billion years ago, was of enormous importance, since it triggered the evolution of photosynthetic eukaryotes and even led, as a consequence, to the expansion of the heterotroph forms of life on the Earth.

During the evolutionary route which changed it into the chloroplast, the cyanobacterium-like ancestor underwent substantial modifications. A significant event was the transfer of most prokaryotic DNA to the host cell nucleus. The genome of a present chloroplast, actually, codes for ~100 proteins, while the DNA of a free-living cyanobacterium, like *Synecocystis*, whose entire sequence is known, encodes more than 3000 proteins. The massive "endosymbiotic gene transfer" possibly occurred to avoid the mutagenic load for organelle genes due to free radicals produced by photosynthetic light reactions, and to escape the accumulation of deleterious mutations caused by the genetic isolation of the organelle DNA in the host cells (the so-called Muller's ratchet).

This transfer of genetic information made it necessary for the chloroplast to recover the proteins encoded in the nucleus and this was achieved by inserting in the nuclear genes a presequence coding for a transit peptide which targeted the choroplast proteins and redirected them to the organelle.

Another essential change undergone by the evolving chloroplast concerned the photosynthetic light-harvesting pigments. With the exception of some algal groups (Rhodophytes and Cryptophytes), the original phycobiliproteins were replaced by chlorophyll forms, in particular by chlorophyll *b* in green organisms.

Chloroplast Organization

Algae and lower plants have chloroplasts which can vary considerably in shape and size, whereas in higher plants these organelles are commonly lens-shaped and measure ~5–10 μm.

Envelope

The chloroplast (Figure 1) is enclosed by a pair of concentric membranes forming the "envelope." The inner envelope membrane is highly selective and contains numerous carriers which regulate the flows of metabolites and ions between chloroplast and the cytosol. The most abundant is the phosphate translocator, which plays a major role in supplying the cell with the products of photosynthesis. The inner membrane also supports some enzymes of biosynthetic pathways, like those of carotenoids, tetrapyrroles, and fatty acids. The outer envelope membrane contains a nonspecific porine-like protein, which allows ions and metabolites of up to ~10 kDa to pass. It is essentially involved in recognizing the cytosol-synthesized chloroplastic proteins which must be transferred into the organelle. This translocation occurs through two multiproteic complexes, one of them inserted in the outer membrane (translocation outer complex, TOC), the other in the inner membrane (translocation inner complex, TIC) of the envelope.

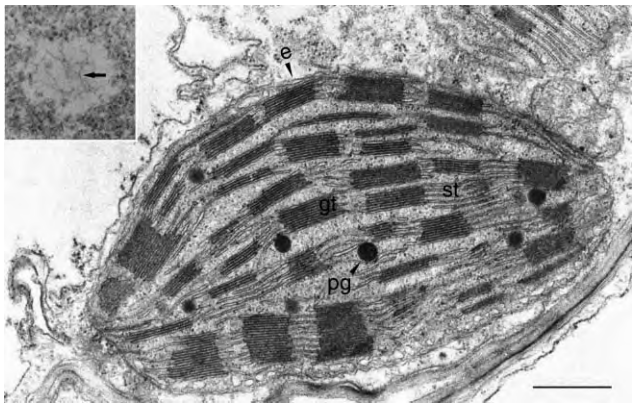

FIGURE 1 Transmission electron microscope (TEM) micrograph of a chloroplast from a mesophyll cell in a maize leaf. Note the envelope (e) the inner membrane system formed by stacked granal thylakoids (gt) and single stromal thylakoids (st). Some plastoglobules (pg) are present in the stroma which look finely granular due to the presence of 70S ribosomes. (bar = 1 μm). The insert shows the region of a chloroplast stroma with DNA microfibrils (arrow).

Stroma

The chloroplast internal milieu, called "stroma", looks finely granular due to the presence of 70S ribosomes. It contains prokaryotic DNA (Figure 1), RNA and the entire protein synthesis machinery allowing the organelle to translate its own genetic information. In the stroma are also inserted the soluble enzymes engaged in the numerous biosynthetic pathways. The ribulose-1, 5-bisphosphate carboxylase/oxygenase (Rubisco), which catalyzes CO_2 fixation in the first reaction of the Calvin–Benson cycle, is the most abundant enzyme, and is even the most abundant protein in the world. Small roundish inclusions, named plastoglobules, made up of plastoquinones, carotenoids, and proteins, are common in the stroma, where also starch grains of photosynthetic origin can occasionally accumulate.

Thylakoid System

Within the chloroplast a membrane system, the "thylakoid system", is present, which contains the multiproteic complexes involved in the light reactions of photosynthesis. The inner membrane system of the chloroplast (Figure 1) consists of coupled lamellae (thylakoid membranes) separated by a narrow intermembrane space. They form flattened cisternae or saccules (thylakoids), intercommunicating to constitute a continuous and closed membrane system, whose internal space (lumen) is totally isolated from the stromal environment.

A feature common to the green plant chloroplasts (Figures 2A and 2B) is the stacking of thylakoids (granal thylakoids) one upon the other to make piles of saccules named "grana" (singular: granum), which are interconnected by single unstacked thylakoids running in the stroma (stromal thylakoids). This kind of organization, which gives rise to a huge surface area of thylakoid membranes, acquires functional significance, taking into account that, as stated above, these membranes support the complexes carrying out the photosynthetic light reactions and the correlated electron transport and ATP synthesis (precisely: photosystem I (PSI), photosystem II (PSII), the cytochrome b_6f complex (Cyt b_6f), and the ATP synthase). These components are diversely and specifically located in the thylakoid membranes (Figure 3). Most of PSII resides in the approached regions of stacked thylakoids (partitions), while PSI and the ATP synthase only occur in the stromal thylakoids and in all the unstacked regions of granal thylakoids (end granal membranes and margins). Finally, the Cyt b_6f is rather homogeneously distributed in the thylakoid system.

A peculiarity of chloroplast membranes, which distinguishes them from the other cell membranes, is the great abundance of glycolipids, represented by two neutral galactolipids, the monogalactosyldiacylglycerol

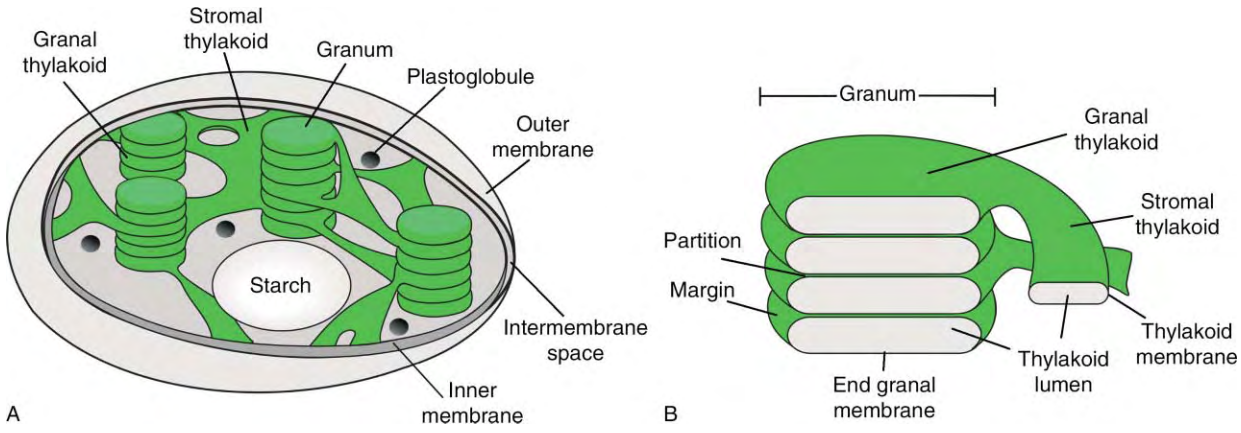

FIGURE 2 (A) Three-dimensional scheme of a chloroplast. (B) Particulars of the thylakoid system organization.

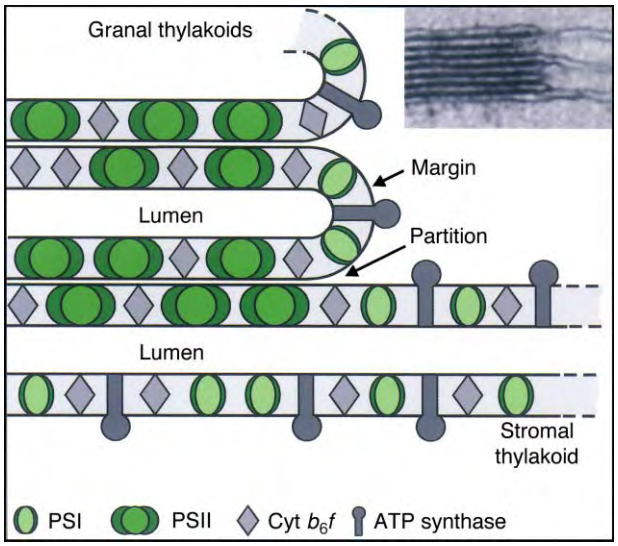

FIGURE 3 Distribution of the multiproteic complexes in the thylakoid membranes.

(MGDG) and the digalactosyldiacylglycerol (DGDG), which account for 70% of the entire acyl-lipid moiety, and by the anionic sulfolipid sulfoquinovosildyacylglycerol (SQDG). Phosphatidylglycerol (PG) is the only phospholipid present in the membranes. A feature of all thylakoid lipids is the high concentration of polyunsaturated fatty acids, which maintain membrane fluidity in spite of the high protein/lipid ratio. Nonpolar lipids, like plastoquinones, phylloquinones, and tocopherols are inserted in the hydrophobic region of the membrane matrix. Plastoquinone-9, a component of the photosynthetic electron transport chain, is particularly abundant.

Chloroplast Biogenesis

In higher plants chloroplasts develop from proplastids, which are small undifferentiated organelles present in the meristematic cells. Chloroplast differentiation involves the synthesis of pigments, proteins, and lipids and the structural and functional organization of the whole thylakoid system, as well as the acquisition of the enzymatic components carrying out the numerous metabolic pathways of the mature organelle. These events are accompanied by the increase in the developing chloroplast size and the rise of the organelle number in the cells. Proplastids and young chloroplasts, indeed, can divide through a process of "binary fission" similar to that occurring in bacteria. The chloroplast division is independent of cell division, being part of the developmental program which defines the final number of photosynthetic organelles in the mature green cell.

The dependence on both nuclear and own genetic information makes chloroplast biogenesis a quite complex process requiring the coordinated expression of genes located in the two cellular compartments. This takes place through environmental cues, the most important of which is light, and through endogenous nucleus–chloroplast signaling. The nucleus exerts a preeminent role in controlling the chloroplast gene expression. However, also chloroplast-to-nucleus signaling pathways exist that greatly affect the transcription of nuclear genes encoding photosynthesis-related proteins. This kind of "retrograde" informational flow is triggered by different chloroplast-generated signals, involving, for instance, chlorophyll precursors or the plastoquinone redox state, and serves to correlate the nuclear gene expression with the chloroplast developmental stage and the organelle functionality, but also to achieve a swift photosystem adjustment in response to qualitative and quantitative light changes in the plant growth environment.

Light and Chloroplast Differentiation

In lower vascular plants as well as in most gymnosperms the events leading to chloroplast differentiation can occur both in light and in darkness. On the contrary, in the angiosperms, light is a key factor for chloroplast biogenesis and the build-up of the thylakoid system. In these more evolved plants, light, by phytochrome mediation, induces the expression of different nuclear genes (photo-genes) coding for essential chloroplast components. Light, for instance, is required for the transcription of the *Cab* genes encoding numerous chlorophyll *a/b*-binding proteins. Moreover, chlorophyll is not produced in the dark because one of the final steps of its biosynthetic pathway, precisely the protochlorophyllide (Pchlide) to chlorophyllide (Chlide) reduction, is carried out by the enzyme Pchlide oxidoreductase (POR) which, in flowering plants, has become light dependent. As a consequence, in dark-grown (etiolated) seedlings of angiosperms, peculiar organelles, named "etioplasts," originate from proplastids in cells that would become green in the presence of light.

Etioplasts

Etioplasts, which are the chloroplast counterparts in darkness, can be formed in nature during the first phase of plantlet growth, before the emergence from soil. An inner membrane system very different from the thylakoid develops in etioplasts (Figure 4). Most membranes have a tubular arrangement and aggregate in a tridimensional semicrystalline network of interconnected tubules, defined "prolamellar body," from which some lamellar membranes (prothylakoids) extend. The prolamellar body membranes contain the

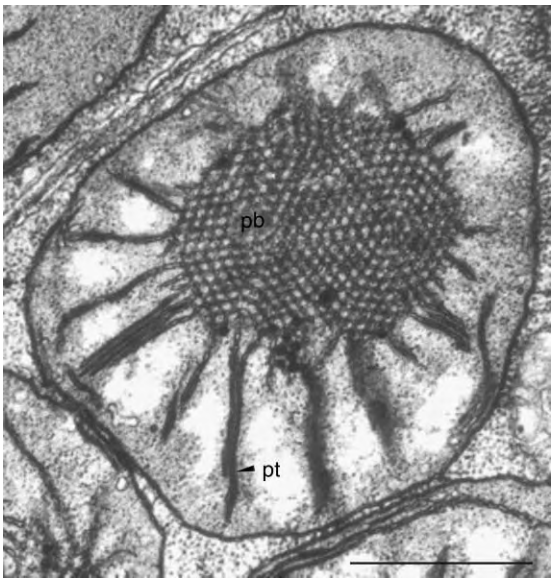

FIGURE 4 TEM micrograph of an etioplast from a dark-grown bean cotyledon. The inner tubular membranes are arranged in a semicrystalline prolamellar body (pb) from which lamellar prothylakoids (pt) extend (bar = 1 μm).

POR associated with Pchlide and NADPH to form a stable "ternary complex," and are particularly rich in MGDG, which favors the tubular arrangement due to its cone- shaped molecular configuration.

Etioplasts exposed to light convert to chloroplasts. The first event of this greening process is the Pchlide reduction that the photo-activated POR carries out by using the NADPH of the ternary complex. Successively the etioplast membranes rearrange to form primary thylakoids and then a massive synthesis *de novo* of chlorophylls and membranes leads to the formation of the well organized and photosynthetically competent chloroplast.

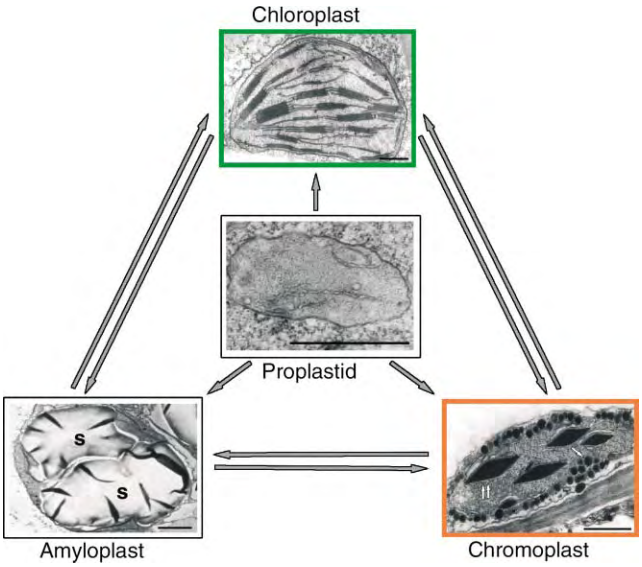

FIGURE 5 The cyclic model of plastid interconversions. The amyloplast from a cell of *Raphanus* hypocotyl contains large starch grains (s). Globular (arrow) and crystalline (double arrow) carotenoid masses are inserted in the chromoplast from a cell of *Ranunculus* petal. Chloroplast and proplastid are from a mesophyll cell and a basal meristem cell of a maize leaf, respectively (bars = 1 μm).

Plastids

The chloroplast belongs to the organellar class of plastids. In lower photoautotroph organisms, like algae, which do not possess cell types with very distinct functions, the photosynthetic chloroplast has remained the sole kind of plastid. On the contrary, in terrestrial plants, which evolved highly specialized tissues and organs, different kinds of plastids with specific structures and functions arose from the original chloroplast. In these plants the class of plastids, besides the green chloroplasts, includes uncolored amyloplasts, whose function is to store large amounts of starch (Figure 5) and yellow-red-brown chromoplasts which synthesize a lot of carotenoids (Figure 5) and have attractive functions. Apart from the lack of thylakoids, these non-photosynthesizing plastids share common characteristics with the chloroplasts, like the envelope membranes, the prokaryotic DNA and the 70S ribosomes. Furthermore, they maintain several biosynthetic pathways carried out by enzymes inserted in the stroma or bound to the envelope, such as those of fatty acids and terpenoids.

All the plastids can differentiate from proplastids. However, the possibility also exists that a plastid derives from the conversion of another kind of plastid, according to the "cyclic model" (Figure 5) proposed already by Schimper at the end of 1800. These reversible plastid interconversions depend on cell developmental programs as well as on endogenous (hormones and nutrients) or environmental (light and temperature) signals. Only the chromoplasts (named gerontoplasts) derived from chloroplast degeneration during a green tissue senescence cannot undergo further conversion.

Biography

Nicoletta Rascio is a Professor of plant physiology at the Department of Biology of the University of Padova (Italy). Her principal research interest is in the biogenesis, organization, and functionality of the photosynthetic apparatus in algae and higher plants at the ultrastructural, molecular, biochemical, and physiological level, in normal and stressful environmental conditions. In this field she has published more than 100 papers in mainstream journals.

Cholesterol Synthesis

Peter A. Edwards
University of California Los Angeles, Los Angeles, California, USA

Cholesterol is a critical component of eukaryotic cell membranes and a precursor of steroid hormones, oxysterols, and bile acids that have important roles in cell signaling and/or lipid absorption. In addition, intermediates in the cholesterol biosynthetic pathway are diverted to the synthesis of diverse polyisoprenoids that have important functions in the cell. Thus, it is not surprising that the cholesterol biosynthetic pathway is highly regulated. Drugs, collectively called statins, that inhibit the rate-limiting enzyme of cholesterol synthesis, have been shown to both reduce plasma LDL cholesterol levels and impair the progression of atherosclerosis and coronary artery disease.

Properties of Cholesterol

Cholesterol is a cyclic hydrocarbon that can be esterified with a fatty acid to form a cholesteryl ester. Both cholesterol and cholesteryl esters are lipids and are essentially insoluble in aqueous solution but soluble in organic solvents. Excess cholesterol esters are stored as lipid droplets within the cytosol. Such droplets are prevalent in steroidogenic tissues where they serve as precursors of the steroid hormones. In eukaroyotic cells, cholesterol is "solubilized" as a result of its interaction with either membrane phospholipids or with phospholipids and bile acid micelles in the gall bladder. In blood, cholesterol and cholesterol esters are "solubilized" within lipoprotein complexes. These lipoproteins, that include low density lipoprotein (LDL), very low density lipoprotein (VLDL), chylomicrons and high density lipoprotein (HDL), function to transport insoluble lipids around the body.

Functions of Cholesterol

Membrane Structure

Cholesterol is absent from prokaryotic cells. However, cholesterol plays an essential structural role in maintaining the fluidity of eukaryotic cell membranes. Cholesterol is not equally distributed in all membranes; the membranes of mitochondria, peroxisomes, and endoplasmic reticulum are cholesterol-poor, whereas the plasma membrane is enriched in the sterol. However, the concentration of cholesterol varies significantly even within the plasma membrane; it is highly enriched in two specialized areas termed lipid rafts and caveolae. Since many receptors are localized to these cholesterol- and sphingomyelin-rich domains, it has been suggested that lipid rafts and caveolae function as "signaling gateways" into the cell. The myelin sheath that surrounds nerves has the highest cholesterol concentration.

Precursor of Signaling Molecules

As shown in Figure 1, cholesterol is a precursor of bile acids, steroid hormones, and oxysterols (oxidized cholesterol). These cholesterol metabolites function to activate specific nuclear receptors that control many metabolic and developmental processes. In addition, intermediates in the cholesterol biosynthetic pathway are themselves precursors for other critical pathways. For example, 7-dehydrocholesterol is a precursor of vitamin D, and farnesyl diphosphate is a precursor of geranylgeranyl diphosphate, ubiquinone, Heme a, and dolichols (Figure 1). Although beyond the scope of this article, it is now clear that modification (prenylation) of many proteins by either farnesyl diphosphate or geranylgeranyl diphosphate is critical for cell survival. Thus, hypolipidemic drugs (e.g., statins) that inhibit HMG-CoA reductase activity must be used at doses that result in partial, not total, inhibition of the pathway.

Sources of Cellular Cholesterol

Diet and Lipoproteins

Insects are cholesterol auxotrophs and must obtain all their cholesterol from the diet. In contrast, other eukaryotes obtain cholesterol from two sources; the diet and endogenous synthesis. Mammals absorb 40–50% of the cholesterol in their diet and transport it to the liver and other tissues in lipoproteins. The plasma lipoproteins bind to cell surface receptors prior to the delivery of the lipid cargo to the cell. Such receptors include the LDL receptor, SR-B1, SR-A, and CD36.

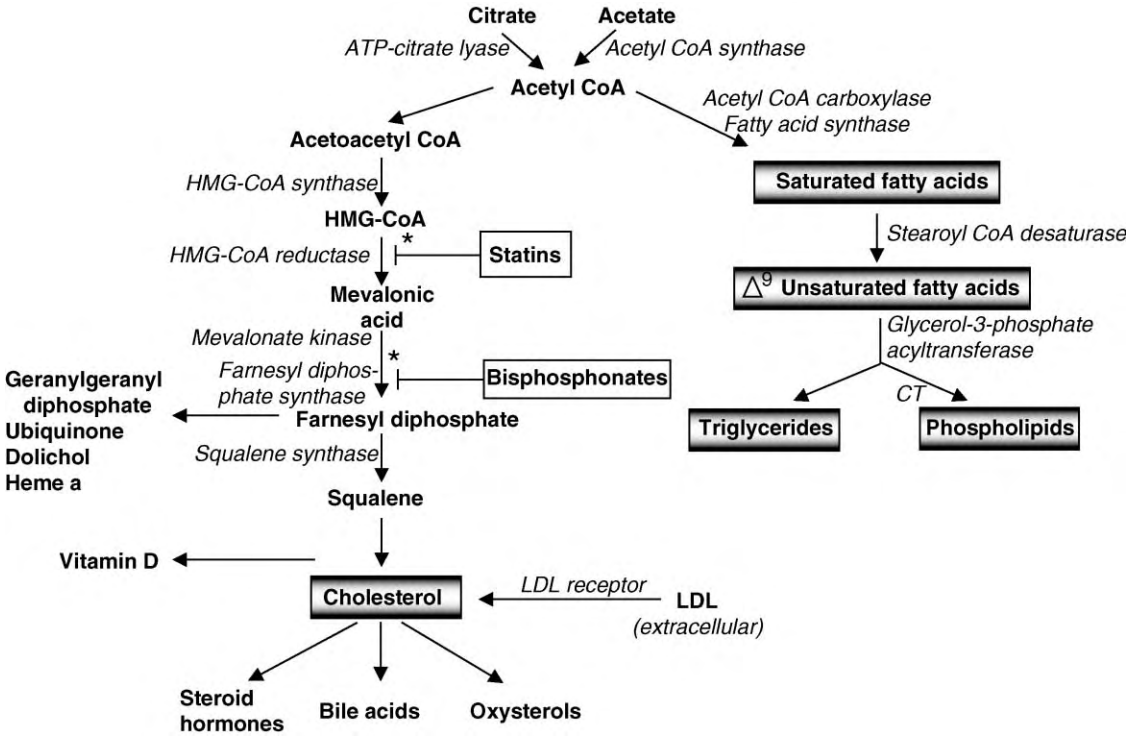

FIGURE 1 The cholesterol and fatty acid biosynthetic pathways are regulated by SREBPs. A few of the intermediates and enzymes of the cholesterol and fatty acid synthetic pathways are shown. Genes that are preferentially regulated by SREBP-2 (left side) or SREBP-1c (right side) are italicized. The inhibition of HMG-CoA reductase or farnesyl diphosphate synthase by statins and bisphosphonates, respectively, is indicated by *, many intermediates and enzymes have been omitted for simplicity, such as CT, CTP, phosphocholine cytidyltransferase.

The LDL receptor is expressed on the surface of most cells and plays a particularly important role in cholesterol homeostasis. This transmembrane protein binds cholesterol-rich LDL and facilitates the delivery of cholesterol into the cell via specialized areas on the cell surface called clathrin-coated pits. However, virtually all mammalian cells also synthesize cholesterol (Figure 1).

Cholesterol Synthesis

There are many reviews on the biosynthesis of cholesterol, possibly in part because work in this area has been extensive and has led to numerous Nobel prizes. All mammalian cells, with the exception of mature red blood cells, utilize more than 30 enzymes to convert the 2 carbon acetate to the 27 carbon cholesterol via isoprenoid intermediates (Figure 1). The rate-limiting enzyme in this pathway, HMG-CoA reductase, is the target for many hypolipidemic drugs (Figures 1 and 2). Together, the cholesterol biosynthetic pathway and the LDL receptor pathway provide sufficient cholesterol necessary for cell growth and division. These two pathways are coordinately controlled by an exquisite mechanism that "senses" cellular cholesterol levels. The mechanism involves the generation of three functionally active transcription factors termed sterol regulatory element binding proteins (SREBPs).

Transcriptional Control of Cholesterol Synthesis

There are two SREBP genes, SREBP-1 and SREBP-2. The SREBP-2 gene produces one protein that preferentially activates genes involved in cholesterol homeostasis. In contrast, two proteins, SREBP-1a and SREBP-1c are produced from the SREBP-1 gene. SREBP-1c preferentially activates genes involved in fatty acid synthesis. SREBP-1a activates both pathways but is expressed at relatively low levels. Newly synthesized SREBP proteins contain two transmembrane domains that form a hairpin-like structure and anchor the proteins in the endoplasmic reticulum, outside the nucleus (Figure 2). If these proteins are anchored to membranes outside the nucleus, how can they function as transcription factors in the nucleus?

The answer came from a series of elegant studies initiated in the laboratory of Goldstein and Brown in Dallas. They showed that generation of nuclear-localized SREBPs requires additional proteins named Insig-1, Insig-2, SCAP, the site 1 protease (S1P), and the site 2 protease (S2P) (Figure 2). The roles of these proteins vary; SCAP functions both as a cholesterol sensor and as an escort protein to transport SREBP to the Golgi where two proteases cleave SREBPs to release the soluble amino terminal fragment. The process is also regulated by the two Insig proteins, which function to

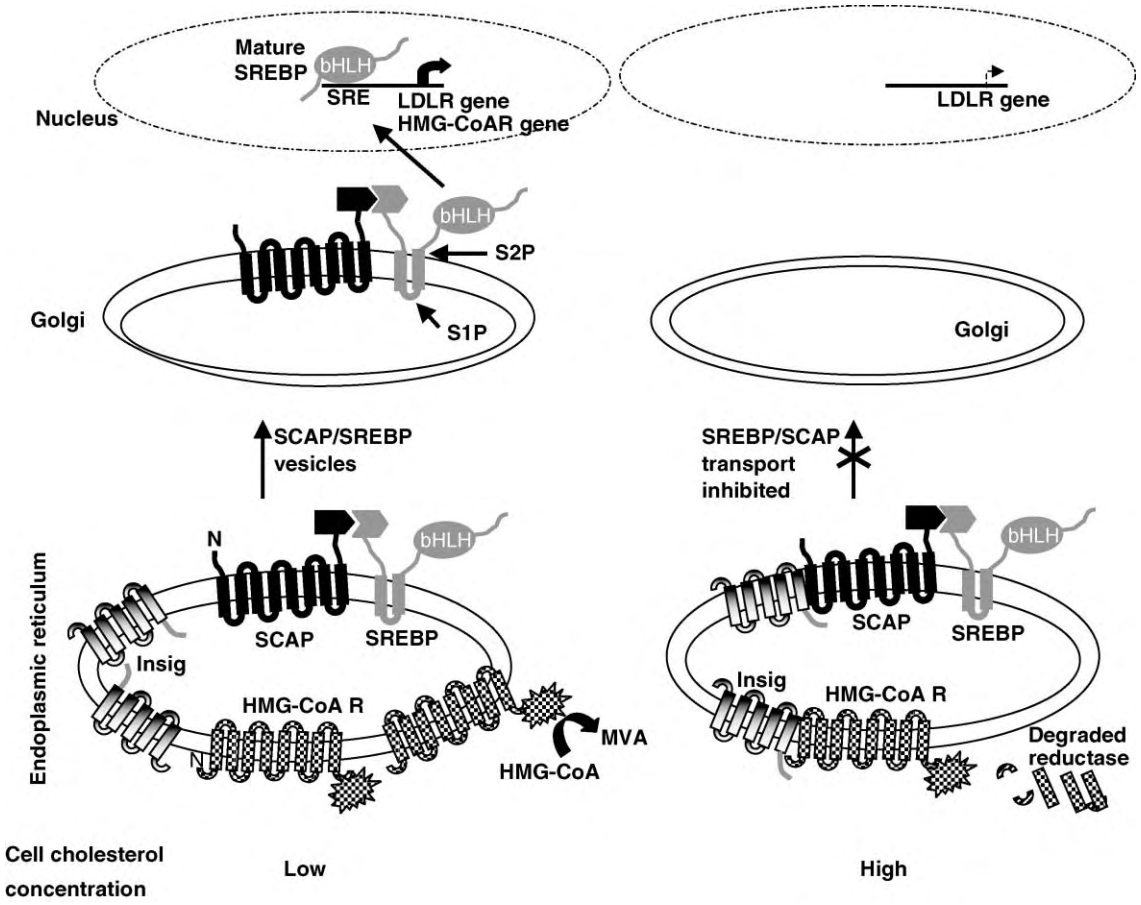

FIGURE 2 Mechanisms involved in the nuclear targeting of SREBP-2 and the altered stability of HMG-CoA reductase. The left side represents conditions where the cholesterol concentration in the cell is low. Under these conditions, SREBP-2 is targeted first to the Golgi and then to the nucleus where it activates many SREBP-2 target genes. For simplicity, only the LDL receptor and HMG-CoA reductase (HMG-CoA R) genes are shown. HMG-CoA reductase protein also accumulates in the endoplasmic reticulum where it catalyzes the reduction of HMG-CoA to mevalonic acid (MVA). The right side represents conditions where cellular cholesterol levels are higher than normal. Under these cholesterol-enriched conditions, Insig complexes with SCAP/SREBP and inhibits the maturation and nuclear localization of SREBP-2. In addition, the rate of degradation of HMG-CoA reductase is increased. The degradation is preceded by the formation of an Insig/HMG-CoA reductase complex. Details are given in the text.

control the release of SCAP/SREBP from the endoplasmic reticulum (Figure 2). In brief, when cells become "cholesterol-poor," for example, after addition of a drug that inhibits cholesterol synthesis, a SCAP/SREBP-2 heterodimeric complex is transported in vesicles that bud from the endoplasmic reticulum and then fuse with the Golgi (Figure 2). The Golgi contains two resident proteases, S1P and S2P, that sequentially cleave the newly arrived SREBP-2 protein; first S1P cleaves SREBP into two parts by cleaving the hairpin loop in the lumen of the Golgi, then S2P cleaves the protein at a second site to release a soluble amino-terminal domain (Figure 2). This soluble amino-terminal fragment, containing a basic helix-loop-helix-leucine zipper transactivation domain (bHLH), migrates into the nucleus where it binds to specific DNA sequences termed sterol responsive elements (SREs) and activates transcription. SREs have been identified in the promoters of many genes involved in cholesterol and fatty acid and lipid synthesis. Such genes include HMG-CoA reductase, HMG-CoA synthase, farnesyl diphosphate synthase, squalene synthase, and the LDL receptor (Figure 1). In summary, a transient decrease in cellular cholesterol levels leads to increased levels of transcriptionally active SREBP-2 in the nucleus and activation of genes involved in cholesterol synthesis and uptake of LDL. The net result is a rapid return of the cellular sterol levels to normal.

In contrast, when cells accumulate cholesterol, the SCAP/SREBP heterodimer complexes with another protein called Insig. Since Insig is a resident protein of the endoplasmic reticulum, the Insig/SCAP/SREBP-2 complex remains localized to this membrane (Figure 2). Consequently, transport of SREBP-2 to the Golgi and subsequent cleavage and nuclear localization of the protein is impaired. As a result, transcription of genes encoding the LDL receptor and cholesterogenic

genes is low. Such changes in gene expression will prevent or reduce subsequent cholesterol accumulation in the cell.

Although beyond the scope of this review, SREBPs, especially SREBP-1c, also activate genes involved in the synthesis of saturated and unsaturated fatty acids, triglycerides, and phospholipids (Figure 1).

Regulated Degradation of HMG-CoA Reductase

HMG-CoA reductase catalyses the NADPH-dependent reduction of HMG-CoA to mevalonic acid (MVA in Figure 2). It is considered to be the rate-limiting enzyme of the cholesterol biosynthetic pathway. Thus, changes in the activity of the enzyme are paralleled by changes in cholesterol synthesis. The activity of the enzyme is regulated by changes in transcription, translation (mechanism unknown) and protein stability.

HMG-CoA reductase contains two domains; an eight transmembrane spanning region that localizes the protein to the endoplasmic reticulum and a carboxy-terminal domain that projects into the cytosol and contains all the catalytic activity (Figure 2). The half-life (a measure of protein stability) of the enzyme varies at least tenfold, depending on the concentration of cholesterol and isoprenoids in the cell. When cellular cholesterol levels are low the enzyme is relatively stable (half-life $\sim$10 h). Thus, active HMG-CoA reductase enzyme accumulates in the endoplasmic reticulum in response to (1) a slow rate of degradation of the protein and (2) increased transcription and enzyme synthesis (Figure 2). Since HMG-CoA reductase is the rate-limiting enzyme, the net result is increased cholesterol synthesis.

However, when cellular cholesterol levels increase, the rate of degradation of HMG-CoA reductase protein is enhanced $\geq$10-fold (half-life $<$45 min) by a process that requires both a sterol and an unidentified non-sterol derived from farnesyl diphosphate (Figure 1). Recent studies have shown that Insig-1 forms a complex with the transmembrane domains of HMG-CoA reductase prior to the ubiquination and degradation of the enzyme in proteosomes (Figure 2).

Thus, Insig appears to have a dual role in cholesterol-enriched cells; it interacts with HMG-CoA reductase to promote degradation of the enzyme, and with SCAP to retain SREBP-2 in the endoplasmic reticulum (Figure 2). It seems likely that these interactions may depend on the partially conserved "sterol-sensing domains" identified in both HMG-CoA reductase and SCAP. In summary, cholesterol-loaded cells have low levels of HMG-CoA reductase protein (and hence low rates of cholesterol synthesis) because (1) the enzyme is rapidly degraded and (2) transcription of the gene is low as a result of the retention of SREBP-2 in the endoplasmic reticulum (Figure 2, right side). Such changes will minimize subsequent cholesterol accumulation in the cell.

Effect of Mutations in the Cholesterol Synthetic Pathway

Mutations in the cholesterol synthetic pathway are rare because they are usually incompatible with life. Mutations in genes encoding mevalonic kinase (an early enzyme in the pathway) and 7-dehydrocholesterol (a late enzyme in the pathway) result in mevalonic acid urea and Smith–Lemli–Opitz syndrome, respectively. It should be emphasized that patients with mevalonic acid urea have residual mevalonic acid kinase activity, sufficient to provide isprenoid intermediates that are necessary for cell survival. Indeed, a complete blockage of early steps in cholesterol biosynthesis leads to embryonic death. Patients with mutations in genes that result in impaired cholesterol synthesis exhibit various neurological dysfunctions. Such observations only emphasize the importance of cholesterol to the neurological system.

Inhibitors of Cholesterol Synthesis; Treatment for Hyperlipidemia and Osteoporosis

Statins

Elevated LDL cholesterol levels (hypercholesterolemia) are relatively common in the West. Hypercholesterolemia is associated with the development of atherosclerosis, coronary heart disease, myocardial infarction and increased mortality. One class of drugs, referred to collectively as statins, have proven to be extremely effective in lowering plasma LDL levels and in reducing the progression of atherosclerosis and clinically associated problems.

Mevinolin is a fungal metabolite that is structurally related to HMG-CoA. It was originally discovered in 1976 by Akira Endo in Japan and shown to be a potent competitive inhibitor of HMG-CoA reductase; it binds to the enzyme with a $K_i \sim 10^{-9}$ M, compared to a K_m of $\sim 10^{-6}$ M for the natural substrate HMG-CoA. Subsequent studies by many investigators led to the identification of a number of natural and synthetic compounds that also inhibit the enzymatic activity of HMG-CoA reductase. These drugs are collectively known as statins. When taken orally, these drugs are absorbed and targeted to the liver where they bind and partially inhibit HMG-CoA reductase and cholesterol synthesis. The liver cells "sense" this decrease in newly synthesized cholesterol and respond by enhancing the cleavage and nuclear localization of SREBP-2 (Figure 2). As a result, expression of a number of genes, including the LDL receptor and HMG-CoA reductase are increased. The increased expression of the LDL receptor

protein on the hepatocyte cell surface results in increased clearance of cholesterol-rich LDL from the plasma into the liver. This is the molecular basis for the clinical effects of the drug. Fortunately, the liver does not become loaded with lipid because it converts the LDL-derived cholesterol to bile acids and excretes the latter in the bile. In summary, oral administration of statins results in an increased rate of removal of LDL from the blood and a 30–50% decline in blood LDL cholesterol levels. Such a change has been shown to reduce both the progression of coronary atherosclerosis and the incidence of myocardial infarction and death.

A number of epidemiological studies have recently reported that statins also reduce osteoporosis and improve the status of patients with Alzeimers. However, at the current time, these latter conclusions are highly controversial and additional studies will be necessary to determine whether these drugs have such additional benefits.

Bisphosphonates

Bisphosphonates are potent inhibitors of bone resorption and are used widely to treat osteoporosis. After absorption, these drugs are targeted to bone, where they are taken up by osteoclasts, the bone-resorping cells. The bisphosphonates inhibit farnesyl diphosphate synthase and isoprenoid synthesis (Figure 1). As a result, the osteoclasts undergo apoptosis and bone resorption is attenuated.

Biography

Dr. Peter Edwards is a Professor of both Biological Chemistry and Medicine at UCLA. His principal interests are centered on the roles of oxysterols and bile acids as agonists of two nuclear receptors, LXR and FXR. He holds a Ph.D. from the University of Liverpool, United Kingdom and received postdoctoral training at Stanford University. His group has purified/cloned and studied the regulation of a number of enzymes involved in cholesterol and isoprenoid biosynthesis.

Chromatin Remodeling

Eric Kallin and Yi Zhang
University of North Carolina, Chapel Hill, North Carolina, USA

A cell's ability to regulate gene expression has been directly linked to DNA packaging within the nucleus. The active process involved in the alteration of DNA packaging has been termed chromatin remodeling. Several types of enzyme complexes have been identified which are capable of altering the packaging state and thus affecting gene expression. To date, three distinct chromatin-remodeling mechanisms, including ATP-dependent nucleosome remodeling, covalent modification of histones, and histone variant incorporation, have been identified and each has been linked to gene expression by regulating chromatin dynamics. This article will briefly describe these three mechanisms as well as explain their relationship with gene expression.

Chromatin Basics

Researchers have known that certain proteins, called histones, were closely associated with DNA even before DNA was identified as the genetic material. When DNA was identified as the genetic material, it was thought that the histones only functioned as scaffolding for the wrapping of DNA so that the long stretch of DNA (3.2 cm long for human) can be contained within the cell nucleus (with a diameter of 4×10^{-3} cm). The first breakthrough in the studies of the role of histones in organizing DNA was made by Roger Kornberg in 1974. He found that core histones exist as defined octamers that are associated with DNA at nearly even intervals similar to that of "beads on a string." The basic repeating unit of chromatin, called the nucleosome, includes two copies of each of the four core histones, H2A, H2B, H3, and H4. Further biochemical analysis has shown that each histone octamer is encircled almost twice by DNA of 146 bp. Large numbers of noncovalent bonds form between the DNA and the histone proteins resulting in a stable complex. A fifth histone protein, called H1, binds to the linker DNA of two adjacent nucleosomes to maintain the higher-order chromatin structure.

The function of a given cell is largely determined by the sets of genes that it expresses. Cells control their gene expression mainly at the transcriptional level which involves binding of specific transcription factors to DNA elements located at the promoter regions of a given gene. Compacting of DNA into chromatin impedes access to transcription factors thus stopping gene expression. Therefore, regulation of chromatin structure and nucleosome placement along the DNA strand has a significant impact on gene expression. Studies in the past 10 years have revealed at least two groups of enzymes capable of modulating chromatin structure. The first group involves factors utilizing the energy derived from ATP hydrolysis to "remodel or relocate nucleosomes." The second group involves enzymes that covalently modify core histone proteins. Recent studies also indicate that substitution of regular histones with their variants also affects chromatin structure.

ATP-Dependent Nucleosome Remodeling

ATP-dependent nucleosome remodeling refers to the use of energy derived from ATP hydrolysis to fuel a reaction that results in the translocation of a nucleosome to another portion of the DNA molecule. If a nucleosome is positioned in such a way that an important regulatory DNA element is blocked from transcription factor binding, relocating that nucleosome to another portion of DNA could expose the binding site and result in gene expression. ATP-dependent nucleosome-remodeling factors usually exist in multiprotein complexes. A common feature of these protein complexes is that they all contain a subunit capable of hydrolyzing ATP. Based on the ATPase subunit, the known remodeling factors have been grouped into three families.

Remodeling Enzymes

SWI/SNF Family

The SWI/SNF family of proteins was first identified in budding yeast by genetic screens to identify genes that are involved in mating type switch (SWI) and sucrose nonfermenting (SNF). Sequence analysis revealed that *SNF2* and *SWI2* encode the same protein which is

the founding member of an ATPase family. Biochemical and genetic studies led to the identification of an 11-subunit complex, named the SWI/SNF complex, capable of increasing the accessibility of nucleosomal DNA by transcription factors. Components of this complex have been linked to ATPase activity (Snf2), nonspecific-DNA-binding activity (Swi1), and nuclear-structure binding (Arp7 and Arp9). A highly related complex called remodels structure of chromatin (RSC) has also been identified in budding yeast. The ATPase subunit of RSC has been named Sth1 and is homologous to Snf2 of the SWI/SNF complex. In comparison with the SWI/SNF complex, RSC is a much more abundant complex. Genes that encode components of the RSC complex are essential for yeast survival. Protein complexes homologous to the yeast SWI/SNF complex have been identified in other multicellular organisms such as *Drosophila* and human.

ISWI Family

Using a functional assay that measures activities capable of disrupting regular nucleosome spacing, Carl Wu and colleagues purified the nucleosome remodeling factor (NURF) complex from *Drosophila* embryo extracts. The complex is composed of four subunits, including the ATPase, imitation switch (ISW) I. In addition to NURF, ISWI was also found to be present in two other *Drosophila* remodeling factors, ACF (ATP-utilizing chromatin assembly and remodeling factor) and CHRAC (chromatin accessibility complex). Although ISWI by itself is able to remodel nucleosomes *in vitro*, it functions in one of the three complexes *in vivo*. At least three homologous complexes containing the ISWI homologue hSNF2h have been identified in humans and two complexes containing the ATPase ISW1 and ISW2 have been identified in budding yeast.

Mi-2 Family

Mi-2 was initially identified as a nuclear autoantigen in patients with dermatomyositis. Two forms, Mi-2α (or CHD3) and Mi-2β (or CHD4), which are 72% identical at the amino acid level, exist in human cells. They both belong to the chromo-helicase-DNA-binding (CHD) protein family, which includes at least four human family members. In addition to the conserved SWI2/SNF2 helicase/ATPase domain present in the ATPase subunit of other nucleosome remodeling factors, the Mi-2 proteins also include two plant homeodomain (PHD) zinc-fingers, two chromo domains, and an HMG-like domain. Biochemical studies indicate that Mi-2 proteins exist in a protein complex named NuRD that possesses both nucleosome remodeling and histone deacetylase activities. Both HDAC1 and HDAC2 (histone deacetylase 1 and 2) are components of the NuRD complex. They interact with the PHD fingers of the Mi-2 protein. Recent studies indicate that the NuRD complex can associate with the methyl-CpG-binding protein MBD2 to form the MeCP1 complex. Thus, the NuRD complex links nucleosome remodeling and histone deacetylation to DNA methylation-mediated gene silencing. Although NuRD-specific subunits were not found in the budding yeast, homologues of Mi-2 and MTA2 proteins exist in *Drosophila* and *Caenorhabditis elegans*. Therefore, it is likely that the functional counterpart of NuRD was evolutionarily conserved in multicellular organisms.

Remodeling Mechanisms

Although all of the remodeling complexes identified so far have a component that possesses ATPase activity, the properties of their respective ATPases appear different. While the SWI2/SNF2 protein and SWI/SNF complexes exhibit DNA-stimulated ATPase activity, the ATPase activity of ISWI alone or in complex is only stimulated by nucleosomes. Moreover, SWI/SNF complexes seem to induce much more dramatic structural changes in nucleosomes than the ISWI complexes. These differences suggest that different remodeling factors may use different remodeling mechanisms. Based on the observation that in the presence of SWI/SNF and ATP, mononucleosomes can generate a novel nucleosome dimer species which has loosened histone–DNA contacts, an interconversion model was proposed to explain how the human SWI/SNF complex works. It is believed that interconversion between the two nucleosome states occurs constantly (Figure 1A). The SWI/SNF complex simply lowers the energy required for this interconversion. An alternative "octamer transfer" model was proposed to explain the mechanism of the RSC function (Figure 1B). The basis for this model was the observation that RSC can completely disrupt histone–DNA contact and transfer the histone octamer to another molecule of DNA. As explained above, histones associate with DNA through a collection of noncovalent interactions. Given the large energy requirement for breaking the histone–DNA interactions, the "octamer transfer" model appears unlikely. Therefore, a third "octamer sliding" model (Figure 1C) was proposed for NURF and CHRAC. In contrast to RSC, NURF and CHRAC increase the mobility of histone octamers along DNA without affecting the integrity of the octamer. The basis of this model is that both NURF and CHRAC can promote nucleosome redistribution to one favored position. Whether any of the models are correct *in vivo* remains to be determined.

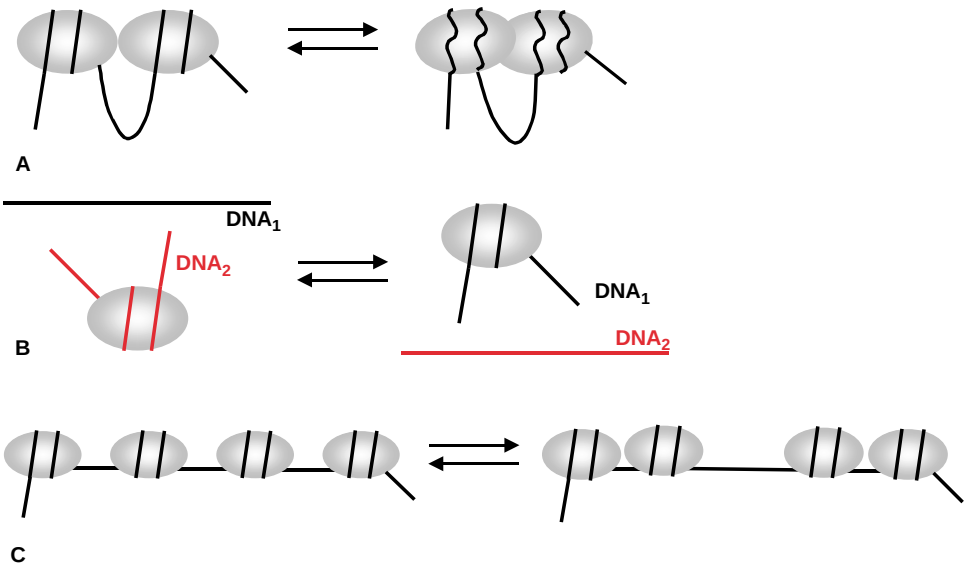

FIGURE 1 Schematic representation of the proposed ATP-dependent remodeling mechanisms. (A) Interconversion model (nucleosome destabilization model). (B) Octamer transfer model showing a histone octamer being transferred from one molecule of DNA to another. (C) Octamer sliding model showing the regularly spaced nucleosomes are disrupted. All three models would result in segments of DNA becoming more accessible to additional protein complexes.

Targeting of Activity

The above-described remodeling factors were first thought to bind and randomly scan DNA for nucleosome targets. However, this view changed when the BRG1 remodeling complex was found to interact with the glucocorticoid receptor, a sequence-specific DNA-binding transcription factor. Recruitment of a remodeling factor by a sequence-specific transcription factor could result in localized nucleosome remodeling and transcriptional activation. Similarly, the methyl-CpG-binding protein MBD2 could recruit the NuRD complex to patches of methylated DNA resulting in targeted remodeling, histone deacetylation, and consequently repression of methylated promoters. A third targeting strategy has developed in SWI/SNF through its ARP7/9 subunits. These proteins have distinct domains that can bind to actin and actin-related proteins which in turn target the protein complex to specific chromatin domains. A common feature of these strategies is to bring the remodeling complex into close proximity with DNA promoter sequences to achieve precise control of gene expression.

Covalent Modifications

As an important component of the nucleosome, each core histone is composed of a structured, three-helix domain called the histone fold and two unstructured tails. Although the histone tails are dispensable for the formation of the nucleosome, they are required for nucleosome–nucleosome interaction. The core histone tails are susceptible to a variety of covalent modifications, including acetylation, phosphorylation, methylation, and ubiquitination (Figure 2). Although these modifications were identified in the early 1960s, their function was not understood until very recently. The identification of the first nuclear histone acetyltransferase (HAT) by David Allis and colleagues has led to intensive studies on the function of these histone modifications. As a result, enzymes responsible for each of the modifications have been identified and the functions of these modifications, particularly in transcriptional regulation, are beginning to be dissected.

Acetylation

Since the discovery of histone acetylation by Allfrey and colleagues in 1964, many studies on this modification have been performed. As a result, this modification is the best-studied histone modification that has a direct effect on gene regulation. In contrast to the N-terminal α-acetylation on many proteins, histone acetylation occurs on the ε-amino group of specific lysine residues in the N-terminal tails. Acetylation involves the transfer of an acetyl group from acetyl-CoA onto the ε-amino group of lysine residues, which neutralizes the positive charge of the histone tails and decreases their affinity for DNA. Deacetylation, on the other hand, involves the removal of the acetyl group, thus introducing a positive charge on the histone tails. Enzymes that catalyze the acetylation process are referred to as histone acetyltransferases (HATs). Enzymes that

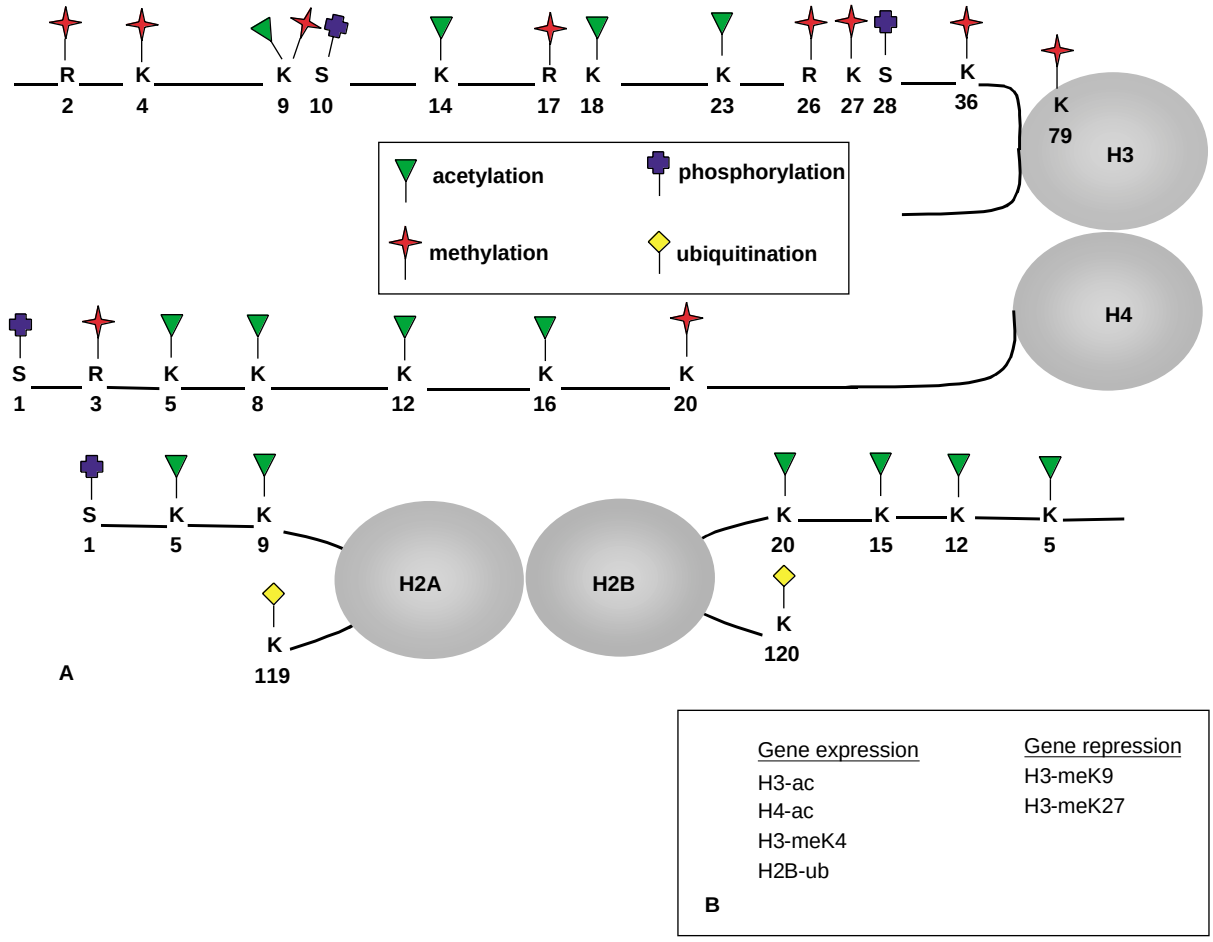

FIGURE 2 (A) Sites of known core histone post-translational modifications. (B) List of general gene expression patterns relating to histone modifications.

catalyze the reverse process are called histone deacetylases (HDACs).

Numerous HATs and HDACs have been identified and several of these enzymes are conserved across the eukaryotic spectra. While a number of the HATs, such as Gcn5, p300, and PCAF, function as transcriptional coactivators; several HDACs function as transcriptional corepressor. In general, histone acetylation leads to the relaxation of chromatin structure and thus correlates with gene activation. In contrast, histone deacetylation leads to condensation of chromatin structure and thus correlates with gene repression. Therefore, histones in the actively transcribed chromatin region, the euchromatin, are hyperacetylated while histones in the silenced chromatin region, the heterochromatin, are hypoacetylated. It has been shown that the enzymatic activities of both HATs and HDACs are important in transcriptional regulation, as inactivation of the enzymatic activity by mutagenesis of the catalytic site impairs both the enzymatic activity and their transcriptional activity. It is believed that histone acetylation levels affect higher-order chromatin structure. Therefore, acetylation likely impacts transcription by affecting the accessibility of transcription factors to their cognate DNA.

Methylation

First described in 1964, histones have long been known to be a substrate for methylation. Early studies using metabolic labeling followed by sequencing of bulk histones have shown that several lysine residues, including lysines 4, 9, 27, 36, and 79 of H3 and lysine 20 of H4, are the preferred sites of methylation. Recent studies indicate that histone methylation can also occur on arginine residues, including arginine 17 of H3 and arginine 3 of H4 (Figure 2). Arginine can be either mono- or dimethylated, with the latter in symmetric or asymmetric configurations. Proteins that catalyze histone arginine methylation belong to the protein arginine methyltransferases (PRMT) family. PRMT1 and PRMT4 catalyze H4-R3 and H3-R17 methylation, respectively. Accumulating evidence indicates that histone arginine methylation plays an important role in nuclear hormone-mediated transcriptional activation.

Although histone arginine methyltransferases were discovered before histone lysine methyltransferases, the latter have recently attracted more attention. Since the discovery of the first lysine methyltransferase SUV39H1, many histone methyltransferases (HMTases) that target to different lysine residues on histone H3 and histone H4 have been discovered. A common feature of these histone lysine methyltransferases is that they all contain an evolutionarily conserved SET domain, a motif shared in the *Drosophila* PEV (*p*osition *e*ffect *v*ariegation) suppressor Su(var)3-9, the *Polycomb*-group protein E(z), and the *trithorax*-group protein Trx. Recent studies, however, have uncovered that lysine 79 of histone H3, located in the globular domain, is also methylated in diverse species from yeast to human. Surprisingly, the responsible enzymes, DOT1 and its homologues, do not contain a SET domain. Thus, lysine methylation can be catalyzed by proteins with or without a SET domain.

Unlike histone acetylation which usually results in gene activation, the effect of histone methylation on transcription is site dependent. While H3-K4 methylation correlates with gene activation, methylation on H3-K9 and H3-K27 usually causes gene silencing. Recent studies indicate that even on the same site, the outcome of methylation may be different depending on whether it is a mono-, di-, or trimethylation. These site-specific or methylation state-specific effects may reflect the fact that different modifications are recognized and interpreted by different protein modules, such as the chromadomain and bromodomain, as suggested by the "histone code" hypothesis. Studies in the past three years have revealed that this modification has significant effects on multiple biological processes ranging from heterochromatin formation and transcriptional regulation to genomic imprinting, X-chromosome inactivation, and DNA methylation. How this modification results in such a diverse effect is currently unknown.

Phosphorylation

Both the linker histone H1 and core histones undergo phosphorylation on specific serine and threonine residues (Figure 2). Phosphorylation of histones is cell-cycle dependent with the highest level of phosphorylation occurring in M phase. H1 phosphorylation occurs on both N-terminal and C-terminal domains and is linked to transcription. For example, inactivation of the MMTV promoter correlates with H1 dephosphorylation while reactivation of the promoter correlates with H1 rephosphorylation.

Recent studies indicate that phosphorylation of serines 10 and 28 of H3 are tightly regulated and are implicated in the establishment of transcriptional competence of immediate early-response genes. For example, induction of early-response genes, such as c-*fos* and c-*jun*, is concurrent with H3 phosphorylation. Both the MAP (mitogen-activated protein kinase) pathway and the stress-activated p38 pathway are involved in this process. At least two kinases, the ERKs-activated Rsk-2 kinase and the related Msk-1 (MAP- and stress-activated kinase 1), are responsible for the rapid H3 phosphorylation. Although phosphorylation of histones correlates with transcriptional activation of a small set of immediate-early genes that are rapidly turned on and off in response to extracellular signals, the bulk of histone phosphorylation occurs in M phase when genes are silenced. Recent studies indicate that mitotic histone phosphorylation correlates with chromosome condensation and is mediated by the Ipl1 and Aurora kinases.

In addition to transcription regulation, histone phosphorylation is also linked to other cellular processes such as DNA damage and apoptosis. For example, H2A.X, an H2A variant in mammalian cells, has been shown to be rapidly phosphorylated on S139 upon exposure to ionizing radiation. Interestingly, the phosphorylated form of H2A.X is localized to mega-base regions of DNA that flank sites of double-strand breaks, suggesting that this modification may function to facilitate access of repair machinery to damaged DNA. Recent studies on H2B indicate that H2B-S14 phosphorylation is tightly associated with apoptotic chromatin and that the caspase-cleaved Mst1 (mammalian sterile twenty) kinase is responsible for this modification.

Ubiquitination

In addition to the modifications discussed above, histones and their variants can also be reversibly ubiquitinated. Unlike other modifications which result in the addition of relatively small moieties, ubiquitin is a highly conserved 76 amino acid protein. Ubiquitination occurs on the ε-amino group of specific lysine residues (H2A-K119 and H2B-K120). In higher eukaryotic cells, about 10% of H2A and 2% of H2B are ubiquitinated. While mono-ubiquitination is the major form of H2B ubiquitination, polyubiquitination, where ubiquitin molecules join to each other by isopeptide bonds, has been reported for H2A.

H2B ubiquitination has long been linked to transcriptionally active genes. It is possible that actively transcribing genes have an open chromatin structure exposing the C terminus of H2B to the enzymes catalyzing the addition of ubiquitin. Studies in the budding yeast have identified Rad6 as an H2B ubiquitination enzyme. Recent studies also indicate that methylation on H3-K4 and H3-K79 in budding yeast is dependent on Rad6 and H2B ubiquitination suggesting that different modifications have "crosstalk." It is believed that ubiquitination may serve as a signal for

the recruitment of other histone-modifying enzymes, such as histone methyltransferases. However, whether this is the case awaits demonstration.

Modification Crosstalk and the "Histone Code" Hypothesis

In addition to the crosstalk between histone methylation and ubiquitination mentioned above, crosstalk also has been shown among other modifications. For example, H3-K9 methylation and H3-S10 phosphorylation inhibit each other. H3-S10 phosphorylation, on the other hand, appears to act synergistically with H3-K14 acetylation. Moreover, it has been demonstrated that methylation on H3-K9 by SUV39H1 inhibits subsequent histone acetylation by p300, while methylation on H3-K4 by SET7 facilitates subsequent histone methylation by p300. Given that histone acetylation is linked to gene expression, the differential effects of histone methylation on subsequent acetylation provide an explanation as to why methylation on different lysine residues results in different outcomes on gene expression.

Based on the observed cross-talks, David Allis and Bryan Turner have proposed a "histone code" hypothesis. This hypothesis predicts that a pre-existing modification affects subsequent modifications on histone tails and that these modifications serve as markers for the recruitment of different proteins or protein complexes to regulate diverse chromatin functions, such as gene expression, DNA replication, and chromosome segregation. The best available evidence supporting this hypothesis is derived from the identification of protein modules that recognize specific modifications on histones. For example, the bromodomain, a motif present in many chromatin-related proteins, can specifically bind to acetylated

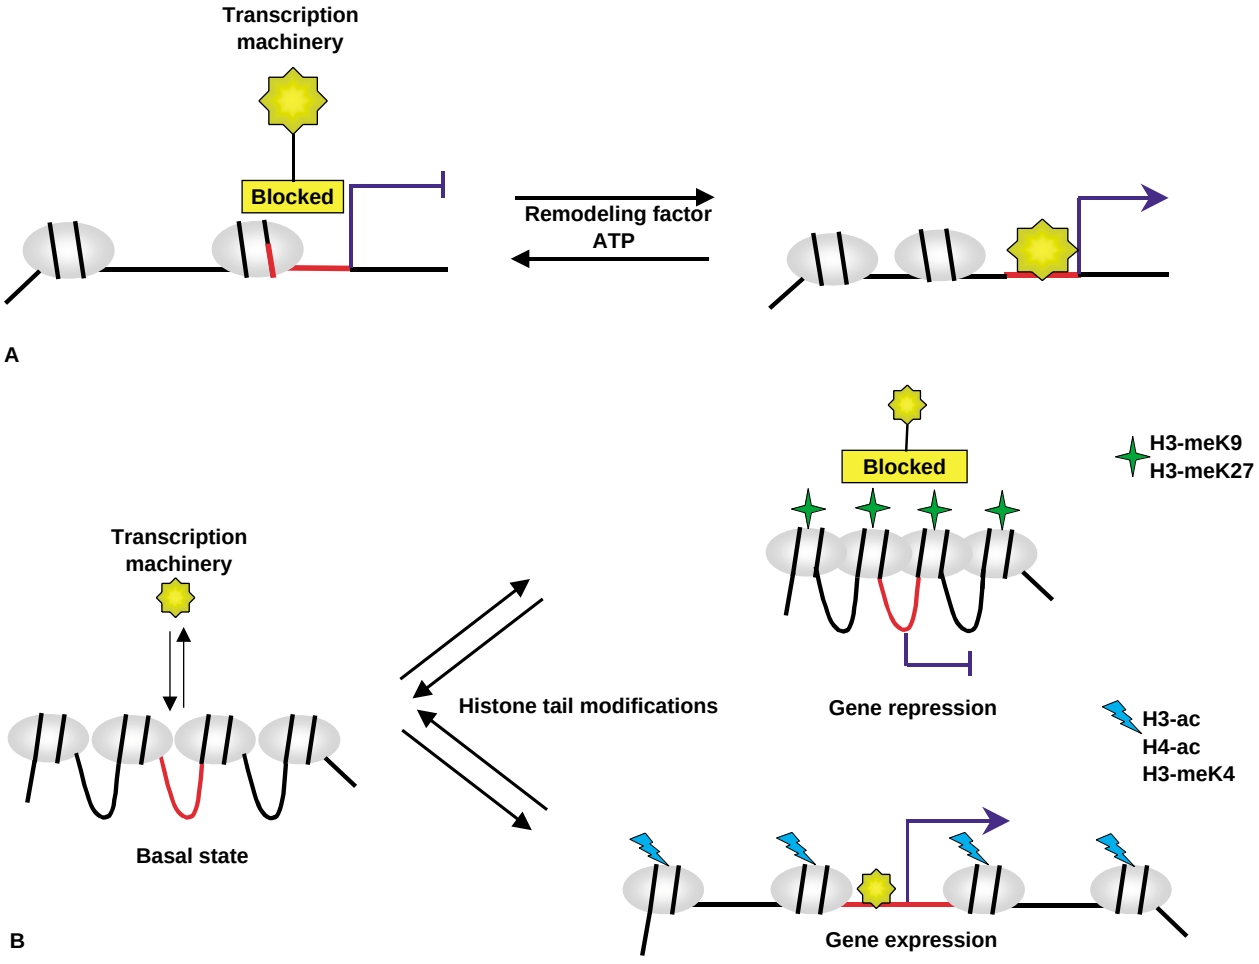

FIGURE 3 General mechanisms of chromatin remodeling and histone modification in relation to gene expression. Sunburst represents transcriptional machinery and associated factors, red lines represent gene promoter regions, stars and lightning bolts represent different histone tail modifications. (A) ATP-dependent chromatin remodeling can lead to blocked promoters becoming accessible to transcription stimulating complexes. (B) Histone tail modifications can lead to gene repression or expression depending on the modification.

lysine residues. Similarly, chromodomain, a motif also present in many chromatin-related proteins, can specifically bind to methylated lysine residues. It is believed that the unique set of covalent modifications present on a given nucleosome serves as a "landing pad" for the recruitment of additional proteins that "read" or "interpret" the "histone code" to decide the outcome. Defining the "histone code" and identifying protein modules that read the code remain a challenge for the people in the chromatin and transcription field.

Histone Variants

A discussion of chromatin and gene expression would not be complete without mention of histone variants. Several variations of "conventional" histone proteins have been identified in all eukaryotes from yeast to man. These variations on the histone proteins are usually found complexed in the octamer with the "normal" versions of the other histone proteins within defined regions of DNA. A well-documented H3 variant called CENP-A has been found to mark centromeres in all eukaryotic organisms studied thus far. Centromeric chromosomal regions have very few genes and are compacted into repressed heterochromatin. In contrast, the H2A variant called H2A.Z has been found to associate with inducible promoters. These are thought to play a role in the signal transduction pathways necessary for the expression of inducible genes. In addition, another H2A variant, H2A.X has been found to be specifically enriched in the proximity of double-strand break.

Putting it All Together

While compacting DNA into a manageable structure is important for cell integrity, it also creates the problem of restricting the access of important regulators from DNA elements. To circumvent this potentially dangerous problem, the cell has developed a rather complex scaffold of histone proteins that can be altered and modified to expose important regions of the DNA. Covalent modifications of histone tails can serve to disrupt higher-order chromatin structure returning DNA to a "beads on a string" state. ATP-dependent nucleosome remodeling machinery can reveal DNA sequences masked by nucleosome interaction to important regulatory proteins, and variant histones can serve to mark complete functional domains within the chromosome (such as repressed centromeric regions) as active or inactive transcriptional regions. Studies in the past 10 years have changed our view of chromatin from a static structure to a dynamic regulatory machine that impacts all aspects of biological processes involving DNA (Figure 3). A combination of all the regulatory systems that a cell uses to modulate chromatin structure is the basis on which the complexity and diversity of life is built.

Glossary

bromodomain A distinct protein domain that is found in chromatin-related proteins in a variety of organisms from mammals to yeast. Bromodomain binds specifically to acetylated lysine residues on histone proteins.

chromatin Name given to the DNA–protein complex present in the nucleus of eukaryotic cells.

chromodomain The chromatin-organization-modifier domain, a conserved region of ~60 amino acids, originally identified in *Drosophila* modifiers of variegation. Recent studies indicate that this domain binds specifically to methylated lysine residues on histone proteins.

nucleosome The repeating unit of chromatin composed of DNA wrapped around a histone octamer consisted of two copies each of H2A, H2B, H3, and H4.

Biography

Eric M. Kallin is a graduate student in the curriculum in Genetics and Molecular Biology at the University of North Carolina at Chapel Hill. He received his B.S. in Biochemistry at the State University of New York at Geneseo. His current research, understanding the role of epigenetic modifications in cell lineage commitment, is being carried out in the laboratory of Dr. Yi Zhang.

Yi Zhang is an assistant Professor of the Department of Biochemistry and Biophysics and a member of the Lineberger Comprehensive Cancer Center at the University of North Carolina at Chapel Hill. His research interest centers on the role of chromatin remodeling and histone tail modification in gene expression and cell lineage commitment. He obtained his Ph.D. from Florida State University in 1995. He made seminal discoveries that link nucleosome remodeling to histone tail modification. His laboratory at UNC has been responsible for the discovery of a number of novel histone methyltransferases.

Chromatin: Physical Organization

Christopher L. Woodcock
University of Massachusetts, Amherst, Massachusetts, USA

The term chromatin was coined by cytologists to designate the brightly staining portions of nuclei exposed to basic dyes. Although this terminology is still in effect, in the context of biological chemistry, chromatin usually refers to the complex of DNA and protein that is present in the interphase nucleus, and can be isolated for study *in vitro*. As with all biological systems, the physical organization of chromatin results from the intrinsic biochemical properties of the components as influenced by the composition of the aqueous medium. Since chromatin organization plays a critical role in many aspects of gene regulation, there is much interest in understanding the basic principles involved. Here, the current status of this challenging task is discussed in terms of the major components of chromatin, their interactions, and the complex, dynamic "biopolymer" that results.

A crude analysis of isolated chromatin reveals a 1:1 ratio of DNA and histones, small, highly conserved basic proteins. Four species of histone (H2A, H2B, H3, and H4) contribute two copies each to the histone core of the nucleosome, a disk-shaped structure 11 nm in diameter and 6 nm in height, while histone H1 binds to the exterior of the nucleosome. Other proteins bound to DNA in chromatin are collectively known as "non-histone chromatin proteins" (NHCPs), and include both structural and enzymatic components. Thus, at the simplest level, the physical organization of chromatin consists of very long linear arrays (one for each chromosome) of nucleosomes arranged in a beads-on-a-string conformation, together with bound NHCPs. This "primary structure" is variously folded and compacted, and (in the interphase nucleus) occupies a distinct volume or "territory" with little or no intermixing with other chromosome territories. Prior to cell division, a complex series of events transforms interphase chromatin into the familiar linear metaphase chromosomes. It is clear that the arrays of nucleosomes are exposed to a wide range of local and global factors that influence the degree of chromatin compaction, and the challenge has been to understand the impact of these factors on the physical organization. There is strong evidence that features of chromatin organization such as compaction level are related to mechanisms of differential gene expression. Further, some aspects of chromatin organization are important in epigenetic inheritance, whereby properties such as differential gene silencing or activation are inherited not as differences in DNA sequence, but as specific chromatin structures and their components.

Global factors that influence the physical organization of chromatin include the ionic milieu of the nucleus, especially the concentrations of monovalent and divalent cations, and polycations such as polyamines. The combination of charge shielding and charge neutralization that results from exposure of chromatin to cations *in vitro* results in stronger intra-chromatin interactions (as the self-repulsive properties of DNA are negated) and greater compaction. Indeed, at the concentration of cations thought to be present in the living nucleus, chromatin *in vitro* tends to aggregate and essentially precipitate. Modulating the effects of cations are local variations in nucleosomes (histone variants, histone modifications), DNA modifications (chiefly cytosine methylation), and bound NHCPs (often related to histone modifications). Thus, the chromatin template has the potential to assume a continuum of compaction levels, and it is this context that its physical organization has to be viewed. In this article, the principal variables that can influence the structure and function of a given portion of the genome are outlined, after which the question of physical organization is discussed.

Variables that may Influence Chromatin Physical Organization

Posttranslational Modifications of Core Histones

The presence of a large variety of core histone modifications has been known for many years, but its role in chromatin was very poorly understood. Recently, however, evidence has grown that the pattern of histone modifications on an individual nucleosome or array of nucleosomes encodes information that is essential in determining a variety of functional states. Many modifications occur on the N termini of the core histones which project from the nucleosome and are

unstructured in the sense that they are not detected in nucleosome crystals by X-ray analysis. Some, such as acetylation and methylation of lysine residues result in the net loss of a positive charge, and may in itself result in a change in chromatin conformation. However, it is clear that the functional implications of histone modification result from far more complex effects than alterations in charge balance.

For example, H4 acetylation can occur at one or more of four lysines in the N terminus, and these modifications alone, and in combination, carry important functional signals. The net acetylation pattern is the result of the balance between histone acetylase (HAT) enzymes and deacetylase (HDAC) enzymes. Both HATs and HDACs tend to occur in large complexes that may contain proteins that serve to target the enzymatic activity to the appropriate gene(s). Specific acetylation patterns also occur on newly synthesized chromatin, and are erased after deposition as nucleosomes close to the replication fork.

Another key set of histone modifications involves the methylation of lysines on histone H3. Here, another level of complexity arises because the methyl transferases may deposit one, two, or three methyl groups, and the number of methyl groups provides another signal. Certain methylation patterns are important in providing binding sites for a group of NHCPs known as heterochromatin protein 1 (HP1). HP1 tends to accumulate on transcriptionally silent chromatin and appears to be involved in the down-regulation of genes.

Variants of Core Histones

Typically, higher organisms have several genes for each of the core histones, some of which may be identical in sequence, while others vary in amino acid sequence. The majority of core histone genes are transcribed only during DNA replication, and are incorporated into nucleosomes in the wake of the replication fork. Others are synthesized constitutively, and incorporated into nucleosomes only at the relatively rare event of displacement of a complete histone octamer. An interesting example is provided by the replication coupled H3 and the H3.3 variant which can be deposited in both replication-coupled and replication-independent pathways, and which differ at only four amino acid positions. Single amino acid changes of H3 toward H3.3 allow replication independent deposition. H3.3 accumulates modifications that favor transcription, while H3 accumulates lysine methylations, a mark of "inactive chromatin." Although H3 is by far the most abundant variant in higher organisms, it is likely to have evolved from H3.3, which is the only H3 isoform in yeast. Another H3 variant which is highly conserved evolutionarily occurs only in centromeric chromatin.

Histone H1

Histone H1, also known as "linker histone," plays a dominant role in establishing the compaction state of an array of nucleosomes, as well as influencing the conformation. H1 has three domains: a central globular domain that binds near the entry/exit site of linker DNA on the nucleosome, and extended N and C termini. The C terminus is particularly rich in the basic amino acids lysine and arginine, and thus has a strong propensity to bind DNA. H1 binding protects an extra $\sim$20 bp of nucleosomal DNA from nuclease digestion, a protection conferred by the globular region alone. There is a general correlation between the amount of H1 in chromatin, and its ability to be transcribed, and most models of transcriptional regulation call for the displacement of H1. The silencing effect of H1 could be due to the "sealing" of two turns of nucleosomal DNA, thus preventing the unwrapping needed for RNA polymerase, or to the H1-induced physical compaction of arrays of nucleosomes or most likely to a combination of both.

Like the core histones, there are several variants of H1 in most higher organisms, but little is known about their individual properties. Genetic manipulations of mice that knock out one or two variants produce no observable phenotype, and the remaining variants are up-regulated to compensate for the loss. The loss of additional variants leads to a depletion in total H1 and eventually embryonic lethality. However, in H1-depleted nuclei, there is no general derepression of transcription, as predicted by the simple model that H1 loss should create "open" and permissive chromatin.

NHCPs

A two-dimensional gel of the proteins bound to the chromatin of an active nucleus reveals hundreds of spots, and it is clear that there are many other proteins present in low abundance that are revealed only after staining with specific antibodies. To date, relatively few of these NHCPs have been studied in detail, and most of these are either abundant in the nucleus, or came to researchers' attention through functional studies of specific genes or classes of genes. Most NHCPs can be eluted from chromatin by treatment with 0.3–0.4 M monovalent ions (usually NaCl), in contrast to H1 which requires 0.5–0.6 M NaCl and the core histones which elute between 0.8 and 2.0 M salt. There is some evidence that the few proteins that remain bound in 2.0 M salt contribute to a nuclear skeleton (karyoskeleton, nuclear matrix), which provides structural integrity to the nucleus, and has an important dynamic role in its spatial organization as well as replication and transcription. However, despite much effort, it has not been possible to reveal an *in vivo* karyoskeleton analogous to the cytoskeleton, and the possibility that

the residual proteins in salt-extracted (and usually DNase-treated) nuclei represent an aggregation phenomenon has not been excluded. The finding that the most abundant nuclear matrix proteins are associated with the peripheral nuclear lamina or are part of the RNA transcript processing machinery has reinforced these concerns.

The ubiquitous and abundant (typically 1 per 10–15 nucleosomes) high mobility group (HMG) proteins elute from nuclei in 0.3–0.4 M salt, and were originally grouped together on the basis of their solubility properties and rapid mobility in gels. A new nomenclature based on the presence of conserved domains or "boxes" distinguishes three classes. Members of the HMG-B group share the "HMG-box" functional domain, which contains three α-helices and, when bound to double-stranded DNA, induces a bend of $\sim 90°$. In contrast, the HMG-N family of proteins bind to nucleosomes via a nucleosome binding domain (NBD), resulting in a change of conformation, and the stimulation of transcription and replication. Finally, the HMG-A family members contain three "A–T hook" motifs that bind preferentially to the minor groove of DNA rich in AT sequences. HMG-A proteins appear to participate in a wide range of chromatin-based processes and are often up-regulated in cancerous cells. The lack of sequence specificity of all the HMG proteins suggests that they are targeted to the appropriate sites by interactions with other nuclear proteins, and evidence is accumulating for many such interactions.

The HP1 family of NHCPs, known to play a role in epigenetic inheritance, is also conserved across a wide range of eukaryotes, with three isoforms, α, β, and γ found in mammalian nuclei. HP1 (as well as several other important NHCPs) molecules share a "chromo" domain which binds not to DNA but to the methylated form of lysine 9 on histone H3. HP1 also interacts with numerous other proteins, including an enzyme that methylates H3. This illustrates the complex interactions and feedback loops that are probably widespread in the nucleus.

The protein families discussed above are certainly only a small subset of the repertoire of NHCPs, but perhaps representative of the different modes of action, which range from modifying chromatin "architecture" to acting as targets for other proteins. Most NHCPs are not stably bound to chromatin, but are remarkably mobile within the nucleus.

Levels of Physical Organization

The large number of variables in chromatin composition have the potential to influence its global and local physical organization, especially the degree of compaction, and the related level of transcriptional competence (higher compaction correlates with reduced transcription). A useful approach is to consider chromatin compaction in terms of hierarchical levels of folding, using a nomenclature based on that devised for proteins (Table I). For chromatin, it is necessary to distinguish between "local" structures that may be confined to specific genes, portions of genes, or groups of genes, and "global" structures that are nucleus wide.

Global Primary Structures – The Nucleosome Repeat Length (NRL)

While the length of DNA incorporated into the nucleosome is fixed at 146 bp, the length of "linker" DNA between nucleosomes is variable. At the level of the whole nucleus, each cell type in an organism has a characteristic average NRL, most mammalian cells having NRLs between 175 and 195 bp. The longest

TABLE I

Hierarchical Classification Scheme for Chromatin Physical Organization

Level of chromatin physical organization	Examples of global features	Examples of local features
Primary – the linear arrangement of nucleosomes on DNA	The nucleosome repeat length	Preferred locations of nucleosomes and features such as DNase hypersensitive sites on a specific DNA sequence.
Secondary – structures formed by interactions of nucleosomes	The "30 nm" chromatin fiber	3D architecture of nucleosomes and regulatory proteins on a specific DNA sequence.
Tertiary – structures formed by interactions between secondary structures	Thicker fibers seen in nuclei and postulated to be composed of 30 nm fibers	Long-distance contacts possibly involving locus control regions, enhancers and promoters, or looped chromatin domains.
Quaternary and above – structures formed by interactions between tertiary structures etc.	No unambiguous examples – see text	Interphase chromosome territories; metaphase chromosomes

NRLs, measured to date, ~240 bp are in echinoderm sperm (which have unusual core and H1 histones), and the shortest, ~165 bp, derived from yeast (*Saccharomyces cerevisiae*), which lack a typical histone H1.

Local Primary Structures

Overlaying the global NRL for a given nucleus, and the general rule that nucleosomes are randomly deposited, there are many instances where nucleosomes on particular genes and gene-regulatory sequences may be positioned with base-pair precision, and the local NRL may differ from the global NRL. This local positioning often contributes to transcriptional regulation. For example, a nucleosome positioned on a promoter sequence may block the binding of proteins and protein complexes that are required for transcription initiation. Relieving such a transcriptional block may be achieved by a nucleosome "remodeling" process. Other cases are known where a specific DNA sequence is normally nucleosome free. These sites, which are most common in gene-regulatory sequences and are probably occupied by NHCPs *in vivo*, may be detected by their hypersensitivity to nucleases.

Specialized DNA sequences may have a characteristic NRL that differs from the global value. The long stretches of gene-free chromatin at the ends (telomeres) of chromosomes, which consist of tandem repeats of TTAGGG typically have a shorter NRL than bulk chromatin.

Local primary structures may also be influenced by cytosine methylation of CpG dinucleotides, followed by binding of methylated DNA-binding proteins (MBDs). Some MBDs have binding sites for HDAC complexes, leading to local histone deacetylation and hence transcriptional silencing, and there is evidence that MBDs may promote chromatin compaction.

Global Secondary Structures – The "30 nm" Chromatin Fiber

If chromatin is isolated from nuclei and observed by electron or atomic force microscopy, it is seen to have a conformation highly dependent on the ionic strength of the medium – at low ionic strength (5–25 mM Na^+), the linear array of nucleosomes is clearly seen, while at higher ionic strengths, increasing compaction occurs, leading to the formation of an irregular fiber ~30 nm in diameter. This reversible transformation, which is dependent on H1, can also be monitored by changes in physical properties such as sedimentation velocity. Much research effort has been expended on determining the physical organization of the 30 nm fiber, and several different models have been proposed. The most widely discussed are solenoidal structures in which the linker DNA continues the superhelix established in the nucleosome, creating a "stack-of-coins" which subsequently coils into a 30 nm diameter fiber, and zigzag structures in which the linker DNA remains more or less straight and compaction results from the accordion-like compression of the zigzag. Among recent results supporting a zigzag arrangement are computer models derived from force-extension curves of individual chromatin fibers (Figure 1), which bear a striking similarity to native chromatin fibers imaged in the hydrated form (Figure 2). The physical irregularity of native chromatin fibers, which probably results largely from the local variations in NRL has contributed to the ongoing controversy. The ability to reconstitute artificial chromatin with regularly spaced nucleosomes may finally provide an unequivocal answer to the structure of the 30 nm fiber.

Local Secondary Structures

There is much evidence that local chromatin secondary structures play a large role in chromatin function by promoting or repressing transcription, but little is known of the precise physical organization of these local structures. In some instances, it has been demonstrated that a stretch of chromatin may accumulate many copies of NHCP that acts as a transcriptional silencer (e.g., HP1), but the difficulty of isolating single gene chromatin for observation precludes rapid progress.

Tertiary and Higher Level Features

Although it is often assumed that native chromatin exists as a series of hierarchical structures above the 30 nm chromatin fiber (and such illustrations are common in textbooks), there is very little solid supporting data. Methods used to examine isolated 30 nm fibers fail to reveal tertiary or higher levels of folding as the ionic

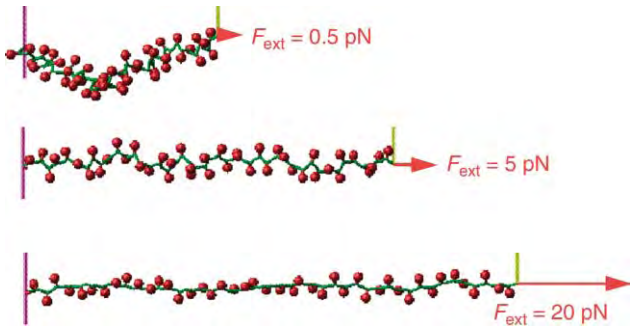

FIGURE 1 Computer models of chromatin secondary structure at different levels of extension (F_{ext}) based on force-extension data derived from pulling single chromatin fibers. Nucleosome core particles are represented by red spheres, and linker DNA by green rods. Modified from Katritch, V., Bustamante, C., and Olson, W. K. (2000). Pulling a single chromatin fiber: Computer simulations of direct physical manipulations. *J. Mol. Biol.* **295**, 29–40.

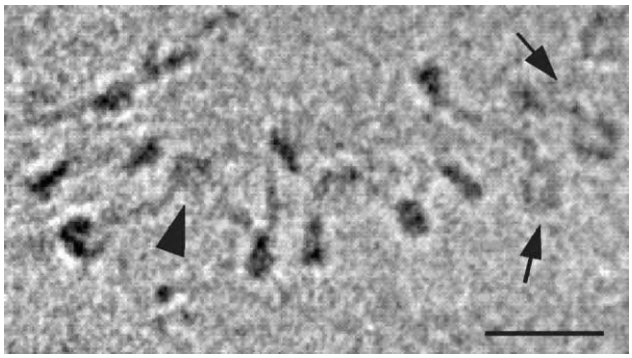

FIGURE 2 Chromatin fiber observed in the frozen hydrated state in 20 mM NaCl. Many of the nucleosomes are viewed edge-on and appear as dark ovals. Arrowheads point to two nucleosome showing the circular enface profile. The zigzag secondary structure bears a strong resemblance to the model in Figure 1. Scale is 30 nm. From Bednar, J., Horowitz, R. A., Grigoryev, S. A., Carruthers, L. M., Hansen, J. C., and Woodcock, C. L. (1998). Nucleosomes, linker DNA, and linker histone form a unique structural motif that directs the higher-order folding and compaction of chromatin. *Proc. Natl Acad. Sci. USA* **95**, 14173–14178.

strength is increased toward the "physiological" level. Rather, chromatin tends to aggregate. Examination of thin sections of nuclei in the electron microscope reveals many different "fiber" diameters ranging up to 240 nm, with no clear hierarchical arrangement. Indeed, only under rather specialized conditions and with inactive nuclei can 30 nm fibers be routinely observed in sections. Whether this lack of order *in situ* is due to problems of adequate structural preservation, or simply to a very unstructured and dynamic native organization remains to be seen.

Chromatin Dynamics

Recent work has revealed that living nuclei are remarkably dynamic. While the nucleosome core histones are long lived and stably incorporated, histone H1 binds to chromatin with a half-life of a few minutes, and most NHCPs have half-lives of a few seconds. Modeling of chromatin fibers based on thermodynamic principals indicates a constant fluctuation in local compaction. Also, individual clusters of genes may change dramatically in compaction state and even location in the nucleus when transcription is stimulated. These observations reinforce the concept of the living nucleus as a highly dynamic entity, both in terms of genetic activity and physical organization.

Glossary

chromatin Generic term used for (1) material in the nucleus that stains strongly with basophilic dyes and (2) the complex of DNA and chromatin that may be extracted from nuclei for *in vitro* study.

histone Family of highly conserved, small basic proteins which constitute the principal protein components of chromatin.

histone modification Covalent addition of one or more chemical groups to a specific amino acid in a histone. Modifications include acetylation, methylation, phosphorylation, poly-ADP ribosylation, and ubiquitination.

histone variant A histone molecule derived from a different gene and having specific amino acid differences from the "canonical" histone type.

nonhistone chromatin proteins Generic term for proteins other than histones that may be bound to chromatin.

nucleosome The complete repeat unit consisting of a nucleosome core particle and the linker DNA that continues to the next nucleosome core particle, often with histone H1.

nucleosome core particle The disc-shaped (11 nm diameter, 6 nm high) complex of 146 bp of DNA and octamer of histones H2A, H2B, H3, and H4 that is the fundamental structural unit of chromatin. The X-ray structure of the core particle has been solved.

Biography

Christopher L. Woodcock received his bachelors and doctoral degrees at University College London, and pursued postdoctoral research at the University of Chicago and Harvard University before joining the University of Massachusetts Amherst in 1972, where he is now Gilbert Woodside Professor of biology and Chair of the biology department. His interest in chromatin organization began in the early 1970s at the inception of nucleosome model of chromatin, and he has focused his research largely on the physical organization of nucleosomal arrays using direct visualization by electron microscopy as the major analytical tool.

Chromosome Organization and Structure, Overview

Elena Gracheva and Sarah C. R. Elgin
Washington University, St. Louis, Missouri, USA

A chromosome is the packaged form of a single linear double-helical DNA molecule. The genome of a eukaryotic organism consists of from 1 to over 200 chromosomes. Chromosomes are located in the nucleus of the cell and exist in the form of chromatin, a complex between the DNA, the histones (small, highly basic proteins), nonhistone chromosomal proteins (both enzymatic complexes and structural components), and a small amount of RNA (both nascent transcripts and structural components). The numbers and sizes of chromosomes vary considerably between species (*Drosophila* has four chromosomes per haploid cell, human has 23, etc.). As cells enter mitosis, the chromatin is condensed into readily observed, rod-shaped structures, the metaphase chromosomes; a complex process, as described below, is required to package the linear DNA molecule in this form, typically achieving 10,000-fold compactness. Metaphase chromosomes were one of the first subcellular structures observed by cell biologists of the 19th century. Chromosomes were subsequently identified as the vehicle for transmission of genetic information during cell division. As the daughter cells return to interphase, the nucleus reforms, and the chromosomes are decondensed and distributed within the nucleus. The level of DNA packing is much lower during interphase, but is of critical importance in the regulation of gene expression.

All genetic information – genes, regulatory elements and signals for structural organization – is arranged linearly along chromosomes. The chromosomes provide not only the means for inheritance, but also the template for transcription, the process of "reading out" the information required by the cell. Different and specific expression profiles are needed for each cell type and stage of development. A full understanding of the mechanisms used in the global regulation of gene expression will not be achieved until the relationships between the linear content of each chromosome, its local and higher-order packaging, or chromatin structure, and the three-dimensional arrangement of the chromosomes in the nucleus have been defined.

The Structure of Chromatin

The nucleotide sequence of DNA represents the primary level of chromosome organization. When a DNA molecule is packaged into chromatin, the latter does not behave as a uniform fiber. The chromosome conformation is affected by regulatory and structural features. These sequence elements include promoter proximal elements that control the activity of individual genes, locus control regions that impact a cluster of genes, and boundary elements that potentially regulate the activity of large (10–100 kb) chromosomal domains. In addition to the unique sequences that code for genes, eukaryotic genomes include a high percentage of repetitious DNA, both tandem arrays of short-repeating motifs (often identified as "satellite" DNA because of its different density) and dispersed relics of transposable elements, retroviruses, and the like. Some of the repetitious DNA is utilized in the generation of special chromosome structures such as the centromere, the site of microtubule attachment during mitosis, and the telomeres, structures that protect the ends of the DNA molecules.

The discovery of nucleosomes, repeating subunits based on DNA folding around an octamer of histones, provided a molecular description of the fundamental unit of chromatin folding and accounted for the first six- to sevenfold linear compaction of the DNA. The octamer, containing two molecules each of the core histones H2A, H2B, H3, and H4 (a tetramer of $[H3 + H4]_2$ plus two dimers of [H2A + H2B]) with 147 bp of DNA wrapped around it in 1 2/3 left-handed turns, makes up the core particle. The high-resolution 2.8 Å structure reveals the details of histone organization within the nucleosome (Figure 1). The C-terminal two-thirds of the histone molecules, folded in a "handshake" motif, form the core of the nucleosome, while their amino-terminal tails extend outwards and are potentially involved in further interactions with DNA, with other proteins, and between adjacent nucleosomes. Typically 170 bp of DNA follows a bent path round the histone core, held strongly by electrostatic bonds between the basic amino acids of the histones and the phosphates of the DNA. The segments of DNA that link adjacent nucleosome core particles ("linker" DNA) are bound by linker histones (H1 and its variants) or

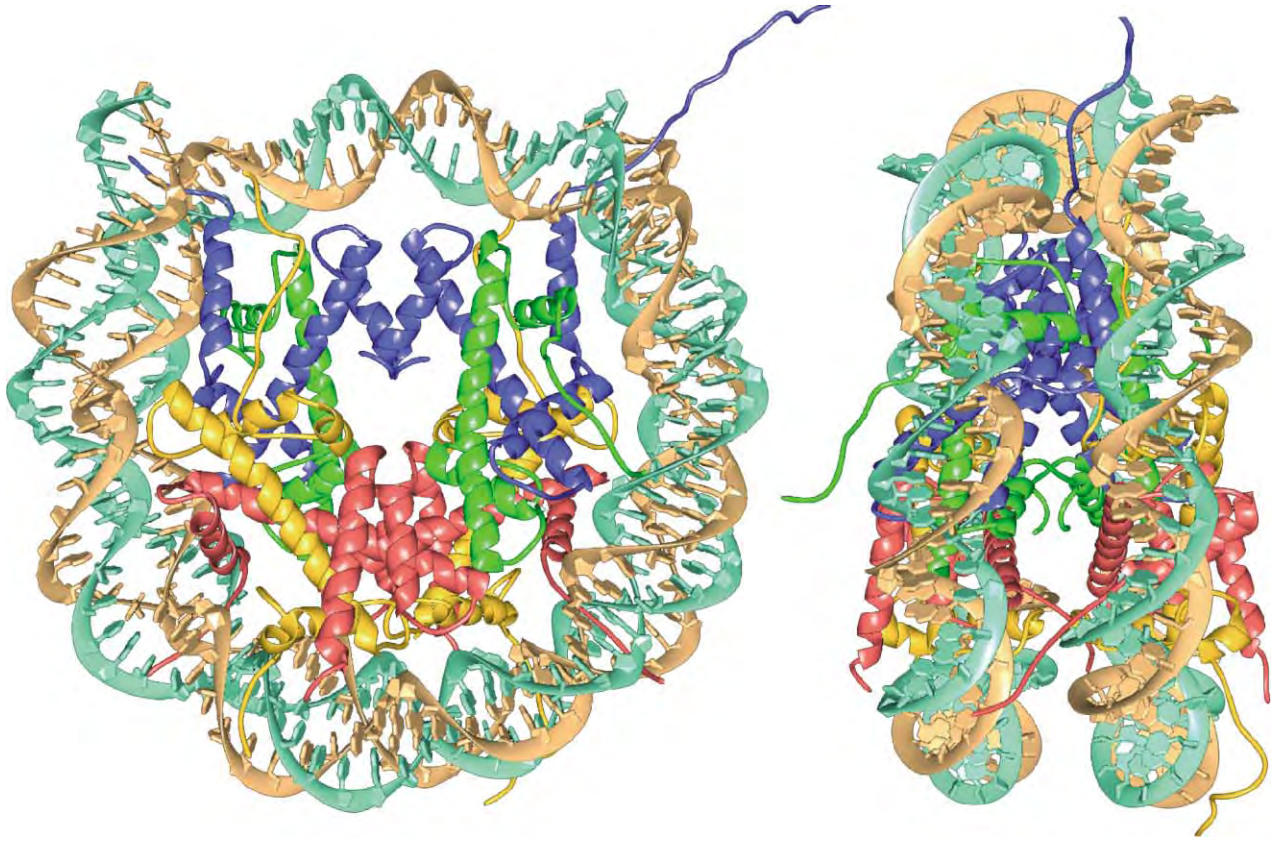

FIGURE 1 The structure of the nucleosome core particle. Brown and green ribbon traces represent the double-stranded 146 bp fragment of DNA. H2A molecules are shown in yellow, H2B in red, H3 in blue, and H4 in green. (Reprinted from Luger, K., Mader, A. W., Richmond, R. K., Sargent, D. F., and Richmond, T. J. (1997). Crystal structure of the nucleosome core particle at 2.8Å resolution. *Nature* **389**(6648), 251–260.)

HMG proteins. These proteins contribute to the further folding of the chromatin fiber, playing a role in the condensation of the 10 nm fiber to form a 30 nm fiber (Figure 2).

The arrangement of nucleosomes within the 30 nm fiber remains largely unknown. A widely utilized model, derived primarily from physical measurements and diffraction studies, is based on a solenoid, in which the nucleosomal fiber is wound in a regular helix, with about six nucleosomes per turn. The linker histones face inwards and help to stabilize the solenoid. However, new single-molecule methods, using microscopy to study single chromatin fibers, suggest a different picture. Both atomic force microscopy (AFM) and cryo-electron microscopy (EM) images show a chromatin fiber that appears as an irregular helix, with a fluctuating zigzag secondary structure. These images do not support the notion of regular solenoids. Comparative studies suggest that the linker DNA with the associated linker histone generates a specific orientation that directs the higher-order folding and compaction of chromatin along the 30 nm fiber axis in an accordion-like manner (Figure 2B).

The 30 nm fiber is thought to be the basic form of much of the chromatin during interphase. However, a subfraction of the chromatin remains condensed, and darkly staining (heteropycnotic), as the cell returns from metaphase to interphase. This condensed fraction is referred to as "heterochromatin," while the more diffuse material is labeled "euchromatin."

Heterochromatic domains contain a high proportion of repetitious DNA sequences (satellite DNA, retrotransposons, and other transposable element relics), have a low gene density, are replicated late in S phase, and show little or no meiotic recombination. Genes normally resident in euchromatin become inactive when placed in or near a heterochromatic environment by rearrangement or transposition. The factors that define specific chromosomal domains as preferred sites of heterochromatin assembly are not well understood, but it appears likely that heterochromatin formation is linked to the presence of repeated DNA sequences. Heterochromatic regions show a more regular nucleosome array (more even spacing) than euchromatic regions; however, the precise nature of the difference in packaging between heterochromatin and euchromatin remains unknown.

Chromatin structure is intimately involved in the regulation of chromosome activities: replication, transcription, and repair. The packaging of a DNA

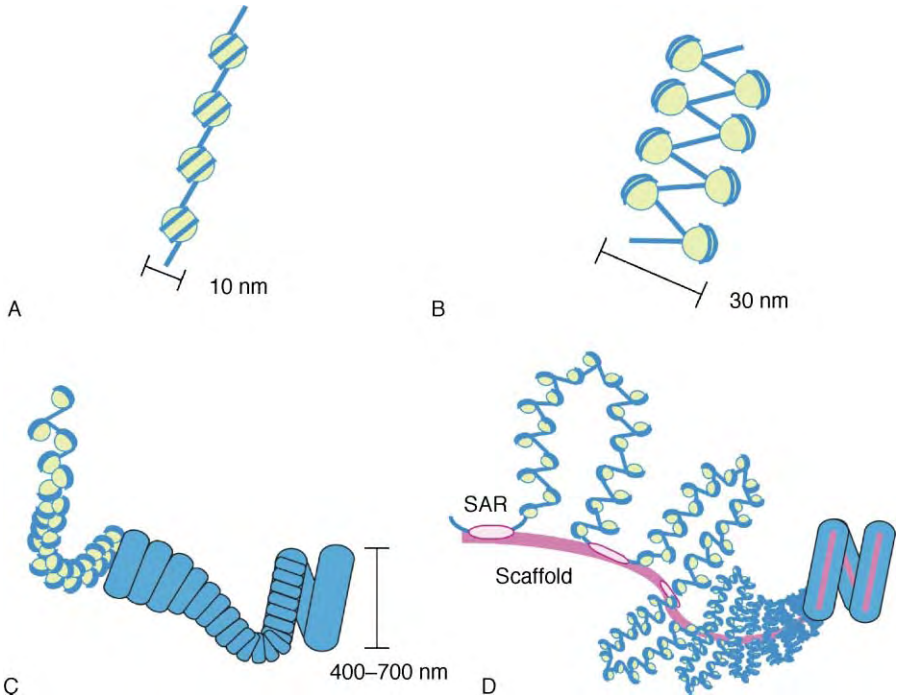

FIGURE 2 Hierarchical levels of chromatin organization. (A) Structure of the 10 nm nucleosome fiber. Histone octamers are shown as yellow circles, the blue line designates double-stranded DNA wrapped around an octamer. (B) Possible structure of the 30 nm chromatin fiber based on a three-dimensional zigzag arrangement. (C) Formation of higher-order chromatin structure by coiling into thicker (400–700 nm) chromatin fibers. (D) Organization of the chromatin into loops radiating out from a scaffold (magenta). Pink ovals represent SAR elements. (Reprinted from Swedlow, J. R., and Hirano, T. (2003). The making of the mitotic chromosome: Modern insights into classical questions. *Molecul. Cell.* **11**(3), 557–569.)

protein-binding motif with histones in a nucleosome often renders that signal invisible to the protein. For example, packaging of a TATA box sequence into a nucleosome blocks initiation of transcription; assembly of a restriction site into a nucleosome blocks cleavage by that restriction enzyme. Thus, it is no surprise that chromatin needs to undergo significant structural change, or "remodeling," to enable the cellular machines that perform various functions to gain access to their template, the double-helical DNA. The challenge to understand chromatin structure and dynamics, and to link chromatin structure to function, is enormous. Current research has highlighted the role of postsynthetic modifications of both the histones and the DNA in "marking" different structural states and providing appropriate signals to the cellular machines.

The core histone proteins are highly conserved; in the most extreme example, there are only two amino acid changes between the sequences of histone H4 from plants and animals. While the globular carboxy-terminal domains make up the nucleosome core, the flexible amino-terminal tails protrude outward from the core structure. These basic tails function as acceptors for a variety of posttranslational modifications, including acetylation, methylation, and ubiquitination of lysine (K) residues, phosphorylation of serine (S) and threonine (T) residues, and methylation of arginine (R) residues. Several studies have shown that histone modifications can be cooperative or conflicting, one modification facilitating or blocking another. The combination of histone modifications present determines the chromatin status of small and large regions of the genome and mediates its functional activity. In particular, histone acetylation is associated with gene expression, while deacetylation, with methylation of histone H3 on lysines 9 and/or 27, is associated with silencing. These patterns can be altered by multiple extracellular and intracellular stimuli that signal to the nucleus. In fact, recent studies have shown that many proteins characterized as activators or silencers of transcription work by causing or facilitating a change in the modification state of the histones at a given locus. Thus, chromatin itself has been proposed to serve as a signaling platform and to function as a genomic integrator of various signaling pathways. Covalent modifications of histone tails are believed to act in concert to establish the "histone code" essential for assembly of the desired chromatin state.

In addition to the proteins that package DNA, there are also sets of proteins that interact with specific sequences to control gene expression, interacting with promoters, enhancers, locus control regions, etc. While some such proteins can recognize DNA sequences in a nucleosome, many cannot. Both targeted alterations in histone modification and the remodeling of nucleosomes

are often required to allow these latter proteins to function. The order of the required operations for activation of transcription varies at different loci.

Other nonhistone proteins contribute to structural elements such as insulators and/or boundary complexes. Insulators define a region of regulatory activity by blocking enhancer/promoter interactions, while boundaries (or barriers) limit the spread of heterochromatin into a euchromatic domain. The arrangement of these genomic features contributes to the functional design of a locus and region. Unfortunately, it has not yet been possible to relate boundary elements, defined by their functional role described above, with the structural elements that anchor loops of DNA, as seen by electron microscopy, or with the protein scaffold that constrains the DNA in supercoiled domains of 10–100 kb. A better understanding of this level of organization will be essential to develop an understanding of how chromosomes function.

The Role of Spatial Organization of the Genome in the Nucleus

The next level of chromosome organization must take into account the three-dimensional arrangement of the chromosomes within the cell nucleus. Approaches to microscopy that allow us to examine the nucleus in three dimensions have shown that individual chromosomes occupy defined subdomains within the nucleus. This organization involves the interaction of different factors bound to specific sites in the chromosomes with regions of the nuclear envelope; the protein-facilitated juxtaposition of chromosome sites to form stable connections between distant sequences, with intervening loops of the chromatin fiber; and the possible interaction of certain DNA regions (MARs, or matrix attachment regions) with some nonchromatin elements of internal nuclear structure. Recently, there has been increasing evidence that both actin and myosin, found inside the nucleus, might have an impact on its internal structure. Unfortunately, our understanding of this higher-level packaging is very meager compared to our knowledge of the primary levels of organization. Nonetheless, such packaging can be thought of as the culmination of the hierarchy of chromatin structures that functionally connect the linear genomic sequence to the mechanisms for information processing inside the cell nucleus.

The Mitotic Chromosome

Substantial differences in the organization of chromosomes occur during mitosis. The most obvious difference is that the chromosome structure is more compact and the shape much better defined than in interphase chromosomes. This more stable structure has offered some advantages for examining the organization and packaging of the single DNA molecule of a chromatid. Several biochemical and structural studies have argued for the partitioning of the genome into a series of defined units (domains) containing 10–100 kb of DNA. Early EM studies suggested the presence of a chromosome scaffold from which loops of chromatin radiate. The scaffold might be considered as either an axial core, presumably made up of DNA and/or protein, or a loose network of DNA/protein complexes whose regulated assembly controls the higher-order structure of the chromosome. In general, scaffold models presume interactions between specific protein factors and *cis*-acting DNA sequences (SARs, or scaffold attachment regions) that determine the limits of the domains. In most models, two neighboring elements, separated by up to 100 kb of DNA, bind to the scaffold forming a loop. Experimentally, a group of very AT-rich sequences has been identified as potential SARs, based on the association of these sequences with the protein scaffold remaining after histones have been extracted from chromosomes. Using fluorescence *in situ* hybridization (FISH), SARs were visualized as a long queue running the length of the chromosome that alternately followed a fairly linear or tightly coiled path. These images were highly variable. Helically folded mitotic chromosomes have been visualized under certain conditions, suggesting that the highest order of folding is a helical winding of the chromosome arm.

However, *cis*-acting elements affecting chromosome architecture have not been identified by genetic criteria, nor have the proposed SARs (identified by biochemical assay) been mapped successfully in relation to cytological preparations. Recently, biophysical approaches for quantifying the elastic properties of mitotic chromosomes have provided important insights into their structure. The mechanical integrity of mitotic chromosomes appears to be maintained by links between chromatin fibers, not by a proteinaceous axial core. Isolation of whole chromosomes and reconstitution of mitotic chromosomes has identified topoisomerase IIa, a five-subunit complex termed condensin, chromokinesin, and the chromatin remodeling ATPase ISWI as major constituents. All presumably contribute to the change from the interphase form to the condensed mitotic chromosome. ATPases are very abundant in mitotic chromosome fractions. Probably these enzymes provide the energy for the aforementioned complexes to induce the local and global conformational changes in chromosomes required to support condensation, and microtubule-dependent movement of assembled chromosomes to opposite poles prior to cell division.

The centromere, observed in all higher eukaryote chromosomes, is a well-known landmark. It takes the form of a distinct primary constriction where the sister chromatids are held together until separated. The constricted region comprises a differentiated chromatin structure onto which microtubules bind to provide proper chromosome movements during the processes of mitosis and meiosis. The centromere in higher eukaryotes is generally made up of massive regions of repetitious sequences. Many observations suggest that there is no specific DNA sequence that is required for centromere formation, strongly implicating an epigenetic mechanism. Five mammalian CENP proteins (CENtromere Proteins) – CENP-A, CENP-B, CENP-C, CENP-G, and CENP-H – are unique and essential to the centromere. Three of these proteins – CENP-A, CENP-B, and CENP-C – have demonstrated DNA-binding activity and are potential candidates for marking the site. CENP-A is a histone H3-like protein that is conserved in mammals and other organisms; it is present only in the nucleosomes of active centromeric regions, where its presence triggers kinetochore formation. A mechanism for centromerization is not identified at present. Most of the chromatin properties of centromeres are not unique. For example, hypoacetylation of histones, a high level of DNA methylation and late replication, are also characteristic features of noncentromeric heterochromatin. The most attractive candidate for the centromeric mark is CENP-A, but the mechanism for incorporation of CENP-A into only one site per chromosome remains a puzzle.

The ends of eukaryotic chromosomes are organized into telomeres, nucleoprotein structures essential for maintaining the integrity of the genome, the so-called "guardians of the chromosome." Telomeric DNA in the majority of eukaryotes is made up of tandem repeats of short guanine-rich sequences. In some cases (e.g., in *Drosophila*), a subset of transposable elements is maintained at the chromosome ends and guanine-rich repeats are not observed. The telomeres show a very special pattern of chromatin fiber organization, distinct from the rest of the genome. The G-rich sequences can form a quadruple helix. *In vivo*, telomeres are not necessarily linear, but can form looped foldback structures, stabilized by protein components. Many of the key proteins in the telomere have been identified, although their functions are still poorly understood.

Summary

A chromosome, then, can be considered to be a single, double helical DNA molecule, running from one telomere through the centromere to the other telomere. Multiple origins of replication, and many genes, are typically found distributed along the length of the DNA molecule. The DNA is packaged first in a nucleosome array, subsequently in a 30 nm fiber, and finally in higher-order structures. This packaging contributes to gene regulation both at the level of individual genes, and at the level of large domains.

Glossary

chromatin The highly dynamic complex of DNA, histones, and nonhistone proteins from which the eukaryotic chromosome is built; it is generally used in reference to the interphase form and can refer to the sum of all chromosomes.

chromosome Structural unit of the genetic material in eukaryotes. It consists of one double-stranded DNA molecule, packaged as interphase chromatin or a metaphase chromosome. Eukaryotes have from 1 to over 200 chromosomes, depending on the species.

nucleosome Fundamental repeating subunit of the chromatin fiber, consisting of a core histone octamer (made up of two molecules each of H2A, H2B, H3, and H4) with DNA wrapped around the surface in nearly two left-handed turns, connected by linker DNA associated with one molecule of linker histone (usually H1) to the next subunit. Each repeating unit (core plus linker) packages about 200 bp of DNA.

Biography

Sarah C. R. Elgin is a Professor in the Department of Biology at Washington University in St. Louis.

Elena Gracheva is a Research Associate in the Elgin lab. The Elgin lab is interested in the role that chromatin structure plays in gene regulation, considering both effects from packaging large domains and local effects of the nucleosome array. Biochemical, genetic, and cytological studies are conducted using *Drosophila melanogaster* as a model organism. Ongoing projects include investigating the mechanisms of gene silencing associated with heterochromatin formation, and investigating the relationship between heterochromatin and euchromatin. Dr. Gracheva is also involved in investigation of the role of GAGA factor in transcription regulation.

Coenzyme A

M. Daniel Lane
Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Coenzyme A (CoA) functions as a cofactor for numerous enzyme-catalyzed reactions in animal, plant, and microbial metabolism. The structure of CoA shows that it is composed of the B-vitamin, i.e., pantothenic acid, β-mercaptoethylamine, and an adenine nucleotide with both a 5′-pyrophosphate and a 3′-monophosphate.

Most carboxylic acids, e.g., fatty acids, must be "activated" to enter metabolic pathways by conversion to their corresponding acyl–S–CoA (R–CO–S–CoA) thioesters. The sulfhydryl group (–SH) of the β-mercaptoethylamine component of CoA is the site at which carboxylic acids (R–CO_2H) bond to form acyl–thioester derivatives. Thioesters are the only form in which CoA is known to function in biological systems. Many of the enzyme-catalyzed reactions in which carboxyl groups (–CO_2H) undergo carbon/carbon-, carbon/nitrogen- or carbon/sulfur-bond formation utilize acyl–S–CoA thioesters as the acyl donor substrate.

Background and Discovery

CoA was discovered by Fritz Lipmann and his colleagues in the early 1950s. The coenzyme was first isolated from large quantities of pig liver extract as the factor required for the acetylation of sulfanilamide, the assay system used to track CoA during its purification. The discovery of CoA and the characterization and determination of its structure (Figure 1) led to Lipmann being awarded the 1953 Nobel prize in Physiology or Medicine. Lipmann's findings opened the door for the discovery of the innumerable roles of CoA, most notably the discovery by Feodor Lynen that "active acetate" was acetyl–CoA, a key intermediate in the metabolism of carbon compounds by all organisms. In 1964, Lynen was awarded the 1964 Nobel prize in Physiology or Medicine for his discovery of acetyl–CoA and of the many metabolic systems that CoA functions. We now know that CoA plays a key role in carbohydrate, lipid, and amino acid metabolism.

Enzymatic Functions of CoA and 4′-Phosphopantetheine

Chemical Mechanisms of Action

CoA occurs in cells either as free CoA or in the form its acyl–S–CoA thioester or as 4′-phosphopantetheine (4′-PP), which is part of a multifunctional enzyme. The sulfhydryl (–SH) group of the coenzyme is the functional site that endows it with its unique chemical/enzymatic properties. In all of the reactions in which it participates, CoA serves to "activate" carboxyl groups (R–CO–OH) in the form of an acyl–CoA thioester derivative (R–CO–S–CoA). In this form the acyl group has favorable energetic and mechanistic properties. Energetically, CoA thioesters have high phosphoryl transfer potential (i.e., a high negative free energy change associated with breaking the C–S bond of the thioester) that facilitates driving the acyl transfer reaction in which it participates toward completion. Mechanistically, the chemistry of CoA thioesters facilitates reactions either at the carbonyl carbon (–CH_2–CO–S–CoA) or the adjacent α-carbon atom (–CH_2–CO–S–CoA).

"Activation" of the Carbonyl- and α-Carbon Atoms in Acyl–CoA Thioesters

All enzymatic reactions of CoA thioesters in metabolism involve "activation" either of the carbonyl-carbon or the adjacent α-carbon atom for facile chemical reaction. Mechanistically, the –CO-carbon (i.e., R–CH_2–CO–S–CoA) of the acyl group reacts with a nucleophilic acceptor molecule ('R^-; see Figure 2, Rx′n 1) or the adjacent alpha carbon (i.e., R–CH_2–CO–S–CoA) reacts with an electrophile ('R^+; see Figure 2, Rx'n 2) to produce a new carbon–carbon bond. These reaction types are illustrated below.

CoA as Donor of 4′-Phosphopantetheine for Fatty Acid Synthase

Fatty acid synthase (FAS) is a large multifunctional enzyme that catalyzes all steps in fatty acid synthesis, catalysis being facilitated by a covalently linked 4′-phosphopantetheine (4′-PP) prosthetic group. The 4′-PP group, which is derived from CoA (Figure 1), is enzymatically transferred to the FAS apoenzyme where it becomes covalently linked to the enzyme. The 4′-PP prosthetic group acts as a long sidearm to which intermediates of the pathway are covalently linked. The 4′-PP sidearm allows translocation of the growing

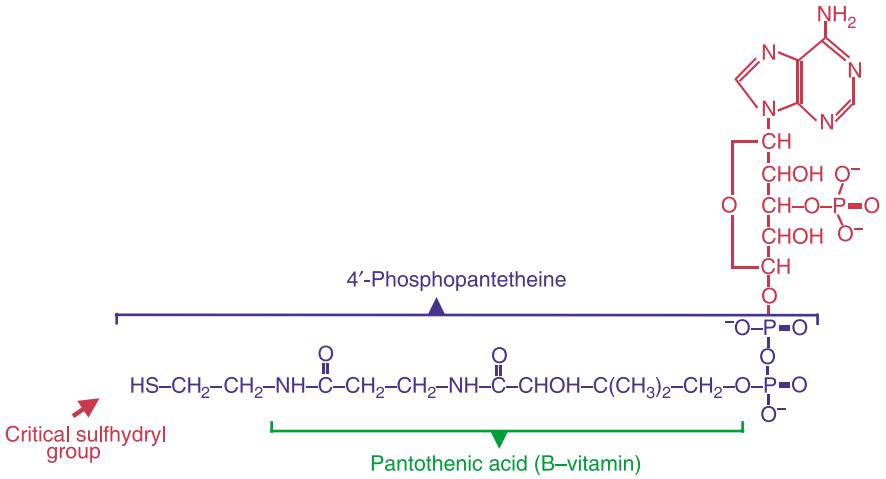

FIGURE 1 Structure of CoA.

fatty acyl chain intermediate from one catalytic site on FAS complex to the next in the cyclic sequence, this leads to formation of a long-chain fatty acid.

Enzymatic Synthesis of Acyl–S–CoA Derivatives from Free Carboxylic Acids and CoA–SH

The enzymatic reactions by which acyl–S–CoA derivative is synthesized from carboxylic acids, such as free fatty acids, occur via a common mechanism (Figure 3).

The reaction illustrated uses fatty acid as example; however, it should be noted that virtually all acyl–CoA's are formed from their cognate carboxylic acids by the same mechanism. The enzymes that catalyze these reactions are referred to as acyl–CoA synthetases. In the initial step (Rx′n 1) the fatty acid attacks the $\tilde{\alpha}$ (innermost) phosphate of ATP releasing pyrophosphate (PP_i) forming an enzyme-bound acyl–AMP intermediate. In the second step (Rx′n 2), CoA–SH attacks the acyl–CO–carbon of the intermediate producing an acyl–S–CoA product and AMP.

Metabolic Roles/Functions

CoA and its derivatives function in a wide variety of metabolic pathways including the tricarboxylic cycle, fatty acid oxidation, ketogenesis, fatty acid biosynthesis, sterol synthesis, complex lipid synthesis, amino acid metabolism, and porphyrin synthesis. (Since most of

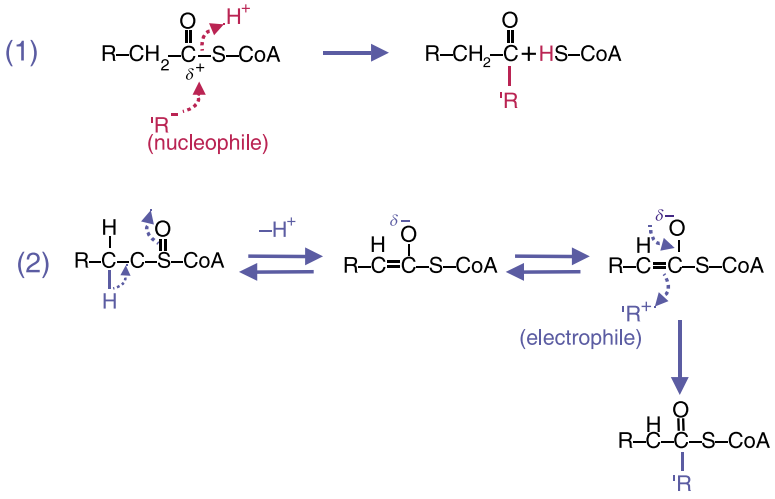

FIGURE 2 Mechanisms of "activation" of the acyl carbonyl- and α-carbon atoms in CoA thioesters.

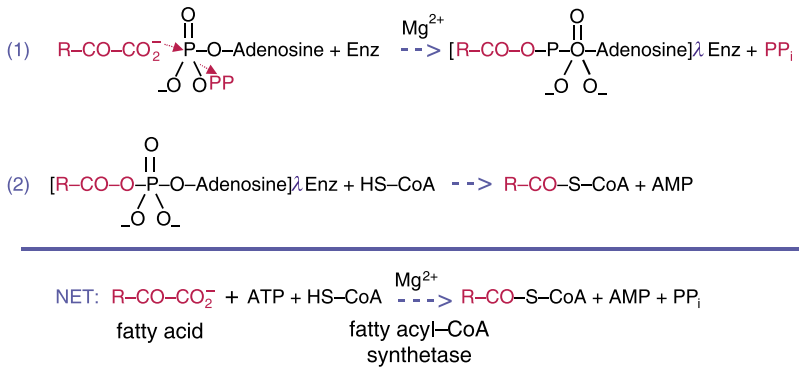

FIGURE 3 Enzymatic synthesis of acyl–S–CoA's.

these are covered elsewhere in this encyclopedia, they are not dealt with in this entry.) As the fatty acid synthase system is unique, in that it makes use of only a fragment of the CoA molecule, 4′-PP, a brief discussion of FAS is warranted.

Fatty Acid Synthase

Fatty acid synthesis in animals is catalyzed by a single large (molecular weight, $\sim 5 \times 10^5$) multifunctional enzyme. All eight steps and thus all eight catalytic centers that carry out fatty acid synthesis occur with the intermediates tethered to the FAS. The intermediates are covalently linked by thioester bonds to the –SH group of the long 4′-PP sidearm which facilitates translocation of intermediates from one catalytic center to the next in sequence until the multiple steps of long-chain fatty acid synthesis are completed. Each round of elongation lengthens the chain by two carbons, a process that is repeated 7 or 8 times for the synthesis of a 16- or 18-carbon containing fatty acids.

The process is initiated by the transfer of an acetyl group to 4′-PP from acetyl–S–CoA. The acetyl group linked to 4′-PP serves as the "primer" onto which the long-chain fatty acid is built. Malonyl units from malonyl–CoA, which serve as the chain-elongating group, condenses with the acetyl-primer concomitant with decarboxylation to produce a 4-carbon intermediate that then undergoes two reductive and "1" dehydration step. Successive malonyl groups are transferred to FAS from malonyl–CoA to provide the basic units for successive steps in the elongation process. The terminal step is catalyzed by a thioesterase releasing the long-chain fatty acid product.

Collagenases

Kenn Holmbeck and Henning Birkedal-Hansen
National Institutes of Health, Bethesda, Maryland, USA

Collagenases are protein capable of cleaving native collagen under physiological conditions *in vivo* and *in vitro*. Here we discuss in brief the history of collagenases, their properties and the definitions assigned to proteins with collagenolytic properties. While collagen cleaving potential is often assessed by simple enzyme substrate incubations it has become increasingly evident that conclusions based on such assay conditions may not necessarily reflect the true nature of enzyme properties. The recent advances in genetic research has demonstrated that some but not all collagen cleaving enzymes functions in that capacity *in vivo*. Conversely, other enzymes previously regarded as unrelated to collagenases have been proven to be important for collagen metabolism.

What Is a Collagenase?

The term "collagenase" was first used by Gross and Lapiere in their 1962 description of an activity released from cultured tissue explants of involuting tadpoles, which dissolved otherwise highly proteinase-resistant, reconstituted collagen fibrils. This was a groundbreaking finding. It was the first demonstration of the existence of an activity operating at neutral pH that was fully capable of dissolving and cleaving native collagen fibrils. It marked the beginning of an exciting period of discovery that led to identification of a large number of distinct matrix metalloproteinases (MMP), almost 6–7 in number with collagen-cleaving capabilities under various *in vitro* conditions (Table I).

Original Definition of Collagenases

The unique resistance of native collagen molecules to proteolysis is a result of the tightly wound, semirigid triple helical structure. However, the resistance is only relative and not absolute. Generally, one of two tests was applied to ascertain whether an enzyme or an activity represented a true collagenase: (1) ability to dissolve reconstituted type I collagen fibrils in the temperature range 35–37°C, and/or (2) ability to cleave type I collagen in solution at neutral pH in the temperature range 15–25°C into two distinct and recognizable 1/4–3/4 fragments (classical collagenase signature cleavage pattern). That the 3/4–1/4 cleavage site is actually utilized *in vivo* was elegantly shown by Robin Poole and co-workers by neo-epitope immunochemistry which convincingly identified collagen molecules in several tissues, which were cleaved at this particular site. Since a number of collagenases cleave this site, the mere detection of this neo-epitope does not necessarily identify any single enzyme responsible for the cleavage. Despite this, the 3/4–1/4 cleavage products are highly useful hallmarks in the analysis and characterization of collagenase activity.

Several lines of evidence support the notion that the collagenase-sensitive cleavage site is subject to local unwinding and therefore constitutes a site of minor resistance. For example, type III collagen has an Arginine-substitution in the susceptible region, and is readily cleaved by trypsin producing a 3/4–1/4 pattern. However, the collagenase-sensitive site in the alpha 1 chain of type I collagen can be mutated in mice without yielding an acute collagen "indigestion" phenotype. The modification leads to a progressive fibrosis, but at a rate indicating that the collagen molecule is cleaved with some efficiency elsewhere. The term "collagenase" based on site specificity may thus be only partially applicable and may in effect obscure the fact that collagen is cleaved at other sites by collagenases, which do not qualify for this designation based on the criteria of generating 3/4–1/4 specific cleavage products.

Revised Definition of "Collagenases"

Based on the observations outlined above, the original definition of a collagenase will therefore have to be revised and broadened to also accommodate other proteinases such as cathepsin K, which clearly is a potent collagen-cleaving enzyme and yet utilizes other cleavage sites in the triple helical region and functions at acidic pH. Ability to cleave native type I collagen in solution within the temperature range 15–25°C at either

TABLE I

Fibrillar Collagenases (Proteinases with Activity Against Fibrillar Collagens)

Enzyme	Other name	Classification	Species
MMP-1	Collagenase-1, interstitial collagenase	Matrix metalloproteinase	Widely expressed except in rodents
McollA		Matrix metalloproteinase	Mice
MMP-2	Gelatinase, type IV collagenase	Matrix metalloproteinase	Widely expressed
MMP-8	Collagenase-2, PMN collagenase	Matrix metalloproteinase	Widely expressed
MMP-13	Collagenase-3, interstitial collagenase	Matrix metalloproteinase	Widely expressed
MMP-14	MT1-MMP	Matrix metalloproteinase	Widely expressed
MMP-18	Collagenase-4	Matrix metalloproteinase	Frog
Cathepsin K		Acidic thiol proteinase	Widely expressed

neutral or acidic pH, or completely dissolve native or reconstituted collagen fibril matrices at 35–37°C still appear to be valid requirements. It is now increasingly being recognized that type I collagen-cleaving ability *in vitro* does not necessarily mean that the enzyme in reality functions as a collagenase *in vivo*. In fact, the assay conditions ordinarily used to assess the collagenolytic activity of putative collagenases may rarely, if ever, entirely mimic the conformation and configuration of the substrate when it is associated with multiple other components of the extracellular matrix and packed to densities rarely achieved in a cell-free system. Conversely, an argument may also be made that enzymes displaying little collagenolytic activity *in vitro* may conceivably be potent collagenases *in vivo*, if by association with other ECM macromolecules, the collagen molecules are made more readily available for cleavage. Standard enzyme kinetic assays measuring substrate conversion are often ill-suited to account for reactions, which take place in a two-dimensional, diffusion-restricted environment such as a cell-membrane or a solid-substrate surface. For collagenolytic enzymes with *trans*-membrane spanning domains, a solution-based assay obviously can change the basic environmental properties under which a molecule ordinarily works, but also molecules commonly recognized as secreted exert their function in close proximity to the peri-cellular (solid phase) environment. Second, the actual enzyme-to-substrate ratio *in vitro* may not adequately mirror that which exists *in vivo*. It may therefore be necessary to revise the definition "collagenase" and assign the term only to enzymes for which there is some evidence, for instance, from naturally occurring mutations or gene ablation studies, that they truly function to cleave collagen *in vivo*.

The Collagenases

Within a few years of the discovery of the tadpole enzyme, similar activities were identified in many vertebrate species including humans. Among these were an enzyme from PMN leukocytes that later turned out to be a genetically distinct collagenase (MMP-8). Gelatinase A/type IV collagenase (MMP-2) was also identified early on and recognized as a probably distinct and separate activity because of its ability to cleave type IV collagen and gelatin. However, it was not recognized until Aimes and Quigley's important study in 1995 that MMP-2 can also be a genuine type I collagen-specific collagenase once the inhibitor TIMP-2, with which it is often complexed, is removed. This finding raises the question whether, and under what conditions, TIMP-2-free proMMP-2 exists *in vivo*? MMP-13 or collagenase-3 is found in both humans and rodents and displays partial homology to the human interstitial collagenase, MMP-1. It was thus originally thought to be the rodent orthologue of MMP-1, but turned out to be a genetically distinct collagenase capable of also dissolving the otherwise highly resistant and slowly cleaved type II collagen. Surprisingly, rodents appear to express MMP-13 in most places where MMP-1 is expressed in humans, thus suggesting that it is a functional equivalent. Yet a closer rodent orthologue of human MMP-1 called Mcol-A has been identified, but so far has been characterized only to some extent. Based on the initial analysis Mcol-A appears to have some collagen-cleaving ability against type I collagen although the specific activity seems fairly low. A collagenase (MMP-18), which was distinct from MMP-1, MMP-13, and MMP-8, was discovered in the frog but no vertebrate orthologue has been identified. The first membrane-type MMP (MT1-MMP or MMP-14) was discovered in 1994 and shortly after, it was shown to have collagen-cleaving activity at least *in vitro*. Later five additional membrane-bound MMPs were identified but it is not yet known whether they possess collagen-cleaving activity. Although most of the collagenases mentioned so far have been matrix metalloproteinases, it is, as previously mentioned, necessary today to also include the thiol cathepsin, cathepsin K. This potent collagen-cleaving enzyme is utilized in the phagocytic pathway of collagen

degradation and in osteoclastic bone resorption, when mineralized type I or type II matrices are dissolved. The various collagenases display somewhat varying substrate preference against type I, II, and III collagens. Type I collagen is most readily cleaved by MMP-8 and MMP-14, while MMP-1 shows preference for type III collagen and MMP-13 for type II collagen.

Recent New Insights

The past decade has dramatically altered our view of the role of classical collagenases in normal growth and development. The advent of gene ablation techniques in combination with various mouse models has enabled detailed exploration of the biologic function of the individual collagenases *in vivo*. Unfortunately, MMP-1 cannot be subjected to this approach because it is not expressed in mice and no human mutations of MMP-1 have been characterized. Although a potent collagenolytic enzyme *in vitro*, the true role of MMP-1 *in vivo* may therefore not be known until a human null-mutation is discovered. No reports have emerged yet with regard to ablation of the weakly collagenolytic, putative murine MMP-1 orthologue, Mcol-A. MMP-2 has been knocked out, but the phenotype is very mild when considering that this enzyme is perhaps the most widely expressed MMP. It was subsequently shown that primary tumor mass and metastatic spread was significantly reduced in MMP-2-deficient animals in two independent tumor models, but it is uncertain whether and/or how these observations relate to collagen degradation. So, at this point there is only limited evidence that MMP-2 indeed serves as a collagenase in mice. Adding confusion to this scenario, however, is the finding by Martignetti and co-workers of the first human MMP-mutation (in MMP-2), which yields a rather spectacular generalized osteolytic bone phenotype. It is dramatically different from that of the mouse but it does have features of a collagen indigestion phenotype. Recently, ablation of the PMN collagenase MMP-8 was reported. Interestingly, MMP-8 deficiency, particularly in male mice, resulted in a dramatic rise in DMBA/TPA-induced skin tumors, diminished inflammatory response, and chemokine processing suggesting that an important protective role, conferred by MMP-8, had been lost. It is so far unresolved whether this effect is a function of the loss of collagenolytic activity by PMNs. An MMP-13-deficient mouse has been generated which shows widening of the growth plate presumably as a result of impairment of cleavage of collagen type II in this area. Moreover, osteoclast differentiation and activity is impaired (S. M. Krane, personal communication) and bone formation is increased. The phenotype is thus consistent with MMP-13 serving as a collagen-cleaving enzyme *in vivo*. MT1-MMP- (MMP-14-) deficient mice display a profound and complex phenotype in which growth, development, and maintenance of multiple collagen-containing matrices (bone, skin, tendon, joints, and ligaments) are severely impaired due to loss of an indispensable and uncompensated collagenolytic activity. Since the MT1-MMP knockout phenotype does not resemble those of either MMP-2 or MMP-13, it is highly unlikely that MT1-MMP functions primarily through activation of these enzymes as has been suggested. Rather, MT1-MMP appears to serve as a highly effective collagenase in its own right *in vivo*. However, it is interesting to note that MT1-MMP displays somewhat weaker collagenolytic activity *in vitro* than, for instance, MMP-1. This finding again points to some level of disconnect between collagenolytic capacity *in vivo* and *in vitro*. In the case of cathepsin K deficiency, the predictions of collagenolytic impairment, however, do hold up *in vivo*. Mouse and human cathepsin K gene mutations give rise to pycnodysostosis in humans and osteopetrosis in the mouse consistent with impairment of osteoclast-mediated type I collagen cleavage. These findings help identify cathepsin K as the acidic collagenase required for removal of type I and type II collagens from mineralized matrices, which can only be dissolved in an acidic environment. It is highly likely that cathepsin K also is responsible for the cleavage of soft tissue collagen fibrils in phago-lysosomes during the often-overlooked phagocytic pathway.

Conclusion

In the aggregate, recent findings have demonstrated that true "collagenases" as defined by their substrate specificity *in vivo* can be found in at least two different classes of proteolytic enzymes (matrix metalloproteinases and cathepsins). Moreover, it is now evident that not all predictions based on enzyme kinetics obtained *in vitro* hold up *in vivo*. Collagenases work in the complex environment of an extracellular matrix. Fortunately, the tools for characterization of enzyme substrate interactions have now entered an exciting new era, which offer multiple genetic approaches to elucidation of these questions. Based on such approaches we have already come to realize that seemingly identical enzymes can perform different roles depending on the species. With this knowledge in mind, the understanding of and search for collagen metabolizing enzymes should continue.

Glossary

cathepsins Lysosymal proteinases, mostly thiol-dependent proteinases of the papain family. Present in multiple forms of which cathepsin K seems to be the most potent collagen-cleaving enzyme.

collagen Major structural proteins of the body with type I being the most abundant protein in soft connective tissue and in bone. The major fibrillar collagens (types I, II, and III) provide much of the structural framework for soft connective tissues, cartilage, and bone. They are generally highly resistant to proteolysis.

collagenase Enzyme capable of cleaving native collagen under specified conditions (temperature and pH).

knockout mouse Mouse rendered deficient for a selected gene by targeted inactivation of the encoding locus in embryonic stem cells, subsequent transmission of the trait to the germ line and breeding of the trait to a homozygous state.

matrix metalloproteinases (MMPs) A group of zinc endopeptidases (metzincins) characterized by zinc binding VAAHEXGHXXGXXH amino acid consensus sequence in the catalytic domain and activation by a so-called cysteine switch. This residue is harbored in the latency-conferring prodomain that is proteolytically cleaved upon activation. This group of enzymes does not include the ADAMS, which contains a characteristic disintegrin domain.

Biography

Henning Birkedal-Hansen is a Scientific Director and Senior Scientist at The National Institute of Dental and Craniofacial Research (NIDCR) at the NIH in Bethesda, Maryland. He also leads the Matrix Metalloproteinase Unit that focuses on the remodeling of collagen fibrils in the extracellular matrix and the biologic function of matrix metalloproteinases and related enzymes. He holds a D.D.S. and a Ph.D. from the Royal Dental College of Copenhagen, Denmark. He served on the faculty of the University of Alabama School of Dentistry in Birmingham, Alabama in various positions from 1979 before becoming Scientific Director at the NIDCR in 1994.

Kenn Holmbeck is a Senior Staff Scientist in the Matrix Metalloproteinases Unit. He holds a Ph.D. from the University of Copenhagen, Denmark, and received postdoctoral training at Children's Hospital Research Foundation, Cincinnati, Ohio and the National Institute of Dental and Craniofacial Research.

Collagens

Darwin J. Prockop
Tulane University Health Sciences Center, New Orleans, Louisiana, USA

Collagens are a large family of proteins widely distributed in nature with a simple, repetitive sequence of amino acids that serves as a defining signature for the proteins. The inherent properties of the signature sequence of amino acids drive spontaneous self-assembly of three similar chains into a distinctive triple-helical structure. The long triple-helical structures found in some collagens drive spontaneous self-assembly of the proteins into large fibrils. The shorter triple helices in other collagens provide rigidity to the proteins to complement the biological activity of other functional domains.

The Signature (Gly-XY-)$_n$ Sequence of Collagens

In the signature amino acid sequence of collagens, every third amino acid is glycine, the amino acid following glycine is usually the five-member ring amino acid proline, and the next amino acid is hydroxyproline. Therefore the signature sequence is usually depicted as (Gly-XY)$_n$ in which the X position is frequently proline and the Y position is frequently hydroxyproline. Under physiological conditions, three chains with the signature (Gly-XY-)$_n$ sequence spontaneously associate into a three-stranded helix that is unique to collagens. The subclass of collagens that form large fibrils consists almost entirely of long (Gly-XY-)$_n$ sequences tightly coiled into triple-helical structures referred to as collagen monomers. The long triple-helical monomers, in turn, spontaneously associate into long, highly ordered fibrils. In some tissues, the long fibrils associate laterally into thick fibers. The two steps in which (Gly-XY-)$_n$ sequences assemble into triple-helical monomers and the triple-helical monomers assemble into fibers resemble the crystallization of small molecules (Figures 1A and 2). Each step is entropy driven by loss of surface water as the larger structure is formed, much as is seen in many crystallization processes. Also, as with crystallizations, each step involves first the slow formation of a small nucleus of a defined structure, and then rapid propagation of the nucleus to form a large structure in which the molecular architecture of the nucleus is extensively replicated. Glycine, the smallest amino acid, must be in every third position in the collagen triple helix because it occupies a very small space where the three chains come together. Additionally, the hydrogens on the α-carbon of glycine allow it to form hydrogen bonds across the three chains. The closed-ring structures of the proline and hydroxyproline residues limit rotation of the polypeptide backbone, thereby providing rigidity to the structure.

Hydroxyproline residues, which are rarely found in other proteins, play a special role in the triple helix. The hydroxyl groups lock the slightly flexible ring of the amino acid into a conformation that further stabilizes the polypeptide backbone. Charged amino acids that occupy the X and Y positions in the repetitive (Gly-XY-)$_n$ sequences point out from the center of the triple helix. The orientation of the charged groups allows them to form salt bridges that bind each triple-helical monomer to surrounding monomers. Most of the monomers in fibrils are staggered one-quarter of their length relative to their nearest neighbors with short gaps between their ends. The gaps are readily seen by staining the surface of the fibrils and examining them by electron microscopy: each fibril has a cross-striated pattern in which the distances between the cross-striations correspond to about one-quarter of the lengths of the monomers. After assembly of the fibrils, the structures are further stabilized by a cross-linking enzyme that generates highly reactive aldehydes by deaminating some of the terminal amino groups on lysine residues that project out from the surface of the monomers. The aldehydes then spontaneously form covalent bonds that link most of the monomers throughout the width and length of the fibril. The result is a highly ordered structure with about the same strength as a steel wire. In essence, the signature (Gly-XY-)$_n$ sequences contain essentially all of the information and driving forces needed to spontaneously generate the highly ordered fibrils and fibers that in some tissues can be several feet long.

The Two Subtypes: The Fibrillar and Non-Fibrillar Collagens

The fibril-forming or fibrillar collagens contain long and uninterrupted (Gly-XY-)$_n$ sequences (Figure 1A). They are among the most abundant proteins in nature,

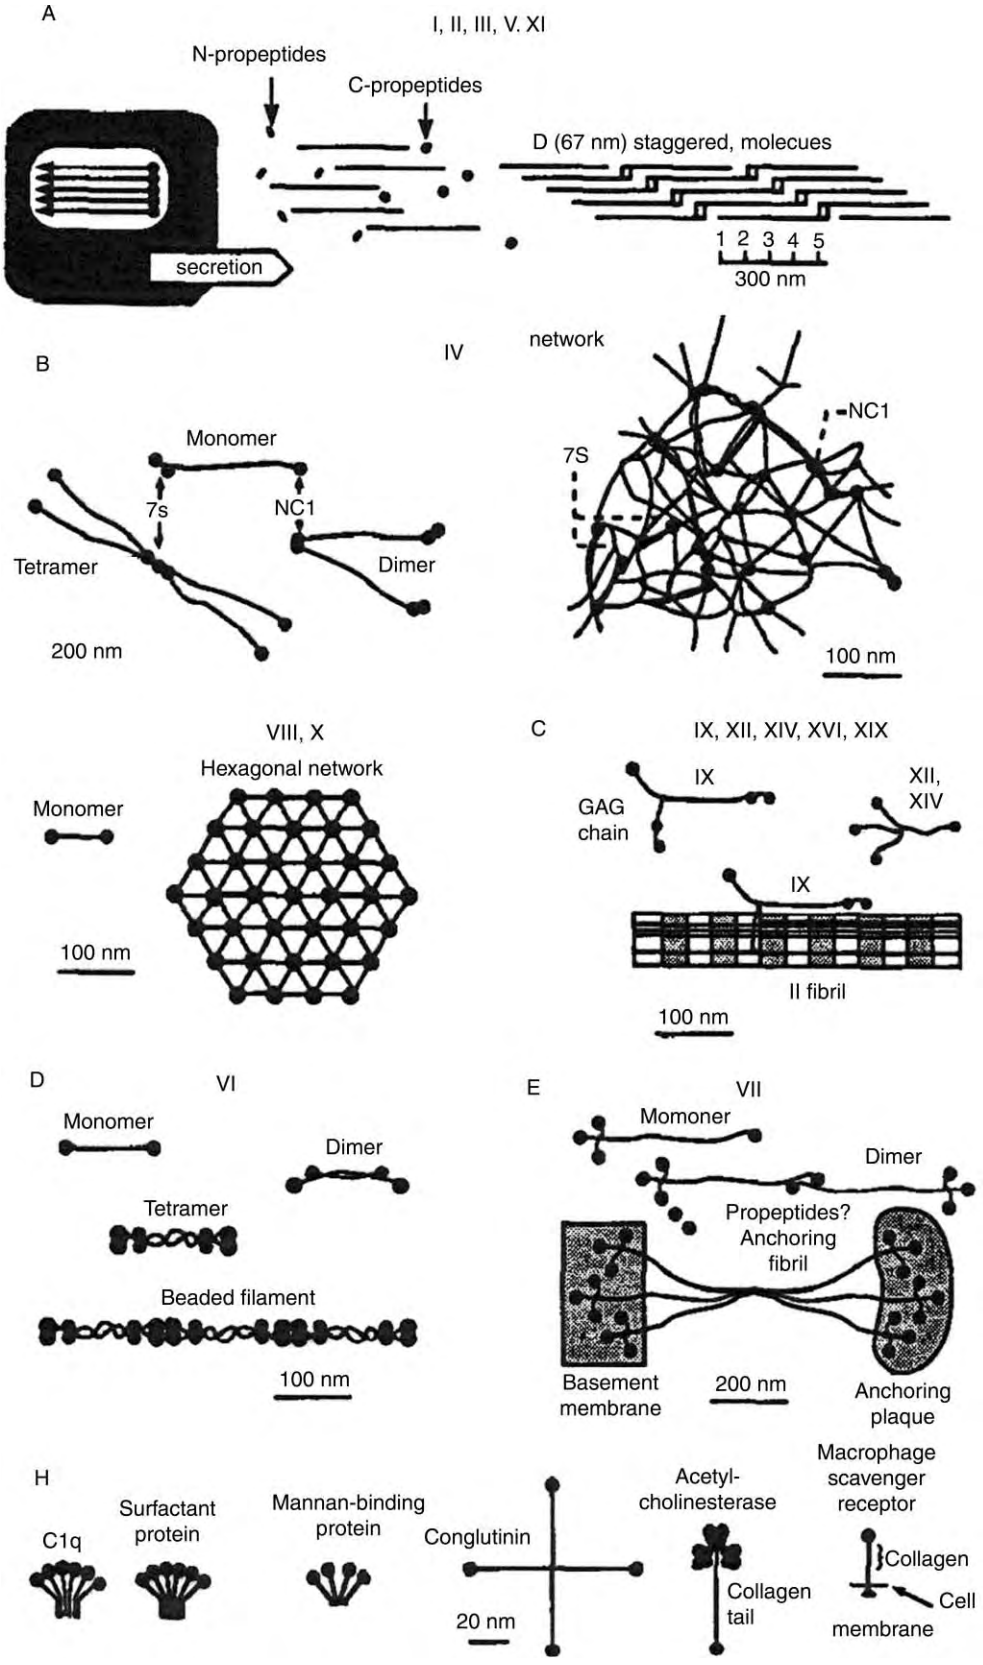

FIGURE 1 Schematic for the structure of various collagens. Reproduced from Prockop, D. J., and Kivirikko, K. I. (1995). Collagens: Molecular biology, diseases, and potentials for therapy. *Annu. Rev. Biochem.* **64**, 403–434.

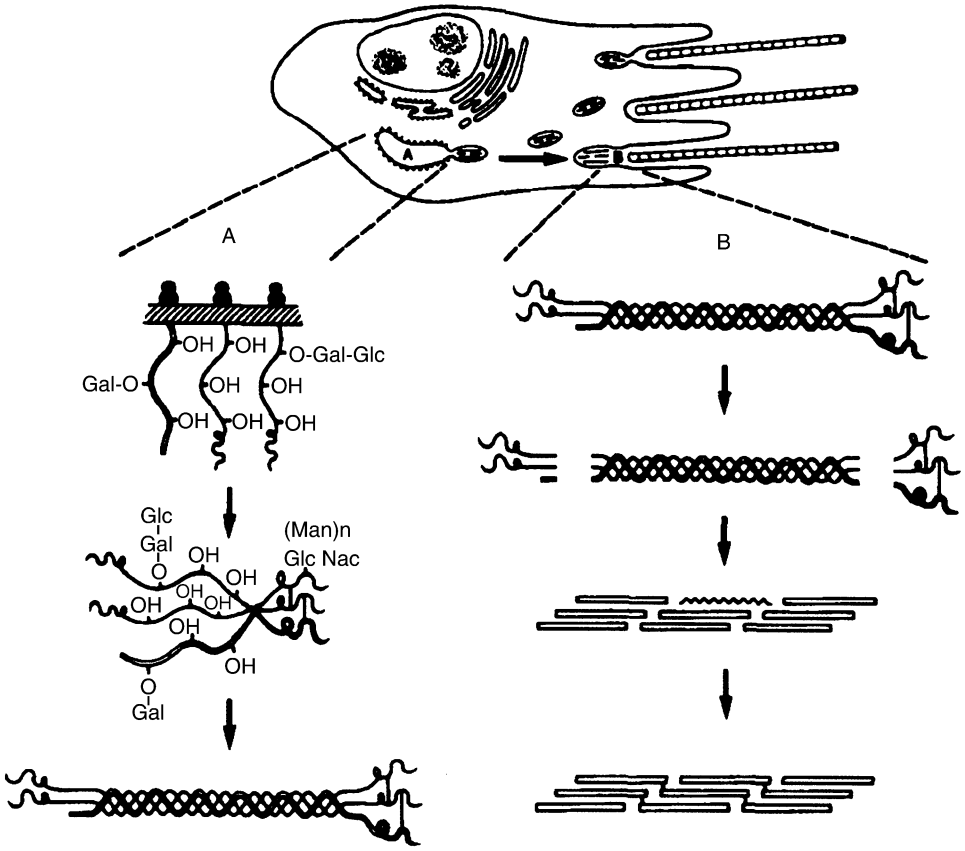

FIGURE 2 Schematic for the biosynthesis of a fibril-forming collagen. (A) Intracellular events that involve posttranslational hydroxylations and glycosylations, association of polypeptide chains, and folding of the triple helix. (B) Extracellular events that involve cleavage of the N- and C-propeptides, self-assembly of collagen into fibrils, and cross-linking of the fibrils. Reproduced from Prockop, D. J., and Kivirikko, K. I. (1995). Collagens: Molecular biology, diseases, and potentials for therapy. *Annu. Rev. Biochem.* **64**, 403–434.

and the most abundant of the fibrillar collagens are referred to as types I, II, and III. They are similar in structure in that each contains three polypeptide chains (α-chains) with approximately 330 -Gly-XY- triplets. They are also similar in that the α-chains spontaneously self-assemble into similar triple-helical monomers and the monomers spontaneously assemble into fibrils. Type I collagen accounts for well over 50% of the dry weight of ligaments, tendons, and demineralized bone. However, the biological properties of the fibrils depend on the still-undefined forces that orient the fibers in tissues. For example, the type I collagen fibrils in ligaments and tendons are present in parallel bundles of thick fibers. In skin, they are randomly oriented in the plane of the skin. In many regions of bone, type I collagen fibrils form highly symmetrical concentric helical arrays around the Haversian canal through which capillaries pass. Type II collagen is very similar to type I collagen in structure, but it is found almost exclusively in cartilage, where it forms very thin fibrils that trap highly charged proteoglycans and water. The result is an arcade-like structure that makes cartilage highly resilient to compression. Type III collagen is also similar to type I collagen in structure and its spontaneous assembly into fibrils. Type III collagen is associated in relatively small amounts with type I collagen in many tissues, but, for reasons that are not apparent, it is particularly abundant in the aorta.

The family of collagen proteins also includes a large number of proteins referred to as nonfibrillar collagens because either they contain only short $(\text{Gly-XY-})_n$ sequences or they contain $(\text{Gly-XY-})_n$ sequences that are interrupted by non-collagen sequences. As a result, the proteins do not assemble into highly ordered fibrils (Figure 1B–1H). One important example of a nonfibrillar collagen is the type IV collagen, which is an abundant constituent of basement membranes (Figure 1B). The protein is a large trimeric monomer with multiple $(\text{Gly-XY-})_n$ sequences that are interrupted by non-collagen sequences; it also contains large globular domains at both ends. The interruptions make the protein flexible, and the globular ends enable the protein to form flexible networks that

bind multiple other proteins. The flexible networks bind epithelial cells and form the barriers that protect the organism from the external environment. Other nonfibrillar collagens are much less abundant and fulfill more specialized functions. Some bind to the surfaces of fibers formed by fibrillar collagens and help either to regulate the assembly process or to provide binding sites for cells or other components of the extracellular matrix. For example, type IX is a short collagen that is flexible because its $(Gly\text{-}XY\text{-})_n$ sequences are interrupted by two non-collagenous sequences (Figure 1C). Type IX collagen binds to both fibrils of type II collagen and proteoglycans to provide one of the connecting links in the arcade-like structure of cartilage. Some nonfibrillar collagens contain very short $(Gly\text{-}XY\text{-})_n$ sequences and triple-helical domains that serve primarily as extension rods for more interactive domains on the ends of the same proteins (Figure 1H).

Collagens and collagen-like proteins are abundant in many multicellular organisms. For example, they are very abundant in diverse invertebrates such as sponges and worms, including the worms found in deep-sea hydrothermal vents. The smallest collagens appear to be minicollagens that contain only 12 to 16 -Gly-XY- repeats, and that are found in the nematocysts with which hydra sting their prey.

The Need to Control the Self-Assembly of $(Gly\text{-}XY\text{-})_n$ Sequences

Viewed with evolution in mind, the special properties of $(Gly\text{-}XY\text{-})_n$ sequences can be seen to have a variety of different purposes. One of the most important of these purposes was to produce tough fibrils to hold together cells and thereby provide a means of developing multicellular organisms. However, it is clear that there had to be controls on the tendency of long polypeptides with repetitive $(Gly\text{-}XY\text{-})_n$ sequences to spontaneously assemble into large fibers. In living systems, the assembly of fibrils cannot be allowed to occur prematurely. If they did, the fibrils would either destroy the cell synthesizing the protein or encase the cell in an impenetrable matrix. Also, the fibrils must be strong but not as rigid as crystals. Their flexibility is critical for most tissues. It is apparently for these reasons that the synthesis of collagens is an elaborate process in which a series of specialized enzymes modifies the polypeptide chains as they are assembled on ribosomes and then pass into the cisternae of the endoplasmic reticulum en route to the Golgi apparatus and secretion from the cell.

Why the Hydroxyproline?

One of the initial intriguing questions about collagens was why they contain large amounts of hydroxyproline, an amino acid very rarely found in other proteins. Early isotope studies demonstrated that after administration of labeled proline to rodents, both labeled proline and hydroxyproline were present in proteins isolated from the animals. After administration of labeled hydroxyproline, however, essentially no labeled hydroxyproline was recovered. Therefore, long before the genetic code was solved, it was apparent that the hydroxyproline in collagen was introduced by an event that did not occur during the initial assembly of the protein but that occurred as a posttranslational event. These observations led to the discovery that the hydroxyproline in collagens was synthesized by prolyl hydroxylase, an enzyme that specifically hydroxylates proline in the Y position in peptides with $(Gly\text{-}XY\text{-})_n$ sequences. The question of why hydroxyproline is introduced in this manner was resolved by demonstrating that if prolyl hydroxylase is inhibited, cells synthesize complete collagen polypeptide chains that cannot fold into a collagen triple helix unless the protein is cooled to about 15 °C below body temperature (Figure 2). The protein folds into a triple helix at body temperature only if about 100 proline residues in each of the 1000-amino-acid-long α-chains of fibrillar collagen are hydroxylated to hydroxyproline. After the protein folds into the triple-helical conformation, prolyl hydroxylase can no longer modify it. In effect, prolyl hydroxylase titers the hydroxyproline content of the proteins so that it folds at body temperature. And, remarkably, the protein is not secreted from cells in significant amounts until it acquires the requisite content of hydroxyproline and folds into a triple helix. This elaborate system is one means of preventing the protein from folding too early in the biosynthetic process. The process by which prolyl hydroxylase gradually titers the hydroxyproline content of collagens serves a second function of ensuring that collagen fibrils are flexible. The monomers are secreted by cells before all the Y position proline residues are fully hydroxylated and before the molecule is a completely rigid rod. Instead, regions of the protein that have low contents of proline and hydroxyproline tend to "breathe" in the sense that they rapidly fold and unfold. Because the monomers are not rigid triple helices, the fibrils they assemble into are not fully crystalline and remain flexible. As might be expected, monomers for fibrillar collagens from organisms with body temperatures ranging from 18° to 40 °C completely unfold at about 4 °C above the body temperatures of the organisms. The fibrillar collagens from organisms with varying body temperatures

have different amino acids found in the X and Y positions that in part explain their different stabilities, but each begins as an unfolded protein that folds as its hydroxyproline content is titered to a critical level by prolyl hydroxylase. After the monomers assemble into fibrils, the lateral interactions of protein make the triple helix stable to about 16 °C above body temperature.

Other Levels of Control

The process of fibril assembly by fibrillar collagens is also controlled at another step. The monomers are first synthesized as larger precursors that are known as procollagens. The procollagens have large non-collagenous domains at both ends that keep the monomers soluble and prevent them from self-assembling until the domains are cleaved by proteinases found outside the cells (Figure 2). Therefore, the proteinases help to regulate the formation of fibrils. In addition, the first fibrils formed begin to accumulate other proteins and components of the extracellular matrix on their surfaces that prevent fusion of the fibrils into large fibers. The rate at which these components are removed provides still another control on the formation of fibrils and fibers.

One Surprise: The Enzymes Involved in Collagen Synthesis Have Other Functions

The biosynthesis of collagen involves processing by a series of separate enzymes that have a number of unusual properties (Figure 2). Because the enzymes carried out processing steps not seen in the synthesis of other proteins, it was initially felt that the enzymes were uniquely dedicated to production of collagen. Subsequently, it became apparent that several of the enzymes had important additional functions. For example, prolyl hydroxylase is unusual among the small number of enzymes that modify proteins in that it requires unfolded peptide substrates. It is also unusual in that it specifically hydroxylates prolyl residues in the Y position of -Gly-X-Pro- sequences. In addition, it is unusual in that the reaction uses iron, molecular oxygen, and ascorbate as well as α-ketoglutarate that is oxidatively decarboxylated to succinate in the reaction. It was surprising, therefore, that cloning of the genes for the two subunits of the enzyme revealed that the β-subunit is identical to protein disulfide isomerase, an enzyme that is required to ensure the correct formation of disulfide bonds during the synthesis of a large number of non-collagen proteins. Perhaps even more surprising was the discovery of three similar but different prolyl hydroxylases that hydroxylate a single proline residue in hypoxia induction factor, a protein that triggers the response of tissues to ischemia. The proline residue in hypoxia induction factor must be hydroxylated for the protein to be degraded by proteosomes. One consequence of this discovery is that inhibitors of prolyl hydroxylase initially designed to limit the excessive deposits of collagen found in scars also increase tissue levels of hypoxia induction factor, thereby enhancing their response to hypoxia. Inhibitors of prolyl hydroxylase therefore appear to provide a new strategy for treatment of diseases such as anemias that are now treated with erythropoietin.

Similar surprises have been encountered with the proteinases that cleave the amino acid extensions on the ends of the procollagen precursors of fibrillar collagens and that keep the proteins from prematurely assembling into collagen fibers. The proteinase that cleaved the large C-terminal globular domains was a large zinc metalloproteinase with an unusual specificity for the similar but different sequences in the cleavage sites for the precursors of types I, II, and III collagens. Therefore, it seemed reasonable to assume that it was a protein with a unique function. Subsequent work demonstrated that the same enzyme was essential for processing a component of basement membranes (laminin-5) and for processing the enzyme (lysyl oxidase) that generates the aldehydes that form the covalent cross-links in fibrils of both collagen and elastin. Even more surprising was the discovery that isoforms of the same enzyme are essential in completely unrelated processes in early embryonic life: they establish a gradient for dorsolateral development by cleaving inhibitors of morphogenic proteins (decapentaplegic/BMP-2/BMP-4).

Evolutionary Origins and Selective Pressures on (Gly-XY-)$_n$ Sequences

The manner in which (Gly-XY-)$_n$ sequences arose and were distributed across biology during evolution cannot be defined any more accurately than many other aspects of evolution. One clue seemed to come from the observation that the genes for the major fibrillar collagens have an unusual structure: most of the codons for the triple helix were found in short exons that were 54 bases long and coded for 18 triplets of (Gly-XY-)$_n$ sequences. Therefore, it appeared that evolutionary pressures had trapped the 54-base exon and replicated it to produce genes for many different collagens. Unfortunately, this attractive hypothesis was not substantiated by data on other collagen genes in which the exons are also relatively short, but the 54-base motif is not a common theme. Independent evidence on the selective pressures on the structure of collagens and the biosynthetic pathway is provided by data on mutations found in patients and a

few animals with genetic diseases. Studies on mutations in fibrillar collagens confirmed that the presence of glycine in (Gly-XY-)$_n$ sequences is critical. Hundreds of mutations that substitute an amino acid with a bulkier side chain for a single glycine distort the triple helix or prevent it from folding. As a result, the mutations produce a large series of diseases of bone, cartilage, blood vessels, and other tissues. Most of the mutations produce severe and rare diseases in children; a few produce variants of common diseases such as osteoporosis or osteoarthritis. The selective pressure for maintaining the signature acid sequences explains why the mutations in collagens differ only slightly from those in organisms that have evolved separately for millions of years. Mutations in the proteinase that cleaves the N-terminal extension on two fibrillar procollagens (types I and II) also produce severe diseases of the skeleton, skin, and other tissues. However, no mutations have been found in either prolyl hydroxylase or the proteinase that cleaves the C-terminal extensions on the procollagen precursors of fibrillar collagens. Such mutations are presumably lethal early in embryonic life.

Summary

The impressive ability of (Gly-XY-)$_n$ sequences to spontaneously undergo self-assembly has been used time and again in biology to provide structures with a variety of important features. However, biological systems need safeguards to control the spontaneous self-assembly of the (Gly-XY-)$_n$ sequences. The principal safeguard is a biosynthetic pathway in which the protein is assembled through a series of complex steps that prevent premature self-assembly and modulate how perfectly the protein crystallizes.

Glossary

collagen fibrils Thin structures, 40 to 500 nm in diameter. Fibrils are assembled laterally into much larger fibers in tissues such as tendons.

collagen monomer A protein containing a collagen triple helix.

collagen triple helix A unique protein structure in which each of three chains with a (Gly-XY-)$_n$ sequence is coiled in a left-handed helix and the three chains are wrapped around each other in a more extended right-handed helix.

procollagens The soluble precursors of fibrillar collagens that contain large, non-collagenous extensions of both ends of the long triple-helical domains.

Biography

Darwin J. Prockop is Director of the Center for Gene Therapy at the Tulane University Health Sciences Center. His degrees include an A.B. from Haverford College; an Honors B.A. from Oxford University; an M.D. from the University of Pennsylvania; and a Ph.D. from George Washington University. His former research interests included collagen biosynthesis, structure and function of collagen genes, and genetic mutations that cause bone and cartilage diseases. His current interests are in defining the biological features of adult stem cells and using adult stem cells for therapy of genetic diseases involving collagen and diseases of the central nervous system, lung, and heart.

Cyclic AMP Receptors of *Dictyostelium*

Dale Hereld
The University of Texas Health Science Center, Houston, Texas, USA

Peter N. Devreotes
The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

When confronted with starvation, the social amoeba *Dictyostelium discoideum* survives by undergoing multicellular development and sporulation. The coordination of these processes is achieved in part through intercellular communication using secreted adenosine 3′,5′-cyclic monophosphate (cAMP) and a family of cell-surface cAMP receptors (cARs). The cARs are examples of G protein-coupled receptors (GPCRs), which enable eukaryotic cells in general to sense and respond to a wide array of environmental and hormonal signals ranging from single photons to large glycoprotein hormones. Due to their involvement in diverse physiological processes, GPCR-targeted drugs are frequently employed in medicine to treat many common conditions including inflammation, hypertension, heart failure, and neurologic and psychiatric disorders. Because GPCRs and the pathways they regulate are conserved in virtually all eukaryotes examined to date, genetically tractable microbes such as *Dictyostelium* have contributed significantly to our understanding of GPCR function and regulation.

Dictyostelium Development and cAMP Signaling

Dictyostelium discoideum is an amoeba found in soil where it feeds on bacteria. In order to survive periods of starvation, 10^4–10^5 amoebae aggregate and execute a 24 h developmental program that yields a fruiting body comprised of a round mass of spores held aloft by a slender stalk (Figure 1A). When nutrients return to the environment, spores germinate to yield amoebae which resume cell division.

Not long after Sutherland and his colleagues discovered cAMP to be an important intracellular second messenger in hormonal signaling, Konijn and his associates demonstrated that cAMP is a potent chemoattractant for *Dictyostelium* and correctly speculated that it was the so-called acrasin secreted by starving amoebae, which mediates their aggregation. Shaffer had proposed that the acrasin would be emitted periodically by cells at aggregation centers and relayed outwardly as waves by surrounding cells. Indeed, exogenous cAMP was shown to elicit the transient activation of adenylyl cyclase and secretion of cAMP. Tomchik and Devreotes later demonstrated the concentric waves of extracellular cAMP waves which arise every ~6 min at aggregation centers and travel radially outward through aggregating populations. Subsequent pharmacologic characterization of these responses established the framework for the identification of the cAMP receptors.

Identification and Properties of cAMP Receptors

The molecular identification of the first cAMP receptor (cAR1) began with its photoaffinity labeling with the cAMP analogue, 8-azido-[^{32}P] cAMP. This approach identified a protein of either 40 or 43 kDa depending on whether or not the cells had been exposed to cAMP, suggesting the existence of a reversible, ligand-induced modification which proved to be phosphorylation. Radiolabeling of cells with [^{32}P] phosphate permitted purification of the 43 kDa phosphorylated form of the receptor. Antibodies directed against purified cAR1 lead to the isolation of a cDNA that encoded a protein of the expected size and hybridized to an mRNA, expressed transiently in early development, consistent with cAMP binding. Formal proof that the isolated cDNA did indeed encode cAR1 came from expression of the cDNA, which resulted in increased cAMP binding, and disruption of the corresponding gene, which obviated cAMP binding and cAR1-mediated responses. The deduced sequence of cAR1 possessed seven putative transmembrane domains (Figure 2) and exhibited weak homology to mammalian G protein-coupled receptors (GPCRs). cAMP stimulation of GTP binding to isolated membranes and GTP hydrolysis was further evidence

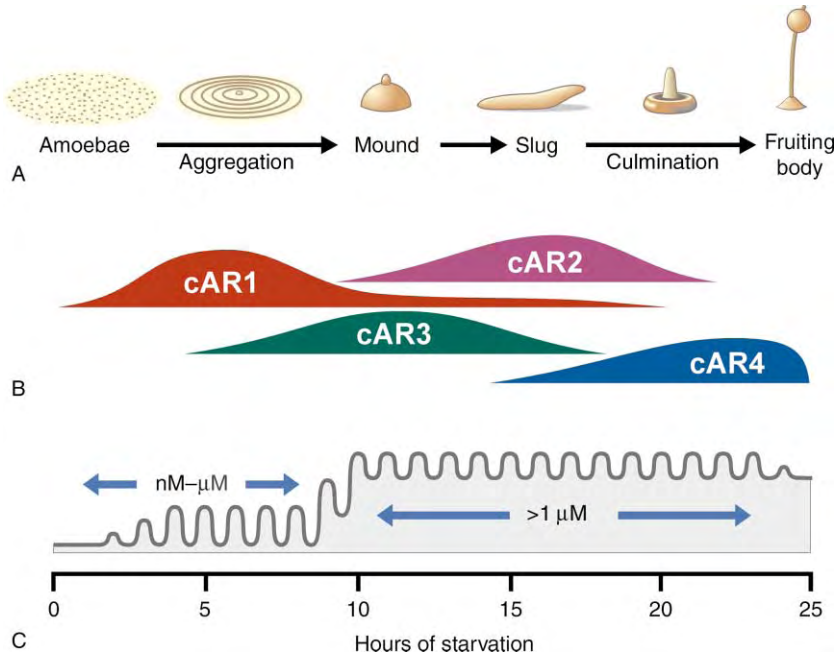

FIGURE 1 Correlation of: (A) developmental morphology, (B) cAR expression, and (C) extracellular cAMP levels. See text for additional details.

that cAR1 is indeed coupled to a G protein. This together with studies of yeast pheromone signaling provided the earliest indications that virtually all eukaryotes have inherited these ancient sensory mechanisms.

Three other highly homologous cAMP receptors, designated cAR2–4, were subsequently identified by hybridization with a cAR1 probe. The cARs are expressed successively during development, peaking in expression at roughly 5 h intervals in the order: cAR1,

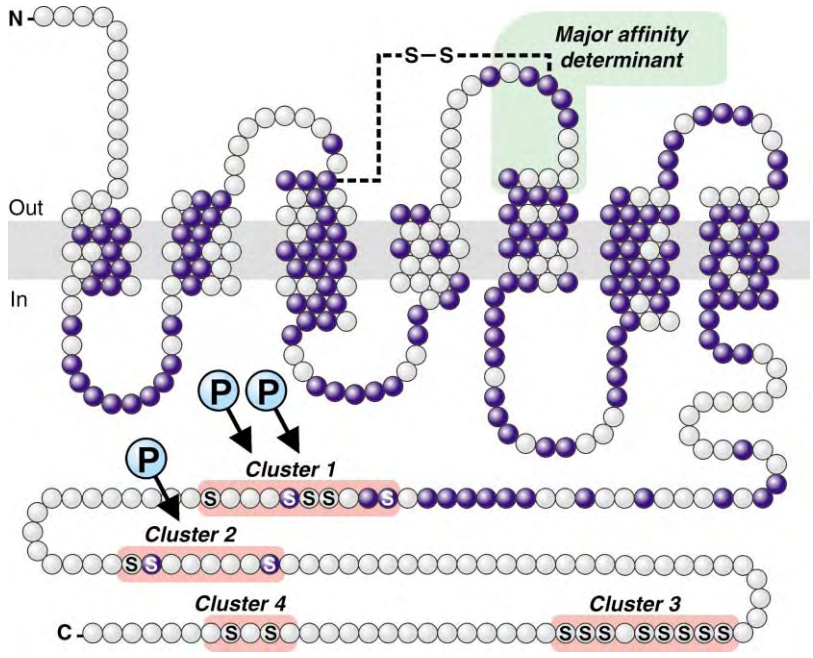

FIGURE 2 Model of cAR1. Dark blue spheres represent amino acids conserved in all four cARs. Densely packed amino acids in the plane of the membrane (gray bar) signify the seven-hydrophobic-transmembrane helices. Nonconserved amino acids (light gray spheres) in the region labeled major affinity determinant are largely responsible for the widely differing cAMP affinities of cAR1 and cAR2 (and possibly other cARs). Clusters of serines in the C-terminal cytoplasmic domain (S), the distribution of ligand-induced phosphorylation (P), and the putative disulfide bridge (––S–S––) are also indicated. cAR2–4 differ in the lengths and sequences of their C-terminal cytoplasmic domains.

cAR3, cAR2, cAR4 (Figure 1B). Disruption of the genes encoding each cAR results in developmental defects consistent with the timing of their expression. cAR1$^-$ cells fail to aggregate. cAR2$^-$ cells arrest shortly after aggregating at the mound stage. cAR3 gene disruption has been variously reported either to have no apparent effect or to interfere with spore cell differentiation late in the mound stage and consequently yield fruiting bodies predominantly comprised of stalk cells. cAR4$^-$ cells develop normally beyond the mound stage but exhibit defects in culmination, resulting in mis-shapen fruiting bodies.

The cARs differ markedly in their affinities for cAMP. The early cARs, cAR1 and cAR3, have high affinities (i.e., low- to mid-nM K_d's), whereas those expressed later in development, cAR2 and cAR4, have low affinities (K_d's > 1 μM). These affinities are appropriate for the extracellular cAMP concentrations that exist at these stages of development (Figure 1C). During aggregation, the cAMP signal oscillates from sub-nM to near-μM concentrations. In contrast, external cAMP oscillates at elevated concentrations exceeding 1 μM in the multicellular stages. Nonconserved residues in the second extracellular loop largely determine whether a cAR has a high or low affinity (Figure 2). By analogy with rhodopsin, this extracellular loop, positioned by disulfide linkage to the extracellular end of the third transmembrane helix, is likely to lie at the entrance to the cAMP binding cleft of cARs and, thereby, influence binding.

Signaling Pathways

cAR1 is perhaps the most versatile GPCR yet to be characterized as it regulates a wide range of downstream effectors and biological responses. Consequently, it serves as a valuable model for understanding diverse modes of GPCR signaling. cAR1 mediates three principal cellular responses during aggregation: (1) propagation of cAMP waves, (2) chemotaxis up the cAMP gradient of each oncoming wave, and (3) regulation of genes required for development. The pathways underlying these responses have been determined to a large extent (Figure 3A). Most striking is the dichotomy between signaling pathways that involve G proteins and those that do not. Comparatively less is known about the pathways governed by cAR2–4 in large measure due to technical challenges posed by multicellularity, although significant progress has been made towards elucidating mechanisms by which these cARs promote cell differentiation in multicellular stages.

G Protein-Dependent Pathways

Dictyostelium possesses at least nine heterotrimeric G proteins composed of distinct α-subunits (designated Gα1–9) and common β- and γ-subunits. Genetic and biochemical evidence indicates that G$\alpha2\beta\gamma$ is the principal G protein to which cAR1 couples. Activation of G$\alpha2\beta\gamma$ by cAR1 liberates the G$\beta\gamma$ dimer and GTP-bound Gα2, which in turn activate various effectors.

The G$\beta\gamma$ dimer is believed to activate the aggregation-stage adenylyl cyclase (ACA) by a mechanism involving activation of phosphoinositide-3-kinase (PI3K), which converts the membrane phospholipid phosphatidylinositol-4,5-bisphosphate (PIP_2) into phosphatidylinositol-3,4,5-trisphosphate (PIP_3). PIP_3, in turn, binds to the PH domain of cytosolic regulator of adenylyl cyclase (CRAC), thus recruiting it to the plasma membrane. How CRAC then activates ACA remains to be determined. The resulting cAMP

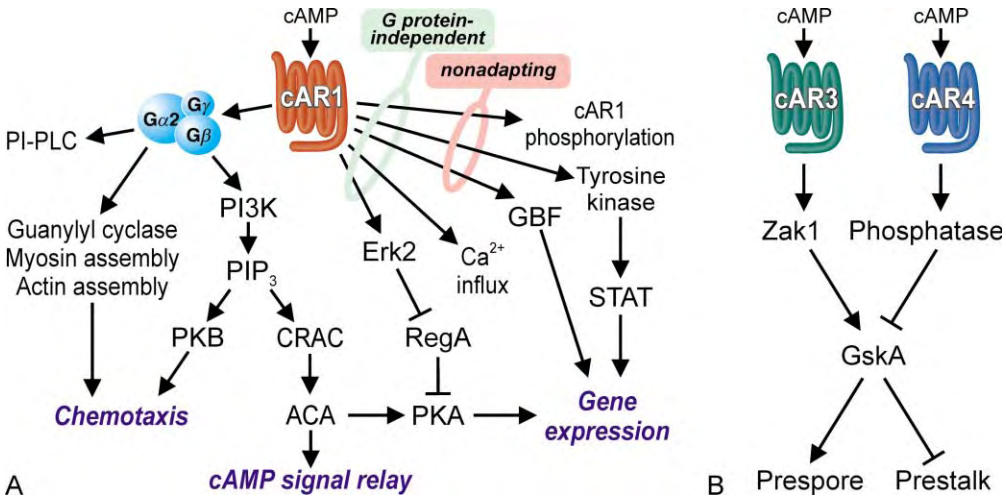

FIGURE 3 cAMP receptor signaling pathways. Pointed (↓) and flat-headed (⊥) arrows indicate activation and inhibition, respectively. (A) cAR1 pathways leading to chemotaxis, cAMP signal relay, and gene regulation. G protein-independent and nonadapting pathways are indicated. In multicellular stages, cAR2–4 might activate some of the pathways shown for cAR1. (B) Role of cARs in the GskA-mediated determination of cell fate. cAR2 (not shown) might promote prestalk cell differentiation at the mound stage in the manner shown for cAR4.

functions intracellularly via protein kinase A (PKA) to modulate gene expression and, in addition, is secreted from the cell in order to relay the cAMP signal to neighboring cells.

G$\beta\gamma$-mediated increases in PIP_3 levels also recruit other PH domain-containing proteins to the plasma membrane including protein kinase B (PKB or Akt), which has been shown to be critical for chemotaxis. In cells undergoing chemotaxis in a shallow cAMP gradient, PKB and other PH domain-containing proteins localize exclusively at the cells' leading edge where they presumably promote actin assembly and pseudopod extension. These mechanistic insights into cAR1-mediated chemotaxis, namely the involvement of PI3K activation and recruitment of PKB to the leading edge, have since been found to also pertain to the chemotaxis of a variety of mammalian cells including neutrophils.

The Gα2 subunit is implicated in the cAR1-dependent activation of guanylyl cyclase (cGMP) which provides another important input to the chemotaxis machinery. The product of cGMP regulates myosin heavy chain kinases and, thereby, promotes the assembly of conventional myosin II in posterior and lateral regions of chemotaxing cells where it can propel the rear of the cell forward upon contraction and suppress lateral pseudopod formation.

G Protein-Independent Pathways

Several cAR-mediated responses appear to be G protein-independent based on their preservation in cells lacking what is believed to be the sole G protein β-subunit gene. These include phosphorylation of cAR1, uptake of Ca^{2+}, and activation of the mitogen-activated protein kinase Erk2, the transcriptional regulators GBF and STAT, and the GSK3 homologue GskA.

cAR1 is phosphorylated on serine residues within its C-terminal cytoplasmic domain. The 18 serines in this domain exist in four clusters (Figure 2). In unstimulated cells, cAR1 is basally phosphorylated within clusters 2 and 3. Upon stimulation with cAMP, cAR1 becomes reversibly hyperphosphorylated due to the addition of approximately two phosphates within cluster 1 and a third phosphate within cluster 2. Cluster 1 phosphorylation causes the 40–43 kDa electrophoretic shift. Other cARs also undergo cAMP-induced phosphorylation commensurate with their affinities.

Erk2 promotes the intracellular accumulation of cAMP by negatively regulating RegA, a cAMP-specific phosphodiesterase. Erk2 is presumably the third of three kinases in a typical MAP kinase cascade. The identity of the upstream kinases as well as the G protein-independent mechanism by which cAR1 activates the cascade remain to be determined.

cAMP triggers the rapid and transient influx of Ca^{2+} ions in aggregation-competent cells. This is mediated largely by cAR1 due to its natural abundance at this stage in development. However, expression of cARs in vegetative cells indicates that the components required for uptake are expressed at this stage and that other cARs can also mediate Ca^{2+} uptake. The magnitude of Ca^{2+} uptake is roughly proportional to receptor level, indicating that cARs are the limiting components for this response.

G-box binding factor (GBF) binds G-rich elements in early postaggregative genes and is required for their induction by cAMP. Gene disruptions suggest that either cAR1 or cAR3 mediate the G protein-independent activation of GBF. In contrast to many aggregation-stage genes whose expression requires periodic cAMP pulses that mimic natural cAMP waves, GBF-mediated gene expression is induced by constant cAMP, indicating that it is not subject to adaptation. Thus, the GBF pathway is appropriately activated upon aggregation when extracellular cAMP rises to levels that persistently occupy cAR1.

STAT proteins have been extensively studied in the context of cytokine signaling in mammalian immune cells. In *Dictyostelium*, exogenous cAMP triggers STATa's phosphorylation on tyrosine, SH2 domain-mediated dimerization, and translocation to the nucleus where it governs prestalk gene expression. cAR1 is required for this response but it can be substituted in this capacity with cAR2, suggesting that multiple cARs might activate STATa during development. The cAR-activated tyrosine kinase involved remains to be identified.

GskA, a homologue of glycogen synthase kinase-3 (GSK3), is an important regulator of cell fate in *Dictyostelium* and cARs play key roles in regulating its activity. GskA activity promotes spore cell differentiation, whereas inactivity results in stalk cell differentiation (Figure 3B). Independent of G proteins, cAR3 activates the nonreceptor tyrosine kinase Zak1 which, in turn, phosphorylates and activates GskA. On the other hand, cAR4 (and perhaps cAR2) activates a phosphotyrosine phosphatase, resulting in the dephosphorylation and inactivation of GskA. The role of G proteins in the latter process, if any, is not known. Therefore, cAR3 signaling promotes spore differentiation and cAR2 and cAR4 favor stalk cell differentiation. Because cAR2 and cAR4 are expressed predominantly in prestalk cells, it is unclear whether these mechanisms determine cell fate or act thereafter in cell-type maintenance.

One known target of cAMP-activated GskA is STATa. GskA phosphorylates multiple serines of STATa, causing it to be exported from the nucleus. This is one mechanism by which cAR3 signaling might oppose prestalk differentiation. As has been described for other developmental systems, GskA may also determine cell fate by phosphorylating β-catenin and thus targeting this transcriptional coactivator for destruction.

Mechanisms of G Protein-Independent Signaling

It remains to be determined how cAMP-occupied cAR1 communicates with and activates these effectors. By analogy with G proteins and also mammalian G protein-coupled receptor kinases (GRKs), the yet to be identified cAR kinase might interact selectively with the ligand-occupied conformation of the receptor's cytoplasmic loops. Other G protein-independent processes such as Ca^{2+} uptake could involve lateral signal transduction within the plane of the membrane by direct interaction of cAR1 with another integral membrane protein, analogous to the interaction of *Halobacterium* sensory rhodopsins (SI and SRII) with their associated histidine kinases (HtrI and HtrII).

Desensitization Mechanisms

In general, receptor-mediated responses are governed by various desensitization mechanisms which attenuate the cell's responsiveness. cAMP triggers the sequential phosphorylation ($t_{1/2} \sim 2$ min) and internalization ($t_{1/2} \sim 15$ min) of cAR1. cAR1 phosphorylation causes a several-fold reduction in the receptor's intrinsic affinity for cAMP, which may extend the range of cAMP concentrations to which the receptor can respond during aggregation. In addition, preliminary results indicate that phosphorylation of cAR1 is a prerequisite for its internalization as in other systems. Prolonged cAMP exposure results in down-regulation of cAR1 levels, the combined effect of diminished cAR1 gene transcription, and cAR1 degradation. Degradation presumably results from delivery of internalized receptors to lysosomes.

On a more rapid timescale, nearly all of the cAR1-mediated responses to abrupt cAMP increases are transient, returning to prestimulus levels in 30 s to several minutes despite constant stimulation. This rapid and reversible attenuation of responses is referred to as adaptation. The few responses that do not adapt include cAR1 phosphorylation and GBF activation. The mechanisms of adaptation are poorly understood and might be distinct for each pathway. cAR1 phosphorylation appears not to be involved as elimination of phosphorylated serine residues in cAR1 by site-directed mutagenesis has little impact on the kinetics of these responses.

Cells adapted to one cAMP concentration can respond to yet higher concentrations (provided the receptor is not saturated). This observation indicates that adaptation is a graded signal that is just sufficient to offset the excitatory signal, the strength of which also reflects receptor occupancy. For the adenylyl cyclase pathway, adaptation can be explained by the transient translocation of PI3K to the plasma membrane and the subsequent degradation of PIP_3 by the phosphatase PTEN. In addition, FRET experiments indicate that the G protein is persistently dissociated in adapted cells. Taken together, these findings suggest that an adaptation pathway emanates from cAR1 and acts upon the adenylyl cyclase excitatory pathway somewhere beyond the G protein, causing PI3K to be released from the membrane. Because PKB activation also depends on PI3K, the same adaptation mechanism is likely to govern chemotaxis.

Gradient Sensing in Chemotaxis

Temporal challenges with fixed cAMP concentrations as described above have been invaluable for deciphering cAR-mediated pathways and revealing the existence of adaptation mechanisms. However, natural cAMP waves also contain spatial information which the cells must rapidly and accurately sense for efficient chemotaxis. Although cAR1 is uniformly distributed in the plasma membrane, shallow cAMP gradients differing by as little as 2% across the length of the cell prompt highly asymmetric localization of various proteins, indicating that the cell senses and amplifies small differences in cAR1 occupancy on this surface. Proteins with PH domains including PKB and CRAC are highly localized to the plasma membrane of cell's leading (or anterior) edge, indicative of elevated PIP_3 levels. This reflects the recruitment of PI3K to the anterior plasma membrane and its subsequent activation. The membrane translocation of PI3K is mediated by its N-terminal domain which presumably binds an entity in the plasma membrane that is generated in response to cAR1 activation. Conversely, PTEN is associated with the posterior plasma membrane via specific interactions with PIP_2. Thus, PTEN is excluded from the anterior membrane where PI3K actively converts PIP_2 to PIP_3 and instead localizes to posterior regions where PIP_2 should be more abundant. Localization of the antagonistic activities of PI3K and PTEN to opposing poles of the cell should result in a steep gradient of PIP_3 and associated PH domain-containing proteins. Precisely how the cell amplifies the directional information of a shallow chemoattractant gradient to achieve extreme gradients of activities within the cell is likely to be critically important for efficient chemotaxis and is under intensive investigation.

Cyclic GMP Phosphodiesterases

Sharron H. Francis and Jackie D. Corbin
Vanderbilt University School of Medicine, Nashville, Tennessee, USA

Cyclic nucleotide (cN) phosphodiesterases (PDEs) are phosphohydrolases that specifically cleave the cyclic phosphodiester bond of 3′,5′-cyclic GMP (cGMP) or 3′,5′-cyclic AMP (cAMP) (Figure 1) to the respective 5′-nucleotides thereby inactivating these signaling molecules. PDEs are largely responsible for lowering the intracellular cN content, and the activities and concentrations of these enzymes are rigorously regulated. Some PDEs are highly specific for either cAMP or cGMP, but others, i.e., dual-specificity PDEs, hydrolyze both. Both types of PDEs contribute importantly to modulation of cGMP-signaling pathways. The competition of cGMP and cAMP for hydrolysis by the dual specificity PDEs can also alter the signaling in the respective pathways. PDEs are integral components in cN signaling pathways (Figure 2) from *Paramecia* through mammals, and in humans, these enzymes are the pharmacological targets for treatment of a number of medical problems including hypertension, male erectile dysfunction, depression, and asthma.

Cyclic GMP and cAMP are prominent second-messenger molecules (Figure 1) and are synthesized by guanylyl cyclases (GC) and adenylyl cyclases (AC), respectively. The balance between the activities of the cyclases and PDEs determines cellular cN levels (see cGMP-signaling pathway, Figure 2). The cyclases specifically synthesize either cAMP or cGMP. The cyclic phosphate ring of cGMP and cAMP is a key feature by which PDEs recognize their substrates, and it is highly resistant to most other phosphohydrolases. Nucleotides lacking this ring do not significantly interact with the catalytic sites of PDEs even at high concentrations. Structural features of the purine (Figure 1) provide the next most critical feature for interaction of the cN with PDEs. For cGMP-specific PDEs, interaction with the oxygen at the C6 position is extremely important.

Distribution of cAMP and cGMP

Cyclic AMP is apparently present in all eukaryotes, but cGMP is less widespread (Figure 1). The yeast genome lacks identifiable sequences for GCs or known cGMP-binding domains. However, *Dictyostelium, Paramecium, Tetrahymena, Trypanosomatids*, and *Plasmodium* contain GCs. The role of cGMP in most of these organisms is not understood, but in *Dictyostelium*, cGMP participates importantly in chemotaxis and osmoregulation. In mammals, cGMP-signaling pathways are prominent in many processes including smooth muscle relaxation, visual transduction, platelet function, neuronal viability, bone growth, apoptosis, water and electrolyte homeostasis, and aldosterone synthesis.

Classification of PDEs

Three evolutionarily distinct classes of PDEs, class I, class II, and class III have been identified; to date, class III contains one PDE that hydrolyzes cAMP and will not be discussed further. Both class I and class II PDEs occur in some species, e.g., *Dictyostelium* and *Saccharomyces*. All known mammalian PDEs and a few PDEs in other species are class I PDEs. In eukaryotes, the cN-binding sites in PDEs are distinguished from those of other known intracellular cN receptors both functionally and evolutionarily; these include cN-binding proteins such as the cAMP- and cGMP-dependent protein kinases (PKA and PKG) which belong to the bacterial catabolite gene activator protein (CAP-related family), the cGMP-binding GAF domains in some PDEs, and some anion transporters.

Class I PDEs

The class I PDE superfamily in mammals contains 11 PDE families that are products of separate genes. Classification is based on the extent of similarity in the DNA sequences. Three are cAMP-specific PDEs (PDEs 4, 7, and 8), three are "cGMP-specific" PDEs (PDEs 5, 6, and 9), and four are dual-specificity PDEs (PDEs 1, 2, 3, 10, and 11) (Figure 3). Among isoforms of the latter group, the relative affinities and turnover rates for cGMP and cAMP can vary significantly as exemplified by PDE1.

Domain Structure of Class I PDEs

Each class I PDE monomer is a chimeric protein that includes a conserved catalytic domain (C domain) of ~270 amino acids that is located more C-terminal to its regulatory domain (R domain); 18 amino acids are

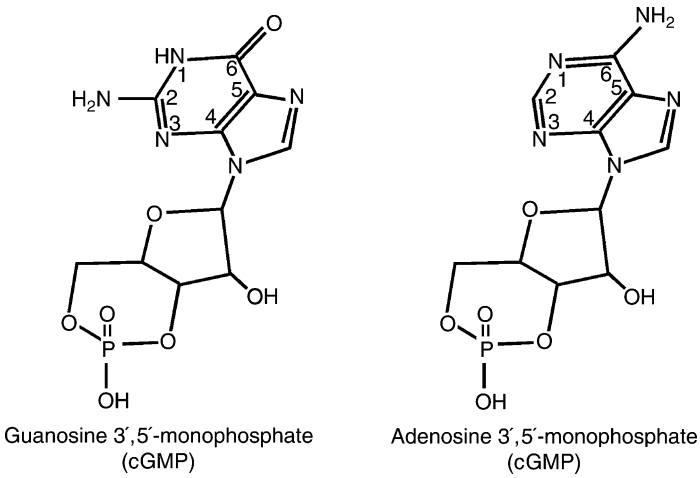

FIGURE 1 Molecular structures of cGMP and cAMP. The structures of cGMP and cAMP differ only at the N-1, C-6, and C-2 positions, but these differences provide for the specific and selective interaction with PDE catalytic sites. The *syn* conformation of both nucleotides is shown.

invariant among mammalian class I PDEs. Among all known class I PEDs, only 14 amino acids are invariant. These most likely provide for critical structural and catalytic features. Diverse regulatory features for each family modulate enzyme functions (Figure 3). The R domains contain varied subdomains including phosphorylation sites, autoinhibitory sequences, subcellular localization signals, dimerization motifs, and GAFs; GAFs are ancient domains of ~120 amino acids that occur in five PDE families. The name is derived from recognition of this motif in a number of diverse proteins (cGMP-binding PDEs, *Anabaena a*denylyl cyclase, and *Escherichia coli F*hla transcription factor). Depending on the PDE in which they are located, GAFs can contribute to for dimerization, interaction with other proteins or with ligands such as cGMP; cAMP interacts weakly with these sites in PDE2, but it does not appear to bind to these sites in other PDEs.

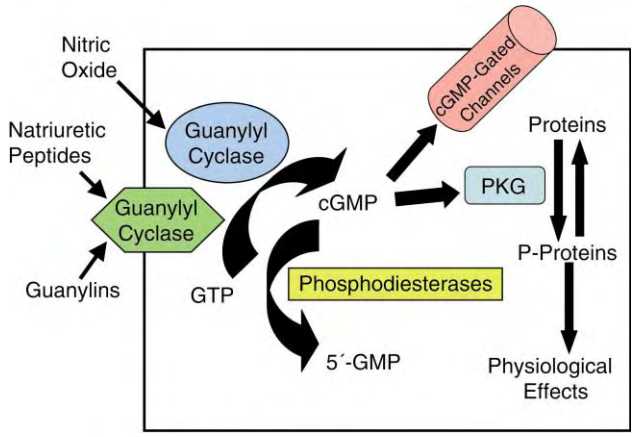

FIGURE 2 Model of cGMP signaling in cells. Intracellular levels of cGMP are determined by the relative activities of guanylyl cyclases and phosphodiesterases. There are two families of guanylyl cyclases; the cytosolic form is activated by nitric oxide and a membrane-bound form is activated by natriuretic peptides and guanylins. Cyclic GMP breakdown is catalyzed by phosphodiesterases that are either cGMP-specific or PDEs that hydrolyzed both cGMP and cAMP, i.e., dual-specificity PDEs. Cyclic GMP interacts with the cGMP-dependent protein kinase (PKG), cGMP-gated cation channels, and cGMP-binding phosphodiesterases to bring about its physiological effects.

C Domains of Class I PDEs

The C domains of class I PDEs contain two prominent functional subdomains; one provides for binding divalent cation(s) and another provides for interaction with the cN purine. Metal and cN apparently bind independently. The subdomains are closely juxtaposed in the tertiary structure in order to effect catalysis. Crystallographic structures of cAMP-specific PDEs (PDE4B and PDE4D), cGMP-specific PDE5, and site-directed mutagenesis of a number of PDEs have identified important amino acids in each subdomain.

Metal Requirements of Class I PDEs

PDEs require divalent cation(s) to support catalysis. Evidence suggests that class I PDEs contain two metals that are bound in close proximity and are critical to the catalytic process. In two cGMP-specific PDEs (PDEs 5 and 6), Zn^{2+} is required for catalysis, and PDE6 contains three Zn^{2+} molecules. Results of site-directed mutagenesis and X-ray crystallographic structures of the catalytic domains of PDEs 4 and 5 indicate that these PDEs contain a tightly bound Zn^{2+} which is coordinated by histidines, aspartic acid, and water molecules. The second metal is coordinated through interactions with an aspartic acid and several water molecules that are in turn linked to histidines and aspartic acid. The metal occupying the second

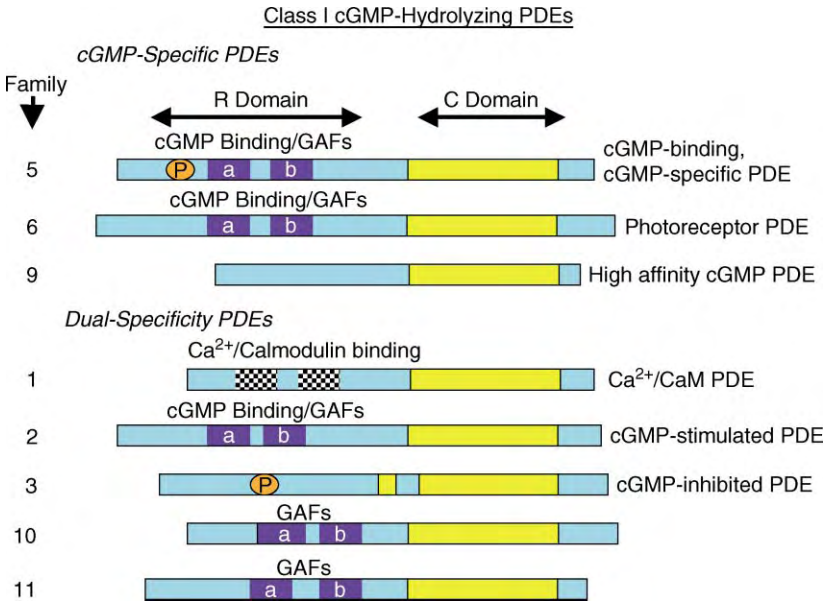

FIGURE 3 Schematic depiction of structural features of mammalian class I cGMP-hydrolyzing PDEs. Arrangements of the regulatory (R) domains and catalytic (C) domains are shown for a monomer, although all known mammalians PDEs exist as dimers. Known sites of phosphorylation (P) are indicated. The cGMP binding/GAFs label denotes allosteric cGMP-binding that is associated with GAF domains in PDEs 2, 5, and 6; all isoforms of these families contain two GAF domains. The role of the GAF domains in PDEs 10 and 11 is not known; isoforms within the PDE11 family contain 1, 2, or no complete GAF domains. The open block in PDE3 is a novel 44 amino acid insert in the catalytic domain of this family. Cross-hatched boxes denote calmodulin-binding domains (1 or 2) in the R domain of PDE1

metal site in PDEs is still unclear and may vary. Both Mg^{2+} and Mn^{2+} have been suggested to be the physiologically relevant cations, but this remains to be definitively demonstrated. Nucleophilic attack by an activated hydroxyl from solvent water that bridges the metals is thought to cleave the phosphodiester bond.

Features that Contribute to cN Specificity

The molecular basis that provides for the affinity and selectivity of PDEs for either cN is poorly understood. Substitution of two amino acids by point mutations shifts the cGMP/cAMP specificity of PDE5 ~100-fold. PDE11, a dual-specificity PDE, and PDE5, a cGMP-specific PDE, are most similar among PDEs. X-ray crystallographic structures of PDEs 4 and 5 suggest that the orientation of the side chain of an invariant glutamine is a critical determinant of specificity for interaction with the purine ring in either cGMP or cAMP.

In solution, cNs are in equilibrium between two conformations, *syn* and *anti*, based on orientation between the purine and ribose moieties. The preferred configuration varies among PDE families, but the *anti* conformer is most commonly preferred. Large substitutions on the ribose 2′-OH or on the N-1 and C-2 positions of the purine are well tolerated by the catalytic sites of both cGMP-specific PDEs 5 and 6 and the dual-specificity PDEs 1 and 2. Some of these analogues are hydrolyzed by the enzymes.

Interaction of Inhibitors with Class I PDEs

Specific structural features in the catalytic sites of cGMP-PDEs provide for interaction with different inhibitors. Some inhibitors compete for access to the catalytic site by mimicking the structure of cGMP. This is true for two specific inhibitors of PDE5, i.e., sildenafil (Viagra) and vardenafil (Levitra); tadalafil (Cialis) also competes with cGMP for the catalytic site, but its structure is not closely patterned on that of cGMP, and it forms different contacts with PDE5 than occur with sildenafil or vardenafil. Studies based on site-directed mutagenesis indicate that sildenafil utilizes many of the amino acids that provide for interaction of cGMP with PDE5. Affinity of PDE5 for these inhibitors is ~1000–10 000 times greater than for cGMP, so additional contacts must be involved.

PDEs 5, 6, and 11 are closely related and share ~50% amino acid sequence homology. Sildenafil inhibits both PDEs 5 and 6, but it has ~4–10 fold lower affinity for isoforms of PDE6 than for PDE5; it is a very weak inhibitor of PDE11. In contrast tadalafil (Cialis) potently inhibits PDE5, is ~40-fold less effective against PDE11, and has little effect on PDE6. PDE1, a dual-specificity PDE, is inhibited by sildenafil with ~100-fold lower potency than that for PDE5. The catalytic sites of

PDEs 1, 5, and 6 have similar preferences for cN analogues, so it is likely that sildenafil exploits shared structural features among these PDEs. In contrast, some other inhibitors selectively inhibit the dual-specificity PDEs 1, 2, and 3 and are ineffective against PDEs 5 and 6. Future development of PDE inhibitors will undoubtedly map the patterns of molecular selectivity to identify compounds that preferentially inhibit particular cGMP PDEs. PDE6 isoforms are novel in that they are specifically inhibited by a small protein, Pγ, that is abundant in photoreceptor cells. Pγ inhibitors appear to be entirely specific for PDE6 isoforms.

Regulation of cGMP-Hydrolyzing Class I PDEs

Cyclic GMP-hydrolyzing PDEs are regulated by both short-term and long-term regulatory mechanisms. These include ligand activation (e.g., Ca^{2+}/calmodulin (PDE1) and cGMP binding to allosteric sites provided by one or more GAF domains (PDEs 2, 5, 6, and perhaps 10 and 11), phosphorylation (PDEs 1, 3, 5, and 11) (Figure 3), and increases in protein levels. In a physiological setting, these provide for sensitive control of PDE activities.

In PDEs 2, 5, and 6, GAFs provide for allosteric cGMP binding, and are evolutionarily distinct from the catalytic sites. Molecular determinants for cGMP interaction with the catalytic site differ markedly from those for cGMP binding to GAF sites. Cyclic GMP is the only ligand that has been shown to bind to GAFs in PDEs; this has been reported only for PDEs 2, 5, and 6. In PDE2, cAMP competes with cGMP binding but with >10-fold lower affinity; it does not measurably compete with cGMP binding in PDEs 5 and 6. In the X-ray crystallographic structure of the PDE2 R domain, cGMP is almost entirely buried within the GAF b site. The tight fit of cGMP agrees well with the fact that few cGMP analogues compete with cGMP at this site. In PDE5, allosteric cGMP binding occurs in the GAF a site.

Characteristics of cGMP-Specific Class I PDEs (PDEs 5, 6, and 9)

PDE5

PDE5 is known as the cGMP-binding, cGMP-specific PDE. There are four isoforms. PDE5 has >100-fold selectivity for cGMP over cAMP at both its catalytic site and allosteric sites; it is a homodimer of ~100 kDa subunits; each R domain contains two GAFs (a and b). GAF*a*, and perhaps GAF*b*, and both provide for allosteric cGMP binding contribute importantly to dimerization. The K_m for cGMP hydrolysis is <1 μM, and the V_{max} is ~5 μmol min^{-1} mg^{-1}. PDE5 is abundant in smooth muscle cells, gastrointestinal epithelial cells, platelets, and certain neuronal cells. It is typically coexpressed with other components of cGMP signaling, including PKGs and GCs. Catalytic activity is stimulated by cGMP binding to the allosteric cGMP-binding sites, by phosphorylation of Ser-102 near the N terminus, and by chemical reduction. Phosphorylation occurs in intact tissues in response to elevation of cGMP and PKG action.

PDE5 is the major cGMP-hydrolyzing PDE in platelets, lung, and the vascular smooth muscle (VSM) of the penile corpus cavernosum (PCC). Sildenafil (Viagra), tadalafil (Cialis), or vardenafil (Levitra) blocks cGMP breakdown by PDE5 leading to increased intracellular cGMP and relaxation of the VSM of blood vessels within and supplying the PCC. The increased blood flow and capacitance of PCC vascular structures facilitate accumulation of blood and improve erectile function. Sildenafil also shows promise in treatment of other diseases involving the vasculature.

PDE6

PDE6 occurs only in mammalian retinal photoreceptor cells. Its activity accounts for the visual response. Rods provide for vision in dim light and contain PDE6$\alpha\beta$, a heterodimer of 100-kDa subunits. Cones provide for vision in bright light and contain PDE6$\alpha'\alpha'$, a homodimer of 100-kDa subunits. In the absence of light, PDE6$\alpha\beta$ and PDE6$\alpha'\alpha'$ are inhibited by specific proteins, Pγs. Activated PDE6 isoforms have high catalytic activity ($V_{max} \sim 300$ μmol min^{-1} mg^{-1}) and $K_m \sim 35$ μM. One or both GAFs in each PDE6 subunit provide for allosteric cGMP binding and/or dimerization.

In the dark, cGMP in photoreceptors is high. This cGMP binds to a cGMP-gated cation channel which then allows for increased conductance of a "dark current." When light strikes the retina, the inhibition of PDE6 by Pγ is relieved, causing a sudden drop in cGMP. At the lower cGMP level cGMP dissociates from the channel; the channel closes, terminating the "dark current." The resulting change in the membrane potential produces the sensation of light. The regulation of PDE6 in cones and rods is specifically adapted to optimally respond to different light intensities, but the overall regulation of the PDE6 isoforms is quite similar.

PDE9

Little is known about the tissue distribution or physiological role of PDE9. It is highly selective for cGMP and has a K_m of 0.1–2 μM for cGMP versus 230 μM for cAMP. It is inhibited by zaprinast ($IC_{50} \sim 35$ μM), but it is insensitive to a wide range of other PDE inhibitors including sildenafil, vinpocetine, IBMX, and dipyridamole.

Characteristics of Class I Dual-Specificity PDEs

A number of mammalian PDEs (PDEs 1, 2, 3, 10, and 11) hydrolyze both cGMP and cAMP. The physiological role of each PDE in hydrolyzing the two nucleotides is likely to be complex. Activities of these PDEs towards either cGMP or cAMP will reflect the respective K_m and V_{max} values for each, but selective action towards one nucleotide can occur simply by mass action. For example, if the cGMP/cAMP content of a tissue selectively changes, increased hydrolysis of one nucleotide (e.g., in response to elevated amounts of that nucleotide) would tend to decrease hydrolysis of the other nucleotide through simple competition for the catalytic site. As a result, the concentration of the second nucleotide would increase.

PDE1

PDE1 is regulated by Ca^{2+}/calmodulin binding (Figure 3). It occurs in many tissues including brain, heart, vascular smooth muscle, and liver. There are three groups of isoforms (PDE1A, IB, and IC) whose relative affinities and turnover rates for cGMP and cAMP vary considerably. In tissues containing primarily one of these isoforms, the relative hydrolytic contribution of PDE1 family to breakdown of cAMP or cGMP will reflect the kinetic features of that particular PDE1. The PDE1 family can provide for responsiveness of cGMP and/or cAMP levels to changes in Ca^{2+} signaling.

PDE2

PDE2 is known as the cGMP-stimulated PDE. It is a homodimer comprised of ~105-kD monomers; there are three isoforms. The V_{max} values for hydrolysis of cAMP and cGMP are similar (150 μmol min^{-1} mg^{-1}), and the K_m values differ ~twofold (15–30 μM for cGMP versus 30–50 μM for cAMP). Cyclic GMP binds to the GAF b in the R domain; this stimulates breakdown of either cAMP or cGMP. PDE2 can therefore potentially lower either or both cNs. PDE2 is abundant in adrenal cortex cells which produce aldosterone in response to cAMP elevation. Elevation of cGMP results in cGMP binding to the PDE2 GAF b, causing increased cAMP hydrolysis and decreased aldosterone production. A similar physiological effect to increase cGMP hydrolysis has not been experimentally demonstrated, but it is likely to occur.

PDE3

PDE3 is abundant in many tissues and occurs as two isoforms (PDE3A and 3B) that are largely membrane bound; both hydrolyze cAMP with a greater V_{max} than cGMP, but the K_m values for the cNs are similar. PDE3B is activated by phosphorylation. Historically, PDE3 was dubbed the "cGMP-inhibited PDE," a misleading descriptor since cGMP "inhibits" cAMP hydrolysis by competing for access to the catalytic site. In platelets, evidence suggests that the antiaggregatory effect of cGMP may occur through a cAMP-signaling pathway due to cGMP competition with cAMP hydrolysis by PDE3. Elevation of cGMP would increase its effectiveness to compete with cAMP for the PDE3 catalytic site, thereby "protecting" cAMP from hydrolysis.

PDEs 10 and 11

Little is known about the physiological functions of these recently characterized PDEs. PDE10 is abundant in neural tissue. It has 26-fold higher affinity for cAMP versus cGMP (K_m values ~0.05 and 13 μM, respectively), but the V_{max} for cGMP is ~5 times that for cAMP. PDE10 R domain contains GAFs, but no ligand has been shown to bind to these GAFs. PDE11 is closely related to PDE5 (50% homology). There are four isoforms whose R domains contain one, two, or partial GAFs, but cN binding has not been demonstrated. PDE11 hydrolyzes cGMP and cAMP at a similar rate, but K_m for cAMP is half that for cGMP (0.5 versus 1 μM, respectively). It is potently inhibited by tadalafil (Cialis) (IC_{50} ~ 80 nM) and by dipyridamole (IC_{50} ~ 0.4–0.9 μM).

Characteristics of Class II PDEs

The few known class II PDEs occur in yeast, bacteria, and *Dictyostelium*. They belong to a family of proteins with a Zn^{2+}-binding hydrolase motif that is thought to mediate hydrolysis of the cN. This family of proteins includes glyoxylases, β-lactamases, and arylsulfatases, but there are no X-ray crystallographic structures. There is no apparent homology with class I PDEs.

Characteristics of Class II PDEs Catalytic Activity

Class II PDEs require divalent cation(s) for catalytic activity. Three of these PDEs hydrolyze cGMP; these include a dual-specificity PDE from *Vibrio fischeri*, and two PDEs from *Dictyostelium* (Figure 4). The *V. fischeri* PDE hydrolyzes cAMP and cGMP with ~20- and 10-fold higher V_{max} values, respectively, than any PDE in either class; one *Dictyostelium* class II PDE is cGMP-specific while the other has dual-specificity.

Regulation of Class II PDEs

Both *Dictyostelium* PDEs described above are activated by cN binding to site(s) in R domains located near the

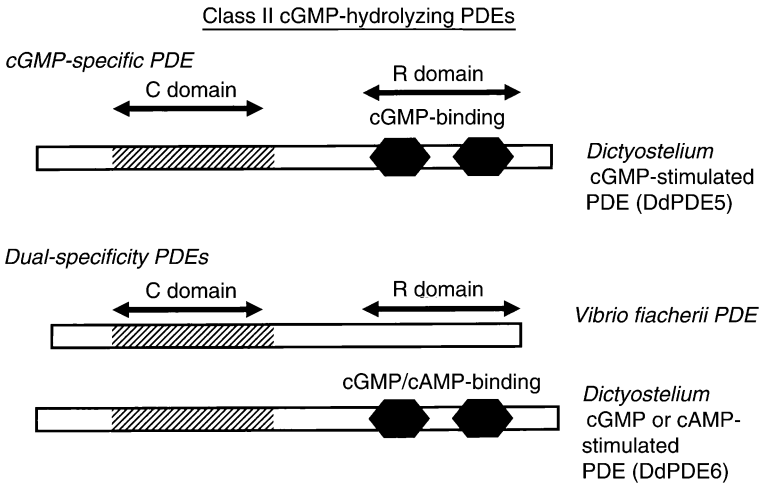

FIGURE 4 Schematic depiction of class II cGMP-hydrolyzing PDEs. Arrangements of functional domains are shown for a monomer. The allosteric cN-binding sites belong to the CAP-related family of cN-binding proteins and are distinct from the allosteric cGMP-binding sites in class I PDEs.

C terminus (Figure 4). In DdPDE5, catalytic activity is stimulated by allosteric cGMP binding, whereas allosteric binding of either nucleotide stimulates catalysis by DdPDE6. This resembles the cGMP effect on catalysis in class I PDEs 2 and 5. However, GAFs are absent in these class II PDEs. Instead, both contain two CAP-related cN-binding domains (Figure 4). Thus, despite little similarity between class I and II PDEs, similar regulatory mechanisms are used, and, remarkably, evolutionarily distinct motifs and arrangements of the motifs in the structures have been employed. In *Dictyostelium*, cellular cGMP is degraded by both of these PDEs as well as by a dual-specificity PDE that is poorly understood.

Concluding Remarks

Cyclic GMP levels are modulated through the action of cGMP-specific PDEs and dual-specificity (cGMP and cAMP) PDEs. Both must be considered when studying physiological changes in intracellular cGMP.

National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland, USA

Eva Degerman
Lund University, Lund, Sweden

Cyclic nucleotide phosphodiesterases (PDEs) constitute a large, diverse, and complex superfamily of metallohydrolases which cleave the 3′,5′-cyclic phosphate bond of cyclic AMP (cAMP) and cyclic cGMP (cGMP), resulting in production of 5′-AMP and 5′-GMP, respectively. Based on differences in primary structures, PDEs have been divided into two major classes, I and II. Class I PDEs, which contain a conserved catalytic domain (~250–300 amino acids), comprise the majority of known PDEs, including the 11 structurally related, highly regulated, and functionally distinct mammalian gene families (PDEs 1–11). Class I PDEs are also found in the parasites *Trypanosoma brucei* and *cruzi*, and in *Drosophila*, nematodes, yeast, and sponges. Only a few enzymes (no mammalian isoforms) have been classified as class II PDEs, which are structurally unrelated to class I PDEs. The evolutionary relationship between the two PDE classes is also not certain; this brief review will focus on mammalian class I PDEs. By catalyzing hydrolysis of cyclic nucleotides, mammalian PDEs regulate their intracellular concentrations, and, consequently, their signaling pathways and myriad physiological effects, including myocardial contractility, visual transduction, vascular and airway smooth muscle relaxation, immune/inflammatory responses, cell proliferation and apoptosis, memory, and many others. At present, mutations in the PDE6 gene represent the only known association of PDE mutations with human disease, in this instance, with certain subclasses of degenerative retinitis pigmentosa. The mammalian PDE superfamily is a major target for drug discovery in treatment of clinically important diseases, i.e., PDE5 inhibitors (Viagra®) for erectile dysfunction, PDE4 inhibitors for inflammatory disorders, etc.

Molecular Diversity

cAMP and cGMP are important intracellular second messengers that modulate many biological processes. The "classical" mechanism for transduction of cyclic nucleotide signals involves cyclic nucleotide-induced activation of cAMP- and cGMP-dependent protein kinases (PKA and PKG, respectively), with subsequent phosphorylation of critical downstream regulatory effectors. Recently, however, cyclic nucleotide-binding proteins have been recognized as direct mediators of cyclic nucleotide actions, e.g., cyclic nucleotide-gated ion channels, cAMP-activated guanine nucleotide exchange factors (EPACs) which regulate Rap1 GTPases (guanosine triphosphatases), and several PDEs, especially PDEs 2, 5, 6, which contain allosteric, non-catalytic cyclic nucleotide-binding sites.

Molecular genetics has revealed the diversity and complexity of the 11 mammalian PDE gene families (PDEs 1–11). PDE families differ in their primary amino sequences, substrate specificities, sensitivities to endogenous effectors and pharmacological agents, cellular functions, and mechanisms whereby they are regulated. Most PDE families comprise more than one gene; within these families multiple, closely related isoforms are generated from the same gene or different genes via alternative mRNA splicing or utilization of different promoters/transcription initiation sites. More than 20 PDE genes probably encode more than 50 PDE proteins. Some cells are relatively enriched in specific PDEs, e.g., photoreceptor PDE6 is virtually exclusively expressed in the retina. Most cells, however, contain representatives of multiple PDE gene families, and different members of the same family, but in different amounts, proportions and subcellular locations. Redundancy in PDEs, i.e., the presence in the same cell of multiple enymes which essentially perform the same reaction of hydrolyzing cyclic nucleotides, does not merely serve a survival or protective function, but rather allows cells to use distinct subsets of differentially regulated and localized PDEs to specifically and selectively regulate and segregate the generation, amplitude, duration, and compartmentation of cyclic nucleotide signals and actions. It is generally accepted that the cellular capacity to degrade cyclic nucleotides far

exceeds their synthesis, and is a major factor in the very rapid turnover of intracellular cAMP and cGMP. The physiological significance and functional consequences of this rapid turnover, and concomitant heat generation (cyclic nucleotide hydrolysis is accompanied by release of $\sim 7 \text{cal mol}^{-1}$), are not understood. This brief review will discuss some general characteristics of PDEs and then focus on the cellular biology and diverse functions of different PDE isoforms and their potential as therapeutic targets.

Structure/Function Analyses

Catalytic Domain

Mammalian PDEs exhibit a common structural organization, with a conserved catalytic domain ($\sim$250–300 amino acids) in the C-terminal portion of the molecules and divergent regulatory domains and modules in N-terminal portions (Figure 1). The catalytic core, more highly conserved among members of the same gene family than different gene families, contains a signature motif [HD (X_2) H (X_4) N], common to all PDEs, and includes consensus metal-binding domains. In addition to common structural elements responsible for cyclic nucleotide hydrolysis, the catalytic core contains family specific sequences responsible for differences in substrate affinities, catalytic properties, and sensitivities to specific inhibitors (Figure 1). Some PDE families are relatively specific for hydrolysis of cAMP (PDEs 4, 7, 8); others, for cGMP (PDEs 5, 6, 9); and some exhibit mixed specificity for both cAMP and cGMP (PDEs 1, 2, 3, 10, 11). While methylxanthines inhibit almost all PDEs, relatively specific and selective inhibitors, i.e., drugs that target individual PDE families with 10–100-fold greater potency than other PDE families, are available for several families, e.g., PDEs 1, 2, 3, 4, 5, 6. These family specific inhibitors are important for both basic research and clinical applications.

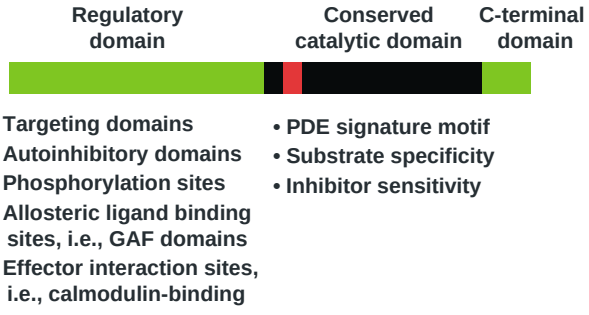

FIGURE 1 Common structural pattern for different PDE gene families.

Regulatory Domain

N-terminal portions of PDE molecules are highly divergent, containing structural determinants and specific amino acid sequences that allow different PDEs to respond selectively to specific regulatory signals (Figure 1). These regulatory regions include autoinhibitory modules (e.g., in PDEs 1, 4, 5), as well as sites and domains that are subject to different types of covalent modification (e.g., sites (in PDEs 1, 3, 4, 5, 10, 11) for phosphorylation by various protein kinases), or that interact with allosteric ligands (e.g., cGMP-binding sites in GAF domains), specific effectors (e.g., Ca^{2+}/calmodulin), protein partners or molecular scaffolds [e.g., AKAPs (anchoring proteins for PKA), B-arrestin], and thereby regulate catalytic activity, protein–protein interactions and/or subcellular compartmentation and localization (Figure 1). Five PDE families (PDEs 2, 5, 6, 10, 11) contain homologous so-called GAF domains, an acronym for proteins (cGMP-binding PDEs, *A*nabena adenylyl cyclase and *f*hlA, an *E. coli* transcriptional regulator) that contain these sequences. Although cGMP binding is not the primary function of GAF domains, in three PDE families (PDEs 2, 5, and 6), GAF domains bind cGMP with high affinity, but with different functional consequences.

PDE Functions

PDEs: Components of Spatially Organized Signaling Networks and Microdomains

PDEs are critical regulators of the generation, amplitude, duration, and termination of intracellular cyclic nucleotide signals. In addition to tight regulation of their concentrations and turnover, intracellular pools of cAMP and cGMP are also temporally, spatially, and functionally compartmentalized. In cardiac myocytes, for example, PGE_1 and catecholamines increase cAMP and activate PKA in different compartments, and cAMP diffusion is spatially restricted and regulated, at least in part, by PDEs. Newer techniques, e.g., use of fluorescence-resonance energy transfer (FRET) and cyclic nucleotide biosensors, also suggest that PDEs play an important role in these spatially-constrained microdomains, i.e., discrete subcellular regions in which cyclic nucleotide gradients are generated, monitored, and regulated, and their signals and effects channeled, transduced, and modulated.

The molecular basis for compartmentalization of cAMP signaling involves anchoring of PKA isoforms at specific intracellular sites via AKAP scaffolding proteins. These proteins organize formation of localized signaling modules/microdomains consisting of kinases, kinase

substrates, phosphatases, PDE4 isoforms, and other proteins. These modules sense intracellular cAMP gradients and effectively compartmentalize activation of substrates and biological responses. In these microdomains, cAMP-induced activation of PKA also results in phosphorylation/activation of PDE4 isoforms associated with AKAPs, resulting in modulation and termination of cAMP signals, and return of PKA to its basal state. For example, in cardiac myocytes, PDE4 isoforms are associated with AKAP complexes thought to modulate effects of cAMP on L-type and ryanodine-sensitive Ca^{2+} channels.

PDE4 isoforms, PKA, and other molecules also interact/associate with β-arrestins, which are scaffolding proteins located in the vicinity of plasma membranes that interact with activated β receptors and are involved in coordination of β receptor signaling and trafficking. This targeting and effective concentrating of PKA and PDE4 in proximity to the activated β receptors not only reduces cAMP generation (via phosphorylation, uncoupling and internalization of β receptors) but also enhances localized degradation of cAMP and desensitizes the complex with respect to further signaling via the β receptor and cAMP.

The subcellular localization of different PDEs, their interactions with molecular scaffolds and interacting partners, and their inclusion in, and contribution to the function of, macromolecular signaling microdomains is becoming a common theme in PDE biology. Anchoring of PDE3B to intracellular membranes via transmembrane hydrophobic helical segments and its interaction with PKB may be important in its activation by insulin. PDE4s also associate, via an N-terminal helical region, with another signaling scaffold protein called RACK1 (receptor for activated protein kinase C 1).

PDEs: Intracellular Effectors

PDEs are not only important determinants in the stringent regulation of intracellular cAMP and cGMP concentrations but they also serve as effectors of cyclic nucleotide actions. Historically, in cells containing multiple PDEs, family specific PDE inhibitors were initially utilized to pharmacologically define roles of specific PDEs in regulating specific signaling pathways and discrete cellular functions. In cultured mammalian oocytes, PDE3 inhibitors, not PDE4 or 5 inhibitors, inhibit meiotic progression and oocyte maturation, implying that PDE3 regulates a cAMP pool that controls maturation. (In fact, female PDE3A KO mice are sterile.) In cultured renal mesangial cells, experiments with PDE3 and PDE4 inhibitors indicated that PDE3 and PDE4 selectively regulated functionally distinct cAMP pools that controlled cell growth, and generation of reactive oxygen species, respectively. These types of studies first suggested a role for PDEs in spatial and/or functional compartmentalization of cyclic nucleotide signals and effects.

In some instances, a specific PDE serves as a critical effector system and regulates a unique cellular function, e.g., in retinal rods and cones, light-induced activation of photoreceptor PDE6 results in hydrolysis of cGMP and initiation of visual signal transduction. Activation of PDE3s by insulin, IGF-1, and leptin is apparently important in their ability to reduce cAMP and thereby regulate lipolysis in adipocytes, glycogenolysis in hepatocytes, insulin secretion from pancreatic β cells, and oocyte maturation. In these instances, PDE3 inhibitors can attenuate or block the effects of insulin, IGF-1 and leptin.

Studies of PDE KO mice do indicate that the ability of specific PDEs to regulate discrete cAMP/cGMP signaling pathways and actions is genetically determined. Female PDE3A KO mice are sterile, most likely due to inhibitory effects of cAMP on meiotic progression and maturation of oocytes, and consequently, their competency for fertilization. PDE3B KO mice, not frankly diabetic, demonstrate signs of disruption in insulin secretion and insulin resistance. Production of TNFα in response to administration of lipopolysaccharide (LPS) in PDE4B KO mice is profoundly ($\sim$90%) inhibited. On the other hand, PDE4D KO mice do not exhibit acetylcholine-induced contraction and hyperreactivity of airway smooth muscle. In PDE4D KO mice, the duration of β-adrenergic-induced anesthesia is reduced by more than 50%, and fertility is decreased due to reduced ovulation.

PDEs: Signal Integrators

With their different intrinsic properties and different responses to regulatory signals, PDEs also integrate multiple inputs, and are a "locus" for crosstalk between different signaling pathways. For example, PDE2, which is allosterically activated by cGMP, is highly concentrated in adrenal zona glomerulosa cells. In these cells, ANF (atrial natriuretic factor) increases cGMP synthesis; cGMP, in turn, activates PDE2, leading to a decrease in cAMP and PKA activity and inhibition of cAMP-stimulated aldosterone production. On the other hand, in other cells, NO activates guanylyl cyclase and increases cGMP, which inhibits PDE3 and increases intracellular cAMP content, resulting, for example, in stimulation of renin secretion from the juxtaglomerular apparatus in the kidney, and inhibition of platelet aggregation.

Newer approaches have suggested that different PDE isoforms may not only coordinate regulation of signals and responses in individual cells, but that differential cellular distribution within tissues may be important in intercellular communication and regulation of tissue

function. Immunohistochemical studies indicate, for example, that PDE1C and PDE2A are expressed in different sets of neurons in the olfactory epithelium, whereas PDE1C and PDE4A are present in different subcellular regions of the same neurons.

PDEs: Homeostatic Regulators

Signaling pathways, in general, also include mechanisms for negative feedback control. PDE3 and PDE4 activities, for example, are acutely up-regulated by cAMP-induced activation of PKA, which results in phosphorylation/activation of PDE3 and PDE4, and enhanced destruction of cAMP. Chronic elevation of cAMP also provides negative feedback, by increasing transcription of PDE3 and PDE4 genes and protein synthesis, resulting in increased enzymatic activities. In some cells, this latter phenomenon is part of mechanisms involved in ligand-induced down-regulation of cellular responses, such as tachyphylaxis or desensitization. Negative feedback control of cGMP hydrolysis by PDE5 is somewhat different, due to the presence of high affinity, non-catalytic, allosteric-binding sites for cGMP in the GAF domains of PDE5. Binding of cGMP to GAF domains results in allosterically-induced conformational changes that increase affinity of the catalytic site for cGMP and also facilitates phosphorylation and activation of PDE5 by PKG. Thus, elevation in intracellular cGMP provides negative feedback control and enhances its own destruction, both via direct cGMP-induced allosteric activation as well as indirect activation due to phosphorylation of PDE5 by PKG.

Family Specific Inhibitors: Clinical Applications

Molecular diversity of PDEs has occasioned the development of family specific PDE inhibitors to replace nonselective PDE inhibitors (theophylline and caffeine) as therapeutic agents for diseases such as asthma. Despite intensive efforts to develop such drugs, only sildenafil (Viagra™), a selective PDE5 inhibitor, has proven to be therapeutically effective in a major disease, i.e. erectile dysfunction, and is showing promise as a treatment modality in pulmonary hypertension. PDE4 enzymes are relatively concentrated in immume/inflammatory cells, and specific PDE4 inhibitors exhibit potent anti-inflammatory actions. Two selective PDE4 inhibitors, cilomilast and rofumilast, are in Phase 3 clinical trials for treatment of chronic obstructive pulmonary disease (COPD) and asthma. PDE3 inhibitors, which enhance myocardial contractility and relaxation of smooth muscle and inhibit platelet aggregation, failed in long-term clinical trials for treatment of chronic heart failure. However, one PDE3 inhibitor, milrinone, is used for acute and short term treatment of adult patients with decompensated and refractory cardiac failure, and another, cilostazol, has FDA approval for treatment for intermittent claudication.

Conclusions

By virtue of their distinct intrinsic characteristics and differential regulation, their intracellular targeting to different subcellular locations and microdomains, and their interactions with cellular structural elements, regulatory partners, and molecular scaffolds such as AKAPs and β arrestin, different PDEs can integrate multiple cellular inputs, and modulate the intracellular diffusion and functional compartmentalization of cyclic nucleotide signals. The combined enormous molecular diversity of receptors and their ligands, adenylyl and guanylyl cyclase systems, PDEs, and cyclic nucleotide-regulated effector systems, coupled with their physical and functional compartmentalization, provides for the complex integration, specificity, and variety of networks and pathways involved in generation, transduction, modulation, and termination of cyclic nucleotide-gated signals and actions. The ability of scaffolding proteins to spatially organize signaling molecules, including protein kinases, phosphatases, kinase substrates, PDEs, and other signaling and effector molecules, effectively allows cells to generate signaling specificity by using small, discrete subsets of proteins which exhibit overlapping or redundant functions. Integration of these myriad combinations establishes the unique cyclic nucleotide networks and phenotypes that characterize individual cells.

Biography

Eva Degerman received her degrees, M.D. in 1991 and Ph.D. in 1988, from Lund University, where she has spent her entire scientific career.

Vincent Manganiello received his degrees, M.D. and Ph.D., from Johns Hopkins University School of Medicine in 1967. After serving as a pediatric intern in the Harriet Lane Service at Johns Hopkins, he came to the National Institutes of Health in 1968, and has pursued his entire scientific career at the National Heart, Lung, and Blood Institute. Drs. Degerman and Manganiello have enjoyed a long-standing collaboration focused on the cyclic nucleotide phosphodiesterase 3 (PDE3) family and its role in metabolic regulation and insulin secretion in adipose tissue, liver and pancreas, important target tissues for actions of insulin, leptin and IGF-1 (insulin-like growth factor-1), and for maintenance of energy homeostasis, as well as for the pathogenesis of type 2 diabetes and obesity.

Cyclic Nucleotide-Dependent Protein Kinases

Sharron H. Francis and Jackie D. Corbin
Vanderbilt University School of Medicine, Nashville, Tennessee, USA

The cyclic nucleotide-dependent protein kinases, cAMP-dependent protein kinase (PKA) and cGMP-dependent protein kinase (PKG), are the major intracellular receptors for adenosine 3′,5′-cyclic monophosphate (cAMP) and guanosine 3′,5′-cyclic monophosphate (cGMP), respectively. Upon elevation of cAMP or cGMP in the cell, these nucleotides can bind to numerous cellular proteins including the cyclic nucleotide-dependent protein kinases. Intracellular levels of cAMP and cGMP are determined by the balance between their synthesis and breakdown. They are synthesized from either ATP or GTP by adenylyl cyclase or guanylyl cyclase, respectively, in response to first messengers in the body (e.g., hormones, neurotransmitters, and various environmental stimuli), and they are broken down by cyclic nucleotide phosphodiesterases (PDEs). The important concept of signaling through second messengers such as cAMP and cGMP is that the hormone, neurotransmitter, or other stimuli can elicit their physiological effects without entering the cell. The protein kinase catalytic activities of cyclic nucleotide-dependent kinases are activated when the cyclic nucleotides bind to their regulatory domains, and the catalytic domains of the kinases can then transfer a phosphate from ATP to many proteins through a process known as phosphorylation. The phosphorylation of these target proteins frequently alters their functions and accounts for most of the known effects of cyclic nucleotides in eukaryotes.

Cyclic Nucleotide-Dependent Protein Kinases as Intracellular Receptors for cAMP and cGMP

The cyclic nucleotide-dependent protein kinases, cAMP-dependent protein kinase (PKA) and cGMP-dependent protein kinase (PKG), are the major intracellular receptors for adenosine 3′,5′-cyclic monophosphate (cAMP) and guanosine 3′,5′-cyclic monophosphate (cGMP), respectively (Figure 1). PKA and PKG are homologous ligand-activated kinases. In the presence of very small amounts of cAMP or cGMP (e.g., concentrations ranging from 10^{-8}–10^{-7} M), these kinases are activated by binding the cyclic nucleotide. The intracellular levels of cAMP and cGMP are determined by the balance between their synthesis and breakdown. They are synthesized from either ATP or GTP by adenylyl cyclase or guanylyl cyclase, respectively, in response to first messengers in the body (e.g., hormones, neurotransmitters, and various environmental stimuli), and they are broken down by cyclic nucleotide phosphodiesterases (PDEs) (Figure 2). The activated PKA or PKG then catalyzes transfer of the γ-phosphate of ATP to selected serine or threonines in many cellular proteins through a process known as phosphorylation. The covalent attachment of phosphate to these proteins converts them into phosphoproteins, a process known as heterophosphorylation because in this case PKA or PKG phosphorylates proteins other than itself. The phosphoproteins frequently have changes in their activities, subcellular localizations, and interactions with other cellular components, including other proteins, DNA, RNA, and lipids. The altered function of these proteins that have been phosphorylated by PKA or PKG mediates the changes induced by many hormones and environmental stimuli, including those in metabolism, gene transcription, neurotransmission, blood pressure, and fluid homeostasis.

Overall Structure of Cyclic Nucleotide-Dependent Protein Kinases

There are several isoforms of PKA and PKG, but all have a similar organization of their functional domains (Figure 3). Both are chimeric proteins comprising a regulatory domain and a catalytic domain, and within each of these there are several subdomains that provide for specific functions. PKA regulatory and catalytic domains are located on separate subunits, the R subunit and C subunit, respectively. In PKG, the regulatory and catalytic domains are on a single polypeptide chain. Both enzymes form dimers through interactions between

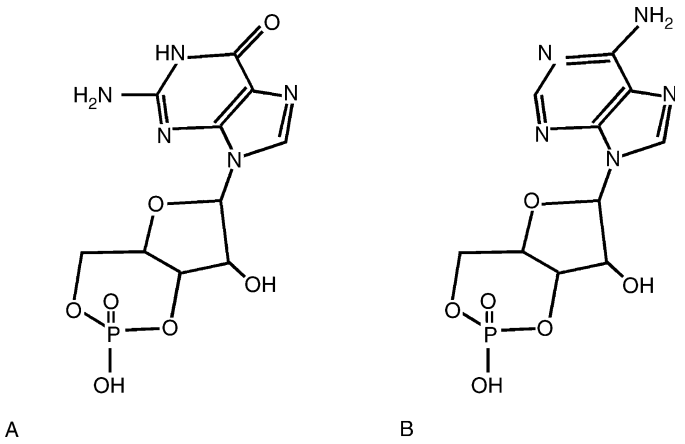

FIGURE 1 Structural models of (A) cGMP and (B) cAMP. cGMP and cAMP differ only in their purine rings. These differences in the purine ring provide for the specificity with which each kinase interacts preferentially with that nucleotide. The cyclic phosphate moiety is required for binding to the cyclic nucleotide-binding sites on PKG and PKA, and the 2′–OH of the ribose provides an important contact in the respective sites. There are two conformations of these nucleotides, *syn* (shown) and *anti*, due to rotation around the bond linking the purine and the ribose. Both PKA and PKG bind the *syn* conformer. Important features of cGMP that contribute to its interaction with PKG include the amino group at C-2 (which interacts with a conserved threonine in sites preferring cGMP), the oxygen at C-6, and a protonated N-1. cAMP has a single substitution on the purine (i.e., an amino group at C-6 and no protonation at N-1).

amino acids near the N terminus within their regulatory domains. However, the salient biochemical features of regulation and catalysis are retained in monomeric forms of PKG and in PKA formed by the combination of a single R subunit and C subunit.

Although dimerization is not necessary for PKA function, it is required for anchoring a portion of the PKA to specific subcellular compartments through a family of proteins known as A kinase anchoring proteins (AKAPs). Anchoring is thought to bring PKA into close proximity with substrates and to thereby facilitate the rapidity and efficiency of cAMP signaling. PKA R

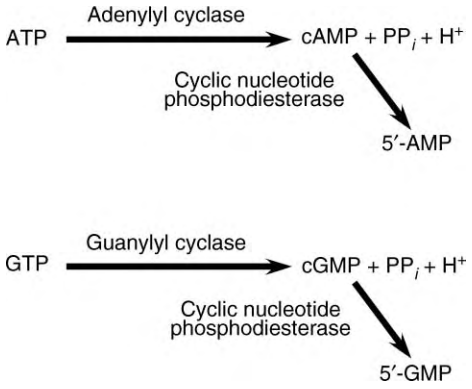

FIGURE 2 The balance between cyclase and phosphodiesterase activities determines cyclic nucleotide levels in the cell. cAMP and cGMP are synthesized from either (A) ATP by adenylyl cyclase or (B) GTP by guanylyl cyclase; when the activities of these cyclases are increased, more cAMP or cGMP is produced. The breakdown of the cyclic nucleotides is catalyzed by cyclic nucleotide phosphodiesterases (PDEs), and the activities of these enzymes lower cAMP and cGMP. The balance between the activities of these two families of enzymes is the major factor in determining the cellular content of cyclic nucleotides.

subunits are aligned in an antiparallel arrangement within the dimer and use hydrophobic interactions, whereas the PKG monomers within the dimer are aligned in a parallel arrangement through interactions of an extended leucine zipper motif.

PKA

PKA is present in the cytosolic and particulate fraction of all mammalian tissues and occurs at concentrations ranging from 0.2 to 2 μM. It is a tetramer comprising two C subunits and two R subunits (R_2C_2) (Figure 3). There are three main genes for mammalian C subunit (Cα, Cβ, Cγ); each is ~36,000 Da. There are two major genes for R subunits (RI and RII) and subtypes within these (RIα, RIβ, RIIα, and RIIβ) are produced by mRNA splicing; each is ~45,000 Da. The nomenclature for PKAs is based on the R subunits; PKAs containing RI subunits are called type I PKA, and those containing RII subunits are called type II PKA. Both types may contain either form of C subunit. Most tissues contain both types of PKA and, in most instances, either type can carry out cAMP-mediated action. Type I PKA is predominantly cytosolic; type II PKA is found in both the cytosol and membrane compartments. The RI and RII content of a particular tissue varies among species.

In the absence of cAMP, an R subunit interacts with a C subunit with high affinity (~0.2 nM) and suppresses its catalytic activity through a process known as autoinhibition. cAMP binding to two cAMP-binding sites on an R subunit causes a conformational change that decreases the affinity of the R subunit for a C subunit by 10,000- to 100,000-fold. An active

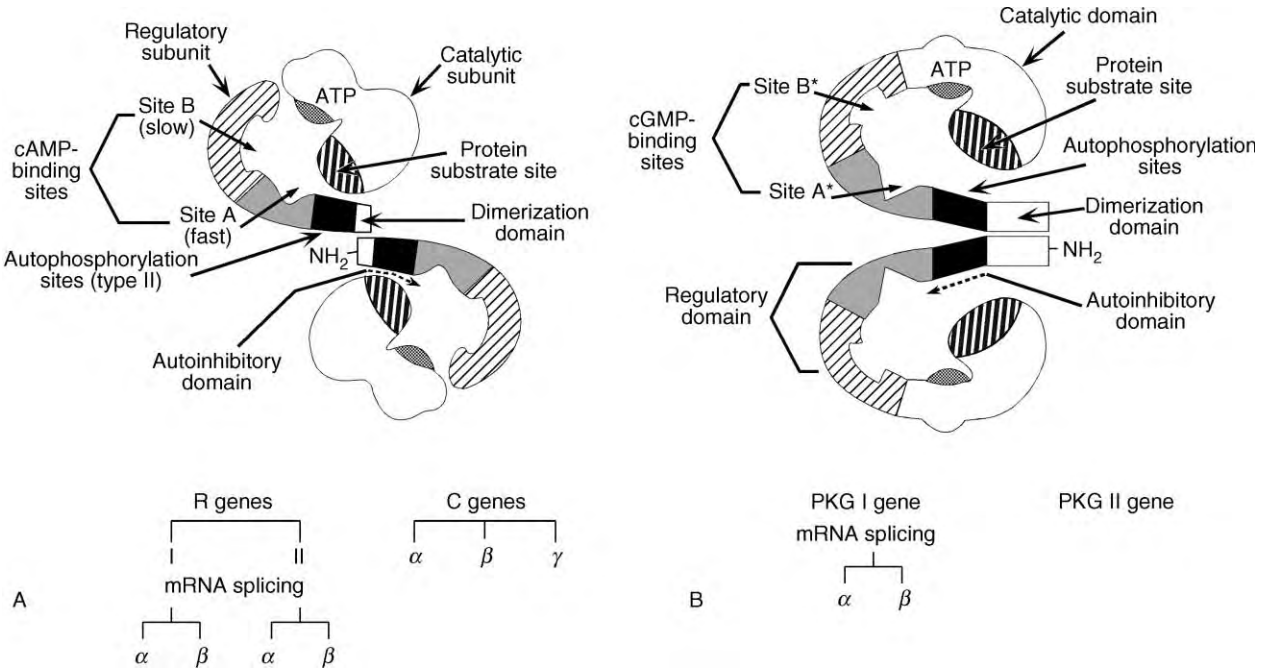

FIGURE 3 Working models of (A) PKAs and (B) PKGs, depicting the overall organization of the functional domains within these enzymes. The major isozymic forms that are products of different genes for each of the kinases are listed below each model. Additional forms of the PKA R subunits and some of the C subunits are produced by alternative mRNA splicing. The alignment of the low-affinity and high-affinity cyclic nucleotide sites within PKA R subunit is the same for all known PKAs. The linear arrangement of the cGMP-binding sites in PKG-II is the same as that found in PKAs. However, in PKG-I, the sites are transposed so that the more N-terminal site is the high-affinity cGMP-binding site and at the more C-terminal position is the low-affinity site.

monomeric C subunit dissociates from the complex and can diffuse throughout the cell, including the nucleus, which excludes R subunits and PKA holoenzymes. The diffusibility of the C subunit is believed to provide for the mechanism by which cAMP elicts its effect in a number of systems. The R subunits remain dimerized and, if anchored to AKAPs, they remain anchored.

X-ray crystallographic structures have been determined for the C subunit and also for the RI and RII subunits, but to date there is no structure for the inactive complex. The C subunit has two lobes that combine to form a catalytic cleft where the phosphate is transferred from ATP to the protein substrate. The smaller, more N-terminal lobe makes most of the contacts with Mg^{2+}/ATP and the larger, more C-terminal lobe makes most of the contacts that precisely position the protein substrate in the catalytic cleft. The binding of Mg^{2+}/ATP and a protein substrate into the catalytic cleft allows a complex set of enzymatic actions to transfer the phosphate from ATP to substrate.

In order to efficiently transfer the phosphate to a peptide or protein, PKA strongly prefers an amino acid sequence of -ArgArgXSer/ThrX- (called a PKA consensus phosphorylation site), and this sequence alone provides in large part for the efficiency with which the C subunit phosphorylates a protein. The amino acids in the positions marked as X affect the affinity of the C-subunit interaction with a substrate and, although arginines (Arg) are highly preferred in this motif, some variation is tolerated.

Each R subunit contains several subdomains. These include an N-terminal dimerization subdomain, a subdomain that includes the autoinhibitory and autophosphorylation regions, and a cyclic nucleotide-binding subdomain that contains two cAMP-binding sites arranged in tandem (Figure 3). In the absence of cAMP, a substrate-like sequence in the R subunit binds tightly to the catalytic site in the C subunit. Although other contacts also contribute to stabilizing the R–C interaction, this substrate-like sequence in the autoinhibitory domain competes with protein substrate binding and provides a major portion of the interactions that hold PKA in a catalytically inactive form in the absence of cAMP. This is known as autoinhibition. The binding of cAMP to both cAMP-binding sites in each R subunit disrupts the R–C subunit interaction.

Most commonly, the PKA tetramer contains a single type of R subunit (either RI or RII). RII subunits contain a sequence in the autoinhibitory domain that mimics a PKA substrate motif, and the serine in this sequence can be autophosphorylated by the C subunit when the subunits are complexed (i.e., in the absence of cAMP). Autophosphorylation of this site in RII increases its affinity for cAMP so that PKA can be activated at lower cAMP concentrations. Type I R subunits contain a pseudosubstrate sequence (-ArgArgXGlyX-), that is, a

substrate-like sequence that lacks a phosphorylatable residue. Therefore, type I PKA R subunits cannot undergo autophosphorylation.

PKA plays a critical role in functions of all mammalian cells. As a result, it is likely that survival requires the presence of the PKA C subunit. A null mutation for C subunit in yeast is lethal. Mice carrying null mutations for either Cα or Cβ are viable, but differ phenotypically; mice lacking either RI or RII subunits are also typically viable and differ phenotypically. These results suggest that these isoforms of the C subunit and R subunit have some selectivity in function.

PKG

The tissue distribution of PKG is more restricted than that of PKA. PKGs play a central role in regulating smooth muscle tone, platelet aggregation, bone growth, and water–salt homeostasis. Cellular concentration of PKG ranges from infinitesimally low to 1 μM. There are two families of PKG (PKG-I and PKG-II) that are the products of separate genes. These families are not co-expressed and appear to have selective functions because the phenotype of PKG-I-null mice differs from that of PKG-II-null animals. PKG-I has two alternative splice variants (PKG-Iα and PKG-Iβ) that vary in the N terminal ~100 amino acids and are typically co-expressed. PKG-I is largely cytosolic, whereas PKG-II is membrane-bound through an N-terminal myristyl group. In some instances, this provides for specific phosphorylation events that do not occur when PKG-II is in its soluble form. The membrane association of PKG-II appears to colocalize PKG-II with the intended substrate. The PKG-I isoforms, PKG-Iα and PKG-Iβ, are largely cytosolic, but they too are specifically localized in some cases. When this occurs, it involves interactions between residues within the conserved leucine zipper motif near the N terminus and another protein, for example, the myosin-binding protein of the myosin phosphoprotein phosphatase. In many cases, the interaction is selective for either PKG-Iα or PKG-Iβ, indicating that the specificity of the interaction involves sequences that are novel to one or the other isoform.

PKG regulatory domains contain several subdomains including an N-terminal dimerization subdomain involving a leucine zipper motif, a subdomain containing both the autoinhibitory and autophosphorylation regions, and a cyclic nucleotide-binding subdomain that contains two cGMP-binding sites arranged in tandem (Figure 3). The role of dimerization is unclear because a monomeric PKG retains the salient features of the dimer.

The autoinhibitory–autophosphorylation subdomain is located just C-terminal to the dimerization domain. This region accounts for autoinhibition of the catalytic site and contains multiple autophosphorylation sites, most of which do not resemble a consensus substrate sequence and are not conserved among PKGs. These sites are autophosphorylated by the catalytic domain within the same PKG monomer; autophosphorylation of PKG-I increases the affinity for cGMP and elevates basal activity. Unlike that for PKA, PKG autophosphorylation increases in the presence of cyclic nucleotide.

The mechanism of autoinhibition of PKGs also differs somewhat from that of PKA. The autoinhibitory domain of all PKGs contains either pseudosubstrate sequences, for example, -LysArgGln*Ala*Ile- in PKG-Iβ, or sequences that only weakly mimic a pseudosubstrate site, for example, -ArgAlaGln*Gly*Ile- in PKG-Iα, where the italicized residue indicates the phosphorylation position in the autoinhibitory PKA sequence. Furthermore, sequences outside the pseudosubstrate sequence contribute more prominently to the autoinhibition of both PKG-I and PKG-II compared to PKA.

PKGs contain two cGMP-binding sites of ~110 amino acids arranged in tandem. A small segment of protein connects the regulatory and catalytic domains of the enzyme. The catalytic domain is thought to resemble that of PKA because the enzymes are homologous. In the absence of cyclic nucleotide, PKG catalytic activity is latent. cGMP binding to the cGMP-binding sites in the regulatory domain causes an elongation of the PKG monomer that relieves the autoinhibition, thereby activating catalytic activity.

Cyclic Nucleotide-Binding Specificity and Affinity

The two homologous cyclic nucleotide-binding sites (~110 amino acids each) in PKA and PKG appear to be the products of an ancient gene duplication that occurred prior to the divergence of these proteins. These sites are evolutionarily related to a bacterial cAMP-binding protein, the catabolite-gene-activating protein (CAP) family of cyclic nucleotide-binding proteins. The cyclic nucleotide-binding sites of cyclic nucleotide-gated channels and cAMP-regulated guanine nucleotide exchange factors (GEFs) are also members of this family. In both PKA and PKG, the two intrasubunit sites differ approximately 10-fold in their affinity for cyclic nucleotide binding and also differ in specificity for cyclic nucleotide analogues. In PKA RI and RII subunits, the more N-terminal site has a lower affinity for cAMP (fast cAMP dissociation) compared to the more C-terminal site (slow cAMP dissociation) (Figure 3). In PKG-II, the cGMP-binding sites are arranged as in PKA, but in PKG-I the higher affinity site is the more N-terminal site. Full activation of either PKA or PKG requires saturation of all the cyclic nucleotide-binding sites.

PKA and PKG have a 50- to 200-fold selectivity for cAMP and cGMP, respectively, and most commonly the

cellular effect of cAMP or cGMP is mediated by the respective kinase. However, in several systems, cAMP or cGMP has been shown to activate the other kinase through a process known as cross-activation. In the X-ray crystallographic structure of the R subunit, cAMP is bound in a deep pocket within each site, and several conserved amino acids (glutamate, arginine, and several glycines) provide direct contact with the cyclic nucleotide or contribute to critical structural features of the site. In sites preferring cGMP, an invariant threonine provides a major portion of the selectivity for cGMP by interacting with the 2′-amino group in the purine (Figure 1). Hydrophobic amino acids in each of the sites contribute importantly to the affinity with which cyclic nucleotide is bound.

Substrate Specificities of PKA and PKG

PKA and PKG-I share many similarities in substrate specificities, and the consensus sequence for phosphorylation by either enzyme is defined as -ArgArgXSer/ThrX-. These kinases can frequently phosphorylate the same proteins, although there are differences. PKG-I phosphorylates numerous proteins in sites that do not conform to this consensus phosphorylation sequence; these sites are not phosphorylated well by PKA. A phenylalanine located C-terminal to the phosphorylation site strongly discriminates against PKA phosphorylation, but not that of PKG, and a basic amino acid adjacent to the phosphorylation site favors PKG-I phosphorylation. The substrate specificity of PKG-II appears to be quite different from those of PKG-I and PKA.

Negative Feedback and Feed-Forward Control of Cyclic Nucleotide Pathways

A two- to fourfold increase in either cAMP or cGMP typically accounts for the physiological responses to these nucleotides. Negative feedback control mechanisms restrict the magnitude or persistence of cyclic nucleotide

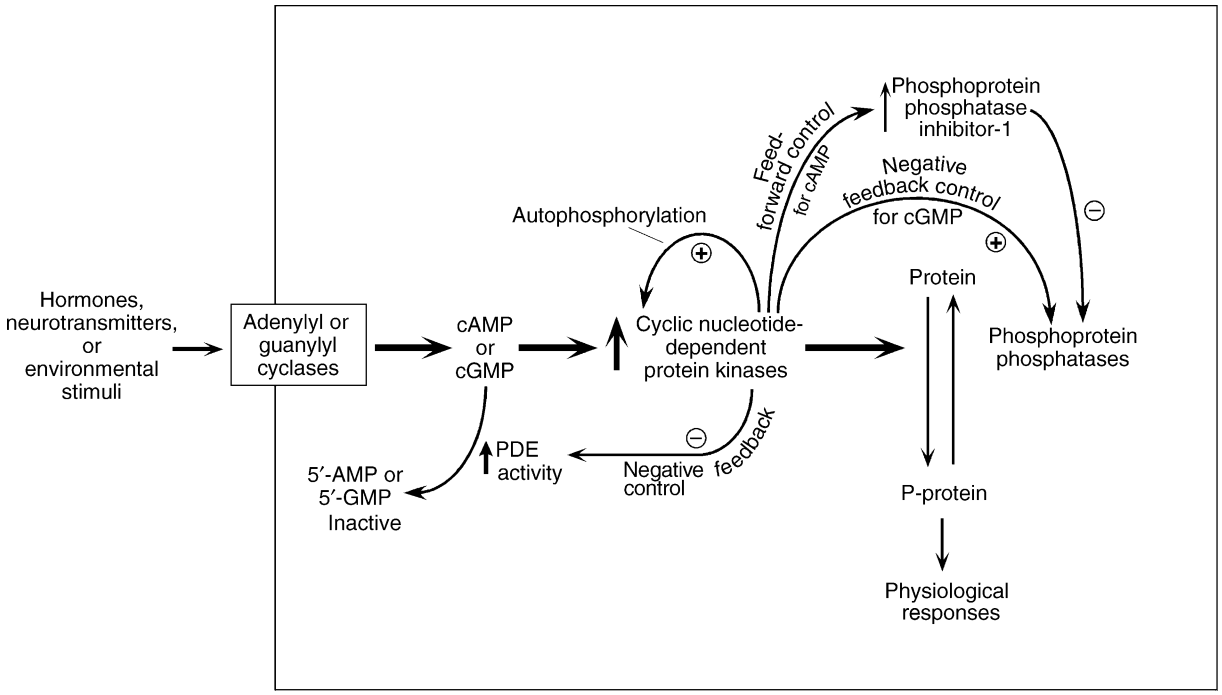

FIGURE 4 Mechanisms involving phosphorylation that contribute to modulation of the cAMP- and cGMP-signaling pathways. Feedback control refers to processes that tend to alter the overall effectiveness of signaling through cyclic nucleotide pathways. Negative feedback control mechanisms decrease the effectiveness of the cyclic nucleotide signal; these include increased activities of cyclic nucleotide phosphodiesterases (PDE activity), which breakdown the cAMP and cGMP, and increased activities of phosphatases that remove phosphates from phosphoproteins that have been phosphorylated by PKG. Feed-forward control (i.e., positive feedback control) mechanisms enhance the effectiveness of the signal. These include autophosphorylation by PKA and PKGI, which increases the affinity of these enzymes for the respective cyclic nucleotides and increases catalytic activity, and increased phosphorylation of the phosphoprotein phosphatase inhibitor-1 by PKA, which inhibits a phosphoprotein phosphatase and blocks its effect of removing phosphate from phosphoproteins involved in the signaling pathway. Circled + and − denote effects that either increase or decrease as the levels of cyclic nucleotides increase or decrease; arrows, ↑ and ↓, denote a change in the catalytic activity of the indicated enzymes that is induced by PKA or PKG phosphorylation or the state of phosphorylation of the phosphoprotein phosphatase inhibitor-1 in response to increased PKA activity.

signaling whereas feed-forward mechanisms potentiate the response to cyclic nucleotide elevation. Both types of mechanisms have been established for the cAMP and cGMP signaling cascades (Figure 4). PKA and PKG can phosphorylate and activate PDEs, which accelerates the breakdown of cyclic nucleotides, thereby favoring inactivation of the kinases. Both cascades also have feed-forward control because the autophosphorylation of type II PKA and PKG-I increases kinase activity and cyclic nucleotide-binding affinity. The cAMP system has an additional feed-forward control because PKA phosphorylates phosphoprotein phosphatase inhibitor-1 to produce a potent inhibition of phosphoprotein phosphatase action, thereby potentiating the effects of PKA phosphorylation.

Dr. Jackie D. Corbin is a Professor in the Department of Molecular Physiology and Biophysics at Vanderbilt University School of Medicine. His career interest has been the mechanism of action of cAMP and cGMP. He has a Ph.D. degree in physiology from Vanderbilt University and did postdoctoral training at the University of California, Davis. He has made seminal discoveries in the mechanisms and functions of cAMP-dependent protein kinases, cGMP-dependent protein kinases, and cyclic GMP-binding cyclic GMP-specific phosphodiesterase (PDE5).

Dr. Sharron H. Francis is a Research Professor in the Department of Molecular Physiology and Biophysics at Vanderbilt University School of Medicine. Her research interest has been the biochemical mechanisms by which cGMP-dependent protein kinases and PDE5 effect and modulate the physiological functions of cGMP. She has a Ph.D. degree in physiology from Vanderbilt University and did postdoctoral training at Washington University and at the National Heart and Lung Institute in Bethesda, MD.

Cyclic Nucleotide-Regulated Cation Channels

Martin Biel
Ludwig-Maximilians-Universität München, Munich, Germany

Franz Hofmann
Technischen Universität München, Munich, Germany

Cyclic nucleotides exert their physiological effects by binding to four major classes of cellular receptors: cAMP- and cGMP-dependent protein kinases, cyclic GMP-regulated phosphodiesterases, cAMP-binding guanine nucleotide exchange factors, and cyclic nucleotide-regulated cation channels. Cyclic nucleotide-regulated cation channels are unique among these receptors because their activation is directly coupled to the influx of extracellular cations into the cytoplasm and to the depolarization of the plasma membrane. Two families of channels regulated by cyclic nucleotides have been identified, the cyclic nucleotide-gated (CNG) channels and the hyperpolarization-activated cyclic nucleotide-gated (HCN) channels. The two channel classes differ from each other with regard to their mode of activation. CNG channels are opened by direct binding of cAMP or cGMP. In contrast, HCN channels are principally operated by voltage. These channels open at hyperpolarized membrane potentials and close on depolarization. Apart from their voltage sensitivity, HCN channels are also activated directly by cyclic nucleotides, which act by increasing the channel open probability.

General Features of Cyclic Nucleotide-Regulated Cation Channels
